Preoperatively, the nurse ensures the patient has received education and counseling about their gender reassignment surgery, the possible risks and benefits, including complications, postsurgical outcomes, and need for possible long-term follow-up appointments. The nurse needs to assess the last time the patient took their hormone treatment (e.g., estrogen or testosterone) because certain procedures require the patient to stop hormones 2 to 3 weeks in advance of surgery. The nurse should ensure the patient completed their bowel preparation, especially in genital reassignment surgery. For patients undergoing phalloplasty, the nurse needs to assess smoking status because most surgeons require the patient to be free of tobacco products or inhaling nicotine and marijuana. This includes electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars (Colebunders, D'Arpa, et al., 2016). Laboratory results, including complete blood count (CBC), electrolytes, blood urea nitrogen (BUN), and creatinine, should be assessed; however, the nurse should be aware that people who receive hormones may have alterations in their laboratory values (Tollinche, Walters, Radix, et al., 2018). For patients who are transitioning, regardless of whether the transition is female to male or male to female, the upper limit for creatinine, hemoglobin and hematocrit, and alkaline phosphatase should be based on male values. For patients who are transitioning from female to male, the lower limit of hemoglobin and hematocrit should be based on male values. For patients who are transitioning from male to female, the lower limit of hemoglobin and hematocrit should be based on female values (WPATH, 2012).

Postoperatively, the nurse assesses the patient to ensure the goals for recovery are met and that the patient exhibits absence of complications secondary to the surgical procedure(s). Gender reassignment surgeries often require very specific assessments to ensure proper healing and prevent complications. It is imperative that the nurse follow the surgeon's

prescribed postoperative care guidelines and educate the patient to prevent both complications and revisional surgeries (Colebunders, Verhaeghe, et al., 2016).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for compromised dignity associated with stigmatization
- Anxiety associated with impending surgery
- Acute pain associated with surgical procedure
- Risk for infection associated with surgical procedure
- Hope associated with gender reassignment surgery

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage
- Venous thromboembolism (VTE)
- Tissue necrosis

Planning and Goals

The major goals for the patient include enhanced sense of dignity and respect, reduction of anxiety about the surgery and postoperative care, relief of pain, absence of infection, enhancement of hope related to life after surgery, effective peripheral tissue perfusion, and absence of postoperative complications.

Nursing Interventions

Ensuring Human Dignity

The nurse needs to promote a welcoming and safe environment for the patient undergoing gender reassignment surgery. In addition, the nurse needs to promote the use of gender-neutral language, preferred third-person pronouns, and utmost respect for the patient and their family (Johnson, Wakefield, & Garthe, 2020). The patient should be able to safely disclose their gender identity and sexual orientation. In addition, nurses and other health care providers should avoid having discussions about the patient that can be overheard by neighboring patients and staff who are not involved in care. While this principle should be applied to all patients, it is of the utmost importance to the care of people who are transgender because of concerns over discriminatory health care treatment (Tollinche et al., 2018).

People who are transgender should be roomed in accordance with their gender identity. Careful communication between the nurse and individuals responsible for room assignments (e.g., charge nurse) is necessary. If a private room is available, it should be offered as an option because it will

provide increased privacy and comfort to the patient. However, the patient should not be forced into a private room because it may make the patient feel isolated (Tollinche et al., 2018).

Reducing Anxiety

The nurse provides the patient preparing for gender reassignment surgery anticipatory guidance as to what to expect during the surgery and postoperatively. The patient's preferred family should be included when possible to help reduce anxiety. Additionally, some surgery centers promote the use of relaxation techniques, such as aromatherapy, nature sounds, and relaxation exercises; the nurse should use these if available (Ertug, Olusoylu, Bal, et al., 2017). People who are transgender are often connected to larger networks, but the nurse can promote local and online support groups. Often, online support groups can become the main support resource after gender reassignment surgery (Cipolletta, Votadoro, & Faccio, 2017) (see Resources section).

Additionally, to help ease the patient's anxiety about postoperative care, the nurse can assist in coordinating services. People who are transgender have higher rates of anxiety and depression than cisgender people. These issues may be exacerbated during a prolonged hospital stay. Thus, the nurse should advocate for the involvement of mental health, social work, and spiritual care as needed to address all of the patient's needs (Tollinche et al., 2018).

Relieving Pain

Evidence shows that patients experiencing postoperative pain should be offered multimodal analgesia, which is the pharmacologic method of combining various groups of medications for pain relief (Manworren, Gordon, & Montgomery, 2018) (see Chapter 9 for further discussion). After surgery, patients are usually prescribed opioid (morphine, hydromorphone) and nonopioid (acetaminophen or NSAIDs) agents. The nurse can administer these agents as prescribed to relieve pain and discomfort. Inadequately controlled postoperative pain can impede functional recovery and reduce quality of life (Manworren et al., 2018), thus nurses need to be vigilant about controlling the patient's pain. Patients undergoing genital reassignment surgery typically need to stay in bed for numerous days; thus, the nurse should help the patient reposition themselves to promote comfort.

Preventing and Monitoring for Infection

Unless the patient undergoing gender reassignment surgery has risk factors (e.g., older adult, weak immune system, smoker, poor nutrition, overweight), they are not at greater risk for developing a postsurgical infection. The nurse should follow usual procedures to prevent and monitor for infection. Preventing infection after surgery requires proper and frequent hand hygiene, maintenance of the surgical site, and administration

of prescribed prophylactic antibiotics. Early signs of infection should be reported to the surgeon immediately, including increased skin redness, pain, or swelling, cloudy or discolored discharge from the surgical site, and fever.

Promoting Hope

People who are transgender often experience greater levels of depression and decreased quality of life as compared with cisgender people. However, people who undergo gender reassignment surgery often experience improved quality of life (Cai, Hughto, Reisner, et al., 2019; Passos, Teixeira, & Almeida-Santos, 2019). The nurse should promote open communication about the patient's feelings, hopes, and goals after their gender reassignment surgery and show a positive regard and sense of hope for the patient. Additionally, the nurse may want to explore unresolved emotions or anxieties.

Monitoring and Managing Potential Complications

After surgery, the nurse assesses the patient for complications from the procedure, such as hemorrhage, VTE, and tissue necrosis.

Hemorrhage. Postoperative hemorrhage is a possible complication after gender reassignment surgery, especially following vaginectomy, which is one of the procedures during a phalloplasty (Colebunders, D'Arpa, et al., 2016). Signs and symptoms of possible hemorrhage include increased pain, frank red blood from the surgical site or rectum, increase in bloody output from any drain that might be in place (e.g., for mastectomy), and typical clinical manifestations (e.g., tachycardia, hypotension, lightheadedness, syncope).

Venous Thromboembolism. People who undergo gender reassignment surgery, especially those undergoing genital surgery and those who are transgender women, are at risk of VTE, including both pulmonary embolism (PE) and deep vein thrombosis (DVT) (Shatzel, Connelly, & DeLoughery, 2017). People who undergo genital reassignment surgery often need to stay in bed for up to 7 days, putting them especially at risk. Additionally, the estrogen hormone treatment among transgender women increases the risk. The patient is typically prescribed mechanical compression (e.g., intermittent pneumatic compression devices) and prophylactic anticoagulation with subcutaneous LMWH agents (e.g., enoxaparin) during hospitalization. Even with these prophylactic measures, some patients still develop DVT and PE, and thus the nurse should monitor for clinical signs (Colebunders, Verhaeghe, et al., 2016; Shatzel et al., 2017) (see Chapter 26 for further discussion on VTE).

Tissue Necrosis. Tissue necrosis from vascular compromise is a complication with certain gender reassignment surgeries, including subcutaneous mastectomy and phalloplasty. After the subcutaneous mastectomy, vascular compromise may occur around the reconstructed

nipple and areola (Colebunders, Verhaeghe, et al., 2016). After the phalloplasty, vascular compromise may occur in the reconstructed shaft, penis glans, or scrotum (Colebunders, D'Arpa, et al., 2016). Signs of tissue necrosis from vascular compromise include skin/tissue discoloration (blue or black), feeling cool to the touch, increased pain or decreased sensation, and poor wound healing. Tissue necrosis is a medical emergency that needs to be addressed immediately.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. People who undergo gender reassignment surgery are typically discharged to home from the hospital within seven days after surgery. General postoperative discharge education includes promptly notifying the surgeon for a temperature greater than 38°C (100.4°F) or for the presence of unusual or bloody drainage from the wound(s). The patient is encouraged to advance the diet as tolerated at home to promote wound healing and to abstain from all tobacco products at least until the surgical wound(s) has healed. Additional education provided is dependent upon the nature of the surgery. For instance, the patient who has had a vaginoplasty or phalloplasty will receive very specific education (Charts 54-4 and 54-5). If the patient has had a mastectomy and has a drain in place, then the patient needs to be educated on managing the drain at home (see Chapter 52, Chart 52-7: Home Care Checklist: Patient with a Drainage Device Following Breast Surgery).

The patient is discharged with specific instructions about follow-up appointments, including visits with their surgical, medical, and psychosocial providers to address their complex needs. Nurses should advocate that these follow-up appointments be made prior to hospital discharge. Additionally, the discharge process should assist the patient in coordinating any type of necessary equipment pickup, transportation to follow-up appointments, and filling medication prescriptions, as needed.

Continuing and Transitional Care. Gender reassignment surgery is very complex, involves numerous different procedures, and can be different from surgeon to surgeon. For these reasons, it is impossible to describe every postsurgical self-care activity. The nurse needs to carefully review the discharge instructions provided by the surgical team. Genital reassignment surgery often has very specific self-care requirements of the patient. The nurse's role is to ensure the patient fully understands the self-care instructions and knows how to monitor for complications.

Chart 54-4 **PATIENT EDUCATION**

Postoperative Education for Patients Who Have Had a Vaginoplasty

The nurse instructs the patient about activity, bathing, swelling, hygiene, and vaginal intercourse as described below.

Activity

- Avoid strenuous activity for 6 weeks
- Avoid swimming or bike riding for 3 months
- May be uncomfortable to sit for the first month; may use donut ring to relieve pressure

Bathing

- Resume showering following first postoperative visit
- Do not submerge groin area in water for 8 weeks

Swelling

- Labial swelling is normal and will resolve in 6 to 8 weeks
- Apply ice to perineum for 20 minutes every hour while awake for 1 week postoperatively
- Increased swelling with pain should be reported to surgeon

Hygiene

- Wash hands before and after contact with genital area
- Wipe genital area from front to back to avoid contamination by bacteria from anal region

Vaginal Intercourse

- May engage in vaginal intercourse 3 months after surgery

Adapted from Meltzer, T. (2016). Vaginoplasty procedures, complications and aftercare. Retrieved on 7/10/2020 at: transcare.ucsf.edu/guidelines/vaginoplasty; University of Utah.

The patient will usually continue to see their surgeon for follow-up appointments for many months. Some procedures, such as a phalloplasty, may require follow-up appointments for up to a year after surgery. The patient will typically need lifelong hormonal treatment and should continue to follow-up with their endocrinology health care provider. Additionally, many people who undergo gender reassignment surgery continue to visit a mental health care provider for counseling.

Evaluation

Expected patient outcomes may include the following:

1. Enhanced human dignity

a. Verbalizes feelings of satisfaction related to the level of respect given to them

2. Minimal anxiety
   a. Has facial expressions, gestures, and activity levels that reflect decreased distress
   b. Demonstrates ability to reassure self
3. Relief of pain
   a. Reports relief of pain
   b. Engages in early mobilization activities as prescribed

Chart 54-5  **PATIENT EDUCATION**

Postoperative Education for Patients Who Have Had a Phalloplasty

The nurse instructs the patient about activity, bathing, swelling, hygiene, and sexual activity as described below.

Activity

- Avoid strenuous activity for 6 weeks
- Do not flex at waist more than 90 degrees
- Do not lift anything heavier than 5 lb with arm with skin graft donor site

Bathing

- Lightly sponge bathe for 1 week postoperatively and then begin gently washing penis with warm soapy water
- Keep skin graft donor site dry; may use plastic bag to protect from water

Swelling

- Minor swelling is expected; however, report increased swelling in groin or change in girth of penis to surgeon

Hygiene

- Wash hands before and after contact with genital area

Sexual Activity

- Do not use penis for any sexual activities until approved by surgeon (including oral, vaginal, or anal insertion)

Adapted from Phalloplasty guide: How to prepare & what to expect during your recovery. Retrieved on 7/10/2020 at: healthcare.utah.edu/transgender-health/gender-affirmation-surgery/phalloplasty-recovery.php

4. Maintenance of asepsis
    a. No evidence of infection (e.g., no fever, no leukocytosis, no increased redness or swelling of surgical sites)
5. Enhanced hope
    a. Verbalizes feelings about their quality of life after having had gender reassignment surgery
    b. Identifies future-oriented goals and hopes
    6. Has no complications (no hemorrhage, VTE, or tissue necrosis)

CRITICAL THINKING EXERCISES

1 A 38-year-old patient is admitted to your hospital unit for a sickle cell crisis. During report from the emergency room nurse, you learn that this patient identifies as transgender. As you prepare to go and greet the patient and conduct the initial history and assessment, you recognize how important it is to provide an inclusive and welcoming environment for this patient. Describe how you should initially greet the patient. Prepare a list of questions to collect information about their preferred name, gender identity, and gender pronouns.

2 ebp An adult patient confides in you that they have been struggling with their gender identity since adolescence. They were assigned male sex at birth but have a strong desire to be a woman. The patient has been seeing a therapist who diagnosed them with gender dysphoria, but they have not yet started medical treatment. The patient plans to see a health care provider to start hormone treatment but says to you, "I would really like some information about hormones before I see my provider." Describe the types of feminizing hormones and the physical effects. Identify evidence-based information you can provide to the patient to inform them about hormone treatment.

3 ipc You are a nurse working in an emergency department when a 60-year-old person who identifies as a transgender woman is admitted. You overhear a resident physician and nurse talk about the patient using derogatory terms. Describe how you can educate the resident physician and nurse to be more culturally sensitive to this patient. Discuss ways to advocate for the unit to be more welcoming, inclusive, and safe for people who identify as LGBTQ. Identify resources that can be shared with fellow staff members.

4 pq A 55-year-old patient who identifies as a transgender woman is admitted to the medical-surgical unit for fever and shortness of breath two weeks after having a vaginoplasty. The patient is taking daily oral estrogen. The patient's BP is 128/95 mm Hg, HR 110 bpm, RR 28 breaths/min, T 38.40 °C (101.1 °F) and SpO_2 of 90%. Describe your priority nursing assessments for this patient. What nursing interventions would you implement first? Discuss the potential causes of this patient's abnormal vital signs.

UNIT 13 Integumentary Function

Case Study

MANAGING AND PREVENTING SKIN CANCER

You are a nurse working in an outpatient dermatology clinic. A 22-year-old White woman with a family history of melanoma presents to the clinic with three moles that look atypical. She undergoes excision and biopsy of the moles. One week later she returns to the clinic for her results. Two of the moles are within

normal limits; however, one mole on her right shoulder is positive for melanoma *in situ*. The dermatologist recommends a total excision of the area with 2.5 cm (1 in) margins. As the patient is leaving the clinic, she asks you if this is the best treatment option and what she can do to prevent further skin cancers. What is the evidence base for managing melanoma *in situ?* What evidence-based recommendations will you make to help her prevent further skin cancers?

QSEN Competency Focus: **Evidence-Based Practice (EBP)**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Evidence-Based Practice Definition: Integrate best current evidence with clinical expertise and patient/family preferences and values for delivery of optimal health care.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Differentiate clinical opinion from research and evidence summaries Describe reliable sources for locating evidence reports and clinical practice guidelines	Identify the sources you would use for evidence-based reports and clinical guidelines for managing abnormal dermatologic skin findings in this patient as well as in others who have similar risk factors. Identify the evidence base for skin cancer prevention recommendations.
Skills	
Read original research and evidence reports related to area of practice Locate evidence reports related to clinical practice topics and guidelines	What is the strength of the evidence for management of melanoma *in situ* and for melanoma prevention in those with a family history? What criteria will you use to judge the strength of the evidence you have identified?
Attitudes	
Appreciate the importance of regularly reading relevant professional journals	Reflect upon what you learned by reviewing current evidence-based practice. Think about how patients rely on the best evidence to determine the most effective treatment. If a patient with a melanoma *in situ* were being treated in 10 years' time, do you think the same evidence-based guidelines or reports will be in use?

55 Assessment of Integumentary Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the structures and functions of the skin, hair, and nails.
2. Discriminate between normal and abnormal assessment findings of the skin, hair, and nails.
3. Recognize and evaluate the major alterations in skin, hair, and nails by applying the patient's health history and physical assessment findings.
4. Compare and contrast the patterns and typical distributions of primary and secondary skin lesions.
5. Distinguish common skin manifestations associated with systemic disease.
6. Identify the common diagnostic tests used in evaluating skin disorders and related nursing implications.

NURSING CONCEPTS

Assessment
Cellular Regulation
Tissue Integrity

GLOSSARY

alopecia: loss of hair from any cause

ecchymosis: bleeding into the skin and tissue, initially evidenced by varied color (e.g., purple, black) that gradually fades to green, yellow, or brown over time

erythema: redness of the skin caused by dilation of the capillaries due to injury, irritation, inflammation, or various skin conditions

hirsutism: the condition of having excessive hair growth

hyperpigmentation: increase in the melanin of the skin, resulting in an increase in pigmentation

hypopigmentation: decrease in the melanin of the skin, resulting in a loss of pigmentation

keratin: an insoluble, fibrous protein that forms the outer skin layer

keratinocytes: arising from the innermost layer of the epidermis, synthesize the insoluble protein, keratin

Langerhans cells: dendritic clear cells in the epidermis that carry surface receptors for immunoglobulin and complement and that are active participants in delayed hypersensitivity of the skin

melanin: the substance responsible for coloration of the skin

melanocytes: cells of the skin that produce melanin

Merkel cells: cells of the epidermis that play a role in transmission of sensory messages

petechiae: pinpoint red spots that appear on the skin as a result of blood leakage into the skin

rete ridges: undulations and furrows that appear at the lower edge of the epidermis at the dermal junction where these two skin layers are cemented together

sebaceous glands: glands that exist within the epidermis and secrete sebum to keep the skin soft and pliable

sebum: fatty secretion of the sebaceous glands

telangiectasias: vascular structures; red marks on the skin caused by distention of the superficial blood vessels

vitiligo: a localized or widespread condition characterized by destruction of the melanocytes in circumscribed areas of the skin, resulting in white patches

Wood light: ultraviolet light used for diagnosing skin conditions

In the United States, as many as one in three people will have a skin disorder or disease at any given time. Skin disorders are commonly observed in inpatient and outpatient nursing practice settings. The assessment of the skin

can provide important information about the general health of the patient or clues to systemic conditions that manifest in the skin.

Any medical treatment can suddenly induce an episode of skin symptoms such as itching, skin discomfort, or rash. The psychological stress of illness or various personal and family problems may be exhibited outwardly as dermatologic disorders. In certain systemic conditions, such as hepatitis and some cancers, dermatologic manifestations may be the first sign of the disorder and the main reason a patient seeks health care.

Anatomic and Physiologic Overview

The skin is the largest organ system of the body and is essential for human life. It participates in many vital body functions; it forms a barrier between the internal and external environment protecting the body from pathogens, helps regulate temperature and water loss, and provides sensory input.

Anatomy of the Skin, Hair, Nails, and Glands of the Skin

Skin

The skin is composed of three layers: epidermis, dermis, and subcutaneous tissue (Fig. 55-1). The epidermis is an outermost layer of stratified epithelial cells, composed predominantly of keratinocytes. It ranges in thickness from about 0.05 mm on the eyelids to about 1.5 mm on the palms of the hands and soles of the feet. Four distinct layers compose the epidermis; from innermost to outermost, they are the stratum germinativum, stratum granulosum, stratum lucidum, and stratum corneum. Each layer becomes more differentiated (i.e., mature and with more specific functions) as it rises from the basal stratum germinativum layer to the outermost stratum corneum layer.

Epidermis

The epidermis, which is contiguous with the mucous membranes and the lining of the ear canals, consists of live, continuously dividing cells called **keratinocytes,** which differentiate and randomly migrate upward. These cells synthesize keratin; eventually they become metabolically inactive and form a thick and protective outer layer. This external layer, called the stratum corneum, is almost completely replaced every 3 to 4 weeks. The dead cells contain large amounts of **keratin,** an insoluble, fibrous protein that forms the outer barrier of the skin and has the capacity to repel pathogens and prevent excessive fluid loss from the body. Keratin is the principal hardening ingredient of the hair and nails.

Melanocytes are the special cells of the epidermis that are primarily involved in producing the pigment **melanin,** which colors the skin and hair. A person's normal skin color is determined by the amount of melanin produced. Most of the skin of people who are dark skinned and the darker areas of the skin on people who are light skinned (e.g., the nipple) contain larger amounts of melanin and are not related to numbers of melanocytes. Normal skin color depends on race and varies from pale, almost ivory, to deep brown, almost pure black. Systemic disease can affect skin color. For example, insufficient oxygenation of the blood will induce cyanosis (a bluish hue in the skin of individuals who are light skinned), significant liver disease manifests as jaundice or icterus (a yellow green skin tone), and **erythema** (a pink or red skin shade caused by dilation of the capillaries) is seen when there is inflammation or fever.

Production of melanin is influenced by several factors including a hormone secreted from the hypothalamus of the brain called *melanocyte-stimulating hormone.* It is believed that melanin production responds in a protective manner with increased ultraviolet light in sunlight.

Two other types of cells are common to the epidermis: Merkel and Langerhans cells. **Merkel cells** are not fully understood but may have a role as receptors that transmit stimuli to the axon (long projection of a nerve cell) through a chemical synapse. **Langerhans cells** are believed to play a significant role in cutaneous immune system reactions. These accessory cells of the afferent immune system process invading antigens and transport the antigens to the lymph system to activate the T lymphocytes.

The characteristics of the epidermis vary in different areas of the body. It is thickest over the palms of the hands and soles of the feet and contains increased amounts of keratin. The thickness of the epidermis can increase with friction and pressure and can result in calluses forming on the hands or corns forming on the feet.

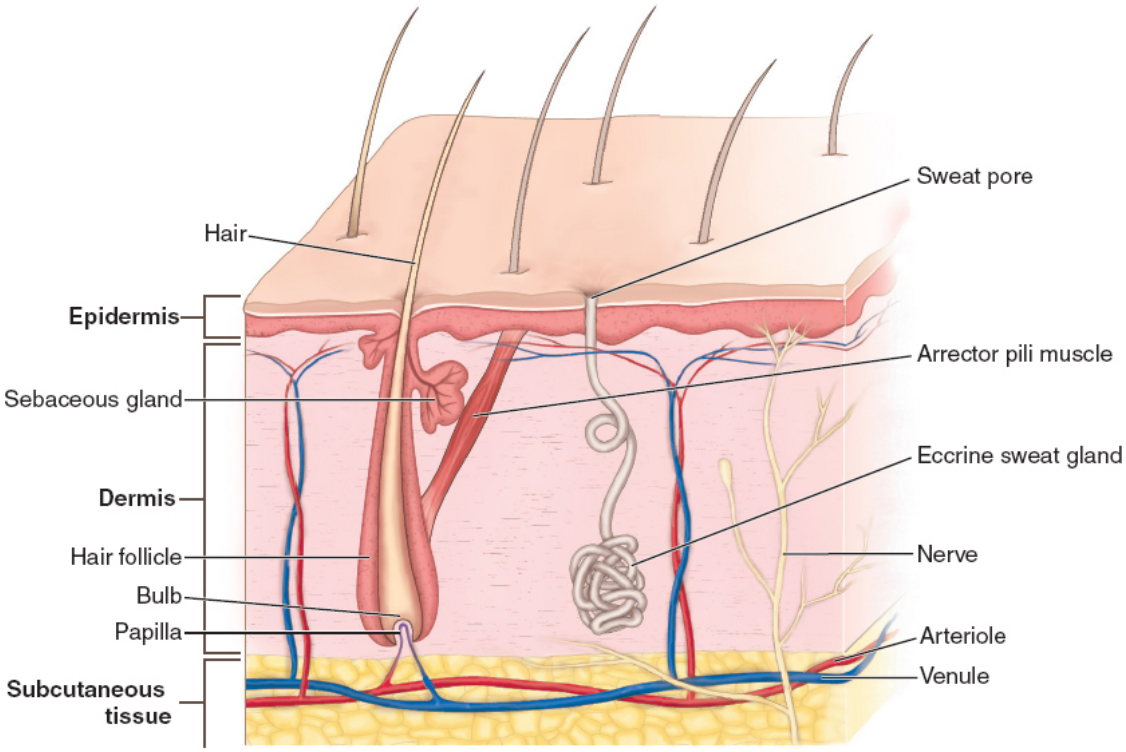

Figure 55-1 • Anatomic structures of the skin.

The junction of the epidermis and dermis is an area of undulations and furrows called **rete ridges** on the epidermal side and dermal papillae on the dermal side. Anchors found in this junction hold together the epidermis and dermis, permitting the free exchange of essential nutrients between the two layers. This interlocking between the dermis and epidermis produces ripples on the surface of the skin. On the fingertips, these ripples are called *fingerprints*. They are a person's most individual physical characteristic, and they rarely change over time (Wilhelmi & Molnar, 2018).

Dermis

The dermis makes up the largest portion of the skin, the connective tissue between the epidermis and subcutaneous tissue. It provides strength and structure in the form of collagen and elastic fibers. It is composed of two layers: papillary and reticular. Collagen fibers are loosely organized in the papillary dermis and are more tightly packed in the reticular dermis. The dermis also contains blood and lymph vessels, nerves, sweat and sebaceous glands, and hair roots.

Subcutaneous Tissue

The subcutaneous tissue, or hypodermis, is the innermost layer of the skin. It is primarily adipose and connective tissue, which provides a cushion between the skin layers and the muscles and bones. This layer also protects the nerve and

vascular structures that transect the layers. It promotes skin mobility, molds body contours, and insulates the body. The subcutaneous tissues and the amount of fat deposited are important factors in body temperature regulation.

Hair

An outgrowth of the skin, hair is present over the entire body except for the palms and soles. The hair consists of a root formed in the dermis and a hair shaft that projects beyond the skin. It grows in a cavity called a *hair follicle.* Proliferation of cells in the bulb portion of the follicle causes the hair to form (see Fig. 55-1).

Throughout a person's life, hair follicles undergo continuous cycles of growth, transition, and rest. The rate of growth varies; beard growth is the most rapid, followed by hair on the scalp, axillae, thighs, and eyebrows. The growth (anagen) phase may last 2 to 6 years for scalp hair, the involution (catagen) phase lasts 2 to 3 weeks, followed by the telogen or resting phase, which lasts 2 to 3 months. During telogen, hair is shed from the body. The hair follicle independently recycles into the growing phase spontaneously (Nicol, 2016). Growing and resting hairs can be found side by side on all parts of the body. About 90% to 95% of the hair follicles on a normal scalp are in the growing (anagen) phase, around 1% are involuting (catagen), and 5% to 10% are in the shedding (telogen) phase at any one time. A person will typically shed approximately 100 scalp hairs each day (Habif, Dinulos, Chapman, et al., 2018).

There is a small bulge on the side of the hair follicle that houses the stem cells that migrate down to the follicle root and begin the hair shaft reproduction cycle. These bulges also contain the stem cells that migrate upward to reproduce skin. The location of these cells on the side of the hair shaft, rather than at the base, is a factor in hair loss. In conditions in which inflammation causes damage to the root of the hair, regrowth is possible. However, if inflammation causes damage to the side of the hair follicle, stem cells are destroyed, and the hair will not grow.

In certain locations on the body, hair growth is controlled by sex hormones. The most obvious example is the growth of hair on the face (i.e., beard, mustache), chest, and back, which is controlled by the male hormones known as androgens. Both men and women produce and need androgens, but in differing amounts. Women with higher levels of the androgen testosterone have hair in the areas generally thought of as masculine, such as the face, chest, and lower abdomen. This is often a normal genetic variation, but if it appears along with irregular menses and weight changes, it may indicate a hormonal imbalance (Habif et al., 2018).

Hair in different parts of the body serves different functions. The hairs of the eyes (i.e., eyebrows, lashes), nose, and ears filter out dust, bugs, and airborne debris. The hair of the skin provides thermal insulation in mammals

with hair or fur. This function is enhanced during cold or fright by piloerection (i.e., hairs standing on end), caused by contraction of the tiny erector muscles attached to the hair follicle. The piloerector response that occurs in humans is probably vestigial (i.e., rudimentary), no longer serving its original purpose.

Hair color is supplied by varying amounts of melanin within the hair shaft. Gray or white hair reflects the loss of pigment. Hair quantity and distribution can be affected by endocrine conditions. For example, Cushing's syndrome causes **hirsutism** (i.e., excessive hair growth), especially in women, and hypothyroidism (i.e., underactive thyroid) causes changes in hair texture. Various factors can cause localized or generalized loss of hair, or **alopecia.** Chemotherapy and radiation therapy cause reversible hair thinning or weakening of the hair shaft. Several autoimmune disorders, including systemic lupus erythematosus and alopecia areata, cause hair loss in smaller defined areas. Folliculitis of the scalp will cause inflammation of the hair roots and may result in scarring hair loss.

Nails

On the dorsal surface of the fingers and toes, a hard, transparent plate of keratin, called the *nail,* overlies the skin. The nail grows from its root, which lies under a thin fold of skin called the *cuticle.* Nail functions include scratching and protecting the highly developed sensory functions of fingers and toes to assist in grasping small items. The nails can also be of psychosocial importance as related to grooming and appearance (Nicol, 2016).

Nail growth is continuous throughout life, with an average growth of 0.1 mm daily. Growth is faster in fingernails than toenails and tends to slow with aging. Complete regeneration of a fingernail takes about 6 months, whereas toenail regeneration takes approximately 18 months (Bolognia, Schaffer, & Cerroni, 2017).

Glands of the Skin

There are two types of skin glands: **sebaceous glands** and sweat glands (see Fig. 55-1). The sebaceous glands are associated with hair follicles. The ducts of the sebaceous glands empty **sebum** (fatty secretions) onto the space between the hair follicle and the hair shaft, thus lubricating the hair and rendering the skin soft and pliable.

Sweat glands are found in the skin over most of the body surface, but they are most heavily concentrated in the palms of the hands and soles of the feet. Only the glans penis, clitoris, labia minora, the margins of the lips, the external ear, and the nail bed are devoid of sweat glands. Sweat glands are subclassified into two categories: eccrine and apocrine.

The eccrine sweat glands are found in all areas of the skin. Their ducts open directly onto the skin surface. The thin, watery secretion called *sweat* is

produced in the basal coiled portion of the eccrine gland and is released into its narrow duct. Sweat is composed predominantly of water and contains about half of the salt content of blood plasma. Sweat is released from eccrine glands in response to elevated ambient temperature and elevated body temperature. The rate of sweat secretion is under the control of the sympathetic nervous system. Excessive sweating of the palms and soles, axillae, forehead, and other areas may occur in response to pain and stress.

The apocrine sweat glands are larger than eccrine sweat glands and are located in the axillae, periumbilical area, nipple, anal region, scrotum, and labia majora. Their ducts generally open onto hair follicles. The apocrine glands become active at puberty. In women, they enlarge and recede with each menstrual cycle. Apocrine glands produce an oily sweat that is sometimes broken down by bacteria, such as *Corynebacterium* species, to produce the characteristic underarm odor. Specialized apocrine glands called *ceruminous glands* are found in the external ear, where they produce cerumen (i.e., wax).

Functions of the Skin

Protection

The skin covering most of the body is no more than 1 mm thick, but intact skin provides highly effective protection against invasion by bacteria and other foreign matter. The thickened skin of the palms and soles protects against the effects of the constant trauma that occurs in these areas.

The stratum corneum—the outer layer of the epidermis—provides the most effective barrier to epidermal water loss and penetration of environmental factors such as ultraviolet radiation, chemicals, microbes, and insect bites.

Various lipids are synthesized in the stratum corneum and are the basis for the barrier function of this layer. These are long-chain lipids that are suited for water-resistant ceramides, cholesterol, and free fatty acids (Bolognia et al., 2017). The presence of these lipids in the stratum corneum creates a relatively impermeable barrier for water loss and for the entry of toxins, microbes, and other substances that contact the surface of the skin.

Some substances do penetrate the skin but meet resistance in trying to move through the channels between the cell layers of the stratum corneum. Microbes and fungi, which are part of the body's normal flora, cannot penetrate unless there is a break in the skin barrier.

The basal layer, at the junction of the epidermis and dermis, is composed of collagen, anchoring fibers, and macromolecules. The basal layer serves four functions. It acts as a support structure for tissue organization and a template for regeneration; it provides selective permeability for migration of cells and proteins; it is a physical barrier between different types of cells; and it binds the epithelium to underlying cell layers (Bolognia et al., 2017).

Sensation

The receptor endings of nerves in the skin allow the body to constantly monitor the conditions of the immediate environment. The main functions of the receptors in the skin are to sense temperature, pain, light touch, and pressure (or heavy touch). Different nerve endings respond to each of the different stimuli. Although the nerve endings are distributed over the entire body, they are more concentrated in the head and distal extremities.

Fluid Balance

The stratum corneum—the outermost layer of the epidermis—has the capacity to absorb water, thereby preventing an excessive loss of water and electrolytes from the internal body and retaining moisture in the subcutaneous tissues. When skin is damaged, as occurs with a severe burn, large quantities of fluids and electrolytes may be lost rapidly, possibly leading to circulatory collapse, shock, and death (see Chapter 57).

The skin is not completely impermeable to water. Small amounts of water continuously evaporate from the skin surface. This evaporation, called *insensible perspiration,* amounts to approximately 500 mL daily in an average-sized adult (Norris, 2019). Insensible water loss varies with temperature, both body and ambient. In a person with a fever, the loss can increase in a predictable fashion, approximately 12% for every 1°C (1.8°F) increase in body temperature (Norris, 2019).

Temperature Regulation

The body, in the process of creating energy, continuously produces heat as a result of the metabolism of food. This heat is dissipated primarily through the skin. Three major physical processes are involved in loss of heat from the body to the environment. The first process—radiation—is the transfer of heat to another object of lower temperature situated at a distance. The second process—conduction—is the transfer of heat from the body to a cooler object in contact with it. The third process—convection, which consists of movement of warm air molecules away from the body—is the transfer of heat by conduction to the air surrounding the body.

Evaporation from the skin aids heat loss by conduction. Heat is conducted through the skin into water molecules on its surface, causing the water to evaporate. The water on the skin surface may be from insensible perspiration, sweat, or the environment.

Normally, all these heat loss mechanisms are used. When the ambient temperature is extremely high, evaporation becomes the only effective means to disperse generated body heat.

Under normal conditions, metabolic heat production is balanced by heat loss, and the internal temperature of the body is maintained constant at

approximately 37°C (98.6°F). The rate of heat loss depends primarily on the surface temperature of the skin, which is a function of the skin blood flow. Under normal conditions, the total blood circulated through the skin is approximately 450 mL/min, or 10 to 20 times the amount of blood required to provide necessary metabolites and oxygen. Blood flow through these skin vessels is controlled primarily by the sympathetic nervous system. Increased blood flow to the skin results in more heat delivered to the skin and a greater rate of heat loss from the body. In contrast, decreased skin blood flow reduces the skin temperature and helps conserve heat for the body. When the temperature of the body begins to fall, as occurs on a cold day, the blood vessels of the skin constrict, thereby reducing heat loss from the body (Bolognia et al., 2017).

Sweating is another process by which the body can regulate the rate of heat loss. Sweating does not occur until the core body temperature exceeds 37°C (98.6°F), regardless of skin temperature. In extremely hot environments, the rate of sweat production may be as high as 1 L/h. Under some circumstances (e.g., emotional stress), sweating may occur as a reflex and may be unrelated to the need to lose heat from the body (Bolognia et al., 2017).

Vitamin Production

Skin exposed to ultraviolet light can synthesize vitamin D (cholecalciferol). Vitamin D is essential for preventing osteoporosis and rickets, a condition that causes bone deformities and results from a deficiency of vitamin D, calcium, and phosphorus. Estimations vary on the amount of sunlight necessary for this synthesis to occur since numerous individual and environmental variables make a uniform recommendation difficult. In some projections, most people would need 5 to 30 minutes of sun exposure twice a week. No studies to date have determined if vitamin D synthesis in the skin can occur without increasing skin cancer risk (Office of Dietary Supplements, National Institutes of Health, 2019). Adequate amounts of Vitamin D should be obtained from a healthy diet and supplementation rather than intentional sun exposure (U.S. Department of Health and Human Services and U.S. Department of Agriculture, 2015).

Immune Response Function

The skin functions not only as a barrier defense against environmental hazards, but also produces immune responses. The skin has the capacity to generate innate and adaptive immune responses (Bolognia et al., 2017). Innate immune functions of the skin include the closely packed layers of the stratum corneum, the nonspecific inflammatory response of pattern recognition receptors, and a chemical environment that inhibits microbial colonization (Norris, 2019). The Langerhans cells of the skin are part of adaptive immunity. They function as

antigen-presenting cells, with the ability to transport foreign substances to nearby lymph nodes for cell-mediated immune reaction (Norris, 2019).

Gerontologic Considerations

The skin undergoes many physiologic changes associated with normal aging that affect functioning; these changes include decreased dermal thickness, degeneration of collagen, decreased sebum production, and increased vascular fragility (Norris, 2019). Other factors such as lifetime of excessive sun exposure, systemic diseases, and poor nutrition can increase the range of skin conditions and the rapidity with which they appear. In addition, certain medications (e.g., antihistamine, antibiotic, and diuretic agents) are photosensitizing and increase the damage that results from sun exposure.

The visible changes in the skin of older adults include dryness, wrinkling, uneven pigmentation, and various proliferative lesions. Cellular changes associated with aging include a thinning at the junction of the dermis and epidermis. The result of this thinning is fewer anchoring sites between the two skin layers, which means that even minor injury or stress to the epidermis can cause it to shear away from the dermis. This phenomenon may account for the increased vulnerability of aged skin to trauma. With increasing age, the epidermis and dermis thin and flatten, causing wrinkles, sags, and overlapping skin folds (Fig. 55-2).

Figure 55-2 • Hands with skin atrophy common to aging skin.

Loss of the subcutaneous tissue substances of elastin, collagen, and fat diminishes the protection and cushioning of underlying tissues and organs,

decreases muscle tone, and results in the loss of the insulating properties of fat.

Cellular replacement slows as a result of aging. As the dermal layers thin, the skin becomes fragile and transparent. The blood supply to the skin also changes with age. Vessels, especially the capillary loops, decrease in number and size. These vascular changes contribute to the delayed wound healing commonly seen in the older adult patient. The dry scaly skin common in aging is likely the consequence of decreased water retention by an impaired stratum corneum and the decreased number and functional ability of sweat and sebaceous glands (Bolognia et al., 2017). Reduced androgen levels are thought to contribute to declining sebaceous gland function.

Hair growth gradually diminishes, especially over the lower legs and dorsum of the feet. Thinning is common in the scalp, axillae, and pubic areas. Other functions affected by normal aging include the barrier function of skin, sensory perception, and thermoregulation.

Damage from excessive sun exposure, called photoaging, has detrimental effects on the normal aging of skin. A lifetime of outdoor work or outdoor activities (e.g., construction work, lifeguarding, sunbathing) without prudent use of covering clothing and sunscreens can lead to profound wrinkling, increased loss of elasticity, mottled, pigmented areas, cutaneous atrophy, and benign or malignant lesions.

Many skin lesions are part of normal aging. Recognizing and differentiating these lesions enables the examiner to assist the patient to feel less anxious about changes in skin. Chart 55-1 summarizes some skin lesions that are expected to appear as the skin ages. These are normal and require no special attention unless the skin becomes infected or irritated.

Assessment

When caring for patients with dermatologic disorders, the nurse obtains important information through the health history and direct observations. The nurse's skill in physical assessment and an understanding of the anatomy and function of the skin can ensure that deviations from normal are recognized, reported, and documented.

Chart 55-1

Benign Changes in the Skin of the Older Adult

- Cherry angiomas (bright red “moles”)
- Diminished hair, especially on scalp and pubic area
- Dyschromias (color variations)
  - Solar lentigo (liver spot)
  - Melasma (dark discoloration of the skin)
  - Lentigines (freckles)
- Neurodermatitis (itchy spots)
- Seborrheic keratoses (crusty brown “stuck-on” patches)
- Spider angiomas (see Chapter 43, Fig. 43-3)
- Telangiectasias (red marks on skin caused by stretching of the superficial blood vessels)
- Wrinkles
- Xerosis (dryness)
- Xanthelasma (yellowish waxy deposits on upper and lower eyelids)

Health History

During the health history interview, the nurse asks about use of hair and skin products, as well as any family and personal history of skin allergies; allergic reactions to food, medications, and chemicals; previous skin conditions; and skin cancer (Weber & Kelley, 2018). The health history addresses the onset, signs and symptoms, location, and duration of any pain, itching, rash, or other discomfort experienced by the patient. The names of cosmetics, soaps, shampoos, and other personal hygiene products are obtained if there have been any recent skin conditions noticed with the use of these products. The patient is questioned about nonprescription or herbal preparations that are being used. Chart 55-2 lists selected questions useful in obtaining appropriate information, and Chart 55-3 provides genetic factors influencing skin conditions.

Unfolding Patient Stories: Vincent Brody • Part 2

Recall from Chapter 3 **Vincent Brody**, with chronic obstructive pulmonary disease (COPD), who spends most of the day in a recliner chair smoking and has a poor nutritional intake due to shortness of breath. He is admitted to the hospital with COPD exacerbation. What are factors related to his diagnosis? What background information can influence skin breakdown? Describe the skin assessment performed by the nurse.

Care for Vincent and other patients in a realistic virtual environment: *vSim*(**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

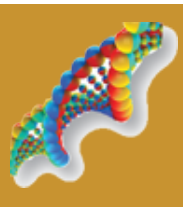
Physical Assessment

Assessment of the skin involves the entire skin area, including the mucous membranes, scalp, hair, and nails. The skin reflects a person's overall health, and alterations commonly correspond to disease in other organ systems. Inspection and palpation are techniques commonly used in examining the skin. The room must be well lighted and warm. A penlight may be used to highlight lesions. The patient completely disrobes and is adequately draped. Gloves are worn during skin examination.

The general appearance of the skin is assessed by observing color, temperature, moisture or dryness, skin texture (rough or smooth), lesions, vascularity, mobility, and the condition of the hair and nails. Skin turgor, possible edema, and elasticity are assessed by palpation.

Assessing Skin Color

The color gradations that occur in people with dark skin are largely determined by genetics; they may be described as light, medium, or dark. In people with dark skin, melanin is produced at a faster rate and in larger quantities than in people with light skin. Healthy dark skin has a reddish base or undertone. The buccal mucosa, tongue, lips, and nails normally are pink. The skin of exposed portions of the body, especially in sunny, warm climates, tends to be more pigmented than the rest of the body. Almost every process that occurs on the skin causes some color change. For example, **hypopigmentation** (i.e., loss of pigmentation) may be caused by a fungal infection, eczema, or **vitiligo** (i.e., white patches); **hyperpigmentation** (i.e., increase in pigmentation) can occur after sun injury or as a result of aging. Dark pigment responds with discoloration after injury or inflammation, and patients with dark skin more often experience postinflammatory hyperpigmentation than those with lighter



skin. The hyperpigmentation eventually fades but may require months to do so.

Chart 55-2  ASSESSMENT

Assessing for Skin Disorders

Patient history relevant to skin disorders may be obtained by asking the following questions:

- When did you first notice this skin problem? (In addition, investigate duration and intensity.)
- Has it occurred previously?
- Are there any other symptoms?
- What site was first affected?
- What did the rash or lesion look like when it first appeared?
- Where and how fast did it spread?
- Do you have any itching, burning, tingling, or crawling sensations?
- Is there any loss of sensation?
- Is the problem worse at a particular time or season?
- How do you think it started?
- Do you have a history of hay fever, asthma, hives, eczema, or allergies?
- Who in your family has skin problems or rashes?
- Did the eruptions appear after certain foods were eaten? Which foods?
- When the problem occurred, had you recently consumed alcohol?
- What relation do you think there may be between a specific event and the outbreak of the rash or lesion?
- What medications are you taking?
- What topical medication (ointment, cream, salve) have you put on the lesion (including over-the-counter medications)?
- What skin products or cosmetics do you use?
- What is your occupation?
- What in your immediate environment (plants, animals, chemicals, infections) might be precipitating this disorder? Is there anything new, or are there any changes in the environment?
- Does anything touching your skin cause a rash?
- How has this affected you (or your life)?
- Is there anything else you wish to talk about in regard to this disorder?

Chart 55-3  GENETICS IN NURSING PRACTICE

Integumentary Conditions

Integumentary conditions influenced by genetic factors include the following:

Autosomal Dominant:

- Ehlers–Danlos
- Legius syndrome
- Loeys–Dietz syndrome
- Neurofibromatosis type 1
- Tuberous sclerosis

Autosomal Recessive:

- Albinism
- Congenital ichthyosis

X-Linked Dominant:

- Incontinentia pigmenti

X-Linked Recessive:

- Hypohidrotic ectodermal dysplasia
- Pseudoxanthoma elasticum

Inheritance pattern is not distinct; however, there is a genetic predisposition for the disease:

- Ectodermal dysplasias
- Eczema
- Port-wine stain
- Psoriasis

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Skin Disorders

- Assess for family members in the past three generations with integumentary impairment or abnormalities.
- Inquire about the nature and type of skin lesions and age at onset (e.g., skin involvement with incontinentia pigmenti occurs in the first few weeks of life with blistering of the skin, whereas lesions of neurofibromatosis type 1 may appear in early childhood through adulthood).
- Note gender of affected individuals (e.g., mostly females with incontinentia pigmenti, mostly males with hypohidrotic ectodermal dysplasia).

- Inquire about the presence of other clinical features, such as unusual hair, teeth, or nails; thrombocytopenia; recurrent infections.

Patient Assessment

- Assess for related clinical features, such as sparse eyebrows and eyelashes, abnormally shaped teeth, alopecia, nail abnormalities (e.g., hypohidrotic ectodermal dysplasia).
- Assess for related alterations in vision, such as nystagmus or strabismus; albinism; retinal abnormalities (e.g., pseudoxanthoma elasticum); Lisch nodules and/or optic glioma (neurofibromatosis type 1).
- Perform a thorough skin assessment.
- Inquire about sensitivity to the sun.
- Obtain history of wounds and delayed healing time.
- Assess for receding gum line (as seen with Ehlers–Danlos).
- Assess, record location and size of all skin lesions (e.g., *café-au-lait* spots, port-wine stains, bruises).
- Assess for abdominal pulsations or distention (abdominal aneurysm common in Loeys–Dietz syndrome).
- Inspect skin for presence and location of freckles (axillary freckles are associated with genetic disorders). Inquire if freckles were present upon birth and if the amount or location of freckles has grown.

See Chapter 6, Chart 6-7 for components of genetic counseling.

Changes in skin color in people with dark skin are more noticeable and may cause more concern because the discoloration is more readily visible. Because of the increased activity of melanocytes in darker skin, pigment changes can become obvious and cause great psychological discomfort. Some variation in skin pigment levels is considered normal. Examples include the pigmented crease across the bridge of the nose, some pigmented streaks in the nails, and pigmented spots on the sclera of the eye. Women often develop a dark line along the midline of the lower abdomen during pregnancy (Weber & Kelley, 2018).

Table 55-1 provides an overview of select color changes in people who are light and dark skinned.

Cyanosis

Cyanosis is the bluish discoloration that results from a lack of oxygen in the blood (Fig. 55-3). It appears with shock or with respiratory or circulatory compromise. In people with light skin, cyanosis manifests as a bluish hue to

the lips, fingertips, and nail beds. Other indications of decreased tissue perfusion include cold, clammy skin; a rapid, thready pulse; and rapid, shallow respirations. The conjunctivae of the eyelids are examined for pallor and **petechiae** (i.e., pinpoint red spots that result from blood leakage into skin) (see Chapter 29, Fig. 29-4).

In a person with dark skin, the skin usually assumes a grayish cast. To detect cyanosis, the areas around the mouth and lips and over the cheekbones and earlobes should be observed.

Ecchymosis

Ecchymosis results from blood leaking into the skin and appears as varied discoloration (e.g., purple, black) which fades to green, yellow, or brown hues over time. It is most often seen following trauma (e.g., skin being struck with a solid object, fall) (Bickley & Szilagyi, 2017; Weber & Kelley, 2018). It is easier to observe in patients who have lighter skin color and may be seen more frequently in older adults due to increased skin fragility associated with collagen loss, decreased elasticity, and ultraviolet damage. The nurse should assess for unusual patterns or changes in ecchymoses that may indicate health disorders or abuse (Bickley & Szilagyi, 2017).

TABLE 55-1 Select Color Changes in Light and Dark Skin

Etiology	Light Skin	Dark Skin
Pallor		
Anemia—decreased hematocrit		
Shock—decreased perfusion, vasoconstriction	Generalized pallor	Brown skin appears yellow-brown, dull; black skin appears ashen gray, dull. (Observe areas with least pigmentation: conjunctivae, mucous membranes.)
Local arterial insufficiency	Marked localized pallor (lower extremities, especially when elevated)	Ashen gray, dull; cool to palpation
Albinism—total absence of pigment melanin	Whitish pink	Tan, cream, white
Vitiligo—a condition characterized by destruction of the melanocytes in circumscribed areas of the skin (may be localized or widespread)	Patchy, milky white spots, often symmetric bilaterally	Same
Cyanosis		
Increased amount of unoxygenated hemoglobin:	Dusky blue	Dark but dull, lifeless; only severe cyanosis is apparent in skin, and may appear grayish. (Observe conjunctivae, oral mucosa, nail beds.)
Central—chronic heart and lung diseases cause arterial desaturation	Nail beds dusky	
Peripheral—exposure to cold, anxiety		
Erythema		
Hyperemia—increased blood flow through engorged arterial vessels, as in inflammation, fever, alcohol intake, blushing	Red, bright pink	Purplish-gray tinge, but difficult to see. (Palpate for increased warmth with inflammation, taut skin, and hardening of deep tissues.)
Polycythemia—increased red blood	Ruddy blue in face, oral mucosa, conjunctivae,	Well concealed by pigment. (Observe for redness in lips.)

cells, capillary stasis	hands and feet	
Carbon monoxide poisoning	Bright, cherry red in face and upper torso	Cherry red nail beds, lips, and oral mucosa
Venous stasis—decreased blood flow from area, engorged venules	Dusky rubor of dependent extremities (a prelude to necrosis with pressure injury)	Easily masked. (Use palpation to identify warmth or edema.)
Jaundice		
Increased serum bilirubin concentration (>2 mg/dL) due to liver dysfunction or hemolysis, as after severe burns or some infections	Yellow first in sclerae, hard palate, and mucous membranes; then over skin	Check sclerae for yellow near limbus; do not mistake normal yellowish fatty deposits in the periphery under eyelids for jaundice. (Jaundice is best noted at junction of hard and soft palate, on palms.)
Carotenemia—increased level of serum carotene from ingestion of large amounts of carotene-rich foods	Yellow-orange tinge in forehead, palms and soles, and nasolabial folds, but no yellowing in sclerae or mucous membranes	Yellow-orange tinge in palms and soles
Uremia—kidney injury causes retained urochrome pigments in the blood	Orange-green or gray overlying pallor of anemia; may also have ecchymoses and purpura	Easily masked. (Rely on laboratory and clinical findings.)
Brown-Tan		
Addison disease—cortisol deficiency stimulates increased melanin production	Bronzed appearance, an "external tan"; most apparent around nipples, perineum, genitalia, and pressure points (inner thighs, buttocks, elbows, axillae)	Easily masked. (Rely on laboratory and clinical findings.)
Café-au-lait spots—caused by increased melanin pigment in basal cell layer	Tan to light brown, irregularly shaped, oval patch with well-defined borders	Often not visible in the person who is very dark skinned

Adapted from Taylor, S. C., Kelly, A. P., Lim, H., et al. (2016). *Dermatology for skin of color* (2nd ed.). New York: McGraw-Hill Medical; Weber, J. W., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

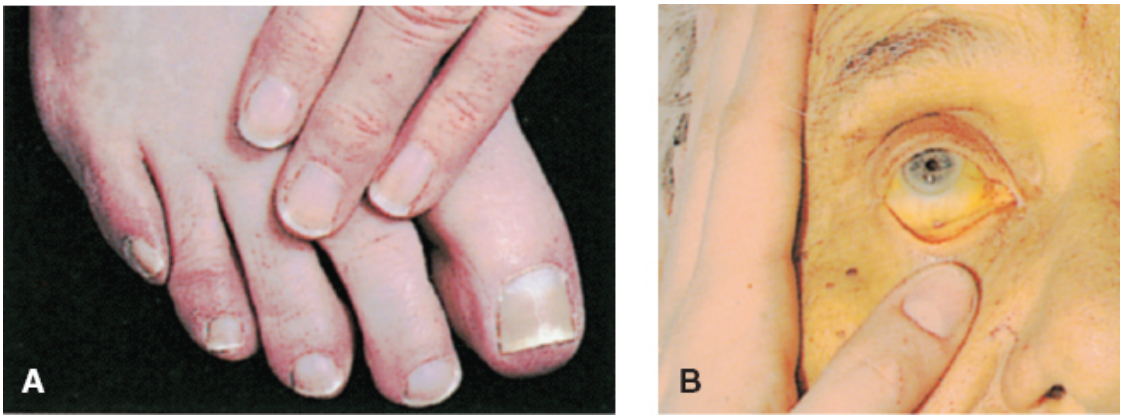

Figure 55-3 • Examples of skin color changes: (**A**) the bluish tint of cyanosis and (**B**) the yellow hue of jaundice. Reprinted with permission from Weber, J. W., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

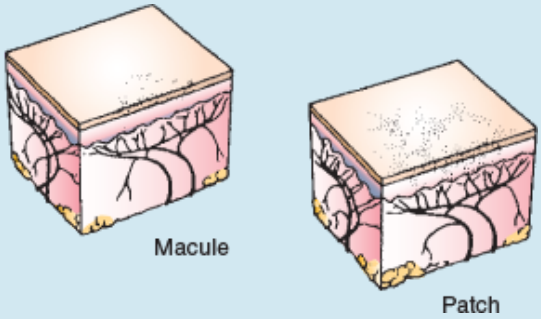
Erythema

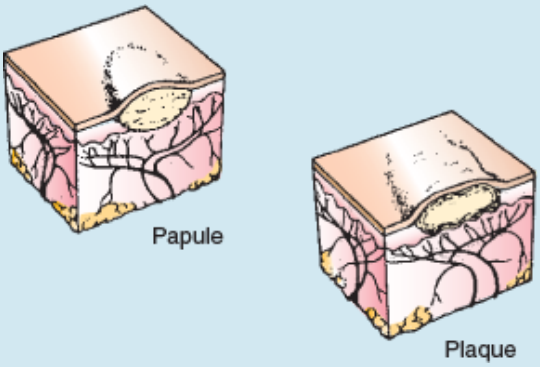
Erythema is redness of the skin caused by the dilation of capillaries. In people who are light skinned, it is easily observable. To determine possible inflammation, the skin is palpated for increased warmth and for smoothness (i.e., edema) or hardness (i.e., intracellular infiltration). Because dark skin tends to assume a purple-gray cast when an inflammatory process is present, it may be difficult to detect erythema.

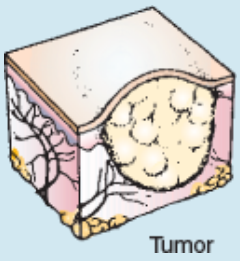
Jaundice

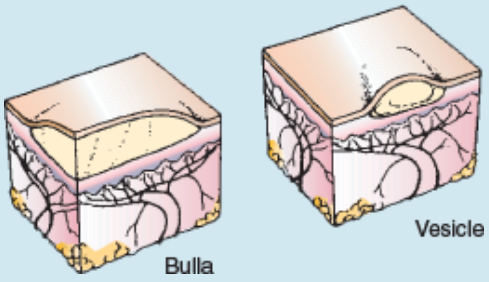
Jaundice, a yellowing of the skin, is directly related to elevations in serum bilirubin and is often first observed in the sclerae and mucous membranes (see Fig. 55-3).

Assessing Rash

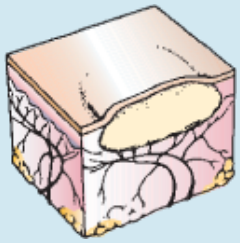


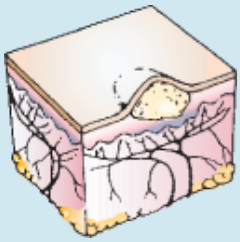


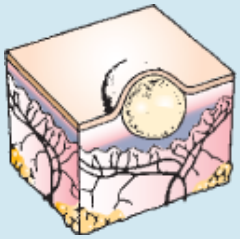




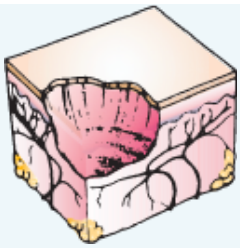
In instances of pruritus (i.e., itching), the patient is asked to indicate which areas of the body are involved. The skin is then stretched gently to decrease the reddish tone and make the rash more visible. Pointing a penlight laterally across the skin may highlight the rash, making it easier to observe. The differences in skin texture are then assessed by running the tips of the fingers lightly over the skin. The borders of the rash may be palpable. The patient's mouth and ears are included in the examination (rubeola, or measles, causes a red cast to appear on the ears, and skin cancers are quite common on the top of the ears). The patient's temperature is assessed, and the lymph nodes are palpated especially in the axillae, inguinal fold, and popliteal area (behind the knees).

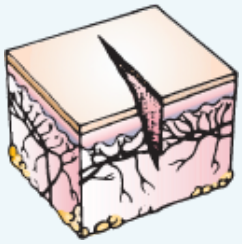


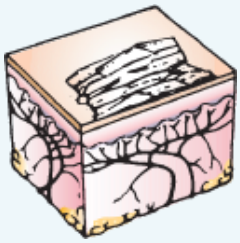


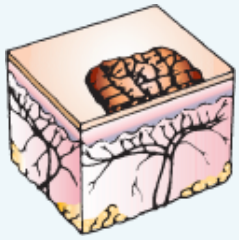


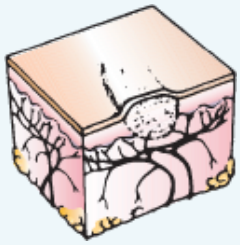
Assessing Skin Lesions



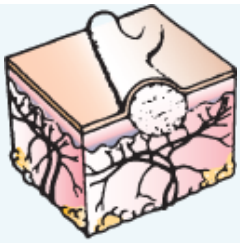


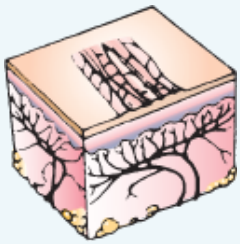






Skin lesions are the most prominent characteristics of dermatologic conditions. They vary in size, shape, and cause and are classified according to their appearance and origin. Skin lesions can be described as primary or secondary. Primary lesions are the initial lesions and are characteristic of the disease itself. Secondary lesions result from changes in primary lesions resulting from external causes, such as scratching, trauma, infections, or changes caused by wound healing. Depending on the stage of development, skin lesions are further categorized by type and appearance (Table 55-2).





A preliminary assessment of the eruption or lesion helps identify the type of dermatosis (i.e., abnormal skin condition) and indicates whether the lesion is primary or secondary. At the same time, the anatomic distribution of the eruption or lesion should be observed because certain diseases more regularly affect certain sites of the body and are distributed in characteristic patterns and shapes (Figs. 55-4 and 55-5). To determine the extent of the regional distribution, the left and right sides of the body should be compared while the color and shape of the lesions are assessed. The degree of pigmentation of the patient's skin may affect the appearance of a lesion. Lesions may be black, purple, or gray on dark skin and tan or red in patients with light skin. A metric ruler is used to measure the size of the lesions so that any further extension can be compared with this baseline measurement. After observation, the nurse palpates the lesions with gloves on to determine their texture, shape, and border and to see if they are soft and filled with fluid or hard and fixed to the surrounding tissue.

TABLE 55-2 Primary and Secondary Skin Lesions

Lesion	Description	Examples
Primary Lesions		
MACULE, PATCH  	Flat, nonpalpable skin color change (color may be brown, white, tan, purple, red) • *Macule:* <1 cm; circumscribed border • *Patch:* >1 cm; may have irregular border	Freckles, flat moles, petechia, rubella, vitiligo, port-wine stains, ecchymosis
PAPULE, PLAQUE  	Elevated, palpable, solid mass with a circumscribed border Plaque may be coalesced papules with flat top • *Papule:* <0.5 cm • *Plaque:* >0.5 cm	*Papules:* Elevated nevi, warts, lichen planus *Plaques:* Psoriasis, actinic keratosis
NODULE, TUMOR  	Elevated, palpable, solid mass that extends deeper into the dermis than a papule • *Nodule:* 0.5–2 cm; circumscribed • *Tumor:* >1–2 cm; tumors do not always have sharp borders	*Nodules:* Lipoma, squamous cell carcinoma, poorly absorbed injection, dermatofibroma *Tumors:* Larger lipoma, carcinoma
VESICLE, BULLA  	Circumscribed, elevated, palpable mass containing serous fluid • *Vesicle:* <0.5 cm • *Bulla:* >0.5 cm	*Vesicles:* Herpes simplex/zoster, varicella, poison ivy, second-degree burn (blister) *Bulla:* Pemphigus, contact dermatitis, large burn blisters, poison ivy,

		bullous impetigo
WHEAL 	Elevated mass with transient borders; often irregular; size and color vary Caused by movement of serous fluid into the dermis; does not contain free fluid in a cavity (e.g., as a vesicle does)	Urticaria (hives), insect bites
PUSTULE 	Pus-filled vesicle or bulla	Acne, impetigo, furuncles, carbuncles
CYST 	Encapsulated fluid-filled or semisolid mass in the subcutaneous tissue or dermis	Sebaceous cyst, epidermoid cysts
Secondary Lesions		
EROSION 	Loss of superficial epidermis that does not extend to dermis; depressed, moist area	Ruptured vesicles, scratch marks
ULCER	Skin loss extending past epidermis; necrotic tissue loss; bleeding and scarring possible	Stasis ulcer of venous insufficiency, pressure injury

		
FISSURE	Linear crack in the skin that may extend to dermis	Chapped lips or hands, tinea pedis
		
SCALES	Flakes secondary to desquamated, dead epithelium that may adhere to skin surface; color varies (silvery, white); texture varies (thick, fine)	Dandruff, psoriasis, dry skin, pityriasis rosea
		
CRUST	Dried residue of serum, blood, or pus on skin surface Large, adherent crust is a scab	Residue left after vesicle rupture: impetigo, herpes, eczema
		
SCAR (CICATRIX)	Skin mark left after healing of a wound or lesion; represents replacement by connective tissue of the injured tissue • *Young scars:* Red or purple • *Mature scars:* White or glistening	Healed wound or surgical incision
		
KELOID	Hypertrophied scar tissue secondary to excessive	Keloid of ear piercing or

	collagen formation during healing; elevated, irregular, red Greater incidence among African Americans	surgical incision
ATROPHY 	Thin, dry, transparent appearance of epidermis; loss of surface markings; secondary to loss of collagen and elastin; underlying vessels may be visible	Aged skin, arterial insufficiency
LICHENIFICATION 	Thickening and roughening of the skin or accentuated skin markings that may be secondary to repeated rubbing, irritation, scratching	Contact dermatitis

Adapted from Bickley, L. S., & Szilagyi, P. G. (2017). *Bates' guide to physical examination and history taking* (12th ed.). Philadelphia, PA: Wolters Kluwer; Weber, J. W., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Skin lesions are described clearly and in detail on the patient's health record, using precise terminology:

- Color of the lesion
  - Any redness, heat, pain, or swelling
  - Size and location of the involved area
  - Pattern of eruption (e.g., macular, papular, scaling, oozing, discrete, confluent)
  - Distribution of the lesion (e.g., bilateral, symmetric, linear, circular)

If acute open wounds or lesions are found on inspection of the skin, a comprehensive assessment should be made and documented. This assessment should address the following issues:

- *Wound bed:* Inspect for necrotic and granulation tissue, epithelium, exudate, color, and odor.
  - *Wound edges and margins:* Observe for undermining (i.e., extension of the wound under the surface skin), and evaluate for condition of

skin (i.e., necrotic).

- *Wound size:* Measure in centimeters, as appropriate, to determine diameter and depth of the wound and surrounding erythema.
- *Surrounding skin:* Assess for color, suppleness and moisture, irritation, and scaling.

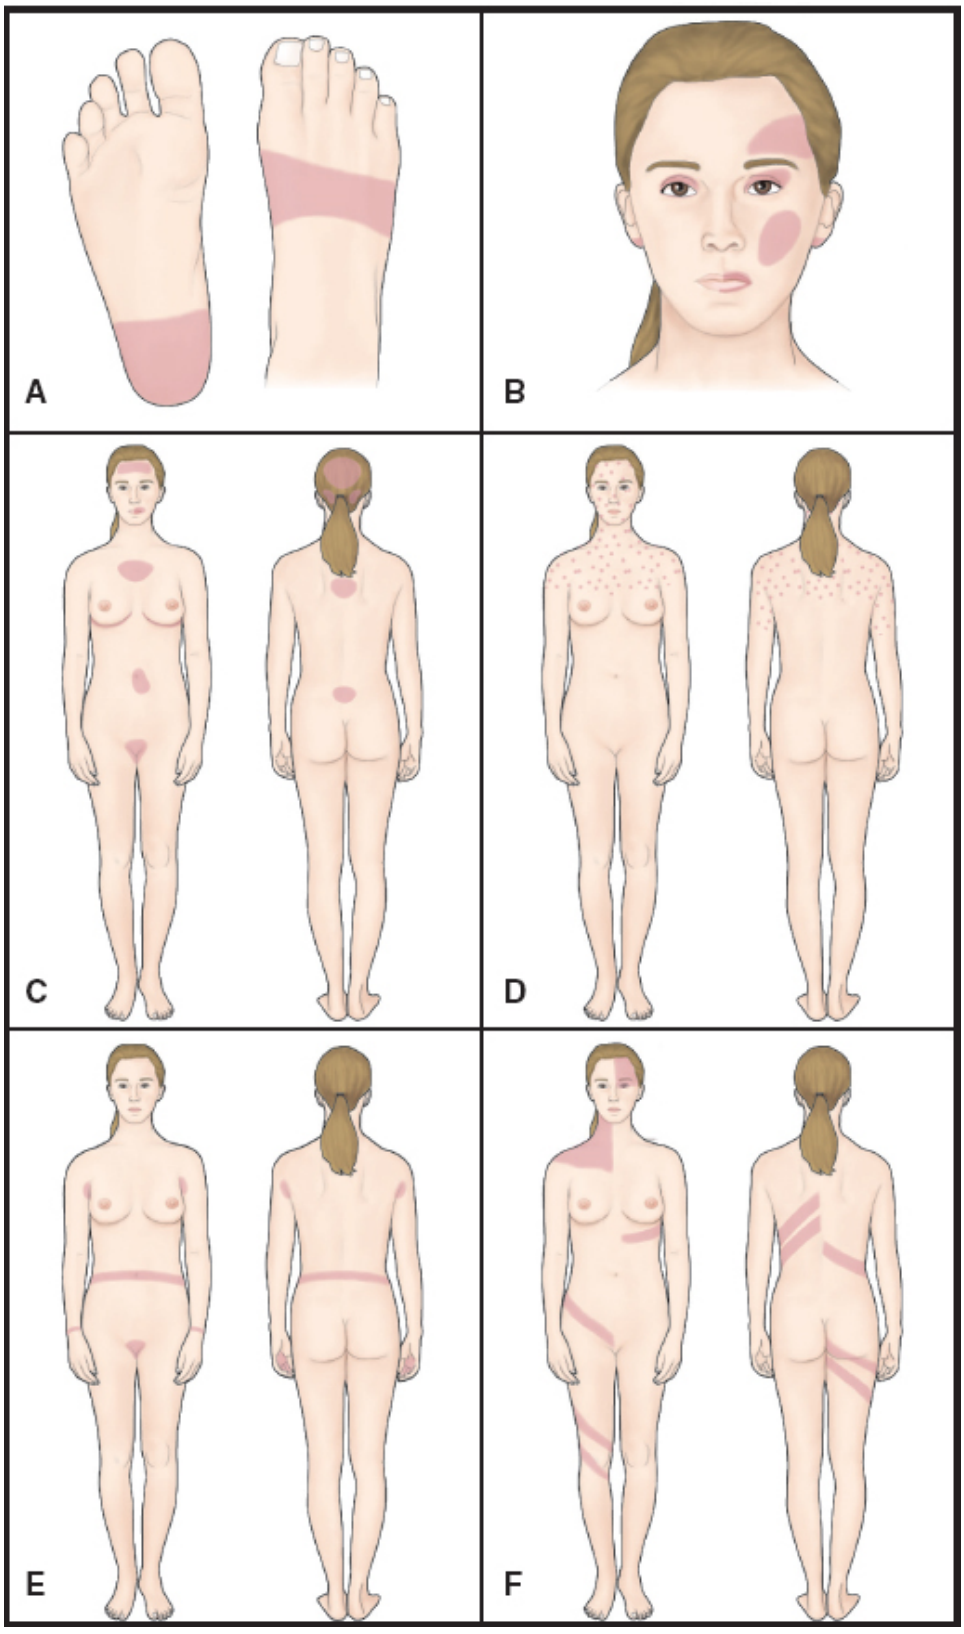


Figure 55-4 • Anatomic distribution of common skin disorders. **A.** Contact dermatitis (shoes). **B.** Contact dermatitis (cosmetics, perfumes, earrings). **C.** Seborrheic dermatitis. **D.** Acne. **E.** Scabies. **F.** Herpes zoster (shingles).

It is also important for the nurse to assess for other signs and symptoms associated with new skin lesions, such as pain, burning, or pruritus (see the Nursing Research Profile in Chart 55-4).

Assessing Vascularity and Hydration

After the color of the skin has been evaluated and lesions have been inspected, an assessment of vascular changes in the skin is performed. A description of vascular changes includes location, distribution, color, size, and the presence of pulsations. Common vascular changes include petechiae, ecchymoses, **telangiectasias** (vascular structures), and angiomas (Table 55-3).

Skin moisture, temperature, and texture are assessed primarily by palpation. The turgor (i.e., elasticity) of the skin, which decreases in normal aging, may be a factor in assessing the hydration status of a patient. To assess skin turgor, the skin should be gently pinched between the thumb and forefinger. The skin is observed to see how long it takes to return to baseline. People who are dehydrated or those with dry skin will display decreased skin turgor, where the skin remains tented after being pinched rather than returning to normal almost immediately. Edema is indicated when the skin appears tense and shiny, when a finger gently pressed into the skin leaves an indentation or "pit" (see Chapter 25, Fig. 25-2). Assessing the depth of the pit and length of time to resolution indicates the extent of edema (Bickley & Szilagyi, 2017).

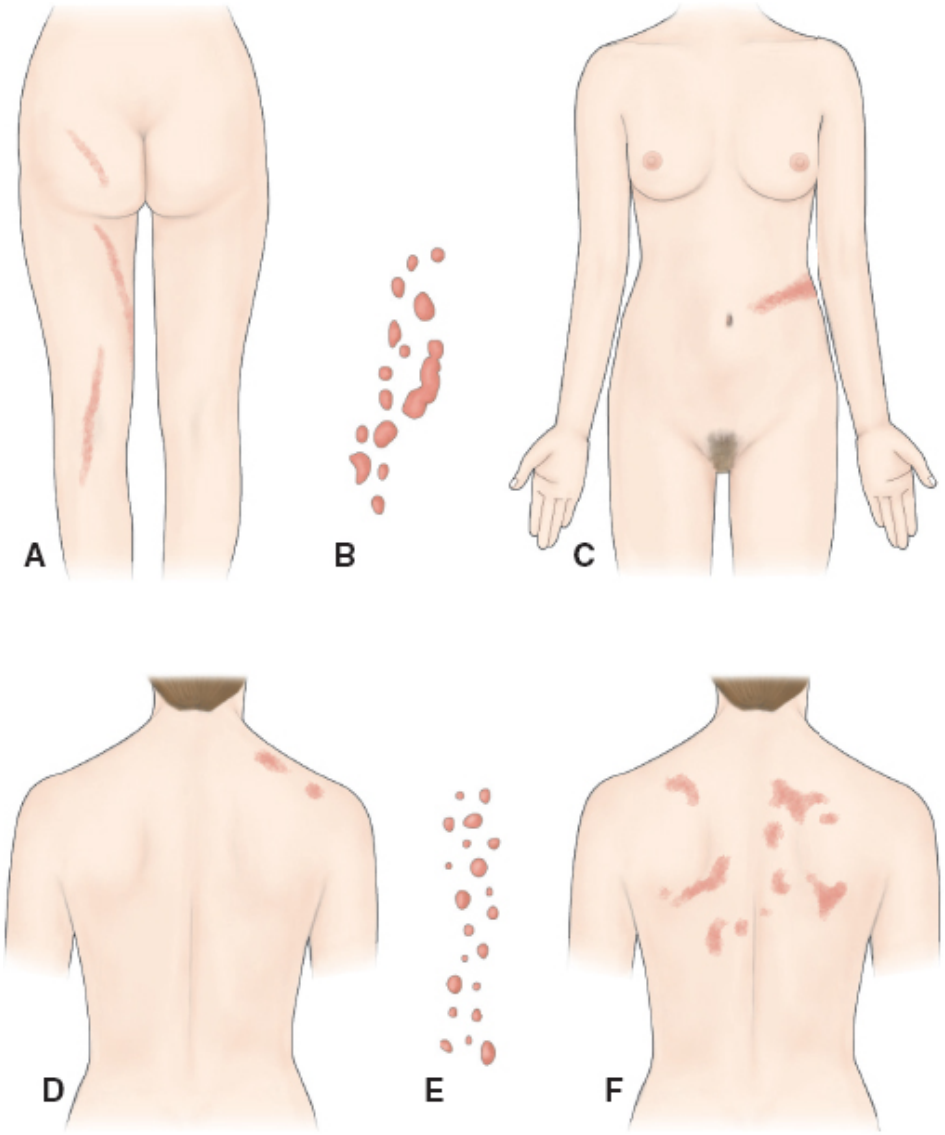

Figure 55-5 • Skin lesion configurations. **A.** Linear (in a line). **B.** Annular and arciform (circular or arcing). **C.** Zosteriform (linear along a nerve route). **D.** Grouped (clustered). **E.** Discrete (separate and distinct). **F.** Confluent (merged).

Assessing the Nails

A brief inspection of the nails includes observation of configuration, color, and consistency. Many alterations in the nail or nail bed reflect local or systemic abnormalities in progress or resulting from past events (Fig. 55-6). Beau lines, a transverse depression in the nails, may reflect retarded growth of the nail matrix because of severe illness or, more commonly, local trauma. Ridging, hypertrophy, and other changes may also be visible because of local trauma. Paronychia, an inflammation of the skin around the nail, is usually accompanied by tenderness and erythema. Pitted surface of the nails is a definite indication of psoriasis. Spoon-shaped nails can indicate severe iron-

deficiency anemia. The angle between the normal nail and its base is 160 degrees. When palpated, the nail base is usually firm. Clubbing of the nails is manifested by a straightening of the normal angle (180 degrees or greater) and softening of the nail base. The softened area feels spongelike when palpated (Bickley & Szilagyi, 2017). Clubbing can be a normal variant, but it is most often associated with pulmonary disease and can be a sign of chronic hypoxia (Norris, 2019).

Chart 55-4  NURSING RESEARCH PROFILE

Supporting Self-Care for Radiation-Related Skin Discomfort

Montpetit, C., & Singh-Carlson, S. (2018). Engaging patients with radiation related skin discomfort in self-care. *Canadian Oncology Nursing Journal = Revue Canadienne de Nursing Oncologique*, *28*(3), 191–200.

Purpose

Radiation dermatitis is a common side effect associated with radiation treatment for breast cancer. Patients undergoing radiation treatment experience varying levels of symptom severity. Some will experience significant discomfort affecting daily life and the ability to perform routine activities. This study evaluated the experience of using InterDry Ag dressing, a moisture-wicking fabric dressing impregnated with antimicrobial silver, and its effectiveness on decreasing skin irritation in women receiving radiation treatment for a diagnosis of breast cancer.

Design

A radiation oncology nurse (RON) affiliated with a regional cancer agency recruited participants for this descriptive study at the onset of their radiation treatment. Individuals were asked to participate if they were able to speak and read English fluently, had no allergy to silver, were receiving radiation treatment for breast cancer, and had developed a skin reaction from the radiation treatment. Skin assessments and skin care education (e.g., application of dressings, use of saline compressions and moisturizers) were provided to all participants receiving radiation. The InterDry Ag dressing was utilized in participants with moderate erythema, pruritus, or burning and evaluated during therapy using the National Cancer Institute: Common Terminology Criteria for Adverse Events (NCI CTCAE) (version 4.03) radiation dermatitis tool. In addition, a questionnaire to assess participants' discomfort and ease of dressing use was administered 5 days after dressing application. Follow-up was also conducted both 1-week (via telephone) and 2-week (in-person) post radiation by the RON. Descriptive statistics were generated to assess study variables (e.g., demographics, erythema, pain, pruritus) and content analysis was conducted to synthesize responses to open-ended questions included in the survey.

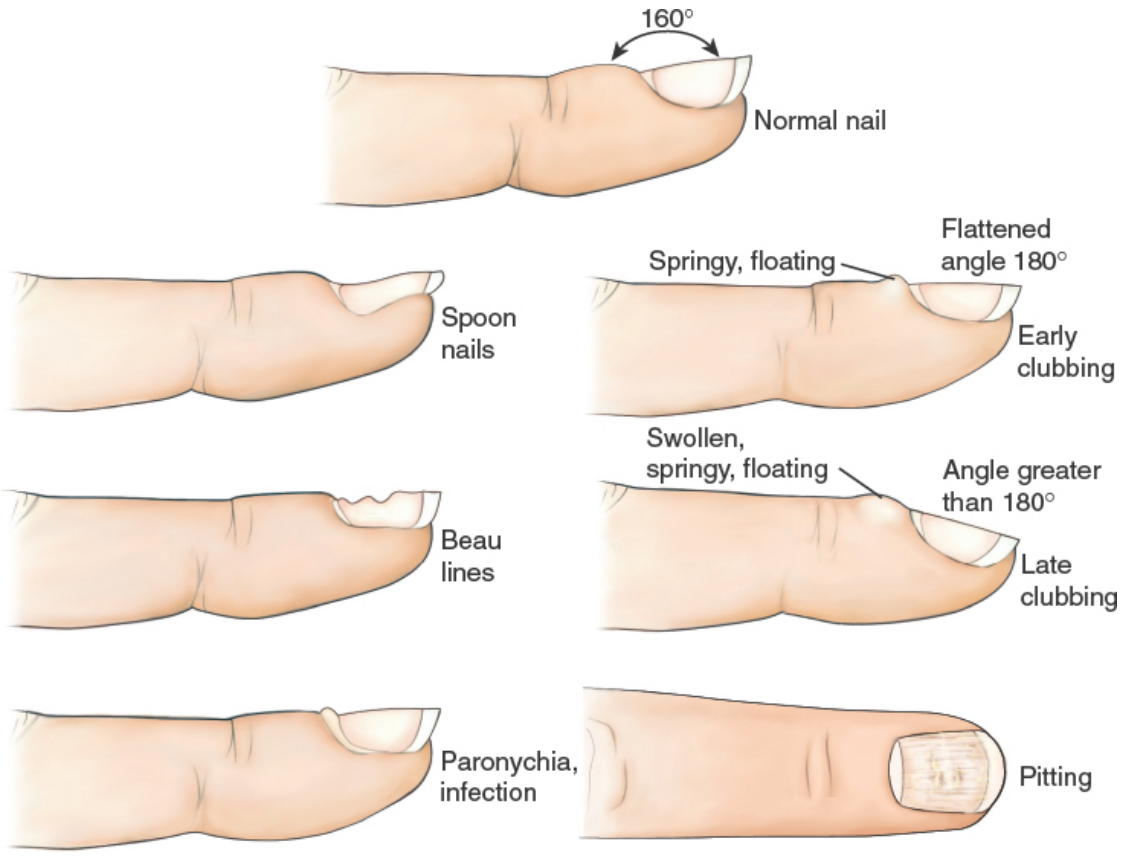
Findings

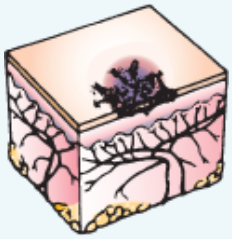
Eighteen participants with a median age of 42 (range 36 to 74 years), completed the study. Breast characteristics (e.g., size, skin tone) and cancer treatment were variable. Skin assessments completed by the RON (5 days post application) noted reductions in pain reported for the chest wall and inframammary fold and improved pruritus for the axilla and chest wall. At 2 weeks post application, the majority of participants either agreed or strongly agreed that the dressing was easy to use (100%) and that it decreased pain (90%), pruritus (88%), and burning (78%); 95% of participants would recommend the dressing to others. Qualitative findings reinforced symptom

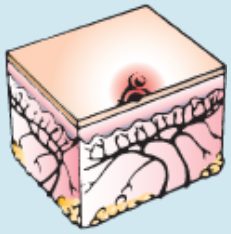
improvement with use of the dressing; however, some participants noted that it was difficult to keep the dressing in place.

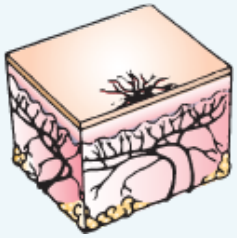
Nursing Implications

This small descriptive study demonstrated preliminary support for the effectiveness of and satisfaction with InterDry Ag dressing in improving the symptoms of radiation dermatitis experienced by women receiving radiation treatment for breast cancer. In addition, participants expressed feelings of safety, control over self-care problems, a sense of emotional support, and satisfaction with the nurse–patient relationship that developed in response to ongoing assessment and follow-up. Nurses should be aware that options are available to minimize radiation-associated skin discomfort for patients with breast cancer and that regular interaction between the patient and nurse may contribute to more satisfactory and personalized cancer care. However, experimental studies that include larger, more diverse samples and collect data using valid and reliable scales over time are necessary to provide stronger evidence of the benefits of the InterDry Ag dressing.









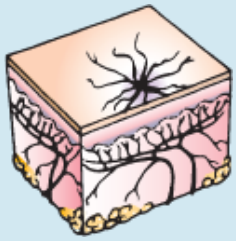


Figure 55-6 • Common nail disorders.

TABLE 55-3 Vascular Lesions

PETECHIA (*PL.* PETECHIAE) 	Round red or purple macule Small (1–2 mm) Secondary to blood extravasation Associated with bleeding tendencies or emboli to skin
ECCHYMOSIS (*PL.* ECCHYMOSES) 	Round or irregular macular lesion Larger than petechia Color varies and changes—purple, black, yellow, and green hues Secondary to blood extravasation Associated with trauma, bleeding tendencies
CHERRY ANGIOMA 	Papular and round Red or purple Noted on trunk, extremities May blanch with pressure Normal age-related skin alteration Usually not clinically significant
SPIDER ANGIOMA 	Red, arteriole lesion Central body with radiating branches Noted on face, neck, arms, trunk Rare below the waist May blanch with pressure Associated with liver disease, pregnancy, vitamin B deficiency
TELANGIECTASIA (VASCULAR STRUCTURE) 	Shape varies—spiderlike or linear Color bluish or red Does not blanch when pressure is applied Noted on legs, anterior chest Secondary to superficial dilation of venous vessels and capillaries Associated with increased venous pressure states (varicosities)

Adapted from Bickley, L. S., & Szilagyi, P. G. (2017). *Bates' guide to physical examination and history taking* (12th ed.). Philadelphia, PA: Wolters Kluwer; Weber, J. W., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Assessing the Hair

The hair assessment is carried out by inspection and palpation. Gloves are worn by the examiner, and the examination room should be well lighted. The hair is separated so that the condition of the skin underneath can be easily seen. The examiner notes the color, texture, and distribution of hair shafts. The wooden end of a cotton swab can be used to make small parts in the hair so that the scalp can be inspected. Any abnormal lesions, evidence of itching, inflammation, scaling, or signs of infestation (i.e., lice or mites) are documented.

Color and Texture

Natural hair color ranges from white to black. Hair begins to turn gray or white with age, when loss of melanin in the hair shaft becomes apparent. Loss of melanin in hair can occur at a younger age and may be due to heredity or genetic traits. The person with albinism (i.e., partial or complete absence of pigmentation) has a genetic predisposition to white hair from birth. The natural state of the hair can be altered by using hair dyes, bleaches, and curling or relaxing products. The use of these products has varying impact on hair, depending on its natural characteristics. For example, the use of straightening chemicals on the hair of most people can cause extensive breakage and hair loss (Bobonich & Nolen, 2014; Richardson, Agidi, Eaddy, et al., 2017).

The texture of scalp hair ranges from fine to coarse, silky to brittle, oily to dry, and shiny to dull, and hair can be straight, curly, or kinky. Dry, brittle hair may result from the overuse of hair dyes, hair dryers, and curling irons or from endocrine disorders, such as thyroid dysfunction. Oily hair is usually caused by increased secretion from the sebaceous glands close to the scalp. If the patient reports a recent change in hair texture, the underlying reason is pursued; the alteration may arise simply from the overuse of commercial hair products or from changing to a new shampoo.

Distribution

Body hair distribution varies with location. Hair over most of the body is fine, except in the axillae and pubic areas, where it is coarse. Pubic hair, which develops at puberty, forms a diamond shape extending up to the umbilicus in cisgender boys and men. Cisgender female pubic hair resembles an inverted triangle. If the pattern found is more characteristic of the opposite gender, it may indicate an endocrine disorder and further investigation is in order. Racial differences in hair are expected, such as straight hair in people of Asian descent and curly, coarse hair in people of African descent.

Men tend to have more body and facial hair than women. Alopecia can occur over the entire body or be localized to a specific area. Scalp hair loss may be patchy or may range from generalized thinning to total baldness. When assessing scalp hair loss, it is important to investigate the underlying cause with the patient. Patchy hair loss may be from habitual hair pulling or twisting; excessive traction on the hair (e.g., braiding too tightly); excessive use of dyes, straighteners, and oils; chemotherapeutic agents (e.g., doxorubicin, cyclophosphamide); bacterial or fungal infection; or moles or lesions on the scalp. Well-defined patches of localized hair loss generally indicate the condition called *alopecia areata.* The precise mechanism is unknown but may be triggered by an interaction between genetic and environmental factors. Regrowth in most cases is spontaneous and occurs in 1 to 3 months, though in some rarer patterns, the hair loss is recurrent or even permanent (Habif et al., 2018).

Hair Loss

The most common cause of male pattern hair loss or baldness is androgenic alopecia, which affects more than half of the male population and is believed to be related to heredity, aging, and androgen (male hormone) levels. Androgen is necessary for male pattern hair loss to develop. The pattern of hair loss begins with receding of the hairline in the frontal temporal area and may progress to gradual thinning and complete loss of hair over the top of the scalp and crown. The typical pattern of male hair loss is illustrated in Figure 55-7A. Although androgenic alopecia is considered a male disorder, millions of women experience female pattern hair loss, which is typically not seen with other signs of hyperandrogenism. For women complete baldness is rare; the typical pattern of hair loss is seen on the vertex scalp, sparing the frontal area (Nicol, 2016) (Fig. 55-7B).

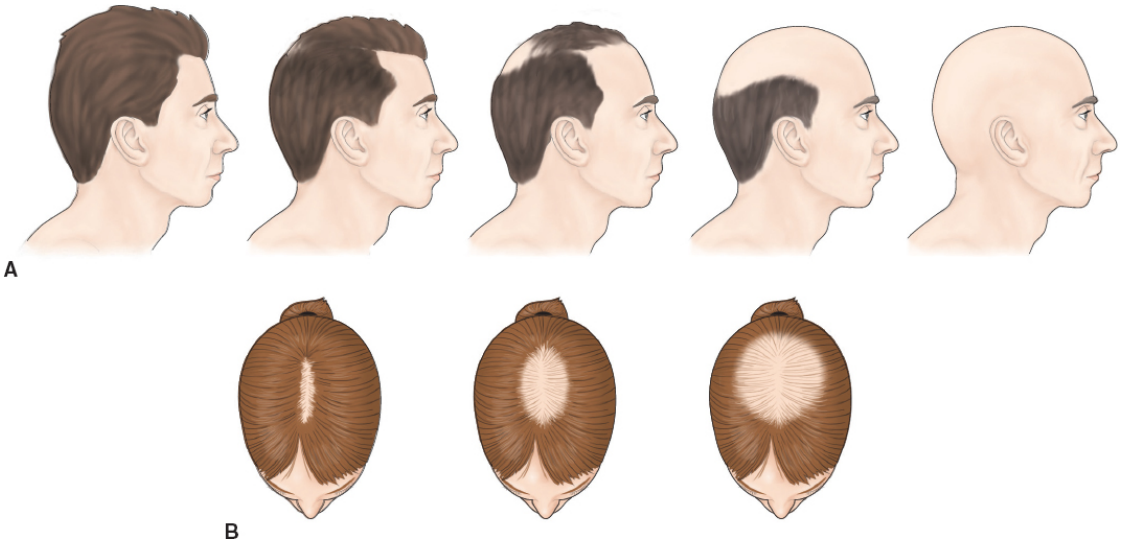

Figure 55-7 • Hair loss. **A.** Progression of male pattern hair loss. **B.** Progression of female pattern hair loss.

Other Changes

Male pattern hair distribution may be seen in some women at the time of menopause, when the hormone estrogen is no longer produced by the ovaries. In women with hirsutism, excessive hair may grow on the face, chest, shoulders, and pubic area. If menopause is ruled out as the underlying cause, other hormonal changes related to pituitary or adrenal dysfunction must be investigated.

Because patients with skin conditions may be viewed negatively by others, these patients may experience psychological distress and avoid interactions and intimacy. Skin conditions can lead to isolation, job loss, and economic hardship as well as poor self-esteem.

Some conditions may lead to feelings of depression, frustration, self-consciousness, poor self-image, and rejection. Itching and skin irritation (features of many skin diseases) may be constant sources of physical distress. These discomforts may result in loss of sleep, anxiety, and depressive symptoms, all of which reinforce the general distress and fatigue that frequently accompany skin disorders.

For patients experiencing physical and psychological discomforts, the nurse needs to provide understanding, explanations of the problem, appropriate education related to treatment, nursing support, and encouragement. It is imperative to overcome any aversion that may be felt when caring for patients with unattractive skin disorders. The nurse should show no sign of hesitancy when approaching patients with skin disorders. Such hesitancy only reinforces the psychological trauma of the disorder.

Skin Consequences of Select Systemic Diseases

Diabetes

Because diabetes causes changes in circulation and cell nutrition, it can have a great impact on skin status. Some of the more common skin conditions encountered in diabetes are discussed in this section. Further information can be found in Chapter 46.

Diabetic Dermopathy

Diabetic dermopathy (shin spots or pigmented pretibial papules) is a frequent occurrence in people with diabetes. These lesions are found most often on the lower anterior legs. They are thought to be caused by diabetes-associated changes in the small vessels that supply the skin and trauma. Each cluster starts as dull red papules that slowly coalesce to brownish atrophic patches (Nicol, 2016).

Stasis Dermatitis

Stasis dermatitis is an eczematous eruption that occurs on the lower legs of patients with venous insufficiency. It is very common in patients with diabetes. Large vessels are damaged, compromising circulation to the lower arms and legs. The skin suffers from lack of nutrients, becoming very dry and fragile. Minor injuries heal slowly, and ulcers form easily. It initially presents with variable erythema and scale and pruritus. When chronic, it leads to permanent changes in skin color, hyper- or hypopigmentation, and either fragile or thicker skin texture (fibrosis).

Skin Infections

Bacterial infections may appear as small pimples around hair follicles (i.e., folliculitis). The most frequently affected sites include the lower legs, lower abdomen, and buttocks. Sometimes, these lesions enlarge to become furuncles or carbuncles. Furuncles begin in a hair follicle, progressively enlarging and invading deeper into tissue to form an abscess. Carbuncles are formed by multiple contiguous lesions (Habif et al., 2018). The skin of patients with diabetes is prone to bacterial and fungal infections. If the blood glucose level is not well controlled, these infections may be very slow to heal.

Fungal infections are quite common in areas that remain moist (under breasts, upper thighs, in axillae). *Candida* (i.e., yeast) infections appear beefy red and often have small pustules around the border of the area, with the skin appearing moist and raw.

Dermatophyte infections are dry and only minimally red, with more scale. Common sites are the toenails and feet.

Nurses must be alert to the signs of these common infections. If necessary, they should bring them to the attention of the patient's primary provider and help the patient or family learn basic skin maintenance techniques.

Leg and Foot Ulcers

Because of changes in peripheral nerves, patients with diabetes do not always sense minor injuries to the lower legs and feet. Infections begin and, if untreated, may lead to ulcerations. Ulcerations are often not noticed and become quite large before being treated. Ulcerations unresponsive to treatment are a leading cause of diabetic foot and leg amputations (Johnson, Osburne, Rispoli, et al., 2018).

Human Immune Deficiency Virus Disease

Cutaneous signs may be the first manifestation of human immune deficiency virus (HIV), appearing in more than 90% of people who are HIV infected as immune function deteriorates. These skin signs correlate with low $CD4^+$ counts. Some disorders such as Kaposi sarcoma, oral hairy leukoplakia, facial molluscum contagiosum, and oral candidiasis may suggest that $CD4^+$ counts are less than 200 to 300 cells/mcL. Skin infections, both bacterial and viral, are common and will appear more severe than expected. Acute flare of chronic conditions such as seborrhea or acne may indicate a new infection. Being sensitive to these changes can alert the nurse so that early interventions can be initiated (Schwartz, 2019).

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with altered integumentary function. The nurse educates the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse also notes trends in results because they provide information about whether lesions are primary or secondary, disease progression, and the patient's response to therapy.

Skin Biopsy

Performed to obtain tissue for microscopic examination, a skin biopsy may be obtained by shave, excision, or by a skin punch instrument that removes a small core of tissue. Biopsies are performed on skin nodules, plaques, blisters, and other lesions to rule out malignancy, to aid in diagnosis, and to perform additional testing such as Gram stain for bacteria or periodic acid–Schiff (PAS) for fungal elements.

Patch Testing

Performed to identify substances to which the patient has developed an allergy, patch testing involves applying the suspected allergens, such as nickel or

fragrances, to normal skin under occlusive patches. Patients wear these occluded strips on their backs for 48 hours, and the area is assessed after 72 hours. The development of redness, fine elevations, or itching is considered a weak positive reaction; fine blisters, papules, and severe itching indicate a moderately positive reaction; and blisters, pain, and ulceration indicate a strong positive reaction. The nurse educates the patient on means to avoid the reactive allergens, which is often quite difficult, due to the prevalence of many of these substances in the patient's environment.

Skin Scrapings

Tissue samples are scraped from suspected fungal lesions with a scalpel blade that has been moistened with oil so that the scraped skin adheres to the blade. The scraped material is transferred to a glass slide, covered with a coverslip, and examined microscopically. The spores and hyphae of dermatophyte infections, as well as infestations such as scabies, can be visualized.

Tzanck Smear

The Tzanck smear is a test used to examine cells from blistering skin conditions, such as herpes zoster, varicella, herpes simplex, and all forms of pemphigus. The secretions from a suspected lesion are applied to a glass slide, stained, and examined.

Wood Light Examination

Wood light is a special lamp that produces long-wave ultraviolet rays, which result in a characteristic blue to dark purple fluorescence. The color of the fluorescent light is best seen in a darkened room, where it is possible to differentiate epidermal from dermal lesions and hypo- and hyperpigmented lesions from normal skin. The patient is reassured that the light is not harmful to skin or eyes. Lesions that still contain melanin almost disappear under ultraviolet light, whereas lesions that are devoid of melanin increase in whiteness with ultraviolet light.

Clinical Photographs

Photographs are taken to document the nature and extent of the skin condition and are used to determine progress or improvement resulting from treatment. They are sometimes used to track the status of moles to document if the characteristics of the mole are changing.

Nursing Implications

The nurse may be responsible to ensure that consent forms are completed for surgical procedures and for clinical photography, that all specimens collected are managed according to protocol, that a log is maintained tracking specimens to and from the laboratory, and that results are received in a timely manner. The nurse educates the patient regarding appropriate care of surgical sites and implication of test results.

CRITICAL THINKING EXERCISES

1 ebp As a recent graduate nurse, you are aware that the U.S. Preventive Service Task Force (USPSTF) has given a grade B recommendation for providing sun protection education for individuals who are fair skinned, parents of young children, adolescents, and young adults. You share this recommendation with a patient, and the patient asks you to explain what a grade B recommendation means. How would you respond? Discuss sun protection behaviors you will include when providing this education. What other factors found when performing a skin examination or in the patient's history may make sun protection counseling advisable outside of this recommendation?

2 pq A 28-year-old woman who has rheumatoid arthritis was recently diagnosed with vitiligo and is expressing concerns about living with this condition. She has questions about how to protect her skin and how to cope with feelings of embarrassment. She also wants to know if her children are at risk for developing this condition. In providing patient education, which question will you address first? What education and resources will you provide and how will you counsel the patient to prioritize her physical, psychological, and emotional health?

56 Management of Patients with Dermatologic Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the medical and nursing management of the patient with a wound, pruritus, dermatologic secretory disorder, infections of the skin, parasitic skin diseases, or noninfectious inflammatory dermatoses.
2. Use the nursing process as a framework for care of the patient with a pressure injury, or with a blistering disorder including toxic epidermal necrolysis and Stevens–Johnson syndrome.
3. Discuss the medical and nursing management of the patient with skin tumors (benign, malignant, and metastatic).
4. Identify the medical and nursing management of the patient undergoing plastic or cosmetic procedures.

NURSING CONCEPTS

Functional Ability
Mobility
Tissue Integrity

GLOSSARY

acantholysis: separation of epidermal cells from each other due to damage or abnormality of the intracellular substance

bullae: large, fluid-filled blisters

carbuncle: localized skin infection involving several hair follicles

cheilitis: inflammation of the lips

comedones: the primary lesions of acne, caused by sebum blockage in the hair follicle

cytotoxic: destructive of cells

débridement: removal of necrotic or dead tissue by mechanical, surgical, chemical, or autolytic means

dermatitis: any inflammation of the skin

dermatosis: any abnormal skin lesion

epidermopoiesis: development of epidermal cells

furuncle: localized skin infection of a single or a few hair follicles (*synonym*: boil)

hydrophilic: a material that absorbs moisture

hydrophobic: a material that repels moisture

hygroscopic: a material that absorbs moisture from the air

lichenification: thickening of the horny layer of the skin (*synonym*: scaling)

liniments: lotions with added oil for increased softening of the skin

pressure injury: localized area of skin breakdown and/or underlying soft tissue damage due to prolonged pressure and insufficient blood supply; formerly known as *pressure ulcer*

pruritus: itching

pyodermas: pus-forming bacterial skin infections

sinus tract: course or path of tissue destruction occurring in any direction from the surface or edge of a wound (*synonym*: tunneling)

slough: soft, moist avascular (devitalized) tissue; may be white, yellow, tan, gray, or green; may be loose or firmly adherent

striae: bandlike streaks on the skin, distinguished by color, texture, depression, or elevation from the tissue in which they are found; usually purplish or white

suspensions: liquid preparations in which powder is suspended, requiring shaking before use

tinea: a common superficial fungal infection on the skin or scalp (*synonym*: ringworm)

undermining: area of destroyed tissue that extends extensively under intact skin along the periphery of a wound

xerosis: overly dry, rough skin

Dermatologic disorders are encountered frequently by nurses across many practice settings. Nursing management of patients with dermatologic disorders can range from simple interventions such as administering topical and systemic medications for prevention to treating complex pressure injuries. The nurse can also be instrumental in educating patients how to care for their skin and provide self-care for wounds. The objectives of nursing interventions are to prevent additional skin and tissue damage, prevent secondary infection, reverse the inflammatory process, and relieve the symptoms.

SKIN CARE

Some skin problems are markedly aggravated by soap and water; therefore, bathing routines are modified according to the condition. Denuded skin, whether the area of desquamation is large or small, is excessively prone to damage by chemicals, trauma, and even bathing. Friction occurs when skin rubs against another surface, which may happen when the skin is vigorously dried with a towel, resulting in damage to the epidermal and upper dermal skin layers (Bryant & Nix, 2016).

Protecting the Skin

The goal of routine skin care should be to maintain the acidic pH of the skin; therefore, alkaline soaps should be avoided. No-rinse, pH-balanced soap is the best. Moisturizing products, such as emollients and humectants, can be applied to help maintain skin moisture. Emollients moisturize and soften the skin; conversely, humectants attract water to moisturize skin with **xerosis** (very dry, rough skin) (Doughty & McNichol, 2016).

Basic skin care in bathing a patient with a skin disorder is as follows:

- A mild, lipid-free soap or soap substitute is used (e.g., Dove sensitive skin™, Cetaphil™, CeraVe™, VANICREAM™).
- The area is rinsed completely and blotted dry with a soft cloth.
- Deodorant soaps are avoided.
- Laundry detergents and fabric softener free of fragrance are used.

Special care is necessary when changing dressings. Sterile saline, or another prescribed solution, helps loosen crusts, remove exudates, or free an adherent dry dressing.

Preventing Secondary Infection

Skin lesions should be regarded as potentially infectious, and proper safety precautions should be observed until the diagnosis is established. Most lesions with purulent drainage contain infectious material. The nurse and primary provider must adhere to standard precautions and wear gloves when inspecting the skin or changing a dressing. The use of standard personal protective equipment (PPE) and proper disposal of any contaminated dressing is carried out according to the Occupational Safety and Health Administration (OSHA) regulations (OSHA, 2011).

Wound Dressing Care

Dressings can be categorized in several ways. An overview of select types of dressings and their indications is provided; however, this is not an exhaustive list of dressing types.

Passive dressings have only a protective function and maintain a moist environment for natural healing. They include those that just cover the area (e.g., DuoDERM™, Tegaderm™) and may remain in place for several days. *Interactive dressings* are capable of absorbing wound exudate while maintaining a moist environment in the area of the wound and allowing the surrounding skin to remain dry. They include hydrocolloids, alginates, and hydrogels. It is thought that interactive dressings are able to modify the physiology of the wound environment by modulating and stimulating cellular activity and by releasing growth factors (Dabiri, Damstetter, & Phillips, 2016). *Active dressings* improve the healing process and decrease the healing time. They include skin grafts and biologic skin substitutes. Both interactive and active dressings create a moist environment at the interface of the wound with the dressing.

Wicker dressings are ropelike dressings used to manage sinus tracts or wounds that have undermining (see later discussion of sinus tracts and undermining in Pressure Injuries). These are effective at absorbing drainage. Wicker dressings can be plain or antimicrobial. *Filler dressings* are best for deeper wounds; these fill the contour of the wound, allowing the wound to heal by secondary intention. *Cover dressings* are appropriate for surface wounds and also can be used as a secondary dressing over filler dressings. These dressings can be absorptive or hydrating, plain or antimicrobial (Doughty & McNichol, 2016).

Because so many wound care products are available, it is often difficult to select the most appropriate product for a specific wound. Selection of products should be made carefully because of their expense. Both clinical

efficacy and health-related outcomes (e.g., decreased pain, increased mobility) should be used to measure the success of a wound care product. Even with the availability of a large variety of dressings, an appropriate selection can be made if certain principles are maintained. These principles are referred to as the five rules of wound care (Dabiri et al., 2016).

1. *Rule 1: Categorization.* The nurse learns about dressings by generic category and compares new products with those that already make up the category. The nurse becomes familiar with indications, contraindications, and side effects. The best dressing may be created by combining products in different categories to achieve several goals at the same time. These categories are discussed in subsequent sections.
2. *Rule 2: Selection.* The nurse selects the safest and most effective, easy-to-use, and cost-effective dressing possible. Nurses follow the primary provider's prescriptions for dressings. They must be prepared to give the primary provider feedback about the dressing's effect on the wound, ease of use for the patient, and other considerations when applicable.
3. *Rule 3: Change.* The nurse changes dressings based on patient, wound, and dressing assessments, not on standardized routines.
4. *Rule 4: Evolution.* As the wound progresses through the phases of wound healing, the dressing protocol is altered to optimize healing. It is rare, especially in cases of chronic wounds, that the same dressing material is appropriate throughout the healing process. The nurse educates the patient or family caregiver about wound care and ensures that the family has access to appropriate dressing choices.
5. *Rule 5: Practice.* Practice with dressing material is required for the nurse to learn the performance parameters of the particular dressing. Refining the skills of applying appropriate dressings correctly and learning about new dressing products are essential nursing responsibilities. Dressing changes should not be delegated to unlicensed personnel; these techniques require the knowledge base and assessment skills of professional nurses.

TABLE 56-1  Functions and Actions of Wound Dressings

Function	Action	Example
Absorption	Absorbs exudates	Alginates, composite dressings, foams, gauze, hydrocolloids, hydrogels
Antimicrobial	Alters wound bed bioburden	Alginates, foams, collagens, composites, contact layers, hydrogels, transparent films, impregnated dressings, wound fillers
Cleansing	Removes purulent drainage, foreign debris, and devitalized tissue	Acetic acid, saline, sodium hypochlorite (Dakin's solution), Vashe Wound Solution™
Débridement	*Autolytic*—covers a wound and allows enzymes to self-digest sloughed skin	Absorption beads, pastes, powders; alginates; composite dressings; foams; gelling fiber; hydrate gauze; hydrogels; hydrocolloids; transparent films; wound care systems
	Chemical or enzymatic—applied topically to break down devitalized tissue	Enzymatic débridement agents
	Mechanical—removes devitalized tissue with mechanical force	Wound cleansers, gauze (wet to dry), whirlpool
Diathermy	Produces electrical current to promote warmth and new tissue growth	
Hydration	Adds moisture to a wound	Gauze (saturated with saline solution), hydrogels, wound care systems
Maintain moist environment	Manages moisture levels in a wound and maintains a moist environment	Composites, contact layers, foams, gauze (impregnated or saturated), hydrogels, hydrocolloids, transparent films, wound care systems
Manage high-output wounds	Manages excessive quantities of exudates	Pouching systems
Pack or fill dead space	Prevents premature wound closure or fills shallow areas and provides absorption	Absorbent beads, powders, pastes; alginates; composites, foams; gauze (impregnated and nonimpregnated)
Protect and cover wound	Provides protection from the external environment	Composites, compression bandages/wraps, foams, gauze dressings, hydrogels, hydrocolloids, transparent film dressings

Protect periwound skin	Prevents moisture and mechanical trauma from damaging delicate tissue around wound	Composites, foams, hydrocolloids, pouching systems, skin sealants, transparent film dressings
Provide therapeutic compression	Provides appropriate levels of support to the lower extremities in venous stasis disease	Compression bandages, wraps, graduated compression stockings

Autolytic Débridement

Autolytic **débridement** is a process that uses the body's own digestive enzymes to break down necrotic tissue. The wound is kept moist with occlusive dressings. Eschar and necrotic debris are softened, liquefied, and separated from the bed of the wound.

Several commercially available products mirror the enzymes that the body produces naturally and are referred to as enzymatic débriding agents; an example is collagenase. Application of these products speeds the rate at which necrotic tissue is removed. This method, although slower than surgical débridement, is more discriminating for tissue removal and does not damage healthy tissue surrounding the wound. When enzymatic débridement is being used under an occlusive dressing, a foul odor and exudate is produced by the breakdown of cellular debris. This odor does not indicate that the wound is infected. The nurse should expect this reaction and help the patient and family understand the reason for the odor. Silver and iodine inactivate collagenase and therefore should not be used with it. Application of collagenase should be nickel thick and changed daily to be effective (Bryant & Nix, 2016).

Categories of Dressings

Table 56-1 provides a guide to the functions and actions of wound dressings.

Occlusive Dressings

Occlusive dressings may be commercially produced or made inexpensively from sterile or nonsterile gauze squares or wrap. Occlusive dressings cover

topical medication that is applied to a skin lesion. The area is kept airtight by using plastic film (e.g., plastic wrap). Plastic film is thin and readily adapts to all sizes, body shapes, and skin surfaces. In general, plastic wrap should be used no more than 12 hours each day. Plastic surgical tape containing a corticosteroid in the adhesive layer can be cut to size and applied to individual lesions. Occlusive dressings are often used to cover surgical incisions for the first 48 hours postoperatively (Doughty & McNichol, 2016).

Moisture-Retentive Dressings

Commercially produced moisture-retentive dressings are efficient at removing exudate because of their higher moisture–vapor transmission rate; some have reservoirs that can hold excessive exudate. A number of moisture-retentive dressings are already impregnated with saline solution, petrolatum, zinc-saline solution, hydrogel, or antimicrobial agents, thereby eliminating the need to coat the skin to avoid maceration. The main advantages of moisture-retentive dressings are improved fibrinolysis, accelerated epidermal resurfacing, reduced pain, fewer infections, less scar tissue, gentle autolytic débridement, and decreased frequency of dressing changes. Depending on the product used and the type of dermatologic conditions encountered, most moisture-retentive dressings may remain in place from 12 to 24 hours; some can remain in place as long as 3 days (Bryant & Nix, 2016; Doughty & McNichol, 2016).

Hydrogels

Hydrogels are polymers with 90% to 95% water content. They are available in impregnated sheets or as gels. Hydrogels provide moisture to maintain a moist wound bed to promote healing. Their high moisture content makes them ideal for autolytic débridement of wounds. They are semitransparent, allowing for wound inspection without dressing removal. They are comfortable and soothing for the painful wound. They require a secondary dressing to keep them in place. Hydrogels are appropriate for partial- and full-thickness, dry to light exudative wounds such as necrotic wounds, minor burns, and radiation burns (Bryant & Nix, 2016; Miline, 2019).

Hydrocolloids

Hydrocolloids are composed of a water-impermeable, polyurethane outer covering separated from the wound by a hydrocolloid material. They are adherent and nonpermeable to water vapor and oxygen. As water evaporates over the wound, it is absorbed into the dressing, which softens and discolors with the increased water content. Hydrocolloids promote

autolysis, reduce the risk for infection and pain, protect the wound, and promote healing (Bryant & Nix, 2016). The dressing can be removed without causing damage to the wound. As the dressing absorbs water, it produces a foul-smelling, yellowish covering over the wound. This is a normal chemical interaction between the dressing and wound exudate and should not be confused with purulent drainage from the wound. Unfortunately, most of the hydrocolloid dressings are opaque, preventing inspection of the wound without removal of the dressing.

Available in sheets and in gels, hydrocolloids are a good choice for both partial- and full-thickness wounds, with light to moderate exudate. They are not recommended for infected wounds and are used cautiously in patients with diabetes (Bryant & Nix, 2016; Miline, 2019). Easy-to-use and comfortable hydrocolloid dressings promote débridement and formation of granulation tissue. Most are changed every 3 to 5 days and most can be submerged in water for bathing or showering.

Foam Dressings

Foam dressings consist of microporous polyurethane with an absorptive **hydrophilic** (water-absorbing) surface that covers the wound and a **hydrophobic** (water-resistant) backing to block leakage of exudate. They are nonadherent; most are designed so that they require a secondary dressing to keep them in place. Adhesive borders are available on some foam dressings, negating the need for a second dressing.

Moisture is absorbed into the foam layer, decreasing maceration of the surrounding tissue. A moist environment is maintained, and removal of the dressing does not damage the wound. The foams are opaque and must be removed for wound inspection. Foams are a good choice for partial- and full-thickness, moderate to heavy exudative wounds. They are especially helpful over bony prominences because they provide contoured cushioning (Bryant & Nix, 2016; Miline, 2019).

Calcium Alginates

Calcium alginates are derived from algae or kelp polysaccharides and consist of very absorbent calcium alginate fibers (Dabiri et al., 2016). They are hemostatic and bioabsorbable and can be used as sheets or mats of absorbent material. As the exudate is absorbed, the fibers turn into a viscous hydrogel. They are useful in areas where the tissue is more irritated or macerated. The alginate dressing forms a moist pocket over the wound while the surrounding skin stays dry. The dressing also reacts with wound fluid, which forms a foul-smelling coating. Alginates work well when packed into a deep cavity, wound, or sinus tract with heavy drainage. They

are nonadherent and require a secondary dressing. Alginates are used for moderate to highly exudative full-thickness wounds, such as pressure injuries, infected wounds, and venous insufficiency ulcers (Bryant & Nix, 2016; Miline, 2019). Wound experts suggest that alginates are superior to other modern dressings for débriding necrotic wounds (Bryant & Nix, 2016).

Antimicrobials

Antimicrobial dressings contain antiseptics, cadexomer iodine, honey, hydrofera blue, mupirocin, or silver to reduce the risk of infection. They are available in many different types of dressings, such as gauze, foams, films, or absorptive or nonadherent materials. Antimicrobial dressings are indicated for partial- or full-thickness wounds that have a risk for infection, such as surgical wounds (Bryant & Nix, 2016; Miline, 2019).

Collagens

Collagen dressings are protein based and derived from animal sources (bovine, equine, porcine, or avian) that promote wound healing. Collagens are used for partial- or full-thickness noninfected wounds with light to moderate drainage, such as pressure injuries, vascular ulcers, skin donor sites, surgical wounds, diabetic ulcerations, and traumatic wounds (Miline, 2019).

Composites

Composite dressings combine components from several dressing types into a single dressing that is absorptive and that provide protection from bacteria and fluids (Bryant & Nix, 2016; Miline, 2019).

Contact Layers

Contact layers are thin, nonadherent, conforming dressings that are directly applied to wounds for protection. They are porous, thus allowing exudate to drain through to a secondary dressing. Contact layers are appropriate for partial- and full-thickness wounds, infected wounds, skin donor sites, and split-thickness skin grafts (Bryant & Nix, 2016; Miline, 2019).

TABLE 56-2 Select Topical Preparations and Medications

Preparation	Indications	Product Name
Moisture barriers	Prevent excess moisture on skin to avoid maceration; protect skin	Calmoseptine™, Cavilon™, Proshield™
Moisturizer creams	Soothe, soften, moisturize, and protect skin	Acid Mantle Cream™, Curél Cream™, Dermasil™, Eucerin™, Lubriderm™, Noxzema Skin Cream™, Remedy™, Resta™
Moisturizer ointments	Soothe, soften, moisturize, and protect skin	Aquaphor Ointment™, Eutra Swiss Skin Cream™, Vaseline Ointment™
Topical anesthetic agents	Relieve pain	Lidocaine of various strengths in the form of spray, ointment, gel; lidocaine 2.5% and prilocaine 2.5%
Topical antibiotic agents	Second-line therapy when infection present; antibiotics are not first choice for treating wounds as they are associated with hypersensitivity reactions and development of antibiotic resistant organisms	Bacitracin™, bacitracin and polymyxin B, mupirocin 2%, erythromycin 2%, clindamycin phosphate 1%, gentamicin sulfate 1%, 1% silver sulfadiazine cream
Topical antimicrobials	Antimicrobial (bactericidal or bacteriostatic)	Acetic acid 0.25%, cadexomer iodine, chlorhexidine 0.02%, honey (medical grade), hydrofera blue, hydrogen peroxide, mupirocin 2%, povidone iodine, silver, sodium hypochlorite, 1% silver sulfadiazine cream

Adapted from Doughty, D., & McNichol, L. (2016). *WOCN Society core curriculum: Wound management*. Philadelphia, PA: Wolters Kluwer; Miline, C. (Ed.). (2019). *Wound source 2019*. Atlantic Beach, FL: Kestrel Health Information, Inc.

Transparent Film Dressings

Transparent film dressings are polymer membranes, permeable to moisture vapors and oxygen, but impermeable to water, liquids, and bacteria. Transparency allows for direct visualization of the wound. The purposes of films are to protect, provide a moist wound bed environment, promote autolysis, and lessen friction. Transparent films are used for partial or

closed wounds with little to no exudate, such as intravenous access sites, skin donor sites, lacerations, and abrasions (Bryant & Nix, 2016; Miline, 2019).

Medical Management

Medical management of skin disorders includes a host of prescribed and over-the-counter (OTC) pharmacologic therapies.

Pharmacologic Therapy

Medicated lotions, creams, ointments, gels, and powders are frequently used to treat skin disorders. In general, moisture-retentive dressings, with or without medication, are used in the acute stage; lotions and creams are reserved for the subacute stage; and ointments are used when inflammation has become chronic and the skin is dry with scaling or **lichenification** (thickening of the horny layer of the skin).

High concentrations of some medications can be applied directly to the affected site with little systemic absorption and with few systemic side effects. However, some medications are readily absorbed through the skin and can produce systemic effects. Because topical preparations may induce allergic contact **dermatitis** (skin inflammation) in patients who are sensitive, any untoward response should be reported immediately and the medication discontinued.

With all types of topical medication, the patient is educated to apply the medication gently but thoroughly and, when necessary, to cover the medication with a dressing to protect clothing. Table 56-2 lists select topical preparations and medications.

Lotions

Lotions are frequently used to replenish lost skin oils or to relieve pruritus. They must be applied every 3 or 4 hours for sustained therapeutic effect. They are usually applied directly to the skin, but a dressing soaked in the lotion can be placed on the affected area. However, if left in place for a longer period, it may crust and cake on the skin.

Lotions are of two types: suspensions and liniments. **Suspensions** consist of either a powder in water that requires shaking before application, or clear solutions, which contain completely dissolved active ingredients. A suspension such as calamine lotion provides a rapid cooling and drying effect as it evaporates, leaving a thin, medicinal layer of powder on the affected skin. **Liniments** are lotions with oil added to prevent crusting. Because lotions are easy to use, therapeutic adherence is generally good.

Powders

Powders usually have a talc, zinc oxide, bentonite, or cornstarch base and are dusted on the skin with a shaker or with cotton sponges. Although their therapeutic action is brief, powders act as **hygroscopic** agents that absorb and retain moisture from the air and reduce friction between skin surfaces and clothing or bedding.

Creams

Creams may be suspensions of oil in water or emulsions of water in oil, with additional ingredients to prevent bacterial and fungal growth. Both may cause an allergic reaction such as contact dermatitis. Oil-in-water creams are easily applied and usually are the most cosmetically acceptable to the patient. Although they can be used on the face, they tend to have a drying effect. Water-in-oil emulsions are greasier and are preferred for drying and flaking dermatoses. Creams usually are rubbed into the skin by hand. They are used for their moisturizing and emollient effects.

Gels

Gels are semisolid emulsions that become liquid when applied to the skin or scalp. They are cosmetically acceptable to the patient because they are not visible after application, and they are greaseless and nonstaining. Water-based gels penetrate the skin more effectively and cause less stinging on application. They are especially useful for acute dermatitis in which there is weeping exudate (e.g., poison ivy) and are applied the same way as creams.

Pastes

Pastes are mixtures of powders and ointments and are used in inflammatory blistering conditions. They adhere to the skin and may be difficult to remove without using an oil (e.g., olive oil, mineral oil). Pastes are applied with a wooden tongue depressor or gloved hand.

Ointments

Ointments retard water loss and lubricate and protect the skin. They are the preferred vehicle for delivering medication to chronic or localized dry skin conditions, such as eczema or psoriasis. Ointments are applied with a wooden tongue depressor or gloved hand.

Sprays and Aerosols

Spray and aerosol preparations may be used on any widespread dermatologic condition. They evaporate on contact and are used infrequently.

Topical Corticosteroids

Corticosteroids are widely used in treating dermatologic conditions to provide anti-inflammatory, antipruritic, and vasoconstrictive effects. The patient is educated to apply this medication according to strict guidelines, using it sparingly but rubbing it into the prescribed area thoroughly. Absorption of topical corticosteroids is enhanced when the skin is hydrated or the affected area is covered by an occlusive or moisture-retentive dressing (Comerford & Durkin, 2020). Inappropriate use of topical corticosteroids can result in local and systemic side effects, especially when the medication is absorbed through inflamed and excoriated skin; it is used under occlusive dressings, or is used for longer time periods on sensitive areas. Local side effects may include skin atrophy and thinning, **striae** (bandlike streaks), and telangiectasias (dilated blood vessels). Thinning of the skin results from the ability of corticosteroids to inhibit skin collagen synthesis. The thinning process can be reversed by discontinuing the medication, but striae and telangiectasia are permanent. Systemic side effects may include hyperglycemia and symptoms of Cushing syndrome (see Chapter 45). Caution is required when applying corticosteroids around the eyes because long-term use may cause glaucoma or cataracts, and the anti-inflammatory effect of corticosteroids may mask existing viral or fungal infections.

Concentrated (fluorinated) corticosteroids should never be applied on the face or intertriginous areas (i.e., axillae and groin) because these areas have a thinner stratum corneum and therefore absorption is enhanced. Persistent use of concentrated topical corticosteroids in any location may produce acnelike dermatitis, known as steroid-induced acne, and hypertrichosis (excessive hair growth). Because some topical corticosteroid preparations are available without prescription, patients should be cautioned about prolonged and inappropriate use. Table 56-3 lists select topical corticosteroid preparations according to potency.

Intralesional Therapy

Intralesional therapy consists of injecting a sterile suspension of medication (usually a corticosteroid) into or just below a lesion. Although this treatment may have an anti-inflammatory effect, local atrophy and discoloration may result if the medication is injected into subcutaneous fat. Skin lesions treated with intralesional therapy include psoriasis, keloids, and cystic acne. Occasionally, immunotherapeutic and antifungal agents are given as intralesional therapy.

TABLE 56-3 Potency: Select Topical Corticosteroids

Potency	Topical Corticosteroid	Preparations
OTC	0.5–1% hydrocortisone	Cream, lotion, ointment
Lowest	Dexamethasone 0.1%	Cream, ointment, aerosol, gel
	Alclometasone 0.05%	Cream, ointment
	Hydrocortisone 2.5%	Cream, lotion, ointment
Low–medium	Desonide 0.05%	Cream, lotion, ointment
	Fluocinolone acetonide 0.025%	Cream, solution
	Hydrocortisone valerate 0.2%	Cream, solution
	Betamethasone valerate 0.1%	Cream, ointment
	Fluticasone propionate 0.05%	Cream, ointment
Medium–high	Triamcinolone acetonide 0.1–0.5%	Cream, ointment, lotion
	Fluocinonide 0.05%	Cream, ointment, gel
	Desoximetasone 0.05–0.25%	Cream, ointment, gel
	Fluocinolone 0.2%	Cream, ointment
	Diflorasone diacetate 0.05%	Cream, ointment
Very high	Clobetasol propionate 0.05%	Cream, ointment, gel
	Betamethasone dipropionate 0.05%	Cream, ointment, gel
	Halobetasol propionate 0.05%	Cream, ointment

OTC, over the counter.

Systemic Medications

Systemic medications are also prescribed for skin conditions. These include corticosteroids for short-term therapy of contact dermatitis or for long-term treatment of a chronic **dermatosis** (skin lesion), such as pemphigus vulgaris. Other frequently used systemic medications include antibiotic, antifungal, antihistamine, sedative, analgesic, tranquilizing, **cytotoxic** (destructive of cells), and immunosuppressive agents.

Nursing Management

Nursing management of the patient prescribed pharmacologic therapy to treat a skin disorder begins with a focused dermatologic health history, direct observation, and a complete physical examination (see Chapter 55). Because of its visibility, a skin condition is usually difficult to ignore or conceal from others and may therefore cause the patient emotional distress.

The major goals for the patient may include maintenance of skin integrity, relief of discomfort, promotion of restful sleep, self-acceptance, knowledge about skin care, and avoidance of complications.

Nursing management for patients who must perform self-care for skin problems, such as applying medications and dressings, focuses on educating the patient about how to cleanse the affected area and pat it dry; apply medication to the lesion while the skin is moist; cover the area with plastic (e.g., Telfa™ pads, plastic wrap, vinyl gloves, plastic bag) if recommended; and cover it with an elastic bandage, dressing, or paper tape to seal the edges. Dressings that contain or cover a topical corticosteroid should be removed for 12 of every 24 hours to prevent adverse events.

Other forms of dressings, such as those used to cover topical medications, include soft cotton cloth and stretchable cotton dressings (e.g., Surgitube™, Tubegauz™) that can be used for fingers, toes, hands, and feet. The hands can be covered with disposable polyethylene or vinyl gloves sealed at the wrists; the feet can be wrapped in plastic bags covered by cotton socks. Gloves and socks that are already impregnated with emollients, making application to the hands and feet more convenient, are also available. When large areas of the body must be covered, cotton cloth topped by an expandable stockinette can be used. Disposable diapers or cloths folded in diaper fashion are useful for dressing the groin and the perineal areas. Axillary dressings can be made of cotton cloth, or a commercially prepared dressing may be used and taped in place or held by dress shields. A turban or plastic shower cap is useful for holding dressings on the scalp. A face mask, made from gauze with holes cut out for the eyes, nose, and mouth, may be held in place with gauze ties looped through holes cut in the four corners of the mask.

Pressure Injury

Pressure injury, formerly called pressure ulcer, is a localized area of necrotic soft tissue that occurs when pressure applied to the skin is greater than the normal capillary closure pressure (approximately 32 mm Hg) over a period of time sufficient to cause tissue injury. Patients who are critically ill have a lower capillary closure pressure and a greater risk of pressure injuries, as are patients who are exposed to prolonged pressure due to immobility, have motor or sensory dysfunction, or have muscular atrophy that reduces padding between the overlying skin and the underlying bone.

A landmark 10-year pressure injury prevalence survey conducted among 918,621 inpatients in the United States from 2006 through 2015 showed an overall decrease in prevalence of pressure injury from 13.5% in 2006 to

9.3% in 2015 (VanGilder, Lachenbruch, Algrim-Boyle, et al., 2017). Despite declining prevalence, pressure injuries nonetheless result in significant pain and suffering, increased morbidity and mortality, higher medical costs and resource use, and lower odds of discharge to the community (VanGilder et al., 2017).

The American Nurses Association tracks hospital-acquired pressure injuries (HAPI) quarterly as part of the National Database of Nursing Quality Indicators® (NDNQI®). In the United States, an estimate of 2.5 million patients in acute care facilities develop HAPIs annually, with approximately 60,000 patient deaths associated with complications from HAPIs. The cost of treatment for a single, full-thickness pressure injury may be as high as $70,000 with an estimated annual total cost of $11 billion for pressure injury treatment in the United States (Agency for Healthcare Research & Quality [AHRQ], 2014). All possible efforts to prevent skin breakdown must be made because the treatment of pressure injuries is costly in terms of health care dollars and quality of life for patients at risk.

The initial sign of pressure is erythema (redness of the skin) caused by reactive hyperemia, which normally resolves in less than 1 hour. Unrelieved pressure results in tissue ischemia or anoxia. The cutaneous tissues become broken or destroyed, leading to progressive destruction and necrosis of underlying soft tissue, and the resulting pressure injury is painful and slow to heal.

NURSING PROCESS

The Patient with Pressure Injury

Assessment

Nursing assessment involves identifying and evaluating risk for development of pressure injuries as well as assessment of the skin.

ASSESSMENT OF RISK FACTORS

Immobility, impaired sensory perception or cognition, decreased tissue perfusion, decreased nutritional status, friction and shear forces, increased moisture, and age-related skin changes and comorbidities all contribute to the development of pressure injuries (Doughty & McNichol, 2016). Chart 56-1 lists risk factors for pressure injuries. Scales such as the Braden scale (Table 56-4) or Norton scale (Norton, McLaren, & Exton-Smith, 1962) may be used to facilitate systematic assessment and quantification of a patient's risk for pressure injury, although the nurse should recognize that the reliability of these scales is not well established for all patient populations.

Chart 56-1  **RISK FACTORS**

Pressure Injuries

- Advanced age
- Comorbidities, such as diabetes, peripheral vascular disease, cancer, stroke, obesity, cognitive impairment
- Excessive moisture, including incontinence of urine or feces
- Excessive skin dryness
- Friction, shearing forces, trauma
- High-acuity patients, such as those in intensive care units
- History of having recurrent pressure injuries
- Immobility, compromised mobility
- Loss of protective reflexes, sensory deficit/loss
- Malnutrition, hypoproteinemia, anemia, vitamin deficiency
- Medical devices, such as casts, traction, restraints
- Medications, such as analgesics or sedatives
- Poor skin perfusion, edema
- Preexisting skin problems on admission
- Prolonged hospitalization
- Prolonged pressure on tissue
- Smoking
- Surgical procedures >3 hours

Adapted from Doughty, D., & McNichol, L. (2016). *Wound, Ostomy and Continence Nurses Society core curriculum: Wound management*. Philadelphia, PA: Wolters Kluwer.

Specific nursing actions related to assessing risk include:

- Evaluate level of mobility.
- Note safety and assistive devices (e.g., restraints, splints).
- Assess neurovascular status.
- Evaluate circulatory status (e.g., peripheral pulses, edema).
- Note present health problems.
- Evaluate nutritional and hydration status.
- Review the results of the patient's laboratory studies, including hematocrit, hemoglobin, electrolytes, albumin, prealbumin, transferrin, and creatinine.

- Determine presence of incontinence.
- Review current medications.

Quality and Safety Nursing Alert

Pressure injuries are associated with increased costs of treatment and length of hospital stay as well as diminished quality of life for patients. It is imperative that nurses perform a skin assessment on every patient admitted to a hospital, inpatient rehabilitation facility, or skilled nursing facility.

Immobility. When a person is immobile and inactive, pressure is exerted on the skin and subcutaneous tissue by objects on which the person rests, such as a mattress, chair seat, or cast. The development of pressure injuries is directly related to the duration of immobility. If pressure continues long enough, small-vessel thrombosis and tissue necrosis occur and a pressure injury is the result. Weight-bearing bony prominences are most susceptible to pressure injury development because they are covered only by skin and small amounts of subcutaneous tissue. Susceptible areas include the sacrum and coccygeal areas, ischial tuberosities (especially in people who sit for prolonged periods), greater trochanter, heel, knee, malleolus, medial condyle of the tibia, fibular head, scapula, and elbow, with the sacrum and heels the most common sites (Doughty & McNichol, 2016) (Fig. 56-1).

Impaired Sensory Perception or Cognition. Patients with sensory loss, impaired level of consciousness, or paralysis may not be aware of the discomfort associated with prolonged pressure on the skin and therefore may not change their positions to relieve the pressure. This prolonged pressure impedes blood flow, reducing nourishment of the skin and underlying tissues. A pressure injury may develop in a short period of time, sometimes within minutes.

Decreased Tissue Perfusion. Any condition that reduces the circulation and nourishment of the skin and subcutaneous tissue (altered peripheral tissue perfusion) increases the risk of pressure injury development. Patients with diabetes have compromised microcirculation. Similarly, patients with edema have impaired circulation and poor nourishment of the skin tissue. Patients with obesity have large amounts of poorly vascularized adipose tissue, which is susceptible to breakdown.

Nutritional Status. Nutritional deficiencies, anemias, and metabolic disorders also contribute to the development of pressure injuries.

Anemia, regardless of its cause, decreases the blood's oxygen-carrying ability and predisposes the patient to pressure injuries. Maintaining good nutrition and preventing malnutrition are essential to prevent pressure injuries and promote wound healing (Doughty & McNichol, 2016). Serum albumin and prealbumin levels are sensitive indicators of protein deficiency. Serum albumin levels of less than 3 g/dL are associated with hypoalbuminemic tissue edema and increased risk of pressure injuries. Prealbumin levels are more sensitive indicators of protein status than the albumin levels, but they are costlier to assess. The nurse should assess the patient's prealbumin and albumin values and electrolyte panel (Bryant & Nix, 2016).

Friction and Shear. Mechanical forces also contribute to the development of pressure injuries. Friction is the force of rubbing two surfaces against each another and is often caused by pulling a patient over a bed sheet or from a poorly fitted prosthetic device. Shear is the result of exerting a parallel force on the patient's body, such as the resistance between the patient and the chair or bed when the patient slides down (Edsberg, Black, Goldberg, et al., 2016). When shear occurs, tissue layers slide over one another, blood vessels stretch and twist, and the microcirculation of the skin and subcutaneous tissue is disrupted. Evidence of deep tissue damage may be slow to develop and may present through the development of a **sinus tract** (also called tunneling), which is an area of destroyed tissue that extends from the edge of a wound; this results in dead space that is susceptible to abscess formation. The sacrum and heels are most susceptible to the effects of shear. Pressure injuries from friction and shear occur when the patient slides down in bed (Fig. 56-2) or when the patient is positioned or moved improperly (e.g., dragged up in bed). Spastic muscles and paralysis increase the patient's vulnerability to pressure injuries related to friction and shear.

Increased Moisture. Prolonged contact with moisture from perspiration, urine, feces, or drainage produces maceration (softening) of the skin. The skin reacts to caustic substances in the excreta or drainage and becomes irritated. Moist, irritated skin is more vulnerable to pressure breakdown. Once the skin breaks, the area is invaded by microorganisms (e.g., streptococci, staphylococci, *Pseudomonas aeruginosa, Escherichia coli*), and infection occurs. Foul-smelling infectious drainage is present. The lesion may enlarge and allow a continuous loss of serum, which may further deplete the body of essential protein needed for tissue repair and maintenance. The lesion may continue to enlarge and extend deep into the fascia, muscle, and

bone, with multiple sinus tracts radiating from the pressure injury. With extensive pressure injuries, life-threatening infections and sepsis may develop, frequently from gram-negative organisms.

TABLE 56-4 Braden Scale for Predicting Pressure Injury Risk

Patient's Name	Evaluator's Name			Date of Assessment				
Sensory Perception Ability to respond meaningfully to pressure-related discomfort	**1. Completely Limited** Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation OR limited ability to feel pain over most of body.	**2. Very Limited** Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness OR has a sensory impairment that limits the ability to feel pain or discomfort over half of body.	**3. Slightly Limited** Responds to verbal commands, but cannot always communicate discomfort or the need to be turned. OR has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities.	**4. No Impairment** Responds to verbal commands. Has no sensory deficit that would limit ability to feel or voice pain or discomfort.				
Moisture Degree to which skin is exposed to moisture	**1. Constantly Moist** Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.	**2. Very Moist** Skin is often, but not always, moist. Linen must be changed at least once a shift.	**3. Occasionally Moist** Skin is occasionally moist, requiring an extra linen change approximately once a day.	**4. Rarely Moist** Skin is usually dry, linen only requires changing at routine intervals.				
Activity Degree of physical activity	**1. Bedfast** Confined to bed.	**2. Chairfast** Ability to walk severely limited or nonexistent. Cannot bear own weight and/or must be assisted into chair or wheelchair.	**3. Walks Occasionally** Walks occasionally during day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.	**4. Walks Frequently** Walks outside room at least twice a day and inside room at least once every 2 hrs during waking hours.				
Mobility Ability to change and control body position	**1. Completely Immobile** Does not make even slight changes in body or extremity position without assistance.	**2. Very Limited** Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.	**3. Slightly Limited** Makes frequent though slight changes in body or extremity position independently.	**4. No Limitation** Makes major and frequent changes in position without assistance.				
Nutrition Usual food intake pattern	**1. Very Poor** Never eats a complete meal. Rarely eats more than a 1/3 of any food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement OR is NPO and/or maintained on clear liquids or IVs for more than 5 days.	**2. Probably Inadequate** Rarely eats a complete meal and generally eats only about 1/2 of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement OR receives less than optimum amount of liquid diet or tube feeding.	**3. Adequate** Eats half of most meals. Eats a total of 4 servings of protein (meat, dairy products) per day. Occasionally will refuse a meal, but will usually take a supplement when offered OR is on a tube feeding or TPN regimen, which probably meets most of nutritional needs.	**4. Excellent** Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.				
Friction and Shear	**1. Problem** Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures, or agitation leads to almost constant friction.	**2. Potential Problem** Moves feebly or requires minimum assistance. During a move, skin probably slides to some extent against sheets, chair, restraints, or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.	**3. No Apparent Problem** Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair.					
				Total Score				

NPO, nothing by mouth; TPN, total parenteral nutrition.

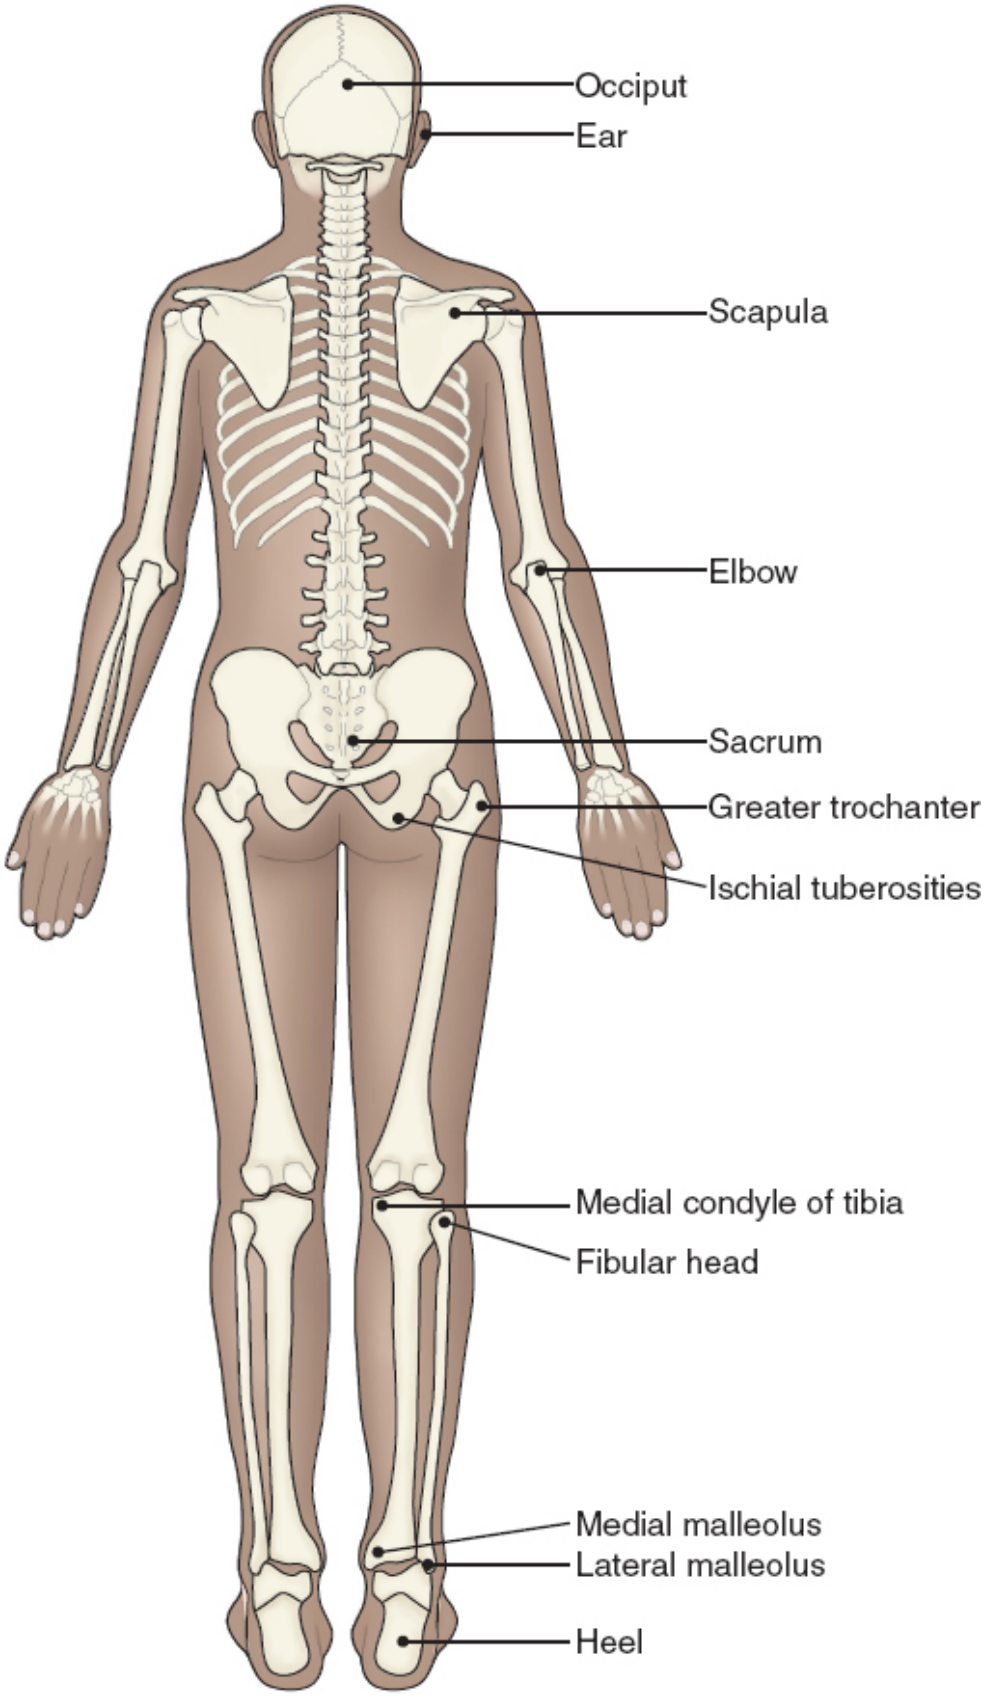

Figure 56-1 • Areas susceptible to pressure injuries.

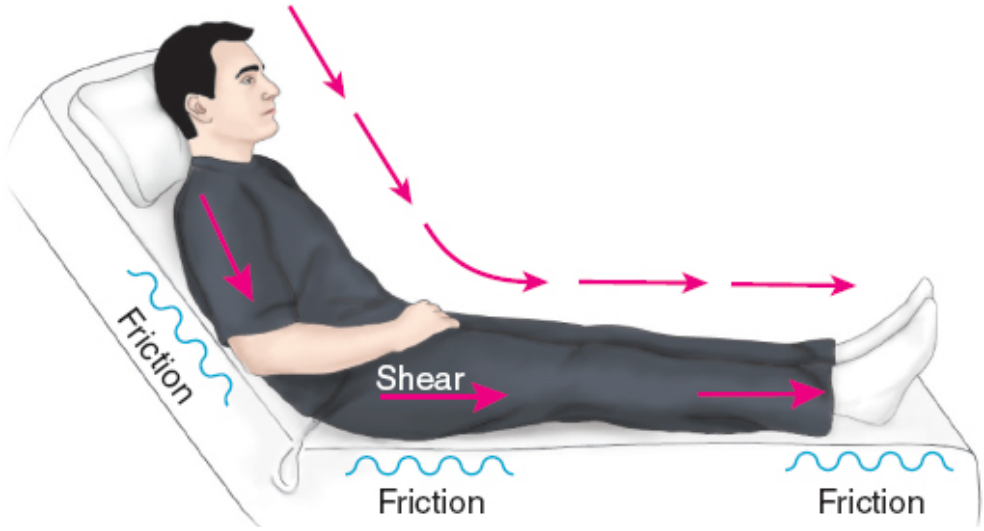

Figure 56-2 • Mechanical forces contribute to pressure injury development. As the person slides down or is improperly pulled up in bed, *friction* resists this movement. *Shear* occurs when one layer of tissue slides over another, disrupting microcirculation of skin and subcutaneous tissue.

Gerontologic Considerations. In older adults, the normal aging process leads to diminished epidermal thickness, dermal collagen, and tissue elasticity. The skin is drier as a result of diminished sebaceous and sweat gland activities. Cardiovascular changes result in decreased tissue perfusion. Muscles atrophy and bone structures become prominent. Diminished sensory perception and reduced ability to reposition oneself contribute to prolonged pressure on the skin. Therefore, older adults are more susceptible to pressure injuries, which cause pain, suffering, and reduced quality of life (Eliopoulos, 2018).

Obesity Considerations. In 2019, an international collaborative comprising members from the European Pressure Ulcer Advisory Panel (EPUAP), the U.S. National Pressure Injury Advisory Panel (NPIAP), and the Pan-Pacific Pressure Injury Alliance (PPPIA) released the third edition of the *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline* (EPUAP, NPIAP, & PPPIA, 2019) to aid clinicians in leveraging the best evidence-based practices to prevent and treat pressure injuries. These updated guidelines include recommendations for adults who have obesity, with specific organization-level considerations, as well as recommendations for bed and equipment selection and repositioning. Please see the NPIAP Web site link at the end of this chapter to review the electronic version of the quick reference guideline.

Assessment of Skin and Existing Pressure Injuries

In addition to assessing risk, nursing actions to assess skin for pressure injuries include:

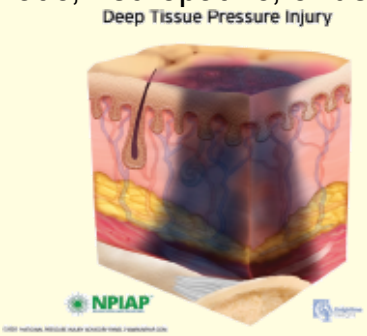
- Assess total skin condition at least twice a day.
- Inspect each pressure site for erythema.
- Assess areas of erythema for blanching response.
- Palpate the skin for increased warmth.
- Inspect for dry skin, moist skin, and breaks in skin.
- Note amount of drainage (scant to heavy); drainage characteristic (bloody, serosanguinous, serous, purulent); and odor.

If a pressure injury is seen, the nurse documents its size and location and uses a grading system to describe its severity and provides a description of the site (Chart 56-2). The appearance of purulent drainage or foul odor suggests an infection. With an extensive pressure injury, deep pockets of infection are often present. Drying and crusting of exudate may be present. Infection of a pressure injury may advance to osteomyelitis, pyarthrosis (pus formation within a joint cavity), sepsis, and septic shock.

Diagnosis

Nursing Diagnoses

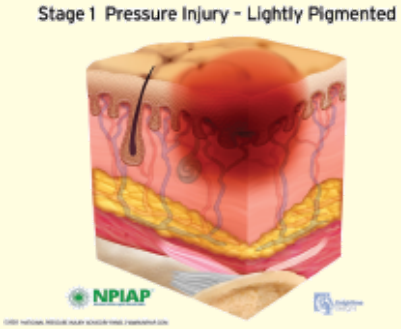
Based on the assessment data, nursing diagnoses may include the following:



- Risk for impaired skin integrity
- Impaired skin integrity associated with immobility, decreased sensory perception, decreased tissue perfusion, decreased nutritional status, friction and shear forces, excessive moisture, or advanced age

Chart 56-2

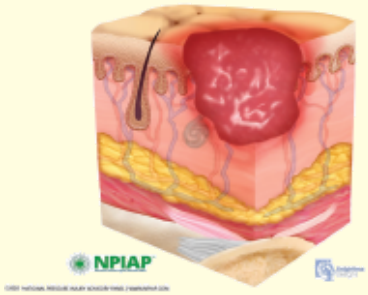
Stages in the Development of Pressure Injuries



Deep Tissue Pressure Injury: Persistent Non-Blanchable Deep Red, Maroon or Purple Discoloration

Intact or non-intact skin with localized area of persistent non-blanchable deep red, maroon, purple discoloration or epidermal separation revealing a dark wound bed or blood filled blister. Pain and temperature change often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury, or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle or other underlying structures are visible, this indicates a full thickness pressure injury (Unstageable, Stage 3 or Stage 4). Do not use DTPI to describe vascular, traumatic, neuropathic, or dermatologic conditions.

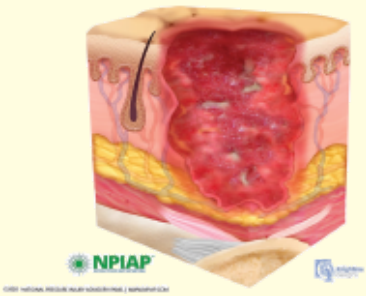
Stage 1 Pressure Injury: Non-Blanchable Erythema of Intact Skin



Intact skin with a localized area of non-blanchable erythema, which may appear differently in darkly pigmented skin. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury.

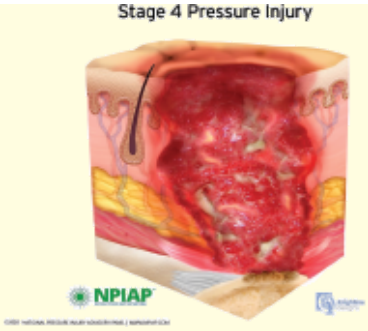
Stage 2 Pressure Injury: Partial-Thickness Skin Loss with Exposed Dermis

Partial-thickness loss of skin with exposed dermis. The wound bed is viable, pink or red, moist, and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible and deeper tissues are not visible. Granulation tissue, slough and eschar are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture associated skin damage (MASD) including incontinence associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive related skin injury (MARSI), or traumatic wounds (skin tears, burns, abrasions).



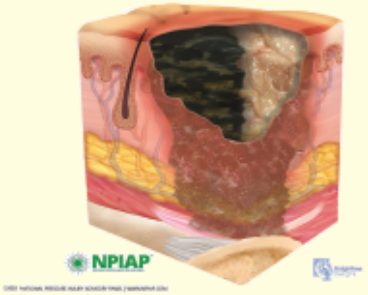
Stage 2 Pressure Injury

Stage 3 Pressure Injury: Full-Thickness Skin Loss



Full-thickness loss of skin, in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present. Slough and/or eschar may be visible. The depth of tissue damage varies by anatomical location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage and/or bone are not exposed. If slough or eschar obscures the extent of tissue loss this is an Unstageable Pressure Injury.

Stage 3 Pressure Injury



Stage 4 Pressure Injury: Full-Thickness Skin and Tissue Loss

Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled edges), undermining and/or tunneling often occur. Depth varies by anatomical location. If slough or eschar obscures the extent of tissue loss this is an Unstageable Pressure Injury.

Unstageable Pressure Injury: Obscured Full-Thickness Skin and Tissue Loss

Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a Stage 3 or Stage 4 pressure injury will be revealed. Stable eschar (i.e. dry, adherent, intact without erythema or fluctuance) on the heel or ischemic limb should not be softened or removed.

Planning and Goals

The major goals may include relief of pressure, improved mobility, maintenance of skin integrity, improved sensory perception, improved tissue perfusion, improved nutritional status, minimized friction and shear forces, dry surfaces in contact with skin, and healing of pressure injury, if present.

Nursing Interventions

Relieving Pressure

Frequent changes of position are needed to relieve and redistribute the pressure on the patient's skin and to promote blood flow to the skin and

subcutaneous tissues. This can be accomplished by instructing the patient to change position or by turning and repositioning the patient. The patient's family members should be educated about how to position and turn the patient at home to prevent pressure injuries. Shifting weight allows the blood to flow into the ischemic areas and helps tissues recover from the effects of pressure. Elevating the head of bed no more than 30 degrees will prevent the patient from sliding down in bed and avoid the effects of shearing (Bryant & Nix, 2016).

For patients who spend long periods in a wheelchair, pressure can be relieved by:

- *Push-ups:* The patient pushes down on armrests and raises buttocks off the seat of the chair (Fig. 56-3).
- *One half push-up:* The patient repeats the push-up on the right side and then the left, pushing up on one side by pushing down on the armrest.

Figure 56-3 • Wheelchair push-up to prevent ischial pressure injuries. These push-ups should become an automatic routine (every 15 minutes) for the person with paraplegia. The person should stay up and out of contact with the seat for several seconds. The wheels are kept in the locked position during the exercise.

- *Moving side to side:* The patient moves from one side to the other while sitting in the chair.
- *Shifting:* The patient bends forward with the head down between the knees (if able) and constantly shifts in the chair.

POSITIONING THE PATIENT

The degree of ability to move independently—the comfort, fatigue, loss of sensation, overall physical and mental status, and specific disorder—

influences plans for changing position. Patients should be positioned laterally, prone, and dorsally in sequence unless a position is not tolerated or is contraindicated. Generally, those who experience discomfort after 30 to 60 minutes of lying prone need to be repositioned. Patients able to shift their weight every 15 to 20 minutes and move independently may change total position every 2 to 4 hours. Indications for routine repositioning every 2 hours or more frequently include loss of sensation, paralysis, coma, and edema.

In addition to regular turning, small shifts of body weight, such as repositioning of an ankle, elbow, or shoulder, are necessary. The skin is inspected at each position change and assessed for temperature elevation. If redness or heat is noted or if the patient complains of discomfort, pressure on the area must be relieved.

Another way to relieve pressure over bony prominences is the bridging technique, accomplished through the correct positioning of pillows. Just as a bridge is supported on pillars to allow traffic to move underneath, the body can be supported by pillows to allow for space between bony prominences and the mattress. A pillow or commercial heel protector may be used to support the heels off the bed when the patient is supine. Placing pillows superior and inferior to the sacrum relieves sacral pressure. Supporting the patient in a 30-degree side-lying position avoids pressure on the trochanter; wedges can be used to accomplish this. In older adult patients, frequent small shifts of body weight may be effective. Placing a small rolled towel or sheepskin under a shoulder or hip allows a return of blood flow to the skin in the area on which the patient is sitting or lying. The towel or sheepskin is moved around the patient's pressure points in a clockwise fashion. A turning schedule can help the family keep track of the patient's turns.

Using Pressure-Relieving Devices

At times, specialty beds or alternative bed surfaces may be indicated to help relieve the pressure on the skin (EPUAP, NPIAP, & PPPIA, 2019). These are referred to as pressure redistribution surfaces because they aim to redistribute pressure. Ideally, they should also control moisture and temperature and minimize friction. These devices are designed to provide support for specific body areas or to distribute pressure evenly. Pressure redistribution surfaces may include specialty mattresses as well as mattress overlays. The use of pressure redistribution surfaces is particularly important for patients who cannot get out of bed and who are at high risk for pressure injury development.

A patient who sits in a wheelchair for prolonged periods should have wheelchair cushions fitted and adjusted on an individualized basis, using

pressure measurement techniques as a guide to selection and fitting. The aim is to redistribute pressure away from areas at risk for injuries; however, no cushion can eliminate excessive pressure completely. The patient should be reminded to shift weight frequently and to rise for a few seconds every 15 minutes while sitting in a chair.

Static support devices (e.g., high-density foam, air, or liquid mattress overlays) distribute pressure evenly by bringing more of the patient's body surface into contact with the supporting surface. Gel-type flotation pads and air-fluidized beds reduce pressure. The weight of a body floating on a fluid system is evenly distributed over the entire supporting surface. Therefore, as the body sinks into the fluid, additional surface becomes available for weight bearing, body weight per unit area is decreased, and there is less pressure on the body parts.

Soft, moisture-absorbing padding is also useful because the softness and resilience of padding provide for more even distribution of pressure and the dissipation and absorption of moisture, along with freedom from wrinkles and friction. Bony prominences may be protected by gel pads, sheepskin padding, or soft foam rubber beneath the sacrum, the trochanters, heels, elbows, scapulae, and back of the head when there is pressure on these sites. Applying a gentle adhesive foam dressing to the sacral area is an effective pressure injury preventive measure (Doughty & McNichol, 2016).

Specialized beds are designed to prevent pressure on the skin. Air-fluidized beds allow the patient to float. Dynamic support surfaces, such as low–air-loss pockets, alternatively inflate and deflate sections to change support pressure for patients at high risk for pressure injuries and who are critically ill and cannot be repositioned to relieve pressure. Oscillating or kinetic beds change pressure by means of rocking movements of the bed that redistribute the patient's weight and stimulate circulation. These beds may be used with patients who have injuries attributed to multiple trauma. The specific needs of each individual patient are considered when choosing an appropriate pressure redistribution surface (Bryant & Nix, 2016).

Improving Mobility

The patient is encouraged to remain active and is ambulated whenever possible. When sitting, the patient is reminded to change positions frequently to redistribute weight. Active and passive exercises increase muscular, skin, and vascular tone. For patients at risk for pressure injuries, turning and exercise schedules are essential, and repositioning must occur around the clock.

Improving Sensory Perception

The nurse helps the patient recognize and compensate for altered sensory perception. Depending on the origin of the alteration (e.g., decreased level of consciousness, spinal cord lesion), specific interventions are selected. Strategies to improve cognition and sensory perception may include stimulating the patient to increase awareness of self in the environment, encouraging the patient to participate in self-care, or supporting the patient's efforts toward active compensation for loss of sensation (e.g., a patient with paraplegia lifting up from the sitting position every 15 minutes). A patient with tetraplegia should be weight shifted every 30 minutes while sitting in a wheelchair. When decreased sensory perception exists, the patient and caregivers are taught to inspect potential pressure areas visually every morning and evening, using a mirror if necessary, for evidence of pressure injury development.

Improving Tissue Perfusion

Activity, exercise, and repositioning improve tissue perfusion. Massage of erythematous areas is avoided because damage to the capillaries and deep tissue may occur (EPUAP, NPIAP, & PPPIA, 2019).

In patients who have evidence of compromised peripheral circulation (e.g., edema), positioning and elevation of the edematous body part to promote venous return and diminish congestion improve tissue perfusion. In addition, the nurse or family must be alert to environmental factors (e.g., wrinkles in sheets, pressure of tubes) that may contribute to pressure on the skin and diminished circulation and remove the source of pressure.

Improving Nutritional Status

The patient's nutritional status must be adequate, and a positive nitrogen balance must be maintained because pressure injuries develop more quickly and are more resistant to treatment in patients with nutritional disorders. The nurse should assess the patient's nutritional status (see Chapter 4). To assess the patient's nutritional status in response to therapeutic strategies, the nurse monitors the patient's hemoglobin, prealbumin level, and body weight weekly.

Carbohydrates, proteins, fats, vitamins, and minerals are essential for wound healing (Bryant & Nix, 2016). Iron preparations may be necessary to raise the hemoglobin concentration so that tissue oxygen levels can be maintained within acceptable limits. Ascorbic acid (vitamin C) is necessary for tissue healing. Other nutrients associated with healthy skin include vitamins A, B, D, E, and K, copper, and zinc. With adequate nutrition and hydration, the skin can remain healthy, and damaged tissues can be repaired (Norris, 2019).

Reducing Friction and Shear

Raising the head of the bed by even a few centimeters increases the shearing force over the sacral area; therefore, the semireclining position is avoided in patients at risk. Proper positioning with adequate support is also important when the patient is sitting in a chair.

Quality and Safety Nursing Alert

To avoid shearing forces when repositioning patients, the nurse must lift and avoid dragging patients across a surface. Lift devices should be used to prevent occupational injuries.

Minimizing Irritating Moisture

Continuous moisture on the skin must be prevented by meticulous hygiene measures. It is important to pay special attention to skin folds, including areas under the breasts, arms, and groin, and between the toes. Perspiration, urine, stool, and drainage must be removed from the skin promptly. The soiled skin should be washed immediately with mild soap and water and blotted dry with a soft towel. The skin may be lubricated with a bland lotion to keep it soft and pliable. Drying agents and powders are avoided. Topical barrier ointments (e.g., petroleum jelly) may be helpful in protecting the skin of patients who are incontinent.

Absorbent pads that wick moisture away from the body should be used to absorb drainage. Patients who are incontinent need to be checked regularly and have their wet incontinence pads and linens changed promptly. Their skin needs to be cleansed and dried promptly.

Promoting Pressure Injury Healing

Regardless of the stage of the pressure injury, the pressure on the area must be eliminated because the injured tissue will not heal until all pressure is removed. The patient must not lie or sit on the pressure injury, even for a few minutes. Individualized positioning and turning schedules must be written in the plan of nursing care and followed meticulously.

In addition, inadequate nutritional status as well as fluid and electrolyte abnormalities must be corrected to promote healing. Wounds from which body fluids and protein drain place the patient in a catabolic state and predispose to hypoproteinemia and serious secondary infections. Protein deficiency must be corrected to promote the healing of the pressure injury. Carbohydrates are necessary to “spare” the protein and to provide an energy source. Vitamin C and trace elements,

especially zinc, are necessary for collagen formation and wound healing. (Refer to Chart 56-2 for descriptions of stages of pressure injuries.)

Deep Tissue Pressure Injury. These tissue injuries may evolve rapidly, and immediate pressure relief to the affected area is indicated. Therefore, the nurse must be vigilant in assessing for these types of injuries (EPUAP, NPIAP, & PPPIA, 2019).

Stage 1 Pressure Injury. To permit healing of stage 1 pressure injuries, the pressure is removed to allow increased tissue perfusion, nutritional and fluid and electrolyte balance is maintained, friction and shear are reduced, and moisture to the skin is avoided (EPUAP, NPIAP, & PPPIA, 2019).

Stage 2 Pressure Injury. In addition to measures listed for stage 1 pressure injuries, a moist environment, in which migration of epidermal cells over the injury surface occurs more rapidly, should be provided to aid wound healing in stage 2 pressure injury. The injured area is gently cleansed with sterile saline solution. The use of a heat lamp to dry the open wound is avoided, as is the use of antiseptic solutions that damage healthy tissues and delay wound healing. Semipermeable occlusive dressings, hydrocolloid wafers, or wet saline dressings are helpful in providing a moist environment for healing and in minimizing the loss of fluids and proteins from the body (EPUAP, NPIAP, & PPPIA, 2019).

Stage 3 Pressure Injury. Stage 3 pressure injuries are characterized by extensive tissue damage, including **slough** (i.e., soft, moist avascular tissue, which may be white, yellow, tan, gray, or green and may be loose or firmly adherent), formation of a sinus tract, and undermining (commonly seen in sheer injuries), to name a few. **Undermining** results in extensive tunneling under the edges of the wound; it is distinguished from a sinus tract in that there is a significant portion of the wound edge involved, whereas sinus tract involves only a small portion of the wound edge. Given the extensive damage to tissue and necrosis that characterize stage 3 pressure injuries, they must be débrided (cleaned) to create an area that will heal, in addition to the measures listed for stage 1 pressure injuries. Necrotic, devitalized tissue favors bacterial growth, delays granulation, and inhibits healing. Wound cleaning and dressing are uncomfortable; therefore, the nurse must prepare the patient for the procedure by explaining what will occur and administering prescribed analgesia (EPUAP, NPIAP, & PPPIA, 2019).

Stage 4 Pressure Injury. Surgical interventions are required for these extensive pressure injuries (EPUAP, NPIAP, & PPPIA, 2019). (See the following Other Treatment Methods section.)

Other Treatment Methods

Débridement may be accomplished by wet-to-damp dressing changes, mechanical flushing of necrotic and infective exudate, application of prescribed enzyme preparations that dissolve necrotic tissue, or surgical dissection. If eschar (dry scab) covers the pressure injury, it is removed surgically to ensure the wound is clean and vitalized. Exudate may be absorbed by dressings or special hydrophilic powders, beads, or gels. Cultures of infected pressure injuries are obtained to guide the selection of antibiotic therapy.

After the pressure injury is clean, a topical treatment is prescribed to promote granulation. New granulation tissue must be protected from reinfection, drying, and damage, and care should be taken to prevent pressure and further trauma to the area. Dressings, solutions, and ointments should not disrupt the healing process. For chronic, noninfected injuries that are healing by secondary intention (healing of an open wound from the base upward by laying down new tissue), vacuum-assisted closure (VAC) or hyperbaric oxygen treatment may be used. VAC involves the use of a negative-pressure sponge dressing in the wound to increase blood flow, increasing formation of granulation tissue and nutrient uptake and decreasing bacterial load. Hyperbaric oxygen therapy involves either applying topical oxygen at increased pressure directly to the wound or placing the patient into a hyperbaric oxygen chamber. Both methods of hyperbaric oxygen therapy promote wound healing by stimulating new vascular growth and aiding in the preservation of damaged tissue. In a randomized control study comparing standard wound care with standard wound care and hyperbaric oxygen therapy for patients with diabetic foot ulcerations, Chen, Wu, Hsu, and colleagues (2017) reported improved wound healing and decreased risk of amputation among study participants who received hyperbaric oxygen therapy.

Multiple agents and protocols are used to treat pressure injuries; however, consistency is an important key to success. Objective evaluation of the pressure injury (e.g., measurement of the size and depth of the pressure injury, inspection for granulation tissue) for response to the treatment protocol must be made every 4 to 6 days. Taking photographs at weekly intervals is a reliable strategy for monitoring the healing process, which may take weeks to months.

Surgical intervention is necessary when the injury is extensive, when complications (e.g., fistula) exist, and when the pressure injury does not respond to treatment. Surgical procedures include débridement, incision and drainage, bone resection, and skin grafting. Osteomyelitis is a

common complication of wounds of stage 4 depth. (See Chapter 36 for more information on osteomyelitis.)

Preventing Recurrence

It may take more than a year for healing tissue to regain the strength of preinjury skin; thus, care must be taken to prevent recurrence of pressure injuries. However, recurrence of pressure injuries should be anticipated; therefore, active, preventive intervention and frequent continuing assessments are essential. Patients with spinal cord injuries are particularly susceptible to pressure injuries and recurrence of pressure injuries; results from one meta-analysis suggest that globally, 23% of patients with spinal cord injuries will have a pressure injury during their lifetime (Chen, Cai, Du, et al., 2020).

The patient's tolerance for sitting or lying on the healed pressure area is increased gradually by increasing the time that pressure is allowed on the area in 5- to 15-minute increments. The patient is instructed to increase mobility and to follow a regimen of turning, weight shifting, and repositioning. The patient education plan includes strategies to reduce the risk for pressure injuries and methods to detect, inspect, and minimize pressure areas. Early recognition and intervention are keys to long-term management of potential impaired skin integrity.

Evaluation

Expected patient outcomes may include:

1. Maintains intact skin
    a. Exhibits no areas of nonblanchable erythema at bony prominences
    b. Avoids massage of bony prominences
    c. Exhibits no breaks in skin
2. Limits pressure on bony prominences
    a. Changes position every 1 to 2 hours
    b. Uses bridging techniques to reduce pressure
    c. Uses special equipment as appropriate
    d. Raises self from the seat of wheelchair every 15 minutes
3. Increases mobility
    a. Performs range-of-motion exercises
    b. Adheres to turning schedule
    c. Advances sitting time as tolerated
4. Has improved sensory and cognitive ability
    a. Demonstrates improved level of consciousness

b. Remembers to inspect potential pressure injury areas every morning and evening

5. Demonstrates improved tissue perfusion
   a. Exercises to increase circulation
   b. Elevates body parts susceptible to edema
6. Attains and maintains adequate nutritional status
   a. Verbalizes the importance of protein and vitamin C in diet
   b. Eats diet high in protein and vitamin C
   c. Exhibits acceptable levels of hemoglobin, electrolyte, prealbumin, transferrin, and creatinine
7. Avoids friction and shear

   Avoids semireclining position

   Uses heel protectors when appropriate

   Lifts body instead of sliding across surfaces
8. Maintains clean, dry skin
   a. Avoids prolonged contact with wet or soiled surfaces
   b. Keeps skin clean and dry
   c. Uses lotion to keep skin lubricated

PRURITUS

Pruritus (itching) is the most common symptom of patients with dermatologic disorders (Song, Xian, Yang, et al., 2018). Pruritus may be general (over all body skin surfaces) or confined to specific regions.

Chart 56-3

Systemic Disorders Associated with Generalized Pruritus

- Chronic kidney disease
- Endocrine disease (thyrotoxicosis, hypothyroidism, diabetes)
- Folliculitis (bacterial, candidiasis, dermatophyte)
- Hematologic disorders (iron deficiency anemia)
- Infestations (scabies, lice, other insects)
- Malignancies (polycythemia vera, Hodgkin lymphoma, lymphoma, leukemia, multiple myeloma, mycosis fungoides, and cancers of the lung, breast, central nervous system, and gastrointestinal tract)
- Neurologic disorders (multiple sclerosis, brain abscess, brain tumor)
- Obstructive biliary disease (primary biliary cirrhosis, extrahepatic biliary obstruction, drug-induced cholestasis)
- Pruritus of pregnancy (pruritic urticarial papules of pregnancy, cholestasis of pregnancy, pemphigoid of pregnancy)
- Psychiatric disorders (emotional stress, anxiety, neurosis, phobias)
- Skin conditions (seborrheic dermatitis, folliculitis, atopic dermatitis)

Adapted from Song, J., Xian, D., Yang, L., et al. (2018). Pruritus: Progress toward pathogenesis and treatment. *BioMed Research International*, *2018*, 9625936.

General Pruritus

Itch receptors are unmyelinated, penicillate (brushlike) nerve endings that are found exclusively in the skin, mucous membranes, and cornea. Although pruritus is usually caused by primary skin disease with resultant rash or lesions, it may occur without a rash or lesion. This is referred to as essential pruritus, which generally has a rapid onset, may be severe, and interferes with normal daily activities.

Pruritus may be the first indication of a systemic internal disease such as diabetes, blood disorders, or cancer (occult malignancy of the breast or colon, lymphoma). It may also accompany kidney, hepatic, and thyroid diseases (Chart 56-3). Some common oral medications such as aspirin, antibiotics, hormones (e.g., estrogens, testosterone, or oral contraceptives), and opioids (e.g., morphine) may cause pruritus directly or by increasing sensitivity to ultraviolet (UV) light. Certain soaps and chemicals, radiation therapy, miliaria (prickly heat), and contact with woolen garments are associated with pruritus as well. Pruritus may also be caused by

psychological factors, such as excessive stress in family or work situations, and is called *psychogenic pruritus* (Song et al., 2018).

Gerontologic Considerations

Pruritus occurs frequently in older adults as a result of dry skin. Older adults are also more likely to have a systemic illness that triggers pruritus, are at higher risk for occult malignancy, and are more likely to be taking multiple medications than younger people. All of these factors increase the incidence of pruritus in older adults (Eliopoulos, 2018).

Pathophysiology

Scratching the pruritic area causes the inflamed cells and nerve endings to release histamine, which produces more pruritus, generating a vicious itch–scratch cycle. If the patient responds to an itch by scratching, the integrity of the skin may be altered, and excoriation, redness, wheals (raised areas), infection, or changes in pigmentation may result. Pruritus usually is more severe at night and is less frequently reported during waking hours, probably because the person is distracted by daily activities. At night, when there are fewer distractions, the slightest pruritus cannot be easily ignored. Severe itching can be debilitating (Bolier, Elferink, & Beuers, 2016).

Medical Management

A thorough history and physical examination usually provide clues to the underlying cause of the pruritus, such as hay fever, allergy, recent administration of a new medication, or a change of cosmetics or soaps. After the cause has been identified, treatment of the condition should relieve the pruritus. Signs of infection and environmental clues, such as warm, dry air or irritating bed linens, should be identified. In general, washing with soap and hot water is avoided. Bath oils containing a surfactant that allows the oil to mix with bathwater (e.g., Lubath™, Alpha Keri™) may be sufficient for cleaning. However, an older adult patient or a patient with unsteady balance should avoid adding oil because it increases the danger of slipping in the bathtub. A warm bath with a mild soap followed by application of a bland emollient to moist skin can control xerosis. Tepid baths, or applying cool compresses or cool agents that contain menthol and camphor (which constrict blood vessels) may also help relieve pruritus (Cornish, 2019).

Pharmacologic Therapy

Topical antipruritic agents (e.g., lidocaine, prilocaine) or capsaicin cream may be useful in providing relief from localized pruritus. Topical corticosteroids are effective when used to diminish pruritus that occurs secondary to inflammatory conditions because of their anti-inflammatory effects. Oral antihistamines are frequently prescribed and may be effective when the pruritus is nocturnal, particularly agents such as diphenhydramine or hydroxyzine, which also cause somnolence, resulting in a restful and comfortable sleep. Other nonsedating antihistamines are not beneficial in relieving pruritus. Selective serotonin reuptake inhibitors (e.g., fluoxetine, sertraline) may be effective, particularly in patients with pruritus that is secondary to cholestasis or the uremia of chronic kidney disease (Bolier et al., 2016; Song et al., 2018).

Nursing Management

The nurse reinforces the reasons for the prescribed therapeutic regimen and educates the patient about specific points of care. The effectiveness of therapy may be gauged by asking the patient to rate the extent of itching pre- and posttherapy (Bolier et al., 2016). If baths have been prescribed, the patient is reminded to use tepid (not hot) water and to shake off the excess water and blot between intertriginous areas (body folds) with a towel. Rubbing vigorously with the towel is avoided because this overstimulates the skin and causes more itching. It also removes water from the stratum corneum. Immediately after bathing, the skin should be lubricated with an emollient to trap moisture.

The patient is instructed to avoid situations that cause vasodilation. Examples include exposure to an overly warm environment and ingestion of alcohol or hot foods and liquids, all of which can induce or intensify pruritus. Using a humidifier is helpful if environmental air is dry. Activities that result in perspiration should be limited because perspiration may irritate and promote pruritus. If itching interferes with sleep, the nurse can advise the patient to wear cotton clothing next to the skin rather than synthetic materials. The room should be kept cool and humidified. Vigorous scratching should be avoided and nails kept trimmed to prevent skin damage and infection. When the underlying cause of pruritus is unknown and further testing is required, the nurse explains each test and its expected outcome.

Perineal and Perianal Pruritus

Pruritus of the genital and anal regions may be caused by small particles of fecal material lodged in the perianal crevices or attached to anal hairs. Alternatively, it may result from perianal skin damage caused by scratching, moisture, and decreased skin resistance as a result of corticosteroid or antibiotic therapy. Other possible causes of perianal itching include local lesions such as hemorrhoids, fungal or yeast infections, and pinworm infestation. Conditions reviewed in Chart 56-3 may also result in pruritus. Occasionally, no cause can be identified.

Management

The patient is instructed to follow proper hygiene measures and to discontinue home and OTC remedies. The perineal or anal area should be rinsed with lukewarm water and blotted dry with cotton balls. Premoistened tissues may be used after defecation (Breen & Bleday, 2020).

As part of health education, the nurse instructs the patient to avoid bathing in water that is too hot and to avoid using bubble baths, sodium bicarbonate, and detergent soaps, all of which aggravate dryness. To keep the perineal or perianal skin as dry as possible, patients should avoid wearing underwear made of synthetic fabrics. The patient should also avoid vasodilating agents (e.g., alcohol), stimulants (e.g., caffeine), and mechanical irritants (e.g., rough or woolen clothing). A diet that includes adequate fiber may help maintain soft stools and prevent minor trauma to the anal mucosa (Breen & Bleday, 2020).

SECRETORY DISORDERS

The main secretory function of the skin is performed by the sweat glands, which help regulate body temperature. These glands excrete perspiration that evaporates, thereby cooling the body. The sweat glands are located in various parts of the body and respond to different stimuli. Those on the trunk generally respond to thermal stimulation; those on the palms and soles respond to nervous stimulation; and those in the axillae and on the forehead respond to both kinds of stimulation. Normal perspiration has no odor. Body odor is produced by the increase in bacteria on the skin and the interaction of bacterial waste products with the chemicals of perspiration (Norris, 2019). As a rule, moist skin is warm, and dry skin is cool, but this is not always true. It is not unusual to observe warm, dry skin in patients who are dehydrated and very hot, dry skin in patients with some febrile states.

Normally, sweat can be controlled with the use of antiperspirants and deodorants. Most antiperspirants are aluminum salts that block the opening to the sweat duct. Pure deodorants inhibit bacterial growth and block the metabolism of sweat; they have no antiperspirant effect. Fragrance-free deodorants are available for those with sensitive skin.

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic suppurative folliculitis of the perianal, axillary, and genital areas or under the breasts. It can produce abscesses or sinuses with scarring. It develops after puberty and diminishes in incidence after 50 years of age. Black Americans are at greater risk for hidradenitis suppurativa, as are patients who smoke and who have obesity. In addition, men are at greater risk for anogenital hidradenitis suppurativa, whereas women are at greater risk for axillary hidradenitis suppurativa. The cause is unknown, but it appears to have a genetic basis (Tchero, Herlin, Bekara, et al., 2019).

Pathophysiology

It had been assumed for many years that hidradenitis suppurativa was caused by the blockage and infection of the sweat glands. However, recent evidence suggests that it is a primary disorder of follicular occlusion, often resulting in infection, that causes eventual hypertrophic formation of scar tissue in the area of the sweat glands (Doughty & McNichol, 2016).

Clinical Manifestations

Hidradenitis suppurativa occurs more frequently in the axillae but also appears in inguinal folds, on the mons pubis, around the buttocks, areolae of the breasts, submammary fold, nape of the neck, and shoulders. The patient may present with a firm, pea-sized nodule that causes discomfort, or with a history of this type of nodule that then ruptures and discharges purulent drainage. The nodule then propagates, and multiple similar nodules will form adjacent to the initial nodule. The nodules become deep seated and, as they rupture, form scars. The nodules may coalesce or form “bridges,” become infected, and result in abscesses. As they coalesce, the patient will present with complaints of persistent pain (Doughty & McNichol, 2016).

Management

The patient is educated to use warm compresses and wear loose-fitting clothes over the nodules or lesions. Oral antibiotic agents such as erythromycin, tetracycline, minocycline, and doxycycline are frequently prescribed. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be indicated to relieve the pain. Silver-impregnated alginate dressings may be useful with some lesions. Incision and drainage of large suppurating areas with gauze packs inserted to facilitate drainage are often necessary. Rarely, the entire area is excised, removing the scar tissue and any infection. This surgery is drastic in that it may require the use of skin grafts (see Chapter 57) and is performed only as a last resort. Carbon dioxide laser surgery (see later discussion) may be more effective than this type of excisional surgery (Tchero et al., 2019).

Seborrheic Dermatitis

Seborrhea is excessive production of sebum (secretion of sebaceous glands), which typically occurs in areas where sebaceous glands are normally found in large numbers, such as the face, scalp, eyebrows, eyelids, sides of the nose and upper lip, malar regions (cheeks), ears, axillae, under the breasts, groin, and gluteal crease of the buttocks. *Dermatosis* refers to a skin disorder; thus, the seborrheic dermatoses are skin disorders caused by an excessive production of sebum. *Dermatitis* refers to an inflammatory skin disorder. Seborrheic dermatitis is a chronic inflammatory disease of the skin with a predilection for areas that are well supplied with sebaceous glands or lie between skin folds, where the bacterial count is high (Doughty & McNichol, 2016).

Clinical Manifestations

Two forms of seborrheic dermatitis can occur: an oily form and a dry form. Either form may start in childhood and continue throughout life. The oily form appears moist or greasy. There may be patches of sallow, greasy skin, with or without scaling, and slight erythema, predominantly on the forehead, nasolabial fold, beard area, scalp, and between adjacent skin surfaces in the regions of the axillae, groin, and breasts. Small pustules or papulopustules resembling acne may appear on the trunk. The dry form, consisting of flaky desquamation of the scalp with a profuse amount of fine, powdery scales, is commonly called *dandruff*. The mild forms of the disease are asymptomatic. When scaling occurs, it is often accompanied by pruritus, which may lead to scratching and secondary infections and excoriation.

Seborrheic dermatitis has a genetic predisposition. Hormones, nutritional status, infection, and emotional stress influence its course. The remissions and exacerbations of this condition should be explained to the patient. If a person has not previously been diagnosed with this condition and suddenly appears with a severe outbreak, a complete history and physical examination should be conducted. Infrequently, it may be a manifestation of a serious disorder, such as Parkinson's disease or human immune deficiency virus (HIV) infection (Sasseville, 2020).

Medical Management

Because there is no known cure for seborrhea, the objectives of therapy are to control the disorder and allow the skin to repair itself. Seborrheic dermatitis of the body and face may respond to a topically applied corticosteroid cream, which allays the secondary inflammatory response. However, this medication should be used with caution near the eyelids because it can lead to glaucoma and cataracts. As an alternative treatment, patients can wash the eyelids using baby shampoo and cotton swabs (Handler, 2019).

Patients with seborrheic dermatitis may develop a secondary candidal (yeast) infection in body creases or folds. To avoid this, patients should be advised to ensure maximum aeration of the skin and to clean carefully areas where there are creases or folds in the skin (Doughty & McNichol, 2016). Patients with persistent candidiasis should be evaluated for diabetes.

The mainstay of dandruff treatment is proper, frequent shampooing (at least three times weekly) with medicated shampoos. Two or three different types of shampoo should be used in rotation to prevent the seborrhea from becoming resistant to a particular shampoo. The shampoo is left on at least 5 to 10 minutes. As the condition of the scalp improves, the treatment can be less frequent. Antiseborrheic shampoos include those containing selenium sulfide suspension, zinc pyrithione, salicylic acid, or sulfur compounds, and tar shampoo that contains sulfur or salicylic acid (Handler, 2019; Sasseville, 2020).

Nursing Management

The patient is educated that seborrheic dermatitis is a chronic condition that tends to reappear. The goal is to keep it under control through adherence to the treatment program (Handler, 2019; Sasseville, 2020). The patient is advised to avoid external irritants, excessive heat, and perspiration; rubbing

and scratching prolong the disorder. To avoid secondary infection, the patient should air the skin and keep skin folds clean and dry.

Instructions for using medicated shampoos are reinforced for people with dandruff who require treatment. Frequent shampooing is contrary to some cultural practices; the nurse should be sensitive to these differences when educating the patient.

Acne Vulgaris

Acne vulgaris is a common disorder affecting susceptible pilosebaceous units (hair follicles and sebaceous glands), most commonly on the face, neck, torso, and upper arms (Dlugasch & Story, 2021; Thiboutot & Zaenglein, 2019). It is a chronic dermatosis characterized by **comedones** (primary acne lesions), both closed (whiteheads) and open (blackheads), and by papules, pustules, nodules, and cysts (Zaenglein, Pathy, Schlosser, et al., 2016) (see Chapter 55, Table 55-2).

Acne is the most commonly encountered skin condition that affects up to 80% of Americans at some time during their lives. Acne is most prevalent during adolescence among males but is more prevalent in adulthood among females. Acne is traditionally considered a skin disorder of adolescence; however, by age 45 years, up to 5% of adults report having acne (Rao & Chen, 2020). Acne appears to stem from an interplay of genetic, hormonal, and bacterial factors (Dlugasch & Story, 2021; Thiboutot & Zaenglein, 2019).

Pathophysiology

During puberty, androgens stimulate the sebaceous glands, causing them to enlarge and secrete sebum (a naturally occurring endogenous oil) that rises to the top of the hair follicle and flows out onto the skin surface. In adolescents who develop acne, androgenic stimulation produces a heightened response in the sebaceous glands, with increased sebum production and hyperkeratinization, causing sebum plug formation within the pilosebaceous ducts. Sebaceous plugging then causes a localized inflammatory response (Dlugasch & Story, 2021; Thiboutot & Zaenglein, 2019).

Clinical Manifestations

The main lesions of acne are comedones. Closed comedones form from impacted lipids or oils and keratin that plug the dilated follicle. Closed

comedones may evolve into open comedones, in which the contents of the ducts are in open communication with the external environment. The color of open comedones results from an accumulation of lipid, bacterial, and epithelial debris. Some closed comedones may rupture, resulting in an inflammatory reaction caused by leakage of follicular contents (e.g., sebum, keratin, bacteria) into the dermis. The resultant inflammation is seen clinically as erythematous papules, inflammatory pustules, and inflammatory cysts. Mild papules and cysts drain and heal without treatment. Deeper papules and cysts cause scarring of the skin (Thiboutot & Zaenglein, 2019).

Assessment and Diagnostic Findings

The diagnosis of acne is based on the history and physical examination, evidence of lesions characteristic of acne, and age. Women may report a history of flare-ups a few days before menses. The presence of the typical comedones along with oily skin is characteristic (Rao & Chen, 2020). Oiliness is more prominent in the midfacial area; other parts of the face may appear dry.

Acne vulgaris can be classified as mild, moderate, or severe based upon the number and type of acne lesions, severity location and scarring. However, currently there is no consensus on the exact number of lesions that constitute mild, moderate, and severe acne (Zaenglein et al., 2016). Generally speaking, mild acne is characterized by the presence of comedones and a few papulopustules; moderate acne is characterized by a greater number of papulopustules and comedones along with the presence of inflammatory pustules; and, severe acne is characterized by the presence of cysts (also called nodules or nodulocysts) that are greater than 5 mm in diameter (Rao & Chen, 2020).

Medical Management

The goals of management are to reduce bacterial colonies, decrease sebaceous gland activity, prevent the follicles from becoming plugged, reduce inflammation, combat secondary infection, minimize scarring, and eliminate factors that predispose the person to acne. The therapeutic regimen depends on the type of lesion (e.g., comedones, papule, pustule, cyst). The duration of treatment depends on the extent and severity of the acne. In severe cases, treatment may extend over years.

Nutrition and Hygiene Therapy

The association between diet and acne is not established. In particular, the association between acne and milk products, chocolate, and fried foods is not well defined. However, there does appear to be a correlation between foods high in refined sugars and acne; therefore, these foods should be avoided (Zaenglein et al., 2016). In general, maintenance of good nutrition equips the immune system for effective action against bacteria and infection.

For mild cases of acne, washing twice a day with a cleansing soap and use of OTC products that contain benzoyl peroxide or salicylic acid (see later discussion) may be all that is required (Dlugasch & Story, 2021; Zaenglein et al., 2016). Oil-free cosmetics and creams should be chosen. These products are usually designated as useful for acne-prone skin.

TABLE 56-5 Medications Indicated for Treatment of Acne Vulgaris

Classification	Recommended Medications
Mild acne	Benzoyl peroxide -or- Topical retinoid -or- Combination[a] topical antibiotic and benzoyl peroxide -or- Combination[a] topical retinoid and benzoyl peroxide -or- Combination[a] topical retinoid and benzoyl peroxide and topical antibiotic
Moderate acne	Combination[a] topical antibiotic and benzoyl peroxide -or- Combination[a] topical retinoid and benzoyl peroxide -or- Combination[a] topical retinoid and benzoyl peroxide and topical antibiotic -or- Oral antibiotic and combination[a] topical retinoid and benzoyl peroxide -or- Oral antibiotic and combination[a] topical retinoid and benzoyl peroxide and topical antibiotic
Severe acne	Oral antibiotic and combination[a] topical retinoid and benzoyl peroxide -or- Oral antibiotic and combination[a] topical antibiotic and benzoyl peroxide -or- Oral antibiotic and combination[a] topical retinoid and benzoyl peroxide and topical antibiotic -or- Oral antibiotic and oral isotretinoin

[a]May be prescribed as combination products or as singular products.

Adapted from Zaenglein, A. L., Pathy, A. L., Schlosser, B. J., et al. (2016). Guidelines of care for the management of acne vulgaris. *Journal of the American Academy of Dermatology*, *74*(5), 945–973.

Pharmacologic Therapy

Pharmacologic treatments for acne are based upon the severity of the acne (Zaenglein et al., 2016). Table 56-5 summarizes medications recommended to manage acne vulgaris based upon severity.

Topical Therapy

Recommended OTC acne medications contain benzoyl peroxide, which is very effective at removing the sebaceous follicular plugs. Benzoyl peroxide preparations produce a rapid and sustained reduction of inflammatory lesions. They depress sebum production and promote breakdown of comedo plugs and have an antibacterial effect (Zaenglein et al., 2016). Initially, benzoyl peroxide causes redness and scaling, but the skin usually adjusts quickly to its use. However, the skin of some people can be overly sensitive to these products, which can cause irritation or excessive dryness, especially when used with some prescribed topical medications. The patient should be instructed to discontinue use of the product if severe irritation occurs. Typically, the patient applies a gel of benzoyl peroxide once daily. In many instances, this is the only treatment needed (Comerford & Durkin, 2020).

OTC salicylic acid preparations are also available for use by patients with mild acne. The effects of these agents are similar to those of benzoyl peroxide products. Although salicylic acid products have long been used by patients with acne, their efficacy has not been demonstrated in clinical trials (Zaenglein et al., 2016). Prescription topical agents used for years that have also not demonstrated efficacy in clinical trials include zinc, sulfur, and resorcinol; and are therefore not recommended for treatment (Zaenglein et al., 2016).

Synthetic vitamin A acids, also called retinoids (e.g., tretinoin, adapalene, tazarotene), are applied topically to clear the keratin plugs from the pilosebaceous ducts. The patient should be informed that symptoms may worsen during early weeks of therapy because inflammation, erythema, and peeling may occur. The patient is cautioned against sun exposure while using this topical medication because it may cause sunburn. Package insert directions should be followed carefully. Improvement may take 8 to 12 weeks. Some patients may benefit from being treated with both a retinoid and benzoyl peroxide and may be prescribed a combination topical gel (e.g., adapalene–benzoyl peroxide) (Zaenglein et al., 2016).

Topical antibiotic treatment for acne is common. Topical antibiotic agents suppress bacterial growth; reduce superficial free fatty acid levels; decrease comedones, papules, and pustules; and produce no systemic side effects (Comerford & Durkin, 2020). Commonly prescribed agents include clindamycin and erythromycin. Topical combination gels that include both benzoyl peroxide and an antibiotic (e.g., benzoyl erythromycin) are commonly prescribed and can be very effective treatment (Zaenglein et al., 2016).

Other less commonly prescribed topical agents that may be effective in treating acne vulgaris include azelaic acid and dapsone gel. Azelaic acid has

comedolytic, antibacterial, and anti-inflammatory effects. It may also have a lightening effect on skin that can be hyperpigmented as a consequence of acne (Zaenglein et al., 2016). Dapsone reduces inflammatory lesions and for reasons poorly understood, seems to work better in female adult patients than in adolescent or male patients (Zaenglein et al., 2016).

Systemic Therapy

Oral antibiotic agents given in small doses over a long period are very effective in treating moderate and severe acne, especially when the acne is inflammatory and results in pustules, abscesses, and scarring. Therapy may continue for months to years. Antibiotics most commonly selected are of the tetracycline class (e.g., tetracycline, doxycycline, minocycline) (Zaenglein et al., 2016). The tetracycline family of antibiotics is contraindicated in pregnant women. Side effects of tetracyclines include photosensitivity (sensitivity to the sun), nausea, diarrhea, cutaneous infection, and vaginitis in women (Comerford & Durkin, 2020). Alternative antibiotics that may be selected include erythromycin, azithromycin, and trimethoprim–sulfamethoxazole (Zaenglein et al., 2016).

Oral retinoids (e.g., isotretinoin) are used with dramatic results in patients with nodular cystic acne unresponsive to conventional therapy. This may prevent scarring that can result from cyst formation. Retinoids reduce sebaceous gland size and inhibit sebum production. They also cause epidermal desquamation (shedding of the epidermis), thereby unseating and expelling existing comedones. The most common side effect is **cheilitis** (inflammation of the lips). Dry and chafed skin and mucous membranes are also frequent side effects. These changes are reversible with the withdrawal of the medication. Retinoids are teratogenic, meaning that they may cause fetal defects. Effective contraceptive measures for women of childbearing age are mandatory during treatment and for about 4 to 8 weeks thereafter (Dlugasch & Story, 2021). To avoid additive toxic effects, patients are cautioned not to take vitamin A supplements while taking retinoids (Comerford & Durkin, 2020).

Estrogen therapy (including progesterone–estrogen preparations) suppresses sebum production and reduces skin oiliness. It is usually reserved for young women when the acne begins somewhat later than usual and tends to flare up at certain times in the menstrual cycle. Estrogen-dominant oral contraceptive compounds may be given on a prescribed cyclic regimen (Rao & Chen, 2020). Estrogen is not given to male patients because of the undesirable side effects such as enlargement of the breasts and decrease in body hair.

Phototherapy

The use of antibiotic therapy runs the risk of developing antibiotic resistance; therefore, phototherapy has been proposed as a potentially viable alternative treatment. The use of light-emitting diode (LED) phototherapy using blue light (i.e., directing wavelengths of 407 to 420 nm to targeted skin) has shown preliminary promise for the treatment of mild to moderate acne. The blue light is believed to cause photoactivation of naturally occurring porphyrins, resulting in free radical formation, which causes cell membrane destruction of *Propionibacterium acne*, the common culprit in inciting comedo formation (Ablon, 2018; Scott, Stehlik, Clark, et al., 2019). To date, there have been no reported adverse effects associated with blue light phototherapy. Patients must commit time to these treatments, which may be self-administered at home twice daily for 30 to 60 minutes for 5 weeks (Scott et al., 2019). At present, the efficacy of phototherapy remains under investigation.

Surgical Management

Treatment includes comedo extraction; injections of corticosteroids into the inflamed lesions; and incision and drainage of large, fluctuant (moving in palpable waves), nodular cystic lesions. Patients with deep scars may be treated with dermabrasion (deep abrasive therapy), in which the epidermis and some superficial dermis are removed down to the level of the scars (Rao & Chen, 2020).

Comedones may be removed with a comedo extractor. The site is first cleaned with alcohol. The opening of the extractor is then placed over the lesion, and direct pressure is applied to cause extrusion of the plug through the extractor. Removal of comedones leads to erythema, which may take several weeks to subside. Recurrence of comedones after extraction is common (Rao & Chen, 2020).

Nursing Management

Nursing care of patients with acne includes monitoring and managing potential complications of skin treatments. Major nursing activities include providing patient education, particularly in proper skin care techniques, and managing potential problems related to the skin disorder or therapy. Providing positive reassurance, listening attentively, and being sensitive to the feelings of the patient with acne are essential to the patient's psychological well-being and understanding of the disease and treatment plan. Having acne, particularly if it persists into adulthood, can lead to anxiety and depression (Zaenglein et al., 2016).

Preventing Scarring

Prevention of scarring is the ultimate goal of therapy. The chance of scarring increases with the severity of the grade of acne. Severe acne usually requires longer-term therapy with systemic antibiotic agents and other treatments that may include combination topical agents or isotretinoin (see Table 56-5). Patients should be warned that discontinuing these medications may lead to more flare-ups and increase the chance of deep scarring. Furthermore, manipulation of the comedones, papules, and pustules increases the potential for scarring.

When acne surgery is prescribed to extract deep-seated comedones or inflamed lesions or to incise and drain cystic lesions, the intervention itself may result in further scarring. Dermabrasion, which levels existing scar tissue, can also increase scar formation. Hyper- or hypopigmentation also may affect the tissue involved. The patient should be informed of these potential outcomes before choosing surgical intervention for acne.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

In addition to providing instructions for taking prescribed medications, the nurse advises patients to wash the face and other affected areas with mild soap and water twice a day to remove surface oils and prevent obstruction of the oil glands. Mild abrasive soaps and drying agents are prescribed to eliminate the oily feeling that troubles many patients. At the same time, patients are cautioned to avoid excessive abrasion, because it makes acne worse.

All forms of friction and trauma are avoided, including propping the hands against the face, rubbing the face, and wearing tight collars, helmets, and face masks. Patients are instructed to avoid manipulation of pimples or blackheads. Squeezing merely worsens the problem, because a portion of the blackhead is pushed down into the skin, which may cause the follicle to rupture. Because cosmetics, shaving creams, and lotions can aggravate acne, these should be avoided.

INFECTIOUS DERMATOSES

Various dermatoses can be caused by bacterial, viral, fungal, or parasitic infections.

Bacterial Skin Infections

Also called **pyodermas**, pus-forming bacterial infections of the skin may be primary or secondary. Primary skin infections originate in previously normal-appearing skin and are usually caused by a single organism. Secondary skin infections arise from a preexisting skin disorder or from disruption of the skin integrity from injury or surgery. In either case, several microorganisms may be implicated (e.g., *Staphylococcus aureus,* group A streptococci). Common primary bacterial skin infections are impetigo and folliculitis. Folliculitis may lead to furuncles or carbuncles.

Impetigo

Impetigo is a superficial infection of the skin caused by staphylococci, streptococci, or multiple bacteria. Bullous impetigo, a more deep-seated infection of the skin caused by *S. aureus,* is characterized by the formation of **bullae** (i.e., large, fluid-filled blisters) from original vesicles. The bullae rupture, leaving raw, red areas. Nonbullous impetigo accounts for approximately 70% of the cases. This type of impetigo tends to affect skin that has already been disrupted by cuts, abrasions, bites, or other types of trauma. *S. aureus* is also commonly implicated, including methicillin-resistant *S. aureus* (MRSA) and gentamycin-resistant *S. aureus*, as well as *Streptococcus pyogenes* (Lewis, 2019).

The exposed areas of the body, face, hands, neck, and extremities are most frequently involved. Impetigo is contagious and may spread to other parts of the patient's skin or to other members of the family who touch the patient or use towels or combs that are soiled with the exudate of the lesions (Lewis, 2019).

Impetigo is seen in people of all races and ages. It is particularly common in children living in poor hygienic conditions. Chronic health problems, poor hygiene, and malnutrition may predispose an adult to impetigo. It is more prevalent in warm, humid climates and is therefore more commonly seen in the southeastern United States than in northern climates (Lewis, 2019).

Clinical Manifestations

The lesions of impetigo are most commonly seen on the face or extremities. They begin as small, red macules, which quickly become discrete, thin-walled vesicles that rupture and become covered with a loosely adherent honey-yellow crust (Fig. 56-4). These crusts are easily removed to reveal

smooth, red, moist surfaces on which new crusts soon develop (Lewis, 2019).

Medical Management

Topical antibacterial therapy (e.g., mupirocin, retapamulin) is typically prescribed when the disease is limited to a small area. The medication must be applied to the lesions several times daily for 5 to 7 days. Lesions are first soaked or washed with soap solution to remove the central site of bacterial growth, giving the topical antibiotic an opportunity to reach the infected site. After the crusts are removed, the prescribed topical antibiotic cream is applied. Gloves are worn when providing patient care (Lewis, 2019).

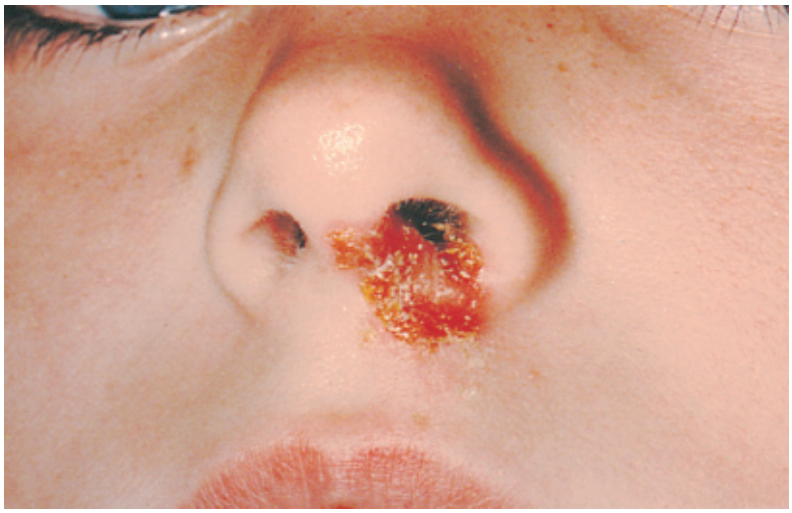

Figure 56-4 • Impetigo of the nostril.

Systemic antibiotic agents may be prescribed to treat infections that are widespread or in cases where there are systemic manifestations (e.g., fever is present). These antibiotics are effective in reducing contagious spread, treating deep infections, and preventing acute glomerulonephritis (kidney infection), which may occur as a consequence of streptococcal skin diseases. Amoxicillin–clavulanate, cloxacillin, or dicloxacillin may be prescribed. In cases where MRSA is present, antibiotics prescribed may include clindamycin, trimethoprim–sulfamethoxazole, levofloxacin, or ciprofloxacin (Lewis, 2019).

Nursing Management

The nurse educates the patient and family members to bathe at least once daily with bactericidal soap. Cleanliness and good hygiene practices help to

prevent the spread of the lesions from one skin area to another and from one person to another. In particular, patients and family members must be educated to practice hand hygiene every time after a lesion is touched. Each person should have a separate towel and washcloth. Because impetigo is a contagious disorder, people who are infected should avoid contact with other people until the lesions heal (Lewis, 2019).

Folliculitis, Furuncles, and Carbuncles

Infectious folliculitis is an inflammatory condition of the cells within the wall and ostia of the hair follicles that may be caused by a bacterial, viral, fungal, or parasitic infection. Lesions may be superficial or deep. Single or multiple papules or pustules appear close to the hair follicles. Folliculitis can affect any hairy part of the body, most commonly the beard area of men who shave, as well as women's legs, if they shave. Other commonly affected areas include the axillae, trunk, and buttocks (Bryant & Nix, 2016).

Pseudofolliculitis barbae (shaving bumps) occur predominantly on the faces of Black men as a result of shaving. The sharp ingrowing hairs have a curved root that grows at a more acute angle and pierces the skin, provoking an irritative reaction. The only entirely effective treatment is to avoid shaving. Other treatments include using special lotions or antibiotics or using a hand brush to dislodge the hairs mechanically. If the patient must remove facial hair, a depilatory cream or electric razor may be used.

A **furuncle** (boil) is an acute inflammation arising deep in one or more hair follicles and spreading into the surrounding dermis (Fig. 56-5). This inflammation is a deep form of folliculitis. Furunculosis refers to multiple or recurrent lesions. Furuncles may occur anywhere on the body but are more prevalent in areas subjected to irritation, pressure, friction, and excessive perspiration, such as the back of the neck, the axillae, and the buttocks.

A furuncle may start as a small, red, raised, painful pimple. Frequently, the infection progresses and involves the skin and subcutaneous fatty tissue, causing tenderness, pain, and cellulitis. The area of redness and induration represents an effort of the body to keep the infection localized. The bacteria (usually staphylococci) produce necrosis of the invaded tissue (Motswaledi, 2018). The characteristic pointing of a boil follows in a few days. When this occurs, the center becomes yellow or black, and the boil is said to have "come to a head."

Figure 56-5 • Painful furuncle on the thigh. Reprinted with permission from Goodheart, H. P. (2003). *Goodheart's photoguide of common skin disorders* (2nd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

A **carbuncle** is an abscess of the skin and subcutaneous tissue that represents an extension of a furuncle that has invaded several follicles and is large and deep seated. It is usually caused by a staphylococcal infection. Carbuncles appear most commonly in areas where the skin is thick and inelastic; the back of the neck and the back are common sites (Ahmad & Siddiqui, 2017). The extensive inflammation frequently prevents a complete walling off of the infection; purulent material may be absorbed, resulting in high fever, pain, leukocytosis, and sepsis.

Furuncles and carbuncles are more likely to occur in older adult patients with underlying systemic diseases, such as diabetes or hematologic malignancies, and in those receiving immunosuppressive therapy for other diseases. Both are more prevalent in hot climates, especially on skin beneath occlusive clothing (Ahmad & Siddiqui, 2017).

Medical Management

In treating staphylococcal infections, it is important not to rupture or destroy the protective wall of induration that localizes the infection. The boil or pimple should never be squeezed. Systemic antibiotic therapy, selected by culture and sensitivity study, is generally indicated. Oral dicloxacillin and cephalosporins are first-line medications. If MRSA is suspected, antibiotic agents selected may include clindamycin,

trimethoprim–sulfamethoxazole, doxycycline, or minocycline (Harris, 2019).

When the pus has localized and is fluctuant, a small incision with a scalpel can speed resolution by relieving the tension and ensuring direct evacuation of the pus and debris. The patient is instructed to keep the draining lesion covered with a dressing.

Nursing Management

Intravenous (IV) fluids, fever reduction, and other supportive treatments are indicated for patients who are acutely ill from infection. Warm, moist compresses hasten resolution of the furuncle or carbuncle. The surrounding skin may be cleansed gently with antibacterial soap, and an antibacterial ointment may be applied. Soiled dressings are handled according to standard precautions. Nursing personnel should carefully follow standard precautions to avoid becoming carriers of staphylococci.

Quality and Safety Nursing Alert

Nurses must take special precautions in caring for boils on the patient's face because the skin area drains directly into the cranial venous sinuses. Sinus thrombosis can develop after manipulating a boil in this location. The infection can travel through the sinus tract and penetrate the brain cavity, causing a brain abscess.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

To prevent and control staphylococcal skin infections such as boils and carbuncles, the staphylococcal pathogen must be eliminated from the skin and environment. Efforts must be made to provide a hygienic environment. If lesions are actively draining, the mattress and pillow should be covered with plastic material and wiped with disinfectant daily; the bed linens, towels, and clothing should be laundered after each use; and the patient should use an antibacterial soap and shampoo for an indefinite period, often several months.

Viral Skin Infections

Cutaneous manifestations may ensue because of viral infections. Viruses implicated in causing dermatologic disorders include the varicella-zoster virus (VZV), the herpes simplex viruses, and the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).

Herpes Zoster

Herpes zoster, also called *shingles,* is an infection caused by VZV. The disease is characterized by painful vesicular eruptions along the areas of distribution of dermatomes (sensory nerves) from one or more posterior ganglia. After a case of primary varicella (chickenpox) runs its course, the VZV lies dormant inside nerve cells near the brain and spinal cord. Later, when the latent virus becomes reactivated because of declining cellular immunity, it travels by way of the peripheral nerves to the skin, where it replicates and create a red rash of small, fluid-filled blisters.

It is thought that during the aging process, natural immunity to the varicella virus wanes, facilitating viral reactivation. Herpes zoster develops naturally over the lifetime of about 10% to 20% of all adults who had chickenpox earlier in life, usually after 50 years of age. The rates of occurrence tend to be the same in both men and women but are slightly lower in Black adults than White adults. There is an increased frequency of herpes zoster infections in patients with weakened immune systems, including those with HIV infection and in those with cancer. In these patients, the infection can become widespread and cause significant complications (Janniger, Eastern, Hospenthal, et al., 2020).

Clinical Manifestations

Manifestations typically occur in three phases, including the preeruptive, acute eruptive, and postherpetic neuralgia phases. During the preeruptive phase, the previously dormant VZV becomes reactivated within the dorsal root ganglia of the spinal cord. Manifestations that follow, therefore, tend to follow the dermatomes that correspond with the ganglia that are affected. The patient will typically complain of pain, or sometimes pruritus or paresthesias, over the sensory region that follows affected dermatomes. This phase lasts from 1 to 10 days, with 48 hours being typical (Janniger et al., 2020).

The acute eruptive phase is heralded by the appearance of unilateral patchy erythematous areas in the dermatomal area that is affected. Vesicles

develop that appear initially clear, then become cloudy, and eventually rupture and crust (Fig. 56-6). The pain that accompanies this stage is typically described as severe and unrelenting. This phase typically lasts between 10 and 15 days (Janniger et al., 2020).

The last phase—postherpetic neuralgia—is variable in terms of both duration and manifestations. The pain is typically localized to the dermatomal area that was affected. Approximately 50% of adults older than 60 years with herpes zoster experience postherpetic neuralgia pain for longer than 60 days (Janniger et al., 2020).

Herpes zoster ophthalmicus is a rare subtype of herpes zoster that causes severe consequences. Typically in herpes zoster ophthalmicus, a branch of the trigeminal nerve is affected that innervates the ocular and periocular structures. This may cause significant pain and morbid ocular complications, including blindness (Janniger et al., 2020).

Medical Management

The effects of herpes zoster can be diminished if oral antiviral agents such as acyclovir, valacyclovir, or famciclovir are given within 72 hours of the onset of symptoms; the prescribed antiviral agent then must continue to be taken for 7 to 10 days in patients who are immune competent. IV acyclovir may be indicated in patients who are immune compromised; length of therapy may continue for up to 21 days (Janniger et al., 2020).

Figure 56-6 • Herpes zoster (shingles).

The goals of herpes zoster management are to relieve the pain and to reduce or avoid complications, which include infection, scarring, and postherpetic neuralgia and eye complications. Pain is controlled with analgesic agents because adequate pain control during the acute phase helps prevent persistent pain patterns. Analgesic agents may include NSAIDs or acetaminophen for mild pain, or opioids such as oxycodone for moderate to severe pain (Beuscher, Reeves, & Harrell, 2017). Systemic corticosteroids have traditionally been prescribed; however, their routine use is currently controversial as benefits have not been seen in research studies (Janniger et al., 2020). Patients with postherpetic neuralgia may be prescribed pregabalin or gabapentin to mitigate its unpleasant effects. Alternative agents that might be prescribed to treat postherpetic neuralgia include tricyclic antidepressants (e.g., amitriptyline, nortriptyline) (Beuscher et al., 2017). Patients with herpes zoster ophthalmicus require emergent treatment by an ophthalmologist (Janniger et al., 2020).

Since 1995, the widespread vaccination of children with the VZV vaccine has led to a marked reduction in the incidence of primary varicella, which presumably will result in marked decrease in rates of herpes zoster in

the future. A zoster vaccine live (ZVL) was introduced to boost VZV cellular immunity in adults 60 years of age and older in 2006. Since that time, consensus guidelines have lowered the age for vaccination to 50 years, and include those with a history of herpes zoster, because it may recur (Janniger et al., 2020). A nonlive, recombinant zoster vaccine (RZV) was approved by the U.S. Food and Drug Administration (FDA) in 2017. In response, the Centers for Disease Control and Prevention (CDC) revised its herpes zoster vaccination guidelines to recommend that adults 50 years of age and older should receive 2 doses of RZV 2 to 6 months apart, regardless of whether or not they have previously received the ZVL vaccine. For those adults who have received the ZVL vaccine, they should not receive a first dose of the RZV vaccine until at least 2 months have elapsed from receipt of the ZVL vaccine (Dooling, Guo, Patel, et al., 2018).

Nursing Management

The patient and family members are instructed about the importance of taking antiviral agents as prescribed and in keeping follow-up appointments with the primary provider. The nurse assesses the patient's discomfort and response to medication and collaborates with the primary provider to make necessary adjustments to the treatment regimen. Vesicles and rashes may be soothed by applying OTC calamine lotion or 5% aluminum acetate (Burow's solution) wet dressings for 30 to 60 minutes four to six times daily (Janniger et al., 2020). The patient is educated about how to follow proper hand hygiene techniques to avoid spreading the virus.

Diversionary activities and relaxation techniques are encouraged to ensure restful sleep and to alleviate discomfort. A caregiver may be required to assist with dressings, particularly if the patient is an older adult and unable to apply them. Food preparation for patients who cannot care for themselves or prepare nourishing meals must be arranged.

Herpes Simplex

Herpes simplex is a common skin infection. There are two types of the causative virus, which are identified by viral typing. In general, herpes simplex type 1 occurs on the skin of the lips, mouth, gums, or tongue (or on the skin around the mouth) and type 2 occurs in the genital area, but both viral types can be found in both locations. See Chapters 18 and 51 for discussion of herpes simplex type 1 and type 2, respectively.

COVID-19 Considerations

SARS-CoV-2, the virion implicated in causing the global pandemic of coronavirus disease 2019 (COVID-19), primarily manifests with respiratory ailments in patients who are infected (e.g., pneumonia, acute respiratory distress syndrome, acute respiratory failure), as its name implies. However, there have been notable dermatologic manifestations of COVID-19; these have been tracked by an international registry of patients with cutaneous manifestations of COVID-19, sponsored by the American Academy of Dermatology (AAD) and the International League of Dermatologic Societies (ILDS). At the time of this writing, the registry has reported dermatologic manifestations of COVID-19 among 716 patients from 31 countries (Freeman, McMahon, Lipoff, et al., 2020b). Although many diverse cutaneous manifestations of COVID-19 have been reported, one that is of particular note involves perniolike acral (fingers, toes) skin lesions (Freeman, McMahon, Lipoff, et al., 2020a; Freeman et al., 2020b).

Pernio (chilblains) is a dermatologic inflammatory manifestation of the superficial vasculature that occurs in response to cold. It exhibits as edema and erythema, sometimes with plaque formation, of affected fingers or toes; ulcerations are sometimes present. The unique perniolike acral manifestations of COVID-19, sometimes called *COVID toes*, are not related to cold/ambient temperature and are not believed to be caused by a vascular response. At the present time, researchers posit that its underlying cause may be idiopathic (unknown), or related to a simple inflammatory response, or related to a prothrombotic coagulopathy incited by the infection (Freeman et al., 2020a). Irrespective of the pathophysiologic mechanisms responsible for this phenomenon, the perniolike acral skin lesions apparently have a predilection for children and young adults rather than middle-aged or older adults with COVID-19. It more commonly affects the toes than the fingers, and in some instances, is the sole manifestation of SARS-CoV-2 infection (Freeman et al., 2020a; Freeman et al., 2020b). Furthermore, the infection tends to be mild and generally may be managed on an outpatient basis (see Chapter 19 for discussion of management of mild COVID-19). Based upon these observations, it is recommended that patients who are otherwise apparently healthy but who present with perniolike acral skin lesions should be tested for COVID-19, regardless of their history of COVID-19 exposure or the presence or absence of other symptoms suggestive of COVID-19 (Feldman & Freeman, 2020).

Fungal (Mycotic) Skin Infections

Fungi are eukaryotic microorganisms that belong to neither the plant nor the animal kingdoms. They are culprits in causing various common skin infections. In some cases, they affect only the skin and its appendages (hair and nails). In other cases, internal organs are involved, and the diseases may be life-threatening. However, superficial infections rarely cause even temporary disability and respond readily to treatment. Secondary infection with bacteria, *Candida,* or both organisms may occur.

The most common fungal skin infection is **tinea**, which is also called *ringworm* because of its characteristic appearance of a ring or rounded tunnel under the skin. Tinea infections affect the head, body, groin, feet, and nails (Sahoo & Mahajan, 2016). Table 56-6 summarizes the tinea infections and treatments.

To obtain a specimen for diagnosis, the lesion is cleaned and a scalpel or glass slide is used to remove scales from the margin of the lesion. The scales are dropped onto a slide to which potassium hydroxide has been added. The diagnosis is made by examination of the infected scales microscopically for spores and hyphae or by isolating the organism in culture. Under Wood's light, a specimen of infected hair appears fluorescent; this may be helpful in diagnosing some cases of tinea capitis (Sahoo & Mahajan, 2016).

Parasitic Skin Infestations

Parasitic skin infestations include those of the skin by lice (pediculosis) and the itch mite (scabies).

Pediculosis: Lice Infestation

Lice infestation affects people of all ages. Three varieties of lice infest humans: *Pediculus humanus capitis* (head louse), *Pediculus humanus corporis* (body louse), and *Pthiriasis pubis* (pubic louse or "crab"). Lice are called *ectoparasites* because they live on the outside of the host's body. They depend on the host for their nourishment, feeding on human blood several times a day. They inject their digestive juices and excrement into the skin, which causes severe itching (CDC, 2017).

Pediculosis Capitis

Pediculosis capitis is an infestation of the scalp by the head louse. The female louse lays her eggs (nits) close to the scalp. The nits become firmly attached to the hair shafts with a tenacious substance. The young lice hatch in about 6 to 9 days and reach maturity in 7 days. Head lice may be transmitted directly by physical contact or indirectly by infested combs, brushes, wigs, hats, helmets, and bedding (CDC, 2017).

Pediculosis Corporis and Pthiriasis Pubis

Pediculosis corporis is an infestation of the body by the body louse. This is a disease of those who live in close quarters. Pthiriasis pubis is extremely common. The infestation is generally localized in the genital region and is transmitted chiefly by sexual contact (Guenther & Maguiness, 2020).

Clinical Manifestations

Head lice are found most commonly along the back of the head and behind the ears. To the naked eye, the eggs look like silvery, glistening oval bodies. The bite of the insect causes intense pruritus, and the resultant scratching often leads to secondary bacterial infection, such as impetigo or furunculosis. The infestation is more common in children and people with long hair (CDC, 2017).

TABLE 56-6  Tinea (Ringworm) Infections

Type and Location	Clinical Manifestations	Treatment
Tinea barbae (fungal infection of beard or moustache of men)	• Red, inflamed abscesslike lesions, pustules, or crusting • May develop secondary infection	• Griseofulvin for 4–6 wks or terbinafine for 2–4 wks • Shampoo beard or moustache twice weekly with selenium sulfide shampoo for 2 wks
Tinea capitis (scalp or eyebrows; contagious fungal infection of the hair shaft)	• Oval, scaling, erythematous patches • Small papules or pustules on the scalp or eyebrows • Brittle hair that breaks easily; patchy alopecia	• Griseofulvin for 4–6 wks or terbinafine for 2–4 wks • Shampoo hair or eyebrows twice weekly with selenium sulfide shampoo for 2 wks
Tinea corporis (body)	• Begins with red macule, which spreads to a ring of papules or vesicles with central clearing • Lesions found in clusters; many spread to the hair, scalp, or nails • Pruritis is a common complaint	• Local infections—topical antifungal creams once or twice daily (e.g., clotrimazole, econazole, ketoconazole) • Extensive infections or concomitant tinea capitis or immunosuppressive conditions (e.g., active neoplasms)—oral antifungal medications (e.g., fluconazole for 2–4 wks, itraconazole for 1 wk, terbinafine for 2 wks)

Tinea cruris (groin area; "jock itch")	• Begins with small, red scaling patches, which spread to form circular elevated plaques • Very pruritic • Clusters of pustules may be seen around borders	• Local infections—see treatment for tinea corporis • Extensive infections or concomitant tinea pedis or immunosuppressive conditions (e.g., active neoplasms)—see treatment for tinea corporis • Educate patients to avoid wearing clothing that is tight over the groin; patients should pat dry skin folds thoroughly (avoid rubbing) after bathing and use separate towels for groin and other body parts
Tinea pedis (foot; "athlete's foot")	• Soles of one or both feet have scaling and mild redness with maceration in the toe webs • More acute infections may have clusters of clear vesicles on dusky base	• Local infections—see treatment for tinea corporis • Extensive infections or concomitant tinea pedis or immunosuppressive conditions (e.g., active neoplasms)—see treatment for tinea corporis • Educate patients: • to put on socks before underwear to avoid cross-contamination to groin • to either dispose of old shoes or treat them with antifungal powder to prevent reinfection • to wear protective footwear at communal pools and tubs
Tinea unguium (toenails; onychomycosis)	• Nails thicken, crumble easily, and lack luster • Whole nail may be destroyed • If untreated, can result in pain, loss of balance, and candida infection	• Oral antifungal medications for 12 wks (e.g., itraconazole, terbinafine) with or without concomitant topical ciclopirox olamine nail lacquer • Nail avulsion may be indicated, either surgically or chemically using a 40–50% urea compound

With body lice, the areas of the skin that come in closest contact with the underclothing (i.e., neck, trunk, and thighs) are chiefly involved. The body louse lives primarily in the seams of underwear and clothing, to which it clings as it pierces the skin with its proboscis. Its bites cause characteristic minute hemorrhagic points. Widespread excoriation may appear as a result of intense pruritus and scratching, especially on the trunk and neck. Among the secondary lesions produced are parallel linear scratches and a slight degree of eczema. In long-standing cases, the skin may become thick, dry, and scaly, with dark pigmented areas (Dlugasch & Story, 2021).

Pruritus, particularly at night, is the most common symptom of lice infestation. Reddish-brown dust (i.e., excretions of the insects) may be found in the patient's underclothing. The pubic area should be examined with a magnifying glass for lice crawling down a hair shaft or nits cemented to the hair or at the junction with the skin. Infestation by pubic lice may coexist with sexually transmitted infections (STIs) such as gonorrhea, herpes, or syphilis. There may also be infestation of the hairs of the chest, axillae, beard, and eyelashes. Gray-blue macules may sometimes be seen on the trunk, thighs, and axillae as a result of either the reaction of the insects' saliva with bilirubin (converting it to biliverdin) or an excretion produced by the salivary glands of the louse (Guenther & Maguiness, 2020).

Medical Management

Treatment of head and pubic lice involves washing the hair with a shampoo containing pyrethrin compounds with piperonyl butoxide or rinsing with permethrin (CDC, 2019). The patient is instructed to shampoo the scalp and hair according to the product directions. After the hair is rinsed thoroughly, it is combed with a fine-toothed comb dipped in vinegar to remove any remaining nits or nit shells freed from the hair shafts. They are extremely difficult to remove and may have to be picked off one by one (CDC, 2019).

The patient with body lice is instructed to bathe with soap and water. Typically, no medications are indicated because the lice live on the patient's clothing. Topical medications used to treat head and pubic lice may be applied to the clothing, however, particularly in the seams of garments (see following discussion about general hygiene measures). If the eyelashes are involved, petrolatum may be thickly applied twice daily for 8 days, followed by mechanical removal of any remaining nits (CDC, 2019).

All articles of clothing, towels, and bedding that may have lice or nits should be washed in hot water—at least 54°C (130°F)—or dry-cleaned to prevent reinfestation. Upholstered furniture, rugs, and floors should be vacuumed frequently. Combs, brushes, and helmets are disinfected or discarded. All family members and close contacts are treated (CDC, 2019).

Complications, such as severe pruritus, pyoderma, and dermatitis, are treated with antipruritics, systemic antibiotics, and topical corticosteroids. Body lice can transmit epidemic rickettsial disease (e.g., epidemic typhus, relapsing fever, and trench fever) to humans. The causative organism may be in the gastrointestinal tract of the insect and may be excreted on the skin surface of the infested person (CDC, 2019).

Nursing Management

The nurse informs the patient that head lice may infest anyone and are not a sign of uncleanliness. Because the condition spreads rapidly, treatment must be started immediately. Epidemics among those living in close quarters (e.g., dormitories, military barracks, camps) may be managed by having everyone shampoo their hair on the same night. Cohabitants and family members should be warned not to share combs, brushes, and hats; they should be inspected for head lice daily for at least 2 weeks.

Treatment is necessary for all family members and sexual contacts of patients with body or pubic lice. The nurse educates them about personal hygiene and methods to prevent or control infestation. The patient and partner must also be scheduled for a diagnostic workup for coexisting STIs.

Scabies

Scabies is an infestation of the skin by the itch mite *Sarcoptes scabiei.* The disease is most commonly found in people living in substandard hygienic conditions and in people who are sexually active. People at increased risk include children, older adults, and those who are immune compromised. The mites frequently involve the fingers, and hand contact may produce infection (Cheng, Mzahim, Koenig, et al., 2020).

Clinical Manifestations

It takes approximately 4 weeks from the time of contact for the patient's symptoms to appear. The patient complains of severe itching caused by a delayed type of immunologic reaction to the mite or its fecal pellets. During examination, the patient is asked where the pruritus is most severe. A magnifying glass and a penlight are held at an oblique angle to the skin while a search is made for the small, raised burrows created by the mites. The burrows may be multiple, straight or wavy, brown or black, threadlike lesions, most commonly observed between the fingers and on the wrists. Other sites are the extensor surfaces of the elbows, the knees, the edges of the feet, the points of the elbows, around the nipples, in the axillary folds, under pendulous breasts, and in or near the groin or gluteal fold, penis, or scrotum. Red, pruritic eruptions usually appear between adjacent skin areas. However, the burrow is not always visible (Cheng et al., 2020).

One classic sign of scabies is the increased itching that occurs during the evening hours, perhaps because the increased warmth of the skin has a stimulating effect on the parasite. Hypersensitivity to the organism and its products of excretion also may contribute to the pruritus. If the infection has spread, other members of the family and close friends also complain of pruritus about 1 month later (Cheng et al., 2020).

Secondary lesions are quite common and include vesicles, papules, excoriations, and crusts. Bacterial superinfection may result from persistent excoriation of the burrows and papules (Cheng et al., 2020).

Gerontologic Considerations

Older adult patients living in long-term care facilities are susceptible to outbreaks of scabies because of close living quarters, poor hygiene due to limited physical ability, and the potential for incidental spread of the organisms by staff members. The vivid inflammatory reaction seen in younger people seldom occurs; rather, the older adult may have peripheral sensory deficits and be less prone to scratch or may be physically unable to scratch. Scratching is an effective mechanism that partially eradicates mite infestation; thus, this results in a more severe subtype. The lesions crust over (causing "crusted scabies") and, in time, may become hyperkeratotic (Cheng et al., 2020).

Health care personnel in extended-care facilities should wear gloves when providing hands-on care to a patient suspected of having scabies until the diagnosis is confirmed and treatment is completed. It is advisable to treat all residents, staff, and families of patients at the same time to prevent

reinfection. The scales that are present with crusted scabies must be removed so that the antiscabicidal medication may be effective. Crusts may be removed with warm water soaks followed by application of 5% salicylic acid in petrolatum cream (Cheng et al., 2020).

Assessment and Diagnostic Findings

The diagnosis is confirmed by recovering *S. scabiei* or the mites' byproducts from the skin. A sample of superficial epidermis is scraped from the top of the burrows or papules with a small scalpel blade. The scrapings are placed on a microscope slide and examined through a microscope at low power to demonstrate evidence of the mite (Cheng et al., 2020).

Medical Management

The patient is instructed to take a warm, soapy bath or shower to remove the scaling debris from the crusts and then to pat the skin dry thoroughly and allow it to cool. A prescription scabicide, 5% permethrin, is considered the medication of choice. It is applied thinly to the entire skin from the neck down, sparing only the face and scalp (which are not affected in scabies). The medication is left on for 12 to 24 hours, after which the patient is instructed to wash thoroughly. One application may be curative, but it is advisable to repeat the treatment for 1 week (Cheng et al., 2020).

Nursing Management

The patient should wear clean clothing and sleep between freshly laundered bed linens. All bedding and clothing should be washed in hot water and dried on the hot dryer cycle. If bed linens or clothing cannot be washed in hot water, dry cleaning is advised.

After treatment is completed, the patient may apply an ointment, such as a topical corticosteroid, to skin lesions because the scabicide may irritate the skin. The patient's hypersensitivity does not cease on destruction of the mites. Pruritus may continue for several weeks as a manifestation of hypersensitivity, particularly in people who are atopic (allergic). This is not a sign that the treatment has failed. The patient is instructed not to apply more scabicide, because it will cause more irritation and increased itching, and not to take frequent hot showers, because they can dry the skin and produce pruritus. Oral antihistamines such as diphenhydramine or hydroxyzine can help control the pruritus. If a secondary infection is

present, treatment with oral antibiotic agents may be indicated (Cheng et al., 2020).

All family members and close contacts should be treated simultaneously to eliminate the mites. Some scabicides are approved for use in infants and pregnant women. If scabies is sexually transmitted, the patient may require treatment for coexisting STI. Scabies may also coexist with pediculosis.

NONINFECTIOUS INFLAMMATORY DERMATOSES

Noninfectious inflammatory dermatoses include dermatologic disorders such as irritant contact dermatitis, psoriasis, and generalized exfoliative dermatitis (also called *erythroderma)*.

Irritant Contact Dermatitis

Contact dermatitis (also called *eczema*) is an inflammatory reaction of the skin to physical, chemical, or biologic agents. The epidermis is damaged by repeated physical and chemical irritations. Contact dermatitis may be of the primary irritant type, in which a nonallergic reaction results from exposure to an irritating substance, or it may be an allergic reaction resulting from exposure of sensitized people to contact allergens (see Chapter 33).

Common causes of irritant contact dermatitis are soaps, detergents, scouring compounds, and industrial chemicals. Predisposing factors include extremes of heat and cold, frequent contact with soap and water, and a preexisting skin disease. Persons at risk include those whose occupations require repeated handwashing (e.g., nurses) or repeated exposure to food or other irritants (e.g., food preparation workers, cleaners, hairdressers). Women tend to be affected more commonly than men (Goldner & Fransway, 2018).

Clinical Manifestations

The eruptions begin when the causative agent contacts the skin. The first reactions include pruritus, burning, and erythema, followed closely by edema, papules, vesicles, and oozing or weeping. In the subacute phase, these vesicular changes are less marked, and they occur alternatively with crusting, drying, fissuring, and peeling. If repeated reactions occur or if the patient continually scratches the skin, lichenification and pigmentation

occur. Secondary bacterial invasion may follow (Goldner & Fransway, 2018).

Management

The objectives of management are to soothe and heal the involved skin and protect it from further damage. The distribution pattern of the reaction is identified to differentiate between allergic and irritant contact dermatitis. A detailed history is obtained. If possible, the offending irritant is removed. Local irritation should be avoided, and soap is not generally used until healing occurs.

Many preparations are advocated for relieving dermatitis. In general, a barrier cream that contains ceramide or dimethicone is used for small patches of erythema. A thin layer of cream or ointment containing a corticosteroid is commonly used, although the efficacy of corticosteroids has not been demonstrated in research (Goldner & Fransway, 2018). The patient is educated about how to treat and prevent future bouts of irritant contact dermatitis (Chart 56-4).

COVID-19 Considerations

The first known outbreak of COVID-19 began in Wuhan, China, in late 2019 and quickly spread through the province of Hubei. Working for long hours caring for patients with COVID-19, Hubei health care workers (HCWs), including nurses and physicians, wore PPE, such as N95 respirators, goggles, face shields, double gloves, and gowns, for extended hours (see Chapter 66 for discussion on PPE). In addition, HCWs spent more time than typical engaging in hand hygiene protocols. As a consequence of these practices that were aimed at protecting themselves and others from SARS-CoV-2 infection, many HCWs on the frontlines of the pandemic in Hubei reported high rates of irritant contact dermatitis. One study of 700 frontline HCWs reported an overall prevalence of irritant contact dermatitis of 97%, with 83.1% of HCWs reporting nasal bridge irritation, presumably from prolonged usage of N95 respirators and goggles (Lan, Song, Miao, et al., 2020). Another group of researchers found that among 61 frontline HCWs, 68.9% reported nasal bridge scarring. These same researchers reported that the incidence of adverse skin reactions to N95 respirators was 95.1%, to gloves 88.5%, and to other PPE 60.7% (Hu, Fan, Li, et al., 2020). In response to these reports, the AAD promulgated a white paper of guidelines that HCWs could adopt to avoid occupationally

induced skin disorders during the COVID-19 pandemic. Key recommendations include the following (AAD, 2020):

Chart 56-4 **PATIENT EDUCATION**

Strategies for Avoiding Irritant Contact Dermatitis

The precautions listed below may help prevent repeated cases of irritant contact dermatitis and should be followed for at least 4 months after skin appears to be completely healed.

The nurse instructs the patient to:

- Study the pattern and location of your dermatitis and think about which things have touched your skin and which things may have caused the problem; try to avoid contact with these materials.
- Avoid heat, soap, and rubbing, all of which are external irritants.
- Choose bath soaps, laundry detergents, and cosmetics that do not contain fragrance.
- Avoid using a fabric softener dryer sheet. Fabric softeners that are added to the washer may be used.
- Avoid topical medications, lotions, or ointments, except those specifically prescribed for your condition.
- Wash your skin thoroughly immediately after exposure to possible irritants.
- Ensure that when wearing gloves (such as for washing dishes or general cleaning), they are cotton lined. Do not wear them more than 15 or 20 minutes at a time.

Adapted from Goldner, R., & Fransway, A. F. (2018). Irritant contact dermatitis in adults. *UpToDate*. Retrieved on 10/12/2020 at: www.uptodate.com/contents/irritant-contact-dermatitis-in-adults

- HCWs should use a moisturizer after engaging in hand hygiene. Continued hand moisturization when off work is also recommended in order to better protect the skin. Moisturizers that contain at least 5% petrolatum are most effective.
- If an HCW uses an N95 respirator that is irritating, the HCW should notify their respective safety officer and request an alternative N95 respirator that might be less irritating. If that is not possible, then a liquid skin sealant/protectant should be applied to the irritated area and

dried before the mask is donned. Petrolatum should *not* be used as a protectant, however, as it can interfere with the seal of the mask.

- All HCWs who utilize PPE should keep their skin clean, dry, and well-moisturized. In particular, the face should be well-moisturized when off work. Cosmetics that include foundations and concealers should not be used. If skin moisturizers are applied, they should be applied at least one hour prior to donning PPE. Irritated areas, particularly the forehead, cheeks, and bridge of the nose, may be treated with petrolatum when off work.
- If masks must be reused, they should be thoroughly dry before they are donned a second time.

Psoriasis

Psoriasis is a chronic inflammatory multisystem disorder of the skin that affects approximately 3.2% of Americans (Nicpon, 2017). Although the primary manifestation of this noncommunicable disease tends to involve the skin, psoriasis may involve the oral cavity, eyes (including the lids, conjunctivae, and corneas), and joints. Psoriasis is typically characterized by the appearance of silvery plaques that most commonly appear on the skin over the elbows, knees, scalp, lower back, and buttocks (Habashy & Robles, 2019). Onset may occur at any age, with a median onset at 28 years. It is more prevalent among women and White Americans. It is thought that most patients with psoriasis have a genetic predisposition to develop the disease. Psoriasis is characterized by periods of remission and exacerbation throughout life (Habashy & Robles, 2019).

Pathophysiology

Current evidence supports an autoimmune basis for psoriasis. Periods of emotional stress and anxiety aggravate the condition, and trauma, infections, and seasonal and hormonal changes may also serve as triggers (Habashy & Robles, 2019).

In this disease, the epidermis becomes infiltrated by activated T cells and cytokines, resulting in both vascular engorgement and proliferation of keratinocytes. Epidermal hyperplasia results. These epidermal cells tend to improperly retain their nuclei, crippling their ability to release lipids that encourage cellular adhesion. This results in rapid turnover of poorly matured cells that do not adhere well to each other, resulting in the classic presentation of plaquelike lesions that have a silvery, scaly, and flaky appearance (Habashy & Robles, 2019).

Clinical Manifestations

Psoriasis may range in severity from a cosmetic source of annoyance to a physically disabling and disfiguring disorder. Lesions appear as red, raised patches of skin covered with silvery scales. The scaly patches are formed by the buildup of living and dead skin (Fig. 56-7). If the scales are scraped away, the dark red base of the lesion is exposed, producing multiple bleeding points. The patches are not moist and may be pruritic. In many cases, the nails are also involved, with pitting, discoloration, crumbling beneath the free edges, and separation of the nail plate (Habashy & Robles, 2019). Psoriasis is classified as mild if the plaques involve less than 5% body surface area (BSA), moderate if they involve between 5% and 10% of BSA, and severe if more than 10% BSA is affected by plaque formation (Nicpon, 2017).

Complications

Asymmetric rheumatoid factor—negative arthritis of multiple joints occurs in up to 42% of people with psoriasis, most typically after the skin lesions appear (Nicpon, 2017). The most typical joints affected include those in the hands or feet, although sometimes larger joints such as the elbows, knees, or hips may be affected (Habashy & Robles, 2019). A rheumatologist should be consulted to assist in the diagnosis and long-term treatment of this disorder. See Chapter 34 for further discussion of spondyloarthropathies, including psoriatic arthritis. Generalized exfoliative dermatitis may also result from psoriasis (see discussion later in this chapter).

Figure 56-7 • Psoriasis.

Assessment and Diagnostic Findings

The presence of the classic plaque-type lesions generally confirms the diagnosis of psoriasis. If in doubt, the health care provider should assess for signs of nail and scalp involvement and for a positive family history. Biopsy of the skin is of little diagnostic value. The presence and extent of plaque should be assessed carefully, to calculate BSA involvement.

Medical Management

The goals of management are to slow the rapid turnover of epidermis, to promote resolution of the psoriatic lesions, and to control the natural cycles of the disease. There is no known cure.

The therapeutic approach should be one that the patient understands; it should be cosmetically acceptable and minimally disruptive of lifestyle. Treatment involves the commitment of time and effort by the patient and possibly the family. Any precipitating or aggravating factors are addressed. An assessment is made of lifestyle because psoriasis is significantly affected by stress. Management of emotional factors should be addressed as part of the overall treatment of psoriasis. The patient is informed that treatment of severe psoriasis can be time-consuming, expensive, and aesthetically unappealing at times. Many patients report difficulty adhering

to treatment plans, either for time reasons or lack of response to the treatment (Feldman, 2020).

Gentle removal of scales is an important principle of psoriasis treatment. This can be accomplished by taking baths with added oils (e.g., olive oil, mineral oil), colloidal oatmeal preparations, or coal tar preparations. A soft brush may be used to gently scrub the psoriatic plaques. After bathing, the application of emollient creams containing alpha-hydroxy acids or salicylic acid can soften thick scales. The patient and family should be encouraged to establish a regular skin care routine that can be maintained even when the psoriasis is not in an acute stage (Feldman, 2020).

Pharmacologic Therapy

Three types of therapy are commonly indicated: topical, phototherapy, and systemic. Topical agents, possibly in tandem with phototherapy, are recommended for mild disease. Patients with moderate or severe disease should receive topical agents, phototherapy, and systemic treatment (Nicpon, 2017).

Topical Agents

Topically applied agents are used to slow the overactive epidermis. Topical corticosteroids may be applied for their anti-inflammatory effects (see Table 56-3). Choosing the correct strength of corticosteroid for the involved site and choosing the most effective vehicle base are important aspects of topical treatment. In general, high-potency topical corticosteroids should not be used on the face and intertriginous areas, and their use on other areas should be limited to a 4-week course of twice-daily applications. A 4-week break should be taken before repeating treatment with the high-potency corticosteroids. For long-term therapy, moderate-potency corticosteroids are used. On the face and intertriginous areas, only low-potency corticosteroids are appropriate for long-term use (Doughty & McNichol, 2016).

Occlusive dressings may be applied to increase the effectiveness of the corticosteroid. Large plastic bags may be used—one for the upper body with openings cut for the head and arms and one for the lower body with openings for the legs. Large rolls of tubular plastic can be used to cover the arms and legs. Another option is a vinyl jogging suit. The medication is applied, and the suit is put on over it. The hands can be wrapped in gloves, the feet in plastic bags, and the head in a shower cap. Occlusive dressings should not remain in place longer than 8 hours. The skin should be inspected carefully for the appearance of atrophy, hypopigmentation, striae, and telangiectasias—all of which are side effects of corticosteroids.

When psoriasis involves large areas of the body, topical corticosteroid treatment can be expensive and involve some systemic risk. The more potent corticosteroids, when applied to large areas of the body, have the potential to cause adrenal suppression through percutaneous absorption of the medication. In this event, other treatment modalities (e.g., nonsteroidal topical medications, UV light) may be used instead or in combination to decrease the need for corticosteroids (Doughty & McNichol, 2016).

Treatment with topical nonsteroidal agents, such as calcipotriene and tazarotene, can suppress **epidermopoiesis** (i.e., development of epidermal cells) and cause sloughing of the rapidly growing epidermal cells. Calcipotriene 0.05% is a derivative of vitamin D_2. It works by decreasing the mitotic turnover of the psoriatic plaques. Its most common side effect is local irritation. The intertriginous areas and face should be avoided when using this medication. The patient should be monitored for symptoms of hypercalcemia. Calcipotriene is available as a cream for use on the body and a solution for the scalp. It is not recommended for use by older adult patients because of their more fragile skin or by pregnant or lactating women (Feldman, 2020).

Tazarotene, a retinoid, causes sloughing of the scales covering psoriatic plaques. As with other retinoids, it causes increased sensitivity to sunlight by loss of the outermost layer of skin, so the patient should be cautioned to use an effective sunscreen and avoid other photosensitizers (e.g., tetracycline, antihistamines). Tazarotene is teratogenic, and the risk of use in pregnant women clearly outweighs any possible benefits. A negative result on a pregnancy test should be obtained before initiating this medication in women of childbearing age, and an effective contraceptive should be continued during treatment. Side effects include burning, erythema, or irritation at the site of application, and worsening of psoriasis (Feldman, 2020).

Intralesional injections of the corticosteroid triamcinolone can be given directly into highly visible or isolated patches of psoriasis that are resistant to other forms of therapy. Care must be taken to ensure that the medication is not injected into normal skin (Habashy & Robles, 2019).

Phototherapy

For patients who do not respond well to topical treatments, phototherapy using narrow-band ultraviolet-B (UVB) therapy may be effective as a single-therapy modality. However, phototherapy is generally more effective when it is given as ultraviolet-A (UVA) in conjunction with a photosensitizing oral medication (a combination referred to as PUVA). Here, the patient takes a photosensitizing medication (i.e., psoralen) in a

standard dose and is subsequently exposed to long-wave UV light as the medication plasma levels peak. It is thought that when psoralen-treated skin is exposed to UVA light, the psoralen binds with DNA and decreases epidermal cellular proliferation. PUVA has been associated with long-term risks of skin cancer, cataracts, and premature aging of the skin (Habashy & Robles, 2019).

The patient is usually treated two or three times each week until the psoriasis clears. An interim period of 48 hours between treatments is necessary to allow any burns resulting from PUVA therapy to become evident. After the psoriasis clears, the patient begins a maintenance program. Once little or no disease is active, less potent therapies are used to keep minor flare-ups under control (Habashy & Robles, 2019).

Systemic Agents

Although systemic corticosteroids may cause rapid improvement of psoriasis, the usual risks and the possibility of triggering a severe flare-up on withdrawal limit their use; therefore, they are not indicated for treatment of psoriasis.

Methotrexate, a systemic cytotoxic agent, is the first-line drug for treating moderate to severe psoriasis (Nicpon, 2017). Methotrexate appears to inhibit DNA synthesis in epidermal cells, thereby reducing the turnover time of the psoriatic epidermis. However, the medication can be toxic, especially to the liver, kidneys, and bone marrow. Laboratory studies must be monitored to ensure that the hepatic, hematopoietic, and renal systems are functioning adequately. The patient should avoid drinking alcohol while taking methotrexate because alcohol ingestion increases the possibility of liver damage. The medication is teratogenic and thus should not be given to pregnant women.

Cyclosporine, a cyclic peptide immunosuppressive agent, may be considered in treatment of severe, therapy-resistant cases of psoriasis. However, its use is limited by side effects such as hypertension and nephrotoxicity and is only indicated for short-term use, generally no longer than 3 to 6 months (Habashy & Robles, 2019).

Another line of treatments for psoriasis includes a group called *biologic agents* because of their derivation from immunomodulators and bioengineered proteins (such as antibodies or recombinant cytokines) and their targeted action directly on the T cells. These agents act by inhibiting activation and migration, eliminating the T cells completely, slowing postsecretory cytokines or inducing immune deviation.

Infliximab is a monoclonal antibody that binds to tumor necrosis factor-alpha (TNF-α) and can only be given by IV infusion. Ustekinumab is also a

monoclonal antibody that specifically interferes with the effect of interleukins (ILs), particularly IL-12 and IL-23. Etanercept is a fusion protein that binds with soluble TNF-α and blocks its interaction with the cell surface receptors. Alefacept is a fusion protein that inhibits T-cell proliferation. Adalimumab is a recombinant human immunoglobulin G1 (IgG1) monoclonal antibody against TNF-α. Secukinumab is a human IgG1 monoclonal antibody and ixekizumab is a humanized monoclonal IgG4 antibody; both of these agents neutralize the effects of the proinflammatory cytokine IL-17A and are administered subcutaneously. All of these biologic agents have significant side effects, making close monitoring essential (Habashy & Robles, 2019).

Nursing Management

Psoriasis may cause despair and frustration for the patient; observers may stare, comment, ask embarrassing questions, or even avoid the person. The disease can eventually exhaust the patient's resources, interfere with their job, and negatively affect many aspects of life.

The nurse assesses the impact of the disease on the patient and the coping strategies used for conducting normal activities and interactions with family and friends. Many patients need reassurance that the condition is not infectious, not a reflection of poor personal hygiene, and not skin cancer. The nurse can create an environment in which the patient feels comfortable discussing important quality of life issues related to their psychosocial and physical response to this chronic illness.

The nurse explains with sensitivity that although there is no cure for psoriasis and lifetime management is necessary, the condition can usually be controlled. The pathophysiology of psoriasis is reviewed, as are the factors that provoke it—irritation or injury to the skin (e.g., cut, abrasion, sunburn), current illness (e.g., pharyngeal streptococcal infection), and emotional stress. It is emphasized that repeated trauma to the skin and an unfavorable environment (e.g., cold) may exacerbate psoriasis. The patient is cautioned about taking any nonprescription medications because some may aggravate mild psoriasis. As well, the patient is advised to seek treatment from the same primary provider for any acute illnesses or chronic conditions to minimize chances of receiving prescriptions that may interfere with each other (Nicpon, 2017).

Reviewing and explaining the treatment regimen are essential to ensure adherence to the therapeutic regimen. For example, if the patient has a mild condition confined to localized areas, such as the elbows or knees, application of an emollient to maintain softness and minimize scaling may

be all that is required. Most patients need a comprehensive plan of care that ranges from using topical medications and shampoos to more complex and lengthy treatment with systemic medications and photochemotherapy, such as PUVA therapy. Patient education materials that include a description of the therapy and specific guidelines are helpful but cannot replace face-to-face discussions (either in-person or online) of the treatment plan.

To avoid injuring the skin, the patient is advised not to pick at or scratch the affected areas. Measures to prevent dry skin are encouraged because dry skin worsens psoriasis. Too-frequent washing produces more soreness and scaling. Water should be warm, not hot, and the skin should be dried by patting with a towel rather than by rubbing. Emollients have a moisturizing effect, providing an occlusive film on the skin surface so that normal water loss through the skin is halted and allowing the trapped water to hydrate the stratum corneum. A bath oil or emollient cleansing agent can comfort sore and scaling skin. Softening the skin can prevent fissures.

A therapeutic relationship between health care professionals and the patient with psoriasis includes education and support. Introducing the patient to successful coping strategies used by others with psoriasis and making suggestions for reducing or coping with stressful situations at home, school, and work can facilitate a more positive outlook and acceptance of the chronicity of the disease.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Printed patient education materials may be provided to reinforce face-to-face discussions about treatment guidelines and other considerations. Patients using topical corticosteroid preparations repeatedly on the face and around the eyes should be aware that cataract development is possible. Strict guidelines for applying these medications should be emphasized, because overuse can result in skin atrophy, striae, and medication resistance.

PUVA, which is reserved for moderate to severe psoriasis, produces photosensitization. If exposure to the sun is unavoidable, the skin must be protected with sunscreen and clothing. Gray- or green-tinted wraparound sunglasses should be worn to protect the eyes during and after treatment, and ophthalmologic examinations should be performed on a regular basis (Nicpon, 2017).

If indicated, referral may be made to a mental health professional who can help to ease emotional strain and give support. Belonging to a support

group may also help patients recognize that they are not alone in experiencing life adjustments in response to a visible, chronic disease. The National Psoriasis Foundation publishes periodic bulletins and reports about new and relevant developments in this condition (see Resources section).

Generalized Exfoliative Dermatitis

Generalized exfoliative dermatitis, also called *erythroderma,* is characterized by a scaling erythematous dermatitis that may involve more than 90% of the skin (César, Cruz, Mota, et al., 2016). Generalized exfoliative dermatitis has a variety of causes. It may occur as a result of a reactive process (e.g., drug allergy) or may be secondary to an underlying skin disease (e.g., psoriasis, contact dermatitis, atopic dermatitis) or a systemic disease (e.g., lymphoma, leukemia). The cause is idiopathic (i.e., unknown) in approximately 16% of cases (Kellen & Berlin, 2016; Umar & Kelly, 2019). Although generalized exfoliative dermatitis may occur at any age, it more commonly appears in those between the ages of 41 and 61 years. It occurs two to four times more commonly in men than in women (Kellen & Berlin, 2016).

Clinical Manifestations

This condition starts as a patchy or generalized erythematous eruption accompanied by fever, malaise, and chills. The skin color changes from pink to dark red. Afterward, the characteristic exfoliation (i.e., scaling) begins, usually in the form of thin flakes that leave the underlying skin smooth and red, with new scales forming as the older ones come off. It may be associated with chills, fever, prostration, and severe pruritus. There is a profound loss of stratum corneum (i.e., outermost layer of the skin), which causes capillary leakage, hypoalbuminemia, and negative nitrogen balance. Because of widespread dilation of cutaneous vessels, large amounts of body heat can be lost. Hair loss may accompany this disorder. The progression of these clinical manifestations varies, depending on the underlying cause. For instance, the progression from fever and scaling may be acute and progress over hours or a couple of days when generalized exfoliative dermatitis results from a drug reaction, or may be insidious and progress over weeks when it is secondary to a skin disease, such as psoriasis (Umar & Kelly, 2019).

Assessment and Diagnostic Findings

The presence of scaling erythematous dermatitis, particularly when it occurs in tandem with a known skin disease or a new prescription medication, increases the suspicion that generalized exfoliative dermatitis may be diagnosed. The patient frequently also presents with hypoalbuminemia and a negative nitrogen balance, as described previously, as well as an increased erythrocyte sedimentation rate that is consistent with an underlying acute inflammatory process. A skin biopsy is indicated, because it may confirm the underlying cause and diagnosis (Umar & Kelly, 2019).

Medical Management

The objectives of management are to discern and treat any underlying disorder, to maintain fluid and electrolyte balance, and to prevent infection. The treatment is individualized and supportive and should be initiated as soon as the condition is diagnosed.

The patient may be hospitalized. All medications that may be implicated are discontinued. A comfortable room temperature should be maintained because the patient does not have normal thermoregulatory control as a result of temperature fluctuations caused by vasodilation and evaporative water loss. Fluid and electrolyte balance must be maintained because there is considerable water and protein loss from the skin surface. Patients in a negative nitrogen balance may be prescribed enteral or parenteral therapy (Umar & Kelly, 2019) (see Chapters 39 and 41).

Nursing Management

Continual nursing assessment is carried out to prevent sepsis. The disrupted, erythematous, moist skin is susceptible to infection and becomes colonized with pathogenic organisms, which produce more inflammation. Antibiotic agents, which are prescribed if infection is present, are selected on the basis of culture and sensitivity.

Hypothermia may occur because of the increased blood flow in the skin, coupled with increased water loss through the skin, leads to heat loss by radiation, conduction, and evaporation. Changes in vital signs are closely monitored and reported. Intake and output are also closely monitored and reported if there is variance.

Topical therapy is used to provide symptomatic relief. Soothing baths, compresses, and lubrication with emollients are used to treat the extensive dermatitis. Topical corticosteroids are the mainstay of treatment (see Table 56-3). The patient is likely to be extremely irritable because of the severe

pruritus; sedating antihistamines (e.g., hydroxyzine) administered before bedtime may be prescribed to relieve the itching and promote sleep (Umar & Kelly, 2019).

The use of oral or parenteral corticosteroids may be prescribed; however, their use is controversial. They are contraindicated when the cause of the condition is either not known or is suspected to be secondary to an underlying skin disease, such as psoriasis. When generalized exfoliative dermatitis occurs as a complication of psoriasis, systemic corticosteroids can exacerbate the condition (Umar & Kelly, 2019). When a specific cause is known, more specific therapy may be used. The patient is advised to avoid all irritants in the future, particularly medications that are known to cause the condition (Kellen & Berlin, 2016).

BLISTERING DISEASES

Blisters of the skin have many origins, including bacterial, fungal, or viral infections; allergic contact reactions; burns; metabolic disorders; and immunologically mediated (i.e., autoimmune) reactions. Some of these have been discussed previously (e.g., herpes simplex and zoster infections, contact dermatitis).

Immunoglobulin-mediated blistering skin diseases are referred to as *pemphigus* disorders. Of these, there are five subtypes. Three of these are immunoglobulin G (IgG)-mediated disorders, including pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus; the remaining two are immunoglobulin A (IgA)-mediated, and include subcorneal pustular dermatosis and intraepidermal neutrophilic dermatosis. Of these five pemphigus disorders, pemphigus vulgaris is the most common; the other four are relatively rare (Estupiñan & Sandhu, 2017; Hertl & Sitaru, 2020). Bullous pemphigoid, another type of IgG-mediated blistering disorder, has distinct characteristics that make this disease different from the pemphigus disorders. Dermatitis herpetiform is another nonpemphigus IgA-mediated blistering skin disorder that occurs as a consequence of gluten sensitivity. The diagnosis for all of these types of blistering skin disorders is made by immunofluorescent and histologic examination of a biopsy specimen (Hertl & Sitaru, 2020).

Pemphigus Vulgaris

Pemphigus vulgaris is characterized by the appearance of bullae of various sizes on apparently normal skin and mucous membranes. Pemphigus vulgaris is an autoimmune disease in which the IgG antibody is directed against a specific cell surface antigen in epidermal cells causing separation between the epidermis and dermis with subsequent blister formation (Doughty & McNichol, 2016). The blisters form from the antigen–antibody reaction. The level of serum antibody is predictive of disease severity. Genetic factors may also have a role in its development, with the highest incidence in people of Jewish or Mediterranean descent. This disorder usually occurs in men and women in middle and late adulthood (Hertl & Sitaru, 2020).

Assessment and Diagnostic Findings

Most patients present with oral lesions appearing as irregularly shaped erosions that are painful, bleed easily, and heal slowly. The skin bullae enlarge, rupture, and leave large, painful eroded areas that are accompanied by crusting and oozing. A characteristic odor emanates from the bullae and the exuding serum. There is blistering or sloughing of uninvolved skin when minimal pressure is applied (Nikolsky sign). The eroded skin heals slowly, and large areas of the body eventually are involved.

Specimens from the blister and surrounding skin demonstrate **acantholysis** (separation of epidermal cells from each other because of damage to or an abnormality of the intracellular substance), and immunofluorescent studies show intraepidermal presence of IgG (Doughty & McNichol, 2016).

The most common complications arise when the disease process is widespread. Skin bacteria have relatively easy access to the bullae as they ooze, rupture, and leave denuded areas exposed to the environment. Fluid and electrolyte imbalance results from fluid and protein loss as the bullae rupture.

Management

The goals of therapy are to bring the disease under control as rapidly as possible, to prevent loss of serum and the development of secondary infection, and to promote reepithelization (i.e., renewal of epithelial tissue).

Corticosteroids are given to control the disease and keep the skin free of blisters. The dosage level is maintained until remission is apparent. Immunosuppressive agents (e.g., azathioprine, mycophenolate mofetil) are prescribed early in the course of the disease to help control the disease and

reduce the corticosteroid dose. The monoclonal antibody rituximab may be chosen as an alternative agent, as well as intravenous immunoglobulin (IVIG). The immunosuppressant agent cyclophosphamide may be tried when other medications fail to induce remission (Hertl & Geller, 2020; Kridin, 2018).

For the procedural guidelines for managing immunoglobulin therapy, go to thepoint.lww.com/Brunner15e.

Bullous Pemphigoid

Bullous pemphigoid is a chronic disease that is characterized by periodic flare-up and remission. If untreated, it may be fatal. It is most commonly seen in older adults, with a peak incidence at about 65 years of age. There is no gender or racial predilection, and the disease can be found throughout the world (Chan, 2018).

Assessment and Diagnostic Findings

Bullous pemphigoid is characterized most commonly by the general appearance of tense bullae that have a particular tendency to appear on the flexor surfaces of the arms. When the blisters break, the skin has shallow erosions that heal fairly quickly. Pruritus can be intense, even before the appearance of the blisters (Chan, 2018).

Immunofluorescent studies of skin biopsy specimens from patients with bullous pemphigoid reveal depositions of IgG and complement C3 at the junction of the dermis and epidermis (Chan, 2018).

Management

Medical treatment includes topical corticosteroids for localized eruptions and systemic anti-inflammatory or immunosuppressant medications for widespread involvement. Systemic corticosteroids (e.g., prednisone) may be continued for months, in alternative-day doses. The patient needs to understand the implications of long-term corticosteroid therapy (see

Chapter 45). Tetracycline may be prescribed, although not for its antimicrobial effectiveness but because its anti-inflammatory properties are believed to be particularly efficacious in treating this disorder. Alternative medications may include immunosuppressive agents (e.g., azathioprine) or monoclonal antibodies (e.g., rituximab). Most patients will achieve remission, although this may require from 6 to 60 months of treatment (Chan, 2018).

Dermatitis Herpetiformis

Dermatitis herpetiformis is an intensely pruritic, chronic disease that manifests with small, tense blisters that are distributed over the extensor surfaces of the elbows and knees, as well as the buttocks and back. It most commonly occurs between 20 and 40 years of age but can appear at any age. It is more common in people of northern European heritage and is slightly more common in men. Patients with dermatitis herpetiformis have a defect in gluten metabolism; many have a concomitant diagnosis of celiac disease (Miller & Zaman, 2020).

Assessment and Diagnostic Findings

Patients typically present with erythematous papules with small, clustered (i.e., herpetiform) vesicles that tend to have a symmetrical distribution on affected extensor surfaces of the skin. Erosions and crusts may also be present, which may result from excoriation and scratching as a reaction to the intense pruritus (Miller & Zaman, 2020).

Immunofluorescent studies of skin biopsy specimens from patients with dermatitis herpetiformis reveal granular patterns of IgA deposits in the papillary dermis (Miller & Zaman, 2020).

Management

Most patients respond to dapsone and to a gluten-free diet. All patients should be screened for glucose-6-phosphate dehydrogenase deficiency because dapsone can induce severe hemolysis in those with this deficiency. Patients benefit from dietary counseling because the dietary restrictions are lifelong, and a gluten-free diet is often difficult to follow (see Chapter 41 for further discussion of gluten-free diets) (Miller & Zaman, 2020). Patients need emotional support as they deal with the process of learning new habits and accepting major changes in their lives.

NURSING PROCESS

Care of the Patient with a Blistering Disease

Assessment

Patients with blistering disorders may experience significant disability. There is constant itching and possible pain in the denuded areas of skin. There may be drainage from the denuded areas, which may be malodorous. Effective assessment and nursing management become a challenge.

Disease activity is monitored clinically by examining the skin for the appearance of new blisters. Particular attention is given to assessing for signs and symptoms of infection. Hyperpigmentation may be seen in areas of resolving blisters.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Acute pain of skin and oral cavity associated with blistering and erosions
- Impaired skin integrity associated with ruptured bullae and denuded areas of the skin
- Disturbed body image associated with the appearance of the skin
- Risk for infection associated with loss of protective barrier of skin and mucous membranes
- Hypovolemia associated with loss of tissue fluids

Planning and Goals

The major goals for the patient may include relief of discomfort from lesions, skin healing, improved body image, absence of infection, and achievement of fluid and electrolyte balance.

Nursing Interventions

Relieving Oral Discomfort

Depending on the skin disorder, the patient's entire oral cavity may be affected with erosions and denuded surfaces. Necrotic tissue may develop over these areas, adding to the patient's discomfort and interfering with eating. Weight loss and hypoproteinemia may result. Meticulous oral hygiene is important to keep the oral mucosa clean and allow the epithelium to regenerate. Frequent rinsing of the mouth with

chlorhexidine solution is prescribed to rid the mouth of debris and to soothe ulcerated areas. Commercial mouthwashes are avoided. The lips are kept moist with petrolatum. Cool mist therapy helps humidify environmental air.

Enhancing Skin Integrity and Relieving Discomfort

The patient with painful and extensive lesions should be premedicated with analgesic agents before skin care is initiated. Patients with large areas of blistering have a characteristic odor that decreases when secondary infection is controlled. After the patient's skin is bathed, it is dried carefully. Tape should never be used because it may produce more blisters. Hypothermia is common, and measures to keep the patient warm and comfortable are priority nursing activities. The nursing management of patients with bullous skin conditions can be similar to that for patients with extensive burns (see Chapter 57).

Promoting a Positive Body Image

Attention to the psychological needs of the patient requires listening to the patient, being available, providing expert nursing care, and educating the patient and the family. The patient is encouraged to express anxieties, discomfort, and feelings of hopelessness. Arranging for a family member or a close friend to spend more time with the patient, either live or via distance technology, can be supportive. When patients receive information about the disease and its treatment, uncertainty and anxiety often decrease, and the patient's capacity to act on their own behalf is enhanced. Psychological counseling may assist the patient in dealing with fears, anxiety, and promote positive self-esteem.

Preventing Infection

The patient is susceptible to infection because the barrier function of the skin is compromised. Bullae are also susceptible to infection, and sepsis may follow (see Chapter 11). The skin is cleaned to remove debris and dead skin and to prevent infection.

Secondary infection may be accompanied by an unpleasant odor from skin or oral lesions. *Candida albicans* of the mouth (i.e., thrush) commonly affects patients receiving corticosteroid therapy. The oral cavity is inspected daily, and any changes are reported. Oral lesions are slow to heal.

Quality and Safety Nursing Alert

Because infection is the leading cause of death in patients with blistering diseases, meticulous assessment for signs and symptoms of local and systemic infection is required. Seemingly trivial complaints or minimal changes are investigated because corticosteroids can mask or alter typical signs and symptoms of infection.

The patient's vital signs are monitored, and temperature fluctuations are documented. The patient is observed for chills, and all secretions and excretions are monitored for changes suggesting infection. Results of culture and sensitivity tests are monitored. Antimicrobial agents are given as prescribed, and response to treatment is assessed. Health care personnel must perform effective hand hygiene and wear gloves.

In patients who are hospitalized, environmental contamination is reduced as much as possible. Isolation measures, standard precautions, and the use of appropriate PPE are warranted. See Chapter 32, Chart 32-5 for a description of standard precautions.

Promoting Fluid Balance

Extensive denudation of the skin leads to fluid and electrolyte imbalance because of significant loss of fluids and sodium chloride from the skin. This sodium chloride loss is responsible for many of the systemic symptoms associated with the disease and is treated by IV administration of saline solution.

A large amount of protein and blood is also lost from the denuded skin areas. Blood component therapy may be prescribed to maintain the blood volume, hemoglobin level, and plasma protein concentration. Serum albumin, protein, hemoglobin, and hematocrit values are monitored.

The patient is encouraged to maintain adequate oral fluid intake. Cool, nonirritating fluids are encouraged to maintain hydration. Small, frequent meals or snacks of high-protein, high-calorie foods (e.g., oral nutritional supplements, eggnog, milk shakes) help maintain nutritional status. Parenteral nutrition is considered if the patient cannot eat an adequate diet.

Evaluation

Expected patient outcomes may include:

1. Reports relief from pain of oral lesions
    a. Identifies therapies that reduce pain

   b. Uses mouthwashes and anesthetic or antiseptic aerosol mouth spray
   c. Drinks chilled fluids at 2-hour intervals
2. Achieves skin healing
   a. States purpose of therapeutic regimen
   b. Adheres to soaks and bath regimen
3. Reports body image has improved
   a. Verbalizes concerns about condition, self, and relationships with others
   b. Participates in self-care
4. Remains free of infections and sepsis
   a. Has cultures from bullae, skin, and orifices that are negative for pathogenic organisms
   b. Has no purulent drainage
   c. Shows signs that skin is clearing
   d. Has normal body temperature
5. Maintains fluid and electrolyte balance
   a. Keeps intake record to ensure adequate fluid intake and normal fluid and electrolyte balance
   b. Verbalizes the rationale for IV infusion therapy
   c. Has urine output that is greater than 400 mL daily
   d. Has serum chemistry and hemoglobin and hematocrit values within normal limits

Toxic Epidermal Necrolysis and Stevens–Johnson Syndrome

Toxic epidermal necrolysis and Stevens–Johnson syndrome are potentially fatal acute skin disorders characterized by widespread erythema and macule formation with blistering, resulting in epidermal detachment or sloughing and erosion formation. These diseases are believed to be one and the same but manifest along a spectrum of reactions, with toxic epidermal necrolysis being the most severe. The mortality rate from toxic epidermal necrolysis is estimated to be 25% to 35% and from Stevens–Johnson syndrome is 1% to 5% (Kellen & Berlin, 2016). Up to 75% of cases of toxic epidermal necrolysis and Stevens–Johnson syndrome are triggered by a reaction to medications, with antibiotics (especially sulfonamides), anticonvulsants, NSAIDs, allopurinol, and oxicam NSAIDs (e.g., meloxicam) frequently implicated (Kellen & Berlin, 2016).

Toxic epidermal necrolysis and Stevens–Johnson syndrome occur in all ages and have a slight predilection for women. The mean age for patients with toxic epidermal necrolysis and Stevens–Johnson syndrome is reported to be between 46 and 63 years. However, older adults who take multiple medications may be at greater risk. There appears to be a genetic component to developing toxic epidermal necrolysis and Stevens–Johnson syndrome. The mechanism leading to toxic epidermal necrolysis and Stevens–Johnson syndrome seems to be a cell-mediated cytotoxic reaction (Cohen, Jellinek, & Schwartz, 2018).

Clinical Manifestations

Toxic epidermal necrolysis and Stevens–Johnson syndrome are characterized initially by conjunctival burning or itching, cutaneous tenderness, fever, cough, sore throat, headache, extreme malaise, and myalgias (i.e., aches and pains). These signs are followed by a rapid onset of erythema involving much of the skin surface and mucous membranes, including the oral mucosa, conjunctiva, and genitalia. In severe cases of mucosal involvement, there may be danger of damage to the larynx, bronchi, and esophagus from ulcerations. Large, flaccid bullae develop in some areas; in other areas, large sheets of epidermis are shed, exposing the underlying dermis. Fingernails, toenails, eyebrows, and eyelashes may be shed along with the surrounding epidermis. The skin is excruciatingly tender, and the loss of skin leaves a weeping surface similar to that of a total-body, partial-thickness burn (Cohen et al., 2018; Kellen & Berlin, 2016).

Complications

Keratoconjunctivitis, sepsis, and multiple organ dysfunction syndrome (MODS) are potential complications of toxic epidermal necrolysis and Stevens–Johnson syndrome. Keratoconjunctivitis can impair vision and result in conjunctival retraction, scarring, and corneal lesions. Sepsis and MODS can be life-threatening (Cohen et al., 2018; Kellen & Berlin, 2016) (see Chapter 11).

Assessment and Diagnostic Findings

Histologic studies of frozen skin cells from a fresh lesion and cytodiagnosis of collections of cellular material from a freshly denuded area are conducted. A history of the use of medications known to precipitate toxic epidermal necrolysis or Stevens–Johnson syndrome may confirm medication reaction as the underlying cause, especially if the medications were prescribed within 4 weeks prior to the onset of illness (Cohen et al., 2018).

Results from a complete blood count (CBC) may show leukopenia and a normochromic normocytic anemia. Skin biopsy results confirm the diagnosis, showing necrotic keratinocytes with full-thickness epithelial necrosis and detachment (Cohen et al., 2018).

Medical Management

The goals of treatment include control of fluid and electrolyte balance, prevention of sepsis, and prevention of ophthalmic complications. Supportive care is the mainstay of treatment.

Any medications that may be implicated as precipitating toxic epidermal necrolysis or Stevens–Johnson syndrome are discontinued immediately. The patient is treated in a regional burn center because aggressive treatment similar to that for severe burns is required. Tissue samples from the nasopharynx, eyes, ears, blood, urine, skin, and unruptured blisters are obtained for culture to identify pathogenic organisms. IV crystalloid fluids are prescribed to maintain fluid and electrolyte balance, using parameters similar to those used to guide care of patients with burns. Similarly, thermoregulation, wound care, and pain management guidelines used to treat patients with burns are also implemented (Cohen et al., 2018) (see Chapter 57). Patients frequently require nutritional and metabolic support with total parenteral nutrition (see Chapter 41).

Initial treatment with systemic corticosteroids (e.g., methylprednisolone), although frequently tried, remains controversial. In many cases, the risk of infection, fluid and electrolyte imbalance, delayed healing, and difficulty in initiating oral corticosteroids early in the course of the disease outweigh its

benefits. Administration of IVIG may provide rapid improvement and skin healing at dosages of 1 g/kg/day for 4 days. Other medications that may be effective include the immunosuppressive agents cyclosporine or cyclophosphamide (Cohen et al., 2018; Kellen & Berlin, 2016).

For the procedural guidelines for managing immunoglobulin therapy, go to thepoint.lww.com/Brunner15e.

Protecting the skin with topical agents is crucial. Various topical antibacterial and anesthetic agents are used to prevent wound sepsis and to assist with pain management. Temporary biologic dressings (e.g., pigskin, amniotic membrane) or plastic semipermeable dressings (e.g., Vigilon™) may be used to reduce pain, decrease evaporation, and prevent secondary infection until the epithelium regenerates. Meticulous oropharyngeal and eye care is essential when there is involvement of the mucous membranes and the eyes.

NURSING PROCESS

Care of the Patient with Toxic Epidermal Necrolysis or Stevens–Johnson Syndrome

Assessment

A careful inspection of the skin is made, including its appearance and the extent of involvement. The normal skin is closely observed to determine if new areas of blisters are developing. Drainage from blisters is monitored for amount, color, and odor. The oral cavity is inspected daily for blistering and erosive lesions; the patient is assessed daily for itching, burning, and dryness of the eyes. The patient's ability to swallow and drink fluids, as well as speak normally, is determined.

The patient's vital signs are monitored, and special attention is given to the presence and character of fever and the respiratory rate, depth, rhythm, and cough. The characteristics and amount of respiratory secretions are observed. Assessment for high fever, tachycardia, and extreme weakness and fatigue is essential because these factors indicate the process of epidermal necrosis, increased metabolic needs, and possible gastrointestinal and respiratory mucosal sloughing. Urine volume, specific gravity, and color are monitored. The insertion sites of IV lines are inspected for signs of local infection. Body weight is recorded daily.

The patient is asked to describe fatigue and pain levels. An attempt is made to evaluate the patient's level of anxiety. The patient's basic coping mechanisms are assessed, and effective coping strategies are identified.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired tissue integrity (i.e., oral, eye, and skin) associated with epidermal shedding
- Hypovolemia associated with loss of fluids from denuded skin
- Risk for hypothermia associated with heat loss secondary to skin loss
- Acute pain associated with denuded skin and oral lesions
- Anxiety associated with the physical appearance of the skin and prognosis

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Sepsis
- Conjunctival retraction, scars, and corneal lesions

Planning and Goals

The major goals for the patient may include skin and oral tissue healing, fluid balance, prevention of heat loss, relief of pain, reduced anxiety, and absence of complications.

Nursing Interventions

Maintaining Skin and Mucous Membrane Integrity

The local care of the skin is an important area of nursing management. The skin denudes easily, especially when the patient is lifted and turned. The nursing staff must take special care to avoid friction involving the skin when moving the patient in bed. The skin should be checked after each position change to ensure that no new denuded areas have appeared. The nurse applies the prescribed topical agents to reduce the bacterial population of the wound surface. Warm compresses, if prescribed, should be applied gently to denuded areas. The topical antibacterial agent may be used in conjunction with hydrotherapy in a tank, bathtub, or shower. The nurse monitors the patient's condition during the treatment and encourages the patient to exercise the extremities during hydrotherapy.

The painful oral lesions make oral hygiene difficult. Careful oral hygiene is performed to keep the oral mucosa clean. Prescribed chlorhexidine mouthwashes, anesthetics, or coating agents are used frequently to rid the mouth of debris, soothe ulcerative areas, and control foul mouth odor. The oral cavity is inspected several times each day, and any changes are documented and reported. Petrolatum or a prescribed ointment is applied to the lips.

Attaining Fluid Balance

The patient's vital signs, urine output, and mental status are assessed for indications of hypovolemia. Mental changes from fluid and electrolyte imbalance, sensory overload, or sensory deprivation may occur. Laboratory test results are evaluated, and abnormal results are reported. The patient is weighed daily.

Oral lesions may result in dysphagia, making tube feeding or parenteral nutrition necessary until oral ingestion can be tolerated. A daily calorie count and accurate recording of all intake and output are essential.

Preventing Hypothermia

The patient with toxic epidermal necrolysis is prone to chilling. Dehydration may be made worse by exposing the denuded skin to a continuous current of warm air. The patient is usually sensitive to changes in room temperature. Measures similar to those implemented for a patient with burns, such as cotton blankets, ceiling-mounted heat lamps, and heat shields, are useful in maintaining body temperature. To minimize shivering and heat loss, the nurse should work rapidly and efficiently when large

wounds are exposed for wound care. The patient's temperature is monitored frequently.

Relieving Pain

The nurse assesses the patient's pain, its characteristics, factors that influence the pain, and the patient's behavioral responses. Prescribed analgesic agents are given on a regular schedule, and the nurse documents pain relief and any side effects. Analgesics are given before painful treatments are performed. Providing thorough explanations and speaking calmly to the patient during treatments can allay the anxiety that may intensify pain. Offering emotional support and reassurance and implementing measures that promote rest and sleep are basic in achieving pain control. As the pain diminishes and the patient has more physical and emotional energy, the nurse may educate the patient in self-management techniques for pain relief, such as progressive muscle relaxation and imagery (see Chapter 9).

Reducing Anxiety

Because the lifestyle of the patient with toxic epidermal necrolysis or Stevens–Johnson syndrome has been abruptly changed to one of complete dependence, an assessment of their emotional state may reveal anxiety, depression, and fear of dying. The patient can be reassured that these reactions are normal. The patient also needs nursing support, honest communication, and hope that the situation can improve. The patient is encouraged to express their feelings. Listening to the patient's concerns and being readily available with skillful and compassionate care are important anxiety-relieving interventions. Emotional support by a psychiatric nurse, spiritual advisor, psychologist, or psychiatrist may be helpful to promote coping during the long recovery period.

Monitoring and Managing Potential Complications

Sepsis. The major cause of death from toxic epidermal necrolysis is from sepsis. Monitoring vital signs closely and noticing changes in respiratory, kidney, and gastrointestinal function may quickly detect the beginning of an infection. Strict asepsis is always maintained during routine skin care measures. Hand hygiene and wearing sterile gloves when carrying out procedures are essential. Visitors should wear protective garments and wash their hands before and after coming into contact with the patient. People with any infections or infectious disease should not visit the patient until they are no longer a danger to the patient. The nurse is critical in identifying early signs and symptoms of infection and notifying the primary provider. Antibiotic agents are not generally begun until there are signs and symptoms of an infection (Cohen et al., 2018).

Conjunctival Retraction, Scars, and Corneal Lesions. The eyes are inspected daily for signs of pruritus, burning, and dryness, which may

indicate progression to keratoconjunctivitis—the principal eye complication. Applying a cool, damp cloth over the eyes may relieve burning sensations. The eyes are kept clean and observed for signs of discharge or discomfort, and the progression of symptoms is documented and reported. Administering an eye lubricant, when prescribed, may alleviate dryness and prevent corneal abrasion. Using eye patches or reminding the patient to blink periodically may also counteract dryness. The patient is instructed to avoid rubbing the eyes or putting any medication into the eyes that has not been prescribed or recommended by the primary provider.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Patients with toxic epidermal necrolysis or Stevens–Johnson syndrome with involvement of large areas of the skin require care that is similar to that of patients with thermal burns. As the patient completes the acute inpatient stage of illness, the focus is directed toward rehabilitation and outpatient care or care in a rehabilitation center. The patient and family members are involved throughout this care and are instructed in the procedures, such as wound care and dressing changes, that will continue at home. The patient and family members are assisted in acquiring dressing supplies that will be needed at home.

The patient and family members are also provided with education about pain management; nutrition; measures to increase mobility; and prevention of complications, including prevention of infection. They are educated about the signs and symptoms of complications and instructed when to notify the health care provider. Written instructions are provided to the patient and family so that they can refer to this information when necessary (Trommel, Hofland, van Komen, et al., 2019).

Continuing and Transitional Care. Interdisciplinary follow-up care is imperative to ensure that the patient's progress continues. Some patients will require care in a rehabilitation center before returning home. Others will require outpatient physical and occupational therapy for an extended period. When the patient returns home, the home health nurse coordinates the care provided by the various members of the health care team (e.g., physician, physical therapist, occupational therapist, dietician). The nurse also monitors the patient's progress, provides ongoing assessment to identify complications, and monitors the patient's adherence to the plan of care. The patient's adaptation to the home care environment and the patient's and family's needs for support and assistance are also assessed. Referrals to community agencies are made as appropriate (Trommel et al., 2019).

Evaluation

Expected patient outcomes may include:

1. Achieves increasing skin and oral tissue healing
   a. Demonstrates areas of healing skin
   b. Swallows fluids and speaks clearly
2. Attains fluid balance
   a. Demonstrates laboratory values within normal ranges
   b. Maintains urine volume and specific gravity within acceptable range
   c. Shows stable vital signs
   d. Increases intake of oral fluids without discomfort
   e. Maintains weight or gains weight, if appropriate
3. Attains thermoregulation
   a. Registers body temperature within normal range
   b. Reports no chills
4. Achieves pain relief
   a. Uses analgesic agents as prescribed
   b. Applies self-management techniques for relief of pain
5. Reports less anxiety
   a. Discusses concerns freely
   b. Sleeps for progressively longer periods
6. Absence of complications, such as sepsis and impaired vision
   a. Has body temperature within normal range
   b. Demonstrates laboratory values within normal ranges
   c. Has no abnormal discharges or signs of infection
   d. Continues to see objects at baseline acuity level
   e. Shows no signs of keratoconjunctivitis

SKIN TUMORS

Tumors of the skin are common and occur along a spectrum from those that are benign to those that are highly malignant.

Benign Skin Tumors

Cysts

Cysts of the skin are epithelium-lined cavities that contain fluid or solid material. Epidermal cysts (epidermoid cysts) occur frequently and may be described as slow-growing, firm, elevated tumors found most frequently on the face, neck, upper chest, and back. Surgical removal with biopsy of the cyst is typically performed (Docik, Johnson, & Rizk, 2019).

Trichilemmal or pilar cysts are most frequently found on the scalp. They originate from the middle portion of the hair follicle and from the cells of the outer hair root sheath. Treatment is surgical removal (Al Aboud, Yarrarapu, & Patel, 2020).

Seborrheic and Actinic Keratoses

Seborrheic keratoses are benign, wartlike lesions of various sizes and colors, ranging from light tan to black. They are usually located on the face, shoulders, chest, and back and are the most common skin tumors seen in middle-aged and older adults. Although these lesions are benign, they should be assessed periodically for changes in appearance that may suggest malignant transformation (see later discussion) (Norris, 2019). They may be cosmetically unacceptable to the patient. Treatment is removal of the tumor tissue by excision, electrodesiccation (destruction of the skin lesions by monopolar high-frequency electric current) and curettage, or application of carbon dioxide or liquid nitrogen.

Actinic keratoses are premalignant skin lesions that develop in chronically sun-exposed areas of the body. They appear as rough, scaly patches with underlying erythema. These lesions may gradually transform into squamous cell carcinoma (see later discussion); they are usually removed by cryotherapy, electrodesiccation, or lasers, or they may be treated with topical chemotherapeutic creams (e.g., 5-fluorouracil cream) (Doughty & McNichol, 2016).

Verrucae: Warts

Warts are common, benign skin tumors caused by infection with the human papillomavirus, which belongs to the DNA virus group. People of all ages may be affected, but the warts occur most frequently between the ages of 12 and 16 years. There are many types of warts.

As a rule, warts are asymptomatic, except when they occur on weight-bearing areas, such as the soles of the feet. They may be treated with locally applied laser therapy, liquid nitrogen, salicylic acid plasters, or electrodesiccation (Dlugasch & Story, 2021).

Warts occurring on the genitalia and perianal areas are known as condylomata acuminata. They may be transmitted sexually and are treated with liquid nitrogen, cryosurgery, electrosurgery, topically applied

trichloroacetic acid, and curettage. Condylomata that affect the uterine cervix predispose the patient to cervical cancer (see Chapter 51).

Angiomas

Angiomas are benign vascular tumors that involve the skin and the subcutaneous tissues. They are present at birth and may occur as flat, violet-red patches (port-wine angiomas) or as raised, bright red, nodular lesions (i.e., hemangiomas of infancy, formerly known as strawberry angiomas). The latter tend to involute spontaneously within the first few years of life, but port-wine angiomas usually persist indefinitely. Most patients use masking cosmetics to camouflage the lesions. Cherry angiomas are small, smooth deep red papules found on the trunk of most adults older than 30 years of age that are benign and generally not considered cosmetically problematic (Norris, 2019).

Pigmented Nevi: Moles

Moles are common skin tumors of various sizes and shades, ranging from yellowish brown to black. They may be flat, macular lesions or elevated papules or nodules that occasionally contain hair. Most pigmented nevi are harmless lesions. However, in rare cases, malignant changes occur, and a melanoma develops at the site of the nevus. Nevi that show a change in color or size, become symptomatic (e.g., itch), or develop irregular borders should be removed to determine if malignant changes have occurred. Moles that occur in unusual places should be examined carefully for any irregularity and for notching of the border and variation in color. Nevi larger than 6 mm should be examined carefully. Excised nevi should be examined histologically (Hunt, Schaffer, & Bolognia, 2020).

Keloids

Keloids are benign overgrowths of fibrous tissue at the site of a scar or trauma. They are more common among people with dark skin. Keloids are asymptomatic but may cause disfigurement and cosmetic concerns. Treatment may consist of surgical excision, intralesional corticosteroid therapy or chemotherapy, laser therapy, or radiation (Doughty & McNichol, 2016).

Dermatofibroma

A dermatofibroma is a common, benign tumor of connective tissue that occurs predominantly on the lower extremities. It is a firm, dome-shaped nodule that may be of the same color as the patient's skin, or may present in a variety of colors, most commonly pink or brown. Treatment is not typically indicated,

unless the patient finds it cosmetically unappealing. The tumor may be removed surgically, although scarring can occur. If the tumor is prominently raised, liquid nitrogen application may be a better option for treatment (Goldstein & Goldstein, 2020).

Neurofibromatosis: Von Recklinghausen Disease

Neurofibromatosis is an autosomal dominant genetic disorder manifested by *café-au-lait* macules (pigmented patches), axillary and inguinal freckling, cutaneous neurofibromas (soft, fleshy, benign skin tumors), and peripheral neurofibromas (benign peripheral nerve sheath tumors) that vary in size. Patients with neurofibromatosis are at risk for developing other benign and malignant tumors (e.g., sarcomas, astrocytomas) (Korf, Lobbous, & Metrock, 2020).

Malignant Skin Tumors

Skin cancer is the most common cancer in the United States. Each year, more people are diagnosed with skin cancer than all other cancers combined. It is estimated that at least one in five Americans will have skin cancer by age 70. The cost of treating Americans with skin cancers is estimated at $8.1 billion annually (Skin Cancer Foundation, 2020a). Because the skin is easily inspected, skin cancer is readily seen and detected and is therefore believed to be amenable to early intervention.

Exposure to UV radiation, including the sun and artificial UV rays (e.g., tanning booths) is the leading preventable cause of skin cancer; incidence is related to the total amount of exposure to UV radiation. Damage is cumulative, and harmful effects may be severe by 18 years of age (Skin Cancer Foundation, 2020a). Skin cancers in adults tend to manifest after a 20- to 50-year latency period post-UV radiation exposure (Bader, 2020) (Chart 56-5). Over 99% of all skin cancers include melanoma and the two most common types of nonmelanoma skin cancers, basal cell carcinoma and squamous cell carcinoma (American Cancer Society [ACS], 2020a).

Basal Cell Carcinoma and Squamous Cell Carcinoma

Basal cell carcinoma is the most prevalent skin cancer in the United States, responsible for 80% of all skin cancers in both men and women. It is rarely associated with any morbidity and rarely causes death. It is twice as common in men than women (Bader, 2020). Although less common than basal cell carcinoma, squamous cell carcinoma is the second most prevalent skin cancer in the United States. It is two to three times more common in men than women

(Najjar, 2020). Although less aggressive than melanoma, squamous cell carcinoma is believed to be responsible for at least 15,000 deaths annually (Skin Cancer Foundation, 2020a).

Chart 56-5 RISK FACTORS

Skin Cancer

- Adults <30 years[a] and >50 years of age; risk increases with age
- Family history of skin cancer
- Having a large number of nevi (i.e., moles) or having dysplastic nevi (i.e., atypical, large moles)
- History of heavy ultraviolent light exposure (e.g., sun exposure, tanning beds, sun lamps)
- History of sunburns
- Immune suppression (e.g., acquired immune deficiency syndrome)[a]
- Males
- People who have blond or red hair
- People who have blue or green eyes
- People who are light skinned, particularly with skin that burns, freckles, or reddens easily
- Personal prior history of skin cancer

[a]These are risks specific to melanoma.

Adapted from American Cancer Society (ACS). (2019b). Melanoma skin cancer causes, risk factors, and prevention. Retrieved on 10/19/2020 at: www.cancer.org/content/dam/CRC/PDF/Public/8824.00.pdf; Centers for Disease Control and Prevention (CDC). (2020). What are the risk factors for skin cancer? Retrieved on 10/19/2020 at: www.cdc.gov/cancer/skin/basic_info/risk_factors.htm

Clinical Manifestations

Basal cell carcinoma generally appears on sun-exposed areas of the body, such as the face, neck, hands, and scalp. Basal cell carcinoma usually begins as a small, waxy nodule with rolled, translucent, pearly borders; telangiectatic vessels may be present. As it grows, it undergoes central ulceration and

sometimes crusting (Fig. 56-8A). The tumors appear most frequently on the face. Basal cell carcinoma is characterized by invasion and erosion of contiguous (adjoining) tissues. It rarely metastasizes, but recurrence is common. However, a neglected lesion can result in the loss of a nose, an ear, or a lip. Other variants of basal cell carcinoma may appear as shiny, flat, gray, or yellowish plaques (Bader, 2020).

Squamous cell carcinoma is a malignant proliferation arising from the epidermis. Its precursor is typically actinic keratosis (see previous discussion). Although it usually appears on sun-damaged skin, it may arise from normal skin or from preexisting skin lesions. It is of greater concern than basal cell carcinoma because it is an invasive carcinoma, metastasizing in 4% to 8% of cases by the blood or lymphatic system (Najjar, 2020).

Squamous cell carcinoma appears as a rough, thickened, scaly tumor that may be asymptomatic or may bleed (Fig. 56-8B). The border of a squamous cell carcinoma lesion may be wider, more infiltrated, and more inflammatory than that of a basal cell carcinoma lesion. Secondary infection can occur. Exposed areas, especially of the upper extremities and of the face, lower lip, ears, nose, and forehead, are common sites (Najjar, 2020). The prognosis for squamous cell carcinoma depends on the incidence of metastases, which is related to the histologic type and the level or depth of invasion. Regional lymph nodes should be evaluated for metastases (Najjar, 2020).

Medical Management

The goal of treatment is to eradicate the tumor. The treatment method depends on the tumor location; the cell type, location, and depth; the cosmetic desires of the patient; the history of previous treatment; whether the tumor is invasive; and whether metastatic nodes are present. Management of basal cell carcinoma and squamous cell carcinoma includes surgical excision, which may include Mohs micrographic surgery, electrosurgery, or cryosurgery. In patients who are not surgical candidates, alternatives such as radiation therapy, photodynamic therapy, or topical chemotherapeutic creams may be viable options (Bader, 2020).

Surgical Management

The main goal is to remove the tumor entirely. The best way to maintain cosmetic appearance is to place the incision properly along natural skin tension lines and natural anatomic body lines. In this way, scars are less noticeable. The size of the incision depends on the tumor size and location but usually involves a length-to-width ratio of 3:1.

The adequacy of the surgical excision is verified by microscopic evaluation of sections of the specimen. When the tumor is large, reconstructive surgery with the use of a skin flap or skin grafting may be required. The incision is

closed in layers to enhance cosmetic effect. A pressure dressing applied over the wound provides support. Infection after a simple excision is uncommon if proper surgical asepsis is maintained.

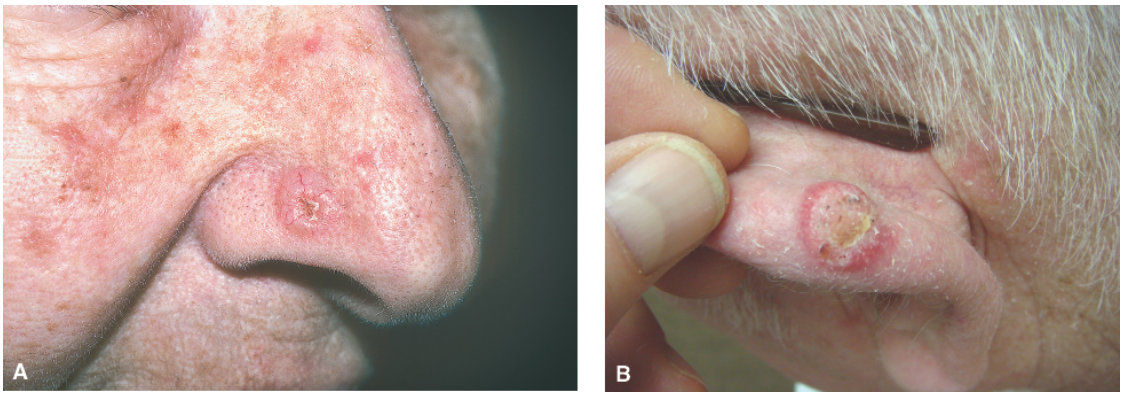

Figure 56-8 • Basal cell carcinoma (**A**) and squamous cell carcinoma (**B**). Reprinted with permission from Goodheart, H. P. (2011). *Goodheart's same-site differential diagnosis: A rapid method of diagnosing and treating common skin disorders*. Philadelphia, PA: Lippincott Williams & Wilkins.

Mohs Micrographic Surgery

This technique is the most accurate surgical technique and best conserves normal tissue. The procedure removes the tumor layer by layer. The first layer excised includes all evident tumor and a small margin of normal-appearing tissue. The specimen is frozen and analyzed by section to determine if all of the tumor has been removed. If not, additional layers of tissue are shaved and examined until all tissue margins are tumor free. In this manner, only the tumor and a safe, normal tissue margin are removed. Mohs surgery is the recommended tissue-sparing procedure, with extremely high cure rates for basal cell carcinoma and squamous cell carcinoma. It is the treatment of choice and the most effective for tumors around the eyes, nose, upper lip, and auricular and periauricular areas (Najjar, 2020).

Electrosurgery

Electrosurgery is the destruction or removal of tissue by electrical energy. The current is converted to heat, which then passes to the tissue from a cold electrode. Electrosurgery may be preceded by curettage (excising the skin tumor by scraping its surface with a curette). Electrodesiccation is then implemented to achieve hemostasis and to destroy any viable malignant cells at the base of the wound or along its edges. Electrodesiccation and curettage is useful for lesions smaller than 1 to 2 cm (0.4 to 0.8 inch) in diameter.

This method takes advantage of the fact that the tumor is softer than the surrounding skin and therefore can be outlined by a curette, which "feels" the

extent of the tumor. The tumor is removed and the base cauterized. The process is repeated twice. Usually, healing occurs within 1 month (Bader, 2020).

Cryosurgery

Cryosurgery destroys the tumor by deep-freezing the tissue. A thermocouple needle apparatus is inserted into the skin, and liquid nitrogen is directed to the center of the tumor until the tumor base is −40° to −60°C (−40° to −76°F). Liquid nitrogen has the lowest boiling point of all cryogens, is inexpensive, and is easy to obtain. The tumor tissue is frozen, allowed to thaw, and then refrozen. The site thaws naturally and then becomes gelatinous and heals spontaneously. Swelling and edema follow the freezing. The appearance of the lesion varies. Normal healing, which may take 4 to 6 weeks, occurs faster in areas with a good blood supply (Bader, 2020).

Nonsurgical Alternative Therapies

Some older adult patients may defer surgical treatment options. Furthermore, in some cases, lesions may be extensive or are located on sites where wide surgical excision is not practical to achieve (e.g., cancer of the eyelid, tip of the nose). In these cases, local radiation therapy (see Chapter 12) or photodynamic therapy may prove reasonable alternatives. Photodynamic therapy involves application of 5-aminolevulinic acid to the lesion, which is then followed by photoactivation with directed blue light for approximately 1 hour. This has the effect of locally destroying the neoplastic cells, with good cosmetic results. Topical application of 5-fluorouracil cream (a chemotherapeutic agent) may be tried as another alternative to managing superficial basal cell carcinoma (Bader, 2020).

The patient should be informed that the skin may become red and blistered after any of these therapies. A bland skin ointment prescribed by the primary provider may be applied to relieve discomfort. The patient should also be cautioned to avoid exposure to the sun.

Nursing Management

Because many skin cancers are removed by excision, patients are usually treated in outpatient surgical units. The role of the nurse is to educate the patient about prevention of skin cancer (Chart 56-6) and self-care after treatment.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The wound is usually covered with a dressing to protect the site from physical trauma, external irritants, and contaminants. The patient is advised when to report for a dressing change or is given written and verbal information on how to change dressings, including the type of dressing to purchase, how to remove dressings and apply fresh ones, and the importance of hand hygiene before and after the procedure.

Chart 56-6  **HEALTH PROMOTION**

Preventing Skin Cancer

Minimize sun exposure:

- To the extent possible, avoid sun between the hours of 10 AM and 4 PM.
- Wear protective clothing (e.g., long-sleeved clothing, broad-brimmed hats).
- Seek shady areas when outdoors.
- Wear sunglasses when outdoors to protect the sensitive skin around the eyes.
- Use caution around snow and water because of reflective sun rays.

Use sunscreen:

- Use a sunscreen with a sun protection factor (SPF) of 15 or higher that protects against both ultraviolet-A (UVA) and ultraviolet-B (UVB) rays.
- Apply generously 20 minutes prior to sun exposure (e.g., going outdoors).
- Reapply every 2 hours, or immediately after swimming.
- Use lip balm with SPF of 15 or higher.

Do not use artificial ultraviolet sources (e.g., tanning beds and booths).

Check your skin regularly:

- Perform self-examination monthly.
- Schedule an examination by primary provider yearly, if over the age of 50 years.

Strengthen your immune system:

- Do not smoke/quit smoking.

Adapted from American Cancer Society (ACS). (2019a). Can basal and squamous cell skin cancers be prevented? Retrieved on 4/5/2020 at: www.cancer.org/cancer/basal-and-squamous-cell-skin-cancer/causes-risks-prevention/prevention.html

The patient is advised to watch for excessive bleeding and tight dressings that compromise circulation. If the lesion is in the perioral area, the patient is instructed to drink liquids through a straw and limit talking and facial movement. Dental work should be avoided until the area is completely healed.

After the sutures are removed, an emollient cream may be used to help reduce dryness. Applying a sunscreen over the wound is advised to prevent postoperative hyperpigmentation if the patient spends time outdoors.

Follow-up examinations should be at regular intervals, usually every 3 months for a year, and should include palpation of the adjacent lymph nodes. The patient should also be instructed to seek treatment for any moles that are subject to repeated friction and irritation and to watch for indications of potential malignancy in moles as described previously. The importance of lifelong follow-up evaluations is emphasized.

Melanoma

A melanoma is a cancerous neoplasm characterized by neoplastic melanocytes present in the epidermis and the dermis (and sometimes the subcutaneous cells). Although melanoma only accounts for 1% of all skin cancers, it is responsible for approximately 6,850 deaths annually (Siegel, Miller, & Jemal, 2020). White Americans are 20 times more at risk for melanoma than Black Americans. It may strike adults of any age; however, the average age at diagnosis is 65 years. It is more prevalent among women than men younger than 50 years of age; by 65 years of age, it is twice as common among men than women and, by 80 years of age, is three times as common among men than women (Tan, 2020). Risk factors for melanoma are noted in Chart 56-5.

Clinical Manifestations

Melanoma may manifest as a change in a nevus or a new growth on the skin, arising from cutaneous epidermal melanocytes. A malignant melanoma is typically dark, red or blue colored, or a mix of any of these, and irregular in shape. It may be associated with itching, rapid growth, ulceration, or bleeding. This type of malignancy is found more frequently in the lower extremities in women, and in the trunk, neck, or head in men (National Cancer Institute [NCI], 2020). Rarely, melanomas may develop in the uveal tract of the eye or the mucosal lining of the gastrointestinal or genitourinary tract (Tan, 2020).

Melanoma can occur in one of the several forms: superficial spreading, lentigo maligna, nodular, acral lentiginous, mucosal lentiginous, desmoplastic, and verrucous melanoma (the last three are rarely seen) (Fig. 56-9). Each of these types have specific histologic features; however, the histologic features do not dictate treatment options and are not associated with differential prognoses (NCI, 2020).

Melanomas spread in two growth phases: radial and vertical. During the first growth phase—the radial phase—the tumor tends to spread radially within the epidermis. It is during this earlier phase of radial growth that the tumor is

most amenable to treatment. The second growth phase—the vertical phase—is characterized by vertical tumor growth into the dermal layer and eventual metastasis. Melanomas that progress more rapidly from the radial to the vertical growth phase are considered more aggressive types and have a poorer prognosis (Tan, 2020).

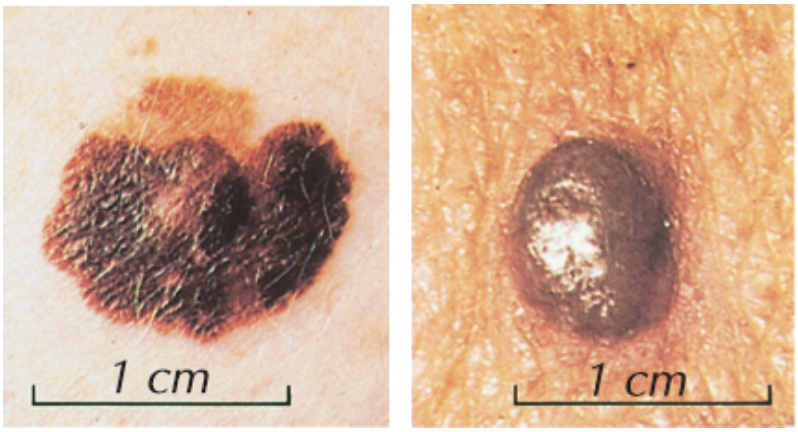

Figure 56-9 • Two forms of melanoma: superficial spreading (**left**) and nodular (**right**).

Assessment and Diagnostic Findings

Biopsy results confirm the diagnosis of melanoma. An excisional biopsy specimen provides information on the type, level of invasion, and thickness of the lesion. A specimen that includes a 1- to 2-cm margin of normal tissue and a portion of underlying subcutaneous fatty tissue is sufficient for staging a melanoma in situ or an early, noninvasive melanoma. Incisional biopsy should be performed when the suspicious lesion is too large to be removed safely without extensive scarring. Biopsy specimens obtained by shaving, curettage, or needle aspiration are not considered reliable histologic proof of disease (Tan, 2020).

A thorough history and physical examination should include a meticulous skin examination and palpation of regional lymph nodes that may drain the area surrounding the tumor. Because melanoma occurs in families, a positive family history of melanoma is investigated so that first-degree relatives, who may be at high risk for melanoma, can be evaluated for atypical lesions. After the diagnosis of melanoma has been confirmed, a chest x-ray, CBC, complete chemistry panel with creatinine, liver function tests, and lactate dehydrogenase (LDH) are usually performed. The LDH may be elevated in the presence of metastatic disease. Depending on the results of these tests, magnetic resonance imaging of the brain, computed tomography scans of the chest, abdomen, or pelvis, and positron emission tomography scans of the lymphatics may be indicated to further stage the extent of disease (Tan, 2020).

Staging of the tumor follows the TNM (tumor, nodes, metastasis) classification system (see Chapter 12) and is used to determine appropriate treatment (NCI, 2020):

- Stage 0: tumor in situ with only epidermal lesion
- Stage 1: tumor 2 mm thick or less without lymph node involvement or distant metastasis
- State 2: tumor more than 2 mm thick without lymph node involvement or distant metastasis
- Stage 3: tumor of any thickness with involvement of at least one lymph node but no distant metastasis
- Stage 4: tumor of any thickness, with or without lymph node involvement, and with distant metastasis

Patients with either stage 0 or stage 1 disease have a better than 99% likelihood of survival 5 years post diagnosis (ACS, 2019c). Early detection and treatment are thus key to ensuring good outcomes over the long term.

Medical Management

Treatment depends on the stage of the tumor and the tumor type. Surgical excision is the treatment of choice for small, superficial lesions. Deeper lesions require wide local excision, after which skin grafting may be necessary. Sentinel lymph node biopsy is commonly performed to examine the nodes nearest the tumor and to spare the patient the long-term sequelae of extensive removal of lymph nodes if the sampled nodes are negative. If these are positive, lymph node dissection may be indicated (Tan, 2020).

Patients with tumor cells present in multiple lymph nodes may benefit from radiation therapy to that chain of lymph nodes post dissection. It is thought that radiation therapy not only thwarts the recurrence of tumor cells within the lymphatics, but also improves the overall efficacy of checkpoint inhibitor therapy, a clear benefit for patients for whom that treatment is indicated (i.e., patients who are *BRAF* negative) (see following discussion) (NCI, 2020).

Patients with stage 2 tumors considered at risk for relapse were traditionally prescribed interferon alfa-2 therapy; however, long-term data did not support its therapeutic benefit. These patients tend to be managed with surgical excision only and then close ongoing monitoring for recurrence or metastasis (ACS, 2019c; NCI, 2020; Tan, 2020).

Patients with stage 3 and stage 4 tumors may be managed with intravenous checkpoint inhibitors, such as pembrolizumab, nivolumab, or ipilimumab. Checkpoint inhibitors enhance the action of T cells by inhibiting a specific "off" switch on their cellular surfaces, making them more effective in targeting and attacking cancer cells (ACS, 2019c; NCI, 2020; Tan, 2020). At least half of all patients with melanoma have a *BRAF* genetic mutation (NIC, 2020; Tan, 2020). These patients may be prescribed a *BRAF* inhibitor, to turn off the

function of the *BRAF* mutation responsible for tumor growth. This therapy is typically prescribed along with an *MEK* inhibitor, as the *MEK* gene works in tandem with the *BRAF* mutation. This type of therapeutic regimen, called *targeted therapy*, may be prescribed in lieu of checkpoint inhibitors. Both *BRAF* inhibitors (dabrafenib, encorafenib, and vemurafenib) and *MEK* inhibitors (trametinib, cobemetinib, and binimetinib) may be administered orally. *BRAF* inhibitors are associated with an increased incidence of squamous cell carcinomas of the skin, however (NCI, 2020).

Patients who are diagnosed with melanoma are at high risk for a second melanoma or a recurrence of their primary tumor. Intralesional injection of an immunotherapeutic vaccine, talimogene laherparepvec, may be indicated in patients with recurrence of tumor that is considered nonresectable. Talimogene laherparepvec is a genetically modified oncolytic agent that is derived from herpes simplex-1 virus. Its use is associated with decreased tumor mass, although there is not an overall improvement in long-term survival (NCI, 2020).

Nursing Management

The best hope for decreasing the incidence of advanced melanoma lies in educating patients to recognize its early signs, when it is amenable to treatment and cure. The nurse educates patients at risk to examine their skin and scalp monthly in a systematic manner and to seek prompt medical attention if changes are detected. This is especially true for patients with a prior history of melanoma, as the likelihood of a second melanoma is higher than in patients without a personal history of having had melanoma (Tan, 2020). The AAD provides multimedia resources on performing skin self-examination (see the Resources section at the end of this chapter).

An important risk factor in the development of melanoma is exposure to UV radiation (e.g., sunlight). Irrespective of the presence or absence of other risks, all patients should be educated about the risks of UV radiation exposure and methods to mitigate that risk (e.g., sunscreen, shade). A group particularly at risk is young adult athletes, especially women (McGuffin, Jordan, Langford, et al., 2019; Orsimarsi, 2019). See the Nursing Research Profile in Chart 56-7.

The presence of nevi, particularly multiple nevi, is another risk factor for melanoma that should be addressed. The nurse educates patients with nevi how to self-assess for signs that may suggest malignant transformation, referred to as the *ABCDEs of Moles* (Chart 56-8). Evidence of these types of changes should be promptly reported to the patient's primary provider for further evaluation. Patients should also be on the alert for formation of the proverbial *Ugly Duckling* nevus, which may appear different from other nevi. In addition, reportable symptoms that may be consistent with a melanotic malignancy

include pruritus, tenderness, and pain at the site of a nevus (Skin Care Foundation, 2020b).

The patient with a new diagnosis of advanced melanoma must be prepared for wide surgical excision. A melanoma may present on any skin surface, although they tend to appear on surfaces exposed to sun (e.g., extremities, head). Surgical removal of melanoma in different locations presents different challenges, taking into consideration the removal of the primary melanoma, and whether or not multiple sentinel lymph nodes evidence cancerous spread, necessitating lymph node dissection. A split- or full-thickness skin graft may be necessary when large defects are created by surgical removal of a melanoma (see Chapter 57 for further discussion of skin grafts). Nursing interventions after surgery for melanoma center on promoting comfort, including anticipating the need for and administration of appropriate analgesic medications (see Chapter 9).

Psychological support is essential when surgery that might be disfiguring is performed (Chart 56-9). Support includes encouraging the patient to express anxieties and feelings about the seriousness of the neoplasm and conveying understanding of these feelings. During the diagnostic workup and staging of the depth, type, and extent of the tumor, the nurse answers questions, provides information, and helps clarify misconceptions. Learning that they have a melanoma can cause the patient considerable fear and anguish. Pointing out the patient's resources, past effective coping mechanisms, and social support systems helps the patient cope with the diagnosis and need for treatment and continuing follow-up. Family members should be included in all discussions to enable them to clarify information, ask questions that the patient might be reluctant to ask, and provide emotional support to the patient.

Chart 56-7  **NURSING RESEARCH PROFILE**

Sun Safety in Female College Athletes

McGuffin, K. S., Jordan, K., Langford, D., et al. (2019). Assessing knowledge, attitudes, and behaviors regarding sun safety in female collegiate athletes. *Journal of the Dermatology Nurses' Association*, *11*(1), 20–33.

Purpose

Melanoma is a common type of cancer among young adults, and its incidence has been rising for the past 30 years. Young adult athletes who compete in outdoor sports are at high risk for melanoma because they spend long hours exposed to ultraviolet (UV) radiation (i.e., sunlight) during games, matches, and practices. Young women are at greater risk for melanoma than young men, and frequently develop melanotic lesions in their extremities. Thus, women college athletes who compete in outdoor sports are especially at risk for melanoma, since their extremities are subjected to long–UV-radiation exposure. The purpose of this research study was to find if an education intervention would improve knowledge, attitudes, and behaviors on sun protection practices among female college athletes.

Design

The setting for this study was a public university in North Carolina. All varsity women athletes who competed in track, soccer, softball, tennis, and cross country were eligible and invited to participate, and all consented (N = 81). The researchers designed a brief 15-minute education intervention with PowerPoint™ images on sun safety practices, and delivered the intervention in a classroom setting in the university athletic offices. Participants took a pretest immediately prior to the intervention, which was a modified version of the Melanoma Risk Behavior Survey. The same survey was taken as the posttest immediately after the intervention was completed, and again 3 months after the intervention was completed. A paired t-test was done between the pretest and the posttests to determine whether or not there were improvements in knowledge, attitudes, and behaviors on sun safety practices among participants.

Findings

Participants' knowledge of sun safety significantly improved from pretest to the first posttest (t = 15.232, $p \leq 0.001$). This improvement was sustained from pretest to the second posttest 3 months post intervention (t = 14.366, $p \leq 0.001$). Moreover, 3 months postintervention, 79.1% of participants self-reported that they applied sunscreen more often than they had preintervention and experienced fewer sunburns post intervention; 91.6% affirmed that they would continue to engage in sun safety in the future.

Nursing Implications

On an anecdotal level, the researchers noted that many participants were surprised to learn of their melanoma risks. In particular, women athletes with

dark skin did not see the need to use sunscreen and practice sun safety. While individuals with darker skin are at lesser risk of skin cancer than those with lighter skin, anyone afflicted with a sunburn has a higher risk of melanoma. This education intervention was concise and yet focused and ultimately, effective in its aim. It can be readily replicated in other college and high school settings. Future interventions could be delivered not only to the athletes, but also to their trainers and coaches, who could continue to encourage sun safety among young adult athletes.

Promoting Home, Community-Based, and Transitional Care

The patient with advanced melanoma will be prescribed either targeted therapy or a checkpoint inhibitor, depending upon the patient's *BRAF* status (see previous discussion). Because the agents that comprise targeted therapy for the patient who is *BRAF* positive may be administered orally, the patient can self-administer them at home, a key advantage. These agents have few side effects, most of which tend to be cutaneous (e.g., rashes, photosensitivity). In addition, patients taking these agents are at greater risk for developing squamous cell carcinomas (ACS, 2019d). Patients on these regimens should be educated to self-assess their skin and promptly report any signs to their primary provider for definitive follow-up. The importance of engaging in sun safety protocols including seeking shade whenever feasible when outdoors, and applying sunscreen, cannot be overemphasized.

The patient who is *BRAF* negative likely will be prescribed a checkpoint inhibitor. These agents must be administered IV; therefore, the patient must anticipate receiving treatments in an infusion center. Treatments are typically administered every 2 to 3 weeks for up to a year. However, the checkpoint inhibitors may be administered via a peripheral vein, and so the patient need not have an IV port placed. Furthermore, these agents tend to be tolerated better than most chemotherapeutic agents. The most commonly noted side effects include fatigue, rash, and diarrhea or constipation (ACS, 2020b). Patients receiving these agents should be educated to monitor for and promptly report side effects and to engage in sun safety protocols.

Chart 56-8  **ASSESSMENT**

Assessing the ABCDEs of Moles

Melanomas may be distinguished from benign nevi, using the following characteristics:

A for Asymmetry

- The lesion does not appear balanced on both sides. If an imaginary line was drawn down the middle, the two halves would not look alike.
- The lesion has an irregular surface with irregular topography (uneven elevations) either palpable or visible. A change in the surface may be noted from smooth to scaly.

B for Irregular Border

- Angular indentations or multiple notches appear in the border.
- The border is fuzzy or indistinct, as if rubbed with an eraser.

C for Variegated Color

- Benign moles are usually a uniform light to medium brown. Darker coloration indicates that the melanocytes have penetrated to a deeper layer of the dermis.
- Colors that may indicate malignancy if found together within a single lesion are shades of red, white, and blue; shades of blue are ominous.
- White areas within a pigmented lesion are suspicious.
- Some melanomas, however, are not variegated but are uniformly colored (bluish-black, bluish-gray, bluish-red).

D for Diameter

- A diameter >6 mm (about the size of a pencil eraser) is considered more suspicious, although this finding without other signs is not significant. Many benign skin growths are larger than 6 mm, whereas some early melanomas may be smaller.

E for Evolving

- Benign moles appear the same over time; when a mole starts to change in appearance, in size, shape, color, or elevation, it may suggest malignancy.

Adapted from Skin Cancer Foundation. (2020b). Warning signs: The ABCDEs of melanoma. Retrieved on 10/23/2020 at: www.skincancer.org/skin-cancer-information/melanoma/melanoma-warning-signs-and-images/#abcde

Chart 56-9  ETHICAL DILEMMA

Should Crowdfunding for Nonevidence–Based Therapies Be Permitted?

Case Scenario

You work as a nurse navigator in a surgical oncology clinic. O.G. is a 29-year-old woman who was referred to the clinic by her dermatologist for evaluation of a melanoma on her right upper arm. The surgical oncologist that examined O.G. wishes to perform a wide excision of her tumor with graft placement. You have an appointment set up with O.G. to coordinate her care between the surgical oncologist, a plastic surgeon (for the anticipated skin graft that will be performed after the tumor is excised), and a medical oncologist (for coordination of postoperative treatments). During your visit, O.G. states that she is reluctant to have the surgery since she believes it will be disfiguring. She tells you that her older sister was diagnosed with a melanoma 2 years ago that was successfully treated using black salve prescribed by a homeopathic physician in Mumbai, India. Although O.G. cannot afford to travel to India to pursue these treatments, her sister has offered to manage a GoFundMe™ site for her so that she might be able to pursue this option, which she finds more palatable than the treatment plan proposed by the surgical oncologist.

Discussion

Using social media to engage in crowdfunding, or online solicitation for donations, has become very popular over the past several years. Crowdfunding to solicit donations for medical procedures, therapies, or travel and other expenses related to pursuing medical treatment, is particularly commonplace. Bioethicists have criticized the use of medical crowdfunding for several reasons. Arguably, donors to crowdfunding platforms tend to favor people who seem more appealing or relatable, which can result in further widening of disparities in access to health care resources (causing a *distributive justice* dilemma). For instance, few people seeking donor support for obesity-related medical services are successful in raising funds on these sites, as persons with obesity may seem less appealing to some donors. Likewise, fewer people from ethnic minority groups tend to be successful in fundraising efforts than people who appear to be White and middle-class. Furthermore, not all people for whom funds are ostensibly raised may fully understand or consent to the setup of their fundraising platforms. These individuals may be coerced to do so by others, or lack the ability to fully comprehend what is being done on their behalf, or may be deceived by their fundraisers and not receive the funds raised for their relief.

Many patients with cancer use complementary and alternative medicine to assist them in managing the myriad of symptoms associated with cancer. Most patients use complementary and alternative therapies to complement mainstream medical treatments (i.e., allopathic medicine). However, some patients may elect to singularly pursue complementary and alternative therapy in lieu of evidence-based allopathic medical treatment. Crowdfunding can be used to try to finance these treatments, which are not covered by

health insurance policies. Crowdfunding platforms have been criticized for not blocking the setup of these types of solicitations from their sites.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Do you believe that O.G. has the right to determine what treatment options are best for her, even when the treatment option she chooses is not evidence-based? How would you assure your role to do what is in O.G.'s best interests without threatening her right to self-determination and without taking on a paternalistic tone (i.e., *I know what is best for you*)?
- How might family dynamics be affecting O.G.'s decision to pursue treatment options? It is not uncommon for patients with melanoma to have first-degree relatives who also have melanoma. How might O.G.'s relationship with her older sister, and her sister's previous treatment for melanoma, affect O.G.'s decision making now?
- What resources might you use to help you advocate for O.G. and assure that resources targeted to treat her melanoma are used in a just manner? How might O.G.'s medical crowdfunding platform affect the well-being of other patients with melanoma?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

Educating Patients About Self-Care

Until a few years ago, patients with metastatic disease had a grim prognosis. With the advent of targeted therapy and checkpoint inhibitors within the past decade, hope for remission and even cure is possible. Patients with metastatic disease and their family members should be given this positive news when they seek treatment. However, there are still instances where remission or cure is not possible. There is some evidence that patients with metastatic disease

who are at end-of-life are not linked into palliative care services appropriately when they are near death, as it is becoming difficult to clearly identify when treatments aimed at remission have failed (Fox, Rosenberg, Ekberg, et al., 2020). The nurse caring for a patient with metastatic melanoma who is nearing end-of-life must advocate for the patient and family so that they receive appropriate and timely palliative care services (see Chapter 13).

Metastatic Skin Tumors

The skin is an important yet uncommon site of metastatic cancer. All types of cancer may metastasize to the skin. Cancers with a predilection to metastasize to the skin include melanomas and cancers of the breast, nasal sinuses, larynx, and oral cavity. Of these, skin metastases from carcinoma of the breast are most frequently seen, accounting for 30% of all cases. The clinical appearance of metastatic skin lesions is not distinctive, except perhaps in some cases of breast cancer in which diffuse, brawny hardening of the skin of the involved breast is seen. In most instances, metastatic lesions occur as multiple cutaneous or subcutaneous nodules of various sizes that may be skin colored or different shades of red (American Osteopathic College of Dermatology, 2020).

Kaposi Sarcoma

Kaposi sarcoma is a malignancy of endothelial cells that line the small blood vessels. Kaposi sarcoma is manifested clinically by lesions of the skin, oral cavity, gastrointestinal tract, and lungs. The skin lesions consist of reddish-purple to dark blue macules, plaques, or nodules. Kaposi sarcoma is subdivided into four categories (ACS, 2018):

- *Classic Kaposi sarcoma* occurs predominantly in older adult men of Mediterranean or Jewish ancestry. Most patients have nodules or plaques on the lower extremities that rarely metastasize beyond this area. Classic Kaposi sarcoma is chronic, relatively benign, and rarely fatal.
- *Endemic (African) Kaposi sarcoma* affects people predominantly in the eastern half of Africa near the equator. Men are affected more often than women, and children can be affected as well. The disease may resemble classic Kaposi sarcoma, or it may infiltrate and progress to lymphadenopathic forms.
- *Iatrogenic/organ transplant–associated Kaposi sarcoma* occurs in transplant recipients and in patients receiving long-term immunosuppressants, such as azathioprine, cyclosporine, or corticosteroids, such as prednisone.

- *AIDS-related or epidemic Kaposi sarcoma* occurs in people with AIDS. This form of Kaposi sarcoma is characterized by local skin lesions and disseminated visceral and mucocutaneous diseases. This is a more aggressive tumor type than other forms of Kaposi sarcoma. More information on AIDS-related Kaposi sarcoma can be found in Chapter 32.

PLASTIC, RECONSTRUCTIVE, AND COSMETIC PROCEDURES

The word *plastic* comes from a Greek word meaning "to form." Plastic or reconstructive procedures are performed to reconstruct or alter congenital or acquired defects to restore or improve the body's form and function. Often the terms *plastic* and *reconstructive* are used interchangeably. This type of surgery includes closure of wounds, removal of skin tumors, repair of soft tissue injuries or burns, correction of deformities, and repair of cosmetic defects. Plastic surgery can be used to repair many parts of the body and numerous structures, such as bone, cartilage, fat, fascia, mucous membrane, muscle, nerve, and cutaneous structures. Bone inlays and transplants for deformities and nonunion can be performed, muscle can be transferred, nerves can be reconstructed and spliced, and cartilage can be replaced. As important as any of these measures is the reconstruction of the cutaneous tissues around the neck and the face; this is usually referred to as aesthetic or cosmetic surgery.

Cosmetic procedures are generally considered to be ones that correct defects that are not life-threatening or caused by diseases. An example would be removal of a benign mole or sebaceous cyst from the face. Most health insurance plans do not cover procedures deemed to be cosmetic, and these procedures can be expensive. Procedures that are performed to correct a surgical defect, such as removal of a skin cancer or correction of a significant congenital defect such as a cleft lip are generally covered by insurance.

Wound Coverage: Grafts and Flaps

Various surgical techniques, including skin grafts and flaps, are used to cover skin wounds.

Skin Grafts

Skin grafting is a technique in which a section of skin is detached from its own blood supply and transferred as free tissue to a distant (recipient) site. Skin grafting can be used to repair almost any type of wound and is the most common form of reconstructive surgery.

Skin grafts are commonly used to repair surgical defects such as those that result from excision of skin tumors, to cover areas denuded of skin (e.g., burns), and to cover wounds in which insufficient skin is available to permit wound closure. They are also used when primary closure of the wound increases the risk of complications or when primary wound closure would interfere with function. Skin grafts may be classified as autografts, homografts, or xenografts (see Chapter 57 for further discussion of skin grafts).

Flaps

Another form of wound coverage is provided by flaps. A flap is a segment of tissue that remains attached at one end (i.e., a base or pedicle) while the other end is moved to a recipient area. Its survival depends on functioning arterial and venous blood supplies and lymphatic drainage in its pedicle or base (del Rosario & Barkley, 2017). A flap differs from a graft in that a portion of the tissue is attached to its original site and retains its blood supply. An exception is the free flap, which is described later.

Flaps may consist of skin, mucosa, muscle, adipose tissue, omentum, and bone. They are used for wound coverage and provide bulk, especially when bone, tendon, blood vessels, or nerve tissue is exposed. Flaps are used to repair defects caused by congenital deformity, trauma, or tumor ablation (removal, usually by excision) in an adjacent part of the body (del Rosario & Barkley, 2017).

Flaps offer an aesthetic solution because a flap retains the color and texture of the donor area; is more likely to survive than a graft; and can be used to cover nerves, tendons, and blood vessels. However, several surgical procedures are usually required to advance a flap. The major complication is necrosis of the pedicle or base as a result of failure of the blood supply.

A free flap or free tissue transfer is completely severed from the body and transferred to another site. A free flap receives early vascular supply from microvascular anastomosis with vessels at the recipient site. The procedure usually is completed in one step, eliminating the need for a series of surgical procedures to move the flap. Microvascular surgery allows surgeons to use a variety of donor sites for tissue reconstruction (Hsieh & Bhatt, 2020).

Cosmetic Procedures

A variety of cosmetic procedures may be performed, including chemical face peels, dermabrasion, facial reconstructive surgery, and rhytidectomy (i.e., face-lift).

Chemical Face Peeling

Chemical face peeling involves application of a chemical mixture to the face for superficial destruction of the epidermis and the upper layers of the dermis to treat fine wrinkles, keratoses, and pigment problems. It is especially useful for wrinkles at the upper and lower lip, forehead, and periorbital areas. The type of chemical used depends on the planned depth of the peel. The patient who is conscious feels a burning sensation that continues for 12 to 24 hours. Frequent small doses of analgesic and tranquilizing agents are prescribed to keep the patient comfortable. The most common complications include discoloration of the skin, infection of the burned area, persistent sensory changes or itching, and occasionally permanent scarring of the skin (Fabbrocini, 2017).

Dermabrasion

Dermabrasion is a form of skin abrasion used to treat acne scarring, aging, and sun-damaged skin. A special instrument (e.g., motor-driven wire brush, diamond-impregnated disc) is used. The epidermis and some superficial dermis are removed by a sanding-type action, and enough of the dermis is preserved to allow reepithelization of the treated areas. Results are best in the face because it is rich in intradermal epithelial elements (Bharti, Kirman, Molnar, et al., 2018).

Patients with a history of herpes simplex viral infection are typically prescribed with prophylactic antiviral medications (e.g., valacyclovir) preprocedurally so that the physiologic stress of the procedure is less likely to cause a cutaneous herpes eruption. Tretinoin cream may be prescribed with instructions to apply it 2 to 3 weeks preoperatively; this is associated with accelerating reepithelialization post dermabrasion. Patients must be educated preprocedurally about the postprocedural dressing regimen and when to return to the primary provider to have dressing changes performed (Wong, Arnold, & Boeckmann, 2016).

Facial Reconstructive Surgery

Reconstructive procedures on the face are individualized to the patient's needs and desired outcomes. They are performed to repair deformities or restore normal function. They may vary from closure of small defects to complicated procedures involving implantation of prosthetic devices to conceal a large defect or reconstruct a lost part of the face (e.g., nose, ear, jaw). Each surgical procedure is customized and involves a variety of incisions, flaps, and grafts. Multiple surgical procedures may be required.

The process of facial reconstruction is often slow and tedious. Because a person's facial appearance affects self-esteem so greatly, this type of reconstruction is often a very emotional experience for the patient.

Rhytidectomy

Rhytidectomy (i.e., face-lift) is a surgical procedure that removes soft tissue folds and minimizes cutaneous wrinkles on the face. It is performed to create a more youthful appearance. Psychological preparation requires that the patient recognize the limitations of surgery and the fact that miraculous rejuvenation will not occur. The patient is informed that the face may appear bruised and swollen after the dressings are removed and that several weeks may pass before the edema subsides. Corticosteroids (e.g., methylprednisolone) and vitamin C are prescribed postoperatively to minimize edema. Prophylactic antibiotic agents such as cephalexin may also be prescribed postoperatively (Neligan, Warren, & Van Beek, 2017).

Laser Treatment of Cutaneous Lesions

Lasers are devices that amplify or generate highly specialized light energy. They can mobilize immense heat and power when focused at close range and are valuable tools in providing dermatologic abrasion therapy. The laser modalities used for this purpose today include scanned carbon dioxide laser, pulsed carbon dioxide laser, pulsed erbium/yttrium-aluminum-garnet (Er:YAG) laser, fractional Er:YAG laser resurfacing, combination of carbon dioxide and Er:YAG lasers, and fractionated photothermolysis (Husain & Alster, 2016).

Each of these lasers is a precise surgical instrument that vaporizes and excises water-containing tissues with minimal damage. Because the beams used can seal blood and lymphatic vessels, they create a dry surgical field that makes many procedures easier and quicker. Therefore, these lasers are generally safe to use on patients with bleeding disorders or those receiving anticoagulant therapy. They are primarily used to improve the appearance of facial wrinkles, although they are also useful in removing epidermal nevi, tattoos, certain warts, skin cancer, ingrown toenails, and keloids. Incisions made with the laser beam heal and scar much like those made by a scalpel. Patients with a history of herpes simplex viral infection typically receive preprocedural antiviral prophylaxis (Husain & Alster, 2016).

TABLE 56-7 Select Nursing Considerations in Cosmetic Procedures

Nursing Consideration	Interventions and Patient Education
Maintaining airway and pulmonary function	Cosmetic surgeries involving the face and neck can cause considerable swelling; bandages can restrict breathing or eating. Check dressings frequently, and ensure that no constriction occurs as swelling develops.
Relieving pain and achieving comfort	Procedures that involve a large surface area will cause considerable pain. Cool compresses or ice packs will relieve the burning of dermabrasion or chemical peels. Oral analgesic agents should be administered regularly to control pain.
Maintaining adequate nutrition	When the face is involved, the patient may be unable to fully open the mouth, and chewing may be painful. Provide soft or liquid diet that is rich in protein to assist with healing.
Enhancing communication	Depending on the type of cosmetic procedure, a nonverbal method of communication might be necessary until pain and swelling have subsided.
Improving self-concept	Recovery time from cosmetic procedures is slow. Expected results will take weeks to become apparent. Patients with darker skin will experience increased pigmentation long after the initial wounds have healed. Helping patients to understand postoperative expectations will allow them to feel more comfortable with the healing process.
Promoting family coping	Most cosmetic procedures are performed in an outpatient facility; therefore, family members are integral to postoperative care. They should understand what to expect as the patient emerges from the procedure room: the type of dressings that will be in place, the skin care plan that is prescribed, and how to help the patient cope with pain.
Monitoring and managing potential complications	Infection is the most common complication, but excessive pain, nerve damage, and emotional distress about appearance are also common. If opioid analgesic agents are used, there may be gastrointestinal upset, mental status changes, or allergic reaction to the medication. Alert the caregiver to signs of these complications and how and when to report changes in status.

Nursing Management

The majority of dermatologic and reconstructive procedures are performed in the physician's office or in an outpatient surgical department; therefore, most care takes place in the home. Most procedures, except very extensive reconstruction, are performed under local anesthesia or moderate sedation, therefore requiring a very short recovery time. Unless there are complications, the patient does not need hospitalization. The nurse must prepare both the patient and the family for what to expect during the postoperative recovery

time. Table 56-7 lists select nursing considerations that must be reviewed in educating the patient and family.

CRITICAL THINKING EXERCISES

1 pq You work as a staff nurse in an emergency department (ED). A 46-year-old woman presents to the ED with complaints of fever, sore throat, and muscle aches for the past 48 hours. Today she began to feel markedly worse and had the sudden onset of widespread erythema, with blistering in her perineum. She has a history of epilepsy and is currently taking prescribed anticonvulsants. The ED physician tells you that the provisional diagnosis might be toxic epidermal necrolysis. What risks might the patient have for toxic epidermal necrolysis? What are your assessment priorities?

2 ipc A 25-year-old man is admitted to the medical-surgical unit where you work to manage his stage 3 sacral pressure injury. The patient had a spinal cord injury 2 years ago that resulted in paraplegia. He had extensive inpatient rehabilitation for the first several months post injury; however, for the past several months he has been living in his own apartment and able to maintain an at-home job as a data analyst. He has not had pressure injuries prior to this and is uncertain how the injuries happened and how to prevent recurrence. What resources might be available to help him effectively manage his own care so that he avoids recurrent pressure injury?

3 ebp You work in a college health office. A 21-year-old woman presents to the health office with a fever and sore throat. During your assessment, you note that she has tenderness of her shoulders and arms, with some mild erythema that is consistent with a sunburn. She plays on the varsity tennis team. You take the opportunity to talk to her about her risks for melanoma and the advisability of using sunscreen during meets and practices. She tells you that she is Latina, and does not need to worry about skin cancer. What is the strength of the evidence that this young woman is at risk for melanoma? How important is it that she engage in sun safety?

57 Management of Patients with Burn Injury

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Identify the incidence and factors that affect severity of burn injury in the United States.
2. Describe the local and systemic effects of a major burn injury.
3. Use the nursing process as a framework for care of the patient in the emergent/resuscitative, acute/intermediate, and rehabilitative phases of a burn injury.
4. Compare priorities of care, including fluid replacement, wound management and psychosocial support, and potential complications for each phase of burn recovery.

NURSING CONCEPTS

Fluids and Electrolytes
Medical Emergencies
Metabolism
Tissue Integrity

GLOSSARY

autograft: a graft derived from one part of a patient's body and used on another part of that same patient's body

carboxyhemoglobin: a compound of carbon monoxide (CO) and hemoglobin formed in the blood with exposure to CO

collagen: a protein present in skin, tendon, bone, cartilage, and connective tissue

contracture: shrinkage of burn scar through collagen maturation

débridement: removal of foreign material and devitalized tissue until surrounding healthy tissue is exposed

donor site: the area from which skin is taken to provide a skin graft for another part of the body

eschar: devitalized tissue resulting from a burn or wound

escharotomy: a linear excision made through eschar to release constriction of underlying tissue

excision: surgical removal of tissue

fasciotomy: an incision made through the fascia to release constriction of underlying muscle

homograft: a graft transferred from one human (living or cadaveric) to another human (*synonym:* allograft)

xenograft: a graft obtained from an animal of a species other than that of the recipient (e.g., pigskin) (*synonym:* heterograft)

Burn injuries can be painful, costly, and disfiguring; they may require intensive and extensive rehabilitation therapy and are often associated with long-term disability. An extensive burn injury is associated with a complex, multisystem pathophysiology that continues to challenge health systems, despite advances that have resulted in significantly reduced comorbidities and length of stay (LOS). These advances in treatment of patients with severe burns include critical-care management, fluid resuscitation, nutrition, surgical débridement, wound coverage, and antimicrobial therapies (Jones, Williams, Cairns, et al., 2017; Weissman, Wagman, Givon, et al., 2017). The role of the nurse in the interdisciplinary treatment team includes provision of holistic evidence-based care during all phases of burn injury recovery to optimize patient outcomes.

Overview of Burn Injury

Burn injuries, which result from damage to the skin or other tissues from heat, chemicals, electricity, or radiation, most commonly occur in the home or work setting. Globally, they account for approximately 180,000 deaths and significant morbidity each year; however, many are preventable (World Health Organization [WHO], 2018).

Incidence

A burn injury can affect people of all ages, ethnicities, and socioeconomic groups. In the United States, an estimated 486,000 people are treated for burns and approximately 40,000 are hospitalized annually (American Burn Association [ABA], 2016). The largest proportion of burns, 41%, was reported as flame related, 35% were scalds, 10% were from direct source contact, 3% were electrical, 3% were chemical contact, 3% were inhalation only, and the remaining 5% were from unspecified or miscellaneous categories. Of those admitted to burn centers, the incidence of burn injuries for men was generally more than twice that for women; for both men and women, adults between 20 and 30 years of age had the highest prevalence of burn injuries. Of the reported injuries, 73% occurred in the home, 8% were industry related, 5% were recreationally related, and the remaining 14% of injuries were from other sources (American Burn Association National Burn Repository [ABA NBR], 2018).

Patients with burn injuries have particularly prolonged hospital LOS. Many require multiple surgical interventions, extensive pain control interventions, prolonged periods of immobilization and rehabilitation, and protracted intravenous (IV) medication regimens, particularly opioids and antibiotics. Historically, LOS projection was one hospital day per percent total body burn surface area (TBSA) burn. This underestimates LOS and resource utilization, most particularly in those over 40 years of age or those with an inhalation injury (Taylor, Sen, Greenhalgh, et al., 2017).

Gerontologic Considerations

Age-related changes such as diminished mobility, postural stability, strength, coordination, sensation, visual acuity, and declining memory predispose older adults to burn injury. The population of older adults continues to grow, as does the number of burn injuries among older adults. Burn Injury Registry data over a 10-year period from 212,820 hospitalized patients with burns suggest that 15% of burn injuries

requiring hospitalization occurred in patients 60 years of age and older, with fire/flame sources accounting for 56% of reported injuries (ABA NBR, 2018). Mortality associated with burns is greater in older adult patients than in younger adult patients when comparing injuries with similar severity. The overall mortality from burns in the adult over 59 years of age is approximately 13%; compared to a 2.9% overall mortality rate for all ages (ABA NBR, 2018). The lethal dose 50 describes the percentage of TBSA burn that results in 50% mortality for a population; for older adults, this remains 30% to 35% TBSA despite advances in treatment (Jeschke & Peck, 2017).

Complications associated with burn injuries are also highest in patients 60 years and older. Of all reported complications, pneumonia was the most common, followed closely by urinary tract infections. Other reported complications include respiratory failure, septicemia, cellulitis, wound infection, kidney injury, arrhythmias, and other hospital-acquired infections such as central line bloodstream infections (ABA NBR, 2018). There is evidence that frailty and high comorbidities can cause critical decompensation in even small TBSA burns for those 50 years of age and older (Maxwell, Rhee, Drake, et al., 2018; Romanowski, Curtis, Palmieri, et al., 2018). Therefore, premorbid physiology should be considered when planning care for the older adult patient with a burn injury.

The skin of the older adult is thinner and less elastic, which affects the depth of injury and its ability to heal. Pulmonary function becomes impaired with age affecting airway exchange, lung elasticity, and ventilation; these effects can be exacerbated by a history of smoking. Decreased cardiac output, presence of coronary artery disease, and decreased cardiovascular compensatory response increase the risk of complications in older adult patients with burn injuries. There may be a very fine line between adequate fluid resuscitation and fluid overload in this population. Decreased kidney and hepatic function can affect medication dosing due to altered medication clearance. Malnutrition may affect morbidity and mortality in older adults, especially those who are institutionalized. Additionally, older adult patients may have varying degrees of mental capacity on admission or throughout the course of care, rendering assessment of pain, anxiety, and delirium a challenge for the burn team.

Comorbidities are common among older adults and, when combined with treatments, result in polypharmacy (i.e., multiple medication prescriptions), which contribute to in-hospital complications and increase the need for discharge to a facility other than the patient’s home after

acute recovery. Nurses need to assess the older adult patient's ability to safely perform activities of daily living (ADLs), assist older adult patients and families to modify their environment to ensure safety, and make referrals as needed. In addition, an assessment of instrumental activities of daily living (IADLs) is warranted (see Chapter 2 for further discussion of IADLs). This is an assessment of the ability to carry out more complex tasks such as meal preparation, traveling to appointments, etc., and is particularly important for those returning home without a caregiver (American Psychological Association, 2020).

Prevention

Almost all burns are preventable. An important goal of nurses in community and home settings is to provide education regarding prevention of burn injuries (see Chart 57-1). The WHO recommends heightened awareness of the burden of burn injury and its risk factors as imperatives to the development of an effective burn prevention program (WHO, 2018).

Chart 57-1  **HEALTH PROMOTION**

Burn Prevention

- Advise that matches and lighters be kept out of the reach of children.
- Emphasize the importance of never leaving children unattended around fire or in bathroom/bathtub.
- Educate about the installation and maintenance of smoke and CO detectors on every level of the home and changing batteries annually on birthday.
- Recommend the development and practice of a home exit fire drill with all members of the household.
- Advocate setting the water heater temperature no higher than 48.9°C (120°F).
- Educate about the perils of smoking in bed, smoking while using home oxygen, or falling asleep while smoking.
- Caution against using flammable liquids to start fires and/or throwing flammable liquids onto an already burning fire.
- Warn of the danger of removing the radiator cap from a hot car engine.
- Recommend avoidance of overhead electrical wires and underground wires when working outside.
- Advise that hot irons and curling irons be kept out of the reach of children.
- Discourage running electric cords under carpets or rugs.
- Recommend storage of flammable liquids well away from a fire source, such as a pilot light.
- Educate about the importance of being aware of loose clothing when cooking over a stovetop or flame.
- Recommend having a working fire extinguisher in the home and knowing how to use it.

Outlook for Survival and Recovery

The WHO (2018) estimated 265,000 annual deaths worldwide are caused by burns, the majority occurring in middle- to low-income populations, while nonfatal burns are a leading cause of morbidity including disfigurement, disability, and social stigma. The overall mortality rate for

all TBSA burns in the United States reported to the National Burn Repository is 3% (ABA NBR, 2018). The strongest predictors for mortality in burn injuries include increased percent of TBSA burned, presence of inhalation injury, and increased age. Provision of evidenced-based, multidisciplinary, holistic care is crucial to improving both survival and recovery culminating in reintegration of the survivor into society.

Great strides in research on burn wound treatments and critical care have improved the survival rate of patients with burn injuries. Evaluation of long-term outcomes is possible because patients with very large burns are surviving their injuries. Continued research and advances in the areas of critical care, rehabilitation, and psychosocial and scar management are essential for continued progress in burn care (Bielson, Duethman, Howard, et al., 2017).

Severity

Multiple factors determine the severity of each burn injury. These factors include age of the patient; depth of the burn; amount of surface area of the body burned; the presence of inhalation injury; presence of other injuries; location of the injury in areas such as the face, the perineum, hands, or feet; and the presence of comorbid conditions. Careful assessment enables the burn team to estimate the likelihood of survival and develop an individualized plan of care for each patient (ABA, 2018).

Age

Young children and older adults have increased morbidity and mortality when compared to other age groups with similar injuries and present a challenge for the burn team. Thinner skin at both ends of the age spectrum leads to deeper burns with more complications. This is an important factor when determining the severity of injury and potential outcomes for the patient.

Burn Depth

Burns are classified according to the depth of tissue destruction as depicted in Table 57-1. First-degree burns are superficial injuries that involve only the outermost layer of skin. These burns are painful and erythematous, but the epidermis is intact; if rubbed, the burned tissue does not separate from the underlying dermis. This is known as a negative Nikolsky's sign. A typical first-degree burn is a sunburn or superficial scald burn.

Second-degree (partial-thickness) burns involve the entire epidermis and varying portions of the dermis. They are painful and typically associated with blister formation. Healing time depends on the depth of dermal injury, typically ranging from 2 to 3 weeks. Hair follicles and skin appendages remain intact. The wound bed is moist due to serous leakage from the peripheral microcirculation.

TABLE 57-1 Characteristics of Burns According to Depth

Causes	Skin Involvement	Clinical Manifestations	Wound Appearance	Recuperative Course and Treatment
First Degree (Superficial)				
Sunburn Low-intensity flash Superficial scald	Epidermis	Tingling Hyperesthesia (hypersensitivity) Pain that is soothed by cooling Peeling Itching	Reddened; blanches with pressure; dry Minimal or no edema Possible blisters	Complete recovery within a few days Oral pain medications, cool compresses, skin lubricants (e.g., ointments, emollients); topical antimicrobial agents not indicated
Second Degree (Partial Thickness)				
Scalds Flash flame Contact	Epidermis, portion of dermis	Pain Hyperesthesia Sensitive to air currents	Blistered, mottled red base; disrupted epidermis; weeping surface Edema	Recovery in 2–3 wks Some scarring and depigmentation possible; may require grafting
Third Degree (Full Thickness)				
Flame Prolonged exposure to hot liquids Electric current Chemical Contact	Epidermis, dermis, and sometimes subcutaneous tissue; may involve connective tissue and muscle	Insensate Shock Myoglobinuria (red pigment in urine) and possible hemolysis (blood cell destruction) Possible contact points (entrance or exit wounds in electrical burns)	Dry; pale white, red brown, leathery, or charred Coagulated vessels may be visible. Edema	Eschar may slough Grafting necessary Scarring and loss of contour and function
Fourth Degree (Full Thickness That Includes Fat, Fascia, Muscle, and/or Bone)				
Prolonged exposure or high-voltage electrical injury	Deep tissue, muscle and bone	Shock Myoglobinuria (red pigment in urine) and possible hemolysis (blood cell destruction)	Charred	Amputations likely Grafting of no benefit given depth and severity of wound(s)

Adapted from American Burn Association. (2018). *Advanced burn life support (ABLS) course provider manual 2018*. Chicago, IL.

Figure 57-1 • Third-degree (full-thickness) burn to arm and upper back with surrounding second-degree (partial-thickness) burn. Used with permission from University of Texas Medical Branch, Galveston, TX.

Third-degree (full-thickness) burns involve total destruction of the epidermis, dermis, and, in some cases, damage of underlying tissue. Wound color ranges widely from pale white to red, brown, or charred. The deeply burned area lacks sensation because the nerve fibers are damaged. The wound appears leathery and dry due to the destruction of the microcirculation. Skin organelles such as hair follicles and sweat glands may be affected. The severity of this burn is often deceiving to patients because they have no pain in the injury area (see Fig. 57-1).

Fourth-degree burns (deep burn necrosis) are those injuries that extend into deep tissue, muscle, or bone (see Fig. 57-2) (ABA, 2018; Strauss & Gillespie, 2018).

Burn depth determines whether spontaneous reepithelialization will occur. Determining burn depth can be difficult even for the experienced burn care provider. The following factors are considered in determining the depth of a burn: how the injury occurred, causative agent (such as flame or scalding liquid), temperature and duration of contact with the causative agent, and thickness of the skin at the injury site.

Figure 57-2 • Fourth-degree burn to second digit. Used with permission from University of Texas Medical Branch, Galveston, TX.

Extent of Body Surface Area Injured

Various methods are utilized to estimate the TBSA affected by burns; among them are the rule of nines, the Lund and Browder method, and the palmer method. These tools assist the treatment team in making decisions about the plan of care, which may include transfer of the patient to a burn center. Burn centers are hospital based and are specially equipped with the resources and personnel to treat patients with burns from the time of injury through their rehabilitation. Burn center designation is conferred jointly by the ABA and the American College of Surgeons (ABA, 2019). Chart 57-2 provides the ABA criteria for referral to a burn center.

Rule of Nines

The most common method of estimating the extent of burns in adults is the rule of nines (see Fig. 57-3). This system is based on anatomic regions, each representing approximately 9% of the TBSA, allowing clinicians to rapidly estimate percent of body burned. If the burn affects

only a portion of an anatomic area, the TBSA is calculated accordingly—for example, if approximately half of one arm were burned, the TBSA burned would be 4.5%.

Lund and Browder Method

A more precise method of estimating the extent of a burn is the Lund and Browder method, which recognizes the percentage of surface area of various anatomic parts, especially the head and legs, as it relates to the age of the patient. By dividing the body into very small areas and providing an estimate of the proportion of TBSA accounted for by each body part, clinicians can obtain a reliable estimate of TBSA burned. The initial evaluation made on arrival of the patient to the hospital should be revised within the first 72 hours, because demarcation of the wound and its depth present themselves more clearly by this time. The Lund and Browder chart is readily available in both printed and electronic formats (ABA, 2018).

Chart 57-2

American Burn Association Criteria for Referral to a Burn Center

- Partial-thickness burns covering 10% of total body surface area or greater
- Burns involving the face, hands, feet, genitalia, perineum, or major joints
- Third-degree burns
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders
- Any patients with burns and concomitant trauma
- Children with burn injuries in facilities that do not specialize in pediatric care
- Patients who will require special social, emotional, or long-term rehabilitation

Adapted from American Burn Association. (2018). *Advanced burn life support (ABLS) course provider manual 2018*. Chicago, IL: Author.

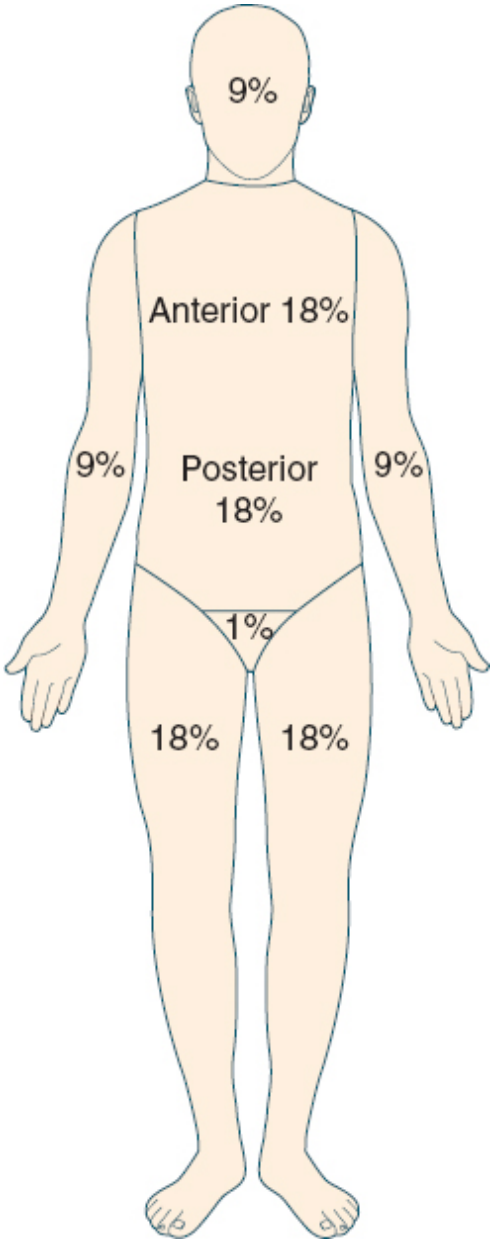

Figure 57-3 • The rule of nines. Estimated percentage of total body surface area (TBSA) in the adult is calculated by sectioning the body surface into areas with a numerical value related to nine. (*Note:* The anterior and posterior head total 9% of TBSA.)

Palmer Method

In patients with scattered burns, or very large burns with minimal sparing, the palmer method is an expeditious method to determine extent of injury. The size of the patient's hand, including the fingers, is approximately 1% of that patient's TBSA (ABA, 2018).

Pathophysiology

Burns are exceptionally traumatic injuries as the initial injury evolves and worsens over time. Burn injury is the result of a chemical exposure or heat transfer from one site to another, causing tissue destruction through coagulation, protein denaturation, or ionization of cellular contents. The burn wound is not homogenous; rather, tissue necrosis generally occurs at the center of the injury with regions of tissue viability toward the periphery. The central area of the wound is termed the *zone of coagulation* due to the characteristic coagulation necrosis of cells that occurs (see Fig. 57-4). The surrounding zone, the *zone of stasis,* describes an area of injured cells that may remain viable but, with persistent ischemia, will undergo necrosis within 24 to 48 hours. The outermost zone, the *zone of hyperemia,* sustains minimal injury and may fully recover spontaneously over time.

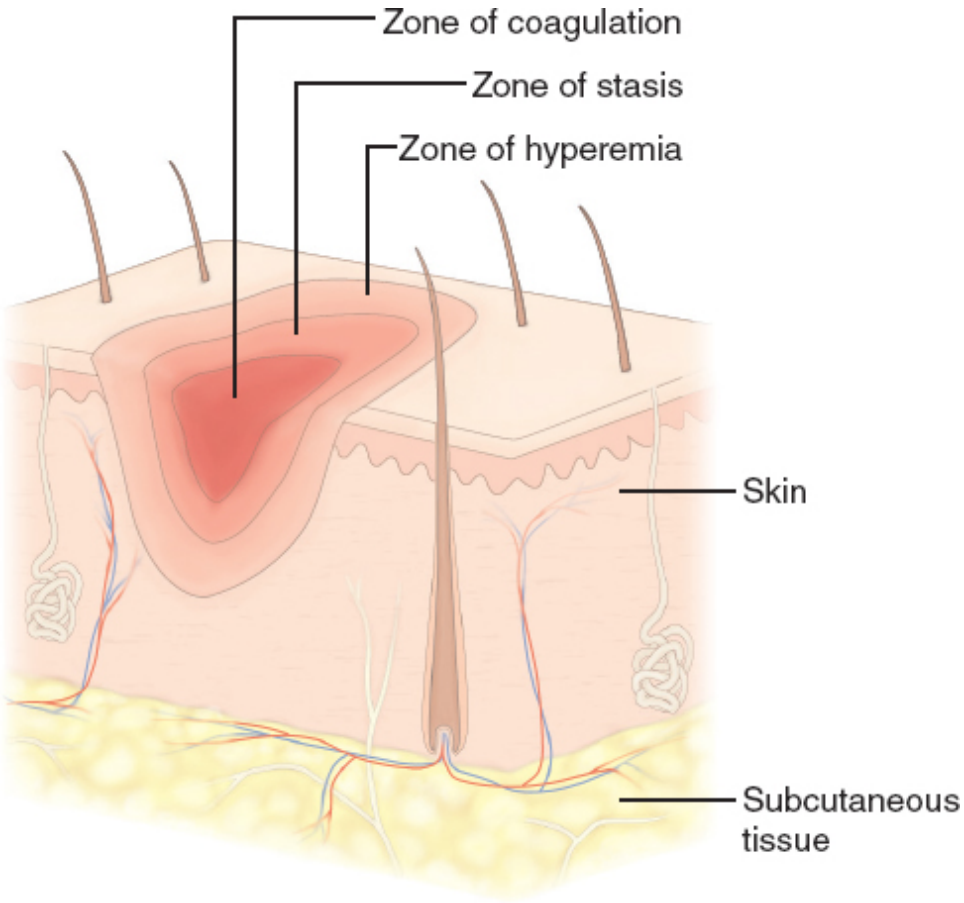

Figure 57-4 • Zones of burn injury. Each burned area has three zones of injury. The zone of coagulation (the innermost area, where cellular death occurs) sustains the most damage. The zone of stasis (the middle area) has a compromised blood supply, inflammation, and tissue injury. The zone of hyperemia (the outermost area) sustains the least damage.

The skin and the mucosa of the upper airways are the most common sites of tissue destruction, although deep tissues, including the viscera, can be damaged by electrical burns (see Chart 57-3) or prolonged contact with a heat or chemical source. The release of local mediators, changes in blood flow, tissue edema, and infection can cause progression in severity of the burn injury.

Another potential mechanism of burn injury is radiation exposure. This has received increased attention because of threats of terrorism and recent world events. Radiation injuries produce two detrimental effects. The first is a thermal effect, which results in cutaneous burn injuries. The second effect is damage to the cellular deoxyribonucleic acid (DNA), which may be localized or affect the whole body. Morbidity and mortality are dose

dependent (see Chapter 68). Treatment for the cutaneous injury is the same as other burns discussed in this chapter.

The depth of a burn injury depends on the temperature of the burning agent and the duration of contact with the agent. In adults, exposure to temperatures of 54°C (130°F) for 30 seconds will result in burn injury. At 60°C (140°F), tissue destruction occurs in 5 seconds (this is a common setting for home water heaters; see Chart 57-1 for discussion of appropriate water heater setting). At 71°C (160°F) or higher, a full-thickness burn occurs instantaneously (ABA, 2018).

It is important to recognize injuries that affect more than approximately 20% TBSA as severe injuries, as they produce both local and systemic effects. The systemic inflammatory response to a severe burn injury signals the release of proinflammatory and anti-inflammatory cytokines, prompting hypermetabolism effects that produce organ dysfunction, a pronounced catabolic response, systemic compromise and, potentially, mortality (Rehou, Shahrokhi, Natanson, et al., 2018).

Chart 57-3

Electrical Burns

Electrical injuries are devastating and complex burns. Heat generated by electricity is directly responsible for tissue damage, but unlike most thermal burns, visual examination of wounds is not predictive of burn size and severity. It is helpful to know the circumstances of the injury to anticipate potential tissue damage and complications. Superficial injuries present themselves as contact points on physical examination. Deep tissue injuries caused by the conduction of electrical current through the body may not be visible on initial clinical presentation, but in most circumstances should be assumed on presentation so that timely intervention may be initiated. Mechanisms of injury include flash, conductive, and lightning injury.

Flash Injury

An electrical flash generates light and heat. Injury occurs from the heat generated to exposed areas or by flames from ignition of clothing. Flash burns are thermal burns and have fewer complications; patients with flash injuries have shorter lengths of stay than those with conductive injuries.

Conductive Injury

Conductive electrical injuries occur when the current overcomes the skin's resistance and travels through the body. The amount and severity of tissue damage is directly proportional to the strength of the current (voltage), duration of contact with the source, which organs lay along the pathway of current, and whether the current is direct or alternating. Conduction of electricity through the nerves and vessels and along the outside of bones generates heat, causing damage to adjacent tissues and direct injury to the peripheral nerves. Deep muscle injury may be present without injury to superficial muscles, masking the true extent of the injury. In addition, electrical current immediately contracts muscles as it travels through the body causing possible skeletal and joint injuries in high-voltage contact. Although the majority of reported electrical injuries are high-voltage (>1000 volts) injuries, significant physical and psychological morbidity also occur with low-voltage (<1000 volts) injuries as well.

Entrance and exit wounds or contact points can help identify the probable current path and therefore anticipated tissue and organ involvement. Direct current (DC) travels in one direction, is associated with an explosion and likely concomitant trauma from the blast. Alternating current (AC) passes back and forth from the point of contact, through the body and back to the source many times per second and

can hold the victim to it, increasing contact time. Compartment syndrome is common with electrical injuries due to the edema that results from injured tissue compounded by the large fluid volumes required for resuscitation to prevent kidney failure. As a result, invasive decompressive therapies such as fasciotomies, nerve releases, ocular releases, and laparotomies may be required.

Lightning Injury

Lightning injuries can result from a direct strike, a high-voltage DC injury that is usually fatal, or a side flash wherein the current discharges from an object nearby through the air to an adjacent object or person. Side flashes are the most common cause of injury and result in immediate deep polarization of the entire myocardium with possible cardiac arrest. Respiratory arrest is also expected because electric current can temporarily inactivate the brain's respiratory center. Lightning strikes carry approximately 10% mortality rate, with many survivors reporting permanent morbidity and debilitating symptoms including neurologic disabilities, depression, sleep disorders, chronic, and at times, intense pain, memory loss, attention deficits, numbness, dizziness, stiffness in joints, irritability, fatigue, weakness, and muscle spasms.

Management

Resuscitation fluid calculations based on total body surface area are inaccurate in conductive electrical injuries, including some lightning injuries. It is difficult to quantify the extent of tissue injury without surgical exploration because the damage may not be visible on physical examination. Serum creatinine kinase levels are useful in determining the degree of muscle injury in the early phases of care. Myoglobinuria, common with muscle damage, may cause kidney failure if not treated. Intravenous (IV) fluid administration titrated to a higher target of urine output per hour than usual may be indicated until the urine is no longer red. It is common practice to add 50 mEq of sodium bicarbonate per liter of IV fluid in an effort to assist in alkalinizing the urine. Serum myoglobin and urine myoglobin levels may be monitored as indicators of the need for continued resuscitation.

Finally, the surgical treatment of an electrical injury is as complex as the injury itself. Vasculature is commonly affected; thus, progressive tissue necrosis occurs over time. Sequential surgical débridement may be necessary, using caution to preserve viable tissue.

80(3 Suppl 2), S113–S118; National Weather Service. (n.d.). *Lightning safety tips and resources*. Retrieved on 11/30/2019 at: www.weather.gov/safety/lightning; Walker, A., & Salerno, A. (2019). Shocking injuries: Knowing the risks and management for electrical injuries. *Trauma Reports*, *20*(4), 1–25.

Severe injuries ultimately encompass changes in pathophysiology of all body systems as presented in Table 57-2. These pathologic responses occur in trauma injuries, but the magnitude, duration, and severity are significantly higher with burn injuries.

Cardiovascular Alterations

When a burn injury occurs, there is an immediate decrease in cardiac output that precedes the loss of plasma volume. The systemic inflammation causes the release of free oxygen radicals that increase capillary permeability, causing increased plasma loss and subsequent peripheral edema as water migrates to the interstitium. As a compensatory response to intravascular fluid loss, the sympathetic nervous system releases catecholamines, resulting in an increase in peripheral resistance (vasoconstriction) and an increase in pulse rate that further decreases tissue perfusion. Due to vasoconstrictive compensatory responses secondary to plasma volume loss through capillary leak, the workload of the heart and oxygen demand increase (Gillenwater & Garner, 2017; Wurzer, Culnan, Cancio, et al., 2018).

Hypovolemia is the immediate consequence of ensuing plasma volume loss and results in decreased perfusion and oxygen delivery to organs and tissues. As capillary leakage continues, vascular volume, cardiac output, and blood pressure decrease. This is the onset of early burn shock. Burn shock is initially a type of hypovolemic shock secondary to intravascular volume loss (see Chapter 11).

Unlike traumatic injuries, often characterized by blood loss, only plasma is lost in the burn injury. Prompt, appropriate enteral or parenteral fluid resuscitation maintains the blood pressure in the low to normal range and improves cardiac output (see later discussion). However, even with adequate fluid resuscitation, cardiac filling pressures (central venous pressure, pulmonary artery pressure, and pulmonary artery wedge pressure) remain low during the initial burn shock period. Unless sufficient IV fluids are administered to maintain vascular volume, distributive shock occurs (see Chapter 11).

TABLE 57-2 Pathophysiologic Changes with Severe Burns

Body System	Physiologic Changes
Cardiovascular	Cardiac depression, edema, hypovolemia
Pulmonary	Vasoconstriction, edema
Gastrointestinal	Impaired motility and absorption, vasoconstriction, loss of mucosal barrier function with bacterial translocation, increased pH
Kidney	Vasoconstriction
Other	Altered thermoregulation, immunodepression, hypermetabolism

Adapted from Bielson, C. B., Duethman, N. C., Howard, J. M., et al. (2017). Burns: Pathophysiology of systemic complications and current management. *Journal of Burn Care & Research*, *38*(1), e469–e481.

Generally, the greatest volume of intravascular fluid leak occurs in the first 24 to 36 hours after the burn injury, peaking at approximately 6 to 8 hours after the initial burn injury. As the capillaries begin to regain their integrity, burn shock resolves and fluid shifts back into the vascular compartment. Intrinsic diuresis will begin and continue for several days to 2 weeks in the previously healthy adult.

Fluid and Electrolyte Alterations

Edema forms rapidly after a burn injury. A superficial burn will cause localized edema to form within 4 hours, whereas a deeper burn will continue to form edema up to 18 hours post injury. The increased perfusion to the injured area in the presence of increased capillary permeability reflects the amount of microvascular and lymphatic damage to the tissue. In burns greater than 20% TBSA, inflammatory mediators stimulate local and systemic reactions resulting in extensive shift of intravascular fluid, electrolytes, and proteins into the surrounding interstitium (Gillenwater & Garner, 2017).

Concept Mastery Alert

For patients in the emergent/resuscitative phase, nurses should do a primary survey and closely monitor circulation. As the taut, burned tissue becomes unyielding to the edema beneath its surface, it begins to act like a tourniquet, especially if the burn is circumferential. As edema increases, pressure on small blood vessels in the distal extremities obstructs blood flow resulting in consequent tissue ischemia and potentially acute compartment syndrome. See Chapter 37 for discussion of acute compartment syndrome. Patients in the acute/intermediate phase must be closely monitored for the development of venous thromboembolism (VTE).

Figure 57-5 • Escharotomy of forearm. Used with permission from University of Texas Medical Branch, Galveston, TX.

Treatments for edema may include elevation of the extremity or, in severe cases, cutting of the **eschar** (i.e., devitalized tissue) via **escharotomy** (i.e., surgical incision through eschar), or decompression of edema formation via **fasciotomy** (i.e., surgical incision through fascia to relieve constricted muscle) to restore tissue perfusion (see Figs. 57-5 and 57-6).

Reabsorption of edema begins about 4 hours post injury and is complete approximately 4 days postburn injury. However, the rate of

reabsorption depends on the depth of injury to the tissue. Although adequate fluid resuscitation is paramount to maintaining tissue perfusion, excessive fluid administration increases edema formation in both burned and unburned tissue causing ischemia and necrosis.

Immediately after burn injury, hyperkalemia (excessive potassium) may result from massive cell destruction. Hypokalemia (potassium depletion) may occur later with fluid shifts and inadequate potassium replacement. Serum sodium levels vary in response to fluid resuscitation. Hyponatremia (serum sodium depletion) may be present from plasma loss or may occur during the first week of the acute phase, as water shifts from the interstitial space and returns to the vascular space.

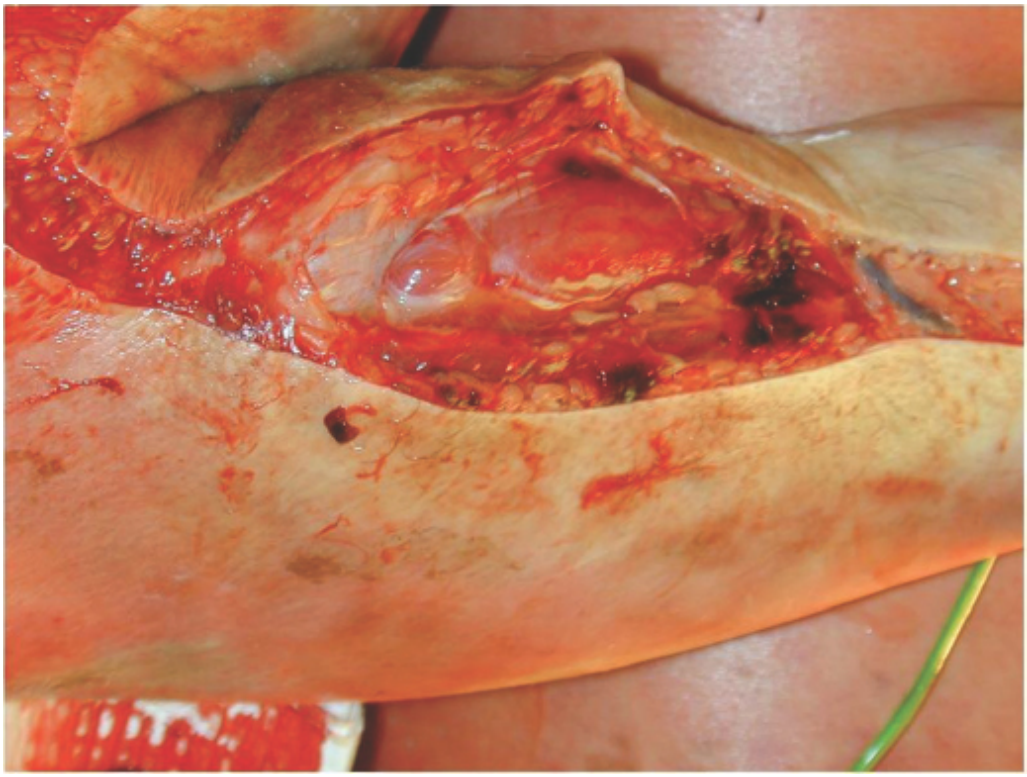

Figure 57-6 • Fasciotomy of upper arm. Used with permission from University of Texas Medical Branch, Galveston, TX.

At the time of burn injury, some red blood cells may be destroyed, and others damaged. Despite this, the early hematocrit may be elevated due to plasma loss (hemoconcentration). Abnormalities in coagulation, including a decrease in platelets (thrombocytopenia) and prolonged clotting and prothrombin times also occur.

Pulmonary Alterations

Inhalation injuries, caused by inhalation of thermal and/or chemical irritants, are categorized as upper airway injury (above the glottis) or lower airway injury (below the glottis). Injuries above the vocal cords can be thermal or chemical, whereas injuries below the vocal cords are usually chemical (ABA, 2018). Approximately 2% to 14% of patients admitted to burn centers have an inhalation injury (ABA, 2018). The presence of inhalation injury is important to recognize, as it is one of the highest causes of mortality, along with age of the patient and burn size. History of the injury, such as a flame injury occurring in an enclosed space, and clinical signs such as singed facial hair or carbonaceous sputum (i.e., sputum with carbon particles which appears black; soot), are indicators for the potential presence of a smoke inhalation injury. Bronchoscopy is considered the standard test for definitive diagnosis as initial chest x-rays appear normal. The extent of pulmonary damage is directly related to the temperature and the concentration of toxic gases.

Upper Airway Injury

Upper airway injury is obstructive; it is caused by severe upper airway edema from direct thermal injury or secondary edema from face or neck burns in the early postburn period. Protective intubation is often warranted to maintain patency of the airway (ABA, 2018; Jones et al., 2017). Because of the cooling effect of rapid vaporization in the oropharynx, direct heat injury does not normally occur below the level of the glottis. However, with steam exposure or in blast injuries, thermal injury to the lower airways is possible because the upper airway cannot effectively protect the lower airway in these cases (Jones et al., 2017).

Lower Airway Injury

Inhalation injury below the glottis results from inhaling the products of incomplete combustion or noxious gases and is often the source of death at the scene of a fire. Smoke inhalation causes loss of ciliary action, triggers an inflammatory response causing hypersecretion, producing severe mucosal edema and potential bronchospasm. A reduction in alveolar surfactant production produces atelectasis (collapse of alveoli) in the parenchyma. Expectoration of carbon particles in the sputum is the cardinal sign of a lower airway inhalation injury. Aggressive pulmonary toilet is critical to maintain airway patency and clear resulting viscous sputum. Outcomes are improved in lower airway injuries when patients can expectorate carbonaceous sputum naturally (i.e., among patients who

are not endotracheally intubated and mechanically ventilated) (Jones et al., 2017).

Noxious gases, such as carbon monoxide (CO) and hydrogen cyanide, contribute to lower airway injuries. CO poisoning is a factor in most fatalities at the scene of a fire as it combines with hemoglobin and displaces oxygen to form **carboxyhemoglobin.** The affinity of hemoglobin for CO is 200 times greater than that for oxygen, and if significant quantities of CO are present, then tissue hypoxia will occur. Treatment is administration of 100% oxygen to displace the CO molecules bound to hemoglobin, bringing the half-life of CO down to 45 minutes (ABA, 2018).

Hydrogen cyanide is a rapid systemic toxin also associated with mortality. Signs and symptoms are similar to CO poisoning and can include shortness of breath, headache, vertigo, confusion, and mucous membrane irritation. The cardiopulmonary effects initially cause a hyperdynamic response followed by bradycardia and hypotension leading to death. Hydrogen cyanide poisoning may be suspected in a patient with persistent lactic acidosis after resuscitation (ABA, 2018). Gaseous cyanide is a result from incomplete combustion of many items found in homes today.

Bronchoconstriction (caused by release of histamine, serotonin, and thromboxane [a powerful vasoconstrictor]) and chest constriction secondary to circumferential torso burns can contribute to deterioration. Even without pulmonary injury, hypoxia may be present. Early in the postburn period, catecholamine release in response to the stress of the burn injury alters peripheral blood flow, thereby reducing oxygen delivery to the periphery. Later, hypermetabolism and continued catecholamine release lead to increased tissue oxygen consumption, which can also lead to hypoxia. Administration of supplemental oxygen will ensure that adequate oxygen is available to the tissues. Restrictive pulmonary excursion may occur with full-thickness burns encircling the thorax resulting in decreased tidal volume. In such situations, an escharotomy may be necessary to restore adequate chest excursion (ABA, 2018).

Kidney Alterations

Kidney function may be altered as a result of decreased blood volume postburn injury due to the compensatory response to intravascular volume loss. Adequate fluid volume replacement can restore renal blood flow, increasing the glomerular filtration rate and urine volume. Additionally, destruction of red blood cells at the injury site may result in free

hemoglobin in the urine. If muscle damage occurs (e.g., from electrical burns), myoglobin is released from the muscle cells and excreted by the kidneys causing the urine to be red. If there is inadequate blood flow through the kidneys caused by the hemoglobin and myoglobin occluding the renal tubules, acute tubular necrosis and acute kidney injury will occur (see Chapter 48). Increased abdominal pressure from the injury can also cause kidney ischemia.

Immunologic Alterations

The immunologic defenses of the body are significantly altered by a burn injury. Skin, the largest barrier to infection, when compromised continually exposes the patient to the environment. The burn injury itself produces systemic release of cytokines and other substances that cause leukocyte and endothelial cell dysfunction. Burn centers must provide an infection-controlled environment to protect the patient and minimize exposure to potentially harmful organisms (Palmieri, 2019).

Thermoregulatory Alterations

Integumentary loss also causes an inability to regulate body temperature resulting in various complications. Patients with burn injuries often exhibit low body temperatures in the early hours after injury not necessarily due to initial first aid, which may include cooling of the wounds, but more likely from the amount of TBSA involved, the IV resuscitation fluids administered, and exposure resulting in increased evaporative heat loss (Ehrl, Heidekrueger, Rubenbauger, et al., 2018). Burn centers often have additional heating sources to help maintain the patient's body temperature through environmental warming.

Gastrointestinal Alterations

Patients who are critically ill, especially those with burns, are predisposed to altered gastrointestinal (GI) motility. Impaired enteric nerve and smooth muscle function, inflammation, surgery, medications such as vasopressors, and inadequate tissue perfusion are some causes of GI dysfunction. Indicators of GI organ ischemia include increased bladder pressure, increasing serum lactate, and feeding intolerance. Three of the most common GI alterations in patients with burns are paralytic ileus (absence of intestinal peristalsis), Curling's ulcer, and translocation of bacteria. Decreased peristalsis and bowel sounds are manifestations of paralytic ileus. Gastric distention and nausea may lead to vomiting;

therefore, gastric decompression is advised. Gastric bleeding secondary to massive physiologic stress may be signaled by occult blood in the stool, regurgitation of "coffee-ground" material from the stomach, or bloody vomitus. These signs suggest gastric or duodenal erosion (Curling's ulcer). Probiotics may be useful in maintaining intestinal barrier function through avoidance of colonization of pathogenic microorganisms (Culnan, Capek, & Sheridan, 2018).

Thermal injury damages the liver through induction of hepatic edema, apoptosis, insulin resistance associated with metabolic derangements, and development of a fatty liver. In addition, with severe burn injury, acute pancreatitis is common and may result in a threefold increase in amylase or lipase, feeding intolerance, or abdominal pain (Culnan et al., 2018).

Patients with large TBSA burns are also at risk for life-threatening abdominal compartment syndrome (ACS) due to large volumes of fluid required for resuscitation, fluid shifts to the interstitium causing edema formation, and decreased abdominal wall compliance due to eschar formation. Increased pressure in the abdominal cavity contributes to GI tract and abdominal organ ischemia (see Chapter 11). Ramirez, Palmieri, Greenhalgh, and colleagues (2018) reviewed 10 years of cases of ACS in patients with burns and found support for early laparotomy as definitive treatment of ACS.

Management of Burn Injury

Burn recovery generally occurs in three phases: emergent/resuscitative, acute/intermediate, and rehabilitation. Although priorities exist for each of the phases, assessment and management of problems and complications will overlap. Table 57-3 summarizes the priorities of care for each phase.

Emergent/Resuscitative Phase

On-the-Scene Care

The first step in management is to remove the patient from the source of injury and stop the burning process while preventing injury to the rescuer. Rescue workers' priorities include establishing an airway, supplying oxygen (100% oxygen if CO poisoning is suspected), inserting at least one large-bore IV catheter for fluid administration, and covering the wound with a clean, dry cloth or gauze. Continuous irrigation of chemical injury must begin immediately. Chart 57-4 describes the procedures and care required at the burn scene. The outward physical appearance of the person burned is often distracting, but the internal systemic effects pose the greater threat to life.

An immediate primary survey of the patient is performed assessing the ABCDEs: *a*irway (A) with consideration given to protecting the cervical spine, gas exchange or *b*reathing (B), *c*irculatory and *c*ardiac status (C), *d*isability (D) including neurologic deficit, and *e*xpose and *e*xamine (E) while maintaining a warm environment (ABA, 2018).

TABLE 57-3  Phases of Burn Care

Phase	Duration	Priorities
Emergent/resuscitative	From onset of injury to completion of fluid resuscitation	• Primary survey: A, B, C, D, E • Prevention of shock • Prevention of respiratory distress • Detection and treatment of concomitant injuries • Wound assessment and initial care
Acute/intermediate	From beginning of diuresis to near completion of wound closure	• Wound care and closure • Prevention or treatment of complications, including infection • Nutritional support
Rehabilitation	From major wound closure to return to individual's optimal level of physical and psychosocial adjustment	• Prevention and treatment of scars and contractures • Physical, occupational, and vocational rehabilitation • Functional and cosmetic reconstruction • Psychosocial counseling

Cowan, A., et al. (2018). Burn rehabilitation along the continuum of care. In D. Herndon (Ed.). *Total burn care* (5th ed.). Edinburgh: Saunders Elsevier.

Chart 57-4

Emergency Procedures at the Burn Scene

- **Extinguish the flames or remove from source.** A fire requires oxygen and fuel once ignited. When clothing catches fire, the flames can be extinguished if the person drops to the floor or ground and rolls ("stop, drop, and roll") or uses anything available, such as a blanket, rug, or coat, to smother the flames. The older adult, or others with impaired mobility, could be instructed to "stop, sit, and pat" to prevent concomitant musculoskeletal injuries. Standing still forces the person to breathe flames and smoke, while running fans the flames. If the burn source is electrical, the electrical source must be disconnected safely before approaching the patient.
- **Cool the burn.** After the flames are extinguished, the burned area and adherent clothing are soaked with *cool* water to cool the wound and halt the burning process. However, *never* apply ice directly to the burn, *never* wrap the person in ice, and *never* use cold soaks or dressings for longer than 20 or so minutes; such procedures may worsen tissue damage and lead to hypothermia in people with larger burns.
- **Remove restrictive objects.** If possible, remove affected, nonadherent clothing immediately. Adherent clothing may be left in place once cooled. Other clothing and all jewelry, including all piercings, should be removed to allow for assessment and to prevent constriction secondary to rapidly developing edema.
- **Cover the wound.** The burn should be covered as quickly as possible to minimize bacterial contamination, maintain body temperature by decreasing evaporative heat loss, and decrease pain by preventing air currents from coming in contact with the exposed nerves in the injured surface. Any clean, dry cloth can be used as an emergency dressing. Ointments and salves should *not* be used. Other than the dressing, no medication or material should be applied to the burn wound at the scene.
- **Irrigate chemical burns.** Chemical burns resulting from contact with a corrosive material are irrigated immediately and continuously with copious amounts of water. Most chemical laboratories have a shower for these types of emergencies. If a chemical contact occurs at home, brush off the chemical agent if dry, remove contaminated and all potentially contaminated clothes immediately, and rinse all areas of the body that have come in contact with the chemical. Rinsing can occur in the shower or any other source of continuous running water. If a chemical gets in or near the eyes, the eyes should be flushed with cool, clean water immediately and copiously. Outcomes for

the patient with chemical burns are significantly improved by rapid, sustained flushing of the injury with water at the scene.

Adapted from American Burn Association. (2018). *Advanced burn life support (ABLS) course provider manual 2018*. Chicago, IL.

Quality and Safety Nursing Alert

Airway patency and breathing must be assessed during the initial minutes of emergency care. Immediate therapy is directed toward establishing a patent airway and giving humidified 100% oxygen. If qualified personnel and equipment are available and the patient with burns has severe respiratory distress and/or airway edema, the rescuers must insert an endotracheal tube and initiate mechanical ventilation. No food or fluid is given by mouth, and the patient is placed in a position that will prevent aspiration of vomitus, because nausea and vomiting may occur, and protection of the airway is always a priority.

The secondary survey focuses on obtaining a history, the completion of the total body systems assessment, initial fluid resuscitation, and provision of psychosocial support of the conscious patient (see Chapter 67) (ABA, 2018).

Medical Management

Long-term outcomes are impacted by the quality of care received in the first few hours after injury (ABA, 2018). Initially, the patient is transported to the nearest emergency department (ED) so that lifesaving measures can be initiated. Early referral to a burn center is then made if indicated.

Initial priorities in the ED remain airway, breathing, and circulation. For mild pulmonary injury, 100% humidified oxygen is given, and the patient is encouraged to cough so that secretions can be expectorated or removed by suctioning. For more severe situations, it may be necessary to remove secretions by bronchial suctioning and administer bronchodilators and mucolytic agents. Continuous monitoring of airway patency is critical; a previously stable airway may rapidly deteriorate as edema increases and toxic effects of smoke inhalation become apparent.

Once urgent respiratory needs are appropriately addressed, fluid resuscitation is initiated. Fluid resuscitation in patients with burns greater than 20% TBSA addresses the intravascular volume deficit to improve tissue and organ perfusion caused by plasma loss, with the least amount of fluid possible. Daily weights and trends in laboratory test results require close monitoring in the immediate postburn (resuscitation) period to monitor fluid status. Both underresuscitation and overresuscitation with IV fluids are associated with poor outcomes. Shock, ischemic complications, and multiple organ dysfunction syndrome (MODS) occur with underresuscitation (see Chapter 11), and heart failure and pulmonary edema occur with overresuscitation (see Chapter 25).

In order to facilitate fluid administration, peripheral IV access may be obtained initially; however, in larger burns, central venous access is recommended due to the large volumes required. Once the TBSA is calculated, fluid resuscitation with lactated Ringer (LR) should be initiated using ABA resuscitation formulas. LR is the crystalloid of choice because its pH and osmolality most closely resemble human plasma.

The ABA (2018) fluid resuscitation formula for adults within 24 hours post thermal or chemical burn is as follows:

2 mL LR × patient's weight in kilograms × %TBSA second-, third-, and fourth-degree burns

For adults with electrical burns:

4 mL LR × patient's weight in kilograms × %TBSA second-, third-, and fourth-degree burns

Timing is one of the most important considerations in calculating fluid needs in the first 24 hours post burn. The starting point is the time of injury—not the time of arrival to the treating facility (ABA, 2018). The infusion is regulated so that half of the total calculated volume is given in the first 8 hours postburn injury. The second half of the calculated volume is infused over the next 16 hours.

These formulas are only guidelines. It is imperative that the rate of infusion be titrated hourly as indicated by physiologic monitoring of the patient's response. Each patient has a unique injury and optimum results require individualized treatments based on patient response (Gillenwater & Garner, 2017). Urinary output continues to be the standard for assessing patient response to fluid resuscitation. A urine output of 0.5 to 1 mL/kg/h in adults indicates appropriate resuscitation in thermal and chemical injuries, whereas in electrical injuries a urine output of 75 to

100 mL/h is desired (ABA, 2018). Other indicators such as blood pressure or heart rate are not useful in assessing adequate intravascular volume in patients with major burns due to the marked inflammatory response.

After adequate respiratory function and circulatory status have been established, the patient is assessed for cervical spine and/or head injuries if involved in a traumatic or electrical injury. All clothing and jewelry are removed because they may contain chemicals, retain heat, or become constrictive as edema rapidly develops. For chemical burns, flushing of the exposed areas with copious amounts of clean water is continued. The patient is checked for contact lenses. These are removed immediately if chemicals have come in contact with the eyes or if facial burns have occurred. In addition, the eyes are examined promptly for injury to the corneas. An ophthalmologist may be consulted for complete assessment via fluorescent staining to assess for corneal damage.

The patient's temperature must be monitored because hypothermia may develop rapidly, and manipulation of the environment may be necessary. A temperature less than 35°C (95°F) causes vasoconstriction, which may increase tissue ischemia and necrosis.

It is important to validate an account of the burn scenario provided by the patient, witnesses at the scene, and first responders. Information should include the time and the source of the burn injury, the scene of injury (particularly if the patient was in an enclosed space), length of exposure, prior treatment, and any history of concomitant traumatic injury. A history of preexisting medical conditions, allergies, medications, and the use of drugs, alcohol, and tobacco is obtained to assist with the treatment plan.

An indwelling urinary catheter is inserted to permit accurate monitoring of urine output and fluid needs and as a measure of kidney function for patients with moderate to severe burns. If the burn exceeds 20% to 25% TBSA, a nasogastric tube is inserted and connected to low intermittent suction. All patients who are intubated should have a nasogastric tube inserted to decompress the stomach, and to prevent vomiting and aspiration. Often, patients with large burns become nauseated as a result of the GI effects of the burn injury, such as paralytic ileus, and the effects of medications such as opioids.

Clean sheets are placed under and over the patient to protect the burn wound from contamination, maintain body temperature, and reduce pain caused by air currents passing over exposed nerve endings. Baseline height, weight, arterial blood gases, hematocrit, serum electrolytes, blood

alcohol level, drug panel, urinalysis, and chest x-rays may be obtained. Because poor tissue perfusion accompanies burn injuries, only IV analgesia is given in small repeated doses, which is crucial for pain reduction in the emergent phase. If the patient has an electrical burn, a baseline electrocardiogram is also obtained and continuous cardiac monitoring is initiated. Because burns are contaminated wounds, tetanus prophylaxis is given if the patient's immunization status is not current or is unknown.

Quality and Safety Nursing Alert

If necessary, a blood pressure cuff may be placed around a patient's burned extremity. The cuff must be of the correct size with accommodations made for edema.

Although the major focus of care during the emergent phase is physiologic stabilization, the nurse must also attend to the patient's and the family's psychological needs. Anxiety accompanies burn injuries and must be addressed on an ongoing basis. A burn injury is a crisis—one that causes varying emotional responses that may result in conflicts that may precipitate ethical dilemmas. The patient's and family's coping abilities and available supports are assessed. The nurse must consider special circumstances surrounding the burn injury when providing care. Examples include cases of abuse, neglect, suicide attempts, and injury/death of other family members or friends from the same event.

Nursing Management

Nursing assessment in the emergent phase of burn injury focuses on the major priorities for any trauma patient; the burn wound is a secondary consideration to stabilization of airway, breathing, and circulation. The nurse monitors respiratory status closely, and pulses are evaluated, particularly in areas of circumferential burn injury to an extremity. Initially, cardiac monitoring is indicated if the patient has a history of cardiac disease, electrical injury, or altered respiratory conditions. The nurse should monitor vital signs with knowledge of expected abnormalities consistent with burn injury such as tachycardia, tachypnea.

If all extremities are burned, determining blood pressure may be difficult. A clean dressing applied under the blood pressure cuff protects the wound from contamination. Because increasing edema makes blood

pressure difficult to auscultate, a Doppler (ultrasound) device or a noninvasive electronic blood pressure device may be helpful. In patients with severe burns, an arterial catheter is preferred for blood pressure measurement and is helpful for collecting blood specimens. Peripheral pulses in burned extremities are checked frequently either by palpation or the use of a Doppler. Elevation of burned extremities above the level of the heart is indicated for edema reduction. Large-bore IV catheters (e.g., 16 to 18 gauge) and an indwelling urinary catheter are inserted, if not already in situ, and the nurse's documentation must include hourly assessment of fluid intake and urine output.

Red-colored urine suggests the presence of hemochromogens from damage to red blood cells and myoglobin, the by-product of muscle damage (ABA, 2018). This anomaly is associated with deep burns caused by electrical injury or prolonged contact with heat or flame. Glycosuria, a common finding in the early postburn hours, results from the release of liver glycogen stores in response to stress.

The nurse assists with calculating the patient's expected fluid requirements and monitoring the patient's response to fluid resuscitation. Nurse-driven resuscitation protocols have been shown to decrease the amount of fluid given and improve patient outcomes in the emergent/resuscitative phase (Stewart, Ladd, Kovler, et al., 2019). Nursing responsibilities consist of appropriate fluid administration, strict monitoring of intake and output, monitoring the patient's response, and notifying the treatment team of significant assessment findings and any abnormal laboratory values.

To help guide treatment, the following are essential: documentation of body temperature, body weight, and pre-burn weight; history of allergies, tetanus immunization, past medical and surgical history, and current illnesses; and a list of current medications. The nurse performs a head-to-toe assessment, focusing on signs and symptoms of concomitant illness, associated trauma, or developing complications. Assessing the extent of the burn wound using the rule of nines or facilitated with anatomic diagrams (described previously) is performed. Additionally, the nurse works with the primary provider to clinically assess and document the initial areas of full- and partial-thickness injury. Psychosocial considerations of the patient and family and communication with the treatment team are imperative early in the course of care.

Nursing care of the patient in the emergent/resuscitative phase of burn injury is detailed in Chart 57-5.

Acute/Intermediate Phase

The acute/intermediate phase of burn care follows the emergent/resuscitative phase and begins 48 to 72 hours after the burn injury. During this phase, attention is directed toward continued assessment and maintenance of respiratory and circulatory status, fluid and electrolyte balance, and GI and kidney function. Infection prevention and control, burn wound care (e.g., wound cleaning and débridement, topical antibacterial/antimicrobial therapy, application of dressings, wound grafting), pain management, modulation of the hypermetabolic response, and early positioning/mobility are priorities in the acute/intermediate stage of recovery.

Medical Management

Pulmonary complications are common in burn injury. Airway obstruction caused by upper airway edema can take as long as 48 hours to develop. Changes detected by x-ray and arterial blood gas analysis may occur as the effects of resuscitative fluid and the chemical reactions of smoke ingredients with lung tissues become evident. Diagnosis is largely based on history and clinical presentation, monitoring of arterial blood gases with carboxyhemoglobin levels, and direct observation of the airway by fiberoptic bronchoscopy (ABA, 2018). To lessen the effects of upper airway edema, elevation of the patient's head of the bed may be helpful. Stridor and dyspnea are ominous because they are late signs of impending airway obstruction. Early protective intubation to maintain airway patency should be considered as obstruction may occur very rapidly. However, intubation and mechanical ventilation are significant contributors to pulmonary infections. Ideally, the best practice is to remove the endotracheal tube as soon as possible so that a route for pathogens is not accessible to the lungs (ABA, 2018).

Late pulmonary complications secondary to inhalation injuries include mucosal sloughing of the airway and cast formation from cellular debris, which can lead to obstruction, increased secretions, inflammation, atelectasis, airway ulceration, pulmonary edema, and tissue hypoxia. Although research results are mixed, nebulized heparin therapy may be administered because it is thought to have some effect on the inflammatory cascade and formation of fibrin casts in the airways (Suresh

& Dries, 2018). Pneumonia, acute lung injury (ALI), and acute respiratory distress syndrome (ARDS) may also occur.

Ventilator-associated pneumonia (VAP) is a common complication of any patient who is hospitalized and mechanically ventilated and is particularly exacerbated in the patient with an inhalation injury. It affects as many as 10% to 20% of patients on mechanical ventilation longer than 48 hours. See Chapter 19, Chart 19-6, for discussion of "bundled" strategies to prevent VAP and Chapter 19 for discussion of respiratory failure and ARDS.

As capillaries regain their integrity, 48 or more hours after the burn, fluid shifts from the interstitial to the intravascular compartment and intrinsic diuresis begins. If cardiac or kidney function is inadequate, fluid overload may occur, and symptoms of heart failure may emerge (see Chapter 25). Administration of fluids and electrolytes continues cautiously during this phase of burn care due to fluid shifts, evaporative fluid loss from large burn wounds, and the patient's physiologic responses to the burn injury. Blood components are given as needed to treat surgical blood loss and anemia.

Hyperthermia is common in patients after burn shock resolves. A resetting of the core body temperature in patients who are severely burned results in a body temperature a few degrees higher than normal for several weeks after the burn. This can be compounded by body temperature increases from sepsis.

Central venous, arterial, or specialty catheters (e.g., hemodialysis catheters, Zoll® catheters) may be required for monitoring hemodynamics. Commonly, patients with major burns need multiple invasive line sites due to the amount and frequency of fluid and medications required. Whenever possible, burned areas of the body are avoided as insertion sites for invasive lines.

One of the most important medical interventions for patients with burns that have positively affected mortality is early **excision** (surgical removal of tissue). The presence of the open wounds or invasive organisms triggers the response to a large burn injury, a systemic cascade of events (Culnan, Sherman, Chung, et al., 2018). Excising the necrotic tissue can ameliorate this response and preserve underlying viable tissue.

Infection Prevention and Control

There are multifactorial reasons why patients with burns incur some of the highest risks for health care–associated infections (HAIs). The systemic response to a burn injury results in dysregulation of the immune

system, predisposing the patient to invasion by environmental pathogens (Lachiewicz, Hauck, Weber, et al., 2017). The wound provides a perfect medium for bacterial proliferation, as well as a conduit to the bloodstream (Ramos, Cornistein, Cerino, et al., 2017). Because of the loss of the epidermal barrier, presence of transmittable bacteria, and the ubiquity of mold species in the environment, it is critical that the nurse prioritizes infection prevention in the plan of care (Sood, Vaidya, Dam, et al., 2018). In addition, to support vital organs and bodily functions, invasive procedures are required which may undermine the body's natural defenses (Ramos et al., 2017).

Chart 57-5 PLAN OF NURSING CARE

Care of the Patient during the Emergent/Resuscitative Phase of Burn Injury

NURSING DIAGNOSIS: Impaired gas exchange associated with carbon monoxide (CO) poisoning, smoke inhalation, and upper airway obstruction

GOAL: Maintenance of adequate tissue oxygenation

Nursing Interventions	Rationale	Expected Outcomes
1. Provide 100% humidified oxygen. 2. Assess breath sounds, and respiratory rate, rhythm, depth and symmetry of chest excursion. Monitor patient for signs of hypoxia. Report abnormalities to primary provider. 3. Observe for the following: a. Erythema or blistering of lips or buccal mucosa b. Singed nasal hairs c. Burns of face, neck, or chest d. Increasing hoarseness e. Soot in sputum or tracheal tissue in respiratory secretions 4. Monitor arterial blood gas values, pulse oximetry readings, and carboxyhemoglobin levels. 5. Prepare to assist with intubation and escharotomies of chest.	1. Humidification provides moisture to injured tissues; supplemental oxygen increases alveolar oxygenation. 2. These factors provide baseline data of assessment and evidence of increasing respiratory compromise. 3. These signs indicate possible inhalation injury and risk of respiratory dysfunction. 4. Increasing $PaCO_2$ and decreasing PaO_2 and O_2 saturation may indicate need for mechanical ventilation. 5. Intubation allows airway protection and mechanical ventilation. Escharotomy enables adequate	• Absence of dyspnea • Arterial oxygen saturation >95% by pulse oximetry (in the absence of CO poisoning) • Arterial blood gas levels within normal limits • Respiratory rate, pattern, and breath sounds normal

	chest excursion in circumferential chest burns.	

NURSING DIAGNOSIS: Impaired airway clearance associated with exposure to smoke

GOAL: Maintain patent airway and adequate airway clearance

Nursing Interventions	Rationale	Expected Outcomes
1. Maintain patent airway through proper patient positioning, removal of secretions, and artificial airway if needed. 2. Provide humidified oxygen as prescribed. 3. Encourage patient to turn, cough, and deep breathe. Encourage patient to use incentive spirometry. Perform endotracheal suction as needed.	1. A patent airway is crucial to respiration. 2. Humidification liquefies secretions and facilitates expectoration. 3. These activities promote mobilization and removal of secretions.	• Patent airway • Respiratory secretions are minimal, colorless, and thin.

NURSING DIAGNOSIS: Hypovolaemia associated with increased capillary permeability and evaporative losses from the burn wound

GOAL: Restoration of optimal fluid and electrolyte balance and perfusion of vital organs

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor vital signs, hemodynamics, and urine output, as well as record strict intake and output and daily weights. 2. Maintain IV lines and regulate fluids at prescribed and	1. Hypovolemia is a major risk immediately following a burn injury. Overresuscitation with IV fluids might cause fluid overload.	• Urine output between 0.5 and 1.0 mL/kg/h (30–50 mL/h; 75–100 mL/h if

appropriate rates following urine output. 3. Observe for symptoms of deficiency or excess of serum sodium, potassium, calcium, phosphorus, and bicarbonate. 4. Elevate head of patient's bed and burned extremities, if not contraindicated. 5. Notify primary provider immediately of decreased urine output and hemodynamic changes.	Adequate fluids are 2. necessary for perfusion of vital organs and maintenance of fluid and electrolyte balance. 3. Rapid shifts in fluid and electrolyte status are possible in the postburn period. 4. Elevation promotes venous return. 5. Rapid fluid shifts must be detected early to prevent complications.	electrical burn injury) • Mean arterial pressure ≥60 mm Hg • Voids clear yellow urine with specific gravity within normal limits • Serum electrolytes within normal limits

NURSING DIAGNOSIS: Hypothermia associated with loss of skin microcirculation and open wounds

GOAL: Maintenance of adequate body temperature

Nursing Interventions	Rationale	Expected Outcomes
1. Assess core body temperature frequently. 2. Provide a warm environment by increasing room temperature or adjunct therapies as needed (overbed warmers, blankets, heat lamps, etc.). 3. Work quickly when wounds must be exposed.	1. Frequent temperature assessments help detect hypothermia. 2. Minimizes resting energy expenditure. 3. Limiting exposure minimizes evaporative heat loss from wound(s).	• Body temperature remains >37°C (98.6°F) • Absence of chills or shivering

NURSING DIAGNOSIS: Acute pain associated with chemical or physical injury

GOAL: Control of pain

Nursing Interventions	Rationale	Expected Outcomes
1. Use pain intensity scale to assess pain level. Differentiate restlessness due to pain from restlessness due to hypoxia. 2. Administer IV antispasmodic agents as prescribed and assess for effectiveness.	1. Pain scales provide baselines for evaluating effectiveness of pain relief measures. Hypoxia can cause similar signs and must be ruled out before analgesic medication is given. 2. IV administration is necessary because of altered tissue	• States pain level is decreased and is acceptable to patient's pain goal • Absence of nonverbal cues of pain

3. Provide emotional support and reassurance.	perfusion from burn injury. 3. Fear and anxiety increase the perception of pain.	

NURSING DIAGNOSIS: Anxiety associated with fear and the emotional impact of burn injury

GOAL: Minimization of patient's and family's anxiety

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's and family's understanding of burn injury, coping skills, and family dynamics. 2. Explain all procedures to the patient and the family in clear, simple terms. 3. Administer prescribed antianxiety medications if the patient remains extremely anxious despite nonpharmacologic interventions.	1. Previous successful coping strategies can be fostered for use in the present crisis. Assessment allows planning of individualized interventions. 2. Increased understanding alleviates fear of the unknown. High levels of anxiety may interfere with understanding of complex explanations. 3. Anxiety levels during the emergent phase may exceed the patient's coping abilities.	• Patient and family verbalize understanding and acceptance of emergent burn care • Patient and family's anxiety levels will be minimized

COLLABORATIVE PROBLEMS: Acute respiratory failure, distributive shock, acute kidney injury, compartment syndrome, paralytic ileus, Curling's ulcer

GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Acute Respiratory Failure		
1. Assess for increasing dyspnea, stridor, changes in respiratory patterns.	1. Such signs reflect deteriorating respiratory status.	• Breathes spontaneously with adequate tidal volume
2. Monitor pulse oximetry, arterial blood gas values.	2. Abnormal findings may indicate respiratory failure.	• Arterial blood gas values within acceptable limits
3. Monitor chest x-ray results.	3. X-ray may disclose pulmonary injury or infection.	• Chest x-ray findings normal
4. Assess for restlessness, confusion, difficulty attending to questions, or decreasing level of consciousness.	4. Such manifestations may indicate cerebral hypoxia.	• Absence of cerebral signs of hypoxia
5. Report deteriorating respiratory status immediately to primary provider.	5. Acute respiratory failure is life-threatening, and immediate intervention is required.	
6. Prepare to assist with intubation or escharotomies as indicated.	6. Intubation allows mechanical ventilation. Escharotomies allow adequate chest excursion with respirations.	

Nursing Interventions	Rationale	Expected Outcomes
Distributive Shock		

1. Assess for decreasing urine output and alterations in vital signs and hemodynamics. 2. Assess for progressive edema as fluid shifts occur. 3. Adjust fluid resuscitation in collaboration with the primary provider in response to physiologic findings.	1. Such signs and symptoms may indicate distributive shock and inadequate intravascular volume. 2. As fluid shifts into the interstitial spaces in burn shock, edema occurs and may compromise tissue perfusion. 3. Optimal fluid resuscitation prevents distributive shock and improves patient outcomes.	• Urine output between 0.5 and 1.0 mL/kg/h (30–50 mL/h; 75–100 mL/h if electrical burn injury) • Blood pressure within patient's normal range • Hemodynamics remain within normal limits • No signs or symptoms of impaired perfusion
Acute Kidney Injury		
1. Monitor urine output, blood urea nitrogen (BUN), and serum creatinine levels. 2. Report decreased urine output or increased BUN and creatinine values to primary provider. 3. Assess urine for hemoglobin or myoglobin. Administer increased fluids as prescribed.	1. These values reflect renal function. 2. These laboratory values indicate possible kidney failure. 3. Hemoglobin or myoglobin in the urine predisposes patient to increased risk of kidney failure. Fluids help to flush hemoglobin and myoglobin from renal tubules.	• Adequate urine output • BUN and serum creatinine values remain normal

Compartment Syndrome		
1. Assess peripheral pulses frequently (with Doppler ultrasound device if needed). 2. Assess warmth, capillary refill, sensation, and movement of extremity frequently. Compare affected with unaffected extremity if possible. 3. Remove blood pressure cuff after each reading. 4. Elevate burned extremities if not contraindicated. 5. Report loss of pulse or sensation or presence of pain to primary provider immediately. 6. Prepare to assist with escharotomies.	1. Pulse assessments are crucial to assess for adequate perfusion. 2. These assessments may signal worsening peripheral perfusion. 3. Cuff may act as a tourniquet as extremities swell. 4. Elevation reduces edema formation. 5. These signs and symptoms may indicate impaired tissue perfusion. 6. Escharotomies relieve the constriction caused by edema.	• Peripheral pulses detectable • Signs of adequate peripheral perfusion
Paralytic Ileus		
1. Auscultate for	1. Presence of bowel	• Normal bowel

bowel sounds, abdominal distention. 2. Maintain nasogastric tube on low intermittent suction until bowel sounds resume.	sounds indicates normal peristalsis. Abdominal distention reflects inadequate decompression. 2. This measure relieves gastric and abdominal distention.	sounds • Absence of abdominal distention
Curling's Ulcer		
1. Assess gastric aspirate and stools for blood. 2. Administer histamine-2 blockers and/or antacids as prescribed.	1. Blood indicates possible gastric or duodenal ulcer bleeding. 2. Such medications reduce gastric acidity and risk of ulceration.	• Gastric aspirate and stools do not contain blood

Causative agents of burn infections include bacteria, fungi, or viruses. Hydrotherapy equipment, direct or indirect contamination from healthcare workers' hands, environmental surfaces, and translocation of microorganisms from other body systems—most notably, the GI tract—are all common sources of potential contamination in the burn unit that require hypervigilance. Whether the burn wound is healing through spontaneous reepithelialization or is being prepared for skin grafting, protection from pathogens is crucial. Infection impedes burn wound healing by promoting excessive inflammation and damaging tissue. Clinical signs of infection include progressive erythema, warmth, tenderness, and malodorous exudate.

A multiple-strategy approach is crucial in prevention and control of burn wound infections. Such strategies include:

- The use of barrier techniques (e.g., gowns, gloves, eye protection, and masks if needed)
- Environmental cleaning with periodic cultures of patient care equipment (with special attention to hydrotherapy equipment)
- Application of appropriate topical antimicrobial agents

- Appropriate use of systemic antibiotic and antifungal agents (careful use and close monitoring of culture sensitivities are needed due to increasing challenges of antibiotic resistance in healthcare environments)
- Early excision and closure of the burn wound
- Control of hyperglycemia (with insulin as indicated, even in a patient without a prior diagnosis of diabetes)
- Management of the hypermetabolic response (see Chapter 11)

There are varying practices in the burn community regarding obtaining cultures for surveillance. In some burn centers, patients may be cultured on admission to screen for the presence of regionally known pathogens. Wounds are generally cultured on admission, prior to cleaning, with each surgical case, and for clinical suspicion of infection. Antimicrobial therapy is tailored to culture results. The broad use of prophylactic antibiotics is not supported by current research (Ramos et al., 2017).

Wound Cleaning

Proper management of burn wounds prevents wound deterioration. The goal of wound care is removal of nonviable tissue and wound exudate, and elimination of previously applied topical agents. Gentle cleaning with mild soap, water, and a washcloth can prevent infection by decreasing the bacteria and debris on the wound surface. Hair in and around the burn area, except the eyebrows, should be clipped short or shaved.

Various processes may facilitate cleaning burn wounds. Patients who are hemodynamically unstable may have their wounds washed at the bedside, whereas patients who are ambulatory may shower themselves or with assistance. Patients who are nonambulatory can be bathed and receive wound care using shower carts—mobile stretchers made with removable sides, drainage holes, and positioning capabilities. Retractable water hoses suspended from walls and ceilings provide the nurse with easy access to a clean water source for washing the wounds. Whatever method employed, the goal is to protect the wound from acute proliferation of pathogenic organisms on the surface through mechanical washing to prevent invasion of deeper tissues until the wounds are closed through spontaneous healing or skin grafting. Strategies for the prevention of cross-contamination include the use of plastic liners on the shower carts and chairs, water filtration systems or point-of-care filters, and thorough decontamination of equipment after each use.

Patient comfort and ability to participate in the prescribed treatment are important considerations. During bathing, patient participation is

encouraged to promote exercise and range of motion of the extremities. During wound cleaning, the nurse inspects all skin for any signs of redness, breakdown, or local infection. This also provides the nurse an opportunity for targeted patient education.

During treatment, the patient is continuously assessed for signs of hypothermia. The temperature of the water is maintained at 37.8°C (100°F), and the temperature of the room should be maintained between 26.6° and 29.4°C (80° and 85°F) to prevent hypothermia. Other assessment considerations include patient fatigue, changes in hemodynamic status, and pain unrelieved by analgesic medications or relaxation techniques.

Topical Antibacterial Therapy

Variations in topical wound care for nonsurgical burn wounds exist among burn centers across the country. Selections are based on the individualized needs of each patient. The goal of topical therapy is to provide a dressing with the following characteristics:

- Effective against gram-positive and gram-negative organisms and fungi
- Penetrates the eschar but is not systemically toxic
- Is cost-effective, available, and acceptable to the patient
- Is easy to apply and remove, decreases the frequency of dressing changes, decreases pain, and minimizes nursing time

No single topical medication is universally effective, and the use of different agents at different times in the postburn period is best practice.

Quality and Safety Nursing Alert

Prudent use and alternation of antimicrobial agents can result in reduction of resistant strains of bacteria, greater effectiveness of the agents, and a decreased risk of sepsis. Table 57-4 describes select topical antimicrobial agents.

Wound Dressing

After the prescribed topical agents are applied, the wound is covered with several layers of dry dressings with lighter dressing over joints to allow for mobility. Dressings may also require modification to accommodate splints or other positioning devices. Circumferential dressings should

always be applied distally to proximally to promote return of excess fluid into the central circulation. In the case of hand or foot burns, the fingers and toes should be wrapped individually to promote mobility and function while healing.

Burns to the face may be left open to air once cleaned and the topical agent has been applied to maintain a moist environment. Careful attention ensures the topical agent does not come in contact with the eyes or mouth. A light, nonrestrictive dressing may be applied to the face to absorb excess exudate if needed.

Occlusive dressings, bulky gauze, and a topical antimicrobial agent may be used over areas with new skin grafts to protect the new graft and promote an optimal condition for its adherence to the recipient site. Ideally, these surgical dressings remain in place for 3 to 5 days, to allow growth of the microcirculation into the new graft before removal for inspection of the graft. When occlusive dressings are applied, precautions are taken to prevent two body surfaces from touching one another, such as fingers or toes, ear and scalp, the areas under the breasts, any point of flexion, or between the genital folds. Functional body alignment positions are maintained by using splints or by regular repositioning of the patient.

Quality and Safety Nursing Alert

Dressings can impede circulation if they are wrapped too tightly. The peripheral pulses must be checked frequently and burned extremities elevated. If the patient's pulse is diminished, this is a critical situation and must be addressed immediately.

TABLE 57-4  Overview of Select Topical Antimicrobial Agents Used for Burn Wounds

Agent	Indication/Comment	Application	Nursing Implications
General			
Antimicrobial ointment	Antibacterial coverage and promotion of a moist wound environment	Apply 1/16-inch layer of ointment with a clean glove daily.	Ensure removal of residual ointment at the time of wound cleaning prior to applying a new layer. Monitor closely for signs and symptoms of local infection.
Specific Agents			
Silver sulfadiazine 1% water-soluble cream	Bactericidal agent for many gram-positive and gram-negative organisms, as well as yeast and *Candida albicans* Minimal penetration of eschar	Apply 1/16-inch layer of cream with a clean glove 1–3 times daily.	Anticipate formation of pseudoeschar (proteinaceous gel), which can be removed.
Mafenide acetate 5% hydrophilic-based solution or cream	Antimicrobial agent for gram-positive and gram-negative organisms Diffuses through eschar and avascular tissue (e.g., cartilage)	Apply twice a day with a clean glove.	Is a strong carbonic anhydrase inhibitor and may cause metabolic acidosis. Application may cause considerable pain initially.
Silver nitrate 0.5% aqueous solution	Effective against most strains of *Staphylococcus* and *Pseudomonas* and many gram-negative organisms. Does not penetrate eschar	Apply solution to gauze dressing and place over wound. Keep the dressing wet but covered with dry gauze and dry blankets to decrease vaporization.	Monitor serum sodium (Na^+) and potassium (K^+) levels and replace as prescribed. Silver nitrate solution is hypotonic and acts as a wick for sodium and potassium. Protect bed linens and clothing from

			contact with silver nitrate, which stains everything it touches.
Silver-impregnated dressings (sheets or mesh)	Broad antimicrobial effects (product specific) Delivers a uniform, antimicrobial concentration of silver ions to the burn wound.	Apply directly to wound. Cover with absorbent secondary dressing if needed.	May produce a pseudoeschar from silver after application. Can be left in place for several days (product specific).

Dressings that adhere to the wound bed may be removed more comfortably and with less damage to healing tissue by moistening the dressing with water or saline. The patient may participate in removing the dressings, providing some degree of control over this painful procedure. The wounds are then cleaned and débrided to remove any remaining topical agent, exudate, and nonviable tissue. Sterile scissors and forceps may be used to trim loose eschar and encourage separation of devitalized tissue. During this procedure, the wound and surrounding skin are carefully inspected. Documentation should include color, odor, size, exudate, signs of reepithelialization, any changes from the previous dressing change, and other key characteristics.

Wound Débridement

The goals of **débridement** (removal of *devitalized* tissue) are:

- Removal of devitalized tissue or burn eschar in preparation for grafting and wound healing
- Removal of tissue contaminated by bacteria and foreign bodies, thereby protecting the patient from invasion of bacteria

There are four types of débridement—natural, mechanical, chemical, and surgical.

Natural Débridement

With natural débridement, the devitalized tissue separates from the underlying viable tissue spontaneously. Bacteria present at the interface of the burned tissue and healthy viable tissue gradually liquefy the fibrils of

collagen, a protein present in skin, tendon, bone, cartilage, and connective tissue, that hold the eschar in place. Proteolytic and other natural enzymes cause this phenomenon. The process may take weeks to months to occur.

Mechanical Débridement

Mechanical débridement involves the use of surgical tools to separate and remove the eschar. This technique, performed by primary providers, specially trained nurses, or physical therapists, is usually performed with routine dressing changes. If bleeding occurs, hemostatic agents or pressure may be applied to achieve hemostasis. Dressing changes and wound cleaning aid the removal of wound debris. Wet-to-dry dressings are not advised for burn care because of the possibility of removing viable epithelial cells along with necrotic tissue. Wet-to-wet or wet-to-moist dressings may be used instead.

Chemical Débridement

Topical enzymatic agents are available to promote débridement of burn wounds. Because such agents usually do not have antimicrobial properties, they may be combined with topical antibacterial therapy to protect the patient from bacterial invasion. Heavy metals such as silver can deactivate débriding agents; therefore, caution is necessary to ensure that the topical antimicrobial agent does not interfere with the chemical débridement. Alternating topical medications may also be effective in achieving débridement without infection.

Surgical Débridement

Early surgical excision to remove devitalized tissue along with early burn wound closure has long been recognized as one of the most important factors contributing to survival in a patient with a major burn injury. Surgical débridement occurs before the natural separation of eschar transpires from bacterial lysis of collagen fibers at the dermal–eschar junction. This may be performed as soon as possible after the burn, once the patient is hemodynamically stable and edema has decreased. Ideally, the wound is covered immediately with a skin graft (if necessary) and a dressing. If the wound bed is not ready for a skin graft at the time of excision, a temporary biologic or synthetic dressing may be applied until an autograft can be successfully applied during a subsequent surgery.

The use of surgical excision carries with it risks and complications, especially with large burns. The procedure creates a high risk of extensive

blood loss with lengthy operating and anesthesia times. Blood losses sustained during surgical procedures, wound care, and ongoing hemolysis exacerbate anemia. Blood transfusions may be required periodically to maintain adequate hemoglobin levels for oxygen delivery to the myocardium. See Chapter 28 for discussion of blood component therapy.

When conducted in a timely and efficient manner, surgical excision results in shorter lengths of stay and decreased risk of complications from invasive burn wound sepsis. Once débrided, granulation tissue fills the void created by the wound, creates a barrier to bacteria, and serves as a bed for epithelial cell growth. A wound covering is applied to keep the wound bed moist and promote the granulation process.

Wound Grafting

The patient with deep partial- or full-thickness burns may be a candidate for skin grafting to decrease the risk of infection; prevent further loss of protein, fluid, and electrolytes through the wound; minimize evaporative heat loss; and reduce scarring. Special attention is warranted when grafting the face (for cosmetic, functional, and psychological reasons); functional areas, such as the hands and feet; and areas over joints. Grafting permits earlier function and reduces scar **contractures** (shrinkage of burn scar through collagen maturation). When burns are very extensive, the order in which areas are grafted is chosen based on the ability to achieve wound closure as soon as possible; therefore, the chest and abdomen or back may be grafted first to reduce the overall open wound size.

Autografts

Autografting remains the preferred autologous method for definitive burn wound closure after excision. **Autografts** are the ideal means of covering burn wounds because the grafts are the patient's own skin and therefore are not rejected by the patient's immune system. They can be split-thickness, full-thickness, or epithelial grafts. Because the **donor site** (the area from which skin is taken to provide the autograft) for a full-thickness graft includes both the epidermis and dermis, its use must be cautiously considered because the donor site cannot heal spontaneously.

Split-thickness autografts are most commonly used and can be applied in sheets (see Fig. 57-7), or they can be expanded by meshing so that they cover more than a given donor site area (see Fig. 57-8). Skin meshers enable the surgeon to cut tiny slits into a sheet of donor skin, making it possible to expand, covering larger areas with smaller amounts of donor

skin. Expanded grafts adhere to the recipient site more easily than sheet grafts and prevent the accumulation of blood, serum, air, or purulent material under the graft that would prevent revascularization and adherence. However, any kind of graft other than a sheet graft contributes to scar formation as it heals. The use of widely meshed (largely expanded) grafts may be necessary in large wounds but should be viewed as a compromise in terms of cosmesis.

Figure 57-7 • Split-thickness sheet graft. Used with permission from University of Texas Medical Branch, Galveston, TX.

If blood, serum, air, fat, or necrotic tissue is present between the recipient site and the graft, there may be partial or total loss of the graft. Infection, mishandling of the graft, sheer injury with mobilization or trauma during dressing changes account for most other instances of graft loss. The use of split-thickness grafts allows the remaining donor site to retain sweat glands and hair follicles, minimizing healing time.

Cultured epithelial autograft (CEA) has emerged as an important procedure in the management of massive burns. In burns that cover more than 90% TBSA, CEA may be the only option because the availability of nonburned skin as donor sites will not be sufficient for grafting. CEA involves obtaining full-thickness biopsies of the patient's unburned skin

that are cultured to promote growth of keratinocytes. The final product is available approximately 3 weeks later for grafting (see Fig. 57-9). Meticulous attention is required to apply CEA to body surfaces because it is extremely fragile and prone to graft loss. Use of CEA can be cost prohibitive; besides its direct costs, it also requires inordinately extended LOS for the patient.

Figure 57-8 • Split-thickness meshed graft. Used with permission from University of Texas Medical Branch, Galveston, TX.

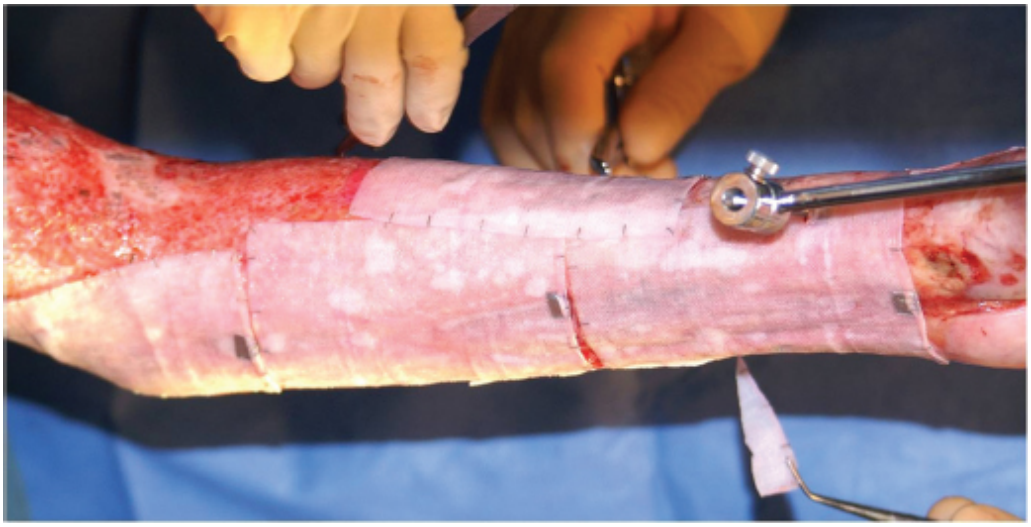

Figure 57-9 • Application of cultured epithelial autologous grafts. Used with permission from University of Texas Medical Branch, Galveston, TX.

Care of the graft site

Protection and immobility are key in caring for skin grafts postoperatively. Occlusive dressings encased in bulky gauze wraps are commonly used initially after grafting to immobilize the graft and support the humid environment required for optimal healing. Occupational or physical therapists may construct splints to immobilize joints affecting newly grafted areas. Homograft, xenograft, or synthetic dressings (discussed later) may also be used to protect fragile grafts or widely expanded meshed grafts.

The first dressing change is usually performed 3 to 5 days after surgery, or earlier if clinical signs of infection or bleeding are present. Infection, bleeding beneath the graft, and shearing forces are the most common reasons for graft loss in the early postoperative period. Patients must be positioned and turned carefully to avoid disturbing the graft or applying pressure on the graft site. If an extremity has been grafted, it is elevated to reduce edema. The patient may begin actively exercising the grafted area 5 to 7 days after surgery. This may vary with individual burn center's protocols.

Care of the donor site

The donor site is a clean, usually superficial wound created in a surgical environment that the surgeon uses to obtain a piece of skin for grafting of the wound bed. After the skin is excised, a hemostatic agent such as thrombin or epinephrine may be applied directly to the donor site to promote hemostasis. A myriad of dressings are available to cover donor

sites once hemostasis is obtained. Because a donor site is usually a partial-thickness wound, it is very painful, an additional potential site of infection, and very susceptible to pressure injury. With proper care, the donor site should heal spontaneously within 7 to 14 days in an adult who was previously healthy and nonsmoking (Foster, Richey, Osborn, et al., 2020).

Homografts and Xenografts

Homografts (or allografts) and **xenografts** (or heterografts) are also referred to as biologic dressings and are intended as temporary wound coverage. Homografts are pieces of skin obtained from recently deceased or living humans other than the patient. Xenografts consist of skin taken from animals (usually pigs). Therefore, the body's immune response will eventually reject either of them as a foreign substance.

In extensive burns, biologic dressings provide temporary wound coverage and protection of granulation tissue until autografting is possible. As a temporary dressing, they also decrease the wound's evaporative water and protein loss, provide an effective barrier against entry of bacteria, and decrease pain by protecting nerve endings. Biologic dressings can be left open to air or covered with a dressing. They stay in place for varying lengths of time, but are removed in instances of bacterial colonization, infection, or rejection of the dressing by the body. They may also be used as a test graft in preparation for autografting to determine if the wound bed will accept the graft. Once the biologic dressing appears to be "taking," or adhering to the granulating surface with minimal underlying exudation, the patient is ready for an autologous skin graft. Another advantage of biologic dressings is that fewer dressing changes may be required.

Homografts tend to be the most expensive biologic dressings. They are available from skin banks in fresh and cryopreserved (frozen) forms. Homografts are thought to provide the best infection control of all biologic or biosynthetic dressings available. Revascularization occurs within 48 hours, and the graft may be left in place for several weeks.

Pigskin, an effective xenograft, is available from commercial suppliers. It is available fresh, frozen, or lyophilized (freeze-dried) for longer shelf life. Pigskin is used for temporary covering of clean wounds such as superficial partial-thickness wounds and donor sites. Although pigskin does not vascularize, it adheres to clean superficial wounds, providing pain control and reducing evaporative fluid loss allowing the underlying wound to reepithelialize (Aly, Dannoun, Jimenez, et al., 2018).

When grafting is not possible, surgically applied skin substitutes have been created that replace the epidermis or the dermis either temporarily or permanently. Each provides advantages and disadvantages that are important to consider in product selection.

Biosynthetic and Synthetic Dressings

Problems with availability, sterility, and cost have prompted the search for biosynthetic and synthetic dressings, which may eventually replace biologic dressings as temporary wound coverings. There are currently many products on the market, but they tend to be cost prohibitive for most patients and in most healthcare settings.

Pain Management

A burn injury is considered one of the most painful types of trauma that a person can experience. The nature of the injury may expose nerve endings to the atmosphere; and the patient may require multiple procedures, débridements, surgeries, and treatments. Moving, changing position, and receiving occupational and physical therapy cause additional discomfort. Adequate pain management must address background, breakthrough, and procedural pain.

Background pain is a continuous level of discomfort experienced even when the patient is inactive or not undergoing any procedures. The goal of treatment is to provide a long-acting analgesic agent that will provide uniform coverage for this long-term discomfort. It is helpful to use small escalating doses when initiating analgesia to reach the level of pain control that is acceptable to the patient and facilitates their participation in recovery. The use of patient-controlled analgesia gives control to the patient and often achieves this goal.

Breakthrough pain is described as acute, intense, and episodic. It is generally related to an activity or movement of the affected area. Short-acting agents are used for breakthrough pain to achieve pain control if needed. Procedural pain is discomfort that occurs with procedures such as daily wound treatments, invasive line insertions, and physical and occupational therapy. The goal is to plan proper analgesia to facilitate comfort for the patient throughout the procedure.

Most severe burns are a combination of partial- and full-thickness burns that influence the amount of pain the patient experiences. Superficial and partial-thickness burns are very painful because the nerve endings are not protected, resulting in excruciating pain with exposure to temperature, pressure, air currents, and movement. In a full-thickness

burn, the nerve endings are destroyed, and there is numbness and decreased sensation to that area. Thus, the patient often underestimates severe injuries. Memories of the pain patients experience may persist for a long time. Educating patients and their families about burn pain and its relationship to the depth of injury as well as the pain management plan is an important priority for the nurse.

Pharmacologic treatment for the management of burn pain includes the use of opioids, nonsteroidal anti-inflammatory drugs, anxiolytics, and anesthetic agents. These and other pain management strategies are discussed in Chapter 9. For treatment of anxiety, benzodiazepines may be used in conjunction with opioids. The use of anesthetics in a nonoperative setting (i.e., moderate sedation) requires administration and monitoring by qualified personnel. Recent advances include the use of agents with rapid onset and short duration, which have been very effective in pain control during a planned procedure. In the provision of holistic patient care, the use of nonpharmacologic pain and anxiety interventions must not be overlooked. Nonpharmacologic therapies include relaxation techniques, distraction, guided imagery, hypnosis, therapeutic touch, humor, music therapy, and virtual reality techniques.

Modulation of Hypermetabolism

Burn injuries produce profound metabolic abnormalities fueled by the exaggerated stress response to the injury. The body's response has been classified as hyperdynamic, hypermetabolic, and hypercatabolic. Hypermetabolism can affect morbidity and mortality by increasing the risk of infection and slowing the healing rate.

Nutrition should be provided as soon as possible upon arrival to the burn center and may require placement of a nasogastric tube for adequate calorie delivery. Patients who are critically ill may even have their feedings continued intraoperatively if the airway is protected. Several formulas exist for estimating the daily metabolic expenditure and caloric requirements of patients with burn injuries. Carbohydrates are the most important energy source for patients who are severely burned (Culnan et al., 2018). Fat, although a required nutrient, should be provided in more limited quantities. When the oral route is used, high-protein, high-calorie meals and supplements are given. Dietary consultations are useful in helping patients meet their nutritional needs. Daily calorie counts aid in assessing the adequacy of nutritional intake.

Early excision and grafting of the burn wound is one of the most important factors in ameliorating hypermetabolism by removing eschar,

thereby lessening the effects of inflammatory mediators. Appropriate manipulation of environmental temperatures decreases energy expenditure by the patient (Rizzo, Rowan, Driscoll, et al., 2017). Insulin therapy in patients with burns is required to treat the hyperglycemia that occurs from accelerated gluconeogenesis and is beneficial in muscle protein synthesis. Oxandrolone, an anabolic steroid, is commonly given to patients with burns because it improves protein synthesis and metabolism. Administration of propranolol (a beta-blocker) decreases heart rate and blocks harmful catecholamine effects.

Nursing Management

Nursing management of the patient in the acute/intermediate phase is focused on the following priorities: restoring fluid balance, preventing infection, modulating hypermetabolism, promoting skin integrity, relieving pain and discomfort, promoting mobility, strengthening coping strategies, supporting patient and family processes, and monitoring and managing complications.

Restoring Normal Fluid Balance

To reduce the risk of fluid overload and consequent heart failure and pulmonary edema, daily weights and careful calculation of intake and output measurement are utilized to guide therapy. Thirst, a normal body response to hypovolemia, may cause the patient to drink excessive amounts of water, driving the serum sodium to dangerously low levels. Serum sodium levels should be trended as fluid shifts may lead to metabolic derangements. Changes in physical assessment and hemodynamic indicators are also useful in evaluating the patient's response to treatment.

Preventing Infection

The patient with burns is at risk for infection from multiple sources, which may include open wounds, lung injury, GI ischemia, and indwelling catheters. Increased temperature, tachycardia, tachypnea, and leukocytosis are inherently present in the patient with burns, masking clinical signs of infection. Therapeutic interventions are complex due to the patient's altered physiology.

A major part of the nurse's role during the acute phase of burn care is detection and prevention of infection. The nurse is responsible for providing a clean environment, including the promotion of protective

isolation interventions. The nurse protects the patient from sources of contamination, including other patients, staff members, visitors, and equipment. Patients can inadvertently promote migration of microorganisms from one burned area to another by touching their wounds or dressings. Bed linens can also spread infection through either colonization with wound microorganisms or fecal contamination. Regular bathing of unburned areas and changing of linens can help prevent infection. Fresh flowers, plants, and fresh fruit baskets are not permitted in the patient's room because of the risk of microorganism growth. Changing invasive lines and tubing routinely in accordance with Centers for Disease Control and Prevention (CDC) recommendations and institutional policy, and then promptly removing them when no longer indicated, will prevent many HAIs.

Modulating Hypermetabolism

The nurse collaborates with the dietitian or nutrition support team to develop a plan that meets the needs of the patient. Family members may be encouraged to bring nutritious and favorite foods to the hospital. High-calorie nutritional supplements may be necessary. Nutritional intake must be accurately documented. Vitamin and mineral supplements may be prescribed.

If caloric goals cannot be met by oral feeding, a feeding tube is inserted and used for continuous or bolus feedings of specific formulas. The volume of residual gastric secretions should be checked periodically to ensure absorption. The patient should be weighed each day and the results tracked to properly assess appropriate weight parameters and to attenuate catabolism of lean muscle mass.

Promoting Skin Integrity

Wound care is usually the single most time-consuming element of burn care after the emergent phase. The primary provider prescribes the desired topical antibacterial agents and specific biologic, biosynthetic, or synthetic wound coverings and plans for surgical excision and grafting. The nurse needs to make astute assessments of wound status, use creative approaches to dressing of wounds, and support the patient during the emotionally distressing and significantly painful experience of wound care.

Assessment of the burn wound requires an experienced eye, hand, and sense of smell. Important wound assessment features include size, color, odor, presence of eschar and exudate, epithelial buds (small pearl-like

clusters of cells on the wound surface), bleeding, granulation tissue, the status of graft take, healing of the donor site, and the condition of the surrounding skin. Any significant changes in the wound are reported to the primary provider because they may indicate burn wound infection and require immediate intervention.

The nurse also assists the patient and family by providing education, support, and encouragement to take an active part in dressing changes and wound care when appropriate. Discharge planning needs for wound care must be anticipated early in the course of burn management, and the strengths of the patient and family are assessed and used in preparing for the patient's eventual discharge and home care needs. Family presence during dressing changes promotes feelings of readiness for discharge.

Relieving Pain and Discomfort

Pain management continues to be a priority during the acute phase of burn recovery. Frequent assessment of pain is required, and analgesic and anxiolytic medications are administered as prescribed. To increase its effectiveness, analgesic medication is provided before the pain becomes severe. Nonpharmacologic interventions can be used to alter the patient's perceptions of and responses to pain. Frequent reassessment of responses to interventions, whether pharmacologic or nonpharmacologic, is essential.

Postburn pruritus (itching) affects almost all patients with burns and is one of the most distressing symptoms in the postburn period. Oral antipruritic agents, environmental conditions, frequent lubrication of the skin with water or silica-based lotion, and diversion activities all help to promote comfort in this phase. The instructions "pat, don't scratch" must be reinforced with patients in order to prevent further discomfort and infectious complications

Lack of sleep and rest interfere with healing, comfort, and restoration of energy. If necessary, sleep aids may be prescribed on a regular basis in addition to analgesic and anxiolytic agents.

Promoting Physical Mobility

An early priority is prevention of the complications of immobility. Deep breathing, turning, and proper positioning are essential nursing practices that prevent atelectasis and pneumonia, control edema, and prevent pressure injuries and contractures. Specialty beds may be useful, and early mobility is strongly encouraged. If the lower extremities are burned, elastic pressure bandages should be applied before the patient is placed in

an upright position to promote venous return and minimize edema formation.

The burn wound is in a dynamic state for at least 1 year after wound closure. During this time, aggressive efforts must be made to prevent contracture and hypertrophic scarring. Both passive and active range-of-motion exercises are initiated from the day of admission and are continued after grafting within prescribed limitations. Splints or functional devices applied to the extremities may lessen contractures through compression and stretch. The nurse monitors the splinted areas for signs of vascular insufficiency, nerve compression, and skin breakdown. Occupational and physical therapists are consulted to develop a patient-specific plan of care throughout hospitalization and recovery.

Strengthening Coping Strategies

Much of the patient's energy goes into maintaining vital physical functions and wound healing in the early postburn weeks, leaving little emotional energy for coping. In the acute phase of burn care, the patient is facing the reality of the burn injury. Grief, depression, anger, regression, and manipulative behavior are common responses of patients who have burn injuries. Withdrawal from participation in required treatments and regression must be viewed with an understanding that such behavior may help the patient cope with an enormously stressful event.

The patient may experience feelings of anger. At times, the anger may be directed inward because of a sense of guilt, perhaps for causing the fire or even for surviving when others perished. The anger may also be directed outward toward those who escaped unharmed or those who are now providing care. One way to help the patient handle these emotions is to enlist someone to whom the patient can express feelings without fear of retaliation. A nurse, social worker, psychiatric liaison nurse, peer supporter, spiritual advisor, or counselor who is not involved in direct care activities may fill this role successfully.

Patients with burn injuries are very dependent on healthcare team members during the long period of treatment and recovery. However, even when physically unable to contribute much to self-care, they should be included in decisions regarding care and encouraged to assert their individuality in terms of preferences and recognition of their unique identities. As the patient improves in mobility and strength, the nurse works with the patient to set realistic expectations for self-care and planning for the future. Many patients respond positively to the use of contractual agreements and other strategies that recognize their

independence, set expectations for behavior, and encourage positive communication.

Supporting Patient and Family Processes

The life-altering burn injury has tremendous psychological, economic, and social impact on the patient and family. The nurse is instrumental in providing support to the patient and family as they adapt to the burn injury. Referrals for social services or psychological counseling should be made as appropriate. This support continues into the rehabilitation phase. Some burn centers offer structured support programs which provide evidenced-based communication training to patients who have survived a burn injury with the goal of helping them to become more effective peer supporters. The peer supporter will visit the hospitalized patient to provide psychosocial support. Many patients appreciate the opportunity to be able to share their experience with another person who has had a burn injury.

With only 70 verified burn centers in the United States (ABA, 2019), patients who experience major burns are commonly sent to burn centers far from home. Because burn injuries are sudden and unexpected, family roles are disrupted. If the primary caregiver or wage earner in the family is injured, roles may change, which adds more stress to the family. Therefore, both the patient and the family need thorough information regarding the patient's burn care and expected course of treatment. Barriers to learning and preferred learning styles are assessed and considered. This information is used to tailor education activities. Patient and family education is a priority and is best provided with a multimedia approach.

Monitoring and Managing Potential Complications

Acute Respiratory Failure and Acute Respiratory Distress Syndrome

The patient's respiratory status is monitored closely for increased difficulty in breathing, change in respiratory pattern, or onset of adventitious (abnormal) breath sounds. Typically, at this stage, signs and symptoms of injury to the respiratory tract become apparent. As described previously, signs of hypoxia, diminished breath sounds, wheezing, tachypnea, stridor, and sputum tinged with soot (or in some cases containing sloughed tracheal tissue) are among the many possible findings. Medical management of the patient with acute respiratory

failure requires intubation and mechanical ventilation (if not already in use). If ARDS has developed, higher oxygen levels, positive end-expiratory pressure, and pressure support are used with mechanical ventilation to promote gas exchange across the alveolar–capillary membrane (see Chapter 19).

Heart Failure and Pulmonary Edema

If the cardiac and renal systems cannot compensate for the excess vascular volume as fluid shifts back to the intravascular space, heart failure and pulmonary edema may result. The patient is assessed for signs of heart failure, including decreased cardiac output, oliguria, jugular vein distention, persistent edema, and the onset of an S_3 or S_4 heart sound. If invasive hemodynamic monitoring is used, increasing central venous, pulmonary artery, and pulmonary artery wedge pressures indicate increased fluid volume.

Crackles in the lungs and increased difficulty with breathing may indicate pulmonary edema, which should be reported promptly to the primary provider. In the meantime, the patient is positioned comfortably, with the head of the bed raised (if not contraindicated by other treatments or injuries) to promote lung expansion and gas exchange. Management of this complication includes providing supplemental oxygen, administering IV diuretic agents, carefully assessing the patient's response, and providing vasoactive medications, if indicated (see Chapter 25).

Sepsis

Sepsis is a leading cause of morbidity and mortality in patients with burn injuries. The signs of early sepsis are subtle, requiring a high index of suspicion and very close monitoring of changes in the patient's status. One of the challenges in recognizing sepsis is that burns are a noninfectious condition that triggers the systemic inflammatory response syndrome (SIRS), making it difficult to predict and diagnosis sepsis (Hill, Percy, Velamuri, et al., 2018). Because patients with burns are hypermetabolic, they display tachycardia, tachypnea, and elevated body temperature. These physiologic norms in patients with burns make the diagnosis of sepsis more challenging. See Chapter 11 for treatment recommendations for sepsis.

Delirium

Delirium, a transient and often reversible state of acute brain dysfunction which manifests as alterations in consciousness or cognitive function

compared to the patient's baseline, may occur in patients secondary to the trauma sustained. Symptoms include restlessness, disorientation, sleep disorders, or anxiety; some patients experience hallucinations, delusions, or even become combative or suicidal. In patients with burns, a higher incidence of delirium has been found in those with a history of psychiatric issues or substance abuse, or in those with larger burns (Low, Meyer, Willebrand, et al., 2018).

There is ample literature to support the negative impact that pain, anxiety, and agitation have on both clinical and functional outcomes for patients with critical illnesses, yet this is not so for patients with burns who are in critical-care units. Depetris, Raineri, Pantet, and colleagues (2018) sought to assess current analgesia, sedation, and delirium monitoring and treatments in critical burn care to evaluate practice variations and adherence to current evidence-based practices. Although they found increasing awareness of patient delirium among burn care providers, delirium prevention practices vary widely, and they recommend further studies to establish burn-specific guidelines for prevention and treatment of this critical complication of severe burns (see Nursing Research Profile in Chart 57-6).

Chart 57-6  **NURSING RESEARCH PROFILE**

Nursing Knowledge, Attitudes, and Beliefs About Delirium in a Burn ICU

Powell, T. L., Nolan, M., Yang, G., et al. (2019). Nursing understanding and perceptions of delirium: Assessing current knowledge, attitudes, and beliefs in a burn ICU. *Journal of Burn Care and Research*, *40*(4), 471–477.

Purpose

Patients with burns are at high risk for the development of delirium due to analgesia and sedation needs, prolonged mechanical ventilation, multiple operative procedures, and extended intensive care unit (ICU) stays. Delirium has grave negative effects on morbidity, mortality, and cognitive function and is common in this population. As the caregiver who spends the most time with the patient, the nurse must be attuned to early signs of delirium and initiate treatment. The purpose of this study was to evaluate and improve nurses' perceptions, attitudes, and knowledge about delirium while increasing compliance with administration of the Confusion Assessment Method for the ICU (CAM-ICU) tool and preventive interventions.

Design

The setting for this study was an 18-bed multispecialty burn ICU for both adults and children. Participants completed a survey that assessed attitudes regarding delirium, use of the CAM-ICU, and general knowledge of delirium before and after an educational intervention designed to improve recognition, prevention, and management of delirium The researchers conducted a review of the literature and sought expert consultation to inform the development of the survey, which included select items used in the American Nurses Association (2015), study on delirium. In addition, post intervention, participants were asked to evaluate the effectiveness of the educational activities. The educational intervention, which occurred over 7 months, consisted of training a group of delirium nurse champions to serve as expert resources for the staff, creating an education board that addressed common questions and myths regarding delirium, and coordinating a week dedicated to delirium educational activities, including short videos and question and answer sessions.

Findings

Twenty-seven (38%) of the 71 burn ICU nurses participated in the project. Staff compliance with administration of the CAM-ICU assessment increased to 90% during the review time, and positive scores on the CAM-ICU decreased from 21% to 14%. Survey results indicated that nurses recognized the importance of assessing delirium

and providing interventions. However, 26% of the nurses did not endorse the need for the CAM-ICU as a screening tool. Qualitative themes described existing knowledge of delirium and knowledge gaps, barriers to implementation of the CAM-ICU, and views on nonpharmacologic and pharmacologic nursing interventions.

Nursing Implications

The results from this study support that targeted education increased awareness and general knowledge of delirium, as well as appropriate nursing interventions. However, the authors found that participants perceived challenges to using the CAM-ICU, including the time it takes to conduct the assessment and the complexity of using it with patients who are non-English speaking, sedated, or intubated, which limited behavioral change or consistent use of the tool. In general, staff perceived the project as empowering, specifically as the project helped to reinforce the role that nurses play in delirium prevention and management and the positive difference that their interventions make in this patient population.

Rehabilitation Phase

Rehabilitation begins immediately after the burn has occurred and often extends for years after the initial injury. For nurses who care for patients with burns, this can be one of the more physically demanding and challenging phases. One important focus of the burn team is to evaluate the patient carefully for late complications related to burn injuries as described in Table 57-5.

Burn rehabilitation is comprehensive, complex, and requires a multidisciplinary approach to optimize the patient's physical and psychosocial recovery related to the injury. As patients begin to recover, they become more aware of the injuries and challenges they face. Individualized plans of care that are specific to the severity and location of injury are developed and reevaluated frequently. The increased survival of patients with significant burn injuries has translated into the need for additional and comprehensive burn rehabilitation programs worldwide. The ultimate goal is to return patients to the highest level of function possible within the context of their injuries. Specially trained occupational and physical therapists are essential for optimal patient outcomes.

Psychological Support

A patient's outlook, motivation, and support system are important to their overall well-being and ability to progress through the rehabilitation phase. Psychiatric disorders may have contributed to the cause of the burn injury itself. Examples include self-inflicted burns, suicide attempts, or intentional infliction on one person by another in cases of abuse. These are a few examples that illustrate the critical need for psychosocial resources in burn recovery. Although psychiatric disorders are not contributory to all burn injuries, the life-altering nature of burn injuries almost always causes temporary or permanent impairment of psychosocial adaptation.

In the acute phase of the injury, acute shock, terror, disbelief, confusion, and anxiety are common. Patients may be at risk for delirium and may experience temporary psychoses. Patients may be confused from medications they are taking, but they have an underlying sense of fear, anxiety, and pain. Early consultation with mental health professionals will assist in best meeting individual needs, which may include pharmacologic interventions with concurrent counseling. The rehabilitation phase may present a new set of challenges. While the patient is physically recovering, the reality and impact of the injury begin to set in as patients recognize that survival is expected. Patients may experience devastating grief and loss. The sense of loss may originate from physical injury, loss of control from the forced dependency on others for care, or loss of family members/friends who may have died from burn injuries. In residential fires, survivors may have lost their homes and all of their possessions.

TABLE 57-5  Complications in Rehabilitation Phase of Burn Care

Complications	Contributing Factors	Interventions
Neuropathies and nerve entrapment	Electrical injury, large deep burns, improper positioning, edema, scar tissue	Assess peripheral pulses and sensation (neurovascular checks). Prevent edema and pressure by elevation, positioning, and prevention of constricting dressings. Assess splints for proper fit and application. Consult OT and PT departments for positioning.
Wound breakdown and/or pressure injury formation	Shearing, pressure, inadequate nutrition	Protect wound from pressure and shearing forces. Educate patient about importance of good nutrition.
Hypertrophic scarring	Partial- and full-thickness burns	Keep skin pliable and soft by using emollients. Apply pressure garments as prescribed. Massage.
Contractures	Partial- and full-thickness burns	Maintain position of joints in alignment. Perform gentle range-of-motion exercises. Consult OT and PT departments for exercises and positioning recommendations.
Joint instability	Burn wound, burn scar, and contractures	Maintain appropriate joint positioning through appropriate application of splints. Monitor joint pinning if indicated.
Complex pain	Trauma and burns	Provide adequate pain management. Consult OT and PT departments for exercises and desensitization. Promote gentle motion of affected extremities.

OT, occupational therapy; PT, physical therapy.

Adapted from Serghiou, M. A., Ott, S., Cowan, A., et al. (2018). Burn rehabilitation along the continuum of care. In D. Herndon (Ed.). *Total burn care* (5th ed.). Edinburgh: Saunders Elsevier; Thananopavarn, P., & Hill J. J. (2017). Rehabilitation of the complex burn patient with multiple injuries or comorbidities. *Clinics in Plastic Surgery*, *44*(4), 695–701.

Posttraumatic stress disorder (PTSD) is a common psychiatric disorder in patients with burns. Patients with PTSD re-experience the injury event, exhibit an intensified perception of threat, and employ avoidance behaviors that sustain the symptoms (Low et al., 2018). Other psychological disorders that may be experienced by patients with burns include anxiety, depression, and sleep disturbances. The symptoms and psychological responses to stress are discussed further in Chapter 5.

As recovery progresses, discharge planning must include strategies to assist the patient in reintegrating into their home, community, workplace, and school. For many patients, issues regarding quality of life may become very real at this point in recovery. This is an emotional time as the patient and family begin to live with new physical limitations and challenges in relationships. In addition to preparing the patient's support system, the patient and family must also prepare for the reactions from strangers.

Organizations such as the Phoenix Society for Burn Survivors, an international support group for patients with burns, offer a myriad of resources, education, opportunities for peer support, and strategies for reintegration. Alan Breslau, a survivor of burn injuries, who recognized the importance of peer support in psychosocial recovery (see the Resources section), founded the Phoenix Society in 1977. Peer support provides opportunities for reflection and personal growth and gives new meaning for the patient with burns through sharing experiences with others with similar burn injuries. Each year, the Phoenix Society hosts the World Burn Congress, which is a conference for survivors, their families, caregivers, burn care professionals, and firefighters. This forum offers education as well as an opportunity for patients with burns and their families to connect with others who have experienced similar life-changing events. Such interaction allows the patient and family to see that adaptation to a burn injury is possible.

Organizations that provide support for reintegration are able to offer education and training geared specifically to patients with burn injuries. Workshops on how to apply makeup to reduce the appearance of scars can benefit those with obvious facial scarring. This is one example of a strategy available to assist patients with burns who have body image

disturbances. Cultural influences play a strong factor in this process, because some cultures are particularly sensitive to physical appearance, a focus of importance which may also be reinforced by current media practices. The role of the nurse is to encourage patients to voice their concerns, provide empathy, and provide them with assistive resources.

Abnormal Wound Healing

Partial-thickness wounds involving the epidermis and superficial dermis tend to heal without scarring. Deeper wounds will likely develop scarring of variable degrees. As with other disorders, risk factors may be stratified as modifiable or nonmodifiable. For example, a nonmodifiable risk factor for scarring is heredity, because some patients are simply more prone to hypertrophic scar formation. The focus of patient education for nurses must be on how to best change or adapt the *modifiable* risk factors. Patients should be strongly encouraged to follow occupational therapist recommendations for scar prevention and management.

Normal scarring occurs in a superficial tissue injury and begins forming within 7 to 10 days post injury and progresses over the next 6 to 12 months. Abnormal scarring occurs after a longer period of wound healing and may form either hypertrophic or keloid scars.

Hypertrophic and Keloid Scars

Hypertrophic scars form within the boundaries of the initial wound and push outward on the perimeter of the wound. They are common in areas over joints and in the younger population. The scar becomes red (due to its hypervascularity), raised, and hard.

Keloid scars are irregularly formed and extend beyond the margins of the original wound. They are large, nodular, and ropelike, often causing itching and tenderness. They are more common in dark-pigmented skin, uncommon in children and older adults, and have familial tendencies.

Prevention and Treatment of Scars

Preventive treatment modalities aimed at scar contractures and excess hypertrophic tissue are routinely employed. Compression is introduced early in burn wound treatment. Elastic bandage wraps used initially help promote adequate circulation, but they can also be used as the first form of compression for scar management, followed by elasticized tubular bandages until the patient can be measured for a customized garment. Application of elastic pressure garments loosens collagen bundles and

encourages parallel orientation of the collagen to the skin surface. As pressure continues over time, collagen restructures and vascularity decreases. Although this therapy is somewhat controversial, pressure has shown to be beneficial in controlling scar formation over time (DeBruler, Baumann, Blackstone, et al., 2019). Recommended garment wear time is 23 hours per day; removing for bathing or wound care only.

Many areas of the body are difficult to compress due to the contours or location of the injury. Inserts, such as silicone sheets, are helpful for these small troublesome areas and are placed beneath the garment or compression dressing to enhance scar compression. Gentle superficial scar massage can be performed with a moisturizer several times a day.

Burn reconstruction is a treatment option after scars have matured and is discussed within the first few years after injury. This decision requires individualized planning, realistic expectations, and patience. The treatment team and the patient will ultimately decide on the best approach for long-term functionality and cosmesis.

NURSING PROCESS

Care of the Patient during the Rehabilitation Phase

Assessment

The nurse obtains information about the patient's education level, occupation, leisure activities, cultural background, religion, and family interactions. The patient's self-concept, mental status, emotional response to the injury and subsequent hospitalization, level of intellectual functioning, previous hospitalizations, response to pain and pain relief measures, and sleep pattern are also essential components of a comprehensive assessment. Information about the patient's general self-concept, self-esteem, and coping strategies in the past are valuable in assessing emotional needs.

Ongoing physical assessments related to rehabilitation goals include range of motion of affected joints, functional abilities in ADLs, early signs of skin breakdown, evidence of neuropathies (nerve damage), activity tolerance, and quality or condition of healing skin. The patient's participation in care and ability to demonstrate self-care in such areas as ambulation, eating, wound cleaning, toileting, and applying pressure wraps are documented on a regular basis.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, nursing diagnoses may include the following:

- Activity intolerance associated with pain with exercise, limited joint mobility, muscle wasting, and limited endurance
- Disturbed body image associated with altered physical appearance and self-concept
- Impaired mobility due to contractures or hypertrophic scarring
- Lack of knowledge about postdischarge home care and recovery needs

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATION

Potential complications may include the following:

- Inadequate psychological adaptation to burn injury

Planning and Goals

The major goals for the patient include increased mobility and participation in ADLs; adaptation and adjustment to alterations in body image, self-concept, and lifestyle; increased understanding and knowledge of the injury, treatment, and planned follow-up care; and absence of complications.

Nursing Interventions

Promoting Activity Tolerance

The extensive physical rehabilitation can be painful and challenging for the patient. Strategies to maintain motivation and participation may be beneficial during this critical phase. The nurse incorporates physical and occupational therapy exercises in the patient's care to prevent muscle atrophy and to maintain the mobility required for daily activities. The patient's activity tolerance, strength, and endurance gradually increase if activity occurs over increasingly longer periods. Monitoring of fatigue and pain tolerance will assist with determining the amount of activity to be encouraged on a daily basis. Activities such as family visits and recreational therapy (e.g., video games, radio, television) can provide diversion, improve the patient's outlook, and increase tolerance for physical activity. In older adult patients and those with chronic illness and disability, rehabilitation must take into account preexisting functional abilities and limitations.

The nurse must schedule care in such a way that the patient has periods of rest and uninterrupted sleep. A good time for planned patient rest is after the stress of dressing changes and exercise, while pain interventions and sedatives are still effective. This plan must be clearly communicated to family members and other care providers. The patient may have insomnia related to frequent nightmares about the burn injury or other fears and anxieties about the outcome of the injury. The nurse reassures the patient and administers agents, as prescribed, to promote sleep. Reducing metabolic stress by relieving pain, preventing chilling or fever, and promoting the physical integrity of all body systems helps the patient conserve energy for therapeutic activities and wound healing.

Improving Body Image and Self-Concept

Patients who have survived burn injuries may lack the benefit of anticipatory grief often seen in a patient who is approaching surgery or dealing with the terminal illness of a loved one. As care progresses, the patient who is recovering from burns becomes aware of daily improvement and begins to express basic concerns: Will I be

disfigured or be disabled? How long will I be in the hospital? What about my job and family? Will I ever be independent again? How will this injury affect my sexual relationships? How can I pay for my care? Was my burn the result of my carelessness? Where will I live now?

When caring for a patient with a burn injury, the nurse needs to be aware that there are prejudices and misunderstandings in society about those viewed as different. Opportunities and accommodations available to others are often denied to those disfigured by scarring associated with a burn injury. These include social participation, employment, prestige, various roles, and status. The healthcare team must actively promote a healthy body image and self-concept in patients with burn injuries so that they can accept or challenge others' perceptions of those who are disfigured or disabled. Survivors themselves must show others who they are, how they function, and how they want to be treated.

Promoting Physical Mobility Through Preventing Contractures or Hypertrophic Scar Formation

With early and aggressive physical and occupational therapy, contractures or hypertrophic scars are rarely a long-term complication. However, surgical intervention is indicated if full range of motion in the patient with burns is not achieved.

Monitoring and Managing Potential Complications

Impaired Psychological Adaptation to the Burn Injury. Some patients, particularly those with limited coping skills or psychological function, or a history of psychiatric problems before the burn injury, may not achieve adequate psychological adaptation to the burn injury. Psychological counseling or psychiatric referral may be made to assess the patient's emotional status, to help the patient develop coping skills, and to intervene if major psychological issues or ineffective coping is identified.

Promoting Home, Community-Based, and Transitional Care

Educating the Patient About Self-Care. The focus of rehabilitative interventions is directed toward outpatient care, home care, or care in a rehabilitation center. This includes wound care, dressing changes, pain management, nutrition, prevention of complications, and other care needs. Information and written instructions are provided about specific exercises and the use of

pressure garments and splints. The patient and family are provided education to assist them in their continued care needs after discharge (see Chart 57-7).

Continuing and Transitional Care. After discharge, care by a multidisciplinary treatment team is necessary. Some patients may require the services of an inpatient rehabilitation center before returning home. Patients should receive follow-up from a burn center when possible for periodic evaluation by the burn team, modification of outpatient treatment plan, and evaluation for reconstructive surgery. Many patients require outpatient physical or occupational therapy several times a week. The nurse coordinates all aspects of care and ensures that the patient's needs are met. Such coordination is an important aspect of assisting the patient to achieve independence.

Some patients may require referral for transitional care after discharge. The nurse assesses the patient's physical and psychological status as well as the adequacy of the home setting for safe and adequate care. The nurse monitors the patient's progress; assesses adherence to the plan of care; and assists the patient and family with wound care, exercises, and other physical needs. Patients experiencing difficulties with psychosocial adjustments are identified and appropriate referrals are made (see Chapter 2, Chart 2-6, for further discussion about assisting the patient's preparation for home care).

Evaluation

Expected patient outcomes may include:

1. Demonstrates adequate activity tolerance
    a. Has energy available to perform daily activities
    b. Shows gradual increased tolerance and endurance in physical activities
    c. Obtains adequate sleep and rest daily
2. Adapts to altered body image
    a. Verbalizes accurate description of alterations in body image and accepts physical appearance
    b. Demonstrates interest in resources that may improve function and perception of body appearance (e.g., cosmetics, wigs, and prostheses as appropriate)
    c. Socializes with significant others, peers, and usual social group
    d. Seeks and achieves return to role in family, school, and community as a contributing member

3. Demonstrates physical mobility adequate to perform ADLs
   a. Demonstrates range of motion appropriate for injury
   b. Absence of complications from wound healing
4. Demonstrates knowledge of required self-care and follow-up care
   a. Verbalizes detailed plan for follow-up care
   b. Demonstrates ability to perform or direct wound care and prescribed exercises
   c. Returns for follow-up appointments as scheduled
   d. Identifies resource people and agencies to contact for specific problems
5. Exhibits no complications
   a. Exhibits psychosocial adaptation to burn injury
   b. Verbalizes understanding of diagnosis and treatment plan

Outpatient Burn Care

The increased availability of outpatient surgery and access to expert burn care in outpatient settings make this option possible for the treatment of minor burns as well as follow-up for the patient with more severe burns once discharged. The goals for treatment in an outpatient setting may include burn wound management, pain management, scar and reconstructive care, psychosocial care, and rehabilitation. However, a number of factors must be considered when determining if outpatient care is appropriate for the patient: age, past medical history, extent and depth of the burn, location of the burn wounds, availability of family support systems and community resources, the patient's ability and willingness to adhere to a therapeutic regimen, distance from home to the outpatient setting, and availability of transportation to and from home and the outpatient setting.

Chart 57-7  **HOME CARE CHECKLIST**

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the burn injury and treatment on physiologic functioning, performance of ADLs and IADLs, roles, relationships, and spirituality.
- State how to contact all members of the treatment team (e.g., interdisciplinary burn team, healthcare providers, home care professionals, and durable medical equipment and supply vendors).
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate psychosocial adaptation and social integration through verbalizing understanding of the following:
  - Changes in lifestyle and emotional adjustment to injury take time. It is not uncommon for patients to report nightmares or “flashbacks” of the injury. If this becomes disruptive, it should be discussed with the treatment team.
  - Resume previous interests and activities gradually.
  - Consider community and other resources such as burn support groups. Many books, videos, and Web sites are also available and may be invaluable in assisting with burn recovery.
  - Programs are available to assist with school reintegration and return to work. The treatment team should be consulted as needed.
  - Burn care (dressings, medications, therapy) can be very expensive. A social worker or care manager may find funding assistance programs if needed.
- Demonstrate adaptation of the home environment, assisted as needed by team members (e.g., social worker, care manager).
- State burn skin precautions:
  - Apply sunblock with the highest sun protection factor (SPF) possible to protect exposed burned skin from the sun. Light-colored clothing, long pants, and long-sleeved shirts may also be necessary to protect from the sun.
  - Use wide-brimmed hats if face or ears have been burned to protect the area from the sun.
  - Avoid further trauma to burned skin; leave blisters that may form intact.

- Lubricate healed burned skin with lotion (as prescribed); avoid scratching.
- Use only mild soaps and lotions (i.e., products without perfume or deodorants) on burned areas. Keeping skin clean overall is important to support good hygiene and prevent infection.
- Avoid tight clothing over burned areas so as not to restrict movement or irritate newly healed areas.
- Select white cotton, loose-fitting clothing so that dyes in colored clothes do not irritate healing skin.
- Wear clothing and gloves to protect healing skin from unnecessary bruises, bumps, and scratches.
- Be aware that tolerance to extremes in temperatures may be affected.
- Itching is a normal, uncomfortable part of healing and burn recovery; do not scratch, pat areas; apply mild moisturizers to decrease itching from dryness. Medications for itching can be discussed with the treatment team.

- Demonstrate wound care technique:
  - Take prescribed pain medications if needed 30 minutes prior to wound care to achieve maximum effectiveness.
  - Use mild soap, water, and a clean washcloth to clean wounds.
  - Apply prescribed topical medications and dressings as instructed.
  - Inspect wounds carefully with each dressing change for signs of infection, including increased redness, swelling, drainage, or foul odor.
- State aspects of ADLs and exercise:
  - Perform as much of own care as possible.
  - Adhere to the exercise regimen given by the therapists. Although physical rehabilitation is tiring, daily participation is essential.
  - Plan for adequate rest and sleep.
  - When at rest, swollen limbs should be elevated.
  - Describe approaches to controlling pain (e.g., take antispasmodic agents as prescribed; use nonpharmacologic interventions).
  - State changes in diet necessary to promote health (e.g., nutrient-rich foods, rather than empty calories).
  - State changes in fluid intake needed to prevent constipation associated with the use of analgesic medications.
- Discuss management of burn scar:

- Massage with mild lotion or cream to stretch skin to maintain/increase its elasticity.
- Wear compression garments 23 hours a day if instructed.
- Discoloration of the skin for many months is an expected normal part of healing.

- Discuss resumption of intimacy:
  - Resumption of sexual relationships is the rule rather than the exception and should occur when comfortable for all.
  - Expect sensitivity of and around the genital area for several months if these areas were burned.
- State correct use of medical devices:
  - Follow occupational therapist's instructions for splint use and cleaning.
  - Use crutches, walkers, or other assistive devices as instructed.
  - If devices such as shower chairs or grab bars are needed in the home, this should be arranged prior to discharge.
- State time and date of follow-up appointments, therapy, and testing:
  - Keep a list of questions to ask team members.
  - Bring medications, or a list of current medications, to each visit for the team to review.
- Identify the need for health promotion, disease prevention, and screening activities.
- Identify the contact details for support services for patients and their caregivers/families.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

The frequency of follow-up visits is individualized. The initial outpatient visit for a discharged patient with burn injuries is usually scheduled within 3 to 5 days after hospital discharge. A survivor's follow-up appointment schedule will vary and decrease in frequency over time, based on patient's needs. Patient and family education is paramount and should include verbal and written instructions as well as return demonstration of the wound or scar care required. The importance of notifying the outpatient setting about changes in symptoms and of keeping follow-up appointments is emphasized to the patient and family. Physical therapy and occupational therapy are often provided in the outpatient burn setting. The rehabilitation goals are to increase range of motion, strengthen muscles, and build the patient's activity tolerance

through a specific, individualized plan of care that includes routine visits for up to 2 years or more following the injury.

The patient's adaptation to lifestyle changes and emotional status should be assessed during the outpatient visits and proper referrals made for counseling services. These assessments may be difficult to recognize due to the infrequent nature of the visits; therefore, it is helpful to incorporate family response and interactions into the assessment. The healthcare team must also be alert to issues of substance abuse, safety concerns, suicidal thoughts, depression, and PTSD.

CRITICAL THINKING EXERCISES

1 ebp A 55-year-old man is hospitalized for a smoke inhalation injury with a 15% TBSA burn to his upper torso and extremities. He has been placed on 100% oxygen per non-rebreather mask and started on a morphine drip for pain control. He awakens when verbally stimulated, but he does not consistently follow directions. Which evidence-based tools should you use to assess the patient's neurologic and pulmonary status, and his response to pain management? What evidence-based nursing interventions should be integrated into the plan of care to support his pulmonary status and to manage the distress associated with his burn and high oxygen requirement?

2 pq A 65-year-old man was admitted overnight to the burn unit with an 18% partial-thickness scald burn. The day after admission, in the early afternoon, you note that the patient's heart rate has increased to 160 bpm, temperature is 38.7°C (101.7°F), and his capillary refill time has increased to greater than 2 seconds. After alerting the charge nurse, what interventions do you anticipate? What are your priority interventions?

3 ipc An 85-year-old woman is admitted to the burn center with a 65% TBSA full-thickness burn. She is a widow, with no living children, but has a neighbor who is her identified surrogate decision maker. Her body mass index (BMI) on admission is 16.7 kg/m^2 and she reports weight loss over the last year and a poor appetite. She takes no medications and has not seen a medical provider for many years. She reports a strong religious background and states that she believes that God has always watched over her and is doing so now. She consents to a workup for a mass that was observed in a routine chest x-ray. A biopsy of the lesion obtained after consent shows a poorly differentiated adenocarcinoma. She continues to agree to daily wound care but refuses surgery. The oncology consulting service states that she may benefit from chemotherapy. The surgery team believes that she would benefit from supplemental feeding via a feeding tube. Her pain is well controlled. What interprofessional consultation service could help to best facilitate patient-centered outcomes for this patient? Describe how the various members of this team could support this patient.

UNIT 14

Sensory Function

Case Study

MAKING A RAPID CHANGE TO TELEHEALTH

A 72-year-old female is due for a follow-up appointment at the outpatient ophthalmology clinic where you work. She has a history of type 2 diabetes, hypertension, and elevated cholesterol. During

her previous visit, she reported her vision was blurred when watching television and that she stopped driving after dark as she could not see properly; she was subsequently diagnosed with diabetic retinopathy. However, there is an outbreak of coronavirus disease 2019 (COVID-19) within your community; the health network system that manages the ophthalmology clinic has responded by mandating that telehealth be used through video conference service to manage all patients for clinic visits. How will you assist the clinic staff as well as the patients, particularly this patient with poor vision, to make a rapid transition to telehealth visits while also assuring continued quality outcomes?

QSEN Competency Focus: **Informatics**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Informatics Definition: Use information and technology to communicate, manage knowledge, mitigate error, and support decision-making.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Identify essential information that must be available in a common database to support patient care	Transitioning to telehealth in a short period of time can be challenging. How can you help communicate essential information and streamline the process of change?
Contrast benefits and limitations of different communication technologies and their impact on safety and quality	What are the benefits and limitations of using telehealth, especially with patients with low vision?
Describe examples of how technology and information management are related to the quality and safety of patient care	Describe how the implementation of telehealth in an outpatient clinic will increase the quality and safety for the patients who receive care there during a pandemic.
Recognize the time, effort, and skill required for computers, databases, and other technologies to become reliable and effective tools for patient care	How does the use of telehealth help the team in the ophthalmology clinic improve outcomes for patients?
Skills	
Seek education about how information is managed in care settings before providing care	How can you influence the safe and effective implementation of telehealth?
Apply technology and information management tools to support safe processes of care	How can you support safe processes of care utilizing this new technology?
Navigate the electronic health record	How will the telehealth system be integrated with the existing electronic health record and used to monitor outcomes of care processes?
Document and plan patient care in an electronic health record	Patients must now navigate the video conference system through the existing patient portal for follow-up visits. How will you communicate these changes to the ophthalmology clinic's mostly older adult patients, many of whom have poor vision and may feel challenged utilizing these types of technologic platforms?
Employ communication technologies to coordinate care for patients	
Respond appropriately to clinical decision-making supports and alerts	
Use information management tools to monitor outcomes of care processes	
Attitudes	

Value technologies that support clinical decision-making, error prevention, and care coordination	Reflect upon how rapid change is implemented within an organization during times of a pandemic. How can you find value in the use of telehealth for clinical decision-making, prevention of errors, and coordination of care?

58 Assessment and Management of Patients with Eye and Vision Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Identify the major internal and external structures and functions of the eye.
2. Specify assessment and diagnostic findings used in the evaluation of ocular disorders.
3. Describe assessment and management strategies for patients with low vision and blindness.
4. List the pharmacologic actions and nursing management of common ophthalmic medications.
5. Recognize the clinical features, assessment and diagnostic findings, as well as the medical or surgical management, and nursing management of the patient with glaucoma, cataracts, and other ocular disorders.

NURSING CONCEPTS

Assessment
Comfort
Infection
Inflammation
Patient Education
Sensory Perception

GLOSSARY

anterior chamber: aqueous-containing space in the eye between the posterior (endothelial) cornea and the anterior iris and pupil

aqueous humor: transparent, nutrient-containing fluid that fills the anterior and posterior chambers of the eye

astigmatism: refractive error due to an irregularity in the curvature of the cornea

binocular vision: normal ability of both eyes to focus on one object and fuse the two images into one

blindness: inability to see, defined as corrected visual acuity of 20/400 or less, or a visual field of no more than 20 degrees in the better eye

cataract: progressive opacity of the lens of the eye

chemosis: edema of the conjunctiva

diplopia: seeing one object as two (*synonym:* double vision)

ectropion: turning out of the lower eyelid

emmetropia: normal refractive condition resulting in clear focus on retina; no optical defects

endophthalmitis: intraocular infection

entropion: turning in of the lower eyelid

enucleation: removal of the eyeball and part of the optic nerve

evisceration: removal of the intraocular contents through a corneal or scleral incision; the optic nerve, sclera, extraocular muscles, and sometimes the cornea are left intact

exenteration: surgical removal of the entire contents of the orbit, surrounding soft tissue, and most or all of the eyelids

exophthalmos: abnormal protrusion of the eyeball (*synonym:* proptosis)

glaucoma: group of conditions characterized by increased intraocular pressure

hyperemia: red eyes resulting from dilation of the vasculature of the conjunctiva

hyperopia: farsightedness; light rays focus behind the retina

hyphema: blood in the anterior chamber

hypopyon: collection of inflammatory cells in the anterior chamber of the eye

injection: congestion of blood vessels

keratoconus: cone-shaped deformity of the cornea

myopia: nearsightedness; light rays focus in front of the retina

neovascularization: growth of abnormal new blood vessels

nystagmus: involuntary oscillation of the eyeball

papilledema: swelling of the optic disc usually due to increased intracranial pressure

photophobia: ocular pain on exposure to light
presbyopia: the loss of accommodative power in the lens due to age
ptosis: drooping eyelid
refraction: determination of the refractive errors of the eye for the purpose of vision correction
scotomas: blind or partially blind areas in the visual field
sympathetic ophthalmia: an inflammatory condition created in the fellow eye by the affected eye
trachoma: an infectious disease caused by the bacterium *Chlamydia trachomatis*—the leading cause of preventable blindness in the world
trichiasis: turning in of the eyelashes
vitreous humor: transparent, colorless gelatinous material that fills the vitreous chamber behind the lens

The eye is a sensitive, highly specialized sense organ subject to various disorders, many of which can lead to impaired vision. Impaired vision may affect individuals in many ways, including their independence in self-care, sense of self-esteem, safety, and overall quality of life. Many of the leading causes of visual impairment are associated with aging (e.g., cataracts, glaucoma, macular degeneration). Younger people are also at risk for eye disorders, particularly traumatic injuries.

Assessment and management of patients with eye and vision disorders occur in various health care settings. In addition to understanding the prevention, treatment, and consequences of eye disorders, nurses in all settings assess visual acuity in patients at risk (e.g., older adults, those with hypertension, diabetes, acquired immune deficiency syndrome [AIDS]), refer patients to eye care specialists as appropriate, implement measures to prevent further visual loss, and help patients adapt to impaired vision.

ASSESSMENT OF THE EYE

Anatomic and Physiologic Overview

Unlike most organs of the body, the eye is available for external examination, and its anatomy is more easily assessed than other body parts (see Fig. 58-1). The eyeball, or globe, is situated in the bony protective orbit (Shaw & Lee, 2017). Lined with muscle and connective and adipose tissues, the orbit is shaped like a four-sided pyramid, surrounded on three sides by the sinuses: ethmoid (medially), frontal (superiorly), and maxillary (inferiorly). The optic

nerve and the ophthalmic artery enter the orbit at its apex through the optic foramen. The eyeball is moved through all fields of gaze by the extraocular muscles. The four rectus muscles and two oblique muscles (see Fig. 58-2) are innervated by cranial nerves (CNs) III, IV, and VI. Normally, the movements of the two eyes are coordinated and the brain perceives a single image.

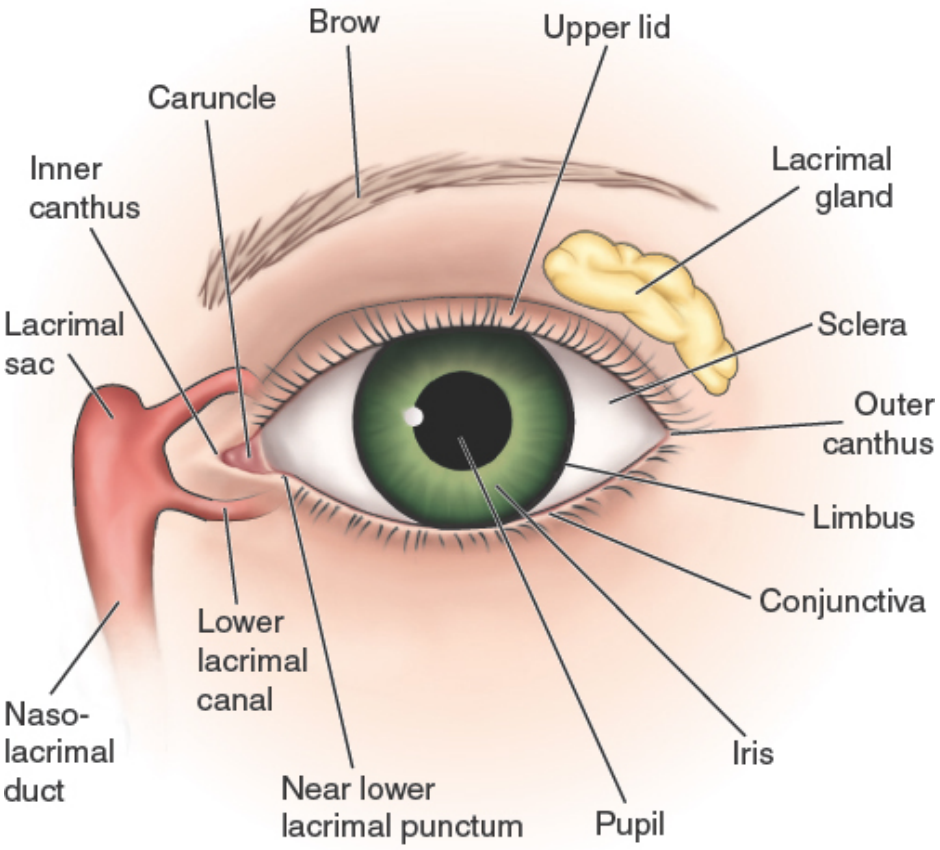

Figure 58-1 • External structures of the eye and position of the lacrimal structures.

The eyelids are composed of thin, elastic skin that covers striated and smooth muscles and protect the anterior portion of the eye. The eyelids contain multiple glands (sebaceous, sweat, and lacrimal). The upper lid normally covers the uppermost portion of the iris and is innervated by the oculomotor nerve (CN III). The lid margins contain meibomian glands, the inferior and superior puncta, and the eyelashes. The triangular spaces formed by the junction of the eyelids are known as the inner or medial canthus and the outer or lateral canthus. With every blink, the eyelids wash the cornea and conjunctiva with tears.

Tears are vital to eye health. Formed by the lacrimal gland and the accessory lacrimal glands, tears are secreted in response to reflex or emotional stimuli. A healthy tear is composed of three layers: lipoid, aqueous, and

mucoid. These layers nourish the cornea and create a smooth optical surface of the cornea and conjunctival epithelium. If there is a defect in the composition of any of these layers, the integrity of the cornea may be compromised.

The conjunctiva, a thin transparent mucous membrane, provides a barrier to the external environment extending under the eyelids (palpebral conjunctiva) and over the sclera (bulbar conjunctiva). The junction of the two portions is known as the fornix. The conjunctiva meets the cornea at the limbus on the outermost edge of the iris.

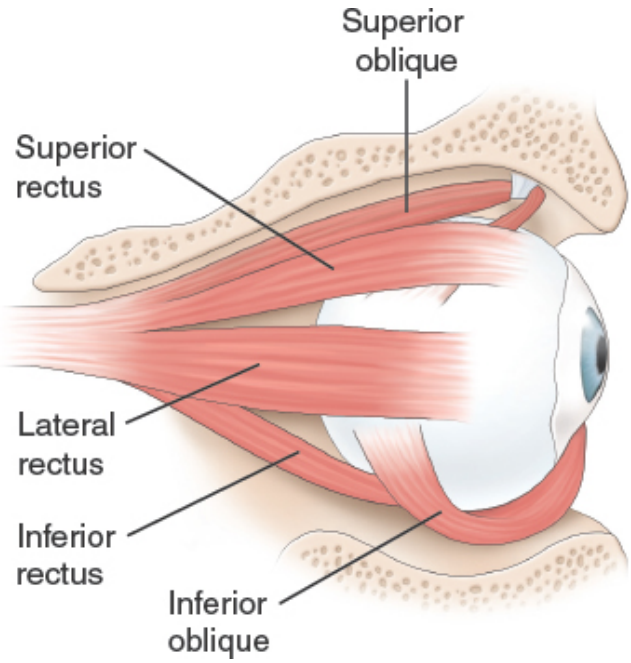

Figure 58-2 • The extraocular muscles responsible for eye movement. The medial rectus muscle (not shown) is responsible for opposing the movement of the lateral rectus muscle.

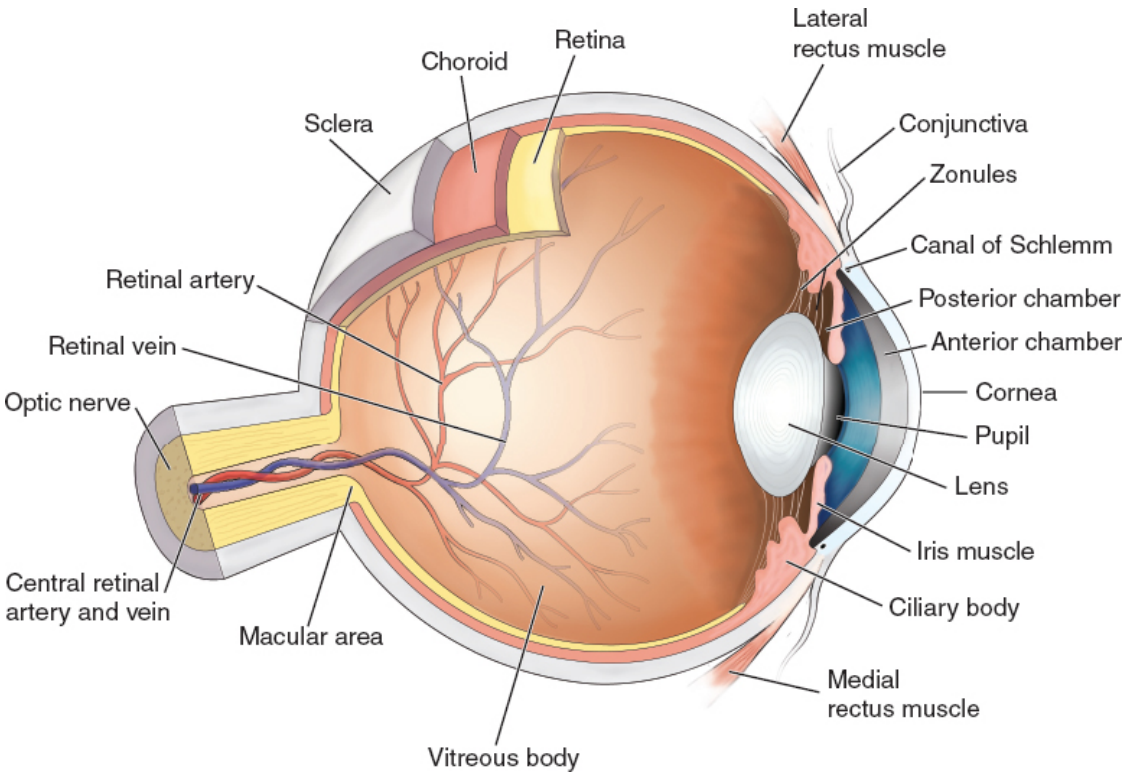

Figure 58-3 • Three-dimensional cross-section of the eye.

The eyeball is composed of the following three layers:

- The outer dense fibrous layer, including the sclera and transparent cornea
- The middle vascular layer, containing the iris, ciliary body, and choroid
- The inner neural layer, including the retina, optic nerve, and visual pathway

The eyeball is divided anatomically into two segments. The anterior segment is between the anterior cornea and posterior iris, including the anterior and posterior chambers. The posterior segment is between the posterior lens and the retina, including the vitreous chamber. The eyeball also has three fluid-containing chambers. The aqueous-filled **anterior chamber** lies between the posterior cornea and the anterior iris and pupil. The posterior chamber is a small aqueous-containing space between the posterior iris and pupil and anterior lens. The vitreous chamber, containing clear gelatinous vitreous fluid, is the largest chamber in the ocular fundus between the lens and retina (see Fig. 58-3).

The **aqueous humor** is transparent, nutrient-containing fluid that fills the anterior and posterior chambers and helps give the eye its shape (Moore, Dalley, & Agur, 2018). The aqueous is produced in the posterior chamber by the ciliary body; it flows through the pupil into the anterior chamber and drains through the trabecular meshwork into the canal of Schlemm. Production of aqueous humor is related to the intraocular pressure (IOP). Normal IOP is less than 21 mm Hg (Sihota, Angmo, Ramaswamy, et al., 2018). **Vitreous humor,**

which is composed mostly of water and encapsulated by a hyaloid membrane, helps maintain the shape of the eye. The vitreous is attached to the retina by scattered collagenous filaments. The vitreous shrinks and shifts with age. Through this degenerative process, the gel-like characteristics liquefy, causing stringy debris known as floaters.

The sclera is the white avascular dense fibrous structure that helps maintain the shape of the eyeball and protects the intraocular contents. Scleral thinning and changes of the scleral collagen fibers can cause the underlying uveal pigment to be seen, resulting in a blue or gray sclera. The episclera is a vascularized loose elastic tissue that overlies the sclera supplying nutritional support and reacting to inflammation.

The cornea, a vulnerable transparent avascular domelike structure, forms the most anterior portion of the eyeball and is the main refracting surface of the eye. It is composed of five layers: the epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium. It contains high concentrations of nerve fibers and is extremely sensitive to pain. The epithelium, the outermost protective layer, absorbs oxygen and nutrients from the tear film nourishing the cornea. The epithelial cells readily regenerate, unlike the innermost endothelial cells, which do not regenerate and result in corneal edema when injured.

The uveal tract is the vascular middle layer of the eye consisting of the iris, ciliary body, and the choroid.

The iris surrounding the pupil is a highly vascularized pigmented collection of fibers that give the eye color. The dilator and sphincter muscles of the iris control pupil size. The dilator muscles are controlled by the sympathetic nervous system. The sphincter muscles are controlled by the parasympathetic nervous system.

The ciliary body consists of ciliary processes, ciliary muscles, and zonular fibers (ligaments) that work together to form aqueous fluid and control focusing through the zonular fibers that suspend the crystalline lens.

The choroid lies between the retina and the sclera, supplying blood and oxygen to the outer retina. Pigmented cells containing melanocytes in the choroid assist to absorb scattered light.

Directly behind the pupil and iris lies the lens, an avascular and almost completely transparent biconvex structure held in position by zonular fibers in the ciliary body. The lens enables focusing for near and distance vision through accommodation, the process by which the lens of the eye adjusts the focal length to focus a clear image on the retina. With aging and certain conditions (e.g., diabetes or trauma), the lens loses its transparency and ability to focus due to formation of a cataract (see later discussion).

The retina—the innermost surface of the fundus composed of neural tissue—is an extension of the optic nerve. Viewed through the pupil, the landmarks of the retina are the optic disc, the retinal vessels, and the macula. The point of

entrance of the optic nerve into the retina is the optic disc. The optic disc is pink, either oval or circular in shape, and has sharp margins. In the disc, a physiologic depression or cup is present centrally, with the retinal blood vessels emerging from it. The retinal tissues arise from the optic disc and line the inner surface of the vitreous chamber. The retinal vessels enter the eye through the optic disc, branching out through the retina and forming superior and inferior branches. The macula is the area of the retina responsible for central vision. The rest of the retina is responsible for peripheral vision. In the center of the macula is the most sensitive area—the fovea—which is avascular and surrounded by the superior and inferior vascular arcades. Two important layers of the retina are the retinal pigment epithelium and the sensory retina. A single layer of cells constitutes the retinal pigment epithelium. These cells have numerous functions, including the absorption of light. The sensory retina contains the photoreceptor cells: rods and cones. The rods are responsible for night or low light vision. The cones are retinal photoreceptor cells essential for visual acuity, color discrimination, and fine detail. Cones are distributed throughout the retina, with their greatest concentration in the fovea. Rods are absent in the fovea.

Visual acuity depends on a healthy functioning eye and an intact visual pathway. This pathway is made up of the retina, optic nerve, optic chiasm, optic tracks, lateral geniculate bodies, optic radiations, and the visual cortex area of the brain. The visual pathway is part of the central nervous system (see Fig. 58-4).

The optic nerve (CN II) transmits impulses from the retina to the occipital lobe of the brain. The optic nerve head, or optic disc, is the physiologic blind spot in each eye. The optic nerve leaves the eye and then meets the optic nerve from the other eye at the optic chiasm. The chiasm is the anatomic point at which the nasal fibers from the nasal retina of each eye cross to the opposite side of the brain. The nerve fibers from the temporal retina of each eye remain uncrossed. Fibers from the right half of each eye, which would be the left visual field, carry impulses to the right occipital lobe. Fibers from the left half of each eye, or the right visual field, carry impulses to the left occipital lobe. Beyond the chiasm, these fibers are known as the optic tract. The optic tract continues on to the lateral geniculate body. The lateral geniculate body is connected by the optic radiations to the cortex of the occipital lobe of the brain.

Assessment

Ocular History

The nurse, through careful questioning, elicits the necessary information that can assist in diagnosis of an ophthalmic condition. Pertinent questions to ask when taking an ocular history are presented in Chart 58-1. Genetics may play a role in the causation and progression of eye and vision disorders (Singh & Tyagi, 2018) (see Chart 58-2).

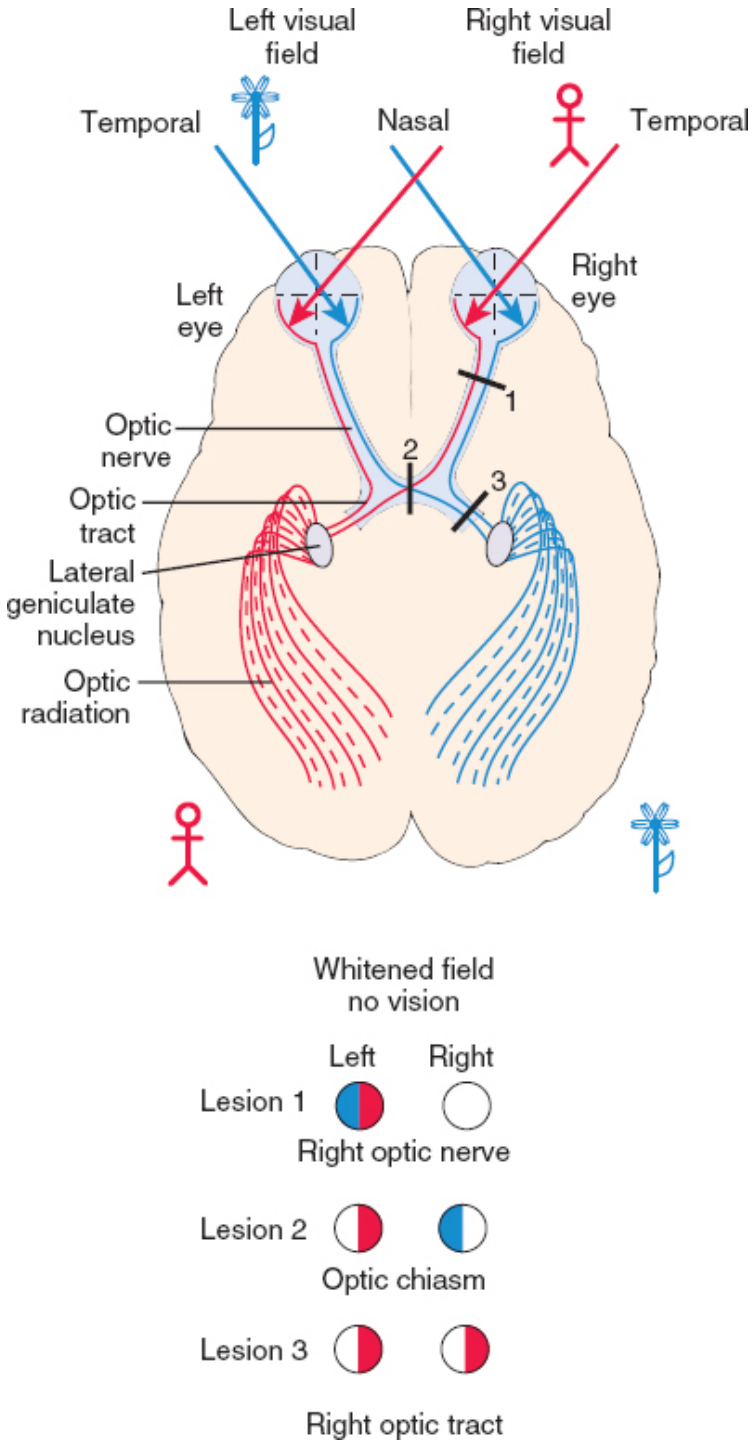

Figure 58-4 • Diagram of optic pathways. The *red* lines indicate the right visual field and the *blue* lines the left visual field. Note the crossing of the fibers from the medial half of each retina at the optic chiasm. Lesion 1 (right optic nerve) produces unilateral blindness. Lesion 2 (optic chiasm) may involve only those fibers that originate in the nasal half of each retina and cross to the opposite side in each field (bitemporal hemianopia). Lesion 3 (right optic tract) interrupts fibers (and vision) originating on the same side of both eyes (homonymous) with loss of vision from half of each field (hemianopia). Reprinted with permission from Norris, T. L. (2019).

Porth's pathophysiology: Concepts of altered health states (10th ed., Fig. 19.23). Philadelphia, PA: Wolters Kluwer.

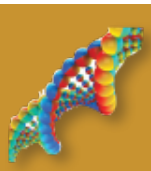
Visual Acuity

Following the health history, the patient's visual acuity is assessed. This is an essential part of the eye examination and a measure against which all therapeutic outcomes are based.

Visual acuity is tested for both near (14 inches away) and distance (20 feet away) vision and is performed on each eye separately with a standardized Snellen chart for distance and a Rosenbaum pocket screener for near vision. A tumbling "E," "illiterate E," number, or picture chart is used if the person is illiterate or unable to read the English alphabet (Weber & Kelley, 2018).

Chart 58-1  **ASSESSMENT**

Taking a History of Patients with Eye and Vision Disorders



- What does the patient perceive to be the problem?
- Is visual acuity diminished?
- Is the patient experiencing blurred, double, or distorted vision?
- Is there pain? Is it sharp or dull? Is it worse when blinking?
- Is the discomfort an itching sensation or more of a foreign-body sensation?
- Are both eyes affected?
- Is there a history of discharge? If so, inquire about color, consistency, and odor.
- Describe the onset of the problem (sudden, gradual). Is it worsening?
- What is the duration of the problem?
- Is this a recurrence of a previous condition?
- How has the patient self-treated?
- What makes the symptoms improve or worsen?
- Has the condition affected performance of activities of daily living?
- Are there any systemic diseases? What medications are used in their treatment?
- What other eye conditions does the patient have?
- Is there a history of eye surgery?
- Have other family members had the same symptoms or condition?

Adapted from Weber, J., & Kelley, J. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

The Snellen chart is composed of a series of progressively smaller rows of letters; the person is asked to read the lowest line possible. The fraction 20/20 is considered the standard of normal vision. Most people can see the letters on the line designated as 20/20. The patient should be encouraged to read every letter possible.

Visual acuity is then recorded. Common abbreviations related to vision and eye health are derived from Latin terms; these include OD (*oculus dexter,* right eye), OS (*oculus sinister,* left eye), and OU (*oculus uterque,* both eyes). The following would be an example of visual acuity documentation: A patient reads all five letters from the 20/20 line on the Snellen chart with the right eye (OD) and three of the five letters on the 20/30 line with the left eye (OS); the visual acuity is documented as OD: 20/20 and OS: 20/30 (Weber & Kelley, 2018).

If the patient cannot see the big "E" at the top of the Snellen chart, the examiner should determine next if the patient can count fingers ("CF" in documentation). Initially, the examiner stands 5 feet from the person, holds up a random number of fingers, and then asks the patient to count the number of fingers seen. If the patient is unable to count fingers at 5 feet, the examiner keeps moving a foot closer until either 1 foot away or the person can correctly count fingers. If the patient correctly counts the number of fingers at 3 feet, for example, the examiner would record vision as CF/3 feet.

Chart 58-2  **GENETICS IN NURSING PRACTICE**

Eye and Vision Disorders

Several eye and vision disorders are associated with genetic abnormalities. Some examples include:
Autosomal dominant:

- Aniridia
- Vitelliform macular dystrophy

Autosomal recessive:

- Achromatopsia
- Homocystinuria
- Leber congenital amaurosis

X linked:

- Choroideremia
- Color blindness

Mitochondrial inheritance:

- Leber hereditary optic neuropathy

Multiple inheritance patterns identified:

- Glaucoma
- Macular degeneration
- Retinitis pigmentosa

Other genetic illnesses that will impact vision:

- Albinism
- Isolated familial congenital cataracts
- Marfan syndrome
- Stickler syndrome
- Tay-Sachs disease
- Usher syndrome

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Vision

- Assess history of family members in the past three generations with glaucoma, cataracts, night blindness (retinitis pigmentosa), color blindness, or other vision impairment.
- Inquire about the age of onset of symptoms (the onset of Leber congenital amaurosis is in childhood, whereas the onset of Leber

hereditary optic neuropathy is in young adulthood).
- Inquire about family members with other disorders that may include visual impairment, such as cutaneous, metabolic, or connective tissue disorders and hearing loss.

Patient Assessment Specific to Vision

- Assess for other systemic and/or clinical features such as cutaneous or skeletal conditions, or hearing loss.
- Look for color and clarity of iris.
- Assess for presence of strabismus (cross-eyes), amblyopia (lazy eye), nystagmus, astigmatism, and near- or farsightedness.
- Assess for changes in visual acuity.
- Assess field of vision.
- Inquire about photophobia, night blindness, or double vision.

Genetics Resources

National Ophthalmic Disease Genotyping Network, eyegene.nih.gov/
See Chapter 6, Chart 6-7 for additional components of genetic counseling.

If the patient cannot count fingers, the examiner raises one hand up and down or moves it side to side and asks in which direction the hand is moving. This level of vision is known as hand motion. A patient who can perceive only light is described as having light perception. The vision of a patient who cannot perceive light is described as no light perception.

External Eye Examination

The nurse uses a systematic approach to perform an external eye examination by first assessing for symmetry and placement of eyelids, pupils, and muscles. CNs III, IV, and VI control movement and pupil size. The eyelids should rest just above and below the corneal limbus without exposure of the sclera. The nurse observes for **ptosis** (drooping of the eyelid), **ectropion** (turning out of the lower eyelid), or **entropion** (turning in of the lower eyelid). Entropion may involve **trichiasis** (turning in of the eyelashes). Eyelids and lashes should be free of drainage or scaling.

The room should be darkened so that the pupils can be examined. The pupillary response is checked with a penlight to determine if the pupils are equally reactive and regular. A normal pupil is black. An irregular pupil may result from trauma, previous surgery, or a disease process.

The patient's eyes are observed in primary or direct gaze, and any head tilt is noted. A head tilt may indicate CN palsy. The patient is asked to stare at a target; each eye is covered and uncovered quickly while the examiner looks for any shift in gaze. The examiner observes for **nystagmus** (involuntary

oscillating movement of the eyeball). The extraocular movements of the eyes are tested by having the patient follow the examiner's finger, pencil, or a hand light through the six cardinal directions of gaze (i.e., up, down, right, left, and both diagonals).

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with eye disorders. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should be aware of contraindications, potential complications, and trends in results. Trends provide information about disease progression as well as the patient's response to therapy.

Direct Ophthalmoscopy

A direct ophthalmoscope is a handheld instrument with various plus and minus lenses (Weber & Kelley, 2018). The lenses can be rotated into place, enabling the examiner to bring the cornea, lens, and retina into focus sequentially. The examiner holds the ophthalmoscope in the right hand and uses the right eye to examine the patient's right eye. The examiner switches to the left hand and left eye when examining the patient's left eye. During this examination, the room should be darkened, and the patient's eye should be on the same level as the examiner's eye. The patient and the examiner should be comfortable, and both should breathe normally. The patient is given a target to gaze at and is encouraged to keep both eyes open and steady.

When the fundus is examined, the vasculature comes into focus first. The veins are larger in diameter than the arteries. The examiner focuses on a large vessel and then follows it toward the midline of the body, which leads to the optic nerve. The central depression in the disc is known as the cup. The normal cup is about one third the size of the diameter of the disc. The size of the physiologic optic cup should be estimated, and the disc margins described as sharp or blurred. A silvery or coppery appearance, which indicates arteriolosclerosis, should be noted. The periphery of the retina is examined by having the patient shift their gaze. The last area of the fundus to be examined is the macula, because this area is the most sensitive to light. The retina of a young person often has a glistening effect, sometimes referred to as a cellophane reflex.

The healthy fundus should be free of any lesions. The examiner looks for intraretinal hemorrhages, which may appear as red smudges, and, if the patient has hypertension, they may be somewhat flame shaped. Lipid with a yellowish appearance may be present in the retina of patients with hypercholesterolemia

or diabetes. Soft exudates that have a fuzzy, white appearance (cotton-wool spots) should be noted. The examiner looks for microaneurysms, which look like little red dots, and nevi. Drusen (small, hyaline, globular deposits), commonly found in macular degeneration, appear as yellowish areas with indistinct edges. Small drusen have a more distinct edge. The examiner should sketch the fundus and document any abnormalities.

Indirect Ophthalmoscopy

The indirect ophthalmoscope is an instrument commonly used by the ophthalmologist to see larger areas of the retina, although in an unmagnified state. It produces a bright and intense light. The light source is affixed with a pair of binocular lenses mounted on the examiner's head. The ophthalmoscope is used with a handheld, 20-diopter lens.

Slit-Lamp Examination

The slit lamp is a binocular microscope mounted on a table. This instrument enables the user to examine the eye with magnification of 10 to 40 times the real image. The illumination can be varied from a broad to a narrow beam of light for different parts of the eye. For example, by varying the width and intensity of the light, the anterior chamber can be examined for signs of inflammation. Cataracts may be evaluated by changing the angle of the light. When a handheld contact lens, such as a three-mirror lens, is used with the slit lamp, the angle of the anterior chamber may be examined, as may the ocular fundus.

Tonometry

Tonometry is a common procedure to measure IOP. The device used for measuring IOP is an accurately calibrated applanation tonometer, which measures the pressure needed to flatten the cornea. This procedure is most commonly used to screen for and monitor IOP in glaucoma.

Nursing Interventions

Providing patient education prior to tonometry helps avoid possible errors in IOP measurement. Patients are cautioned to avoid squeezing the eyelids, holding their breath, or performing a Valsalva maneuver, because these may result in abnormally increased IOP.

Color Vision Testing

The ability to differentiate colors has a dramatic effect on the activities of daily living (ADLs). For example, the inability to differentiate between red and green can compromise traffic safety. Some careers (e.g., commercial artist, [color] photographer, airline pilot, electrician) may be closed to people with significant color deficiencies. The photoreceptor cells responsible for color vision are the cones, and the greatest area of color sensitivity is in the macula —the area of densest cone concentration.

A screening test, such as the polychromatic plates discussed in the next paragraph, can be used to establish whether a person's color vision is within normal range. Color vision deficits can be inherited. For example, red–green color deficiencies are inherited in an X-linked manner, affecting approximately 8% of men and 0.5% of women (Colour Blind Awareness, 2019). Acquired color vision losses may be caused by medications (e.g., digitalis) or pathology (e.g., cataracts). A simple test, such as asking a patient if the red top on a bottle of eye drops appears redder to one eye than the other, can be an effective tool. A difference in the perception of the intensity of the color red between the two eyes can be a symptom of a neurologic problem and may provide information about the location of the lesion.

Because alteration in color vision sometimes indicates conditions of the optic nerve, color vision testing is often performed in a neuro-ophthalmologic workup. The most common color vision test is performed using Ishihara polychromatic plates. These plates are bound together in a booklet. On each plate of this booklet are dots of primary colors that are integrated into a background of secondary colors. The dots are arranged in simple patterns, such as numbers or geometric shapes. Patients with diminished color vision may be unable to identify the hidden shapes. Patients with central vision conditions (e.g., macular degeneration) have more difficulty identifying colors than those with peripheral vision conditions (e.g., glaucoma) because central vision identifies color.

Amsler Grid

The Amsler grid is a test often used for patients with macular problems, such as macular degeneration. It consists of a geometric grid of identical squares with a central fixation point. The grid should be viewed by the patient wearing normal reading glasses. Each eye is tested separately. The patient is instructed to stare at the central fixation spot on the grid and report any distortion in the squares of the grid itself. For patients with macular disorders, some of the squares may look faded, or the lines may be wavy. Patients with age-related macular degeneration (AMD) are commonly given these Amsler grids to take home. The patient is encouraged to check the grids frequently, as often as daily, to monitor macular function for early detection of changes requiring

immediate attention (Gerstenblith & Rabinowitz, 2017; Weber & Kelley, 2018).

Ultrasonography

Lesions in the globe or the orbit may not be directly visible and are evaluated by ultrasonography. Ultrasonography is a valuable diagnostic technique, especially when the view of the retina is obscured by opaque media such as cataract or hemorrhage. An ultrasonography B-scan identifies pathology such as orbital tumors, retinal detachment, and vitreous hemorrhage. Ultrasonography A-scans are used to measure the axial length for implants prior to cataract surgery (Gerstenblith & Rabinowitz, 2017).

Optical Coherence Tomography

Optical coherence tomography is a technology that involves low-coherence interferometry (Gerstenblith & Rabinowitz, 2017). Light is used to evaluate retinal and macular diseases as well as anterior segment conditions. This method is noninvasive and involves no physical contact with the eye.

Fundus Photography

Fundus photography is used to detect and document retinal lesions. The patient's pupils are usually widely dilated before the procedure. The resulting fundus photographs can be viewed stereoscopically so that elevations such as macular edema can be identified.

Laser Scanning

Various scanning techniques use laser light in the diagnostic evaluation of eye disorders. Confocal laser scanning ophthalmoscopy provides a three-dimensional image of the optic nerve topography and is used alone or in conjunction with fundus photography to provide comparative data for suspected optic nerve disease such as glaucoma and **papilledema** (swelling of the optic disc due to increased intracranial pressure) (Gerstenblith & Rabinowitz, 2017). Laser scanning polarimetry is used to measure nerve fiber layer thickness and is an important indicator of glaucoma progression.

Angiography

Angiography is done using fluorescein or indocyanine green as contrast agents. Fluorescein angiography is used to evaluate clinically significant macular edema, document macular capillary nonperfusion, and identify retinal

and choroidal **neovascularization** (growth of abnormal new blood vessels) in AMD. It is an invasive procedure in which fluorescein dye is injected, usually into an antecubital vein. Within 10 to 15 seconds, this dye can be seen coursing through the retinal vessels. Over a 10-minute period, serial black-and-white photographs are taken of the retinal vasculature (Fischbach & Fischbach, 2018).

Indocyanine green angiography is used to evaluate abnormalities in the choroidal vasculature, which often are seen in macular degeneration. Indocyanine green dye is injected intravenously (IV), and multiple images are captured using digital video angiography. The dye is quickly removed from circulation by the liver, mostly clearing within 10 to 20 minutes (Norat, Soldozy, Elsarrag, et al., 2019).

Nursing Interventions

Prior to the angiography, the patient's blood urea nitrogen and creatinine should be checked to ensure that the kidneys will excrete the contrast agent (Fischbach & Fischbach, 2018). The patient should be well hydrated, and clear liquids are usually permitted up to the time of the test. The patient is instructed to remain immobile during the angiogram process and is told to expect a brief feeling of warmth in the face, behind the eyes, or in the jaw, teeth, tongue, and lips, and a metallic taste when the contrast agent is injected.

Nursing care after angiography includes observation of the injection site (usually the antecubital vein) for bleeding or hematoma formation (a localized collection of blood). Fluorescein may impart a gold tone to the skin in some patients, and urine may turn deep yellow or orange. This discoloration usually disappears in 24 hours. Indocyanine green dye is generally well tolerated, but some patients experience nausea and vomiting. Allergic reactions are rare; however, indocyanine green angiography is contraindicated in patients with a history of iodide reactions. Fluids are encouraged following the procedure to facilitate excretion of the contrast agent (Fischbach & Fischbach, 2018).

Perimetry Testing

Perimetry testing evaluates the field of vision. Visual field testing (i.e., perimetry) helps identify which parts of the patient's central and peripheral visual fields have useful vision. It is most helpful in detecting central **scotomas** (blind or partially blind areas in the visual field) in macular degeneration and the peripheral field defects in glaucoma and retinitis pigmentosa. Visual field evaluation and optic nerve assessment are major components of monitoring and detecting glaucoma progression.

IMPAIRED VISION

Refractive Errors

In refractive errors, vision is impaired because a shortened or elongated eyeball prevents light rays from focusing sharply on the retina. Blurred vision from refractive error can be corrected with eyeglasses or contact lenses. Ophthalmic **refraction** is the determination of the refractive errors of the eye for the purpose of vision correction and consists of placing various types of lenses in front of the patient's eyes to determine which lens best improves the patient's vision.

The depth of the eyeball is important in determining refractive error (see Fig. 58-5). Patients for whom the visual image focuses precisely on the macula and who do not need eyeglasses or contact lenses are said to have **emmetropia,** a normal refractive condition resulting in clear focus on retina with no optical defects (normal vision). Some people have deeper eyeballs, in which case the distant visual image focuses in front of, or short of, the retina; those with **myopia** are said to be nearsighted and have blurred distance vision. Other people have shallower eyeballs, in which case the visual image focuses beyond the retina; those with **hyperopia** are said to be farsighted and have excellent distance vision but blurry near vision (Weber & Kelley, 2018).

Wavefront technology to measure unique refractive imperfections of the cornea or higher aberrations (i.e., myopia, hyperopia, astigmatism) can be used to customize laser-assisted in situ keratomileusis (LASIK) procedures. These procedures are described later in this chapter.

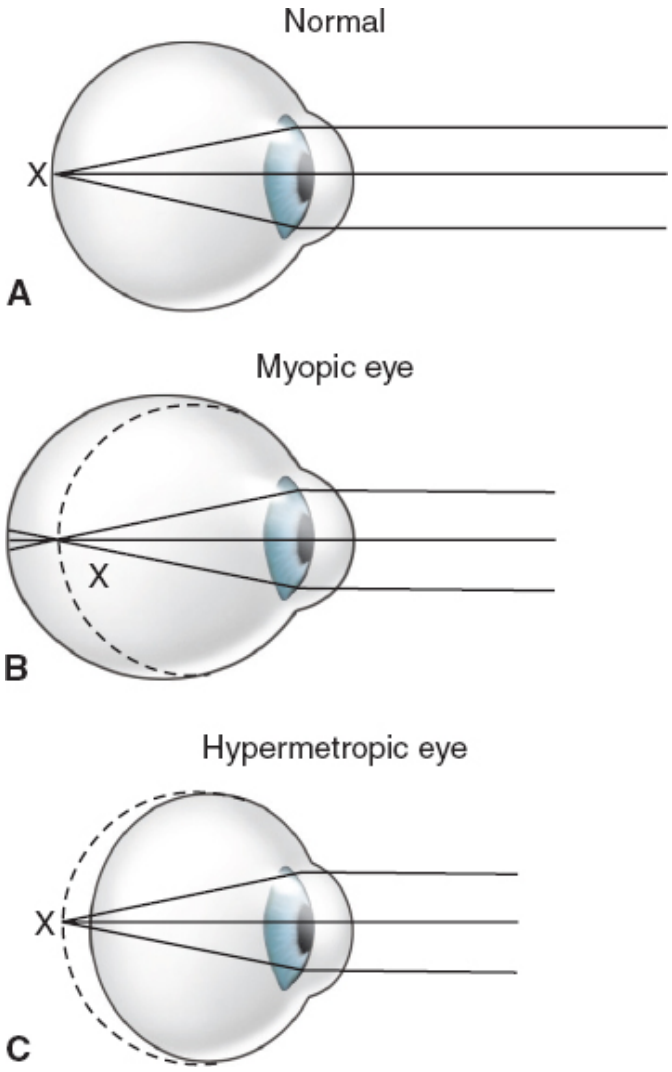


Figure 58-5 • Eyeball shape determines visual acuity in refractive errors. **A.** Normal eye. **B.** Myopic eye. **C.** Hypermetropic eye.

Vision Impairment and Blindness

Vision impairment is defined as having central visual acuity of 20/40 or worse in the better eye with the best possible correction. *Low vision* describes visual impairment that requires the use of devices and strategies to perform visual tasks.

Blindness is having best possible corrected central visual acuity that can range from 20/400 to no light perception. The clinical definition of absolute blindness is the absence of light perception. Legal blindness is a condition of impaired vision and is defined as having central visual acuity of 20/200 or worse in the better eye with the best possible correction or whose widest visual field diameter is 20 degrees or less (Bright Focus Foundation, 2020b). This definition neither equates with functional ability nor classifies the degrees of visual impairment. Legal blindness ranges from an inability to perceive light to

having some vision remaining. A person who meets the criteria for legal blindness may be eligible for government financial assistance through disability.

Assessment and Diagnostic Testing

Assessment of vision impairment includes a thorough history and examination of distance and near visual acuity, visual field, contrast sensitivity, glare, color perception, and refraction. Specially designed, low-vision visual acuity charts are used to evaluate patients.

Patient Interview

During history taking, the potential cause and duration of the patient's visual impairment are identified. Patients with retinitis pigmentosa, for example, have a genetic abnormality. Patients with diabetic macular edema typically have fluctuating visual acuity. Patients with macular degeneration have central acuity problems that cause difficulty in performing activities that require finer vision, such as reading. People with peripheral field defects have more difficulties with mobility. The patient's customary ADLs, medication regimen, habits (e.g., smoking), acceptance of the physical limitations brought about by the visual impairment, and realistic expectations of low-vision aids are identified and included in the plan of care, as well as provision of guidelines for safety and referrals to social services.

Contrast-Sensitivity Testing and Glare Testing

Contrast-sensitivity testing measures visual acuity in different degrees of light and dark contrast to determine visual function. Glare testing is also used to determine visual function. Glare can reduce a person's ability to see, especially in patients with cataracts. Those affected by loss of contrast sensitivity and glare have difficulty functioning in low light, or driving at night or in foggy conditions. People with a loss of contrast sensitivity may benefit from better illumination.

Gerontologic Considerations

Approximately half of all individuals who are identified as legally blind each year are 65 years of age or older (Eliopoulos, 2018). With aging, structural and functional changes occur in the eye (see Chart 58-3). **Presbyopia,** the loss of accommodative power in the lens, interferes with the ability to adequately focus and is the factor responsible for most older adults requiring some form of corrective lenses (Eliopoulos, 2018). Age-related changes in the eye are summarized in Table 58-1.

Impaired vision is often accompanied by difficulty in performing functional activities. People with visual acuity of 20/80 to 20/100 with a visual field restriction of 60 degrees to greater than 20 degrees can read at a nearly normal level with optical aids. Their visual orientation is near normal but requires increased scanning of the environment (i.e., systematic use of head and eye movements). In a visual acuity range of 20/200 to 20/400 with a 20-degree to greater than 10-degree visual field restriction, the person can read slowly with optical aids.

The most common causes of blindness and visual impairment among adults 40 years and older are diabetic retinopathy, macular degeneration, glaucoma, and cataracts (Centers for Disease Control and Prevention [CDC], 2019). Macular degeneration is more prevalent among Caucasians, whereas glaucoma is more prevalent among African Americans (Eliopoulos, 2018).

Medical Management

Managing vision impairment involves magnification and image enhancement through the use of low-vision aids and strategies, as well as referrals to social services and community agencies. The goals are to optimize the patient's remaining vision and assist the patient to perform customary activities. Table 58-2 presents low-vision aids. Medications are prescribed for glaucoma. Ongoing research suggests that gene therapy may replace or be an adjunct to pharmacologic or surgical treatment for ocular disorders in the near future (Jolly, Bridge, & MacLaren, 2019).

Chart 58-3  **ETHICAL DILEMMA**

Should Preservation of Patient Autonomy Threaten the Welfare of Others?

Case Scenario

You work as a staff nurse on a subacute care unit. D.P. is an 85-year-old man who has made daily visits to see his wife who has been a patient on the unit for the past week for daily physical and occupational therapy after having hip surgery. During your morning rounds today, D.P.'s wife tells you that her husband did not visit her yesterday and she is worried about him. After lunch, D.P. arrives on the subacute care unit with a sheepish grin on his face and a bandage on his forehead. When D.P.'s wife tells him that she was worried about him, he replies "Do not worry about me! I got into a fender bender yesterday but I am okay." D.P.'s wife shakes her head and says "Why are you so stubborn? You cannot see well at all anymore and should not be driving!" With tears in his eyes, D.P. says to his wife "But how else would I get here to see you, my sweetheart? Nothing could ever keep me away from you!" Based on previous conversations you have had with D.P. and his wife, you know that they live alone together in a two-bedroom ranch home that they have shared for the past 60 years. They have two adult sons who both live several hundred miles away.

Discussion

In American society, being able to drive is seen as consistent with being able to maintain an independent lifestyle. It is not uncommon for older adults to feel threatened by a possible loss of driving rights. D.P.'s apparent devotion to his wife and inability to identify an acceptable alternative means to visit her seems to be compounding his feelings of vulnerability.

There are some states that require health care providers to report drivers whom they think are impaired and unsafe. As a witness to this verbal exchange between D.P. and his wife, you may be obligated to investigate this situation further, or be liable for civil or criminal penalties.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Is it possible to preserve D.P.'s autonomy while ensuring that neither D.P. nor others are harmed should he continue to drive?
- Regardless of the legal requirements in your state, what are your ethical and moral obligations to D.P., his wife, and to others who may be impacted by D.P.'s driving?
- What resources might you mobilize to be of assistance to you, to D.P., and to D.P.'s wife? It is not uncommon for spouses to neglect their own health needs when their partner becomes ill. You may wish to explore whether D.P. has had a recent focused visual examination, to find whether he has visual deficits amenable to correction. In addition, although D.P.'s children do not live close, D.P. and his wife may have

other social support networks that they could tap into to assist them so that D.P. can continue his daily visits with his wife. Local Area Agencies on Aging can also provide a wealth of contacts and support services for older adults that could be explored.

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

TABLE 58-1  Age-Related Changes in the Eye

External Eye	Structural Change	Functional Change	History and Physical Findings
Eyelids and lacrimal structures	Loss of skin elasticity and orbital fat, decreased muscle tone; wrinkles develop	Lid margins turn in, causing entropion; or lid margins turn out, resulting in ectropion.	Reports of burning, foreign-body sensation, epiphora; injection, inflammation, and ulceration may occur.
Refractive changes; presbyopia	Loss of accommodative power in the lens with age	Reading materials must be held at increasing distance in order to focus.	Patient reports, "Arms are too short!"; need for increased light; reading glasses or bifocals needed.
Cataract	Opacities in the normally crystalline lens	Interference with the focus of a sharp image on the retina.	Patients report increased glare, decreased vision, changes in color values (blue and yellow especially affected).
Posterior vitreous detachment	Liquefaction and shrinkage of vitreous body	May lead to retinal tears and detachment.	Reports light flashes, cobwebs, floaters.
Age-related macular degeneration (AMD)	Drusen (yellowish aging spots in the retina) appear and coalesce in the macula. Abnormal choroidal blood vessels may lead to formation of fibrotic disciform scars in the macula	Central vision is affected; onset is more gradual in dry AMD, more rapid in wet AMD; distortion and loss of central vision may occur.	Reading vision is affected; words may be missing letters, faded areas appear on the page, straight lines may appear wavy; drusen, pigmentary changes in retina; abnormal submacular choroidal vessels.

TABLE 58-2 Activities Affected by Visual Impairment and Suggestions for Low-Vision Aids

Activity	Optical Aids	Nonoptical Aids
Shopping	Hand magnifier	Lighting, color cues
Fixing a snack	Bifocals	Color cues; consistent food storage plan
Eating out	Hand magnifier	Flashlight, portable lamp
Identifying money	Bifocals, hand magnifier	Arrange paper money in wallet compartments
Reading print	High-power spectacle, bifocals, hand magnifier, stand magnifier, closed-circuit television	Lighting, high-contrast print, large print, reading slit
Writing	Hand magnifier	Lighting, bold-tip pen, black ink
Using a telephone	Hand magnifier	Large-print buttons, hand-printed directory Braille phones, picture/photo phones, and talking phones Accessibility settings on smartphones
Crossing streets	Lightweight handheld monoscopes/telescopes	Cane; ask directions
Finding taxis and bus signs	Lightweight handheld monoscopes/telescopes	Ask for assistance
Using ride-sharing services	Lightweight handheld monoscopes/telescopes	Ask for assistance
Reading medication labels	Hand magnifier	Color codes, large print
Reading stove dials	Hand magnifier	Color codes, raised dots
Adjusting the thermostat	Hand magnifier	Enlarged-print model, digital thermostats that can be controlled via voice or apps
Using a computer or electronic tablet	Spectacles	High-contrast color, large-print program. Screen-reader programs convert text on the computer screen to synthesized speech
Reading signs	Spectacles	Move closer
Watching sporting event	Lightweight handheld monoscopes/telescopes	Sit in front rows

Adapted from Pagliuca, L. M., Macêdo-Costa, K. N., Rebouças, C. B., et al. (2014). Validation of the general guidelines of communication between the nurse and the blind. *Revista Brasileira de Enfermagem*, *67*(5), 715–721.

Referrals to community agencies may be necessary for patients with low vision who live alone and cannot self-administer their medications. Community agencies, such as the Lighthouse Guild, offer a wide variety of vision and health care services to patients with low vision and blindness.

Nursing Management

Nurses need to be sensitive to the challenges faced by patients with visual impairments. Coping with blindness involves emotional, physical, and social adaptation. The emotional adjustment to blindness or severe visual impairment determines the success of the physical and social adjustments of the patient. Successful emotional adjustment means acceptance of blindness or severe visual impairment.

Promoting Coping

Effective coping may not occur until the patient recognizes the permanence of the low vision or blindness. A patient who is newly visually impaired and their family members undergo the various steps of grieving: denial and shock, anger and protest, restitution, loss resolution, and acceptance. The ability to accept the changes that must come with visual loss and willingness to adapt to those changes influence the successful rehabilitation of the patient with vision loss. Additional aspects to consider are value changes, independence–dependence conflicts, coping with stigma, and learning to function in social settings without visual cues and landmarks.

Promoting Spatial Orientation and Mobility

A person who is blind or severely visually impaired requires strategies for adapting to the environment. ADLs, such as walking to a chair from a bed, require spatial concepts. The person needs to know where they are in relation to the rest of the room, to understand the changes that may occur, and to know how to approach the desired location safely. This requires a collaborative effort between the patient and the responsible adult who serves as the sighted guide. The nurse must assess the degree of physical assistance the person with vision loss requires and communicate this to other health care personnel.

The nurse should be aware of the importance of techniques in providing physical assistance, encouraging independence, and ensuring safety. Strategies for interacting with the patient with vision loss are presented in Chart 58-4. Research supports the use of a validated protocol to educate staff to perform therapeutic communication, deliver services, and minimize communication

barriers with patients who are blind (Pagliuca, Macêdo-Costa, Rebouças, et al., 2014). The readiness of the patient and family to learn must be assessed before initiating orientation and mobility training.

Promoting Home, Community-Based, and Transitional Care

The nurse, social worker, family, and others collaborate to assess the patient's home condition and support system. A low vision specialist or occupational therapist should be consulted, particularly for patients for whom identifying and administering medications pose challenges. Referral for vision rehabilitation should be provided for appropriate patients (Shah, Schwartz, Gartner, et al., 2018).

Chart 58-4

Strategies for Interacting with People Who Are Blind or Have Low Vision

- Remember that the only difference between you and people who are blind or have low vision is that they are not able to see through their eyes what you are able to see through yours.
- Do not be uncomfortable when in the company of a person who is blind or has low vision. Talk with the person as you would talk with any other person, honestly and with respect, courtesy, and empathy; do not be concerned about using words like “see” and “look.” There is no need to raise your voice unless the person asks you to do so.
- Identify yourself as you approach the person and before you make physical contact. Tell the person your name and your role. If another person approaches, introduce them. When you leave the room, be sure to tell the person that you are leaving and if anyone else remains in the room.
- Keep in mind that it is often appropriate to touch the person’s hand or arm lightly to indicate that you are about to speak.
- When talking, face the person and speak directly to them using a normal tone of voice.
- Be specific when communicating direction. Mention a specific distance or use clock cues when possible (e.g., walk left about 2 yards; walk about 20 feet to the right; the telephone is at 2 o’clock). Avoid using phrases such as “over there.”
- When you offer to assist someone, allow the person to hold on to your arm just above the elbow and to walk a half step behind you.
- When offering the person a seat, place the person’s hand on the back or the arm of the seat.
- When you are about to go up or down a flight of stairs, tell the person and place their hand on the banister.
- Make sure that the environment is free of obstacles; close doors and cabinets so that they are not in the path.
- Offer to read written information, such as a menu.
- If you serve food to the person, use clock cues to specify where everything is on the plate.
- When the person who is blind or has low vision is a patient in a health care facility:
  - Make sure all objects the person will need are close at hand.
  - Identify the location of objects that the person may need (e.g., “The call light is near your right hand”; “The telephone is on the table on the left side of your bed.”)
  - Remove obstacles that may be in the person’s pathway and could cause a fall.
  - Place all assistive devices that the person uses close at hand; let the person feel the devices so that they know their location.

- Do not distract a service animal unless the owner has given permission.
- Ask the person, “How can I help you?” At some times, the person needs help; at other times, help may not be needed.

Adapted from Pagliuca, L. M., Macêdo-Costa, K. N., Rebouças, C. B., et al. (2014). Validation of the general guidelines of communication between the nurse and the blind. *Revista Brasileira de Enfermagem*, *67*(5), 715–721.

Other interventions that are appropriate for some people with visual impairment or blindness include Braille and service animals. There has been an ever-increasing reliance on print magnification technology as well as technology-assisted speech output. However, although the use of Braille may be less important for adults who have already learned language and grammar skills, educators and low vision specialists have continued to advocate that children who are legally blind be given the opportunity to learn Braille.

Guide dogs, also known as service dogs, are dogs that are specially bred, raised, and rigorously trained to assist people who are blind. The guide dog is a constant companion to the person who is blind (also referred to as the animal’s handler) and is allowed on airplanes and in restaurants, stores, hotels, and other public places. With the assistance of the guide dog, the person who is blind can be extremely mobile and accomplish normal activities both within and outside of the home and workplace. A dog in harness is a working dog, not a pet. The dog should not be distracted from his job by well-intentioned strangers who want to pet, feed, or play with the animal. The dog’s handler should always be consulted before approaching the working guide dog. Most health care facilities have a service animal policy that outlines the responsibilities of the handler with regard to the care of the animal.

Unfolding Patient Stories: Vernon Watkins • Part 2

Recall from Chapter 14 Vernon Watkins, who came to the emergency department with severe abdominal pain and underwent a hemicolectomy for a bowel perforation. During postoperative care the nurse determines that he has poor vision. What measures can the nurse take to maintain a safe environment for a patient with visual impairment? How will the discovery of impaired vision impact the nursing plan of care, discharge planning, and delivery of patient education?

Care for Vernon and other patients in a realistic virtual environment: vSim(**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

OCULAR MEDICATION ADMINISTRATION

Because medications are often prescribed to treat ocular disorders, nurses must understand the actions of the commonly used medications and effective administration. The main objective of ocular medication delivery is to maximize the amount of medication that reaches the ocular site of action in sufficient concentration to produce a beneficial therapeutic effect. This is determined by the dynamics of ocular pharmacokinetics: absorption, distribution, metabolism, and excretion.

Ocular absorption involves the entry of a medication into the aqueous humor through the different routes of ocular medication administration. The rate and extent of aqueous humor absorption are determined by the characteristics of the medication and the anatomy and physiology of the eye. Natural barriers of absorption that diminish the efficacy of ocular medications include the following:

- *Limited size of the conjunctival sac.* The conjunctival sac can hold only 50 mcL, and any excess is wasted. The volume of one eye drop from commercial topical ocular solutions typically ranges from 20 to 35 mcL.
- *Corneal membrane barriers.* The epithelial, stromal, and endothelial layers are barriers to absorption.
- *Blood–ocular barriers.* Blood–ocular barriers prevent high ocular tissue concentration of most ophthalmic medications because they separate the

bloodstream from the ocular tissues and keep foreign substances from entering the eye, thereby limiting a medication's efficacy.

- *Tearing, blinking, and drainage.* Increased tear production and drainage due to ocular irritation or an ocular condition may dilute or wash out an instilled eye drop; blinking expels an instilled eye drop from the conjunctival sac.

Distribution of an ocular medication into the ocular tissues varies by tissue type—the conjunctiva, cornea, lens, iris, ciliary body, and choroids absorb medications to varying degrees. Medications penetrate the corneal epithelium either by intracellular diffusion (passing through the cells) or by intercellular diffusion (passing between the cells). Hydrophilic (water soluble) medications diffuse through the intracellular route, and lipophilic (fat soluble) medications diffuse through the intercellular route. Topical administration usually does not reach the retina in significant concentrations. Because the space between the ciliary process and the lens is small, medication diffusion in the vitreous is slow. When high concentrations of medication in the vitreous are required, intraocular injection is often chosen to bypass the natural ocular anatomic and physiologic barriers (American Society of Ophthalmic Registered Nurses [ASORN], 2013).

Aqueous solutions are most commonly used for the eye. They are the least expensive medications and interfere the least with vision. However, corneal contact time is brief because tears dilute the medication. Ophthalmic ointments have extended retention time in the conjunctival sac and provide a higher concentration than eye drops. The major disadvantage of ointments is the blurred vision that results after application. In general, eyelids and eyelid margins are best treated with ointments. The conjunctiva, limbus, cornea, and anterior chamber are treated most effectively with instilled solutions or suspensions. Subconjunctival injection may be necessary for better absorption in the anterior chamber. If high medication concentrations are required in the posterior chamber, intravitreal injections or systemically absorbed medications are considered. Contact lenses and collagen shields soaked in antibiotic agents are alternative delivery methods for treating corneal infections.

Of all these delivery methods, the topical route of administration—instilled eye drops and applied ointments—remains the most common and widely recommended (ASORN, 2013). Topical instillation, which is the least invasive method, permits self-administration of medication and produces fewer side effects.

Preservatives are commonly used in ocular medications. Benzalkonium chloride, for example, prevents the growth of organisms and enhances the corneal permeability of most medications; however, some patients are allergic to this preservative. This may be suspected even if the patient had never before experienced an allergic reaction to systemic use of the medication in question. Eye drops without preservatives can be prepared by pharmacists.

Common Ocular Medications

Common ocular medications include topical anesthetic, mydriatic, and cycloplegic agents that reduce IOP; anti-infective medications; corticosteroids; nonsteroidal anti-inflammatory drugs (NSAIDs); antiallergy medications; eye irrigants; and lubricants.

Topical Anesthetic Agents

One or two drops of proparacaine hydrochloride and tetracaine hydrochloride are instilled before diagnostic procedures such as tonometry and minor ocular procedures such as removal of sutures or conjunctival or corneal scrapings. Topical anesthetic agents are also used for severe eye pain to allow the patient to open their eyes for examination or treatment (e.g., eye irrigation for chemical burns). Anesthesia occurs within 20 seconds to 1 minute and lasts 10 to 20 minutes.

Quality and Safety Nursing Alert

To prevent injury, the nurse educates the patient not to rub the eyes while anesthetized because this may result in damage to the cornea.

Mydriatic and Cycloplegic Agents

Mydriasis, or pupil dilation, is the main objective of the administration of mydriatics and cycloplegics (see Table 58-3). These two types of medications function differently and are used in combination to achieve the maximal dilation that is needed during surgery and fundus examinations to give the ophthalmologist a better view of the internal eye structures. Mydriatics potentiate alpha-adrenergic sympathetic effects that result in the relaxation of the ciliary muscle. This causes the pupil to dilate. However, this sympathetic action alone is not enough to sustain mydriasis because of its short duration of action. The strong light used during an eye examination also stimulates miosis (i.e., pupillary contraction). Cycloplegic medications are given to paralyze the iris sphincter.

The patient is educated about the temporary effects of mydriasis on vision, such as glare and the inability to focus properly. The patient may have difficulty reading. The effects of the various mydriatics and cycloplegics can last 3 hours to several days. The patient is advised to wear sunglasses (most eye clinics provide protective sunglasses). The ability to drive depends on the person's age, vision, and comfort level. Some patients can drive safely with the use of sunglasses, whereas others may need to be driven home.

Mydriatic and cycloplegic agents affect the central nervous system. Their effects are most prominent in younger and older adult patients; these patients must be assessed closely for symptoms, such as increased blood pressure, tachycardia, dizziness, ataxia, confusion, disorientation, incoherent speech, and hallucination. These medications are contraindicated in patients with narrow angles or shallow anterior chambers and in patients taking monoamine oxidase inhibitors or tricyclic antidepressants.

Medications Used to Treat Glaucoma

Therapeutic medications for glaucoma are used to lower IOP by decreasing aqueous production or increasing aqueous outflow. Because glaucoma calls for lifetime therapy, the patient must be educated with regard to both the ocular and systemic side effects of the medications. See section on glaucoma later in this chapter.

Anti-Infective Medications

Anti-infective medications include antibiotic, antifungal, and antiviral agents. Most are available as drops, ointments, or subconjunctival or intravitreal injections. Antibiotics include penicillin, cephalosporins, aminoglycosides, and fluoroquinolones. The main antifungal agent is amphotericin B. Side effects of amphotericin are serious and include severe pain, conjunctival necrosis, iritis, and retinal toxicity. Antiviral medications include acyclovir and ganciclovir. They are used to treat ocular infections associated with herpes virus and cytomegalovirus (CMV). Patients receiving ocular anti-infective agents are subject to the same side effects and adverse reactions as those receiving oral or parenteral medications.

TABLE 58-3 Mydriatics and Cycloplegics

Medication	Available Preparation/ Concentration	Indication/Dosage	Peak		Recovery Time	
			Mydriasis (Minutes)	Cycloplegia (Minutes)	Mydriasis	Cycloplegia
atropine	Ointment (0.5–2%) Solutions (0.5–3%)	In uveitis, or after surgery, 2–4 × daily	30–40	60–180	7–10 days	6–12 days
cyclopentolate hydrochloride	Solution (0.5–2%)	Given with mydriatics every 5–10 min × 3 or until the pupils are fully dilated for ophthalmoscopy and surgical procedures	30–60	25–75	1 day	6–24 h
phenylephrine hydrochloride	Solutions (2.5%, 10%)	Given with cycloplegics in pupillary dilation for ophthalmoscopy and surgical procedures every 5–10 min × 3	10–60	—	3–5 h	—
scopolamine hydrobromide	Solution (0.25%)	Same as atropine	20–30	30–60	3–7 days	3–7 days
homatropine	Solution (5–2.5%)	Same as atropine and scopolamine	40–60	30–60	1–3 days	1–3 days

Corticosteroids and Nonsteroidal Anti-Inflammatory Drugs

Topical preparations of corticosteroids are commonly used in inflammatory conditions of the eyelids, conjunctiva, cornea, anterior chamber, lens, and uvea. In posterior segment diseases that involve the posterior sclera, retina, and optic nerve, topical agents are less effective and parenteral and oral routes are preferred. When a suspension is prescribed, the patient is instructed to shake the bottle several times to promote mixture of the medication and maximize its therapeutic effect. The most common ocular side effects of long-term topical corticosteroid administration are glaucoma, cataracts, susceptibility to infection, impaired wound healing, mydriasis, and ptosis. High IOP may develop, which is reversible after corticosteroid use is discontinued. To avoid the side effects of corticosteroids, NSAIDs are used as an alternative in controlling inflammatory eye conditions and postoperatively to reduce inflammation.

Antiallergy Medications

Ocular hypersensitivity reactions, such as allergic conjunctivitis, are extremely common. These conditions result primarily from responses to environmental allergens. Most allergens are airborne or carried to the eye by the hand or by other means, although allergic reactions may also be drug induced. Corticosteroids are commonly used as anti-inflammatory and immunosuppressive agents to control ocular hypersensitivity reactions.

Ocular Irrigants and Lubricants

Most irrigating solutions are used to cleanse the external lids to maintain lid hygiene, to irrigate the external corneal surface to regain normal pH (e.g., in chemical burns), to irrigate the corneal surface to eliminate debris, or to inflate the globe intraoperatively. These solutions have various compositions that include sodium, potassium, magnesium, calcium, bicarbonate, glucose, and glutathione (i.e., substance found in the aqueous humor). Sterile irrigating solutions for lid hygiene are available. Irrigating solutions are safe to use with an intact corneal surface; however, the corneal surface should not be irrigated in cases of threatened corneal perforation. For patients with severe corneal ulcer, specific instructions from the ophthalmologist must be obtained regarding whether it is safe to irrigate the corneal surface or just to cleanse the external lids. Although it is good practice to promote hygiene, prevention of complications must be the primary concern. Normal saline solutions are commonly used to irrigate the corneal surface when chemical burns occur.

Lubricants, such as artificial tears, help alleviate corneal irritation, such as dry eye syndrome. Artificial tears are topical preparations of carboxymethylcellulose or hydroxypropyl methylcellulose that are prepared as eye drop solutions, ointments, or ocular inserts (inserted at the lower conjunctival cul-de-sac once each day). The eye drops can be instilled as often as every hour, depending on the severity of symptoms.

Nursing Management

The objectives in administering ocular medications are to ensure proper administration to maximize the therapeutic effects and to ensure the safety of the patient by monitoring for systemic and local side effects (ASORN, 2013). Absorption of eye drops by the nasolacrimal duct is undesirable because of the potential systemic side effects of ocular medications. To diminish systemic absorption and minimize the side effects, it is important to occlude the puncta (see Chart 58-5). This is especially important for patients who are most vulnerable to medication overdose, including older adults; women who are pregnant or lactating; and patients with cardiac, pulmonary, hepatic, or kidney disease. A 5-minute interval between instillation of different types of ocular drops is recommended.

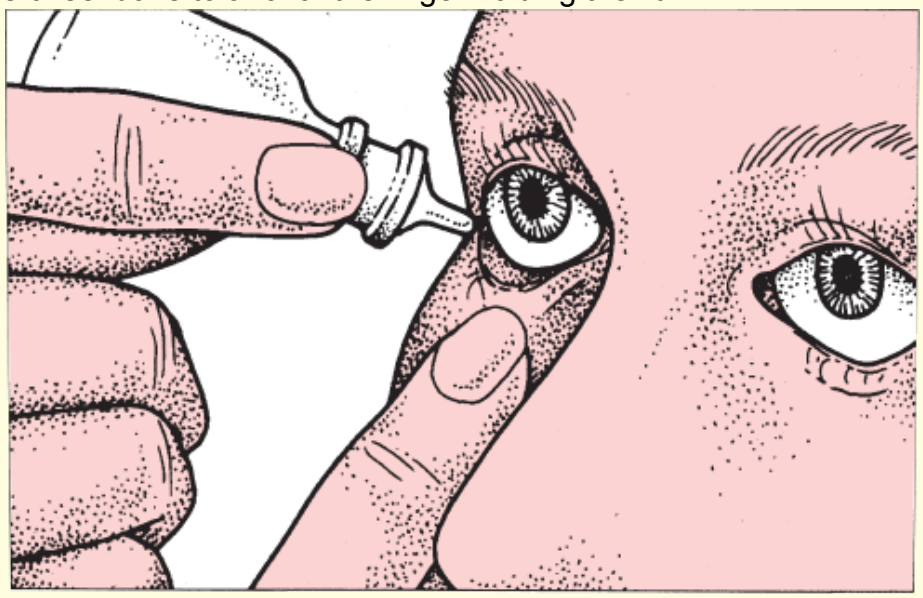
Before the administration of ocular medications, the nurse warns the patient that blurred vision, stinging, and a burning sensation are symptoms that ordinarily occur after instillation and are temporary. Risk for interactions of the ocular medication with other ocular and systemic medications must be emphasized; therefore, a careful patient interview regarding the medications being taken must be obtained.

Quality and Safety Nursing Alert

To prevent infection, meticulous hand hygiene before and after medication instillation is crucial. In addition, the tip of the eye drop bottle or the ointment tube must never touch any part of the eye, and the medication must be recapped immediately after each use.

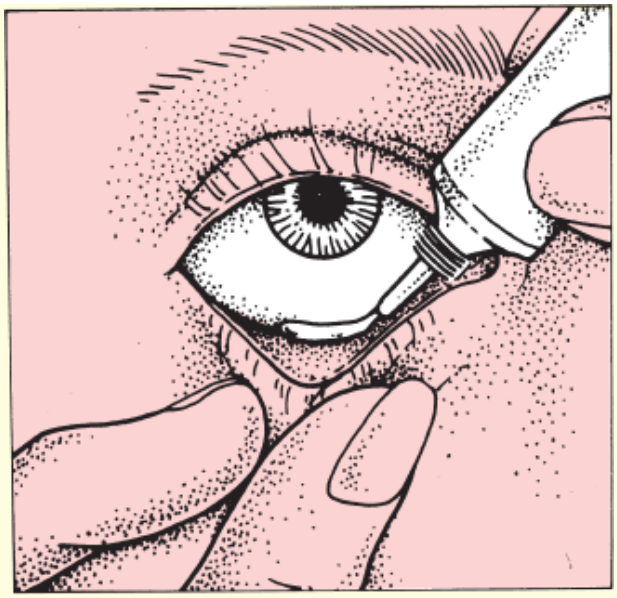
If a patient who instills their own medications cannot feel the eye drops when they are instilled, the eye medication may be refrigerated, because a cold drop is easier to detect. A 5-minute interval between successive administrations allows adequate drug retention and absorption. The patient or the caregiver at home should be asked to demonstrate actual eye drop or ointment instillation and punctal occlusion.

GLAUCOMA



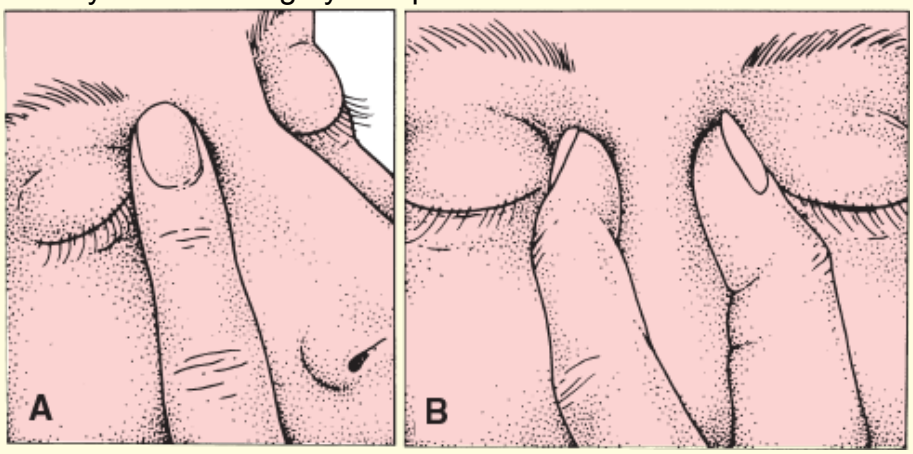
The term **glaucoma** is used to refer to a group of ocular conditions characterized by elevated IOP (McMonnies, 2017). If left untreated, the increased IOP damages the optic nerve and nerve fiber layer, but the degree of harm is highly variable (Eliopoulos, 2018). The optic nerve damage is related to the IOP caused by congestion of aqueous humor in the eye. A range of IOPs are considered "normal," but these may also be associated with vision loss in some patients.

Chart 58-5  **PATIENT EDUCATION**



Instilling Eye Medications

The nurse instructs the patient to:



- Never use eye solutions that have changed colors.
- Perform hand hygiene before and after the procedure.
- Ensure adequate lighting.
- Read the label of the eye medication to verify that it is the correct medication.
- Remove contact lens as needed.
- Assume a comfortable position.
- Avoid touching the tip of the medication container to any part of the eye or face.
- Hold the lower lid down; do not press on the eyeball. Apply gentle pressure to the cheekbone to anchor the finger holding the lid.

- Instill eye drops before applying ointments.
- Apply a 0.25- to 0.5-inch ribbon of ointment to the lower conjunctival sac.

- Keep the eyelids closed, and apply gentle pressure on the inner canthus (punctal occlusion) near the bridge of the nose for 1 or 2 minutes immediately after instilling eye drops.

- Use a clean tissue to gently pat skin to absorb excess eye drops that run onto the cheeks.
- Wait 5 minutes before instilling another eye drop and 10 minutes before instilling another ointment.
- Reinsert contact lens if applicable.

Adapted from American Society of Ophthalmic Registered Nurses (ASORN). (2013). *ASORN recommended practice: Use of multi-dose medications*. San Francisco, CA: Author; Glaucoma Research Foundation. (2020). Eye drop tips. Retrieved on 2/11/2020 at: www.glaucoma.org/treatment/eyedrop-tips.php

Glaucoma is estimated to affect three million Americans, approximately 50% of whom are undiagnosed (Moore et al., 2018). Glaucoma is more prevalent in people older than 40 years, and it is the third most common age-related eye disease in the United States. Chart 58-6 presents the risk factors for

glaucoma. There is no cure for glaucoma, but the disease can be controlled (Glaucoma Research Foundation, 2019).

Physiology

Aqueous humor flows between the iris and the lens, nourishing the cornea and lens. Most (90%) of the fluid then flows out of the anterior chamber, draining through the spongy trabecular meshwork into the canal of Schlemm and the episcleral veins (see Fig. 58-6). About 10% of the aqueous fluid exits through the ciliary body into the suprachoroidal space and then drains into the venous circulation of the ciliary body, choroid, and sclera (Norris, 2019). Unimpeded outflow of aqueous fluid depends on an intact drainage system and an open angle (about 45 degrees) between the iris and the cornea. A narrower angle places the iris closer to the trabecular meshwork, diminishing the angle. The amount of aqueous humor produced tends to decrease with age, in systemic diseases such as diabetes, and in ocular inflammatory conditions.

Chart 58-6  **RISK FACTORS**

Glaucoma

- Black or Asian race
- Cardiovascular disease
- Diabetes
- Family history of glaucoma
- Migraine syndromes
- Myopia (nearsightedness)
- Obstructive sleep apnea
- Older age
- Previous eye trauma
- Prolonged use of topical or systemic corticosteroids
- Thin cornea

Adapted from McMonnies, C. W. (2017). Glaucoma history and risk factors. *Journal of Optometry*, *10*(2), 71–78; Norris, T. (2019). *Porth's pathophysiology: Concepts of altered health status* (10th ed.). Philadelphia, PA: Wolters Kluwer.

IOP is determined by the rate of aqueous production, the resistance encountered by the aqueous humor as it flows out of the passages, and the venous pressure of the episcleral veins that drain into the anterior ciliary vein.

When aqueous fluid production and drainage are in balance, the IOP is between 10 and 21 mm Hg. When aqueous fluid is inhibited from flowing out, pressure builds up within the eye. Fluctuations in IOP occur with time of day, exertion, diet, and medications. IOP tends to increase with blinking, tight lid squeezing, and upward gazing. Systemic conditions such as diabetes and intraocular conditions such as uveitis and retinal detachment have been associated with elevated IOP. Glaucoma may not be recognized in people with thin corneas because measurement of the IOP may be falsely low as a result of this thinness.

Pathophysiology

There are two theories regarding how increased IOP damages the optic nerve in glaucoma. The direct mechanical theory suggests that high IOP damages the retinal layer as it passes through the optic nerve head. The indirect ischemic theory suggests that high IOP compresses the microcirculation in the optic nerve head, resulting in cell injury and death. Some glaucomas appear as exclusively mechanical, and some are exclusively ischemic types. Typically, most cases are a combination of both.

Classification of Glaucoma

There are several types of glaucoma. Forms of glaucoma are identified as wide-angle glaucoma; narrow-angle glaucoma; congenital glaucoma; and glaucoma associated with other conditions, such as developmental anomalies or corticosteroid use. Glaucoma can be primary or secondary, depending on whether associated factors contribute to the rise in IOP. The two common clinical forms of glaucoma in adults are wide- and narrow-angle glaucoma, which are differentiated by the mechanisms that cause impaired aqueous outflow (Norris, 2019). Table 58-4 summarizes the characteristics of the different types of adult glaucoma.

Clinical Manifestations

Glaucoma is often called the “silent thief of sight” because most patients are unaware that they have the disease until they have experienced visual changes and vision loss. The patient may not seek health care until they experience blurred vision or “halos” around lights, difficulty focusing, difficulty adjusting eyes in low lighting, loss of peripheral vision, aching or discomfort around the eyes, and headache.

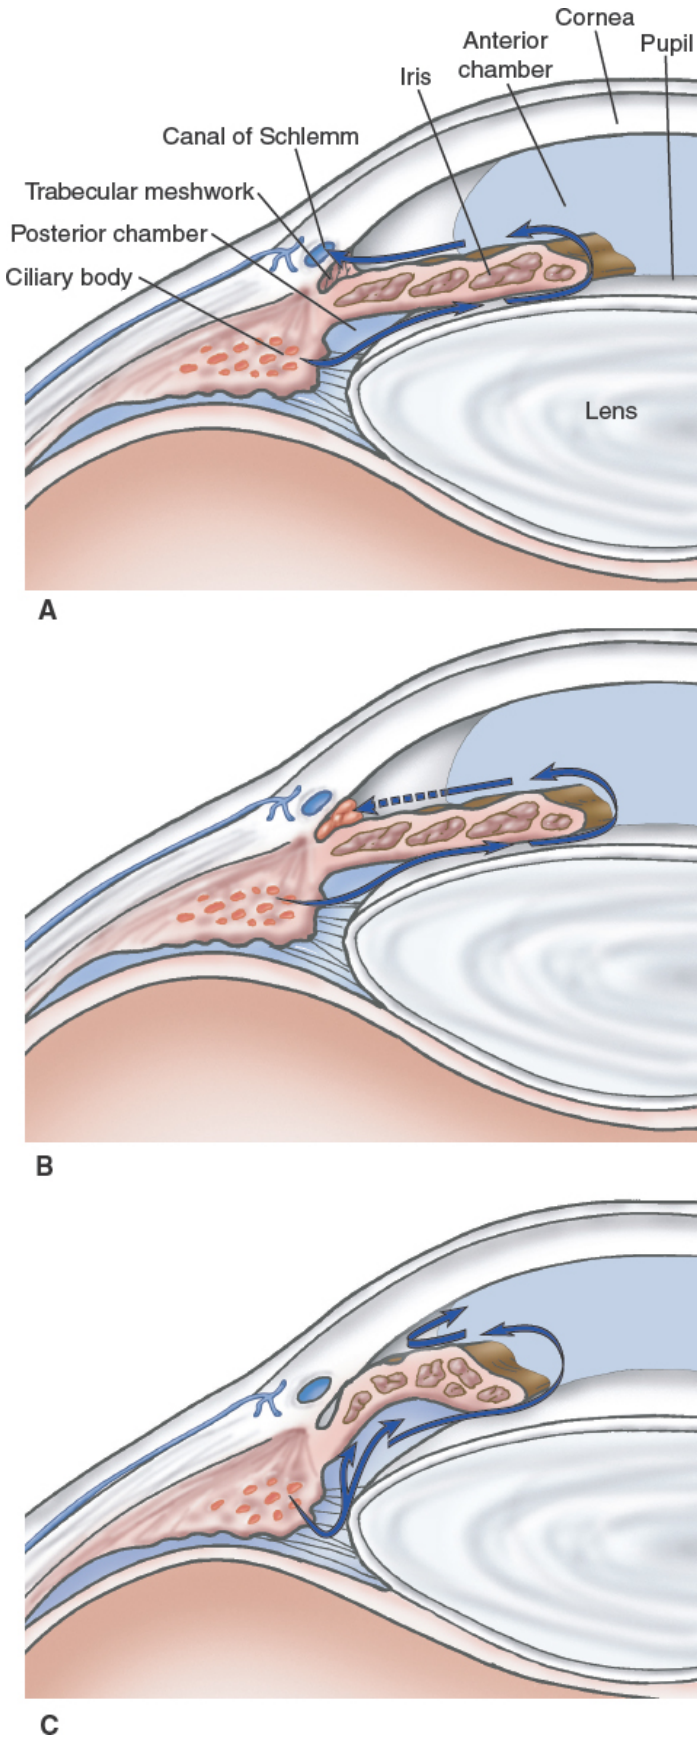


Figure 58-6 • **A.** Normally, aqueous humor, which is secreted in the posterior chamber, gains access to the anterior chamber by

flowing through the pupil. In the angle of the anterior chamber, it passes through the canal of Schlemm into the venous system. **B.** In wide-angle glaucoma, the outflow of aqueous humor is obstructed at the trabecular meshwork. **C.** In narrow-angle glaucoma, the aqueous humor encounters resistance to flow through the pupil. Increased pressure in the posterior chamber produces a forward bowing of the peripheral iris so that the iris blocks the trabecular meshwork. Reprinted with permission from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed., Fig. 19.11). Philadelphia, PA: Wolters Kluwer.

TABLE 58-4 Glaucoma Types, Clinical Manifestation, and Treatment

Types of Glaucoma	Clinical Manifestations	Treatment
Wide Angle		
Usually bilateral, but one eye may be more severely affected than the other. In wide-angle glaucoma, the anterior chamber angle is open and appears normal.		
Normal-tension glaucoma	IOP ≤21 mm Hg. Optic nerve damage, visual field defects.	If medical treatment is unsuccessful, LT can decrease IOP by 20%. Glaucoma filtering surgery if continued optic nerve damage despite medication therapy and LT.
Ocular hypertension	Elevated IOP. Possible ocular pain or headache.	The best management for normal-tension glaucoma management is yet to be established. Goal is to lower the IOP by at least 30%.
Narrow Angle		
Obstruction in aqueous humor outflow due to the complete or partial closure of the angle from the forward shift of the peripheral iris to the trabecula. The obstruction results in an increased IOP.		
Acute angle–closure glaucoma	Rapidly progressive visual impairment, periocular pain, conjunctival hyperemia, and congestion. Pain may be associated with nausea, vomiting, bradycardia, and profuse sweating. Reduced central visual acuity, severely elevated IOP, corneal edema. Pupil is vertically oval, fixed in a semidilated position, and unreactive to light and accommodation.	Ocular emergency; administration of hyperosmotics, acetazolamide, and topical ocular hypotensive agents. Possible laser iridotomy (incision in the iris) to release blocked aqueous and reduce IOP. Other eye is also treated with pilocarpine eye drops and/or surgical management to avoid a similar spontaneous attack.
Subacute angle–closure glaucoma	Transient blurring of vision, halos around lights; temporal headaches and/or ocular pain; pupil may be semidilated.	Prophylactic peripheral laser iridotomy. Can lead to acute or chronic angle–closure glaucoma if untreated.
Chronic angle–closure glaucoma	Progression of glaucomatous cupping and significant visual field loss; IOP may be normal or elevated; ocular pain and headache.	Management includes laser iridotomy and medications.

IOP, intraocular pressure; LT, laser trabeculoplasty.

Adapted from McMonnies, C. W. (2017). Glaucoma history and risk factors. *Journal of Optometry*, *10*(2), 71–78; Norris, T. (2019). *Porth's pathophysiology: Concepts of altered health status* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Assessment and Diagnostic Findings

The purpose of a glaucoma workup is to establish the diagnostic category, assess the optic nerve damage, and formulate a treatment plan. The patient's ocular and medical history must be detailed to investigate the history of predisposing factors. The types of examinations used in glaucoma include tonometry to measure the IOP, ophthalmoscopy to inspect the optic nerve, and central visual field testing (Glaucoma Research Foundation, 2019; Norris, 2019).

The changes in the optic nerve related to glaucoma are pallor and cupping of the optic nerve disc. The pallor of the optic nerve is caused by a lack of blood supply. Cupping is characterized by exaggerated bending of the blood vessels as they cross the optic disc, resulting in an enlarged optic cup that appears more basinlike compared with a normal cup. The progression of cupping in glaucoma is caused by the gradual loss of retinal nerve fibers and the loss of blood supply.

As the optic nerve damage increases, visual perception decreases. The localized areas of visual loss (i.e., scotomas) represent loss of retinal sensitivity and nerve fiber damage and are measured and mapped on a graph. In patients with glaucoma, the graph has a distinct pattern that is different from other ocular diseases and is useful in establishing the diagnosis. Figure 58-7 shows the visual changes caused by glaucoma.

Medical Management

The aim of all glaucoma treatment is prevention of optic nerve damage. Lifelong therapy is necessary because glaucoma cannot be cured. Treatment focuses on pharmacologic therapy, laser procedures, surgery, or a combination of these approaches, all of which have potential complications and side effects. The object is to achieve the greatest benefit at the least risk, cost, and inconvenience to the patient. Although treatment cannot reverse optic nerve damage, further damage can be controlled. The goal is to maintain an IOP within a range unlikely to cause further damage (Sheybani, Scott, Samuelson, et al., 2020). The initial target for IOP among patients with elevated IOP and those with low-tension glaucoma with progressive visual field loss is typically set at 30% lower than the current pressure. The patient is monitored for changes in the appearance of the optic nerve. If there is evidence of progressive damage, the target IOP is again lowered until the optic nerve shows stability.

Figure 58-7 • Visual changes associated with glaucoma. Photo courtesy of the National Eye Institute, National Institutes of Health.

TABLE 58-5  Select Medications Used in the Management of Glaucoma

Medication	Action	Side Effects	Nursing Implications
Cholinergics (miotics) (pilocarpine, carbachol intraocular)	Increase aqueous fluid outflow by contracting the ciliary muscle and causing miosis (constriction of the pupil) and opening of trabecular meshwork	Periorbital pain, blurry vision, difficulty seeing in the dark	Caution patients about diminished vision in dimly lit areas. Pilocarpine can be stored at room temperature for up to 8 wks and then should be discarded.
Beta-blockers (timolol maleate)	Decrease aqueous humor production	Can have systemic effects, including bradycardia, exacerbation of pulmonary disease, and hypotension	Contraindicated in patients with asthma, chronic obstructive pulmonary disease, second- or third-degree heart block, bradycardia, or heart failure; educate patients about punctal occlusion to limit systemic effects (see Chart 58-5).
Alpha-adrenergic agonists (apraclonidine, brimonidine)	Decrease aqueous humor production	Eye redness, dry mouth and nasal passages	Educate patients about punctal occlusion to limit systemic effects (see Chart 58-5).
Carbonic anhydrase inhibitors (acetazolamide, dorzolamide)	Decrease aqueous humor production	Oral medications (acetazolamide) are associated with serious side effects, including anaphylactic reactions, electrolyte loss, depression, lethargy, gastrointestinal upset, impotence, and weight loss; side effects of topical form (dorzolamide) include topical allergy	Do not administer to patients with sulfa allergies; monitor electrolyte levels.
Prostaglandin analogues (latanoprost, bimatoprost)	Increase uveoscleral outflow	Darkening of the iris, conjunctival redness, possible rash	Instruct patients to report any side effects.

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Pharmacologic Therapy

Medical management of glaucoma relies on systemic and topical ocular medications that lower IOP. Periodic follow-up examinations are essential to monitor IOP, the appearance of the optic nerve, the visual fields, and side effects of medications. Therapy takes into account the patient's health and stage of glaucoma. Comfort, affordability, convenience, lifestyle, and functional ability are factors to consider in the patient's adherence to the medical regimen (Eliopoulos, 2018).

The patient is usually started on the lowest dose of topical medication and then advanced to increased concentrations until the desired IOP level is reached and maintained. Beta-blockers are the preferred initial topical medications because of their efficacy, minimal dosing (can be used once each day), and low cost. One eye is treated first, with the other eye used as a control in determining the efficacy of the medication; once efficacy has been established, treatment of the other eye is started. If the IOP is elevated in both eyes, both are treated. When results are not satisfactory, a new medication is substituted. The main markers of the efficacy of the medication in glaucoma control are lowering of the IOP to the target pressure, stable appearance of the optic nerve head, and the visual field.

Many ocular medications are used to treat glaucoma (see Table 58-5), including miotics, beta-blockers, alpha$_2$-agonists (i.e., adrenergic agents), carbonic anhydrase inhibitors, and prostaglandins. Cholinergics (i.e., miotics) increase the outflow of the aqueous humor by affecting ciliary muscle contraction and pupil constriction, allowing flow through a larger opening between the iris and the trabecular meshwork. Beta-blockers and carbonic anhydrase inhibitors decrease aqueous production. Prostaglandin analogues reduce IOP by increasing aqueous humor outflow (Comerford & Durkin, 2020; Norris, 2019).

Surgical Management

Surgery is reserved for patients in whom pharmacologic treatment has not controlled the IOP. This minimally invasive procedure is specifically designed to improve fluid drainage from the eye to balance IOP. By restoring the eye's natural fluid balance, trabeculectomy surgery stabilizes the optic nerve and minimizes further visual field damage (Sheybani et al., 2020). The surgery is performed through a small incision and does not require creation of a permanent hole in the eye wall or an external filtering bleb or an implant.

In laser trabeculoplasty for glaucoma, a laser beam is applied to the inner surface of the trabecular meshwork to open the intratrabecular spaces and

widen the canal of Schlemm, promoting outflow of aqueous humor and decreasing IOP. The procedure is indicated when IOP is inadequately controlled by medications, and it is contraindicated when the trabecular meshwork cannot be fully visualized because of a narrow angle.

In peripheral iridotomy for pupillary block glaucoma, an opening is made in the iris to eliminate the pupillary blockage. Laser iridotomy is contraindicated in patients with corneal edema, which interferes with laser targeting and strength. Potential complications include burns to the cornea, lens, or retina; transient elevated IOP; closure of the iridotomy; uveitis; and blurring.

Filtering procedures for glaucoma are used to create an opening or fistula in the trabecular meshwork to drain aqueous humor from the anterior chamber to the subconjunctival space into a bleb (fluid collection on the outside of the eye), thereby bypassing the usual drainage structures. This allows the aqueous humor to flow and exit by different routes (i.e., absorption by the conjunctival vessels or mixing with tears). Trabeculectomy is the standard filtering technique used to remove part of the trabecular meshwork (Shaw & Lee, 2017). Complications include hemorrhage, an extremely low (hypotony) or extremely elevated IOP, uveitis, cataracts, bleb failure, bleb leak, and **endophthalmitis** (i.e., intraocular infection).

Drainage implants or *shunts* are tubes implanted in the anterior chamber to shunt aqueous humor to the episcleral plate in the conjunctival space. Implants are used when failure has occurred with one or more trabeculectomies in which antifibrotic agents were used. A fibrous capsule develops around the episcleral plate and filters the aqueous humor, thereby regulating the outflow and controlling IOP.

Nursing Management

Nurses in all settings encounter patients with glaucoma. Even patients with long-standing disease and those with glaucoma as a secondary diagnosis should be assessed for knowledge level and adherence to their prescribed therapeutic regimen.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The medical and surgical management of glaucoma slows the progression of the disease but does not cure it. The lifelong therapeutic regimen mandates patient education. The nature of the disease and the importance of strict adherence to the medication regimen must be included in an individualized

education plan. A structured self-management program may increase adherence to the treatment regime. A thorough discussion of the medication program, particularly the interactions of glaucoma-control medications with other medications, is essential. For example, the diuretic effect of acetazolamide may have an additive effect on the diuretic effects of other antihypertensive medications (Comerford & Durkin, 2020). The effects of glaucoma-control medications on vision must also be explained. Miotics and sympathomimetics result in altered focus; therefore, patients need to be cautious in navigating their surroundings. Chart 58-5 presents patient education about instilling eye medications and preventing systemic absorption with punctal occlusion. Chart 58-7 contains additional educational information to review with patients with glaucoma.

Continuing and Transitional Care

Patients with severe glaucoma and impaired function may need referral to home, community-based or transitional services that provide assistance in the home. The loss of peripheral vision impairs mobility the most. These patients also benefit from a referral for low vision and rehabilitation services. Patients who meet the criteria for legal blindness should be offered referrals to agencies that can assist them in obtaining federal assistance.

Chart 58-7  **PATIENT EDUCATION**

Managing Glaucoma

The nurse instructs the patient to:

- Know your intraocular pressure measurement and the desired range.
- Be informed about the extent of your vision loss and optic nerve damage.
- Keep a record of your eye pressure measurements and visual field test results to monitor your own progress.
- Review all of your medications (including over-the-counter and herbal medications) with your ophthalmologist, and mention any side effects each time you visit.
- Ask about potential side effects and drug interactions of your eye medications.
- Ask whether generic or less costly forms of your eye medications are available.
- Review the dosing schedule with your ophthalmologist, and inform them if you have trouble following the schedule.
- Participate in the decision-making process. Let your primary provider know what dosing schedule works for you and other preferences regarding your eye care.
- Have the nurse observe you instilling eye medication to determine whether you are administering it properly (see Chart 58-5).
- Be aware that glaucoma medications can cause adverse effects if used inappropriately. Eye drops are to be given as prescribed, not when eyes feel irritated.
- Ask your ophthalmologist to send a report to your primary provider after each appointment.
- Keep all follow-up appointments.

Reassurance and emotional support are important aspects of care. A lifelong disease involving possible loss of sight has psychological, physical, social, and vocational ramifications. The family must be integrated into the plan of care, and because the disease has a familial tendency, family members should be encouraged to undergo examinations at least once every 2 years to detect glaucoma early.

CATARACTS

A **cataract** is a lens opacity or cloudiness (see Fig. 58-8). Cataracts are responsible for visual disability in 18 million people worldwide (Norris, 2019). By 80 years of age, more than half of all Americans have cataracts. Cataracts are a leading cause of blindness in the world (Prevent Blindness America, 2020).

Pathophysiology

Cataracts can develop in one or both eyes at any age. The three most common types are traumatic, congenital, or senile cataract (Norris, 2019). There are a variety of risk factors, the most common one being age (see Chart 58-8).

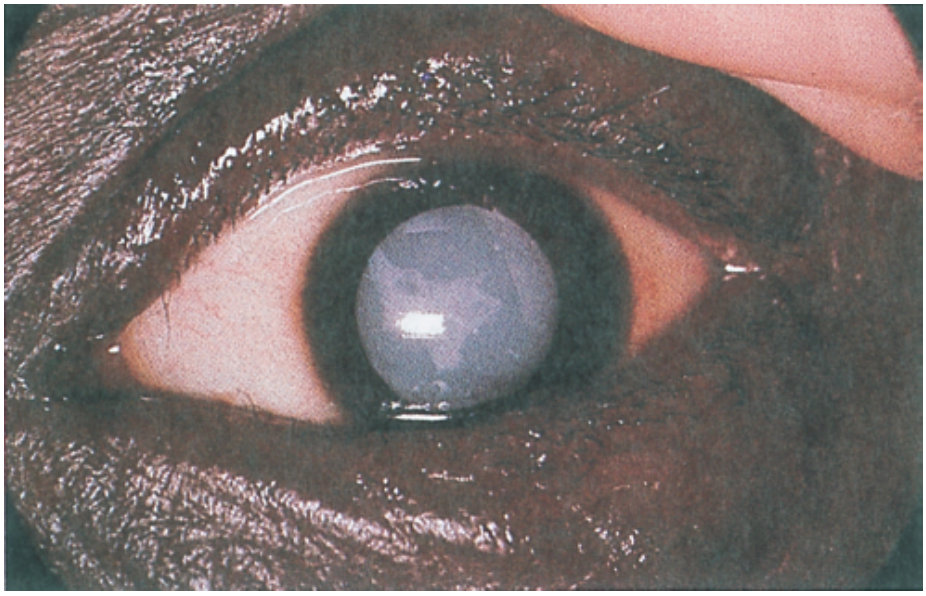

Figure 58-8 • A cataract is a cloudy or opaque lens. On visual inspection, the lens appears gray or milky. Reprinted with permission from Strayer, D. S., Rubin, E., Saffitz, J. E., et al. (2015). *Rubin's pathology: Clinicopathologic foundations of medicine* (7th ed., Fig. 33.2). Philadelphia, PA: Wolters Kluwer.

Clinical Manifestations

Painless, blurry vision is characteristic of cataracts. The person perceives that surroundings are dimmer, as if their glasses need cleaning. Light scattering is common, and the person experiences reduced contrast sensitivity, sensitivity to glare, and reduced visual acuity. Other effects include myopic shift (return of ability to do close work [e.g., reading fine print] without eyeglasses), **astigmatism** (refractive error due to an irregularity in the curvature of the cornea), monocular **diplopia** (double vision), and color changes as lens becomes more brown in color (Eliopoulos, 2018; Shaw & Lee, 2017).

Assessment and Diagnostic Findings

Decreased visual acuity is directly proportionate to cataract density. The Snellen visual acuity test, ophthalmoscopy, and slit-lamp biomicroscopic examination are used to establish the degree of cataract formation. The degree of lens opacity does not always correlate with the patient's functional status.

Some patients can perform normal activities despite clinically significant cataracts. Others with less lens opacification have a disproportionate decrease in visual acuity; hence, visual acuity is an imperfect measure of visual impairment.

Medical Management

No nonsurgical treatment (e.g., medications, eye drops, eyeglasses) cures cataracts or prevents age-related cataracts. Optimal medical management is prevention. Patients should be educated by primary providers about risk reduction strategies such as smoking cessation, weight reduction, optimal blood glucose control for patients with diabetes, and should be advised to wear sunglasses outdoors to prevent early cataract formation (Shaw & Lee, 2017).

Surgical Management

In general, if reduced vision from cataract does not interfere with normal activities, surgery may not be needed. In deciding when cataract surgery is to be performed, the patient's functional and visual status should be a primary consideration (Eliopoulos, 2018). Cataract removal is common, with more than one million such surgeries performed in the United States each year (Prevent Blindness America, 2020). Surgery is performed on an outpatient basis and usually takes less than 1 hour, with the patient being discharged in 30 minutes or less afterward. Although complications from cataract surgery are uncommon, they can have significant effects on vision (see Table 58-6). Restoration of visual function through a safe and minimally invasive procedure is the surgical goal, which is achieved with advances in topical anesthesia, smaller wound incision (i.e., clear cornea incision), and lens design (i.e., foldable and more accurate intraocular lens [IOL] measurements).

Chart 58-8 RISK FACTORS

Cataract Formation

Aging

- Accumulation of a yellow-brown pigment due to the breakdown of lens protein
- Clumping or aggregation of lens protein (which leads to light scattering)
- Decreased oxygen uptake
- Decrease in levels of vitamin C, protein, and glutathione (an antioxidant)
- Increase in sodium and calcium
- Loss of lens transparency

Associated Ocular Conditions

- Infection (e.g., herpes zoster, uveitis)
- Myopia
- Retinal detachment and retinal surgery
- Retinitis pigmentosa

Toxic Factors

- Alkaline chemical eye burns, poisoning
- Aspirin use
- Calcium, copper, iron, gold, silver, and mercury, which tend to deposit in the pupillary area of the lens
- Cigarette smoking
- Corticosteroids, especially at high doses and in long-term use
- Ionizing radiation

Nutritional Factors

- Obesity
- Poor nutrition
- Reduced levels of antioxidants

Physical Factors

- Blunt trauma, perforation of the lens with a sharp object or foreign body, electric shock
- Dehydration associated with chronic diarrhea, the use of purgatives in anorexia nervosa, and the use of hyperbaric

oxygenation
- Ultraviolet radiation in sunlight and x-ray

Systemic Diseases and Syndromes

- Diabetes
- Disorders related to lipid metabolism
- Down syndrome
- Musculoskeletal disorders
- Renal disorders

Adapted from Norris, T. (2019). *Porth's pathophysiology: Concepts of altered health status* (10th ed.). Philadelphia, PA: Wolters Kluwer; Prevent Blindness. (2020). Know the risk factors for cataract. Retrieved on 2/16/2020 at: www.preventblindness.org/know-risk-factors-cataract

TABLE 58-6 Potential Complications of Cataract Surgery

Complication	Effects	Management and Outcome
Immediate Preoperative		
Retrobulbar hemorrhage—can result from retrobulbar infiltration of anesthetic agents if the short ciliary artery is located by the injectia	Increased IOP, proptosis, lid tightness, and subconjunctival hemorrhage with or without edema	Emergent lateral canthotomy (slitting of the canthus) is performed to stop central retinal perfusion when the IOP is dangerously elevated. If this procedure fails to reduce IOP, a puncture of the anterior chamber with removal of fluid is considered. The patient must be closely monitored for at least a few hours. Postponement of cataract surgery for 2–4 wks is advised. Complications such as iris prolapse, vitreous loss, and choroidal hemorrhage could result in a catastrophic visual outcome.
Intraoperative		
Rupture of the posterior capsule	May result in loss of vitreous	Anterior vitrectomy is required if vitreous loss occurs.
Suprachoroidal (expulsive) hemorrhage—profuse bleeding into the suprachoroidal space	Extrusion of intraocular contents from the eye or opposition of retinal surfaces	Closure of the incision and administration of a hyperosmotic agent to reduce IOP or corticosteroids to reduce intraocular inflammation. Vitrectomy is performed 1–2 wks later. Visual prognosis is poor; some useful vision may be salvaged on rare occasions.
Early Postoperative		
Acute bacterial endophthalmitis—devastating complication that occurs in about 1 in 1000 cases; the most common causative organisms are *Staphylococcus epidermidis, Staphylococcus aureus, Pseudomonas,* and *Proteus* species	Characterized by marked visual loss, pain, lid edema, hypopyon, corneal haze, and chemosis	Managed by aggressive antibiotic therapy. Broad-spectrum antibiotics are given while awaiting culture and sensitivity results. Once results are obtained, the appropriate antibiotics are given via intravitreal injection. Corticosteroid therapy is also given.
Toxic anterior segment syndrome—noninfectious inflammation that is a complication of anterior chamber	Corneal edema occurs <24 h after surgery; symptoms include reduced	If there is no growth of microorganisms, the treatment is topical steroids alone.

surgery; caused by a toxic agent such as an agent used to sterilize surgical instruments	visual acuity and pain	
Late Postoperative		
Suture-related problems	Toxic reactions or mechanical injury from broken or loose sutures	Suture removal relieves the symptoms. Topical corticosteroids are used when the incision is not healed and sutures cannot be removed.
Malposition of the IOL	Results in astigmatism, sensitivity to glare, or appearance of halos	Miotics are used for mild cases, whereas IOL removal and replacement is necessary for severe cases.
Chronic endophthalmitis	Persistent, low-grade inflammation, and granuloma	Corticosteroids and antibiotics are given systemically. If the condition persists, removal of the IOL and capsular bag, vitrectomy, and intravitreal injection of antibiotics are required.
Opacification of the posterior capsule—most common late complication of extracapsular cataract extraction	Visual acuity is diminished	Nd:YAG laser is used to create a hole in the posterior capsule. Blurred vision is cleared immediately.

IOL, intraocular lens; IOP, intraocular pressure; Nd:YAG, Neodymium: yttrium aluminum garnet.

Adapted from Shaw, M., & Lee, A. (2017). *Ophthalmic nursing* (5th ed.). Boca Raton, FL: CRC Press Taylor & Francis Group.

Injection-free topical and intraocular anesthesia, such as 1% lidocaine gel applied to the surface of the eye, eliminates the hazards of regional (retrobulbar and peribulbar) anesthesia, such as ocular perforation, retrobulbar hemorrhage, optic injuries, diplopia, and ptosis, and is ideal for patients receiving anticoagulants. Furthermore, patients can communicate and cooperate during surgery. IV sedation may be used to minimize anxiety and discomfort.

When both eyes have cataracts, one eye is treated first, with at least several weeks, preferably months, separating the two procedures. Because cataract surgery is performed to improve visual functioning, the delay for the other eye gives time for the patient and the surgeon to evaluate whether the results from the first surgery are adequate to preclude the need for a second operation. The delay also provides time for the first eye to recover; if there are any

complications, the surgeon may decide to perform the second procedure differently.

Phacoemulsification

In this method of extracapsular cataract surgery, a portion of the anterior capsule is removed, allowing extraction of the lens nucleus and cortex while the posterior capsule and zonular support are left intact. An ultrasonic device is used to liquefy the nucleus and cortex, which are then suctioned out through a tube. An intact zonular–capsular diaphragm provides the needed safe anchor for the posterior chamber IOL. The pupil is dilated to 7 mm or greater (Shaw & Lee, 2017). The surgeon makes a small incision on the upper edge of the cornea and a viscoelastic substance (clear gel) is injected into the space between the cornea and the lens. This prevents the space from collapsing and facilitates insertion of the IOL. Because the incision is smaller than the manual extracapsular cataract extraction, the wound heals more rapidly, and there is early stabilization of refractive error and less astigmatism.

Lens Replacement

After removal of the crystalline lens, the patient is referred to as aphakic (i.e., without lens). The lens, which focuses light on the retina, must be replaced for the patient to see clearly. There are three lens replacement options: aphakic eyeglasses, contact lenses, and IOL implants.

Aphakic glasses, although effective, are rarely used. Objects are magnified by 25%, making them appear closer than they actually are. This magnification creates distortion. Peripheral vision is also limited, and **binocular vision** (i.e., ability of both eyes to focus on one object and fuse the two images into one) is impossible if the other eye is aphakic (without a natural lens).

Contact lenses provide patients with almost normal vision, but because contact lenses need to be removed occasionally, the patient also needs a pair of aphakic glasses. Contact lenses are not advised for patients who have difficulty inserting, removing, and cleaning them. Frequent handling and improper disinfection increase the risk of infection.

Insertion of IOLs during cataract surgery is the most common approach to lens replacement (Eliopoulos, 2018). After cataract extraction, or phacoemulsification, the surgeon implants an IOL. Cataract extraction and posterior chamber IOLs are associated with a relatively low incidence of complications (e.g., eye infection, loss of vitreous humor, slipping of the implant) (Eliopoulos, 2018). IOL implantation is contraindicated in patients with recurrent uveitis, proliferative diabetic retinopathy, neovascular glaucoma, or rubeosis iridis.

Nursing Management

Providing Preoperative Care

The patient with cataracts receives the usual preoperative care for ambulatory surgical patients undergoing eye surgery. The standard battery of preoperative tests (e.g., complete blood count, electrocardiogram, urinalysis) commonly performed for most surgeries is prescribed only if indicated by the patient's medical history.

Alpha-antagonists (particularly tamsulosin, which is used for treatment of enlarged prostate) are known to cause a condition called *intraoperative floppy iris syndrome.* Alpha-antagonists can interfere with pupil dilation during the surgical procedure, resulting in miosis and iris prolapse and leading to complications. Intraoperative floppy iris syndrome can occur even though a patient has stopped taking the drug. The nurse needs to ask patients about a history of taking alpha-antagonists. Surgical team members are then alerted to the risk of this complication (Comerford & Durkin, 2020).

Dilating drops are given prior to surgery. Nurses in the ambulatory surgery setting begin patient education about eye medications (antibiotic, corticosteroid, and anti-inflammatory drops) that will need to be self-administered to prevent postoperative infection and inflammation.

Providing Postoperative Care

Before discharge, the patient receives verbal and written education regarding eye protection, administration of medications, recognition of complications, activities to avoid, and obtaining emergency care (see Chart 58-9). An eye shield is usually worn at night for the first week to avoid injury. The nurse also explains that there should be minimal discomfort after surgery and educates the patient about taking a mild analgesic agent, such as acetaminophen, as needed. Antibiotic, anti-inflammatory, and corticosteroid eye drops or ointments are prescribed postoperatively. Patients prescribed anti-inflammatory or corticosteroid eye drops are monitored for possible increases in IOP (Phulke, Kaushik, Kaur, et al., 2017).

Chart 58-9  **HOME CARE CHECKLIST**

Intraocular Lens Implant

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Describe ongoing postoperative therapeutic regimen and activities to limit or avoid (e.g., lifting weights, driving a car, engaging in contact sports).
  - Wear glasses or eye shield following surgery as instructed.
  - Always wash hands before touching or cleaning the postoperative eye.
  - Clean postoperative eye with a clean tissue; wipe the closed eye with a single gesture from the inner canthus outward.
  - When bathing or showering, shampoo hair cautiously or seek assistance.
  - Avoid lying on the side of the affected eye the night after surgery.
  - Keep activity light (e.g., walking, reading, watching television). Resume the following activities only as directed by the ophthalmologist: driving, sexual activity, unusually strenuous activity.
  - Avoid lifting, pushing, or pulling objects heavier than 15 lb.
  - Avoid bending or stooping for an extended period.
  - Be careful when climbing or descending stairs.
- Describe signs and symptoms of complications (e.g., vision change, continuous flashing lights appear to the affected eye, redness, swelling or increased pain near the eye, change in amount or type of eye drainage, any eye injury, significant pain not relieved by prescribed analgesia).
- Relate how to reach ophthalmologist with questions or complications.
- State time and date of follow-up appointments.
- Identify sources of assistance (e.g., meals, transportation) and support (e.g., friends, relatives, faith community).
- Identify the need for health promotion, disease prevention, and screening activities

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

To prevent inadvertent rubbing or poking of the eye, the patient wears a protective eye patch for about the first 24 hours after surgery, followed by eyeglasses worn during the day and an eye shield at night. The nurse educates the patient and family about applying and caring for the eye shield, if one is recommended. Sunglasses should be worn while outdoors during the day because the eye is sensitive to light.

Slight morning discharge, some redness, and a scratchy feeling may be expected for a few days. A clean, damp washcloth may be used to remove slight morning eye discharge. Because cataract surgery increases the risk of retinal detachment, the patient must know to notify the surgeon if new floaters (moving dots) in vision, flashing lights, decrease in vision, pain, or increase in redness occur.

Continuing and Transitional Care

If an eye patch is worn, it is removed after the first follow-up appointment, which should occur within 48 hours of surgery. Nurses should educate patients about the importance of keeping their follow-up appointments, because monitoring of visual status and prompt intervention of postoperative complications enhance good visual outcome. Vision is stabilized when the eye is completely healed, usually within 6 to 12 weeks, when final corrective prescription is completed. Visual correction may still be needed for any remaining refractive errors. Patients who choose multifocal IOLs should be aware that increased night glare and contrast sensitivity may occur.

CORNEAL DISORDERS

Corneal Dystrophies

Corneal dystrophies are inherited as autosomal dominant traits and manifest when the person is about 20 years of age. They are characterized by deposits in the corneal layers. Decreased vision is caused by the irregular corneal surface and corneal deposits. Corneal endothelial decomposition leads to corneal edema and blurring of vision. Persistent edema leads to bullous keratopathy or the formation of blisters that cause pain and discomfort on rupturing. The two main types are keratoconus and Fuchs endothelial dystrophy.

Keratoconus

Keratoconus, the most common type of corneal dystrophy, is characterized by a conical protuberance of the cornea with progressive thinning on protrusion and irregular astigmatism. This hereditary condition has a higher incidence among women. Onset occurs at puberty; the condition may progress for more than 20 years and is bilateral. Corneal scarring occurs in severe cases. Blurred vision is a prominent symptom. Rigid, gas-permeable contact lenses correct irregular astigmatism and improve vision. Advances in contact lens design have reduced the need for surgery. Penetrating keratoplasty (PKP) is indicated when contact lens correction is no longer effective (Allard & Zetterberg, 2018).

Fuchs Endothelial Dystrophy

Fuchs (pronounced *Fooks*) dystrophy is manifested by a slow death of cells in the endothelial cornea. It affects women more than men and is usually not noted until 50 years of age. Corneal endothelial cell death leads to corneal edema and blurring of vision. Persistent edema leads to bullous keratopathy. A bandage contact lens is used to flatten the bullae, protect the exposed corneal nerve endings, and relieve discomfort. Symptomatic treatments, such as hypertonic drops or ointment (5% sodium chloride), may reduce epithelial edema. Currently, the only cure is a corneal transplant (Moshirfar, Ding, & Shah, 2018).

Corneal Surgeries

Among the surgical procedures used to treat diseased corneal tissue are phototherapeutic keratectomy (PTK), PKP and corneal endothelial transplantation, and Descemet's stripping endothelial keratoplasty (DSEK).

Phototherapeutic Keratectomy

PTK is a laser procedure that is used to treat diseased corneal tissue by removing or reducing corneal opacities and smoothing the anterior corneal surface to improve functional vision. PTK is contraindicated in patients with active herpetic keratitis because the ultraviolet rays may reactivate latent virus. Common side effects are induced hyperopia and stromal haze. Complications are delayed re-epithelialization (particularly in patients with diabetes) and bacterial keratitis. Postoperative management consists of oral analgesic agents for eye pain. Re-epithelialization is promoted with a pressure patch or therapeutic soft contact lens. Antibiotic and corticosteroid ointments and NSAIDs are prescribed postoperatively. Follow-up examinations are required for up to 2 years.

Penetrating Keratoplasty

PKP (corneal transplantation or corneal grafting) involves replacing abnormal host tissue with healthy donor (cadaver) corneal tissue. Common indications are keratoconus, corneal scarring from herpes simplex, keratitis, and chemical burns.

Several factors affect the success of the graft: the condition of the ocular structures (e.g., lids, conjunctiva), quality of the tears, adequacy of blinking, and viability of the donor endothelium. Contraindications for the use of donor tissue are outlined in Chart 58-10.

In PKP, the surgeon determines the graft size before the procedure, and the appropriate size is marked on the surface of the cornea. The surgeon prepares the donor cornea and the recipient bed, removes the diseased cornea, places the donor cornea on the recipient bed, and sutures it in place. Sutures remain in place for 12 to 18 months and are then removed. Potential complications include early graft failure due to poor quality of donor tissue, surgical trauma, acute infection, and persistently increased IOP and late graft failure due to rejection.

Chart 58-10

Contraindications to the Use of Donor Tissue for Corneal Transplantation: Donor Characteristics

Systemic Disorders

- Death from unknown cause
- History or suspected history of the following:
  - Acquired immune deficiency syndrome or high risk for human immune deficiency virus infection
  - Creutzfeldt–Jakob disease
  - Eye infection
  - Hepatitis
  - Rabies
  - Systemic infection

Intrinsic Eye Disease

- Disorders of the conjunctiva or corneal surface involving the optical zone of the cornea
- Malignant tumors of anterior segment
- Ocular inflammation
- Retinoblastoma

Other

- Corneal scars
- History of eye trauma
- Previous surgical eye procedures such as corneal graft or LASIK eye surgery

Postoperatively, the patient receives mydriatics for 2 weeks and topical corticosteroids for 12 months (daily doses for 6 months and tapered doses thereafter). These mydriatics and corticosteroid drops should be preservative free to prevent a reactive inflammation. Patients typically describe a sensation of postoperative eye discomfort rather than acute pain.

Additional Keratoplasty Surgeries

For many years, PKP was the standard of care for patients with corneal endothelial failure but with poor refractive results. Subsequently, other techniques have been developed. Anterior lamellar keratoplasty (ALK) involves a partial-thickness graft for disorders such as anterior corneal dystrophies or scarring not involving the endothelial portion of the cornea. Deep anterior lamellar keratoplasty (DALK) involves replacement of only anterior corneal layers and not Descemet's membrane or endothelial layers for

disorders such as keratoconus. Posterior lamellar keratoplasty (PLK or EK) and DSEK (which replaces only the endothelial layer of the cornea) are procedures indicated for conditions such as Fuchs endothelial dystrophy or bullous keratopathy (Moshirfar et al., 2018). In DSEK, layers of the cornea are dissected and selectively replaced by donor cornea tissue. DSEK offers several advantages, such as less postoperative astigmatism, faster visual recovery, and stronger wound integrity. Theoretically, the risk of rejection is less because less of the patient's tissue is replaced.

Keratoprosthesis

An additional therapeutic option for patients with multiple graft failures or severe corneal disease is keratoprosthesis (artificial cornea; e.g., U.S. Food and Drug Administration [FDA]-approved Boston Keratoprosthesis [KPro] and AlphaCor). The design of the keratoprosthesis consists of a central optic core and an outer rim that secures the prosthesis. This procedure has serious potential complications (e.g., glaucoma, endophthalmitis) and requires close follow-up and monitoring (Shalaby Bardan, Al Raqqad, Zarei-Ghanavati, et al., 2018).

Nursing Management

For corneal surgeries, the nurse reinforces instructions regarding visual rehabilitation and visual improvement. A technically successful graft may initially produce disappointing results because the procedure has produced a new optical surface. Only after several months do patients start seeing the natural and true colors of their environment. Correction of a resultant refractive error with eyeglasses or contact lenses determines the final visual outcome. The nurse assesses the patient's support system and their ability to comply with long-term follow-up, which includes frequent clinic visits for several months for tapering of topical corticosteroid therapy, selective suture removal, and ongoing evaluation of the graft site and visual acuity. The nurse also initiates appropriate referrals to community services as indicated.

Because graft failure is an ophthalmic emergency that can occur at any time, the primary goal of nursing care is to educate the patient to identify signs and symptoms of graft failure. The early symptoms are blurred vision, discomfort, tearing, or redness of the eye. Decreased vision results after graft destruction. The patient must contact the ophthalmologist as soon as symptoms occur. Treatment of graft rejection usually involves prompt administration of hourly topical corticosteroids and periocular corticosteroid injections. Systemic immunosuppressive agents may be necessary for severe, resistant cases.

Refractive Surgeries

Refractive surgeries are elective procedures performed to correct refractive errors (myopia or hyperopia) and astigmatism by reshaping the cornea (Gomel, Negari, Frucht-Pery, et al., 2018). Laser vision correction alters the major optical function of the eye and carries risks. Refractive surgery does not alter the normal aging process of the eye. If the reason for the procedure is to meet vision requirements for the patient's occupation, the results must satisfy both the patient and the employer. Precise visual outcome cannot be guaranteed.

The corneal structure must be normal, and the refractive error must be stable. The patient is required to discontinue using contact lenses for a period before the procedure (2 to 3 weeks for soft lenses and 4 weeks for hard lenses). Patients with conditions that are likely to adversely affect corneal wound healing (e.g., corticosteroid use, immunosuppression, elevated IOP) are not good candidates for the procedure. Any superficial eye disease must be diagnosed and fully treated before a refractive procedure.

Patient satisfaction is the ultimate goal; therefore, patient education and counseling about potential risks, complications, and postoperative follow-up are critical. Minimal postoperative care includes topical corticosteroid or NSAID and antibiotic drops.

Laser Vision Correction Photorefractive Keratectomy

Photorefractive keratectomy (PRK) is used to treat myopia and hyperopia with or without astigmatism (Gomel et al., 2018). The excimer laser is applied directly to the cornea according to carefully calculated measurements. For myopia, the relative curvature is decreased; for hyperopia, the relative curvature is increased. A bandage contact lens is placed over the cornea to promote epithelial healing and reduce pain, which is similar to that of a severe corneal abrasion.

Laser-Assisted In Situ Keratomileusis

LASIK involves flattening the anterior curvature of the cornea by removing a stromal lamella or layer. The surgeon creates a corneal flap with a microkeratome, which is an automatic corneal shaper. The surgeon retracts a flap of corneal tissue less than one third the thickness of a human hair to access the corneal stroma and then uses the excimer laser on the stromal bed to reshape the cornea according to calculated measurements (see Fig. 58-9). Data are insufficient to determine whether LASIK or PRK is better at correcting nearsightedness (Gomel et al., 2018). There are few adverse outcomes of either procedure.

Perioperative Complications

Surgically Induced Abnormalities

Corneal surface irregularities can occur after LASIK treatment. These include central islands (central areas of stiffness or elevation), decentered ablations resulting from misalignment of the laser treatment or from involuntary eye movement during laser treatment, and forms of irregular astigmatism. Symptoms of central islands and decentered ablations include monocular diplopia or ghost images, halos, glare, and decreased visual acuity.

Phakic Intraocular Lenses

Increasingly, phakic IOL implantation has been used for patients with moderate to severe myopia (Igarashi, 2019). Phakic IOLs may be used in either the anterior or posterior chamber. The implantation of such devices is reversible because the natural lens is left in place and the normal architecture of the cornea is preserved. This procedure provides more predictable refractive results than procedures that alter the corneal curvature, is safer, and has higher patient satisfaction scores (Igarashi, 2019). Potential complications include cataract, iritis or uveitis, endothelial cell loss, and increased IOP.

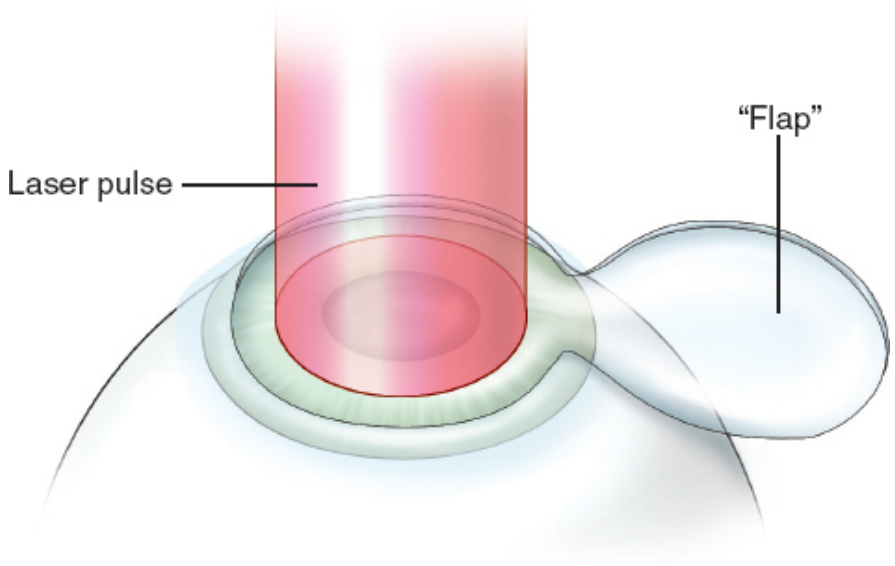

Figure 58-9 • LASIK combines delicate surgical procedures and laser treatment. A flap is surgically created and lifted to one side. A laser is then applied to the cornea to reshape it. With permission from the Wilmer Laser Vision Center, Lutherville, MD.

Conductive Keratoplasty

Another innovation in refractive surgery for the correction of low to mild hyperopia uses the principles of thermal keratoplasty by applying

radiofrequency current to the peripheral cornea using a thin, handheld probe. It does not involve the removal of cornea tissue.

RETINAL DISORDERS

Although the retina is composed of multiple microscopic layers, the two innermost layers—the sensory retina and the retinal pigment epithelium—are most commonly implicated in retinal disorders (Norris, 2019).

Retinal Detachment

Retinal detachment refers to the separation of the retinal pigment epithelium from the neurosensory layer (Norris, 2019). The four types of retinal detachment are rhegmatogenous, traction, a combination of rhegmatogenous and traction, and exudative. *Rhegmatogenous retinal detachment* is the most common form (Liao & Zhu, 2019). In this condition, a hole or tear develops in the sensory retina, allowing some of the liquid vitreous to seep through the sensory retina and detach it from the retinal pigment epithelium (see Fig. 58-10). People at risk for this type of detachment include those with high myopia or those who have aphakia (absence of the natural lens) after cataract surgery. Trauma may also play a role in rhegmatogenous retinal detachment. Between 5% and 10% of all rhegmatogenous retinal detachments are associated with proliferative retinopathy—a retinopathy associated with diabetic neovascularization (see Chapter 46).

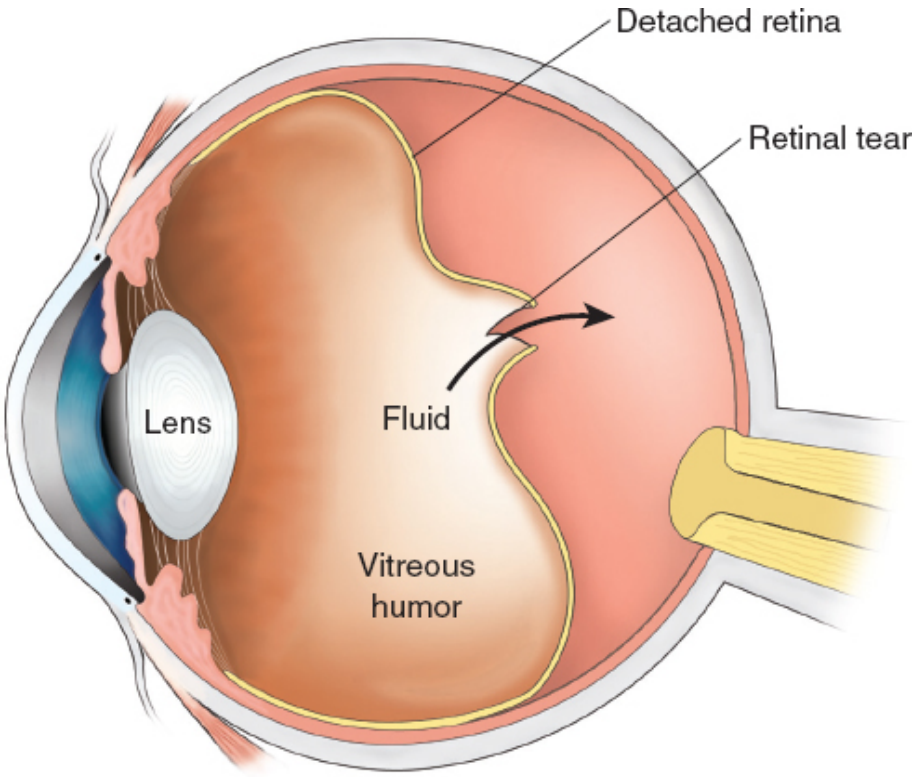

Figure 58-10 • Retinal detachment.

Tension, or a pulling force, is responsible for *traction retinal detachment.* An ophthalmologist must ascertain all of the areas of retinal break and identify and release the scars or bands of fibrous material providing traction on the retina. In general, patients with this condition have developed fibrous scar tissue from conditions such as diabetic retinopathy, vitreous hemorrhage, or the retinopathy of prematurity. The hemorrhages and fibrous proliferation associated with these conditions exert a pulling force on the delicate retina.

Patients can have both rhegmatogenous and traction retinal detachment. *Exudative retinal detachments* are the result of the production of a serous fluid under the retina from the choroid. Conditions such as uveitis and macular degeneration may cause the production of this serous fluid.

Clinical Manifestations

Patients may report the sensation of a shade or curtain coming across the vision of one eye, cobwebs, bright flashing lights, or the sudden onset of a great number of floaters. Patients do not complain of pain but retinal detachment is an ocular emergency, requiring immediate surgical intervention for optimal outcomes.

Assessment and Diagnostic Findings

After visual acuity is determined, the patient must have a dilated fundus examination using an indirect ophthalmoscope as well as slit-lamp biomicroscopy. Stereo fundus photography and fluorescein angiography are commonly used during the evaluation.

Increasingly, optical coherence tomography and ultrasound are used for the complete retinal assessment, especially if the view is obscured by a dense cataract or vitreal hemorrhage. All retinal breaks, all fibrous bands that may be causing traction on the retina, and all degenerative changes must be identified.

Surgical Management

In rhegmatogenous retinal detachment, an attempt is made to surgically reattach the sensory retina to the retinal pigment epithelium. In traction retinal detachment, the source of traction must be removed and the sensory retina reattached. The most commonly used surgical interventions are the scleral buckle and vitrectomy (Park, Lee, & Lee, 2018).

Scleral Buckle

The retinal surgeon compresses the sclera (often with a scleral buckle [see Fig. 58-11] or a silicone band) to indent the scleral wall from the outside of the eye and bring the two retinal layers in contact with each other (Park et al., 2018).

Vitrectomy

A vitrectomy is an intraocular procedure that allows the introduction of a light source through an incision; a second incision serves as the portal for the vitrectomy instrument. The surgeon dissects preretinal membranes under direct visualization while the retina is stabilized by an intraoperative vitreous substitute.

Traction on the retina may be relieved through vitrectomy and may be combined with scleral buckling to repair retinal detachments. A gas bubble, silicone oil, or perfluorocarbon and liquids may be injected into the vitreous cavity to help push the sensory retina up against the retinal pigment epithelium.

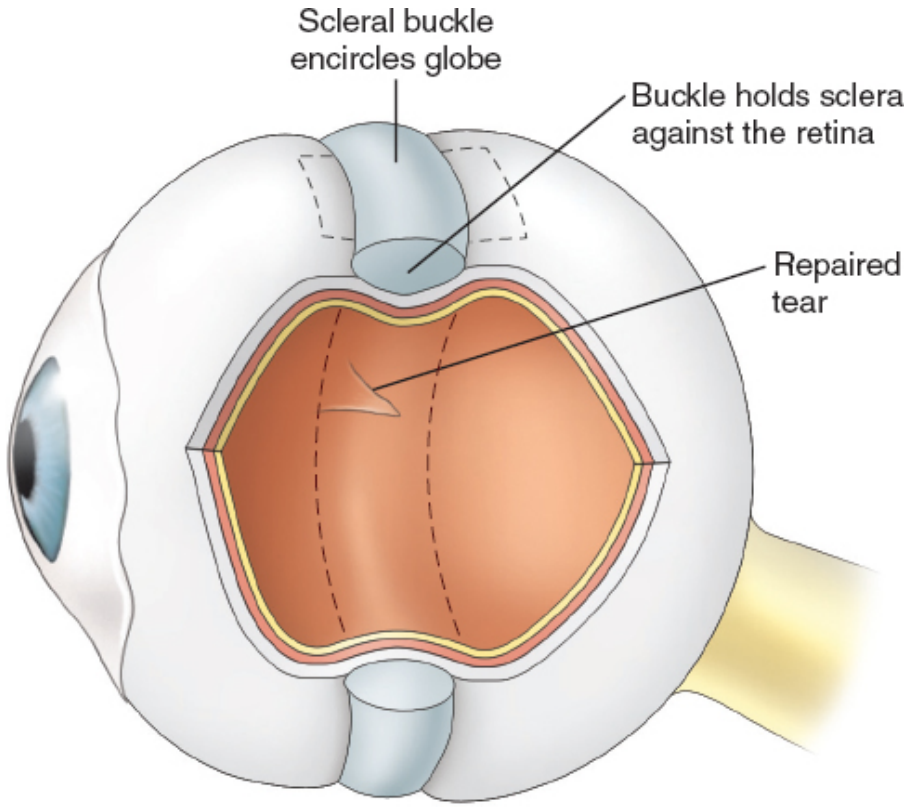

Figure 58-11 • Scleral buckle.

Nursing Management

Nursing management consists of educating the patient and providing supportive care. Postoperative positioning of the patient is critical when a gas bubble is used because the injected bubble must remain in position overlying the area of detachment, providing consistent pressure to reattach the sensory retina. The patient must maintain a prone position that would allow the gas bubble to act as a tamponade for the retinal break (Shaw & Lee, 2017). Patients and family members should be made aware of these needs beforehand so that the patient can be made as comfortable as possible.

In most cases, vitreoretinal procedures are performed on an outpatient basis, and the patient is seen the next day for a follow-up examination. Postoperative complications may include increased IOP, endophthalmitis, retinal detachment, and development of cataracts. Patients must be educated about the signs and symptoms of complications, particularly of increasing IOP and postoperative infection. Contact details for the ophthalmic team are provided and the patient is encouraged to call immediately if complications occur.

Retinal Vascular Disorders

Loss of vision can occur from occlusion of a retinal artery or vein. Such occlusions may result from atherosclerosis, valvular heart disease, venous stasis, hypertension, or increased blood viscosity. Associated risk factors include diabetes, glaucoma, and aging.

Central Retinal Vein Occlusion

Blood supply to and from the ocular fundus is provided by the central retinal artery and vein. Central retinal vein occlusions (CRVOs) are found most often in people older than 50 years. Patients who suffer a CRVO report decreased visual acuity ranging from mild blurring to severely limited.

Direct ophthalmoscopy of the retina shows optic disc swelling, venous dilation and tortuousness, retinal hemorrhages, cotton-wool spots, and a bloody appearance of the retina. The better the initial visual acuity, the better is the general prognosis.

Fluorescein angiography may show extensive areas of capillary closure. The patient should be monitored carefully over the ensuing several months for signs of neovascularization and neovascular glaucoma. Laser panretinal photocoagulation may be necessary to treat the abnormal neovascularization. Neovascularization of the iris may cause neovascular glaucoma. Macular edema, macular nonperfusion, and vitreous hemorrhage from the neovascularization are among the potential complications of CRVO (Schmidt-Erfurth, Garcia-Arumi, Gerendas, et al., 2019).

Branch Retinal Vein Occlusion

Some patients with branch retinal vein occlusion (BRVO) are symptom free, whereas others complain of a sudden loss of vision if the macular area is involved. A more gradual loss of vision may occur if macular edema associated with BRVO develops.

On examination, the ocular fundus appears similar to that found in CRVO. The occlusions generally occur at the arteriovenous crossings. The diagnostic evaluation and follow-up assessments and complications are the same as for CRVO. Associated conditions include glaucoma, systemic hypertension, diabetes, and hyperlipidemia (Schmidt-Erfurth et al., 2019).

Central Retinal Artery Occlusion

Patients with central retinal artery occlusion, a relatively rare disorder that accounts for approximately 1 in 10,000 ophthalmologic visits, present with a sudden loss of vision. Visual acuity is reduced to being able to count the examiner's fingers, or the field of vision is tremendously restricted. A relative afferent pupillary defect is present. Examination of the ocular fundus reveals a

pale retina with a cherry-red spot at the fovea. The retinal arteries are thin, and emboli are occasionally seen in the central retinal artery or its branches. Central retinal artery occlusion is a true ocular emergency. Various treatments may include ocular massage, anterior chamber paracentesis, hyperbaric oxygen therapy, topical ocular hypotensive agents, anticoagulation, and intravenous mannitol and acetazolamide. An aggressive stepwise approach may be beneficial, depending on the underlying cause of the occlusion and the amount of time from onset of occlusion to treatment. Most visual loss associated with central retinal artery occlusion is severe and permanent (Schmidt-Erfurth et al., 2019).

Age-Related Macular Degeneration

AMD is the leading cause of irreversible blindness and visual impairment in the world (Bright Focus Foundation, 2020a). AMD is characterized by drusen beneath the retina (see Fig. 58-12). Most people older than 60 years have at least a few small drusen, which are clusters of debris or waste material. When drusen are located in the macular area, they can affect vision. Patients with AMD have a wide range of visual loss, but only a small portion experience total blindness. Central vision is generally the most affected, with most patients retaining peripheral vision (see Fig. 58-13). There are two types of AMD: the dry type and the wet type (Bright Focus Foundation, 2020a).

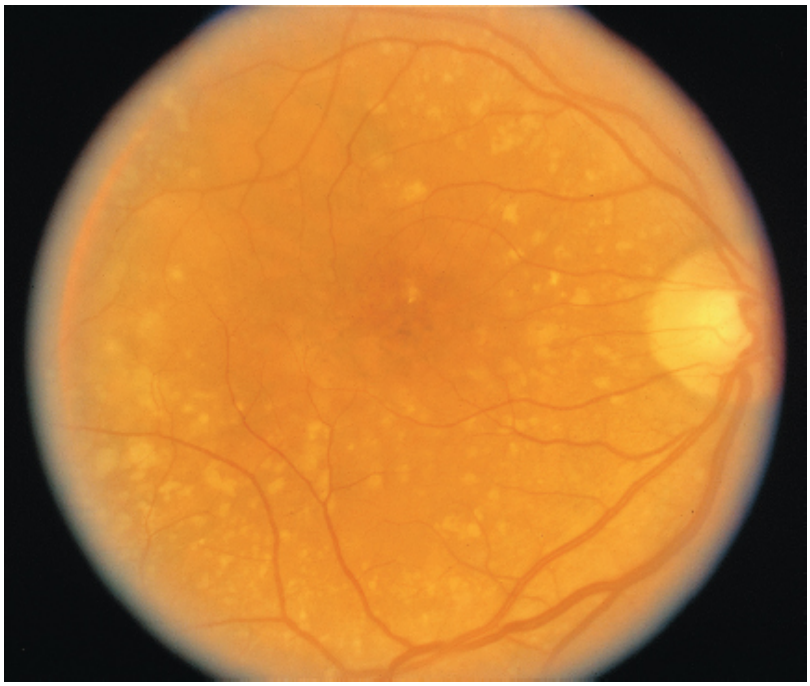

Figure 58-12 • Retina showing drusen and age-related macular degeneration.

Between 85% and 90% of people with AMD have the dry (nonneovascular, nonexudative) type of the condition, in which the outer layers of the retina slowly break down. With this breakdown comes the appearance of drusen. When the drusen occur outside of the macular area, patients generally have no symptoms. When the drusen occur within the macula, however, there is a gradual blurring of vision that patients may notice when they try to read.

The second type of AMD, the wet (neovascular, exudative) type, may have an abrupt onset and is more damaging to the vision (Bright Focus Foundation, 2020a). Patients report that straight lines appear crooked and distorted or that letters in words appear broken. This effect results from proliferation of abnormal blood vessels growing under the retina, within the choroid layer of the eye, a condition known as choroidal neovascularization. The affected vessels can leak fluid and blood, elevating the retina. Some patients can be treated with laser therapy to stop leakage from these vessels.

Chart 58-11 **PATIENT EDUCATION**

Education for Patients About Preventing Eye Injuries

The nurse instructs the patient in the following measures to prevent eye injuries:

In and Around the House

- Make sure that all spray nozzles are directed away from yourself before pressing down on the handle.
- Read instructions carefully before using cleaning fluids, detergents, ammonia, or harsh chemicals, and wash hands thoroughly after use.
- Use grease shields on frying pans to decrease spattering.
- Use opaque goggles to avoid burns from sunlamps.
- Wear special goggles to shield the eyes from fumes and splashes when using powerful chemicals.

In the Workshop

- Protect the eyes from flying fragments, fumes, dust particles, sparks, and splashed chemicals by wearing safety glasses.
- Read instructions thoroughly before using tools and chemicals, and follow precautions for their use.

Around Children

- Educate children about the correct way to handle potentially dangerous items, such as scissors and pencils.
- Pay attention to age and maturity level of a child when selecting toys and games, and avoid projectile toys, such as darts and pellet guns.
- Supervise children when they are playing with toys or games that can be dangerous.

In the Garden

- Avoid letting anyone stand at the side of or in front of a moving lawn mower.
- Avoid low-hanging branches.
- Direct pesticide spray can nozzles away from the face.
- Pick up rocks and stones before going over them with the lawn mower (stones can be hurled out of the rotary blades and rebound off curbs or walls, causing severe injury to the eye).

Around the Car

- Put out all smoking materials and matches before opening the hood of the car.
- Take standard safety precautions when using jumper cables (wear goggles; make sure the cars are not touching one another; make sure the jumper

cable clamps never touch each other; never lean over the battery when attaching cables; and never attach a cable to the negative terminal of a dead battery).
- Use a flashlight, not a match or lighter, to look at the battery at night.
- Wear goggles when grinding metal or striking metal against metal while performing auto body repair.

In Sports

- Wear protective caps, helmets, or face protectors when appropriate, especially for sports such as ice hockey.
- Wear protective safety glasses, especially for sports such as racquetball, squash, tennis, baseball, and basketball.

Around Fireworks

- Avoid explosive fireworks.
- Avoid standing near others when lighting fireworks.
- Douse firework duds in water instead of attempting to relight them.
- Never allow children to ignite fireworks.
- Wear eyeglasses or safety goggles.

Medical Management

There is no known effective treatment or cure for dry advanced macular degeneration (Bright Focus Foundation, 2020a).

An important component of treatment of wet (neovascular, exudative) AMD targets development and progression of angiogenesis (abnormal blood vessel formation). Vasoproliferation in wet AMD is believed to be caused by an underlying angiogenic stimulus known as vascular endothelial growth factor (VEGF) (Bright Focus Foundation, 2020a). Examples of VEGF inhibitors given by intravitreal injection include ranibizumab and brolucizumab (Bright Focus Foundation, 2020a; Comerford & Durkin, 2020).

Nursing Management

Amsler grids are given to patients to use in their homes to monitor for a sudden onset or distortion of vision. These may provide the earliest sign that macular degeneration is getting worse. Patients should be encouraged to look at these grids, one eye at a time, several times each week with glasses on if needed for corrected near vision. If there is a change in the way the grid appears to the patient (e.g., if the lines or squares appear distorted or faded), the patient should notify the ophthalmologist immediately and should arrange

to be seen promptly. There are digital versions of these grids as well that pick up abnormal changes quicker.

Orbital and Ocular Trauma

Whether affecting the eye or the orbit, trauma to the eye and surrounding structures may have devastating consequences for vision. It is preferable to prevent injury rather than treat it. Chart 58-11 details measures to prevent eye injuries.

Orbital Trauma

Injury to the orbit is usually associated with a head injury; hence, the patient's general medical condition must first be stabilized before conducting an ocular examination (Hickey & Strayer, 2020). Only then is the globe assessed for soft tissue injury. During inspection, the face is meticulously assessed for underlying fractures, which should always be suspected in cases of blunt trauma. To establish the extent of ocular injury, visual acuity is assessed as soon as possible, even if it is only a rough estimate. Soft tissue orbital injuries often result in damage to the optic nerve. Major ocular injuries indicated by a soft globe, prolapsing tissue, ruptured globe, and hemorrhage require immediate surgical attention.

Soft Tissue Injury and Hemorrhage

The signs and symptoms of soft tissue injury from blunt or penetrating trauma include tenderness, ecchymosis, lid swelling, **exophthalmos** (abnormal protrusion of the eyeball), and hemorrhage. Closed injuries lead to contusions with subconjunctival hemorrhage, commonly known as a black eye. Blood accumulates in the tissues of the conjunctiva. Hemorrhage may be caused by a soft tissue injury to the eyelid or by an underlying fracture.

Management of soft tissue hemorrhage that does not threaten vision is usually conservative and consists of thorough inspection, cleansing, and repair of wounds. Cold compresses are used in the early phase, followed by warm compresses. Hematomas that appear as swollen, fluctuating areas may be surgically drained or aspirated; if they are causing significant orbital pressure, they may be surgically evacuated.

Orbital Fractures

Orbital fractures are detected by facial x-rays. Depending on the orbital structures involved, orbital fractures can be classified as blowout, zygomatic or

tripod, maxillary, midfacial, orbital apex, and orbital roof fractures. Blowout fractures result from compression of soft tissue and the sudden increase in orbital pressure when the force is transmitted to the orbital floor, which is the area of least resistance (McQuillan & Makic, 2020).

The inferior rectus and inferior oblique muscles, with their fat and fascial attachments, or the nerve that courses along the inferior oblique muscle may become entrapped, resulting in enophthalmos (inward displacement of the globe). Computed tomography (CT) scanning can identify the muscle and its auxiliary structures that are entrapped. These fractures are usually caused by the blunt force from a fist or baseball (McQuillan & Makic, 2020).

Orbital roof fractures are dangerous because of potential complications to the brain. Surgical management of these fractures requires a neurosurgeon and an ophthalmologist. The most common indications for surgical intervention are displacement of bone fragments disfiguring the normal facial contours, interference with normal binocular vision caused by extraocular muscle entrapment, interference with mastication in zygomatic fracture, and obstruction of the nasolacrimal duct. Surgery is usually nonemergent, and a period of 10 to 14 days gives the ophthalmologist time to assess ocular function, especially the extraocular muscles and the nasolacrimal duct. Emergency surgical repair is usually not performed unless the globe is displaced into the maxillary sinus. Surgical repair is primarily directed at freeing the entrapped ocular structures and restoring the integrity of the orbital floor.

Foreign Bodies

Foreign bodies that enter the orbit are usually tolerated, except for steel, copper, iron, and vegetable materials such as those from plants or trees, which may cause purulent infection. X-rays and CT scans are used to identify the foreign body. A careful history is important, especially if the foreign body has been in the orbit for a period of time and the incident forgotten. It is important to identify metallic foreign bodies because they prohibit the use of magnetic resonance imaging (MRI) as a diagnostic tool.

After the extent of the orbital damage is assessed, the decision to use conservative treatment or surgical removal is made. In general, orbital foreign bodies are removed if they are superficial and anterior in location; have sharp edges that may affect adjacent orbital structures; or are composed of copper, iron, or vegetable material. Surgical intervention is directed at preventing further ocular injury and maintaining the integrity of the affected areas. Cultures are usually obtained, and the patient is placed on prophylactic IV antibiotic medications that are later changed to an oral route.

Ocular Trauma

Ocular trauma is a leading cause of blindness among children and young adults, especially male trauma victims (Buc´an, Matas, Lovric´, et al., 2017). Ocular trauma occurs with occupational injuries (e.g., construction industry), contact sports, weapons (e.g., air guns, BB guns), assaults, motor vehicle crashes (e.g., broken windshields), and explosions (e.g., blast fragments).

There are two types of ocular trauma in which the first response is critical: chemical burn and foreign object in the eye. With a chemical burn, the eye should be immediately irrigated with tap water or normal saline. With a foreign body, no attempt should be made to remove the foreign object. The object should be protected from jarring or movement to prevent further ocular damage. No pressure or patch should be applied to the affected eye. All other traumatic eye injuries should be protected using a patch or shield if available or a stiff paper cup until medical treatment can be obtained (see Fig. 58-14).

Assessment and Diagnostic Findings

A thorough history is obtained, particularly assessing the patient's ocular history, such as pre-injury vision in the affected eye or past ocular surgery. Details related to the injury that help in the diagnosis and assessment of the need for further tests include the nature of the ocular injury (i.e., blunt or penetrating trauma); the type of activity that caused the injury to determine the nature of the force striking the eye; and whether onset of vision loss was sudden, slow, or progressive. For chemical eye burns, the chemical agent must be identified and tested for pH if the agent is available. The corneal surface is examined for foreign bodies, wounds, and abrasions, after which the other external structures of the eye are examined. Pupil size, shape, and light reaction of the pupil of the affected eye are compared with the other eye. Ocular motility (ability of the eyes to move synchronously up, down, right, and left) is also assessed.

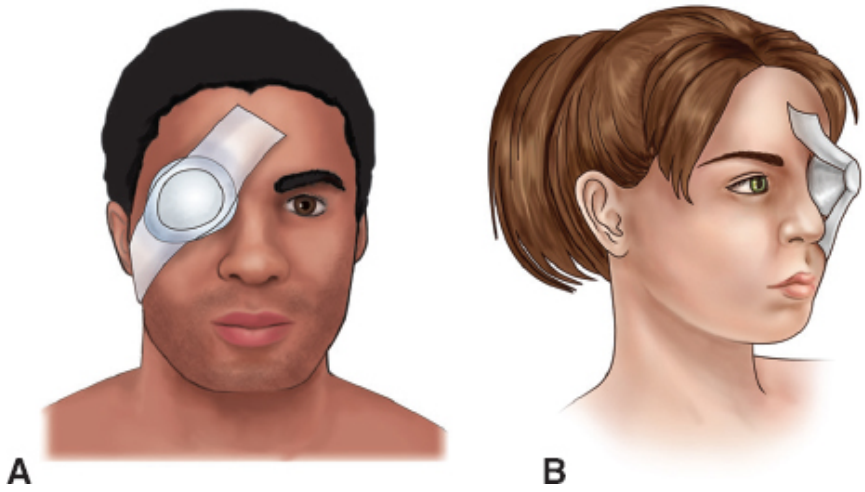

Figure 58-14 • Two kinds of eye patches. **A.** Aluminum shield. **B.** Stiff paper cup shield (innovative substitute when aluminum shield is unavailable).

Medical Management

Splash Injuries

Splash injuries are irrigated with normal saline solution before further evaluation occurs. In cases of a ruptured globe, cycloplegic agents (agents that paralyze the ciliary muscle) or topical antibiotics must be deferred because of potential toxicity to exposed intraocular tissues. Further manipulation of the eye must be avoided until the patient is under general anesthesia. Parenteral, broad-spectrum antibiotics are initiated. Tetanus antitoxin is given, if indicated, as well as analgesic agents. (Tetanus prophylaxis is recommended for full-thickness ocular and skin wounds.) Any topical ophthalmic medication (e.g., anesthetic, dyes) must be sterile.

Foreign Bodies and Corneal Abrasions

After removal of a foreign body from the surface of the eye, an antibiotic ointment is applied and the eye is patched. The eye is examined daily for evidence of infection until the wound is completely healed.

Contact lens wear is a common cause of corneal abrasion. The patient experiences severe pain and **photophobia** (ocular pain on exposure to light). Corneal epithelial defects are treated with antibiotic ointment and, in some instances, a pressure patch to immobilize the eyelids. Topical anesthetic eye drops must not be given to the patient to take home for repeated use after corneal injury because their effects mask further damage, delay healing, and can lead to corneal scarring.

Penetrating Injuries and Contusions of the Eyeball

Sharp penetrating injury or blunt contusion force can rupture the eyeball. When the globe, cornea, and sclera rupture, rapid decompression or herniation of the orbital contents into adjacent sinuses can occur. Blunt traumatic injuries (with an increased incidence of retinal detachment, intraocular tissue avulsion, and herniation) have a worse prognosis than penetrating injuries. Most penetrating injuries result in marked loss of vision with the following signs: hemorrhagic **chemosis** (edema of the conjunctiva), conjunctival laceration, shallow anterior chamber with or without an eccentrically placed pupil, **hyphema** (blood within the anterior chamber), or vitreous hemorrhage.

Hyphema is caused by contusion forces that tear the vessels of the iris and damage the anterior chamber angle. Preventing rebleeding and prolonged increased IOP are the goals of treatment for hyphema. In severe cases, the patient is hospitalized with moderate activity restriction. An eye shield is applied. Topical corticosteroids are prescribed to reduce inflammation. An antifibrinolytic agent (aminocaproic acid) stabilizes clot formation at the site of hemorrhage. Aspirin is contraindicated. A ruptured globe and severe injuries with intraocular hemorrhage require surgical intervention. Vitrectomy is performed for traumatic retinal detachments (Park et al., 2018). Primary **enucleation** (complete removal of the eyeball and part of the optic nerve) is considered only if the globe is irreparable and has no light perception. It is a general rule that enucleation is performed within 2 weeks of the initial injury (in an eye that has no useful vision after sustaining penetrating injury) to prevent the risk of **sympathetic ophthalmia** (an inflammation created in the uninjured eye by the affected eye that can result in blindness of the uninjured eye).

Intraocular Foreign Bodies

A patient who complains of blurred vision and discomfort should be questioned carefully about recent injuries and exposures. Patients may be injured in a number of different situations and experience an intraocular foreign body (IOFB). Precipitating circumstances can include working in construction, striking metal against metal, being involved in a motor vehicle crash with facial injury, a gunshot wound, grinding-wheel work, and explosions.

IOFB is diagnosed and localized by slit-lamp biomicroscopy and indirect ophthalmoscopy, as well as CT or ultrasonography scanning. MRI is contraindicated because most foreign bodies are metallic and magnetic. It is important to determine the composition, size, and location of the IOFB and affected eye structures. Every effort should be made to identify the type of IOFB and whether it is magnetic. Iron, steel, copper, and vegetable matter may cause intense inflammatory reactions. The incidence of endophthalmitis is high. Surgical excision of the foreign body depends on its location and composition and associated ocular injuries. Specially designed IOFB forceps

and magnets are used to grasp and remove the foreign body. Any damaged area of the retina is treated to prevent retinal detachment.

Ocular Burns

Alkali, acid, and other chemically active organic substances, such as Mace and tear gas, cause chemical burns. Alkali burns (e.g., lye, ammonia) result in the most severe injury because they penetrate the ocular tissues rapidly and continue to cause long-term damage. Increased IOP also occurs. Acids (e.g., bleach, car batteries, refrigerant) generally cause less damage because the precipitated necrotic tissue proteins form a barrier to further penetration and damage. Chemical burns may appear as superficial punctate keratopathy (i.e., spotty damage to the cornea), subconjunctival hemorrhage, or complete marbleizing of the cornea.

In treating chemical burns, every minute counts. Immediate irrigation with tap water should be started on site before transport of the patient to an emergency department. A brief history and examination are performed. Critical information, if available, is the name of the substance that went into the eye (the actual container is best). Material safety data sheets (MSDSs) should be accessed for reference (see Chapter 68). The corneal surfaces and conjunctival fornices are immediately and copiously irrigated with normal saline or any neutral solution. A local anesthetic is instilled, and a lid speculum is applied to overcome blepharospasm (i.e., spasms of the eyelid muscles that result in closure of the lids). Particulate matter must be removed from the fornices using moistened, cotton-tipped applicators and minimal pressure on the globe. Irrigation continues until the conjunctival pH normalizes (between 7.3 and 7.6). The pH of the corneal surface is checked by placing a pH paper strip in the fornix. Antibiotic agents are instilled, and the eye usually is patched.

The goal of intermediate treatment is to prevent tissue ulceration and promote re-epithelialization of the cornea. Intense lubrication using artificial tears without preservatives (to avoid allergic reactions) is essential. Patching or therapeutic soft lenses may also be used to promote corneal healing, and the patient is closely monitored. Prognosis depends on the type of injury and adequacy of the irrigation immediately after exposure. Long-term treatment consists of two phases: restoration of the ocular surface through grafting procedures and surgical restoration of corneal integrity and optical clarity.

Thermal injury is caused by exposure to a hot object (e.g., curling iron, tobacco, ash), whereas photochemical injury results from ultraviolet irradiation or infrared exposure (e.g., exposure to the reflections from snow, sun gazing, viewing an eclipse of the sun without an adequate filter). These injuries can cause corneal epithelial defect, corneal opacity, conjunctival chemosis and **injection** (congestion of blood vessels), and burns of the eyelids and periocular

region. Antibiotic agents and a patch for 24 hours constitute the treatment of mild injuries.

INFECTIOUS AND INFLAMMATORY CONDITIONS

Inflammation and infections of eye structures are common. Table 58-7 summarizes select infections and their treatment.

Dry Eyes

Dry eyes can be caused by decreased tear production or increased tear evaporation, which can be episodic or chronic (Norris, 2019). Decreased tear production (aqueous deficiency) can be caused by systemic disease (Sjögren, connective tissue disease), lacrimal gland obstruction, and systemic drugs (e.g., diuretics, antihistamines, psychotropic drugs). Increased tear evaporation (evaporative dry eye) can be caused by meibomian gland deficiency, lid aperture disorder, vitamin A deficiency, reduced lid blinking rate, preservatives from topical drugs, ocular surface disease (allergy), and contact lens wear. Risk factors include increasing age, smoking, recent refractive surgery, and postmenopausal status (in women). An increase in the intake of omega-3 fatty acids may be beneficial in reducing the risk (Norris, 2019).

Clinical Manifestations

The most common complaints are photophobia, foreign-body sensation, burning and stinging, redness, and decreased tearing.

Assessment and Diagnostic Findings

Chronic dry eyes may result in chronic conjunctival and corneal irritation that can lead to corneal erosion, scarring, ulceration, thinning, or perforation that can seriously threaten vision. Secondary bacterial infection can occur.

Management

Management of dry eyes requires the cooperation of the patient with a regimen that needs to be followed at home for a long period; otherwise, complete relief of symptoms is unlikely. Instillation of artificial tears during the day and an ointment at night is the usual regimen to hydrate and lubricate the eye and preserve a moist ocular surface. Cyclosporine ophthalmic emulsion is an effective agent that increases tear production and is used once daily. Anti-

inflammatory medications are also used, and moisture chambers (e.g., moisture chamber spectacles, swim goggles) may provide additional relief.

Patients may become hypersensitive to chemical preservatives such as benzalkonium chloride and thimerosal. For these patients, preservative-free ophthalmic solutions are used. Management of dry eyes also includes the concurrent treatment of infections, such as chronic blepharitis and acne rosacea, and treating the underlying systemic disease, such as Sjögren syndrome (an autoimmune disease).

TABLE 58-7 Select Infections and Inflammatory Disorders of Eye Structures

Disorder	Description	Management
Hordeolum (stye)	Acute suppurative infection of the glands of the eyelids caused by *Staphylococcus aureus*. The lid is red and edematous with a small collection of pus in the form of an abscess. There is considerable discomfort.	Warm compresses are applied directly to the affected lid area three to four times a day for 10–15 min. If the condition is not improved after 48 h, incision and drainage may be indicated. Application of topical antibiotics may be prescribed thereafter.
Chalazion	Sterile inflammatory process involving chronic granulomatous inflammation of the meibomian glands; can appear as a single granuloma or multiple granulomas in the upper or lower eyelids.	Warm compresses applied three to four times a day for 10–15 min may resolve the inflammation in the early stages. Most often, however, surgical excision is indicated. Corticosteroid injection to the chalazion lesion may be used for smaller lesions.
Blepharitis	Chronic bilateral inflammation of the eyelid margins. There are two types: staphylococcal and seborrheic. Staphylococcal blepharitis is usually ulcerative and is more serious due to the involvement of the base of hair follicles. Permanent scarring can result.	The seborrheic type is chronic and is usually resistant to treatment, but the milder cases may respond to lid hygiene. Staphylococcal blepharitis requires topical antibiotic treatment. Instructions on lid hygiene (to keep the lid margins clean and free of exudates) are given to the patient.
Bacterial keratitis	Infection of the cornea by *S. aureus, Streptococcus pneumoniae,* and *Pseudomonas aeruginosa.*	Fortified (high-concentration) antibiotic eye drops are given every 30 min around the clock for the first few days, then every 1–2 h. Systemic antibiotics may be given. Cycloplegics are given to reduce pain caused by ciliary spasm.
Herpes simplex keratitis	Symptoms are severe pain, tearing, and photophobia. The dendritic ulcer has a branching, linear pattern with feathery edges and terminal bulbs at its ends. Herpes simplex keratitis can lead to recurrent stromal keratitis and persist to 12 mo with residual corneal scarring.	Many lesions heal without treatment and residual effects. The treatment goal is to minimize the damaging effect of the inflammatory response and eliminate viral replication within the cornea. Penetrating keratoplasty is indicated for corneal scarring and must be performed when the herpetic disease has been inactive for many months.

Adapted from Shaw, M., & Lee, A. (2017). *Ophthalmic nursing* (5th ed.). Boca Raton, FL: CRC Press Taylor & Francis Group.

Surgical treatment includes punctal occlusion, grafting procedures, and lateral tarsorrhaphy (uniting the edges of the lids). Punctal plugs are made of silicone material for the temporary or permanent occlusion of the puncta. These help to preserve the volume of natural tears and prolong the effects of artificial tears (Norris, 2019).

Conjunctivitis

Conjunctivitis (inflammation of the conjunctiva) is a common ocular disorder worldwide. It is characterized by a pink appearance (hence the common term *pink eye*) because of subconjunctival blood vessel congestion.

Clinical Manifestations

General symptoms include foreign-body sensation, scratching or burning sensation, itching, and photophobia. Conjunctivitis may be unilateral or bilateral, but the infection usually starts in one eye and then spreads to the other eye by hand contact.

Assessment and Diagnostic Findings

The four main clinical features important to evaluate are the type of discharge (watery, mucoid, purulent, or mucopurulent), type of conjunctival reaction (follicular or papillary), presence of pseudomembranes or true membranes, and presence or absence of lymphadenopathy (enlargement of the preauricular and submandibular lymph nodes where the eyelids drain). Pseudomembranes consist of coagulated exudate that adheres to the surface of the inflamed conjunctiva. True membranes form when the exudate adheres to the superficial layer of the conjunctiva, and removal results in bleeding. Follicles are multiple, slightly elevated lesions encircled by tiny blood vessels; they look like grains of rice. Papillae are hyperplastic conjunctival epithelium in numerous projections that are usually seen as a fine mosaic pattern under slit-lamp examination. Diagnosis is based on the distinctive characteristics of ocular signs, acute or chronic presentation, and identification of any precipitating events. Positive results of swab smear preparations and cultures confirm the diagnosis.

Types of Conjunctivitis

Conjunctivitis is classified according to its cause. The major causes are microbial infection, allergy, and irritating toxic stimuli. A wide spectrum of organisms can cause conjunctivitis, including bacteria (e.g., *Chlamydia*),

viruses, fungus, and parasites. Conjunctivitis can also result from an existing ocular infection or can be a manifestation of a systemic disease.

Microbial Conjunctivitis

Bacterial Conjunctivitis

Bacterial conjunctivitis can be acute or chronic. The acute type can develop into a chronic condition. Signs and symptoms can vary from mild to severe. Chronic bacterial conjunctivitis is usually seen in patients with lacrimal duct obstruction, chronic dacryocystitis, and chronic blepharitis. The most common causative microorganisms are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Staphylococcus aureus*.

Bacterial conjunctivitis manifests with an acute onset of redness, burning, and discharge. There is papillary formation, conjunctival irritation, and injection in the fornices. The exudates are variable but are usually present on waking in the morning. The eyes may be difficult to open because of adhesions caused by the exudate. Purulent discharge occurs in severe acute bacterial infections, whereas mucopurulent discharge appears in mild cases. In gonococcal conjunctivitis, the symptoms are more acute. The exudate is profuse and purulent, and there is lymphadenopathy. Pseudomembranes may be present.

Trachoma is an infectious disease caused by the bacterium *Chlamydia trachomatis,* an ancient disease and the leading cause of preventable blindness in the world (Norris, 2019). It is prevalent in areas with hot, dry, and dusty climates and in areas with poor living conditions. It is spread by direct contact or by carrier (e.g., insects such as flies and gnats). The onset of trachoma in children is usually insidious, but it can be acute or subacute in adults. The initial symptoms include red inflamed eyes, tearing, photophobia, ocular pain, purulent exudates, preauricular lymphadenopathy, and lid edema. Initial ocular signs include follicular and papillary formations. At the middle stage of the disease, there is an acute inflammation with papillary hypertrophy and follicular necrosis, after which trichiasis and entropion begin to develop. The lashes that are turned in rub against the cornea and, after prolonged irritation, cause corneal erosion and ulceration. The late stage of the disease is characterized by scarred conjunctiva, subepithelial keratitis, abnormal vascularization of the cornea (pannus), and residual scars from the follicles that look like depressions in the conjunctiva (Herbert pits). Severe corneal ulceration can lead to perforation and blindness.

Inclusion conjunctivitis affects sexually active people who have genital chlamydial infection. Transmission is by oral–genital sex or hand-to-eye transmission. Indirect transmission can occur in inadequately chlorinated swimming pools. The eye lesions usually appear a week after exposure and

may be associated with a nonspecific urethritis or cervicitis. The discharge is mucopurulent, follicles are present, and there is lymphadenopathy.

Viral Conjunctivitis

Viral conjunctivitis can be acute and chronic. The discharge is watery, and follicles are prominent. Severe cases include pseudomembranes. The common causative organisms are adenovirus and herpes simplex virus. Conjunctivitis caused by adenovirus is highly contagious. The condition is usually preceded by symptoms of upper respiratory infection. Corneal involvement causes extreme photophobia. Symptoms include tearing, redness, and foreign-body sensation that can involve one or both eyes. There is lid edema, ptosis, and conjunctival **hyperemia** (red eyes caused by dilation of blood vessels) (see Fig. 58-15). These signs and symptoms vary from mild to severe. Viral conjunctivitis, although self-limited, tends to last longer than bacterial conjunctivitis.

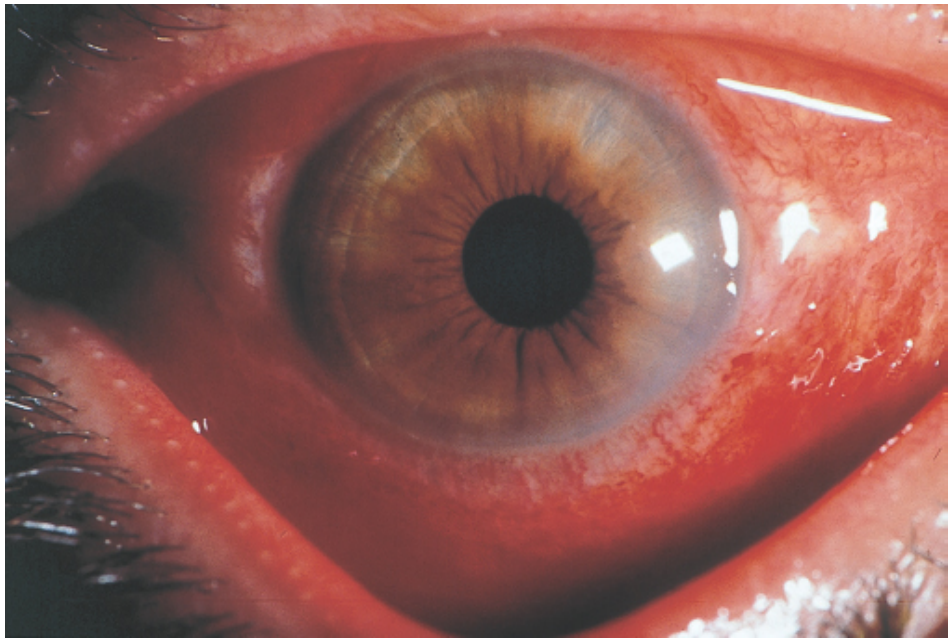

Figure 58-15 • Conjunctival hyperemia in viral conjunctivitis.

Epidemic keratoconjunctivitis is a highly contagious viral conjunctivitis that is easily transmitted from one person to another among household members, schoolchildren, and health care workers. The outbreak of epidemics is seasonal, especially during the summer when people use swimming pools. Epidemic keratoconjunctivitis is most often accompanied by preauricular lymphadenopathy and occasionally periorbital pain. There are marked follicular and papillary formations. This type of conjunctivitis can lead to keratopathy.

Allergic Conjunctivitis

Immunologic or allergic conjunctivitis is a hypersensitivity reaction that occurs as part of allergic rhinitis (hay fever), or it can be an independent allergic reaction. The patient usually has a history of an allergy to pollens and other environmental allergens. There is extreme pruritus, epiphora (excessive secretion of tears), injection, and usually severe photophobia. The stringlike mucoid discharge is usually associated with rubbing the eyes because of severe pruritus. Vernal conjunctivitis is also known as seasonal conjunctivitis because it appears mostly during warm weather. There may be large formations of papillae that have a cobblestone appearance. It is more common in children and young adults. Most affected people have a history of asthma or eczema.

Toxic Conjunctivitis

Chemical conjunctivitis can be the result of medications; chlorine from swimming pools; exposure to toxic fumes among industrial workers; or exposure to other irritants such as smoke, hair sprays, acids, and alkalis.

Medical Management

The management of conjunctivitis depends on the type. Most types of mild and viral conjunctivitis are self-limiting, benign conditions that may not require treatment and laboratory procedures. For more severe cases, topical antibiotic agents, eye drops, or ointments are prescribed. Patients with gonococcal conjunctivitis require urgent antibiotic therapy. If left untreated, this ocular disease can lead to corneal perforation and blindness. The systemic complications can include meningitis and sepsis.

Bacterial Conjunctivitis

Acute bacterial conjunctivitis is almost always self-limiting, lasting 2 weeks if left untreated. If treated with antibiotics, it may last a few days, except for gonococcal and staphylococcal conjunctivitis.

For trachoma, usually broad-spectrum antibiotic agents are given topically and systemically. Surgical management includes the correction of trichiasis to prevent conjunctival scarring.

Adult inclusion conjunctivitis requires 1 week of antibiotics. Prevention of reinfection is important, and affected people and their sexual partners must seek treatment for sexually transmitted infection, if indicated.

Viral Conjunctivitis

Viral conjunctivitis is not responsive to any treatment. Cold compresses may alleviate some symptoms. Viral conjunctivitis, especially epidemic keratoconjunctivitis, is highly contagious. Patients must be made aware of the

contagious nature of the disease, and adequate education must be provided (see Chart 58-12).

Proper steps must be taken to avoid health care–associated infections. Frequent hand hygiene and procedures for environmental cleaning and disinfection of equipment used for eye examination must be strictly followed at all times. To prevent spread during outbreaks of conjunctivitis caused by adenovirus, health care facilities must set aside specified areas for treating patients diagnosed with or suspected of having conjunctivitis caused by adenovirus. All forms of tonometry must be avoided unless medically indicated. All multidose ophthalmic medications must be discarded at the end of each day or when contaminated. Employees who are infected and others must not be allowed to work or attend school until symptoms have resolved, which can take 3 to 7 days.

Chart 58-12  **PATIENT EDUCATION**

Education for Patients with Viral Conjunctivitis

Viral conjunctivitis is a highly contagious eye infection that can easily spread from one person to another. The symptoms can be alarming but are not serious.

The nurse instructs the patient about this eye condition and the following self-care strategies:

- Be aware that your eyes will look red and will have watery discharge, and your lids will be swollen for about a week.
- Expect to experience eye pain, a sandy sensation in your eye, and sensitivity to light.
- Keep in mind that symptoms will resolve after about 1 week.
- Use lightweight cold compresses over your eyes for about 10 minutes four to five times a day to soothe the pain.
- Use artificial tears for the sandy sensation in your eye and mild pain medications such as acetaminophen.
- Stay at home and do not go outside. You may return to work or school after 7 days, when the redness and discharge have cleared. Obtain a note from your primary provider to return to work or school.
- Do not share towels, linens, makeup, or any items that have come in contact with your eyes.
- Wash your hands thoroughly with soap and water frequently.
- Use a new tissue every time you wipe the discharge from your eye. Dampen the tissue with clean water to clean the outside of the eye.
- Wash your face and take a shower as you normally do.
- Discard all of your makeup articles and do not apply makeup until the infection has resolved.
- Wear dark glasses if bright lights bother you.
- Note if the discharge from your eye turns yellowish and purulent or if your vision changes and return to the primary provider for an examination.

Allergic Conjunctivitis

Patients with allergic conjunctivitis, especially recurrent vernal or seasonal conjunctivitis, are usually given corticosteroids in ophthalmic preparations. Depending on the severity of the disease, they may be given oral preparations. The use of vasoconstrictors, such as topical epinephrine solution, cold compresses, ice packs, and cool ventilation usually provide comfort by decreasing swelling.

Toxic Conjunctivitis

For conjunctivitis caused by chemical irritants, the eye must be irrigated immediately and profusely with saline or sterile water.

Uveitis

Uveitis, or inflammation of the uveal tract, can affect the iris, the ciliary body, or the choroid. There are two types of uveitis: nongranulomatous and granulomatous.

The more common form of uveitis is the nongranulomatous type, which manifests as an acute condition with pain, photophobia, and a pattern of conjunctival injection, especially around the cornea. The pupil is small or irregular, and vision is blurred. There may be small, fine precipitates on the posterior corneal surface and cells in the aqueous humor (i.e., cell and flare). If the uveitis is severe, a **hypopyon** (accumulation of inflammatory cells in the anterior chamber of the eye) may develop. The condition may be unilateral or bilateral and may be recurrent. Repeated attacks of nongranulomatous anterior uveitis can cause anterior synechiae (peripheral iris adheres to the cornea and impedes outflow of aqueous humor). Posterior synechiae (adherence of the iris and lens) block aqueous outflow from the posterior chamber. Secondary glaucoma can result from either anterior or posterior synechiae. Cataracts may also occur as a sequela to uveitis.

Granulomatous uveitis can have a more insidious onset and can involve any portion of the uveal tract. It tends to be chronic. Symptoms such as photophobia and pain may be minimal. Vision is markedly and adversely affected. Conjunctival injection is diffuse, and there may be vitreous clouding. In a severe posterior uveitis, such as chorioretinitis, there may be retinal and choroidal hemorrhages.

Medical Management

Because photophobia is a common symptom, patients should wear dark glasses outdoors. Ciliary spasm and synechia are best avoided through mydriasis; cyclopentolate and atropine are commonly used. Local corticosteroid drops instilled four to six times a day are also used to decrease inflammation.

If the uveitis is recurrent, a careful history should be initiated to discover any underlying causes. This evaluation should include a complete history, physical examination, and diagnostic tests, including a complete blood count, erythrocyte sedimentation rate, antinuclear antibodies, and Venereal Disease Research Laboratory (VDRL) and Lyme disease titers. Underlying causes include autoimmune disorders such as ankylosing spondylitis and sarcoidosis

as well as toxoplasmosis, herpes zoster virus, ocular candidiasis, histoplasmosis, herpes simplex virus, tuberculosis, and syphilis.

Orbital Cellulitis

Orbital cellulitis is inflammation of the tissues surrounding the eye that may result from bacterial, fungal, or viral inflammatory conditions of contiguous structures, such as the face, oropharynx, dental structures, or intracranial structures. It can also result from foreign bodies and preexisting ocular infection, such as dacryocystitis and panophthalmitis, or from sepsis. Infection of the sinuses is the most frequent cause. Infection originating in the sinuses can spread easily to the orbit through the thin bony walls and foramina or by means of the interconnecting venous system of the orbit and sinuses. The most common causative organisms are staphylococci and streptococci in adults. The symptoms include pain, eyelid swelling, conjunctival edema, proptosis, and decreased ocular motility. With such edema, optic nerve compression can occur and IOP may increase.

The severe intraorbital tension caused by abscess formation and the impairment of optic nerve function in orbital cellulitis can result in permanent visual loss. Because of the orbit's proximity to the brain, orbital cellulitis can lead to life-threatening complications, such as intracranial abscess and cavernous sinus thrombosis.

Medical Management

Immediate administration of high-dose, broad-spectrum, systemic antibiotics is indicated. Cultures and Gram-stained smears are obtained. Monitoring changes in visual acuity, degree of proptosis, central nervous system function (e.g., nausea, vomiting, fever, cognitive changes), displacement of the globe, extraocular movements, pupillary signs, and the fundus is extremely important. Consultation with an otolaryngologist is necessary, especially when rhinosinusitis is suspected. In the event of abscess formation or progressive loss of vision, surgical drainage of the abscess or sinus is performed. Sinusotomy and antibiotic irrigation are also performed.

ORBITAL AND OCULAR TUMORS

Benign Tumors of the Orbit

Benign tumors can develop from infancy and grow rapidly or slowly and present in later life. Some benign tumors are superficial and are easily identifiable by external presentation, palpation, and x-rays, but some are deep and may require a CT scan to diagnose. There can be significant proptosis, and visual function may be jeopardized. Benign tumors are masses characterized by the lack of infiltration in the surrounding tissues. Examples are cystic dermoid cysts and mucocele, hemangiomas, lymphangiomas, lacrimal tumors, and neurofibromas.

To prevent recurrence, benign masses are excised completely when possible. Excision may be difficult because of the involvement of some portions of the orbital bones, such as deep dermoid cysts, in which dissection of the bone is required. Subtotal resection may be indicated in deep benign tumors that intertwine with other orbital structures, such as optic nerve meningiomas. Complete removal of the tumor may endanger visual function.

Benign Tumors of the Eyelids

There are a wide variety of benign tumors that increase in frequency with age. Nevi may be unpigmented at birth and may enlarge and darken in adolescence or may never acquire any pigment at all. Hemangiomas are vascular capillary tumors that may be bright, superficial, red lesions (formerly known as strawberry angiomas) or bluish and purplish deeper lesions. Milia are small, white, slightly elevated cysts of the eyelid that may occur in multiples. Xanthelasma are yellowish, lipoid deposits on both lids that commonly appear as a result of the aging of the skin or a lipid disorder. Molluscum contagiosum lesions are flat, symmetric growths along the lid margin caused by a virus that can result in conjunctivitis and keratitis if the lesion grows into the conjunctival sac.

Treatment of benign congenital lid lesions is rarely indicated except when visual function is affected. Corticosteroid injection to the hemangioma lesion is usually effective, but surgical excision may be performed. Benign lid lesions usually present aesthetic problems rather than visual function problems. Surgical excision, or electrocautery, is primarily performed for cosmetic reasons, except for cases of molluscum contagiosum, for which surgical intervention is performed to prevent an infectious process that may ensue.

Benign Tumors of the Conjunctiva

Conjunctival nevus, a congenital benign neoplasm, is a flat, slightly elevated, brown spot that becomes pigmented during late childhood or adolescence. This should be differentiated from the pigmented lesion melanosis, which is

acquired at middle age and may become melanoma. Keratin- and sebum-containing dermoid cysts are congenital and can be found in the conjunctiva. Dermolipoma is a congenital tumor that manifests as a smooth, rounded growth in the conjunctiva near the lateral canthus. Papillomas are usually soft with irregular surfaces and appear on the lid margins. Treatment consists of surgical excision.

Malignant Tumors of the Orbit

Rhabdomyosarcoma is the most common malignant primary orbital tumor in childhood; it can also develop in older adults (Tang, Zhang, Lu, et al., 2018). The symptoms of rhabdomyosarcoma include sudden painless proptosis of one eye followed by lid swelling, conjunctival chemosis, and impairment of ocular motility. CT or MRI scans of these tumors establish the size, configuration, location, and stage of the disease; delineates the degree of bone destruction; and is useful in estimating the field for radiation therapy. The most common site of metastasis is the lung.

Management of these primary malignant orbital tumors involves three major therapeutic modalities: surgery, radiation therapy, and adjuvant chemotherapy. The degree of orbital destruction is important in planning the surgical approach. Resection often involves removal of the eyeball. The psychological needs of the patient and family are paramount in planning the management approach.

Malignant Tumors of the Eyelid

Basal cell carcinoma is the most common malignant tumor of the eyelid. Squamous cell carcinoma occurs less frequently but is considered the second most common malignant tumor. Melanoma is rare. Malignant eyelid tumors occur more frequently among people with a fair complexion who have a history of chronic exposure to the sun (Norris, 2019).

Basal cell carcinoma appears as a painless nodule that may ulcerate. The lesion is invasive, spreads to the surrounding tissues, and grows slowly but does not metastasize. It usually appears on the lower lid margin near the inner canthus with a pearly white margin. Squamous cell carcinoma of the eyelids may resemble basal cell carcinoma initially because it also grows slowly and painlessly. It tends to ulcerate and invade the surrounding tissues, but it can metastasize to the regional lymph nodes. Melanoma may not be pigmented and can arise from nevi. It spreads to the surrounding tissues and metastasizes to other organs.

Complete excision of these carcinomas is followed by reconstruction with skin grafting if the surgical excision is extensive. The ocular postoperative site and the graft donor site are monitored for bleeding. Donor graft sites may include the buccal mucosa, the thigh, or the abdomen. The patient is referred to an oncologist for evaluation of the need for radiation therapy and monitoring for metastasis. Early diagnosis and surgical management are the basis of a good prognosis. These conditions have life-threatening consequences, and surgical excisions may result in facial disfigurement. Emotional support is an extremely important aspect of nursing management.

Malignant Tumors of the Conjunctiva

Conjunctival carcinoma most often grows in the exposed areas of the conjunctiva. The typical lesions are usually gelatinous and whitish due to keratin formation. They grow gradually, and deep invasion and metastasis are rare. Melanoma is rare but may arise from a preexisting nevus or acquired melanosis during middle age. Squamous cell carcinoma is also rare but invasive.

The management is surgical incision. Some benign tumors and most malignant tumors recur. To avoid recurrences, patients usually undergo radiation therapy and cryotherapy after the excision of malignant tumors. Cosmetic disfigurement may result from extensive excision when deep invasion by the malignant tumor is involved.

Malignant Tumors of the Globe

Ocular melanoma is a rare malignant choroidal tumor sometimes discovered on a retinal examination. In its early stages, it could be mistaken for a nevus. In addition to a complete physical examination to discover any evidence of metastasis (to the liver, lung, and breast), retinal fundus photography, fluorescein angiography, and ultrasonography are performed. The diagnosis is confirmed at biopsy after enucleation.

Tumors are classified according to boundary lines (apical height and basal diameter) as small, medium, or large. Small tumors are generally monitored, whereas medium and large tumors require treatment. Treatment consists of radiation, enucleation, or both. Radiation therapy may be achieved by external beam performed in repeated episodes over several days or through the implantation of a small plaque that contains radioactive iodine (I-125) pellets over the tumor.

SURGICAL PROCEDURES AND ENUCLEATION

Orbital Surgeries

Orbital surgeries may be performed to repair fractures, remove a foreign body, or remove benign or malignant growths. Surgical procedures involving the orbit and lids affect facial appearance, or cosmesis. The goals are to recover and preserve visual function and to maintain the anatomic relationship of the ocular structures to achieve cosmesis. During the repair of orbital fractures, the orbital bones are realigned to follow the anatomic positions of facial structures.

Orbital surgical procedures involve working around delicate structures of the eye, such as the optic nerve, retinal blood vessels, and ocular muscles. Complications of orbital surgical procedures may include blindness as a result of damage to the optic nerve and its blood supply. Sudden pain and loss of vision may indicate intraorbital hemorrhage or compression of the optic nerve. Ptosis and diplopia may result from trauma to the extraocular muscles during the surgical procedure, but these conditions typically resolve after a few weeks.

Prophylaxis with IV antibiotic agents is the usual postoperative regimen after orbital surgery, especially with repair of orbital fractures and intraorbital foreign-body removal. IV corticosteroids may be used if there is concern about optic nerve swelling. Topical ocular antibiotics are typically instilled, and antibiotic ointments are applied externally to the skin suture sites.

For the first 24 to 48 hours postoperatively, ice compresses are applied over the periocular area to decrease periorbital swelling, facial swelling, and hematoma. The head of the patient's bed should be elevated to a comfortable position (30 to 45 degrees).

Discharge education should include information about oral antibiotic agents, instillation of ophthalmic medications, and application of ice compresses.

Enucleation

Enucleation is removal of the eyeball (globe) from the orbit, leaving the muscles and orbital contents intact. It may be surgically performed for the following conditions:

- Injury resulting in prolapse of uveal tissue or loss of light perception
- A blind, painful, deformed, or disfigured eye, usually caused by glaucoma, retinal detachment, or chronic inflammation
- An eye without useful vision that is producing or has produced sympathetic ophthalmia in the other eye

- Intraocular tumors that are untreatable by other means

The procedure for enucleation involves the separation and cutting of each of the ocular muscles and surrounding soft tissue and cutting of the optic nerve from the eyeball. The insertion of an orbital implant typically follows, and the conjunctiva is closed. A large pressure dressing is applied over the area.

Evisceration involves the removal of the intraocular contents through an incision or opening in the cornea or sclera. Evisceration may be surgically performed to treat severe ocular trauma with ruptured globe, severe ocular inflammation, or severe ocular infection. The optic nerve, sclera, extraocular muscles, and sometimes the cornea are left intact. The main advantage of evisceration over enucleation is that the final cosmetic result and motility after fitting the ocular prosthesis are enhanced.

Exenteration is the surgical removal of the entire contents of the orbit, surrounding soft tissue, and most or all of the eyelids. This surgery is indicated in malignancies of the orbit that are life-threatening or when more conservative modalities of treatment have failed or are inappropriate. An example is squamous cell carcinoma of the paranasal sinuses, skin, and conjunctiva with deep orbital involvement. In its most extensive form, exenteration may include the removal of all orbital tissues and resection of the orbital bones.

Ocular Prostheses

Orbital implants and conformers (ocular prostheses usually made of silicone rubber) maintain the shape of the eye after enucleation or evisceration to prevent a contracted, sunken appearance. The temporary conformer is placed over the conjunctival closure after the implantation of an orbital implant. A conformer is placed after the enucleation or evisceration procedure to protect the suture line, maintain the fornices, prevent contracture of the socket in preparation for the ocular prosthesis, and promote the integrity of the eyelids.

All ocular prosthetics have limitations in their motility. There are two designs of eye prostheses. The anophthalmic ocular prostheses are used in the absence of the globe. Scleral shells look just like the anophthalmic prosthesis (see Fig. 58-16) but are thinner and fit over a globe with intact corneal sensation. An eye prosthesis usually lasts about 6 years, depending on the quality of fit, comfort, and cosmetic appearance. When the anophthalmic socket is completely healed, conformers are replaced with prosthetic eyes.

An ocularist is a specially trained and skilled professional who makes prosthetic eyes. After the ophthalmologist is satisfied that the anophthalmic socket is completely healed and is ready for prosthetic fitting, the patient is referred to an ocularist. The healing period is usually 6 to 8 weeks. It is advisable for the patient to have a consultation with the ocularist before the

fitting. Obtaining accurate information and verbalizing concerns can lessen anxiety about wearing an ocular prosthesis.

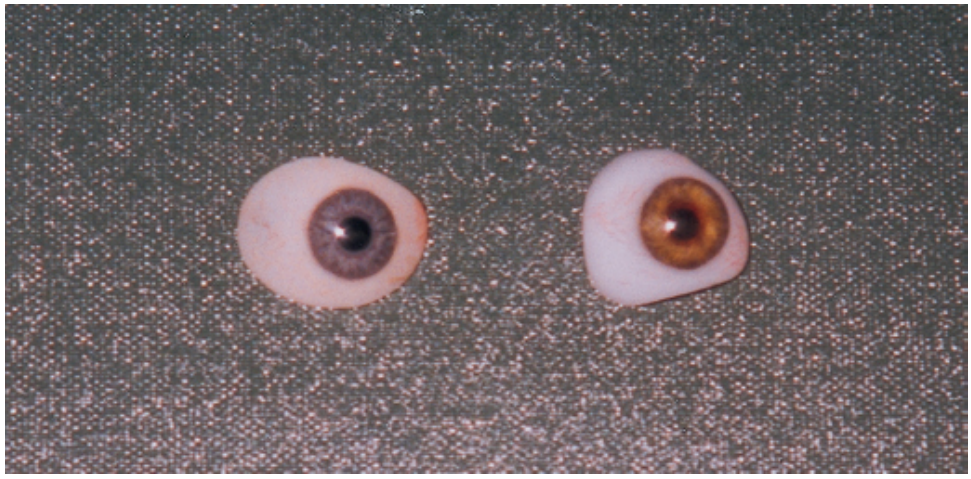

Figure 58-16 • Eye prostheses. (***Left***) Anophthalmic ocular prosthesis. (***Right***) Scleral shell.

Medical Management

Removal of an eye has physical, social, and psychological ramifications for any person. The significance of loss of the eye and vision must be addressed in the plan of care. The patient's preparation should include information about the surgical procedure and placement of orbital implants and conformers and the availability of ocular prosthetics to enhance cosmetic appearance. In some cases, patients may choose to see an ocularist before the surgery to discuss ocular prosthetics.

Nursing Management

Providing Education About Postsurgical and Prosthetic Care

Patients who undergo eye removal need to know that they will usually have a large ocular pressure dressing, which is typically removed after a week, and that an ophthalmic topical antibiotic ointment is applied in the socket three times daily.

After the removal of an eye, there is a loss of depth perception. Patients must be advised to take extra caution in their ambulation and movement to avoid miscalculations that may result in injury. It may take some time to adjust to monocular vision.

The patient must be advised that conformers may inadvertently fall out of the socket. If this happens, the conformer must be washed, wiped dry, and placed back in the socket.

When surgical eye removal is unexpected, such as in severe ocular trauma, leaving no time for the patient and family to prepare for the loss, the nurse's role in providing emotional support is crucial.

Promoting Home, Community-Based, and Transitional Care

The patient with a new prosthetic eye may need referral to home, community-based or transitional services that provide assistance in the home. These patients also benefit from a referral for rehabilitation services.

Educating Patients About Self-Care

Patients need to be educated about how to insert, remove, and care for the prosthetic eye. Proper hand hygiene must be observed before inserting and removing an ocular prosthesis. A suction cup may be used if there are problems with manual dexterity. Precautions, such as draping a towel over the sink and closing the sink drain, must be taken to avoid loss of the prosthesis. When educating patients or family members, a return demonstration is important to assess the level of understanding and ability to perform the procedure.

Before insertion, the inner punctal or outer lateral aspects and the superior and inferior aspects of the prosthesis must be identified by locating the identifying marks, such as a reddish color in the inner punctal area. For people with low vision, other forms of identifying markers, such as dots or notches, are used. The upper lid is raised high enough to create a space and then the patient learns to slide the prosthesis up, underneath, and behind the upper eyelid. Meanwhile, the patient pulls the lower eyelid down to help put the prosthesis in place and to have its inferior edge fall back gradually to the lower eyelid. The lower eyelid is checked for correct positioning.

To remove the prosthesis, the patient cups one hand on the cheek to catch the prosthesis, places the forefinger of the free hand against the midportion of the lower eyelid, and gazes upward. Gazing upward brings the inferior edge of the prosthesis nearer the inferior eyelid margin. With the finger pushing inward, downward, and laterally against the lower eyelid, the prosthesis slides out into the cupped hand.

Continuing and Transitional Care

An eye prosthesis can be worn and left in place for several months. Hygiene and comfort are usually maintained with daily irrigation of the prosthesis in place with normal saline solution, hard contact lens solution, or artificial tears. In the case of dry eye symptoms, the use of ophthalmic ointment lubricants or oil-based drops, such as vitamin E and mineral oil, can be helpful. Removing crusting and mucus discharge that accumulate overnight is performed with the

prosthesis in place. Malpositions may occur when wiping or rubbing the prosthesis in the socket. The prosthesis can be repositioned with the use of clean fingers. Proper wiping of the prosthesis should be a gentle temporal-to-nasal motion to avoid malpositions.

The prosthesis needs to be removed and cleaned when it becomes uncomfortable and when there is increased mucus discharge. The socket should also be rendered free of mucus and inspected for any signs of infection. Any unusual discomfort, irritation, or redness of the globe or eyelids may indicate excessive wear, debris under the shell, or lack of proper hygiene. Any infection or irritation that does not resolve needs medical attention.

OCULAR CONSEQUENCES OF SYSTEMIC DISEASE

Diabetic Retinopathy

Advancements in the treatment of diabetes have enabled patients to have a relatively a normal lifespan, but many have complications of long-term diabetes. One of the most serious complications of diabetes is retinopathy. Patients with diabetes are also at higher risk of cataracts and best practices for glycemic control during cataract surgery are not known (Kiziltoprak, Tekin, Inanc, et al., 2019). See Chapter 46 for a detailed discussion of diabetic retinopathy.

Cytomegalovirus Retinitis

Many ophthalmic complications have been associated with AIDS, and CMV is the most common cause of retinal inflammation in patients with AIDS. Early symptoms of CMV retinitis vary from patient to patient. Some patients complain of floaters or a decrease in peripheral vision. Some have a paracentral or central scotoma, whereas others have fluctuations in vision from macular edema. The retina often becomes thin and atrophic and susceptible to retinal tears and breaks.

CMV retinitis generally takes one of three forms: hemorrhagic, brushfire, or granular. In the hemorrhagic type, large areas of white, necrotic retina may be associated with retinal hemorrhage. In the brushfire type, a yellow-white margin begins at the edge of burned-out atrophic retina. This retinitis expands and, if untreated, involves the entire retina. In the granular type, white granular lesions in the periphery of the retina gradually expand. The white, feathery infiltration of the retina destroys sensory retina and leads to necrosis, optic atrophy, and retinal detachment.

Medical Management

Management of CMV retinitis consists of prescribing the appropriate pharmacologic agent.

Pharmacologic Therapy

Pharmacologic agents available for the treatment of CMV retinitis include ganciclovir, foscarnet, and cidofovir.

Ganciclovir is administered IV, orally, or intravitreously in the acute stage of CMV retinitis. The intravitreous form is available as a 4-mm intraocular implant or insert containing the medication embedded in a polymer-based system that slowly releases the medication. The insert is surgically placed in the posterior segment of the eye, and the medication diffuses locally to the site of the infection over a period of 5 to 8 months before the insert must be replaced. When given systemically, ganciclovir is a very potent medication; it can cause neutropenia, thrombocytopenia, anemia, and elevated serum creatinine levels. The surgically implanted sustained-release insert enables higher concentrations of ganciclovir to reach the CMV retinitis, but there are risks and complications associated with the inserts, including endophthalmitis, retinal detachment, and hypotony.

Foscarnet inhibits viral deoxyribonucleic acid (DNA) replication. It may be the medication of choice when ganciclovir is ineffective. It may be administered by IV or intravitreal injections. The combination of foscarnet and ganciclovir has been more effective than either medication alone. Nephrotoxicity may occur with systemic foscarnet, and renal function must be monitored carefully.

Cidofovir impedes CMV replication and is administered IV. Cidofovir has been shown to delay the progression of CMV retinitis significantly. Nephrotoxicity, proteinuria, and increased serum creatinine levels are significant side effects.

A nucleoside analogue such as zidovudine given in combination with one or more protease inhibitors such as ritonavir in the management of patients with AIDS has led to a major therapeutic success, gradually altering the course of the disease and transforming HIV/AIDS into a chronically manageable disease (Iacob, Iacob, & Jugulete, 2017). The immune system can then recover to a functional level. Some patients develop immune recovery uveitis, characterized by intraocular inflammation, cystoid macular edema, and the formation of epiretinal membranes. Immune recovery uveitis is managed by corticosteroids or by injection of corticosteroids into the sub-Tenon area of the eye.

Hypertension-Related Eye Changes

Long-standing hypertension is associated with atherosclerosis, and retinal changes are evidenced by the development of retinal arteriolar changes, such as tortuousness, narrowing, and a change in light reflex (Weber & Kelley, 2018). Fundoscopic examination reveals a copper or silver coloration of the arterioles and venous compression (arteriovenous nicking) at the arteriolar and venous crossings. Intraretinal hemorrhages from hypertension appear flame shaped because they occur in the nerve fiber layer of the retina.

Hypertension can also occur as an acute consequence of conditions such as pheochromocytoma, acute kidney injury, and pregnancy-induced hypertension. The retinopathy associated with these crisis states is extensive, and the manifestations include cotton-wool spots, retinal hemorrhages, retinal edema, and retinal exudates, often clustered around the macula (Weber & Kelley, 2018).

The choroid is also affected by the profound and abrupt rise in blood pressure and resulting vasoconstriction, and ischemia may result in serious retinal detachments and infarction of the retinal pigment epithelium. Ischemic optic neuropathy and papilledema may also result. Blood pressure in these more severe stages should be lowered in a controlled gradual fashion to avoid ischemia of the optic nerve and brain secondary to a too-rapid fall in blood pressure. See Chapter 27 for further information about hypertension.

CRITICAL THINKING EXERCISES

1 pq You are a home health nurse visiting a 72-year-old male who has a long history of uncontrolled diabetes. He reports that recently he has been having trouble with his vision. Define nursing assessment techniques that are important in evaluating this patient. Describe your nursing priorities of care for a patient with low vision. How would these priorities change if the patient were blind?

2 ipc A 45-year-old woman presents to the emergency department complaining she has had progressive loss of vision of her left eye since the morning. She lives alone and is very afraid of going blind. The patient is diagnosed with a retinal detachment and scheduled for surgery. What members of the interdisciplinary team are essential to include? How will you facilitate an interprofessional discussion to develop strategies to decrease her fear?

3 ebp An 80-year-old patient reports to you that he has been diagnosed with AMD. What is the evidence base for offering guidelines for managing this condition? What evidence-based educational information can you share? Identify the criteria used to evaluate the strength of the evidence for these practices.

59 Assessment and Management of Patients with Hearing and Balance Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the anatomy and physiology of the ear as well as the methods used to assess hearing and balance disorders.
2. List the manifestations that may be exhibited by a person with hearing and balance disorders.
3. Identify ways to communicate effectively with a person with a hearing disorder, incorporating the differences between Deaf culture and deafness.
4. Differentiate disorders of the external ear from those of the middle ear and inner ear.
5. Compare the various types of surgical procedures used for managing middle ear disorders and appropriate nursing care.
6. Use the nursing process as a framework for care of the patient undergoing mastoid surgery or of the patient with vertigo.
7. Recognize the different types of inner ear disorders, including the clinical manifestations, diagnosis, and management.

Stress

GLOSSARY

acute otitis media: inflammation in the middle ear lasting less than 6 weeks

cholesteatoma: tumor of the middle ear or mastoid, or both, that can destroy structures of the temporal bone

chronic otitis media: repeated episodes of acute otitis media causing irreversible tissue damage

conductive hearing loss: loss of hearing in which efficient sound transmission to the inner ear is interrupted by some obstruction or disease process

Deaf culture: a community that consists of a group of people who are connected by their use of sign language

deafness: partial or complete loss of the ability to hear

dizziness: altered sensation of orientation in space

endolymphatic hydrops: dilation of the endolymphatic space of the inner ear; the pathologic correlate of Ménière's disease

exostoses: small, hard, protrusions in the lower posterior bony portion of the ear canal

external otitis: inflammation of the external auditory canal (*synonym:* otitis externa)

labyrinthitis: inflammation of the labyrinth of the inner ear

Ménière's disease: condition of the inner ear characterized by a triad of symptoms: episodic vertigo, tinnitus, and fluctuating sensorineural hearing loss

middle ear effusion: fluid in the middle ear without evidence of infection

myringotomy: incision in the tympanic membrane (*synonym:* tympanotomy)

nystagmus: involuntary rhythmic eye movement

ossiculoplasty: surgical reconstruction of the middle ear bones to restore hearing

otalgia: sensation of fullness or pain in the ear

otorrhea: drainage from the ear

otosclerosis: a condition characterized by abnormal spongy bone formation around the stapes

presbycusis: progressive hearing loss associated with aging

rhinorrhea: drainage from the nose

sensorineural hearing loss: loss of hearing related to damage to the end organ for hearing or cranial nerve VIII, or both

tinnitus: subjective perception of sound with internal origin; unwanted noises in the head or ear most often described as ringing in the ears

tympanoplasty: surgical repair of the tympanic membrane

vertigo: illusion of movement in which the individual or the surroundings are sensed as moving

The ear is a delicate sensory organ with the dual functions of hearing and balance. The sense of hearing is essential for normal development and maintenance of speech as well as the ability to communicate with others. Balance, or equilibrium, is essential for maintaining body movement, position, and coordination.

The early detection and accurate diagnosis of disorders is necessary for preservation of normal hearing and balance. The diagnosis and treatment of these disorders requires skilled health care professionals such as otolaryngologists, internists, audiologists, and nurses. This chapter provides an overview of the anatomy and physiology of the ear and addresses the general assessment and management of hearing and balance disorders common to adults seen in many health care settings.

ASSESSMENT OF THE EAR

Anatomic and Physiologic Overview

The cranium encloses and protects the brain and surrounding structures, providing attachment for various muscles that control head and jaw movements. The ears are located on either side of the cranium at approximately eye level.

Anatomy of the External Ear

The external ear includes the auricle (pinna) and the external auditory canal (see Fig. 59-1). The external ear is separated from the middle ear by a disc-shaped structure called the *tympanic membrane* (eardrum).

Auricle

The auricle, attached to the side of the head by skin, is composed mainly of cartilage, except for the fat and subcutaneous tissue in the earlobe. The auricle collects the sound waves and directs vibrations into the external auditory canal.

External Auditory Canal

The external auditory canal is approximately 2 to 3 cm long (Norris, 2019). The lateral third is an elastic cartilaginous and dense fibrous framework to

which thin skin is attached. The medial two thirds is bone lined with thin skin. The external auditory canal ends at the tympanic membrane.

The skin of the canal contains hair, sebaceous glands, and ceruminous glands, which secrete a brown, waxlike substance called *cerumen* (ear wax). The ear's self-cleaning mechanism moves old skin cells and cerumen to the outer part of the ear.

Just anterior to the external auditory canal is the temporomandibular joint. The head of the mandible can be felt by placing a fingertip in the external auditory canal while the patient opens and closes the mouth.

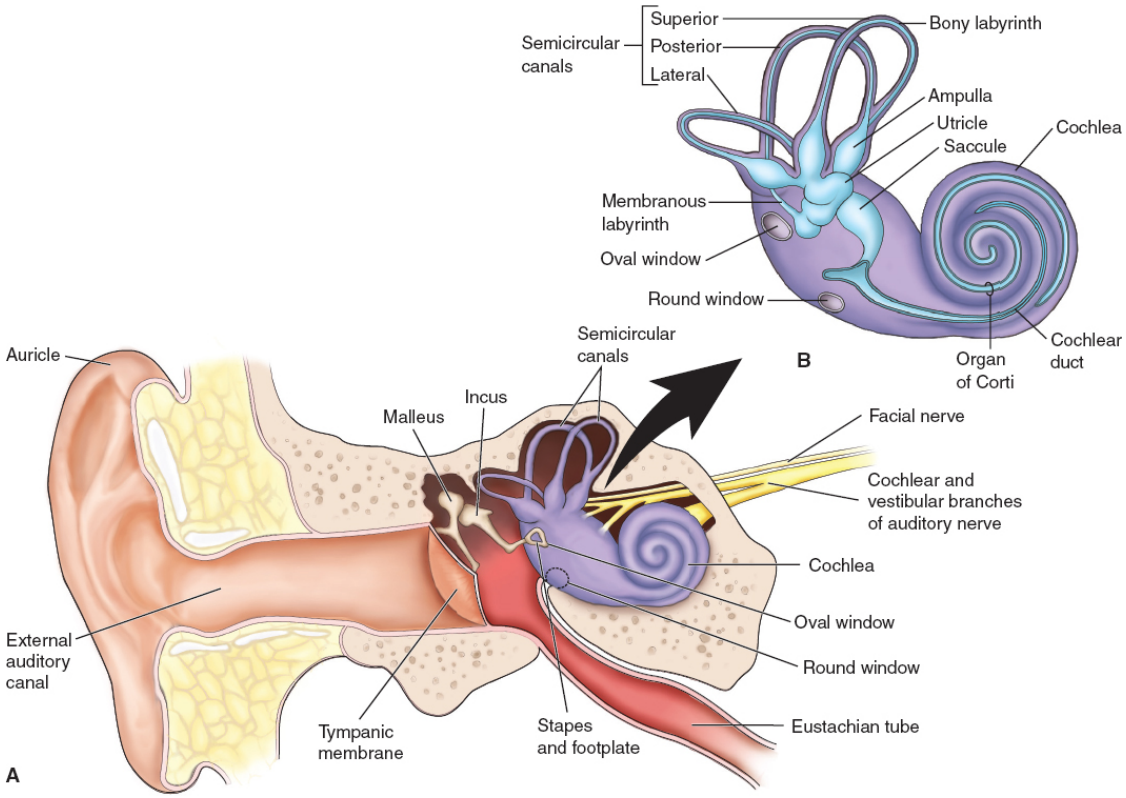

Figure 59-1 • **A.** Anatomy of the ear. **B.** The inner ear.

Anatomy of the Middle Ear

The middle ear, an air-filled cavity, includes the tympanic membrane laterally and the otic capsule medially. The middle ear cleft lies between the two. The middle ear is connected to the nasopharynx by the eustachian tube and is continuous with air-filled cells in the adjacent mastoid portion of the temporal bone.

The eustachian tube, which is approximately 1 mm wide and 35 mm long, connects the middle ear to the nasopharynx. Normally, the eustachian tube is closed, but it opens by action of the tensor veli palatini muscle when the person performs a Valsalva maneuver, yawns, or swallows. It drains normal

and abnormal secretions of the middle ear and equalizes pressure in the middle ear with that of the atmosphere.

Tympanic Membrane

The tympanic membrane (eardrum), about 1 cm in diameter and very thin, is normally pearly gray and translucent (Weber & Kelley, 2018). It consists of three layers of tissue: an outer layer, continuous with the skin of the ear canal; a fibrous middle layer; and an inner mucosal layer, continuous with the lining of the middle ear cavity. Approximately 80% of the tympanic membrane is composed of all three layers and is called the *pars tensa.* The remaining 20% lacks the middle layer and is called the *pars flaccida.* The absence of this fibrous middle layer makes the pars flaccida more vulnerable to pathologic disorders than the pars tensa. Distinguishing landmarks include the annulus, the fibrous border that attaches the eardrum to the temporal bone; the short process of the malleus; the long process of the malleus; the umbo of the malleus, which attaches to the tympanic membrane in the center; the pars flaccida; and the pars tensa (see Fig. 59-2).

The tympanic membrane protects the middle ear and conducts sound vibrations from the external canal to the ossicles. The sound pressure is magnified 22 times as a result of transmission from a larger area to a smaller one.

Ossicles

The middle ear contains the ossicles, the three smallest bones of the body: the malleus, the incus, and the stapes (Norris, 2019). The ossicles, which are held in place by joints, muscles, and ligaments, assist in the transmission of sound. Two small fenestrae (oval and round windows), located in the medial wall of the middle ear, separate the middle ear from the inner ear. The footplate of the stapes sits in the oval window, secured by a fibrous annulus (ring-shaped structure). The footplate transmits sound to the inner ear. The round window, covered by a thin membrane, provides an exit for sound vibrations (see Fig. 59-1).

Anatomy of the Inner Ear

The inner ear is housed deep within the temporal bone. The organs for hearing (cochlea) and balance (semicircular canals), as well as cranial nerves VII (facial nerve) and VIII (vestibulocochlear nerve), are all part of this complex anatomy (see Fig. 59-1). The cochlea and semicircular canals are housed in the bony labyrinth. The bony labyrinth surrounds and protects the membranous labyrinth, which is bathed in a fluid called *perilymph.*

Membranous Labyrinth

The membranous labyrinth is composed of the utricle, the saccule, the cochlear duct, the semicircular canals, and the organ of Corti, all of which are surrounded by a fluid called *endolymph*. The three semicircular canals—posterior, superior, and lateral, which lie at 90-degree angles to one another—contain sensory receptor organs that are arranged to detect rotational movement. These receptor end organs are stimulated by changes in the rate or direction of a person's movement. The utricle and saccule are involved with linear movements.

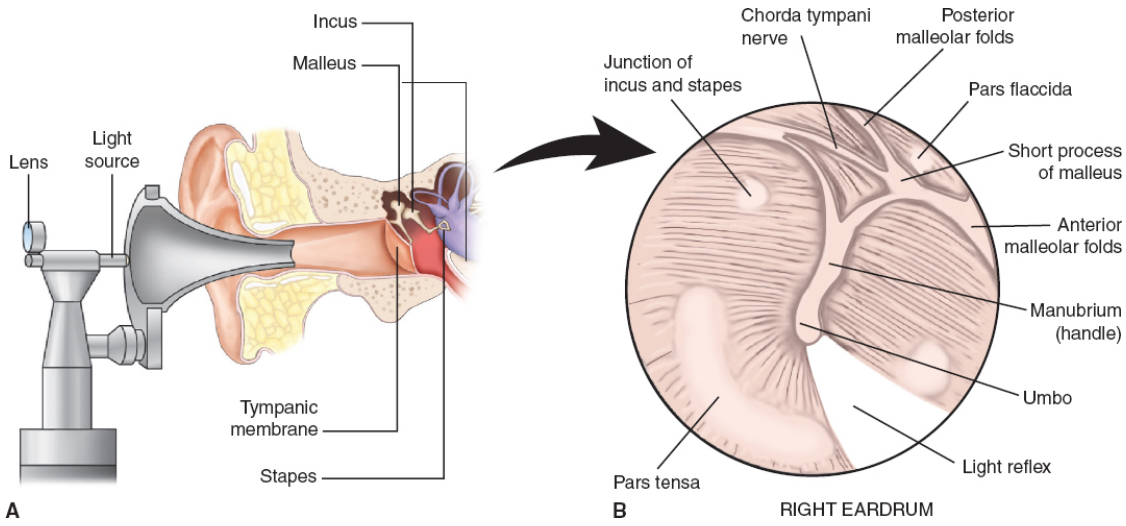

Figure 59-2 • Technique for using the otoscope (**A**) to see the tympanic membrane (**B**).

Organ of Corti

The organ of Corti is housed in the cochlea, a snail-shaped, bony tube about 3.5 cm long with two and a half spiral turns. Membranes separate the cochlear duct (scala media) from the scala vestibuli and the scala tympani from the basilar membrane. The organ of Corti is located on the basilar membrane that stretches from the base to the apex of the cochlea. As sound vibrations enter the perilymph at the oval window and travel along the scala vestibuli, they pass through the scala tympani, enter the cochlear duct, and cause movement of the basilar membrane. The organ of Corti, also referred to as the end organ for hearing, transforms mechanical energy into neural activity and separates sounds into different frequencies. This electrochemical impulse travels through the acoustic nerve to the temporal cortex of the brain to be interpreted as meaningful sound. In the internal auditory canal, the cochlear (acoustic) nerve, arising from the cochlea, joins the vestibular nerve, arising from the semicircular canals, utricle, and saccule, to become the vestibulocochlear nerve (cranial nerve VIII). This canal also houses the facial nerve and the blood supply from the ear to the brain.

Function of the Ears

Hearing

Hearing is conducted over two pathways: air and bone. Sounds transmitted by air conduction travel over the air-filled external and middle ear through vibration of the tympanic membrane and ossicles. Sounds transmitted by bone conduction travel directly through bone to the inner ear, bypassing the tympanic membrane and ossicles. Normally, air conduction is the more efficient pathway.

Sound Conduction and Transmission

Sound enters the ear through the external auditory canal and causes the tympanic membrane to vibrate. These vibrations transmit sound through the lever action of the ossicles to the oval window as mechanical energy. This mechanical energy is then transmitted through the inner ear fluids to the cochlea, stimulating the hair cells, and is subsequently converted to electrical energy. The electrical energy travels through the vestibulocochlear nerve to the central nervous system, where it is interpreted in its final form as sound.

Vibrations transmitted by the tympanic membrane to the ossicles of the middle ear are transmitted to the cochlea, located in the labyrinth of the inner ear. The stapes rocks, causing vibrations (waves) in fluids contained in the inner ear. These fluid waves cause movement of the basilar membrane, stimulating the hair cells of the organ of Corti in the cochlea to move in a wavelike manner. The movements of the tympanic membrane initiate electrical currents that stimulate the various areas of the cochlea. The hair cells generate neural impulses that are encoded and then transferred to the auditory cortex in the brain, where they are decoded into a sound message.

The footplate of the stapes receives impulses transmitted by the incus and the malleus from the tympanic membrane. The round window, which opens on the opposite side of the cochlear duct, is protected from sound waves by the intact tympanic membrane, permitting motion of the inner ear fluids by sound wave stimulation. For example, in the normally intact tympanic membrane, sound waves stimulate the oval window first, and a lag occurs before the terminal effect of the stimulus reaches the round window. However, this lag phase is changed when a perforation of the tympanic membrane allows sound waves to impinge on the oval and round windows simultaneously. This effect cancels the lag and prevents the maximal effect of inner ear fluid motility and its subsequent effect in stimulating the hair cells in the organ of Corti. The result is a reduction in hearing ability (see Fig. 59-3).

Bone conduction occurs by directly stimulating bones of the skull, which send sound to the inner ear. The way in which this occurs can be demonstrated

by striking a tuning fork and placing it directly on the skull above the ear. Sound is transmitted to the inner ear.

Balance and Equilibrium

Body balance is maintained by cooperation of muscles and joints of the body (proprioceptive system), the eyes (visual system), and the labyrinth (vestibular system). These areas send their information about equilibrium, or balance, to the brain (cerebellar system) for coordination and perception in the cerebral cortex. The brain obtains its blood supply from the heart and arterial system. A problem in any of these areas, such as arteriosclerosis or impaired vision, can cause a disturbance of balance. The vestibular apparatus of the inner ear provides feedback regarding the movements and the position of the head and body in space.

Assessment 

Assessment of hearing and balance involves inspection of the external, middle, and inner ear. Evaluation of gross hearing acuity also is included in every physical examination.

Inspection of the External Ear

Inspection of the external ear is a simple procedure, but it is often overlooked. The external ear is examined by inspection and direct palpation; the auricle and surrounding tissues should be inspected for deformities, lesions, and discharge, as well as size, symmetry, and angle of attachment to the head. Manipulation of the auricle does not normally elicit pain. If this maneuver is painful, acute external otitis is suspected (Cash & Glass, 2017). Tenderness on palpation in the area of the mastoid may indicate acute mastoiditis or inflammation of the posterior auricular node. Occasionally, sebaceous cysts and tophi (subcutaneous mineral deposits) are present on the pinna. A flaky scaliness on or behind the auricle usually indicates seborrheic dermatitis and can be present on the scalp and facial structures as well.

Otoscopic Examination

The tympanic membrane is inspected with an otoscope and indirect palpation with a pneumatic otoscope. To examine the external auditory canal and tympanic membrane, the otoscope should be held in the examiner's right hand, in a pencil-hold position, with the examiner's hand braced against the patient's face (see Fig. 59-4). This position prevents the examiner from inserting the

otoscope too far into the external canal. Using the opposite hand, the auricle is grasped and gently pulled back to straighten the canal in the adult.

The speculum is slowly inserted into the ear canal, with the examiner's eye held close to the magnifying lens of the otoscope to visualize the canal and tympanic membrane. The largest speculum that the canal can accommodate (usually 5 mm in an adult) is guided gently down into the canal and slightly forward. Because the distal portion of the canal is bony and covered by a sensitive layer of epithelium, only light pressure can be used without causing pain. The external auditory canal is examined for discharge, inflammation, or a foreign body.

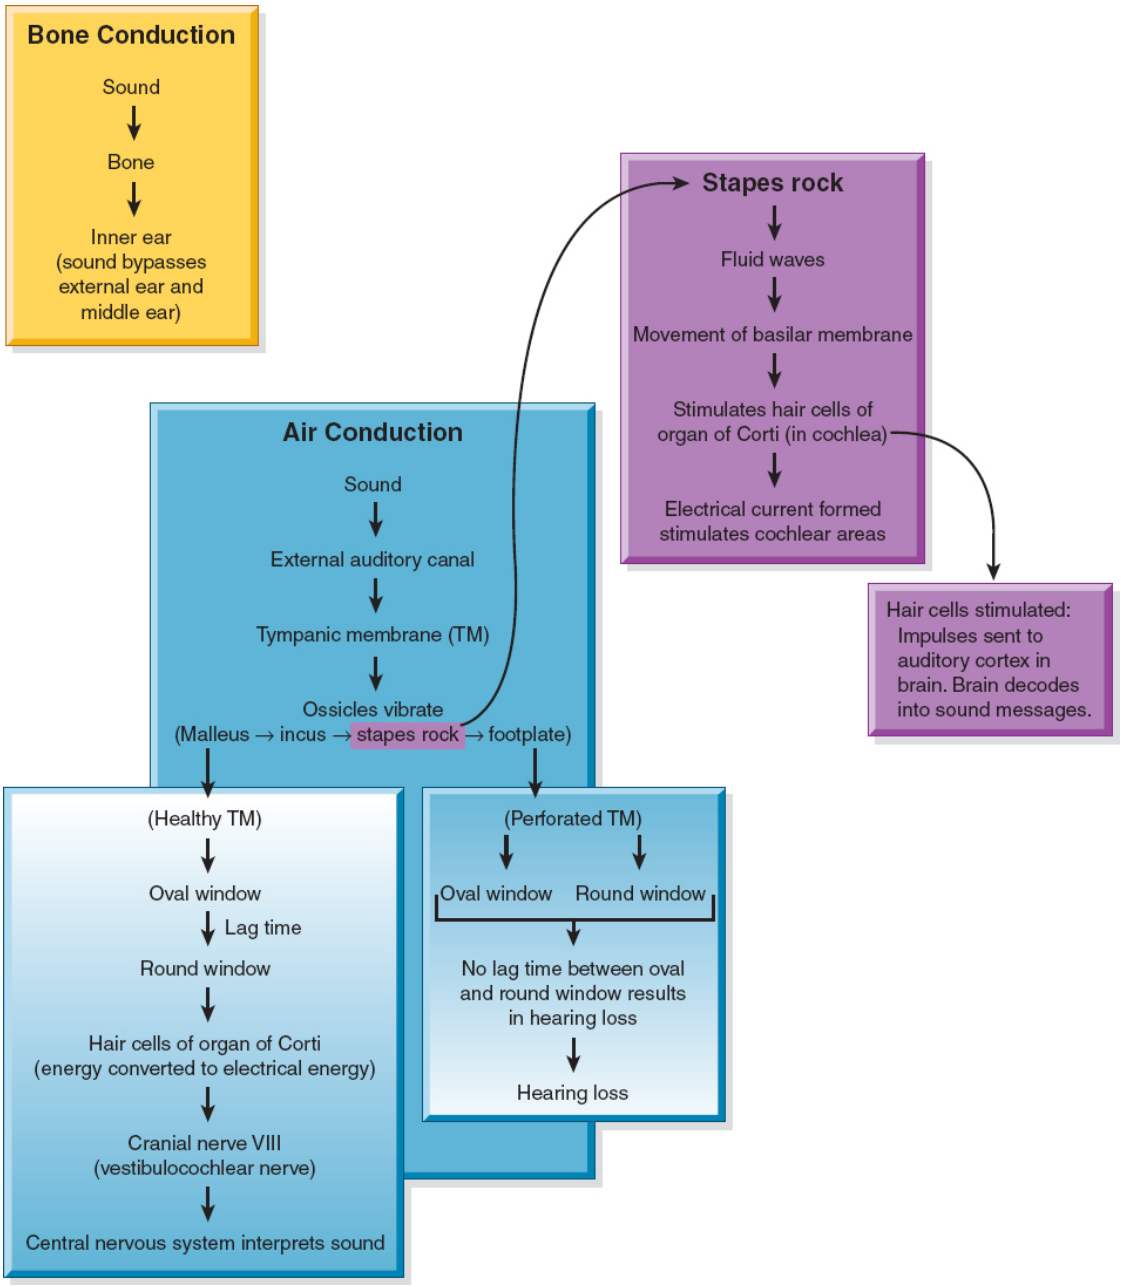

Figure 59-3 • Bone conduction compared to air conduction.

The healthy tympanic membrane is pearly gray and is positioned obliquely at the base of the canal. The following landmarks are identified, if visible (see Fig. 59-2): the pars tensa, the umbo, the manubrium of the malleus, and its short process. A slow, circular movement of the speculum allows further visualization of the malleolar folds and periphery. The position and color of the membrane and any unusual markings or deviations from normal are documented. Presence of fluid, air bubbles, blood, or masses in the middle ear should also be noted.

Proper otoscopic examination of the external auditory canal and tympanic membrane requires that the canal be free of large amounts of cerumen. Cerumen is normally present in the external canal, and small amounts should not interfere with otoscopic examination. If the tympanic membrane cannot be visualized because of cerumen, the cerumen may be removed using several methods (see later discussion of cerumen removal in section Cerumen Impaction). Cerumen buildup is a common cause of local irritation, **tinnitus** (i.e., an unwanted noise commonly described as ringing in the ears), and reversible hearing loss (Norris, 2019).

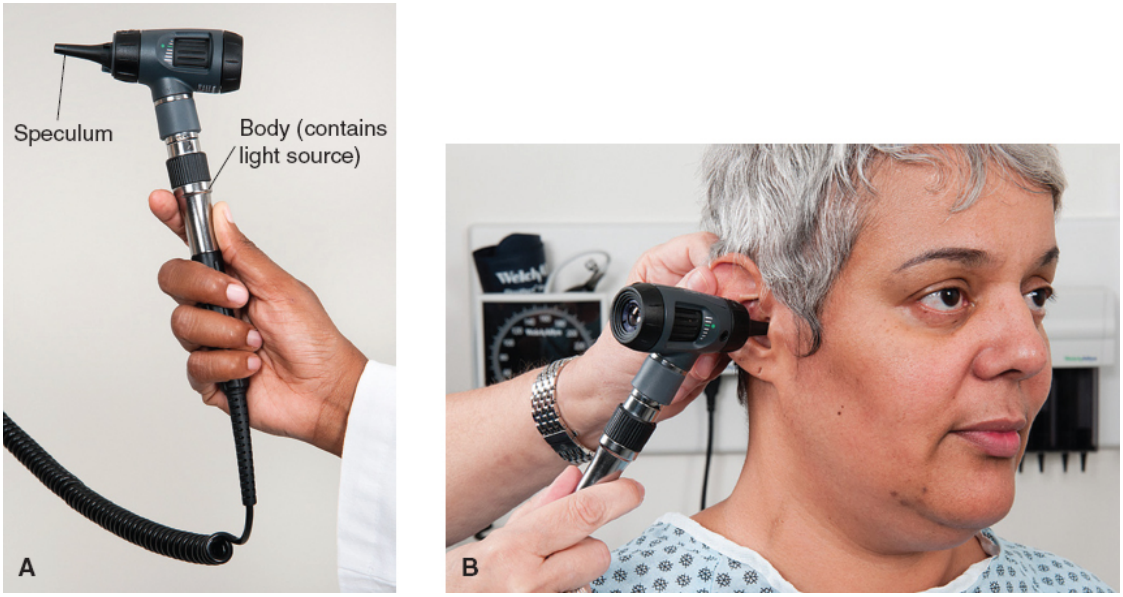

Figure 59-4 • **A.** The otoscope. **B.** Proper technique for examining the ear. Hold the otoscope in the right or left hand, in a "pencil-hold" position. Reprinted with permission from Weber, J., & Kelley, J. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Evaluation of Gross Auditory Acuity

A general estimate of hearing can be made by assessing the patient's ability to hear a whispered phrase, testing one ear at a time. The Weber and Rinne tests may be used to distinguish conductive loss from sensorineural loss when

hearing is impaired (Weber & Kelley, 2018). These tests are part of a regular screening physical examination and are useful if a more specific assessment is needed, if hearing loss is detected, or if confirmation of audiometric results is desired.

Whisper Test

To exclude one ear from the testing, the examiner covers the untested ear with the palm of the hand. The examiner then whispers softly from a distance of 1 or 2 feet from the unoccluded ear and out of the patient's sight. The patient with normal acuity can correctly repeat what was whispered.

Weber Test

The Weber test uses bone conduction to test lateralization of sound. A tuning fork (ideally, 512 Hertz [Hz]), set in motion by grasping it firmly by its stem and tapping it on the examiner's knee or hand, is placed on the patient's head or forehead (see Fig. 59-5A). A person with normal hearing hears the sound equally in both ears or describes the sound as centered in the middle of the head. A person with conductive hearing loss, such as from otosclerosis or otitis media, hears the sound better in the affected ear. A person with sensorineural hearing loss, resulting from damage to the cochlear or vestibulocochlear nerve, hears the sound in the better-hearing ear. The Weber test is useful for detecting unilateral hearing loss (see Table 59-1).

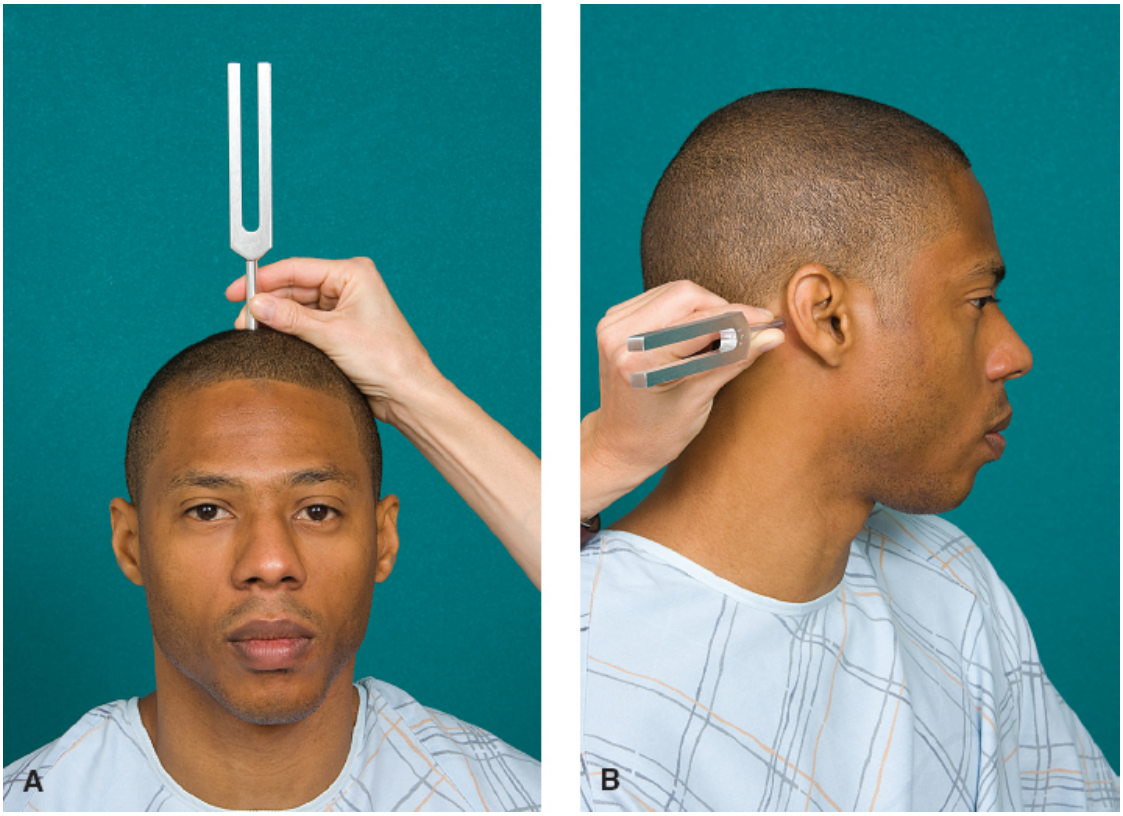

Figure 59-5 • **A.** The Weber test assesses bone conduction of sound. **B.** The Rinne test assesses both air and bone conduction of sound.

TABLE 59-1 Comparison of Weber and Rinne Tests

Hearing Status	Weber	Rinne
Normal hearing	Sound is heard equally in both ears.	Air conduction is audible longer than bone conduction in both ears.
Conductive hearing loss	Sound is heard best in affected ear (hearing loss).	Sound is heard as long or longer in affected ear (hearing loss).
Sensorineural hearing loss	Sound is heard best in normal hearing ear.	Air conduction is audible longer than bone conduction in affected ear.

Adapted from Weber, J., & Kelley, J. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Results of the Weber test are used to determine whether the patient has conductive hearing loss (sounds are heard better in the affected ear) or sensorineural hearing loss (sounds are heard better in the normal ear) (see later discussion of hearing loss).

Rinne Test

In the Rinne test (pronounced *rin-ay*), the examiner shifts the stem of a vibrating tuning fork between two positions: 2 inches from the opening of the ear canal (for air conduction) and against the mastoid bone (for bone conduction) (see Fig. 59-5B). As the position changes, the patient is asked to indicate which tone is louder or when the tone is no longer audible.

The Rinne test is useful for distinguishing between conductive and sensorineural hearing loss. A person with normal hearing reports that air-conducted sound is louder than bone-conducted sound. A person with a conductive hearing loss hears bone-conducted sound as long as or longer than air-conducted sound. A person with a sensorineural hearing loss hears air-conducted sound longer than bone-conducted sound.

Cultural Considerations

Deaf culture is distinguished with an uppercase *D*, whereas deafness as an audiologic condition is indicated by a lowercase *d*. In a sociocultural context, Deaf refers to individuals who were born with limited hearing or developed hearing loss before developing a spoken language and who use sign language (e.g., American Sign Language [ASL]) as their primary means of communication (Pendergrass, Newman, Jones, et al., 2019). Core cultural values include a sacred respect for and use of the hands, disassociation from speech, complete acceptance of being Deaf as a normal existence, full access to communication and information sharing, and self-determination (Holcomb, 2013; Padden, 1980).

According to the World Federation of the Deaf (World Federation of the Deaf [WFD], 2020), membership in the Deaf community depends on self-identification, acceptance of other members, and proficiency in a signed language. The Deaf community rejects the term *hearing-impaired* as demeaning and use of this term is discouraged (Holcomb, 2013; Moore & Levitan, 2016). Health professionals should be aware of individual differences and use the appropriate terminology when referring to Deaf, deaf, and people who are hard of hearing. Other appropriate terms used to identify Deaf people include Deaf signers, Deaf ASL users, or culturally Deaf adults.

Deaf and people who are hard of hearing are often hampered by communication barriers and an inadequate level of understanding about their language and culture by the hearing majority (Holcomb, 2013). When communicating with Deaf signers, nurses need to know that one's ability to speak is irrelevant and asking about the details of one's audiologic status is considered rude unless the individual offers this information (Mindess, 2014). Although a person who is deaf may have the ability to speak, it is important to remember that speech benefits the hearing population and the individual is in fact, deaf. As patient advocates, nurses should be mindful of the differences and similarities among Deaf signers, nonsigning deaf, and hard of hearing as

well as their own beliefs about these differences and similarities (Lewis & Keele, 2020). See the Nursing Research Profile in Chart 59-1. Although various methods may be necessary, communication should always be based on patient preference.

Diagnostic Evaluation

Many diagnostic procedures are available to measure the auditory and vestibular systems indirectly. These tests are usually performed by a certified audiologist. The nurse educates the patient about the purpose, what to expect, and any possible side effects related to testing. The nurse notes trends in results because they provide information about disease progression as well as the patient's response to therapy.

Audiometry

In detecting hearing loss, audiometry is the single most important diagnostic instrument. Audiometric testing is of two kinds: pure-tone audiometry, in which the sound stimulus consists of a pure or musical tone (the louder the tone before the patient perceives it, the greater the hearing loss), and speech audiometry, in which the spoken word is used to determine the ability to hear and discriminate sounds and words.

When evaluating hearing, three characteristics are important: frequency, pitch, and intensity. *Frequency* refers to the number of sound waves emanating from a source per second, measured as cycles per second, or Hertz. The normal human ear perceives sounds ranging in frequency from 20 to 20,000 Hz. The frequencies from 500 to 2000 Hz are important in understanding everyday speech and are referred to as the speech range or speech frequencies. *Pitch* is the term used to describe frequency; a tone with 100 Hz is considered of low pitch, and a tone of 10,000 Hz is considered of high pitch.

The unit for measuring loudness (*intensity* of sound) is the decibel (dB), the pressure exerted by sound. Hearing loss is measured in decibels—a logarithmic function of intensity that is not easily converted into a percentage. The critical level of loudness is approximately 30 dB. The shuffling of papers in quiet surroundings is about 15 dB; a low conversation, 40 dB; and a jet plane 100 feet away, about 150 dB. Sound louder than 80 dB is perceived by the human ear to be harsh and can be damaging to the inner ear. Table 59-2 classifies hearing loss based on decibel level. In surgical treatment of patients with hearing loss, the aim is to improve the hearing level to 30 dB or better within the speech frequencies.

Chart 59-1  NURSING RESEARCH PROFILE

Nurses' Beliefs Toward Deaf and Hard of Hearing Interaction

Lewis, A., & Keele, R. (2020). Development and validation of instrument to measure nurses' beliefs toward Deaf and hard of hearing interaction. *Journal of Nursing Measurement*, *28*(2). doi: 10.1891/JNM-D-19-00024

Purpose

Nurse–patient communication has a significant effect on health outcomes and quality of care. Investigating what nurses believe about interacting with Deaf signers, nonsigning deaf, and hard of hearing patients is an important step in minimizing barriers and improving nursing care. The purpose of this research was to develop and test the validity and reliability of an instrument to measure registered nurses' (RNs) beliefs toward interaction with patients who are Deaf signers, nonsigning deaf, and hard of hearing, as well as with certified interpreters.

Design

This study used a quantitative methodologic design.

Findings

Noteworthy findings were associated with the social constructs of power and control. Participant responses strongly indicated the belief that it is acceptable to relinquish the autonomy and self-determination of a Deaf signer, a nonsigning deaf, or a hard of hearing person to a hearing person. This belief is apparent in at least 65% of respondents from three groups of RNs who agreed that "questions or responses for a person who is a Deaf signer, a nonsigning deaf, or hard of hearing should be directed to hearing family members" and at least 60% of respondents from both groups of RNs agreed that "during health care interactions, most Deaf signers prefer to get by without a certified interpreter."

Data collection and analyses resulted in a 25-item D/deaf and Hard of Hearing Interaction Beliefs Scale for Registered Nurses. Psychometric analysis of two separate groups of data concluded that the newly developed scale is a reliable and valid scale to measure nurses' beliefs toward interaction with patients who are either Deaf signers, nonsigning deaf, or hard of hearing. Results of confirmatory factor analysis supported the hypothesized structure of the scale and provided some evidence for its factorial validity.

Nursing Implications

Understanding the beliefs that nurses hold toward interactions with Deaf signers, nonsigning deaf, and hard of hearing persons may shed light on nurses' general beliefs toward individuals who are Deaf signers, nonsigning deaf, and hard of hearing. Furthermore, these beliefs may influence nurses' views about the importance of appropriate and effective interaction with patients who have diverse communication needs. This understanding can

lead to the development of standards of practice and organizational policies that reflect federal laws mandating equal communication access for all. Attention to equal communication access can create a nursing culture that views communication diversity not as a barrier, but as an opportunity to open doors and promote every patient's right to autonomy and self-determination.

With audiometry, the patient wears earphones and signals to the audiologist when a tone is heard. When the tone is applied directly over the external auditory canal, air conduction is measured. When the stimulus is applied to the mastoid bone, bypassing the conductive mechanism (i.e., the ossicles), nerve conduction is tested. For accuracy, testing is performed in a soundproof room. Responses are plotted on a graph known as an audiogram, which differentiates conductive from sensorineural hearing loss.

TABLE 59-2 Severity of Hearing Loss

Loss in Decibels	Interpretation
0–15	Normal hearing
>15–25	Slight hearing loss
>25–40	Mild hearing loss
>40–55	Moderate hearing loss
>55–70	Moderate to severe hearing loss
>70–90	Severe hearing loss
>90	Profound hearing loss

Tympanogram

A tympanogram, or impedance audiometry, measures middle ear muscle reflex to sound stimulation and compliance of the tympanic membrane by changing the air pressure in a sealed ear canal. Compliance is impaired with middle ear disease.

Auditory Brain Stem Response Audiometry

The auditory brain stem response (ABR) audiometry is a detectable electrical potential from cranial nerve VIII and the ascending auditory pathways of the brain stem in response to sound stimulation. Electrodes are placed on the patient's scalp and on each earlobe (Fischbach & Fischbach, 2018). Acoustic stimuli (e.g., clicks) are made in the ear. The resulting electrophysiologic measurements can determine at which decibel level a patient hears and whether there are any impairments along the nerve pathways (e.g., tumor on cranial nerve VIII). Patients are instructed to wash and rinse their hair prior to this study but to avoid applying any other hair product. ABR audiometry

assessment should be used in conjunction with behavioral audiometry for the most accurate results (Bhattacharyya, 2017).

Electronystagmography

Electronystagmography is the measurement and graphic recording of the changes in electrical potentials created by eye movements during spontaneous, positional, or calorically evoked nystagmus (see discussion of nystagmus later in this chapter). It is also used to assess the oculomotor and vestibular systems and their corresponding interaction. It helps to diagnose causes of unilateral hearing loss of unknown origin, vertigo, or tinnitus. Any vestibular suppressants, such as caffeine and alcohol, are withheld for 48 hours before testing. Medications such as tranquilizers, stimulants, or antivertigo agents are withheld for 5 days before the test (Fischbach & Fischbach, 2018).

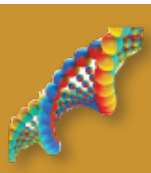
Platform Posturography

Platform posturography is recommended for patients with dizziness and balance disorders (American Academy of Otolaryngology—Head and Neck Surgery, 2014). It can be used to determine if a patient's vertigo is worsening or to evaluate a patient's response to treatment. The integration of visual, vestibular, and proprioceptive cues (i.e., sensory integration) with motor response output and coordination of the lower limbs is tested. The patient stands on a platform, surrounded by a screen, and different conditions such as a moving platform with a moving screen or a stationary platform with a moving screen are presented. The responses from the patient are measured and indicate which of the anatomic systems may be impaired. Preparation for the testing is the same as for electronystagmography.

Sinusoidal Harmonic Acceleration

Sinusoidal harmonic acceleration, or a rotary chair, is used to assess the vestibuloocular system by analyzing compensatory eye movements in response to the clockwise and counterclockwise rotation of the chair. Although such testing cannot identify the side of the lesion in unilateral disease, it helps to identify the disease (e.g., Ménière's disease and tumors of the auditory canal) and evaluate the course of recovery. The same patient preparation is required as that for electronystagmography.

Middle Ear Endoscopy



Using instruments called endoscopes that have very small diameters and acute angles, the ear can be examined by an endoscopist specializing in

otolaryngology. Middle ear endoscopy is performed safely and effectively as an office procedure to evaluate suspected perilymphatic fistula and new-onset conductive hearing loss, the anatomy of the round window before transtympanic treatment of Ménière's disease, and the tympanic cavity before ear surgery to treat chronic middle ear and mastoid infections.

The tympanic membrane is anesthetized topically for about 10 minutes before the procedure. Then, the external auditory canal is irrigated with sterile normal saline solution. With the aid of a microscope, a tympanotomy is created with a laser beam or a myringotomy knife so that the endoscope can be inserted into the middle ear cavity. Video and photo documentation can be accomplished through the scope.

HEARING LOSS

In the United States, hearing loss has been reported to occur in approximately 2 to 3 of every 1000 births (U.S. Department of Health and Human Services [HHS], 2016). More than half of the 4000 infants born deaf each year have a hereditary disorder associated with genetic sensorineural hearing loss (Antonio, 2018). Genetic syndromes associated with hearing impairment include Waardenburg syndrome, Usher syndrome, Pendred syndrome, and Jervell and Lange-Nielsen syndrome (Antonio, 2018). Chart 59-2 contains more information about hearing disorders that have a genetic cause. Hearing loss may also be acquired; causes include TORCH infections (TOxoplasmosis, Rubella, Cytomegalovirus, Herpes) during pregnancy as well as trauma or chronic exposure to loud noise (Antonio, 2018). Most hospitals or birthing centers offer universal hearing screenings for newborns after birth and prior to discharge.

Chart 59-2  **GENETICS IN NURSING PRACTICE**

Hearing Disorders

Several hearing disorders are associated with genetic mutations and have various patterns of inheritance:

Autosomal dominant:

- Branchiootorenal syndrome
- Neurofibromatosis type 2
- Otosclerosis
- Stickler syndrome
- Waardenburg syndrome

Autosomal recessive:

- Connexin 26 gene hearing loss (majority of cases are recessive; however, there is an autosomal dominant form that occurs less commonly)
- Jervell and Lange-Nielsen syndrome
- Pendred syndrome
- Refsum disease
- Usher syndrome

X-linked syndromic hearing loss:

- Alport syndrome

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Hearing Loss

- Assess for other family members in several generations with hearing loss (autosomal dominant hearing loss).
- Inquire about genetic relatedness (e.g., individuals who are related, such as first cousins, have a higher chance to share the same recessive genes—autosomal recessive hearing loss).
- Inquire about age at onset of hearing loss.

Patient Assessment Specific to Genetic-Related Hearing Loss

- Assess for:
  - Dizziness
  - Facial numbness or weakness
  - Headaches
  - Tinnitus
- Assess for related genetic conditions, such as vision impairment (e.g., retinitis pigmentosa in Usher syndrome; thyroid disorder in Pendred

syndrome).
- Assess for iris, pigment, and hair alterations (white forelock) seen in Waardenburg syndrome.
- Assess for exposure to loud noises (e.g., industrial).
- Assess for presence of rubella, toxoplasmosis, herpes, or cytomegalovirus during pregnancy.
- Determine if patient had taken medications associated with ototoxicity.

Genetics Resources

Genetics of Hearing Loss, www.cdc.gov/ncbddd/hearingloss/genetics.html

Neurofibromatosis Network, www.nfnetwork.org/
See Chapter 6, Chart 6-7 for components of genetic counseling.

Hearing loss occurs in men more often than in women. Approximately 2% of adults between the ages of 45 and 54 years have disabling hearing loss. This percentage increases to 8.5% in the 55 to 64 age group, to 25% of adults in the 65 to 74 age group, and up to 50% for those over 75 years of age (HHS, 2016). Hearing loss is an important health issue; and as people age, hearing screening and treatment are recommended.

Many people are exposed on a daily basis to noise levels that produce high-frequency hearing loss. Occupations such as carpentry, plumbing, and coal mining have the highest risk of noise-induced hearing loss. Wise Ears was developed by the National Institute on Deafness and Other Communication Disorders (NIDCD) and the National Institute for Occupational Safety and Health (NIOSH). It aims to educate the public about noise-induced hearing loss and ways to prevent this hearing loss (NIDCD, 2010).

Conductive hearing loss usually results from an external ear disorder, such as impacted cerumen, or a middle ear disorder, such as otitis media or otosclerosis. In such instances, the efficient transmission of sound by air to the inner ear is interrupted. A **sensorineural hearing loss** involves damage to the cochlea or vestibulocochlear nerve.

Mixed hearing loss and functional hearing loss also may occur. Patients with mixed hearing loss have conductive loss and sensorineural loss, resulting from dysfunction of air and bone conduction. A functional (or psychogenic) hearing loss is nonorganic and unrelated to detectable structural changes in the hearing mechanisms; it is usually a manifestation of an emotional reaction.

Clinical Manifestations

Deafness is the partial or complete loss of the ability to hear. Early manifestations may include tinnitus, increasing inability to hear when in a group, and a need to turn up the volume of the television. Hearing loss can also

trigger changes in attitude, the ability to communicate, the awareness of surroundings, and even the ability to protect oneself, thus affecting a person's quality of life. In a classroom, a student with hearing loss may be uninterested and inattentive and have failing grades. A pedestrian with hearing loss may attempt to cross the street and fail to hear an approaching car. People with hearing loss may miss parts of conversations, and may gradually interact with others less, leading to feelings of isolation. Many people are unaware of their gradual hearing loss. Often, it is not the person with the hearing loss but the people with whom they are communicating that recognizes the change (see Chart 59-3).

For various reasons, some people with hearing loss refuse to seek medical attention or wear a hearing aid. They may feel self-conscious about wearing a hearing aid. Other people, however, may feel comfortable asking those with whom they are trying to communicate to let them know whether difficulties in communication exist. The attitudes and behaviors of patients who need hearing assistance should be taken into account when counseling them. The decision to wear a hearing aid is a personal one that is affected by these attitudes and behaviors.

Chart 59-3  **ASSESSMENT**

Assessing for Hearing Loss

The nurse should be alert to the following:

Speech deterioration: The person who slurs words, drops word endings, or produces flat-sounding speech may not be hearing correctly. Hearing guides the voice, both in loudness and in pronunciation.

Fatigue: If a person tires easily when listening to conversation or to a speech, fatigue may be the result of straining to hear. Under these circumstances, a person may become easily irritable.

Indifference: It is easy for the person who cannot hear what others say to become depressed and disinterested in life in general.

Social withdrawal: Not being able to hear what is going on causes a person who is hard of hearing to withdraw from situations that might prove embarrassing.

Insecurity: Lack of self-confidence and fear of mistakes create a feeling of insecurity in many people who are hard of hearing. No one likes to say the wrong thing or do anything that might appear foolish.

Indecision and procrastination: Loss of self-confidence makes it increasingly difficult for a person who is hard of hearing to make decisions.

Suspiciousness: The person who is hard of hearing—who often hears only part of what is being said—may suspect that others are talking about them, or that portions of the conversation are deliberately spoken softly so that they will not hear them.

False pride: The person who is hard of hearing wants to conceal the hearing loss and thus often pretends to be hearing when they actually is not.

Loneliness and unhappiness: Although everyone wishes for quiet now and then, enforced silence can be boring and even somewhat frightening. People with a hearing loss often feel isolated.

Tendency to dominate the conversation: Many people who are hard of hearing tend to dominate the conversation, knowing that as long as it is centered on them and they can control it, they are unlikely to be embarrassed by some mistake.

Prevention

Many environmental factors have an adverse effect on the auditory system and with time result in permanent sensorineural hearing loss. The most common is noise. Noise (unwanted and unavoidable sound) has been identified as one of today's environmental hazards. The volume of noise that surrounds us daily has increased into a potentially dangerous source of physical and psychological damage.

Loud, persistent noise has been found to cause constriction of peripheral blood vessels, increased blood pressure and heart rate (because of increased secretion of adrenalin), and increased gastrointestinal activity. Although research is needed to address the overall effects of noise on the human body, a

quiet environment is more conducive to peace of mind. A person who is ill feels more at ease when noise is kept to a minimum.

Chart 59-4 RISK FACTORS

Hearing Loss

- Congenital malformations of the cranial structure (ear)
- Family history of sensorineural impairment
- Low birth weight (<1500 g)
- Perforation of the tympanic membrane
- Recurrent ear infections
- Use of ototoxic medications (e.g., gentamycin, loop diuretics)

Adapted from Norris, T. (2019). *Porth's pathophysiology: Concepts of altered health status* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Numerous factors contribute to hearing loss (see Chart 59-4). *Noise-induced hearing loss* refers to hearing loss that follows a long period of exposure to loud noise (e.g., heavy machinery, engines, artillery, rock-band music). *Acoustic trauma* refers to hearing loss caused by a single exposure to an extremely intense noise, such as an explosion. Usually, noise-induced hearing loss occurs at a high frequency (about 4000 Hz). However, with continued noise exposure, the hearing loss can become more severe and include adjacent frequencies. The minimum noise level known to cause noise-induced hearing loss, regardless of duration, is about 85 to 90 dB.

Noise exposure is inherent in many jobs (e.g., mechanics, printers, pilots, flight attendants, musicians) and in hobbies such as woodworking and hunting. Occupational noise level regulations are based on the amount of noise a person is exposed to over an 8-hour work shift, with the maximum legal limits being 85 dB per the NIOSH or 90 dB per the Occupational Safety and Health Administration (OSHA), with a peak sound pressure of 135 dB (Centers for Disease Control and Prevention [CDC], 2018). NIOSH recommends and OSHA requires that workers wear ear protection to prevent noise-induced hearing loss when exposed to noise above the legal limits. Ear protection against noise is the most effective preventive measure available. Hearing loss due to noise is permanent because the hair cells in the organ of Corti are destroyed.

Gerontologic Considerations

With aging, changes occur in the ear that may eventually lead to hearing deficits. Although few changes occur in the external ear, cerumen tends to become harder and drier, posing a greater chance of impaction. In the middle ear, the tympanic membrane may atrophy or become sclerotic. In the inner ear, cells at the base of the cochlea degenerate. A familial predisposition to sensorineural hearing loss is also seen, manifested by inability to hear high-frequency sounds, followed in time by the loss of middle and lower frequencies. The term **presbycusis** is used to describe this progressive hearing loss (Eliopoulos, 2018).

In addition to age-related changes, other factors can affect hearing in the older adult population, such as lifelong exposure to loud noises. Psychogenic factors, other disease processes (e.g., diabetes), and medications may be partially responsible for sensorineural hearing loss. Certain medications, such as aminoglycosides, aspirin, loop diuretics, and platinum-based antineoplastic medications have ototoxic effects when kidney changes result in delayed medication excretion and increased levels of the medications in the blood.

Even with the best health care, people with hearing loss must learn to adjust. Care of older patients includes recognizing emotional reactions related to hearing loss, such as suspicion of others because of an inability to hear adequately; frustration and anger, with repeated statements such as "I didn't hear what you said!"; and feelings of insecurity because of the inability to hear the telephone or alarms. The Americans with Disabilities Act (ADA) of 1990 requires that all emergency services are accessible to people who have text message telephones (teletypewriters [TTYs]). In addition, all 911 centers in the United States must be accessible to people with TTYs.

Depression, isolation, and a decrease in cognitive function can have a negative impact on quality of life in the older adult with hearing loss. Feelings of social isolation, confusion, alterations in daily living activities, and increasing risk of falls have all been associated with hearing loss in older adults (Shukla, Reed, Armstrong, et al., 2019). Hearing loss has also been identified as a factor associated with a significant increase in the risk of hospitalization, readmission, and increased mortality (Hsu, McKee, Roscigno, et al., 2019). Additionally, hearing loss can interfere with relationships due to a loss of communication. A hearing screening is recommended as one component of the physical examination for the older adult when joining Medicare for the first time. "Welcome to Medicare" examinations and annual screenings are also important.

Medical Management

If a hearing loss is permanent or untreatable or if the patient elects not to be treated, aural rehabilitation (discussed at the end of the chapter) may be beneficial.

Nursing Management

Early detection of hearing loss is in the plans for *Healthy People 2030,* and nurses are in a position to assist in meeting this goal if included (Haskins, 2017; HHS, 2017). Another possible objective is for people diagnosed with hearing loss or deafness to use rehabilitation services and supplemental devices to improve communication with hearing people. Resources are available in workplaces and in schools. Questions used to assess for hearing loss may include:

- Have you experienced any hearing loss in the past?
- Are you experiencing any hearing loss now?
- Do your family members think that you are having difficulty hearing or experiencing any hearing loss?

These questions should be included in any routine nursing assessment and referrals made for further evaluation as needed.

Nurses who understand the different types of hearing loss are more successful in adopting a communication style to fit the needs and preferences of each patient. Trying to speak in a loud voice to a person who cannot hear high-frequency sounds only makes understanding more difficult. However, strategies such as talking into the better-hearing ear and using gestures and facial expressions can help (see Chart 59-5).

Chart 59-5

Communicating with People Who Are Deaf or Have Severe Hearing Loss

For the Person Who Is Hard of Hearing Whose Speech Is Difficult to Understand

- Determine how the person prefers to communicate with others. Do not assume that writing, gestures, or other means are the best or preferred technique.
- Consider if the person uses sign language. Interpreters are available from American Sign Language Services, Inc. (ASLI). These specialists provide the best means of communication, providing accurate, professional services.
- Devote full attention to what the person is saying. Look and listen—do not try to attend to another task while listening.
- Engage the speaker in conversation when it is possible for you to anticipate the replies. This enables you to become accustomed to any peculiarities in speech patterns.
- Try to determine the essential context of what is being said; you can often fill in the details from context.
- Do not try to appear as if you understand if you do not.
- If you cannot understand at all or have serious doubt about your ability to understand what is being said, have the person write the message rather than risk misunderstanding. Having the person repeat the message in speech, after you know its content, also aids you in becoming accustomed to the person's pattern of speech.
- Written communication is an excellent resource. Material should be written at a third-grade level so that the majority of people can understand it.

For the Person Who Is Hard of Hearing Who Speech Reads

- Be aware that speech or lip reading is ineffective because the majority of English sounds are not clearly visible on the lips and even the most proficient lip readers understand less than 30% of verbal communication.
- When speaking, always face the person as directly as possible.
- Make sure that your face is as clearly visible as possible. Locate yourself so that your face is well lighted; avoid being silhouetted against strong light. Do not obscure the person's view of your mouth in any way; avoid talking with any object held in your mouth.
- Be sure that the patient knows the topic or subject before going ahead with what you plan to say. This enables the person to use contextual clues in speech reading.
- Speak slowly and distinctly, pausing more frequently than you would normally.

- If you question whether some important direction or instruction has been understood, check to be certain that the patient has the full meaning of your message.
- If, for any reason, your mouth must be covered (as with a mask), you must direct or instruct the patient, write or communicate the message by another means.

A major issue for many people who are deaf or hard of hearing is that they have other health problems that often do not receive attention, in large part because of communication barriers with their health care providers. To meet the health care needs of these patients, providers are legally obligated to make accommodations for the most effective patient communication and understanding. Providing certified interpreters for those who can communicate through sign language is essential in many situations to ensure effective communication.

During health care and screening procedures, the provider (e.g., dentist, physician, nurse) must be aware that patients who are deaf or hard of hearing are unable to read lips, see a signer, or read written materials in the dark rooms required during some diagnostic tests. The same situation exists if the provider is wearing a mask or is not in sight (e.g., x-ray studies, magnetic resonance imaging [MRI], colonoscopy).

Nurses and other health care providers must work with patients who are deaf or hard of hearing and their families to identify practical and effective means of communication. Nurses can serve as catalysts throughout the health care system to ensure that accommodations are made to meet the communication needs of every patient.

CONDITIONS OF THE EXTERNAL EAR

Cerumen Impaction

Cerumen normally accumulates in the external canal in various amounts and colors. Although wax does not usually need to be removed, impaction occasionally occurs, causing **otalgia** (a sensation of fullness or pain in the ear) with or without a hearing loss. Accumulation of cerumen as a cause of hearing loss is especially significant in older adult patients (Eliopoulos, 2018). Attempts to clear the external auditory canal with matches, hairpins, and other implements are dangerous because trauma to the skin, infection, and damage to the tympanic membrane can occur.

Management

Cerumen can be removed by irrigation, suction, or instrumentation. Unless the patient has a perforated eardrum or an inflamed external ear (i.e., otitis externa), gentle irrigation with warm water usually helps remove impacted cerumen, particularly if it is not tightly packed in the external auditory canal. For successful removal, the water stream must flow behind the obstructing cerumen to move it first laterally and then out of the canal. To prevent injury, the lowest effective pressure should be used. However, if the eardrum behind the impaction is perforated, water can enter the middle ear, producing acute vertigo and infection. If irrigation is unsuccessful, direct visual, mechanical removal can be performed by a trained health care provider on a patient who is cooperative.

Quality and Safety Nursing Alert

Warm water (never cold or hot) and gentle (not forceful) irrigation should be used to remove cerumen. Irrigation that is too forceful can cause perforation of the tympanic membrane, and ice water causes vomiting.

Instilling a few drops of warmed glycerin, mineral oil, or half-strength hydrogen peroxide into the ear canal for 30 minutes prior to irrigation can soften cerumen before its removal. Ceruminolytic agents, such as peroxide in glyceryl, are available. The use of any softening solution two or three times a day for several days is generally sufficient. If cerumen cannot be dislodged by these methods, instruments, such as a cerumen curette, aural suction, and a binocular microscope for magnification, can be used. The use of instruments such as a cerumen curette for cerumen removal is reserved for otolaryngologists and nurses with specialized training because of the danger of perforating the tympanic membrane or excoriating the external auditory canal.

Foreign Bodies

Some objects are inserted intentionally into the ear by adults who may have been trying to clean the external canal or relieve itching, or by children who introduce peas, beans, pebbles, toys, and beads. Insects may also enter the ear canal. In either case, the effects may range from no symptoms to profound pain and decreased hearing.

Management

Removing a foreign body from the external auditory canal can be quite challenging. The three standard methods for removing foreign bodies are the same as those for removing cerumen: irrigation, suction, and instrumentation. The contraindications for irrigation are also the same. Foreign vegetable bodies and insects tend to swell; thus, irrigation is contraindicated. Usually, an insect can be dislodged by instilling mineral oil, which will kill the insect and allow it to be removed.

Attempts to remove a foreign body from the external canal may be dangerous in unskilled hands. The object may be pushed completely into the bony portion of the canal, lacerating the skin and perforating the tympanic membrane. In rare circumstances, the foreign body may have to be extracted in the operating room with the patient under general anesthesia.

External Otitis (Otitis Externa)

External otitis (i.e., otitis externa) refers to an inflammation of the external auditory canal. Causes include water in the ear canal (swimmer's ear); trauma to the skin of the ear canal, permitting entrance of organisms into the tissues; and systemic conditions, such as vitamin deficiency and endocrine disorders. Bacterial or fungal infections are most frequently encountered. The most common bacterial pathogens associated with external otitis are *Staphylococcus aureus* and *Pseudomonas* species. The most common fungus isolated in both normal and infected ears is *Aspergillus* (Norris, 2019). External otitis is often caused by a dermatosis such as psoriasis, eczema, or seborrheic dermatitis. Even allergic reactions to hair spray, hair dye, and permanent wave lotions can cause dermatitis, which clears when the offending agent is removed.

Clinical Manifestations

Patients usually report pain; discharge from the external auditory canal; aural tenderness (usually not present in middle ear infections); and occasionally fever, cellulitis, and lymphadenopathy. Other symptoms may include pruritus and hearing loss or a feeling of fullness in the ear. On otoscopic examination, the ear canal is erythematous and edematous. Discharge may be yellow or green and foul smelling. In fungal infections, hairlike black spores may be visible.

Medical Management

The principles of therapy are aimed at relieving the discomfort, reducing the swelling of the ear canal, and eradicating the infection. Patients may require analgesic medications for the first 48 to 96 hours. Treatment most often

includes antimicrobial or antifungal otic medications given by dropper at room temperature. In bacterial infection, a combination antibiotic and corticosteroid agent may be used to soothe inflamed tissues (Norris, 2019).

Nursing Management

Nurses should instruct patients not to clean the external auditory canal with cotton-tipped applicators and to avoid events that traumatize the external canal, such as scratching the canal with the fingernail or other objects. Trauma may lead to infection of the canal. Patients should also avoid getting the canal wet when swimming or shampooing the hair. A cotton ball or lamb's wool can be covered in a water-insoluble gel such as petrolatum jelly and placed in the ear as a barrier to the canal getting wet. Infection can be prevented by using antiseptic otic preparations after swimming (e.g., Swim-Ear, Ear Dry), unless there is a history of tympanic membrane perforation or a current ear infection (see Chart 59-6).

Malignant External Otitis

A more serious, although rare, external ear infection is malignant external otitis (temporal bone osteomyelitis). This is a progressive, debilitating, and occasionally fatal infection of the external auditory canal, the surrounding tissue, and the base of the skull. *Pseudomonas aeruginosa* is usually the infecting organism in patients with low resistance to infection (e.g., patients with acquired immune deficiency syndrome (AIDS). Successful treatment includes administration of antibiotics (usually intravenously [IV]) and aggressive local wound care. Standard parenteral antibiotic treatment includes the combination of an antipseudomonal agent and an aminoglycoside, both of which have potentially serious side effects. Because aminoglycosides are nephrotoxic and ototoxic, serum aminoglycoside levels and kidney and auditory function must be monitored during therapy. Local wound care includes limited débridement of the infected tissue, including bone and cartilage, depending on the extent of the infection.

Chart 59-6  **PATIENT EDUCATION**

Prevention of Otitis Externa

The nurse instructs the patient to:

- protect the external canal when swimming, showering, or washing hair. Use ear plugs or place a cotton ball covered in petrolatum jelly in the ear, and wear a swim cap. The external canal may be dried afterward with a hair dryer on low heat.
- place alcohol drops in the external canal to act as an astringent to help prevent infection after water exposure.
- prevent trauma to the external canal. Procedures, foreign objects (e.g., bobby pin), scratching, or any other trauma to the canal that breaks the skin integrity may cause infection.
- be aware that if otitis externa is diagnosed, refrain from any water sport activity for approximately 7 to 10 days to allow the canal to heal completely. Recurrence is highly likely unless you allow the external canal to heal completely.

Masses of the External Ear

Exostoses are small, hard, bony protrusions found in the lower posterior bony portion of the ear canal; they usually occur bilaterally. The skin covering the exostosis is normal. It is believed that exostoses are caused by exposure to cold water, as in scuba diving or surfing. The usual treatment, if any, is surgical excision.

Malignant tumors also may occur in the external ear. Most common are basal cell carcinomas on the pinna and squamous cell carcinomas in the ear canal. If untreated, squamous cell carcinoma may spread through the temporal bone, causing facial nerve paralysis and hearing loss. Carcinomas must be treated surgically.

CONDITIONS OF THE MIDDLE EAR

Tympanic Membrane Perforation

Perforation of the tympanic membrane is usually caused by infection or trauma. Sources of trauma include skull fracture, injury from explosion, or a severe blow to the ear. Less frequently, perforation is caused by foreign objects (e.g., cotton-tipped applicators, hairpins, keys) that have been pushed too far into the external auditory canal. In addition to tympanic membrane perforation,

injury to the ossicles and even the inner ear may result from this type of trauma. During infection, the tympanic membrane can rupture if the pressure in the middle ear exceeds the atmospheric pressure in the external auditory canal.

Medical Management

Although most tympanic membrane perforations heal spontaneously within weeks after rupture, some may take several months to heal. Some perforations persist because scar tissue grows over the edges of the perforation, preventing extension of the epithelial cells across the margins and final healing. In the case of a head injury or temporal bone fracture, a patient is observed for evidence of cerebrospinal fluid **otorrhea** or **rhinorrhea**—a clear, watery drainage from the ear or nose, respectively. While healing, the ear must be protected from water entering the ear canal.

Surgical Management

Perforations that do not heal on their own may require surgery. The decision to perform a tympanoplasty (see later section in this chapter) is usually based on the need to prevent potential infection from water entering the ear or the desire to improve the patient's hearing. Performed on an outpatient basis, tympanoplasty may involve a variety of surgical techniques. In all techniques, tissue (commonly from the temporalis fascia) is placed across the perforation to allow healing. Surgery is usually successful in closing the perforation permanently and improving hearing.

Acute Otitis Media

Ear infections can occur at any age; however, they are most commonly seen in children. **Acute otitis media (AOM)** is an acute infection of the middle ear, lasting less than 6 weeks. Pathogens that cause AOM are usually bacterial or viral and enter the middle ear after eustachian tube dysfunction caused by obstruction related to upper respiratory infections, inflammation of surrounding structures (e.g., rhinosinusitis, adenoid hypertrophy), or allergic reactions (e.g., allergic rhinitis) (Norris, 2019). Bacteria can enter the eustachian tube from contaminated secretions in the nasopharynx and the middle ear from a tympanic membrane perforation. A purulent exudate is usually present in the middle ear, resulting in a conductive hearing loss.

Clinical Manifestations

Symptoms of otitis media vary with the severity of the infection. The condition, usually unilateral in adults, may be accompanied by otalgia. The pain is relieved after spontaneous perforation or therapeutic incision of the tympanic membrane. Other symptoms may include drainage from the ear, fever, and hearing loss. Table 59-3 differentiates acute otitis externa from AOM. Risk factors for AOM include younger age, chronic upper respiratory infections, medical conditions that predispose the patient to ear infections (e.g., Down syndrome, cystic fibrosis, cleft palate), and chronic exposure to secondhand cigarette smoke.

Medical Management

The outcome of AOM depends on the efficacy of therapy (the prescribed dose of an oral antibiotic and the duration of therapy), the virulence of the bacteria, and the physical status of the patient. With early and appropriate broad-spectrum antibiotic therapy, otitis media may resolve with no serious sequelae. If drainage occurs, an antibiotic otic preparation is usually prescribed. The condition may become subacute (lasting 2 weeks to 3 months) with persistent purulent discharge from the ear. Rarely does permanent hearing loss occur. Secondary complications involving the mastoid and other serious intracranial complications, such as meningitis or brain abscess, although rare, can occur.

TABLE 59-3 Clinical Features of Otitis

Feature	Acute Otitis Externa	Acute Otitis Media
Otorrhea	May or may not be present	Present if tympanic membrane perforates; discharge is profuse
Otalgia	Persistent; may awaken patient at night	Relieved if tympanic membrane ruptures
Aural tenderness	Present on palpation of auricle	Usually absent
Systemic symptoms	Absent	Fever, upper respiratory infection, rhinitis
Edema of external auditory canal	Present	Absent
Tympanic membrane	May appear normal	Erythema, bulging, may be perforated
Hearing loss	Conductive type	Conductive type

Adapted from Weber, J., & Kelley, J. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Surgical Management

A **myringotomy** (i.e., tympanotomy) is an incision in the tympanic membrane. The tympanic membrane is numbed with a local anesthetic agent such as

phenol or by iontophoresis (i.e., in which electrical current flows through a lidocaine and epinephrine solution to numb the ear canal and tympanic membrane). The procedure is painless and takes less than 15 minutes. Under microscopic guidance, an incision is made through the tympanic membrane to relieve pressure and to drain serous or purulent fluid from the middle ear.

Normally, this procedure is unnecessary for treating AOM, but it may be performed if pain persists. Myringotomy also allows the drainage to be analyzed (by culture and sensitivity testing) so that the infecting organism can be identified and appropriate antibiotic therapy prescribed. The incision heals within 24 to 72 hours.

If AOM recurs and there is no contraindication, a ventilating, or pressure-equalizing, tube may be inserted. The ventilating tube, which temporarily takes the place of the eustachian tube in equalizing pressure, is retained for 6 to 18 months. The ventilating tube is then extruded with normal skin migration of the tympanic membrane, with the hole healing in nearly every case. Ventilating tubes are used to treat recurrent episodes of AOM.

Serous Otitis Media

Middle ear effusion, or serous otitis media, involves the presence of fluid, without evidence of active infection, in the middle ear. In theory, this fluid results from a negative pressure in the middle ear caused by eustachian tube obstruction. When this condition occurs in adults, an underlying cause for the eustachian tube dysfunction must be sought. Middle ear effusion is frequently seen in patients after radiation therapy or barotrauma and in patients with eustachian tube dysfunction from a concurrent upper respiratory infection or allergy. Barotrauma results from sudden pressure changes in the middle ear caused by changes in barometric pressure, as in scuba diving or airplane descent. A carcinoma (e.g., nasopharyngeal cancer) obstructing the eustachian tube should be ruled out in adults with persistent unilateral serous otitis media.

Clinical Manifestations

Patients may complain of hearing loss, fullness in the ear or a sensation of congestion, or popping and crackling noises that occur as the eustachian tube attempts to open. The tympanic membrane appears dull on otoscopy, and air bubbles may be visualized in the middle ear. Usually, the audiogram shows a conductive hearing loss.

Management

Serous otitis media need not be treated medically unless infection (i.e., AOM) occurs. If the hearing loss associated with middle ear effusion is significant, a myringotomy can be performed, and a tube may be placed to keep the middle ear ventilated. Corticosteroids in small doses may decrease the edema of the eustachian tube in cases of barotrauma. Decongestants have not proved to be effective. A Valsalva maneuver, which forcibly opens the eustachian tube by increasing nasopharyngeal pressure, may be cautiously performed; this maneuver may cause worsening pain or perforation of the tympanic membrane.

Chronic Otitis Media

Chronic otitis media is recurrent AOM that causes irreversible tissue pathology. Chronic infections of the middle ear damage the tympanic membrane, destroy the ossicles, and involve the mastoid but are rare in developed countries.

Clinical Manifestations

Symptoms may be minimal, with varying degrees of hearing loss and a persistent or intermittent, foul-smelling otorrhea. Pain is not usually experienced, except in cases of acute mastoiditis, when the postauricular area is tender and may be erythematous and edematous. Otoscopic examination may show a perforation, and cholesteatoma can be identified as a white mass behind the tympanic membrane or coming through to the external canal from a perforation.

Cholesteatoma is a cystlike lesion of the external layer of the eardrum into the middle ear. It is generally caused by a chronic retraction pocket of the tympanic membrane, creating a persistently high negative pressure of the middle ear. The skin forms a sac that fills with degenerated skin and sebaceous materials. The sac can attach to the structures of the middle ear, mastoid, or both.

Chronic otitis media can cause chronic mastoiditis and lead to the formation of cholesteatoma. The location will dictate the type of surgery to be performed. If untreated, cholesteatoma will continue to enlarge, possibly causing damage to the facial nerve and horizontal canal and destruction of other surrounding structures.

Cholesteatomas are cystlike lesions of the middle ear (Norris, 2019). They usually do not cause pain; however, if treatment or surgery is delayed, they may burst or destroy the mastoid bone. Cholesteatomas found in older adult patients generally develop in the external canal.

Cholesteatomas may be asymptomatic, or they may cause hearing loss, facial pain and paralysis, tinnitus, or vertigo. Audiometric tests often show a conductive or mixed hearing loss. Based on presenting symptoms, diagnosis may be made by visual examination or by computed tomography (CT) or MRI scan. Therapy includes treatment of the acute infection and surgical removal of the mass to restore hearing.

Medical Management 

Local treatment for chronic otitis media consists of careful suctioning of the ear under otoscopic guidance. Instillation of antibiotic drops or application of antibiotic powder is used to treat purulent discharge. Systemic antibiotic agents are prescribed only in cases of acute infection.

Surgical Management

Surgical procedures, including tympanoplasty, ossiculoplasty, and mastoidectomy, are used if medical treatments are ineffective.

Tympanoplasty

The most common surgical procedure for chronic otitis media is **tympanoplasty**, or surgical reconstruction of the tympanic membrane. Reconstruction of the ossicles may also be required. The purposes of a tympanoplasty are to reestablish middle ear function, close the perforation, prevent recurrent infection, and improve hearing.

There are five types of tympanoplasties. The simplest surgical procedure, type I (myringoplasty), is designed to close a perforation in the tympanic membrane. The other procedures, types II through V, involve more extensive repair of middle ear structures. The structures and the degree of involvement can differ, but all tympanoplasty procedures include restoring the continuity of the sound conduction mechanism.

Tympanoplasty is performed through the external auditory canal with a transcanal approach or through a postauricular incision. The contents of the middle ear are carefully inspected, and the ossicular chain (malleus and incus unit) is evaluated. Ossicular interruption is most common in chronic otitis media, but problems of reconstruction can also occur with malformations of the middle ear and ossicular dislocations due to head injuries. Dramatic improvement in hearing can result from closure of a perforation and reestablishment of the ossicles. Surgery is usually performed in an outpatient facility under moderate sedation or general anesthesia.

Ossiculoplasty

Ossiculoplasty is the surgical reconstruction of the middle ear bones to restore hearing. Prostheses made of materials such as Teflon, stainless steel, and hydroxyapatite are used to reconnect the ossicles, thereby reestablishing the sound conduction mechanism. However, the greater the damage, the lower the success rate for restoring normal hearing.

Mastoidectomy

The objectives of mastoid surgery are to remove the cholesteatoma, gain access to diseased structures, and create a dry (noninfected) and healthy ear. If possible, the ossicles are reconstructed during the initial surgical procedure. Occasionally, extensive disease or damage dictates that this be performed as part of a two-stage operation.

A mastoidectomy is usually performed through a postauricular incision. Infection is eliminated by removing the mastoid air cells. A second mastoidectomy may be necessary to check for recurrent or residual cholesteatoma. The hearing mechanism may be reconstructed at this time. The success rate for correcting this conductive hearing loss is approximately 75%. Surgery is usually performed in an outpatient setting. The patient has a mastoid pressure dressing, which can be removed 24 to 48 hours after surgery. Although infrequently injured, the facial nerve, which runs through the middle ear and mastoid, is at some risk for injury during mastoid surgery. As the patient awakens from anesthesia, any evidence of facial paresis should be reported to the primary provider.

NURSING PROCESS

The Patient Undergoing Mastoid Surgery

Although several otologic surgical procedures are performed under moderate sedation, mastoid surgery is performed using general anesthesia.

Assessment

The health history includes a complete description of the ear disorder, including infection, otalgia, otorrhea, hearing loss, and vertigo. Data are collected about the duration and intensity of the disorder, its causes, and previous treatments. Information is obtained about other health problems and all medications that the patient is taking. Medication allergies and family history of ear disease also should be obtained.

Physical assessment addresses erythema, edema, otorrhea, lesions, and characteristics such as odor and color of discharge. The results of the audiogram are reviewed.

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Anxiety associated with surgical procedure, potential loss of hearing, potential taste disturbance, and potential loss of facial movement
- Acute pain associated with mastoid surgery
- Risk for infection associated with mastoidectomy; placement of grafts, prostheses, and electrodes; and surgical trauma to surrounding tissues and structures
- Impaired verbal communication associated with ear disorder, surgery, or packing
- Risk for injury associated with impaired balance or vertigo during the immediate postoperative period, dislodgment of the graft or prosthesis, or injury to facial nerve (cranial nerve VII) and chorda tympani nerve
- Lack of knowledge about mastoid disease, surgical procedure, and postoperative care and expectations

Planning and Goals

Major goals of caring for a patient undergoing mastoidectomy include reduction of anxiety, freedom from pain and discomfort, prevention of infection, stable or improved hearing and communication, absence of vertigo and related injury, and increased knowledge regarding the disease, surgical procedure, and postoperative care.

Nursing Interventions

Reducing Anxiety

The nurse reinforces the information discussed by the otologic surgeon with the patient, including anesthesia, the location of the incision (postauricular), and expected surgical results (e.g., hearing, balance, taste, facial movement). The patient also is encouraged to discuss any anxieties and concerns about the surgery.

Relieving Pain

Although most patients complain very little about incisional pain after mastoid surgery, they do have some ear discomfort. Aural fullness or pressure after surgery is caused by residual blood or fluid in the middle ear. The prescribed analgesic medication may be taken for the first 24 hours after surgery and then only as needed.

A wick or external auditory canal packing is used if tympanoplasty was performed at the time of the mastoidectomy. For the next 2 to 3 weeks after surgery, the patient may experience sharp, shooting pains intermittently as the eustachian tube opens and allows air to enter the middle ear. Constant, throbbing pain accompanied by fever may indicate infection and should be reported to the primary provider.

Preventing Infection

Measures are initiated to prevent infection in the operated ear. The external auditory canal wick, or packing, may be impregnated with an antibiotic solution before instillation. Prophylactic antibiotic agents are given as prescribed, and the patient is instructed to prevent water from entering the external auditory canal for 6 weeks. A cotton ball or lamb's wool covered with a water-insoluble substance (e.g., petroleum jelly) and placed loosely in the ear canal usually prevents water from entering the ear canal and should be used when the patient showers or washes their hair, or in any situations in which water may enter the ear canal. The postauricular incision should be kept dry for the first 2 days. Signs of infection such as an elevated temperature and purulent drainage should be reported. Some serosanguineous drainage from the external auditory canal is normal after surgery.

Improving Hearing and Communication

Hearing in the operated ear may be reduced for several weeks because of edema, accumulation of blood and tissue fluid in the middle ear, and dressings or packing. Measures are initiated to improve hearing and communication, such as reducing environmental noise, facing the patient when speaking, speaking clearly and distinctly without shouting, providing good lighting, and using nonverbal clues (e.g., facial expression, pointing, gestures), writing, picture boards, electronic tablets, and other forms of communication. Family members or significant others are instructed about

effective ways to communicate with the patient. If the patient uses assistive hearing devices, one can be used in the unaffected ear.

Preventing Injury

Vertigo may occur after mastoid surgery if the semicircular canals or other areas of the inner ear are traumatized. Antiemetic or antivertiginous medications (e.g., antihistamines) can be prescribed if a balance disturbance or vertigo occurs. Safety measures such as assisted ambulation are implemented to prevent falls and injury. The patient is instructed to avoid heavy lifting, straining, exertion, and nose blowing for 2 to 3 weeks after surgery to prevent dislodging the tympanic membrane graft or ossicular prosthesis.

Facial nerve injury is a potential, although rare, complication of mastoid surgery. The patient is instructed to report immediately any evidence of facial nerve (cranial nerve VII) weakness, such as drooping of the mouth on the operated side, slurred speech, decreased sensation, and difficulty swallowing. A more frequent occurrence is a temporary disturbance in the chorda tympani nerve, which is a small branch of the facial nerve that runs through the middle ear. Patients experience a taste disturbance and dry mouth on the side of surgery for several months until the nerve regenerates.

Chart 59-7  **PATIENT EDUCATION**

Self-Care After Middle Ear or Mastoid Surgery

Postoperative instructions for patients who have had middle ear and mastoid surgery may vary among otolaryngologists. The nurse instructs the patient in the following general guidelines:

- Take antibiotics and other medications as prescribed.
- Avoid nose blowing for 2 to 3 weeks after surgery.
- Sneeze and cough with the mouth open for a few weeks after surgery.
- Avoid heavy lifting (>10 lb), straining, and bending over for a few weeks after surgery.
- Be aware that popping and crackling sensations in the operative ear are normal for approximately 3 to 5 weeks after surgery.
- Note that temporary hearing loss is normal in the operative ear due to fluid, blood, or packing in the ear.
- Report excessive or purulent ear drainage to the physician.
- Avoid getting water in the operative ear for 2 weeks after surgery. You may shampoo the hair 2 to 3 days postoperatively if the ear is protected from water by saturating a cotton ball with petroleum jelly (or some other water-insoluble substance) and loosely placing it in the ear. If the postauricular suture line becomes wet, pat (not rub) the area and cover it with a thin layer of antibiotic ointment.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. Patients require education about medication therapy, such as analgesic and antivertiginous agents (e.g., antihistamines) prescribed for balance disturbance. Education includes information about the expected effects and potential side effects of the medication. Patients also need instruction about any activity restrictions. Possible complications such as infection, facial nerve weakness, or taste disturbances, including the signs and symptoms to report immediately, are included (see Chart 59-7).

Continuing and Transitional Care. Some patients, particularly older adult patients, who have had mastoid surgery may require the services of a home, community-based, or transitional care nurse for a few days after returning home. However, most people find that assistance from a family member or a friend is sufficient. The caregiver and patient are cautioned that the patient may experience some vertigo and will therefore require help with ambulation to avoid falling. Any symptoms of complications are to be reported promptly to the primary provider. The importance of scheduling and keeping follow-up appointments is also stressed.

Evaluation

Expected patient outcomes may include:

1. Demonstrates reduced anxiety about surgical procedure
   a. Verbalizes and exhibits less stress, tension, and irritability
   b. Verbalizes acceptance of results of surgery and adjustment to possible hearing loss
2. Remains free of discomfort or pain
   a. Exhibits no facial grimacing, moaning, or crying, and reports absence of pain
   b. Uses analgesic agents appropriately
3. Demonstrates no signs or symptoms of infection
   a. Has normal vital signs, including temperature
   b. Demonstrates absence of purulent drainage from the external auditory canal
   c. Describes method for preventing water from contaminating packing
4. Exhibits signs that communication and hearing have stabilized or improved
   a. Describes surgical goal for hearing and judges whether the goal has been met
   b. Verbalizes that hearing has improved
5. Remains free of injury and trauma
   a. Reports absence of vertigo or balance disturbance
   b. Experiences no injury or fall
   c. Avoids activities that can cause dislodgement of graft or prosthesis
   d. Reports no taste disturbance, mouth dryness, or facial weakness
6. Verbalizes the reasons for and methods of care and treatment
   a. Discusses the discharge plan formulated with the nurse with regard to rest periods, medication, and activities permitted and restricted
   b. Lists symptoms that should be reported to the primary provider
   c. Keeps follow-up appointments

Otosclerosis

Otosclerosis involves the stapes and is thought to result from the formation of new, abnormal spongy bone, especially around the oval window, with resulting fixation of the stapes (Norris, 2019). The efficient transmission of sound is prevented because the stapes cannot vibrate and carry the sound as conducted from the malleus and incus to the inner ear. Otosclerosis is more common in

women, is a familial condition, and can progress to complete deafness (Eliopoulos, 2018; Norris, 2019).

Clinical Manifestations

Otosclerosis may involve one or both ears and manifests as a progressive conductive or mixed hearing loss. The patient may or may not complain of tinnitus. Otoscopic examination usually reveals a normal tympanic membrane. Bone conduction is better than air conduction on Rinne testing. The audiogram confirms conductive hearing loss or mixed loss, especially in the low frequencies.

Medical Management

The management of otosclerosis can be surgical or medical. Amplification with a hearing aid may help (Norris, 2019).

Surgical Management

One of two surgical procedures may be performed: the stapedectomy or the stapedotomy. A stapedectomy involves removing the stapes superstructure and part of the footplate and inserting a tissue graft and a suitable prosthesis (see Fig. 59-6). In a stapedotomy, the surgeon drills a small hole into the stapes, instead of removing it, to hold a prosthesis. In both procedures, the prosthesis bridges the gap between the incus and the inner ear, providing better sound conduction. The majority of patients experience resolution of conductive hearing loss following stapes surgery. The use of sodium fluoride in the postoperative period increases the success rate and hearing ability postoperatively (Norris, 2019). Balance disturbance or true vertigo may occur during the postoperative period for several days. Long-term balance disorders are rare.

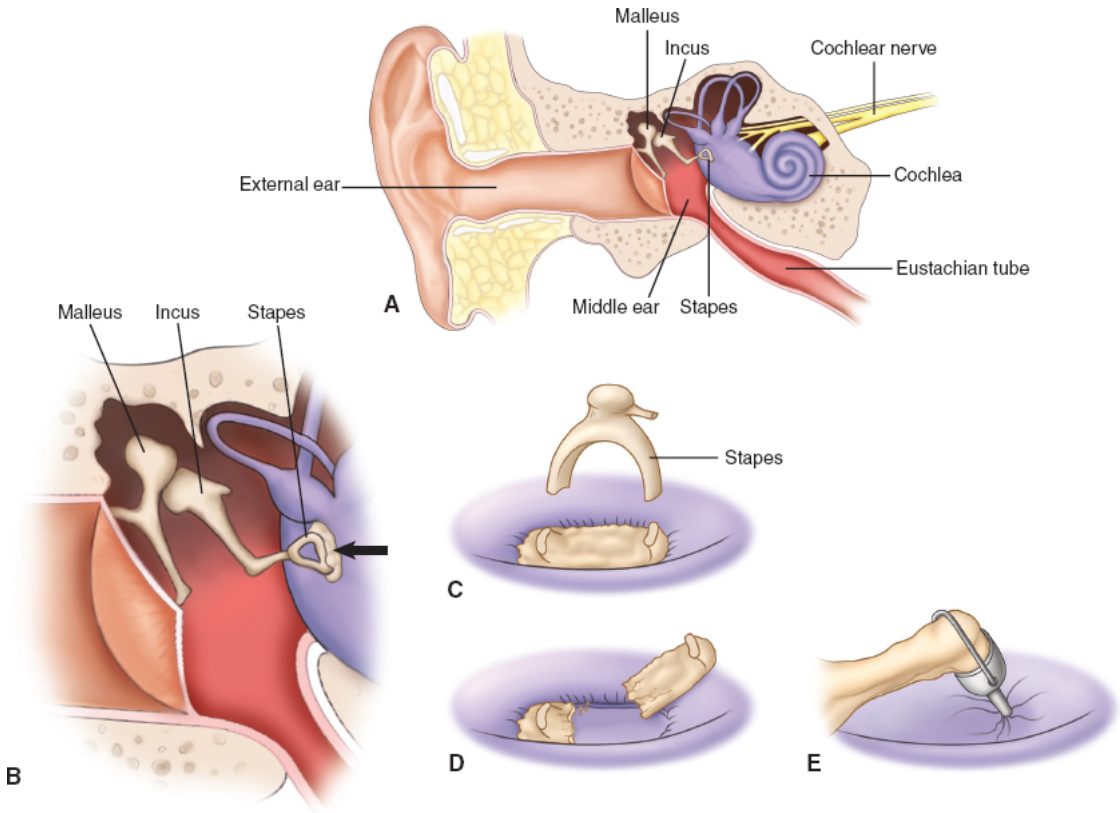

Figure 59-6 • Stapedectomy for otosclerosis. **A.** Normal anatomy. **B.** *Arrow* points to sclerotic process at the foot of the stapes. **C.** Stapes broken away surgically from its diseased base. The hole in the footplate provides an area where an instrument can grasp the plate. **D.** The footplate is removed from its base. Some otosclerotic tissue may remain, and tissue is placed over it. **E.** Robinson stainless steel prosthesis in position.

Middle Ear Masses

Other than cholesteatoma, masses in the middle ear are rare. Glomus tympanicum is a tumor that arises from Jacobson nerve (in the temporal bone of the skull) and remains limited to the middle ear. On otoscopy, a red blemish on or behind the tympanic membrane is seen. Glomus jugulare tumors are rarely malignant; however, because of their location, treatment may be necessary to relieve symptoms. The treatment is surgical excision, except in patients who are poor surgical candidates, in whom radiation therapy is used.

A facial nerve neuroma is a tumor on cranial nerve VII. These types of tumors are usually not visible on otoscopic examination but are suspected when a patient presents with a facial nerve paresis. X-ray evaluation is used to identify the site of the tumor along the facial nerve. The treatment is surgical removal.

CONDITIONS OF THE INNER EAR

Disorders of balance are common and dizziness may increase the risk of falls (NIDCD, 2018). The term **dizziness** is used frequently by patients and health care providers to describe any altered sensation of orientation in space and is more commonly referred to as lightheadedness (Weber & Kelley, 2018). **Vertigo** is the misperception or illusion of motion of the person or the surroundings. Most patients with vertigo describe a spinning sensation or say they feel as though objects are moving around them. Ataxia is a failure of muscular coordination and may be present in patients with vestibular disease. Syncope, fainting, and loss of consciousness are not forms of vertigo and usually indicate disease in the cardiovascular system.

Nystagmus is an involuntary rhythmic movement of the eyes. Nystagmus occurs normally when a person watches a rapidly moving object (e.g., through the side window of a moving car or train). However, pathologically, it is an ocular disorder associated with vestibular dysfunction. Nystagmus can be horizontal, vertical, or rotary and can be caused by a disorder in the central or peripheral nervous system.

Motion Sickness

Motion sickness is a disturbance of equilibrium caused by a conflict in motion receptor stimuli. For example, it can occur aboard a ship, in a car, while riding on a merry-go-round or swing, or even while viewing virtual motion on a large screen (Brainard & Gresham, 2014).

Clinical Manifestations

The syndrome manifests itself in sweating, pallor, nausea, and vomiting caused by vestibular overstimulation. These manifestations may persist for several hours after the stimulation stops.

Management

Over-the-counter antihistamines such as dimenhydrinate or meclizine may provide some relief of nausea and vomiting by blocking the conduction of the vestibular pathway of the inner ear. Anticholinergic medications, such as scopolamine patches, may also be effective because they antagonize the histamine response. These must be applied 4 hours before exposure to motion and replaced every 3 days (Brainard & Gresham, 2014). Side effects such as dry mouth and drowsiness may occur. Potentially hazardous activities such as

driving a car or operating heavy machinery should be avoided if drowsiness occurs.

Ménière's Disease

Ménière's disease is an abnormality in inner ear fluid balance caused by a malabsorption in the endolymphatic sac or a blockage in the endolymphatic duct (NIDCD, 2017b). **Endolymphatic hydrops** (dilation of the endolymphatic space) frequently occurs, causing either increased pressure in the system or rupture of the inner ear membrane, producing symptoms of Ménière's disease (van Steekelenburg, van Weijnen, de Pont, et al., 2020).

Ménière's disease affects 10 to 12 of 1000 people in the United States. It is estimated that there are 615,000 cases in the United States, with approximately 45,500 new cases diagnosed annually (NIDCD, 2017b). More common in adults, onset is generally seen when adults reach their 40s, with symptoms usually beginning between the ages of 20 and 60 years. Ménière's disease appears to be equally common in men and women, and is usually bilateral (Norris, 2019).

Clinical Manifestations

Ménière's disease is characterized by a triad of symptoms: episodic vertigo, tinnitus, and fluctuating sensorineural hearing loss (Luryi, Morse, & Michaelides, 2019). It may also include a feeling of pressure or fullness in the ear and incapacitating vertigo, often accompanied by nausea and vomiting (NIDCD, 2017b). These symptoms range in severity from a minor nuisance to extreme disability, especially if the attacks of vertigo are severe. At the onset of the disease, usually only one or two of the symptoms are manifested.

The disease may be characterized into two subsets: cochlear and vestibular. Cochlear Ménière's disease is recognized as a fluctuating, progressive sensorineural hearing loss associated with tinnitus and aural pressure in the absence of vestibular symptoms or findings. Vestibular Ménière's disease is characterized as the occurrence of episodic vertigo associated with aural pressure but no cochlear symptoms. Patients may experience either cochlear or vestibular disease symptoms at first; however, eventually all of these symptoms develop.

Assessment and Diagnostic Findings

Vertigo is usually the most troublesome complaint related to Ménière's disease. A careful history is taken to determine the frequency, duration,

severity, and character of the vertigo attacks. Vertigo may last minutes to hours, possibly accompanied by nausea or vomiting. Diaphoresis and a persistent feeling of imbalance or disequilibrium may awaken patients at night. Some patients report that these feelings last for days. However, they usually feel well between attacks. Hearing loss may fluctuate, with tinnitus and aural pressure waxing and waning with changes in hearing. These feelings may occur during or before attacks, or they may be constant.

Physical examination findings are usually normal, with the exception of those of cranial nerve VIII. Sounds from a tuning fork (Weber test) may lateralize to the ear opposite the hearing loss, the one affected with Ménière's disease. An audiogram typically reveals a sensorineural hearing loss in the affected ear. This can be in the form of a pattern that looks like a hill or mountain. A sensorineural loss in the low frequencies occurs as the disease progresses. The electronystagmogram may be normal or may show reduced vestibular response.

Medical Management

Most patients with Ménière's disease can be successfully treated with diet and medication. Many patients can control their symptoms by adhering to a low-sodium (1000 to 1500 mg/day or less) diet. Chart 59-8 describes dietary guidelines that may be useful in Ménière's disease. The amount of sodium is one of many factors that regulate the balance of fluid within the body. Sodium and fluid retention disrupts the delicate balance between endolymph and perilymph in the inner ear. Psychological evaluation and cognitive therapy may be indicated if a patient is anxious, uncertain, fearful, or depressed (NIDCD, 2017b).

Chart 59-8  **PATIENT EDUCATION**

Dietary Guidelines for Patients with Ménière's Disease

The nurse instructs the patient to:

- limit foods high in salt or sugar. Be aware of foods with hidden salts and sugars.
- eat meals and snacks at regular intervals to stay hydrated. Missing meals or snacks may alter the fluid level in the inner ear.
- eat fresh fruits, vegetables, and whole grains. Limit the amount of canned, frozen, or processed foods with high sodium content.
- drink plenty of fluids daily. Water, milk, and low-sugar fruit juices are recommended. Limit intake of coffee, tea, and soft drinks. Avoid caffeine because of its diuretic effect.
- limit alcohol intake. Alcohol may change the volume and concentration of the inner ear fluid and may worsen symptoms.
- avoid monosodium glutamate (MSG), which may increase symptoms.
- pay attention to the intake of foods containing potassium (e.g., bananas, tomatoes, oranges) if taking a diuretic that causes potassium loss.
- avoid aspirin and aspirin-containing medications. Aspirin may increase tinnitus and dizziness.

Adapted from National Institute on Deafness and Other Communication Disorders (NIDCD). (2017b). Ménière's disease. Retrieved on 2/22/2020 at: www.nidcd.nih.gov/health/menieres-disease

Pharmacologic Therapy

Pharmacologic therapy for Ménière's disease consists of antihistamines, such as meclizine, which shortens the attack (NIDCD, 2017b). Tranquilizers such as diazepam may be used in acute instances to help control vertigo. Antiemetic agents such as promethazine suppositories help control the nausea and vomiting and the vertigo because of their antihistamine effect. Diuretic therapy (e.g., hydrochlorothiazide, triamterene, spironolactone) may relieve symptoms by lowering the pressure in the endolymphatic system (Norris, 2019). Intratympanic injection of gentamicin is used to cause ablation of the vestibular hair cells; however, the risk of significant hearing loss is high (NIDCD, 2017b).

Surgical Management

Although most patients respond well to conservative therapy, some continue to have disabling attacks of vertigo. If these attacks reduce their quality of life, patients may elect to undergo surgery for relief. Surgical procedures include endolymphatic sac procedures and vestibular nerve section (NIDCD, 2017b). However, hearing loss, tinnitus, and aural fullness may continue, because the

surgical treatment of Ménière's disease is aimed at eliminating the attacks of vertigo.

Endolymphatic Sac Decompression

Endolymphatic sac decompression, or shunting, theoretically equalizes the pressure in the endolymphatic space. A shunt or drain is inserted in the endolymphatic sac through a postauricular incision. This procedure is favored by many otolaryngologists as a first-line surgical approach to treat the vertigo of Ménière's disease because it is relatively simple and safe and can be performed on an outpatient basis.

Vestibular Nerve Sectioning

Vestibular nerve sectioning provides the greatest success rate (approximately 98%) in eliminating the attacks of vertigo. It can be performed by a translabyrinthine approach (i.e., through the hearing mechanism) or in a manner that can conserve hearing (i.e., suboccipital or middle cranial fossa), depending on the degree of hearing loss. Most patients with incapacitating Ménière's disease have little or no effective hearing. Cutting the nerve prevents the brain from receiving input from the semicircular canals. This procedure may require a brief hospital stay. A plan of nursing care for the patient with vertigo is presented in Chart 59-9.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo is a brief period of incapacitating vertigo that occurs when the position of the patient's head is changed with respect to gravity, typically by placing the head back with the affected ear turned down (Muñoz, Moreno, Balboa, et al., 2019; NIDCD, 2017b). The onset is sudden and followed by a predisposition for positional vertigo, usually for hours to weeks but occasionally for months or years.

Benign paroxysmal positional vertigo is thought to be due to the disruption of debris within the semicircular canal. This debris is formed from small crystals of calcium carbonate from the inner ear structure (the utricle). This is frequently stimulated by head trauma, infection, or other events. In severe cases, vertigo may easily be induced by any head movement. The vertigo is usually accompanied by nausea and vomiting; however, hearing loss does not generally occur.

Chart 59-9  **PLAN OF NURSING CARE**

Care of the Patient with Vertigo

NURSING DIAGNOSIS: Risk for fall-related injury associated with impaired balance, gait disturbance, and vertigo

GOAL: Remains free of physical trauma associated with imbalance and falls

Nursing Interventions	Rationale	Expected Outcomes
1. Assess for balance disturbance or vertigo, including history, onset, description of attacks, duration, frequency, and any associated ear symptoms (hearing loss, tinnitus, aural fullness). 2. Perform examination for nystagmus, positive Romberg, and inability to perform tandem Romberg. 3. Assess extent of disability (i.e., visual acuity and proprioceptive deficits) in relation to activities of daily living. 4. Instruct or reinforce vestibular/balance therapy as prescribed. 5. Administer, or educate about administration of, antivertiginous medications or vestibular sedation medication; instruct patient about side effects. 6. Encourage patient to sit down and restrict activity when dizzy. 7. Place pillow on each side of head to restrict movement. 8. Assist patient in identifying aura that	1. Health history provides basis for interventions. 2. Peripheral vestibular disorders cause these signs and symptoms. 3. Extent of disability indicates risk of falling. Balance depends on visual, vestibular, and proprioceptive systems. 4. Exercises hasten labyrinthine compensation, which may decrease vertigo and gait disturbance. 5. Alleviates acute symptoms of vertigo. 6. Decreases possibility of falling and injury. 7. Movement aggravates vertigo. 8. Recognition of aura may trigger the need to take medication before an attack occurs,	• Experiences no physical trauma due to balance disturbance • Visual and proprioceptive risks identified • Activity level increases • Performs exercises as prescribed • Takes prescribed medications appropriately • Assumes safe position when vertigo is present • Keeps head still when vertigo is present • Identifies a characteristic fullness or sense of pressure in the ear as occurring before an attack occurs • Reports measures that help reduce vertigo

suggests an impending attack. 9. Recommend that the patient keep eyes open and stare straight ahead when lying down and experiencing vertigo. 10. Help identify hazards or use rehabilitative devices in home environment.	thereby minimizing the severity of effects. 9. Sensation of vertigo decreases and motion decelerates if eyes are kept in a fixed position. 10. Adaptation of home environment can reduce risk of falls.	• Home environment free of hazards • Has adapted home environment or uses rehabilitative devices to reduce risk of falling
NURSING DIAGNOSIS: Risk for negative quality of life associated with unpredictability of vertigo **GOAL:** Modifies lifestyle to decrease disability and exert maximum control and independence within limits posed by chronic vertigo		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Encourage patient to identify personal strengths and roles that can still be fulfilled. 2. Provide information about vertigo and what to expect. 3. Include family and significant others in rehabilitative process. 4. Encourage patient to maintain sense of control by making decisions and assuming more responsibility for care.	1. Maximizes sense of regaining control and independence. 2. Reduces fear and anxiety. 3. Perceived beliefs of significant others are important for patient's adherence to medical regimen. 4. Reinforces positive psychological and social outcomes.	• Exerts maximum control of environment and independence within limits imposed by vertigo • Is informed about condition • Family and significant others are included in rehabilitation process • Uses strengths and potentials to engage in the most independent

		and constructive lifestyle
NURSING DIAGNOSIS: Risk for hypovolaemia associated with increased fluid output, altered intake, and medications **GOAL:** Maintains normal fluid and electrolyte balance		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess, or have patient assess, intake and output (including emesis, liquid stools, urine, and diaphoresis). Monitor laboratory values of electrolytes. 2. Assess indicators of dehydration, including blood pressure (orthostasis), pulse, skin turgor, mucous membranes, and level of consciousness. 3. Encourage oral fluids as tolerated; discourage beverages containing caffeine (a vestibular stimulant).	1. Accurate records provide basis for fluid replacement. 2. Prompt recognition of dehydration allows early intervention. 3. Oral replacement is begun as soon as possible to replace losses.	• Laboratory values within normal limits • Alert and oriented; vital signs within normal limits, skin turgor normal; electrolytes normal • Mucous membranes are moist • Vomiting has stopped; usual oral intake is resumed
4. Administer, or educate about administration of, antiemetic medications as prescribed and needed. Educate patient about side effects.	4. Antiemetic medications reduce nausea and vomiting, reducing fluid losses and improving oral intake.	
NURSING DIAGNOSIS: Anxiety associated with threat of, or change in, health status and disability effects of vertigo **GOAL:** Experiences less or no anxiety		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess level of anxiety. Help patient identify	1. Guides therapeutic	• Fear and anxiety about

coping skills used successfully in the past. 2. Provide information about vertigo and its treatment. 3. Encourage patient to discuss anxieties and explore concerns about vertigo attacks. 4. Educate patient about stress management techniques or make appropriate referral. 5. Provide comfort measures and avoid stress-producing activities. 6. Instruct patient in aspects of treatment regimen.	interventions and participation in self-care. Past coping skills can relieve anxiety. 2. Increased knowledge helps to decrease anxiety. 3. Promotes awareness and understanding of relationship between anxiety level and behavior. 4. Improved stress management can reduce the frequency and severity of some vertiginous attacks. 5. Stressful situations may exacerbate symptoms of the condition. 6. Patient knowledge helps to decrease anxiety.	attacks of vertigo reduced or eliminated • Acquires knowledge and skills to deal with vertigo • Feels less tension, apprehension, and uncertainty • Uses stress management techniques when needed • Avoids upsetting encounters • Repeats instructions given and verbalizes understanding of treatments

NURSING DIAGNOSIS: Impaired self feeding, impaired ability to perform hygiene, impaired ability to dress, and impaired self toileting associated with labyrinth dysfunction and episodes of vertigo

GOAL: Able to care for self

Nursing Interventions	Rationale	Expected Outcomes
1. Administer, or educate about administration of, antiemetic and other prescribed medications to relieve nausea and vomiting associated with vertigo.	1. Antiemetic and sedative-type medications depress stimuli in the cerebellum. 2. Spacing activities is important because episodes	• Carries out necessary functions during symptom-free periods and takes medications to

2. Encourage patient to perform self-care when free of vertigo. 3. Review diet with patient and caregivers. Offer fluids as necessary.	of vertigo vary in occurrence. 3. Sodium restriction helps improve an inner ear fluid imbalance in some patients, thereby decreasing vertigo. Fluids help prevent dehydration.	relieve nausea, vomiting, or vertigo • Carries out daily activities • Accepts dietary plan and reports its effectiveness • Drinks fluids in sufficient amounts
NURSING DIAGNOSIS: Risk for powerlessness associated with illness regimen and feeling helpless in certain situations due to vertigo/balance disturbance **GOAL:** Experiences increased sense of control over life and activities despite vertigo/balance disturbance		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess patient's needs, values, attitudes, and readiness to initiate activities. 2. Provide opportunities for patient to express feelings about self and illness. 3. Help patient identify previous coping behaviors that were successful.	1. Involving patient in planning activities and care enhances potential for mastery. 2. Expressing feelings increases understanding of individual coping styles and defense mechanisms. 3. Awareness increases understanding of stressors that trigger feeling of powerlessness. Awareness of past successes enhances self-confidence.	• Does not restrict activities unnecessarily due to vertigo • Verbalizes positive feelings about own ability to achieve a sense of power and control • Identifies previous successful coping behaviors

Bed rest is recommended for patients with acute symptoms. Repositioning techniques can be used to treat vertigo. The canalith repositioning procedure is commonly used (Bhattacharyya, Gubbels, Schwartz, et al., 2017). This noninvasive procedure, which involves quick movements of the body, rearranges the debris in the canal. The procedure is performed by placing the patient in a sitting position, turning the head to a 45-degree angle on the affected side, and then quickly moving the patient to the supine position. The procedure is safe, inexpensive, and easy to perform.

Patients with acute vertigo may be treated with meclizine for 1 to 2 weeks. After this time, the meclizine is stopped and the patient is reassessed. Patients who continue to have severe positional vertigo may be premedicated with prochlorperazine 1 hour before the canalith repositioning procedure is performed.

Vestibular rehabilitation can be used in the management of vestibular disorders. This strategy promotes active use of the vestibular system through an interdisciplinary team approach, including medical and nursing care, stress management, biofeedback, vocational rehabilitation, and physical therapy. A physical therapist prescribes balance exercises that help the brain compensate for the impairment to the balance system.

Tinnitus

Tinnitus may be a symptom of an underlying disorder of the ear that is associated with hearing loss or it may be benign. This condition affects approximately 25 million people in the United States and is most prevalent in adults (NIDCD, 2017c). The severity of tinnitus may range from mild to severe. Patients describe tinnitus as a roaring, buzzing, or hissing sound in one or both ears. Numerous factors may contribute to the development of tinnitus, including several ototoxic substances (see Chart 59-10). Underlying disorders that contribute to tinnitus may include cardiovascular disease, thyroid disease, hyperlipidemia, vitamin B_{12} deficiency, psychological disorders (e.g., depression, anxiety), fibromyalgia, otologic disorders (Ménière's disease, acoustic neuroma), and neurologic disorders (head injury, multiple sclerosis).

A physical examination should be performed to determine the cause of tinnitus. Diagnostic testing determines if hearing loss is present. An audiograph speech discrimination test or a tympanogram may be used to help determine the cause. Some forms of tinnitus are irreversible; therefore, patients may need education and counseling about ways of adjusting to their treatment and dealing with tinnitus in the future.

Labyrinthitis

Labyrinthitis, an inflammation of the labyrinth of the inner ear, can be bacterial or viral in origin. Bacterial labyrinthitis is rare because of antibiotic therapy, but it sometimes occurs as a complication of otitis media. The infection can spread to the inner ear by penetrating the membranes of the oval or round windows. Viral labyrinthitis is a common diagnosis, but little is known about this disorder, which affects hearing and balance. The most common viral causes are mumps, rubella, rubeola, and influenza. Viral illnesses of the upper respiratory tract and herpetiform disorders of the facial and acoustic nerves (i.e., Ramsay Hunt syndrome) also cause labyrinthitis.

Chart 59-10

Select Ototoxic Substances

- **Aminoglycoside antibiotic agents**: amikacin, gentamicin, kanamycin, netilmicin, neomycin, streptomycin, tobramycin
- **Anti-inflammatory agents**: salicylates (aspirin), indomethacin
- **Antimalarial agents**: quinine, chloroquine
- **Chemicals**: alcohol, arsenic
- **Chemotherapeutic (antineoplastic) agents**: cisplatin, nitrogen mustard, carboplatin
- **Loop diuretic agents**: ethacrynic acid, furosemide, acetazolamide, torsemide, azosemide, ozolinone, indacrinone, piretanide
- **Metals:** gold, mercury, lead
- **Other antibiotic agents:** erythromycin, azithromycin, clarithromycin, minocycline, polymyxin B, vancomycin

Adapted from Mudd, P. (2019). Ototoxicity. *Medscape*. Retrieved on 3/7/2020 at: emedicine.medscape.com/article/857679-overview

Clinical Manifestations

Labyrinthitis is characterized by a sudden onset of incapacitating vertigo, usually with nausea and vomiting, various degrees of hearing loss, and possibly tinnitus. The first episode is usually the worst; subsequent attacks, which usually occur over a period of several weeks to months, are less severe.

Management

Treatment of bacterial labyrinthitis includes IV antibiotic therapy, fluid replacement, and administration of an antihistamine (e.g., meclizine) and antiemetic medications. Treatment of viral labyrinthitis is based on the patient's symptoms.

Ototoxicity

A variety of medications may have adverse effects on the cochlea, vestibular apparatus, or cranial nerve VIII. All but a few, such as aspirin and quinine, cause irreversible hearing loss. Aspirin toxicity can produce bilateral tinnitus. IV medications, especially the aminoglycosides, are a common cause of ototoxicity, because they destroy the hair cells in the organ of Corti (see Chart 59-10). Antineoplastic agents also cause hair cell death in the cochlea, which can lead to hearing loss (Mudd, 2019). These medications can be found in the body several months later; side effects are dose dependent, with higher doses causing increased ototoxicity. Therefore, hearing loss may occur at any time, even several months after the last dose of the medication was given.

To prevent loss of hearing or balance, patients receiving potentially ototoxic medications should be counseled about their side effects. These medications should be used with caution in individuals that are at high risk for complications, such as children, older adults, patients who are pregnant, patients with kidney or liver problems, and patients with current hearing disorders. Blood levels of the medications should be monitored, and patients receiving long-term IV antibiotics should be monitored with an audiogram twice each week during therapy.

Acoustic Neuroma

Acoustic neuromas, also referred to as vestibular schwannomas, are slow-growing, benign tumors of cranial nerve VIII, usually arising from the Schwann cells of the vestibular portion of the nerve. Acoustic tumors typically arise within the internal auditory canal and extend into the cerebellopontine angle to press on the brain stem, possibly destroying the vestibular nerve. Most acoustic neuromas are unilateral, except in von Recklinghausen disease (neurofibromatosis type 2), in which bilateral tumors occur (Norris, 2019).

Acoustic neuromas develop in one of every 100,000 people in the United States per year (NIDCD, 2017d). These neuromas account for 8% of all intracranial tumors and seem to occur with equal frequency in men and women at any age, although most occur during middle age (Carlson, Tveiten, Driscoll, et al., 2015).

Assessment and Diagnostic Findings

The most common assessment findings of patients with acoustic neuromas are unilateral tinnitus and hearing loss with or without vertigo or balance disturbance. It is important to identify asymmetry in audiovestibular test results so that further workup can be performed to rule out an acoustic neuroma. Although conflicting data exist, the only known risk factor for

acoustic neuroma is cell phone usage (Park, Vernick, & Ramakrishna, 2019). An MRI scan with a contrast agent (i.e., gadolinium or gadopentetate) is the imaging study of choice. If the patient is claustrophobic or cannot undergo an MRI scan for other reasons, or if the scan is unavailable, a CT scan with contrast dye is performed. However, MRI is more sensitive than CT in delineating a small tumor.

Management

Three options for managing an acoustic neuroma include: (1) surgical removal, (2) radiation, and (3) observation (Carlson et al., 2015; NIDCD, 2017d). Conservative treatment and routine monitoring are recommended for patients with tumors less than 1.5 cm and for those who are older. For patients who are at low risk, surgical removal of the acoustic tumor is the treatment of choice because these tumors do not respond well to radiation or chemotherapy. Because treatment of acoustic tumors crosses several specialties, the interdisciplinary treatment approach involves a neurologist and a neurosurgeon. The objective of the surgery is to remove the tumor while preserving facial nerve function. Most acoustic tumors have damaged the cochlear portion of cranial nerve VIII resulting in hearing loss. In these patients, surgery is performed using a translabyrinthine approach, and the hearing mechanism is destroyed. If hearing is still good before surgery, a suboccipital or middle cranial fossa approach to removing the tumor may be used. This procedure exposes the lateral third of the internal auditory canal and preserves hearing (Park et al., 2019).

Potential complications of surgery include facial nerve paralysis, cerebrospinal fluid leakage, meningitis, and cerebral edema. Death from acoustic neuroma surgery is rare (Park et al., 2019).

AURAL REHABILITATION

If hearing loss is permanent or cannot be treated by medical or surgical means or if the patient elects not to undergo surgery, aural rehabilitation may be beneficial. The purpose of aural rehabilitation is to maximize the communication skills of the person with hearing loss. Aural rehabilitation includes auditory training, speech reading, speech training, and the use of hearing aids and hearing guide dogs.

Auditory training emphasizes listening skills, so the person with hearing loss practices concentrating on the speaker. Speech reading (also known as lip reading) can help fill the gaps left by missed or misheard words. The goals of speech training are to conserve, develop, and prevent deterioration of current communication skills.

It is important to identify the type of hearing loss so that rehabilitative efforts can be appropriate for each individual. Surgical correction may be all that is necessary to treat and improve a conductive hearing loss by eliminating the cause of the hearing loss. Advances in hearing aid technology have greatly improved amplification for patients with sensorineural hearing loss.

Hearing Aids

A hearing aid is a device through which speech and environmental sounds are received by a microphone, converted to electrical signals, amplified, and reconverted to acoustic signals. Many aids available for sensorineural hearing loss depress the low frequencies, or tones, and enhance hearing for the high frequencies. A general guideline for assessing the patient's need for a hearing aid is a hearing loss exceeding 30 dB in the range of 500 to 2000 Hz in the better-hearing ear.

A hearing aid makes sounds louder, but it does not improve a patient's ability to discriminate words or understand speech. People who have low discrimination scores (i.e., 20%) on audiograms may derive little benefit from a hearing aid. Hearing aids amplify all sounds, including background noise, which may be particularly disturbing to the first-time wearer. Chart 59-11 identifies additional problems associated with hearing aid use. Computerized hearing aids are available to compensate for background noise or allow amplification at certain programmed frequencies rather than at all frequencies. Occasionally, depending on the type of hearing loss, binaural aids (i.e., one for each ear) may be indicated. Chart 59-12 provides tips for hearing aid care.

Chart 59-11

Hearing Aid Problems

Whistling Noise

- Loose ear mold
- Improperly made
- Improperly worn
- Worn out

Improper Aid Selection

- Too much power required in aid, with inadequate separation between microphone and receiver
- Open mold used inappropriately
- Inadequate amplification
- Dead batteries
- Cerumen in ear
- Cerumen or other material in mold
- Wires or tubing disconnected from aid
- Aid turned off or volume too low
- Improper mold
- Improper aid for degree of loss

Pain From Mold

- Improperly fitted mold
- Ear skin or cartilage infection
- Middle ear infection
- Ear tumor
- Unrelated conditions of the temporomandibular joint, throat, or larynx

Chart 59-12  **PATIENT EDUCATION**

Tips for Hearing Aid Care

The nurse instructs the patient how to clean a hearing aid, check for malfunctions, and recognize complications:

Cleaning

- Keep in mind that the ear mold is the only part of the hearing aid that may be washed frequently.
- Wash the ear mold daily with soap and water.
- Allow the ear mold to dry completely before it is snapped into the receiver.
- Clean the cannula with a small pipe cleaner–like device.
- Note that properly caring for the ear device and keeping the ear canal clean and dry can prevent complications.

Checking for Malfunctions

- Be aware that inadequate amplification, a whistling noise, or pain from the mold can occur when a hearing aid is not functioning properly.
- Check for malfunctions:
  - Is the switch on properly?
  - Are the batteries charged and positioned correctly?
  - Is the ear mold clogged with cerumen? Ear wax can be easily removed with pin, pipe cleaner, or wax loop.
- Notify the hearing aid dealer if the hearing aid is still not working properly.
- Keep in mind that if the unit requires extended time for repair, the dealer may lend you a hearing aid until the repair can be accomplished.

Recognizing Complications

- Understand that common medical complications include external otitis media and pressure injury in the external auditory canal. Signs and symptoms of these infections include painful ear, especially when the external ear is touched; canal swelling; redness; difficulty hearing; pain radiating to the jaw area; and fever.
- Notify your health care provider for evaluation if any of these symptoms are present. You may need medication to treat infection, pain, or both.

A hearing aid should be fitted according to the patient's needs (e.g., type of hearing loss, manual dexterity, and preference), rather than brand name, by a certified audiologist licensed to dispense hearing aids. Many states have consumer protection laws that allow the hearing aid to be returned after a trial use if the patient is not completely satisfied. In addition, to protect the health

and safety of people with hearing loss, the U.S. Food and Drug Administration (FDA) has established certain regulations. A medical evaluation of the hearing loss by a physician must be obtained within 6 months before the purchase of a hearing aid. However, the written statement from a physician may be waived if the patient (a fully informed adult 18 years or older) signs a document to this effect. Health care professionals who dispense hearing aids are required to refer prospective users to a physician if any of the following otologic conditions are evident:

- Visible congenital or traumatic deformity of the ear
- Active drainage from the ear within the previous 90 days
- Sudden or rapidly progressive hearing loss within the previous 90 days
- Complaints of dizziness or tinnitus
- Unilateral hearing loss that has occurred suddenly or within the previous 90 days
- Audiometric air–bone gap of 15 dB or more at 500, 1000, and 2000 Hz
- Significant accumulation of cerumen or a foreign body in the external auditory canal
- Pain or discomfort in the ear

A user instruction brochure is provided with every hearing aid device. In this brochure, the following information is presented:

- Notification that good health practice requires a medical evaluation before purchasing a hearing aid
- Notification that any of the otologic conditions listed previously should be investigated by a physician before purchase of a hearing aid
- Instructions for proper use, maintenance, and care of the hearing aid, as well as instructions for replacing or recharging the batteries
- Repair service information
- Description of avoidable conditions that could damage the hearing aid
- List of any known side effects that may warrant physician consultation (e.g., skin irritation, accelerated cerumen accumulation)

The evolution in technology has led to the availability of many smaller and more effective devices as well as different options and features of hearing aids (FDA, 2018a) (see Chart 59-13). The majority of hearing aids sold today are behind-the-ear, in-the-ear, or in-the-canal types (see Table 59-4). One model is the Lyric, which is placed in the ear canal just 4 mm from the tympanic membrane. Its volume is controlled by a magnet, and when its batteries no longer function (1 to 4 months), a physician can remove it with the magnet and reinsert a new device. This device does not have many of the problems (e.g., feedback noise, overamplification of background noise) associated with other hearing aids, and it does not involve the expense and uncertainty of surgical procedures. However, Lyric is not an option if the ear canal is too narrow to accommodate the device.

Chart 59-13

Options and Features of Hearing Aids to Consider

- *T-Coil:* May improve hearing on the telephone by switching the settings from normal to telephone setting. This feature also assists in amplifying voices when the patient is in larger areas, such as theaters, auditoriums, and gymnasiums. Background noise may be toned down to adequately hear close conversation.
- *Directional Microphone:* Useful in environments with a lot of background noise and activity. The microphone may be directed toward the speaker and amplifies conversation while diminishing background noise.
- *Direct Audio Input:* Allows direct connection from a remote microphone or an FM assistive listening system to devices such as a computer, television, or stereo.
- *Feedback Suppression:* Suppresses whistling feedback noise.

Adapted from U.S. Food and Drug Administration. (2018a). Medical devices: Types of hearing aids. Retrieved on 2/22/2020 at: www.fda.gov/medical-devices/hearing-aids/types-hearing-aids

TABLE 59-4 Hearing Aids

Site (Range of Hearing Loss)	Advantages	Disadvantages
Body, usually on the trunk (mild–profound)	Separation of receiver and microphone prevents acoustic feedback, allowing high amplification; generally used in a school setting	Bulky; requires long wire, which may be cosmetically displeasing; some loss of high-frequency response
Behind the ear (mild–profound)	Economical; powerful, with no long wires; easily used by children—adapts easily as the child grows, with only the ear mold needing replacement	Large size
In the ear (mild–moderately severe)	One-piece custom fit to contour of ear; no tubes or cords; miniature microphone located in the ear, which is a more natural placement; more cosmetically appealing due to easy concealment	Smaller size limits output; patients who have arthritis or cannot perform tasks requiring good manual dexterity may have difficulty with the small size of aid or battery; can require more repair than the behind-the-ear aid
In the canal (mild–moderately severe)	Same as in-the-ear aids; less visible, so more cosmetically pleasing	Even smaller than in-the-ear aids; requires good manual dexterity and good vision

Implanted Hearing Devices

There are several types of implanted hearing devices, ranging from implantable to semi-implantable devices (FDA, 2018b).

Bone conduction devices, which transmit sound through the skull to the inner ear, are used in patients with a conductive hearing loss if a hearing aid is contraindicated (e.g., those with chronic infection). The device is implanted postauricularly under the skin into the skull, and an external device—worn above the ear, not in the canal—transmits the sound through the skin. There are two types of implantable hearing aids. The bone-anchored hearing aid (BAHA) is implanted behind the ear in the mastoid area. The middle ear implant (MEI) is implanted in the middle ear cavity. The BAHA is used for conductive or mixed hearing loss, whereas the MEI is used for sensorineural hearing loss (FDA, 2018b).

The implantable middle ear hearing device (IMEHD) comes in two styles: piezoelectric and electromagnetic, which are partially or totally implanted. Patients must be 18 years or older, must be diagnosed with mild to severe

sensorineural loss, and must have tried other conventional devices with poor results to be considered candidates for this type of device. The implantable device has several advantages—for example, it may eliminate feedback, achieve good cosmetic results, and allow the patient to perform most preferred leisure activities (e.g., dancing, swimming). Disadvantages are that this device is expensive, necessitates surgery, requires periodic recharging of batteries, and has unpredictable power output (FDA, 2018b).

The FDA has also approved the semi-implantable Vibrant Soundbridge (electromagnetic) and the total implantable Envoy Esteem (piezoelectric) devices. The Vibrant Soundbridge has an external device attached to the postauricular bone that transmits sound to the magnet in the middle ear that is attached to the long process of the incus. The magnet surrounds the long axis of the stapes, which in turn vibrates and sound is heard. The Envoy Esteem works similarly to the natural ear. The piezoelectric transducer is located at the head of the incus, which sends a signal that is amplified, filtered, and then converted back to a vibration signal. This vibration is delivered by the driver (piezoelectric transducer) and attached to the stapes capitulum; then, via the stapes bone, the inner ear receives the signal and is converted into a nerve impulse and translated into sound by the brain. The incus is removed prior to insertion of this device to prevent feedback from the sensor. Clinical trials reported that in best-fit aided conditions, speech reception thresholds improved from 41.2 dB to 29.4 dB and word recognition score at 50 dB hearing level improved from best-fit aided of 46.3% to 68.9% with the Envoy Esteem (Kraus, Shohet, & Catalano, 2011). A 5-year follow-up study of the same group found that word recognition scores were improved by 17%; word recognition score at 50 dB hearing level improved in 49%, and remained the same in 41%; and speech reception threshold improved at every annual follow-up (Shohet, Kraus, Catalano, et al., 2018).

A cochlear implant is an auditory prosthesis used for people with profound sensorineural hearing loss bilaterally who do not benefit from conventional hearing aids. The cochlear implant directly stimulates the auditory nerve and has made it possible for people who have severe hearing loss or who are deaf to hear sound (NIDCD, 2017a). The hearing loss may be congenital or acquired. An implant does not restore normal hearing; rather, it helps the person detect medium to loud environmental sounds and conversation. The implant provides stimulation directly to the auditory nerve, bypassing the nonfunctioning hair cells of the inner ear. The microphone and signal processor, worn outside the body, transmit electrical stimuli to the implanted electrodes. The electrical signals stimulate the auditory nerve fibers and then the brain, where they are interpreted.

Worldwide, more than 324,200 people have received cochlear implants. In the United States, approximately 58,000 adults and 38,000 children have received cochlear implants (NIDCD, 2017a). Studies report that older adult

patients with cochlear implants experience improved understanding of speech and better cognition. Patients with cochlear implants were also noted to have more social interactions with others and improved quality of life. Research has reported that hearing improvement with a cochlear implant delays the occurrence as well as the progression of dementia (Sarant, Harris, Busby, et al., 2019). Candidates for a cochlear implant, who are usually at least 1 year of age, are selected after careful screening by otologic history, physical examination, audiologic testing, x-rays, and psychological testing. Criteria for choosing adults who may benefit from a cochlear implant include:

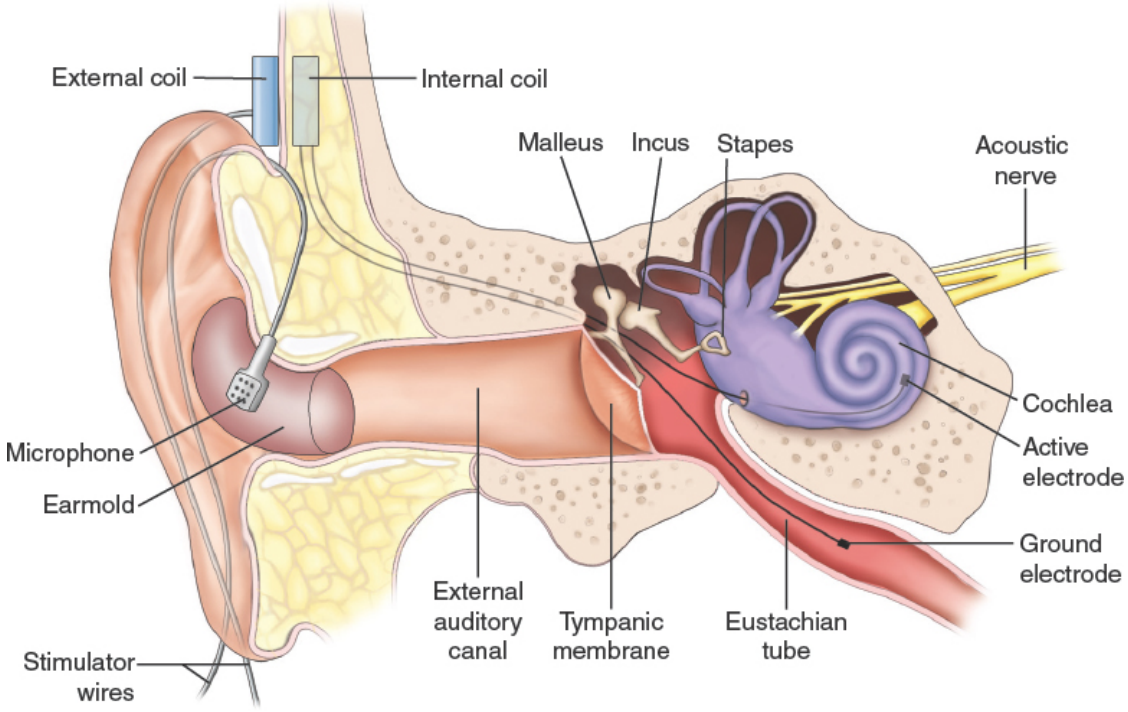

Figure 59-7 • The cochlear implant. The internal coil has a stranded electrode lead. The electrode is inserted through the round window into the scala tympani of the cochlea. The external coil (the transmitter) is held in alignment with the internal coil (the receiver) by a magnet. The microphone receives the sound. The stimulator wire receives the signal after it has been filtered, adjusted, and modified so that the sound is at a comfortable level for the patient. Sound is passed by the external transmitter to the inner coil receiver by magnetic conduction and is then carried by the electrode to the cochlea.

- Profound sensorineural hearing loss in both ears
- Inability to hear and recognize speech well with hearing aids
- No medical contraindication to a cochlear implant or general anesthesia
- Indications that being able to hear would enhance the patient's life

The surgery involves implanting a small receiver in the temporal bone through a postauricular incision and placing electrodes into the inner ear (see Fig. 59-7). The microphone and transmitter are worn on an external unit. The patient undergoes extensive cochlear rehabilitation with the multidisciplinary team, which includes an audiologist and speech pathologist. Several months may be needed to learn to interpret the sounds heard. Children and adults who lost their hearing before they learned to speak take much longer to acquire speech. There are wide variations of success with cochlear implants, and there is also controversy about their use, especially among the Deaf community. Patients who have had a cochlear implant are cautioned that an MRI scan will inactivate the implant; MRI should be used only when there is no other diagnostic option.

Hearing Guide Dogs

Specially trained dogs (service dogs) are available to assist the person with a hearing loss. People who live alone are eligible to apply for a dog trained by International Hearing Dog, Inc. The dog reacts to the sound of a telephone, a doorbell, an alarm clock, a baby's cry, a knock at the door, a smoke alarm, or an intruder. The dog alerts its master by physical contact; the dog then runs to the source of the noise. In public, the dog positions itself between the person who is deaf or has severe hearing loss and any potential hazard that the person cannot hear, such as an oncoming vehicle or a loud, hostile person. A certified hearing guide dog is legally permitted access to public transportation, public eating places, and stores, including food markets.

CRITICAL THINKING EXERCISES

1 ebp A 65-year-old woman visits the clinic where you work for a routine well-woman examination. She mentions that her friend was recently diagnosed with hearing loss and fitted for a hearing aid. She has no perceived hearing loss, but she wonders whether she needs a hearing aid. What evidence-based recommendations would you make for this patient about hearing loss screening and diagnosis? What is the strength of the evidence for your recommendations?

2 pq A 40-year-old man has complained of hearing loss that has gradually worsened over the past few months. He has difficulty hearing the television and having a telephone conversation. After seeing the primary provider today, he was diagnosed with cerumen impaction. Discuss how you will educate the patient about the diagnosis of cerumen impaction. What is your priority for care of this patient? Give your rationale.

3 ipc A 54-year-old man had a cochlear implant placed 5 years ago and has been admitted to the medical-surgical unit due to implant malfunction. Develop a plan of action for communicating with this patient. What should you know about cochlear implants to communicate effectively with the patient? What environmental conditions should be considered to promote patient safety and well-being? Which members of the health care team should be informed about this patient's communication needs?

UNIT 15

Neurologic Function

Case Study

DEVELOPING A TEAM-BASED PLAN OF CARE

You are the nurse caring for a 70-year-old man with Parkinson's disease who was recently admitted to the skilled nursing facility where you work. The patient was diagnosed with Parkinson's

disease 5 years ago but has only recently had a significant decline in function. He can no longer dress himself because he lacks the ability to control fine motor movements in his hands. In addition, he has lost 10 lb in the past 3 months as a result of difficulty feeding himself because of the constant tremors. The patient's wife has reported feeling exhausted prior to her husband's admission; she had not been sleeping well due to her husband having nightmares and trying to get up during the night. You form a task force to help develop a plan of care that is focused on increasing the patient's functionality so that he might be discharged home. Specifically, you invite a staff nutritionist, pharmacist, physical therapist, occupational therapist, and social worker to work with you in developing the plan of care for this patient.

QSEN Competency Focus: **Teamwork and Collaboration**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Teamwork and Collaboration Definition: Function effectively within nursing and interprofessional teams, fostering open communication, mutual respect, and shared decision-making to achieve quality patient care.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Describe scopes of practice and roles of health care team members Describe strategies for identifying and managing overlaps in team member roles and accountabilities Recognize contributions of other individuals and groups in helping patient/family achieve health goals	How can you help the patient and his wife identify health goals to manage his Parkinson's disease? Based upon your knowledge of their scopes of practice, identify why you decided which team members to include when you formed the task force. Identify the contributions of the different members of the team in meeting the patient's and wife's goals.
Skills	
Assume role of team member or leader based on the situation Initiate requests for help when appropriate to situation Clarify roles and accountabilities under conditions of potential overlap in team member functioning Integrate the contributions of others who play a role in helping patient/family achieve health goals	What skills will you need to assume the role of team leader and advocate for the needs of both the patient and his wife? What subjective and objective assessment criteria can you use to determine which team members need to be consulted for which specific problem or to help the patient and his wife meet specific goals? Once the consults have been made, what is your role in ensuring that the plan of care for this patient is being implemented?
Attitudes	
Value the perspectives and expertise of all health team members Respect the centrality of the patient/family as core members of any health care team Respect the unique attributes that members bring to a team, including variations in professional orientations and accountabilities	How will you demonstrate to the patient and his wife the value of the various team members? How can team members ensure respect for each other? How will each member of the team maintain accountability for the plan of care?

60 Assessment of Neurologic Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the structures and functions of the central and peripheral nervous systems.
2. Differentiate between pathologic changes that affect motor control and those that affect sensory pathways.
3. Compare and contrast the functioning of the sympathetic and parasympathetic nervous systems.
4. Explain the significance of physical assessment to the diagnosis of neurologic dysfunction.
5. Discuss diagnostic tests used for assessment of suspected neurologic disorders and the related nursing implications.

NURSING CONCEPTS

Assessment
Intracranial Regulation
Mobility
Mood and Affect
Patient Education
Sensory Perception

GLOSSARY

agnosia: loss of ability to recognize objects through a particular sensory system; may be visual, auditory, or tactile

ataxia: inability to coordinate muscle movements, resulting in difficulty in walking, talking, and performing self-care activities

autonomic nervous system: division of the nervous system that regulates the involuntary body functions

axon: portion of the neuron that conducts impulses away from the cell body

Babinski reflex (sign): a reflex action of the toes; in adults is indicative of abnormalities in the motor control pathways leading from the cerebral cortex

clonus: abnormal movement marked by alternating contraction and relaxation of a muscle occurring in rapid succession

delirium: an acute, confused state that begins with disorientation and if not recognized and treated early can progress to changes in level of consciousness, irreversible brain damage, and sometimes death

dendrite: portion of the neuron that conducts impulses toward the cell body

flaccidity: displaying lack of muscle tone; limp, floppy

parasympathetic nervous system: division of the autonomic nervous system active primarily during nonstressful conditions, controlling mostly visceral functions

position (postural) sense: awareness of position of parts of the body without looking at them *(synonym:* proprioception)

reflex: an automatic response to stimuli

rigidity: increase in muscle tone at rest characterized by increased resistance to passive stretch

Romberg test: test for cerebellar dysfunction that can be done with the patient seated or standing; inability to maintain position for 20 seconds is a positive test

spasticity: sustained increase in tension of a muscle when it is passively lengthened or stretched

sympathetic nervous system: division of the autonomic nervous system with predominantly excitatory responses (*synonym*: the “fight-or-flight” system)

vertigo: illusion of movement in which the individual or the surroundings are sensed as moving

Nurses in many practice settings encounter patients with altered neurologic function. Disorders of the nervous system can occur at any time during the lifespan and can vary from mild, self-limiting symptoms to devastating, life-threatening disorders. Nurses must be skilled in the general assessment of neurologic function and be able to focus on specific areas as needed. Assessment requires knowledge of the anatomy and physiology of the nervous system and an understanding of the array of tests and procedures used to diagnose neurologic disorders. Knowledge about the nursing implications and interventions related to assessment and diagnostic testing is also essential.

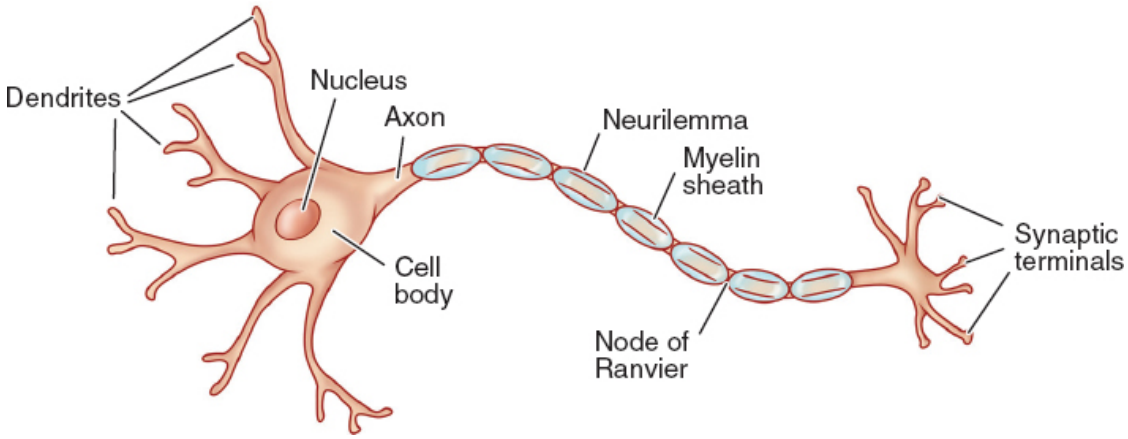

Figure 60-1 • Neuron.

Anatomic and Physiologic Overview

The nervous system consists of two major parts: the central nervous system (CNS), including the brain and spinal cord, and the peripheral nervous system, which includes the cranial nerves, spinal nerves, and autonomic nervous system. The function of the nervous system is to control motor, sensory, autonomic, cognitive, and behavioral activities. The brain itself contains more than 100 billion cells that link the motor and sensory pathways, monitor the body's processes, respond to the internal and external environment, maintain homeostasis, and direct all psychological, biologic, and physical activity through complex chemical and electrical messages (Klein & Stewart-Amidei, 2017).

Cells of the Nervous System

The basic functional unit of the brain is the neuron (see Fig. 60-1). It is composed of dendrites, a cell body, and an axon. The **dendrites** are branch-type structures for receiving electrochemical messages. The **axon** is a long projection that carries electrical impulses away from the cell body. Some axons

have a myelinated sheath that increases speed of conduction. Nerve cell bodies occurring in clusters are called *ganglia* or *nuclei.* A cluster of cell bodies with the same function is called a *center* (e.g., the respiratory center). Neurons are supported, protected, and nourished by glial cells, which are 50 times greater in number than neurons (Hickey & Strayer, 2020).

Neurotransmitters

Neurotransmitters communicate messages from one neuron to another or from a neuron to a target cell, such as muscle or endocrine cells. Neurotransmitters are manufactured and stored in synaptic vesicles. As an electrical action potential moves along the axon and reaches the nerve terminal, neurotransmitters are released into the synapse. The neurotransmitter is transported across the synapse, binding to receptors on the postsynaptic cell membrane. A neurotransmitter can either excite or inhibit activity of the target cell. Usually, multiple neurotransmitters are at work in the neural synapse. The source and action of major neurotransmitters are described in Table 60-1. Once released, enzymes either destroy the neurotransmitter or reabsorb it into the neuron for future use.

Many neurologic disorders are due, at least in part, to an imbalance in neurotransmitters. For example, Parkinson's disease develops from decreased availability of dopamine, whereas acetylcholine binding to muscle cells is impaired in myasthenia gravis (Norris, 2019). All brain functions are modulated through neurotransmitter receptor site activity, including memory and other cognitive processes (Hickey & Strayer, 2020).

TABLE 60-1 Major Neurotransmitters

Neurotransmitter	Source	Action
Acetylcholine (major transmitter of the parasympathetic nervous system)	Neurons in many areas of the brain; autonomic nervous system	Usually excitatory; parasympathetic effects sometimes inhibitory (stimulation of heart by vagal nerve)
Serotonin	Brain stem, hypothalamus, dorsal horn of the spinal cord	Inhibitory; helps control mood and sleep, inhibits pain pathways
Dopamine	Neurons on the substantia nigra and basal ganglia	Usually inhibitory; affects behavior (attention, emotions) and fine movement
Norepinephrine (major transmitter of the sympathetic nervous system)	Brain stem, hypothalamus, postganglionic neurons of the sympathetic nervous system	Usually excitatory; affects mood and overall activity
Gamma-aminobutyric acid	Nerve terminals of the spinal cord, cerebellum, basal ganglia, some cortical areas	Inhibitory
Enkephalin, endorphin	Nerve terminals in the spine, brain stem, thalamus and hypothalamus, pituitary gland	Excitatory; pleasurable sensation, inhibits pain transmission

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Ongoing research is evaluating diagnostic tests that can detect abnormal levels of neurotransmitters in the brain. Positron emission tomography (PET), for example, can detect dopamine, serotonin, and acetylcholine. Single-photon emission computed tomography (SPECT), similar to PET, can detect changes in some neurotransmitters, such as dopamine in Parkinson's disease (Fischbach & Fischbach, 2018). Both PET and SPECT are discussed in more detail later in this chapter.

The Central Nervous System

The CNS consists of the brain and the spinal cord.

The Brain

The brain accounts for approximately 2% of the total-body weight; in an average young adult, the brain weighs approximately 1400 g, whereas in an average older adult, the brain weighs approximately 1200 g (Hickey & Strayer,

2020). The brain is divided into three major areas: the cerebrum, the brain stem, and the cerebellum. The cerebrum is composed of two hemispheres, the thalamus, the hypothalamus, and the basal ganglia. The brain stem includes the midbrain, pons, and medulla. The cerebellum is located under the cerebrum and behind the brain stem (see Fig. 60-2).

Cerebrum

The outside surface of the hemispheres has a wrinkled appearance that is the result of many folded layers or convolutions called *gyri,* which increase the surface area of the brain, accounting for the high level of activity carried out by such a small-appearing organ. Between each gyrus is a sulcus or fissure that serves as an anatomic division. In between the cerebral hemispheres is the great longitudinal fissure that separates the cerebrum into the right and left hemispheres. The two hemispheres are joined at the lower portion of the fissure by the corpus callosum. The external or outer portion of the hemispheres (the cerebral cortex) is made up of gray matter approximately 2 to 5 mm in depth; it contains billions of neuron cell bodies, giving it a gray appearance. White matter makes up the innermost layer and is composed of myelinated nerve fibers and neuroglia cells that form tracts or pathways connecting various parts of the brain with one another. These pathways also connect the cortex with lower portions of the brain and spinal cord. The cerebral hemispheres are divided into pairs of lobes as follows (see Fig. 60-2):

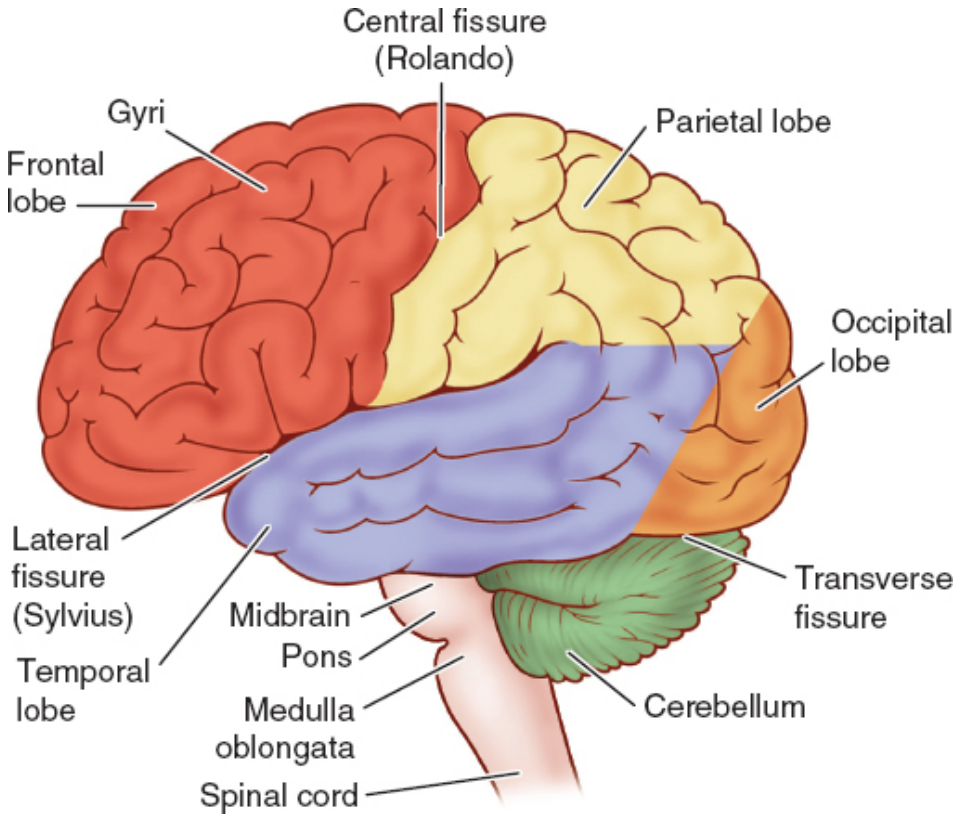

Figure 60-2 • View of the external surface of the brain showing lobes, cerebellum, and brain stem.

- *Frontal*—the largest lobe, located in the front of the brain. The major functions of this lobe are concentration, abstract thought, information storage or memory, and motor function. It contains Broca area, which is in the left hemisphere and is critical for motor control of speech. The frontal lobe is also responsible in large part for a person's affect, judgment, personality, and inhibitions (Hickey & Strayer, 2020).
- *Parietal*—a predominantly sensory lobe posterior to the frontal lobe. This lobe analyzes sensory information and relays the interpretation of this information to other cortical areas and is essential to a person's awareness of body position in space, size and shape discrimination, and right–left orientation (Hickey & Strayer, 2020).
- *Temporal*—located inferior to the frontal and parietal lobes, this lobe contains the auditory receptive areas and plays a role in memory of sound and understanding of language and music.
- *Occipital*—located posterior to the parietal lobe, this lobe is responsible for visual interpretation and memory.

The corpus callosum (see Fig. 60-3), a thick collection of nerve fibers that connects the two hemispheres of the brain, is responsible for the transmission of information from one side of the brain to the other. Information transferred includes sensation, memory, and learned discrimination. Right-handed people

and some left-handed people have cerebral dominance on the left side of the brain for verbal, linguistic, arithmetic, calculation, and analytic functions. The nondominant hemisphere is responsible for geometric, spatial, visual, pattern, and musical functions. Nuclei for cranial nerves I and II are also located in the cerebrum.

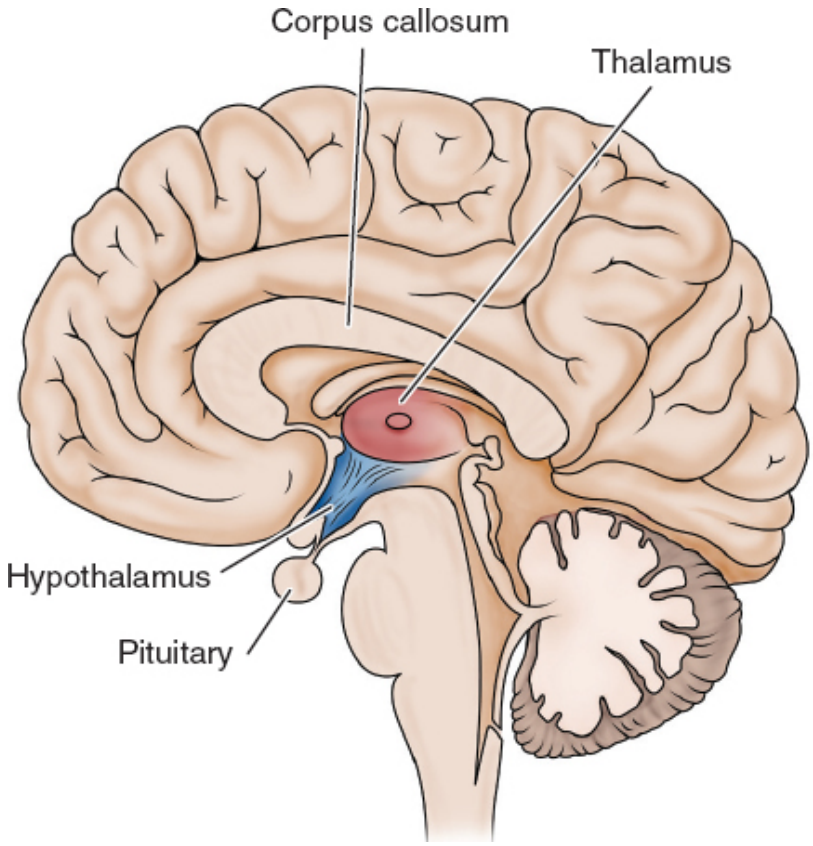

Figure 60-3 • Medial view of the brain.

The thalami lie on either side of the third ventricle and act primarily as a relay station for all sensation except smell. All memory, sensation, and pain impulses pass through this section of the brain. The hypothalamus (see Fig. 60-3) is located anterior and inferior to the thalamus, and beneath and lateral to the third ventricle. The infundibulum of the hypothalamus connects it to the posterior pituitary gland. The hypothalamus plays an important role in the endocrine system because it regulates the pituitary secretion of hormones that influence metabolism, reproduction, stress response, and urine production. It works with the pituitary to maintain fluid balance through hormonal release and maintains temperature regulation by promoting vasoconstriction or vasodilatation. In addition, the hypothalamus is the site of the hunger center and is involved in appetite control. It contains centers that regulate the sleep–wake cycle, blood pressure, aggressive and sexual behavior, and emotional responses (e.g., blushing, rage, depression, panic, fear). The hypothalamus also controls and regulates the autonomic nervous system. The optic chiasm (the

point at which the two optic tracts cross) and the mammillary bodies (involved in olfactory reflexes and emotional response to odors) are also found in this area.

The basal ganglia are masses of nuclei located deep in the cerebral hemispheres that are responsible for control of fine motor movements, including those of the hands and lower extremities.

Brain Stem

The brain stem consists of the midbrain, pons, and medulla oblongata (see Fig. 60-2). The midbrain connects the pons and the cerebellum with the cerebral hemispheres; it contains sensory and motor pathways and serves as the center for auditory and visual reflexes. Cranial nerves III and IV originate in the midbrain. The pons is situated in front of the cerebellum between the midbrain and the medulla and is a bridge between the two halves of the cerebellum, and between the medulla and the midbrain. Cranial nerves V through VIII originate in the pons. The pons also contains motor and sensory pathways. Portions of the pons help regulate respiration.

Motor fibers from the brain to the spinal cord and sensory fibers from the spinal cord to the brain are in the medulla. Most of these fibers cross, or decussate, at this level. Cranial nerves IX through XII originate in the medulla. Reflex centers for respiration, blood pressure, heart rate, coughing, vomiting, swallowing, and sneezing are also located in the medulla. The reticular formation, responsible for arousal and the sleep–wake cycle, begins in the medulla and connects with numerous higher structures.

Cerebellum

The cerebellum is posterior to the midbrain and pons, and below the occipital lobe (see Fig. 60-2). The cerebellum integrates sensory information to provide smooth coordinated movement. It controls fine movement, balance, and **position (postural) sense** or proprioception (awareness of position of extremities without looking at them).

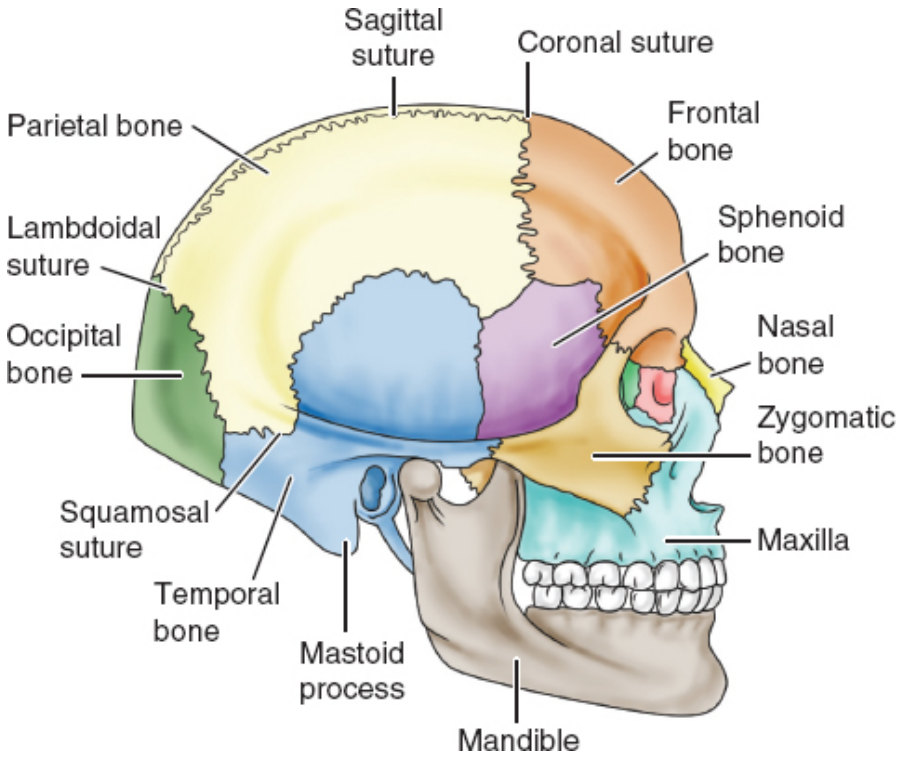

Figure 60-4 • Bones and sutures of the skull.

Structures Protecting the Brain

The brain is contained in the rigid skull, which protects it from injury. The major bones of the skull are the frontal, temporal, parietal, occipital, and sphenoid bones. These bones join at the suture lines (see Fig. 60-4) and form the base of the skull. Indentations in the skull base are known as fossae. The anterior fossa contains the frontal lobe, the middle fossa contains the temporal lobe, and the posterior fossa contains the cerebellum and brain stem.

The meninges (fibrous connective tissues that cover the brain and spinal cord) provide protection, support, and nourishment. The layers of the meninges are the dura mater, arachnoid, and pia mater (see Fig. 60-5):

- *Dura mater*—the outermost layer; covers the brain and the spinal cord. It is tough, thick, inelastic, fibrous, and gray. There are three major extensions of the dura: the falx cerebri, which folds between the two hemispheres; the tentorium, which folds between the occipital lobe and cerebellum to form a tough, membranous shelf; and the falx cerebelli, which is located between the right and left side of the cerebellum. When excess pressure occurs in the cranial cavity, brain tissue may be compressed against these dural folds or displaced around them, a process called *herniation.* A potential space exists between the dura and the skull, and between the periosteum and the dura in the vertebral column, known as the epidural space. Another potential space, the subdural space, also

exists below the dura. Blood or an abscess can accumulate in these potential spaces.

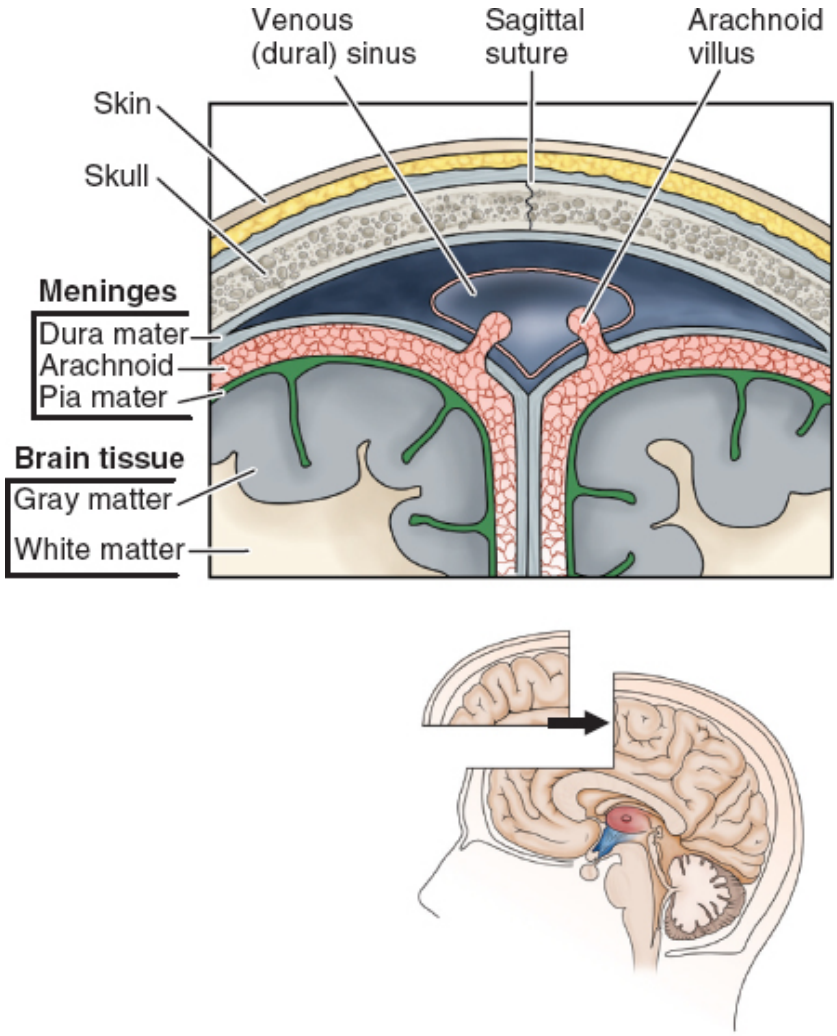

Figure 60-5 • Meninges and related structures.

- *Arachnoid*—the middle membrane; an extremely thin, delicate membrane that closely resembles a spider web (hence the name *arachnoid*). The arachnoid membrane has cerebrospinal fluid (CSF) in the space below it, known as the subarachnoid space. This membrane has arachnoid villi, which are unique finger-like projections that absorb CSF into the venous system. When blood or bacteria enter the subarachnoid space, the villi become obstructed and *communicating* hydrocephalus (increased size of ventricles) may result.
- *Pia mater*—the innermost, thin, transparent layer that hugs the brain closely and extends into every fold of the brain's surface.

Cerebrospinal Fluid

CSF is a clear and colorless fluid that is produced in the choroid plexus of the ventricles and circulates around the surface of the brain and the spinal cord. There are four ventricles: the right and left lateral and the third and fourth ventricles. The two lateral ventricles open into the third ventricle at the interventricular foramen (also known as the foramen of Monro). The third and fourth ventricles connect via the aqueduct of Sylvius. The fourth ventricle drains CSF into the subarachnoid space on the surface of the brain and spinal cord, where it is absorbed by the arachnoid villi. Blockage of the flow of CSF anywhere in the ventricular system produces *obstructive* hydrocephalus.

CSF is important in immune and metabolic functions in the brain. It is produced at a rate of about 500 mL/day; the ventricles and subarachnoid space contain approximately 125 to 150 mL of fluid (Hickey & Strayer, 2020). The composition of CSF is similar to other extracellular fluids (such as blood plasma), but the concentrations of the various constituents differ. A laboratory analysis of CSF indicates color (clear), specific gravity (normal 1.007), protein count, cell count, glucose, and other electrolyte levels (see Table A-5 in Appendix A on thePoint). Normal CSF contains a minimal number of white blood cells and no red blood cells. The CSF may also be tested for immunoglobulins or the presence of bacteria. A CSF sample may be obtained through a lumbar puncture or intraventricular catheter (Hickey & Strayer, 2020).

Cerebral Circulation

The brain does not store nutrients and requires a constant supply of oxygen. These needs are met through cerebral circulation; the brain receives approximately 15% of the cardiac output, or 750 mL per minute of blood flow. Brain circulation is unique in several aspects. First, arterial and venous vessels are not parallel as in other organs in the body; this is due in part to the role the venous system plays in CSF absorption. Second, the brain has collateral circulation through the circle of Willis (see later discussion), allowing blood flow to be redirected on demand. Third, blood vessels in the brain have two rather than three layers, which may make them more prone to rupture when weakened or under pressure.

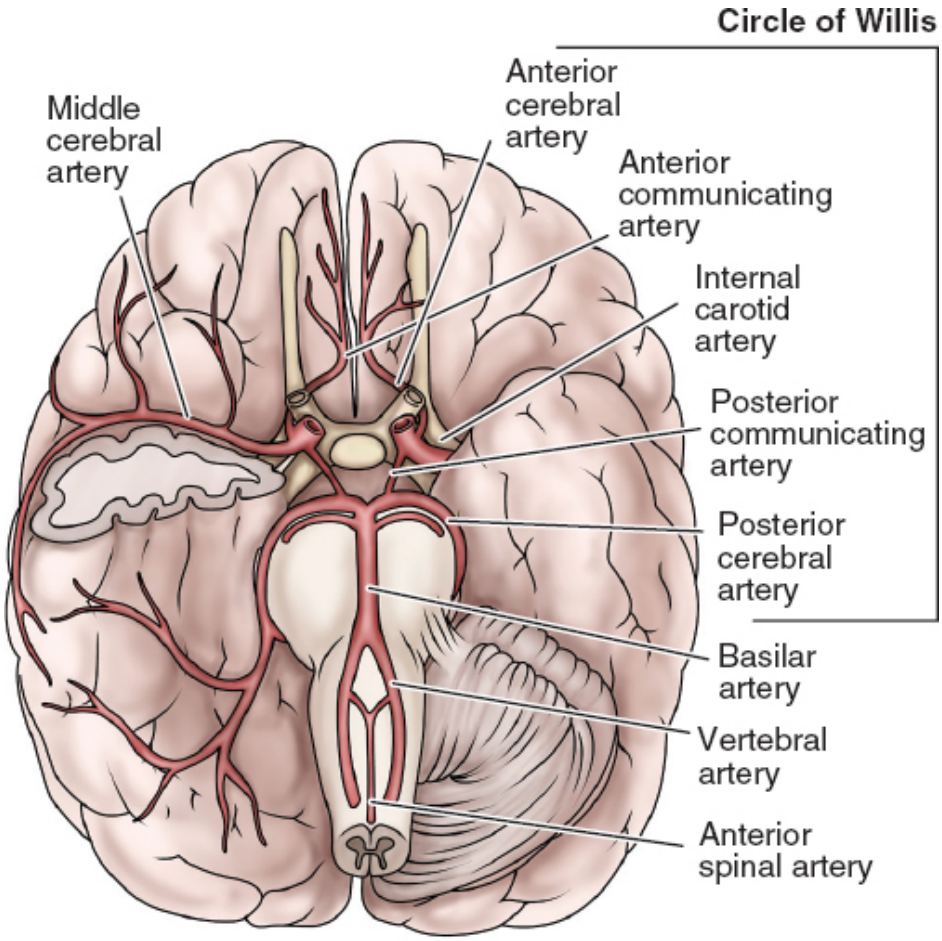

Figure 60-6 • Arterial blood supply of the brain, including the circle of Willis, as viewed from the ventral surface.

Arteries

Arterial blood supply to the anterior brain originates from the common carotid artery, which is the first bifurcation of the aorta. The internal carotid arteries arise at the bifurcation of the common carotid. Branches of the internal carotid arteries (the anterior and middle cerebral arteries) and their connections (the anterior and posterior communicating arteries) form the circle of Willis (see Fig. 60-6).

The vertebral arteries branch from the subclavian arteries to supply most of the posterior circulation of the brain. At the level of the brain stem, the vertebral arteries join to form the basilar artery. The basilar artery divides to form the two branches of the posterior cerebral arteries. Functionally, the posterior and anterior portions of the circulation usually remain separate. However, the circle of Willis can provide collateral circulation through communicating arteries if one of the vessels supplying it becomes occluded or is ligated.

The bifurcations along the circle of Willis are frequent sites of aneurysm formation. Aneurysms are outpouchings of the blood vessel due to vessel wall

weakness. Aneurysms can rupture and cause a hemorrhagic stroke. See Chapter 62 for a more detailed discussion of aneurysms.

Veins

Venous drainage for the brain does not follow the arterial circulation as in other body structures. The veins reach the brain's surface, join larger veins, and then cross the subarachnoid space and empty into the dural sinuses, which are the vascular channels embedded in the dura (see Fig. 60-5). The network of the sinuses carries venous outflow from the brain and empties into the internal jugular veins, returning the blood to the heart. Cerebral veins are unique, because unlike other veins in the body, they do not have valves to prevent blood from flowing backward and depend on both gravity and blood pressure for flow.

Blood–Brain Barrier

The CNS is inaccessible to many substances that circulate in the blood plasma (e.g., dyes, medications, antibiotic agents) because of the blood–brain barrier. This barrier is formed by the endothelial cells of the brain's capillaries, which form continuous tight junctions, creating a barrier to macromolecules and many compounds. All substances entering the CSF must filter through the capillary endothelial cells and astrocytes. The blood–brain barrier has a protective function but can be altered by trauma, cerebral edema, and cerebral hypoxemia; this has implications for treatment and selection of medications for CNS disorders (Hickey & Strayer, 2020).

The Spinal Cord

The spinal cord is continuous with the medulla, extending from the cerebral hemispheres and serving as the connection between the brain and the periphery. Approximately 45 cm (18 inches) long and about the thickness of a finger, it extends from the foramen magnum at the base of the skull to the lower border of the first lumbar vertebra, where it tapers to a fibrous band called the *conus medullaris.* Continuing below the second lumbar space are the nerve roots that extend beyond the conus, which are called the *cauda equina* because they resemble a horse's tail. Meninges surround the spinal cord.

In a cross-sectional view, the spinal cord has an H-shaped central core of nerve cell bodies (gray matter) surrounded by ascending and descending tracts (white matter) (see Fig. 60-7). The lower portion of the H is broader than the upper portion and corresponds to the anterior horns. The anterior horns contain cells with fibers that form the anterior (motor) root and are essential for the voluntary and reflex activity of the muscles they innervate. The thinner posterior (upper horns) portion contains cells with fibers that enter over the

posterior (sensory) root and thus serve as a relay station in the sensory/reflex pathway.

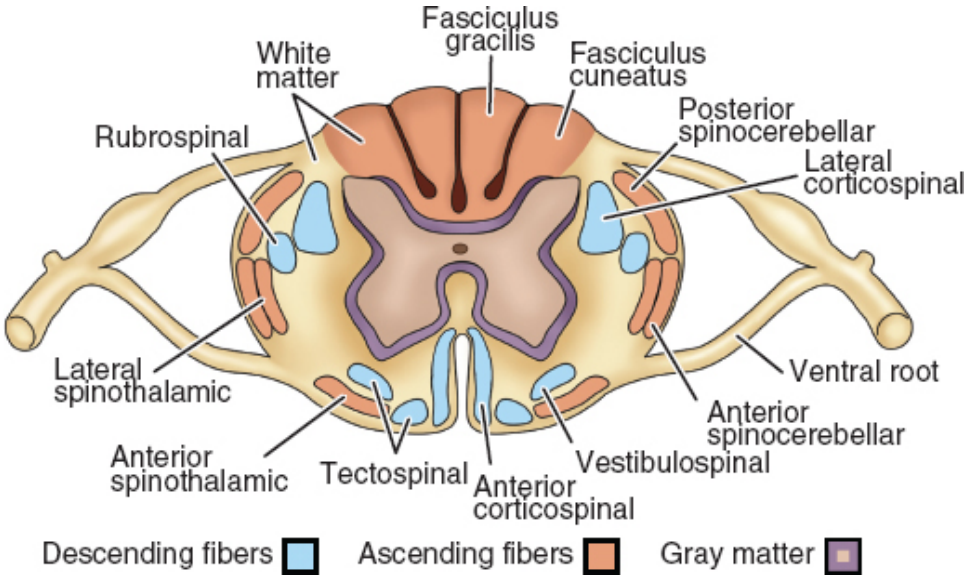

Figure 60-7 • Cross-sectional diagram of the spinal cord showing major spinal tracts.

The thoracic region of the spinal cord has a projection from each side at the crossbar of the H-shaped structure of gray matter called the *lateral horn.* It contains the cells that give rise to the autonomic fibers of the sympathetic division. The fibers leave the spinal cord through the anterior roots in the thoracic and upper lumbar segments.

The Spinal Tracts

The white matter of the spinal cord is composed of myelinated and unmyelinated nerve fibers. The fast-conducting myelinated fibers form bundles; fiber bundles with a common function are called *tracts.*

There are six ascending tracts (see Fig. 60-7). Two tracts, known as the fasciculus cuneatus and gracilis or the posterior columns, conduct sensations of deep touch, pressure, vibration, position, and passive motion from the same side of the body. Before reaching the cerebral cortex, these fibers cross to the opposite side in the medulla. The anterior and posterior spinocerebellar tracts conduct sensory impulses from muscle spindles, providing necessary input for coordinated muscle contraction. They ascend uncrossed and terminate in the cerebellum. The anterior and lateral spinothalamic tracts are responsible for conduction of pain, temperature, proprioception, fine touch, and vibratory sense from the upper body to the brain. They cross to the opposite side of the cord and then ascend to the brain, terminating in the thalamus (Klein & Stewart-Amidei, 2017).

There are eight descending tracts (see Fig. 60-7). The anterior and lateral corticospinal tracts conduct motor impulses to the anterior horn cells from the opposite side of the brain, cross in the medulla, and control voluntary muscle activity. The three vestibulospinal tracts descend uncrossed and are involved in some autonomic functions (sweating, pupil dilation, and circulation) and involuntary muscle control. The corticobulbar tract conducts impulses responsible for voluntary head and facial muscle movement and crosses at the level of the brain stem. The rubrospinal and reticulospinal tracts conduct impulses involved with involuntary muscle movement.

Vertebral Column

The bones of the vertebral column surround and protect the spinal cord and normally consist of 7 cervical, 12 thoracic, and 5 lumbar vertebrae, as well as the sacrum (a fused mass of 5 vertebrae) and terminate in the coccyx. Nerve roots exit from the vertebral column through the intervertebral foramina (openings). The vertebrae are separated by discs, except for the first and second cervical, the sacral, and the coccygeal vertebrae. Each vertebra has a ventral solid body and a dorsal segment or arch, which is posterior to the body. The arch is composed of two pedicles and two laminae supporting seven processes. The vertebral body, arch, pedicles, and laminae all encase and protect the spinal cord.

The Peripheral Nervous System

The peripheral nervous system includes the cranial nerves, the spinal nerves, and the autonomic nervous system.

Cranial Nerves

Twelve pairs of cranial nerves emerge from the lower surface of the brain and pass through openings in the base of the skull. Three cranial nerves are entirely sensory (I, II, VIII), five are motor (III, IV, VI, XI, and XII), and four are mixed sensory and motor (V, VII, IX, and X). The cranial nerves are numbered in the order in which they arise from the brain (see Fig. 60-8). The cranial nerves innervate the head, neck, and special sense structures. Table 60-2 provides a summary of the cranial nerves.

Spinal Nerves

The spinal cord is composed of 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Each spinal nerve has a ventral root and a dorsal root. The dorsal roots are sensory and transmit sensory impulses from specific areas of the body known as dermatomes (see Fig. 60-9) to the dorsal horn ganglia. The sensory fiber may be somatic, carrying

information about pain, temperature, touch, and position sense (proprioception) from the tendons, joints, and body surfaces; or visceral, carrying information from the internal organs.

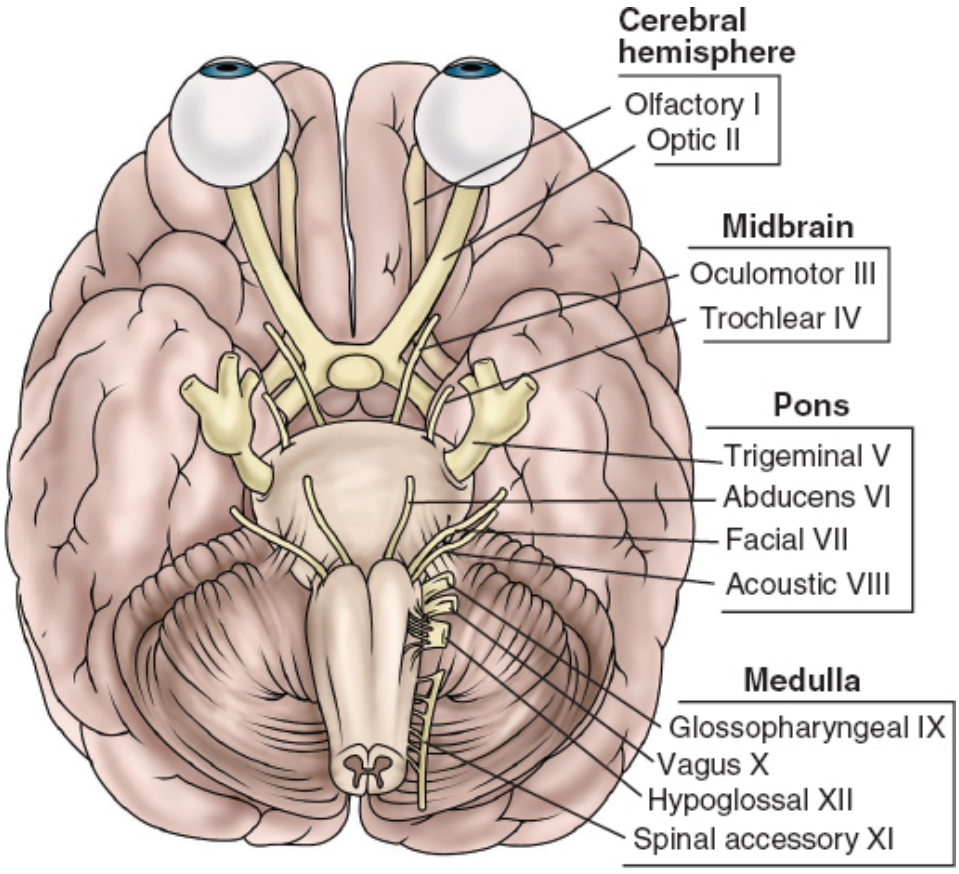

Figure 60-8 • Diagram of the base of the brain showing location of the cranial nerves.

TABLE 60-2 Summary of Cranial Nerves

Nerve (Number)	Type	Functions	Methods for Examining Nerve
Olfactory (I)	Sensory	Sense of smell	Test each nostril for smell reception with various agents and interpretation
Optic (II)	Sensory	Sense of vision	Test vision for acuity and visual fields
Oculomotor (III)	Motor	Pupil constriction	
	Raise eyelids	Test pupillary reaction to light and ability to open and close eyelids	
Trochlear (IV)	Motor/proprioceptor	Downward, inward eye movement	Test for downward and inward movement of the eye
Trigeminal (V)	Motor	Jaw movements—chewing and mastication	Ask patient to open and clench jaws while you palpate the jaw muscles
	Sensory	Sensation on the face and neck	Test face and neck for pain sensations, light touch, and temperature
Abducens (VI)	Motor	Lateral movement of the eyes	Test ocular movement in all directions
Facial (VII)	Motor	Muscles of the face	Ask the patient to raise eyebrows, smile, show teeth, and puff out cheeks
	Sensory	Sense of taste on the anterior two thirds of the tongue	Test for the taste sensation with various agents
Acoustic (VIII)	Sensory	Sense of hearing	Test hearing ability
Glossopharyngeal (IX)	Motor	Pharyngeal movement and swallowing	Ask the patient to say “ah,” and have patient yawn to observe upward movement of the soft palate; elicit gag

			response; note ability to swallow
	Sensory	Sense of taste on the posterior one third of the tongue	Test for taste with various agents
Vagus (X)	Motor/sensory	Swallowing and speaking	Ask the patient to swallow and speak; note hoarseness
Accessory (XI)	Motor/sensory	Movement of shoulder muscles	Ask the patient to shrug shoulders against your resistance
Hypoglossal (XII)	Motor	Movement of the tongue; strength of the tongue	Ask the patient to protrude tongue; ask patient to push tongue against cheek

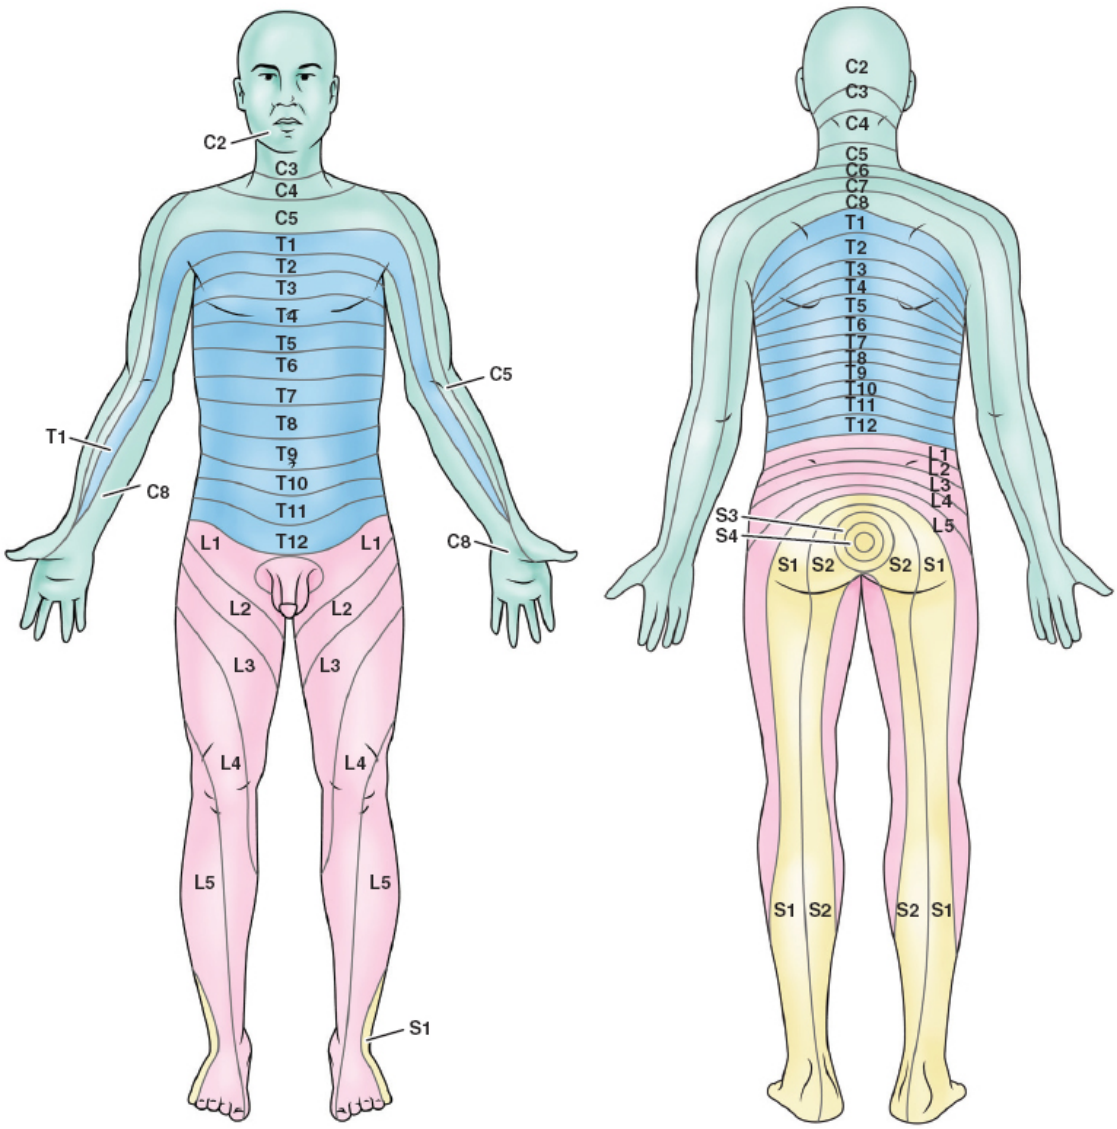

Figure 60-9 • Dermatome distribution.

The ventral roots are motor and transmit impulses from the spinal cord to the body; these fibers are also either somatic or visceral. The visceral fibers include autonomic fibers that control the cardiac muscles and glandular secretions.

Autonomic Nervous System

The **autonomic nervous system** regulates the activities of internal organs such as the heart, lungs, blood vessels, digestive organs, and glands (see Fig. 60-10). Maintenance and restoration of internal homeostasis is largely the responsibility of the autonomic nervous system. There are two major divisions: the **sympathetic nervous system**, with predominantly excitatory responses (i.e., the "fight-or-flight" response), and the parasympathetic nervous system, which controls mostly visceral functions.

The autonomic nervous system innervates most body organs. Although usually considered part of the peripheral nervous system, this system is regulated by centers in the spinal cord, brain stem, and hypothalamus.

The hypothalamus is the major subcortical center for the regulation of autonomic activities, serving an inhibitory–excitatory role. The hypothalamus has connections that link the autonomic system with the thalamus, the cortex, the olfactory apparatus, and the pituitary gland. Located here are the mechanisms for the control of visceral and somatic reactions that were originally important for defense or attack and are associated with emotional states (e.g., fear, anger, anxiety); for the control of metabolic processes, including fat, carbohydrate, and water metabolism; for the regulation of body temperature, arterial pressure, and all muscular and glandular activities of the gastrointestinal tract; for control of genital functions; and for the sleep cycle.

The autonomic nervous system is separated into the anatomically and functionally distinct sympathetic and parasympathetic divisions. Most of the tissues and the organs under autonomic control are innervated by both systems. For example, the parasympathetic division causes contraction (stimulation) of the urinary bladder muscles and a decrease (inhibition) in heart rate, whereas the sympathetic division produces relaxation (inhibition) of the urinary bladder and an increase (stimulation) in the rate and force of the heartbeat. Table 60-3 compares the sympathetic and the parasympathetic effects on the different systems of the body.

Sympathetic Nervous System

The sympathetic division of the autonomic nervous system is best known for its role in the body's fight-or-flight response. Under stress from either physical or emotional causes, sympathetic impulses increase greatly. As a result, the bronchioles dilate for easier gas exchange; the heart's contractions are stronger and faster; the arteries to the heart and voluntary muscles dilate, carrying more blood to these organs; peripheral blood vessels constrict, making the skin feel cool but shunting blood to essential organs; the pupils dilate; the liver releases glucose for quick energy; peristalsis slows; hair stands on end; and perspiration increases. The main sympathetic neurotransmitter is norepinephrine (noradrenaline). A sympathetic discharge releases epinephrine (adrenalin)—hence, the term *adrenergic* is often used to refer to this division.

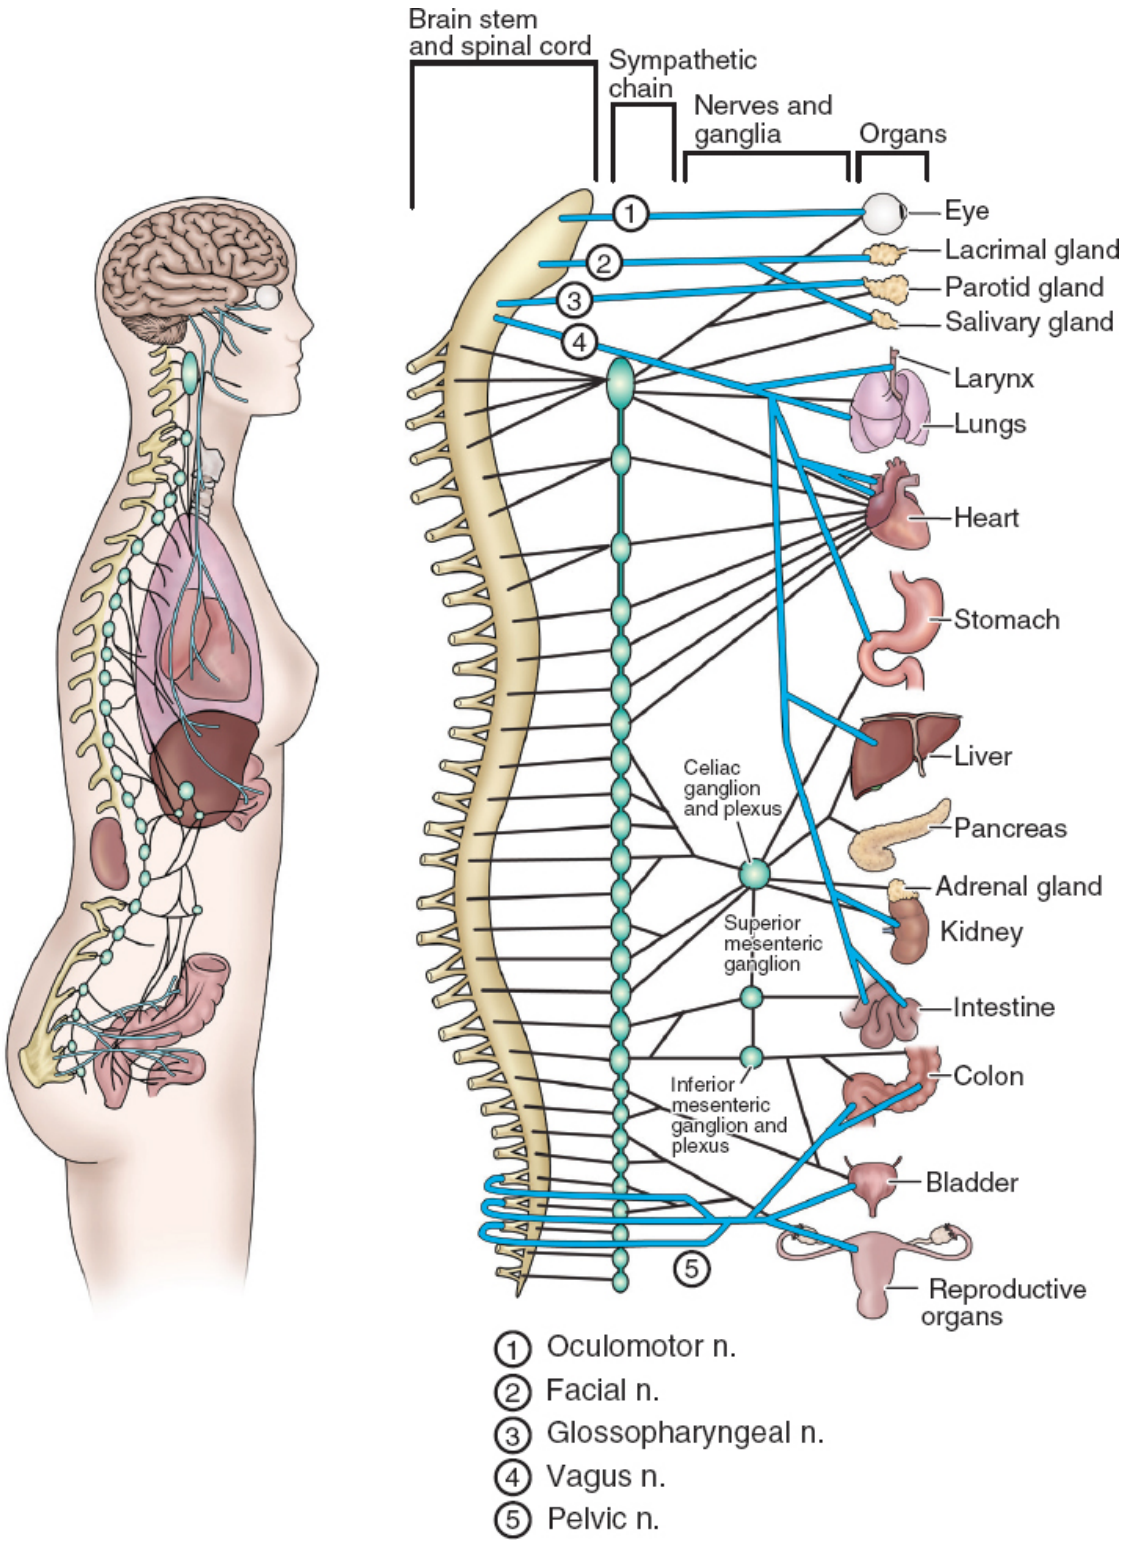

Figure 60-10 • Anatomy of the autonomic nervous system.

Sympathetic neurons are located primarily in the thoracic and lumbar segments of the spinal cord, and their axons, or the preganglionic fibers, emerge by way of anterior nerve roots from the eighth cervical or first thoracic segment to the second or third lumbar segment. A short distance from the cord,

these fibers diverge to join a chain, composed of 22 linked ganglia, that extends the entire length of the spinal column, adjacent to the vertebral bodies on both sides. Some form multiple synapses with nerve cells within the chain. Others traverse the chain without making connections or losing continuity to join large "prevertebral" ganglia in the thorax, the abdomen, or the pelvis or one of the "terminal" ganglia in the vicinity of an organ, such as the bladder or the rectum at the end of the colon (see Fig. 60-10). Postganglionic nerve fibers originating in the sympathetic chain rejoin the spinal nerves that supply the extremities and are distributed to blood vessels, sweat glands, and smooth muscle tissue in the skin. Postganglionic fibers from the prevertebral plexuses (e.g., the cardiac, pulmonary, splanchnic, pelvic plexuses) supply structures in the head and neck, thorax, abdomen, and pelvis, respectively, having been joined in these plexuses by fibers from the parasympathetic division.

TABLE 60-3  Effects of the Autonomic Nervous System

Structure or Activity	Parasympathetic Effects	Sympathetic Effects
Pupil of the Eye	Constricted	Dilated
Circulatory System		
Rate and force of heartbeat	Decreased	Increased
Blood vessels		
In heart muscle	Constricted	Dilated
In skeletal muscle	*a*	Dilated
In abdominal viscera and the skin	*a*	Constricted
Blood pressure	Decreased	Increased
Respiratory System		
Bronchioles	Constricted	Dilated
Rate of breathing	Decreased	Increased
Gastrointestinal System		
Peristaltic movements of digestive tube	Increased	Decreased
Muscular sphincters of digestive tube	Relaxed	Contracted
Secretion of salivary glands	Thin, watery saliva	Thick, viscid saliva
Secretions of stomach, intestine, and pancreas	Increased	*a*
Conversion of liver glycogen to glucose	*a*	Increased
Genitourinary System		
Urinary bladder		
Muscle walls	Contracted	Relaxed
Sphincters	Relaxed	Contracted
Muscles of the uterus	Relaxed; variable	Contracted under some conditions; varies with menstrual cycle and pregnancy
Blood vessels of external genitalia	Dilated	*a*
Integumentary System		
Secretion of sweat	*a*	Increased
Pilomotor muscles	*a*	Contracted (goose flesh)
Adrenal Medulla	*a*	Secretion of epinephrine and norepinephrine

[a]No direct effect.

The adrenal glands, kidneys, liver, spleen, stomach, and duodenum are under the control of the giant celiac plexus, commonly known as the solar plexus. This receives its sympathetic nerve components by way of the three splanchnic nerves, composed of preganglionic fibers from nine segments of the spinal cord (T4 to L1), and is joined by the vagus nerve, representing the parasympathetic division. From the celiac plexus, fibers of both divisions travel along the course of blood vessels to their target organs.

Certain syndromes are distinctive to the sympathetic nervous system. For example, sympathetic storm is a syndrome associated with changes in level of consciousness, altered vital signs, diaphoresis, and agitation that may result from hypothalamic stimulation of the sympathetic nervous system following traumatic brain injury (Fischbach & Fischbach, 2018).

Parasympathetic Nervous System

The **parasympathetic nervous system** functions as the dominant controller for most visceral functions; the primary neurotransmitter is acetylcholine. During quiet, nonstressful conditions, impulses from parasympathetic fibers (cholinergic) predominate. The fibers of the parasympathetic system are located in two sections: one in the brain stem and the other from spinal segments below L2. Because of the location of these fibers, the parasympathetic system is referred to as the craniosacral division, as distinct from the thoracolumbar (sympathetic) division of the autonomic nervous system.

The parasympathetic nerves arise from the midbrain and the medulla oblongata. Fibers from cells in the midbrain travel with the third oculomotor nerve to the ciliary ganglia, where postganglionic fibers of this division are joined by those of the sympathetic system, creating controlled opposition, with a delicate balance always maintained between the two systems.

Motor and Sensory Pathways of the Nervous System

Motor pathways within the CNS are responsible for voluntary, involuntary, and coordination of movement. Sensory pathways receive, integrate, and transmit a wide variety of sensations within the CNS.

Motor Pathways

The corticospinal tract begins in the motor cortex, a vertical band within each frontal lobe, and controls voluntary movements of the body. The exact locations within the brain at which the voluntary movements of the muscles of the face, thumb, hand, arm, trunk, and leg originate are known (see Fig. 60-11). To initiate movement, these particular cells must send the stimulus along their fibers. Stimulation of these cells with an electric current also results in muscle contraction. En route to the pons, the motor fibers converge into a tight bundle known as the internal capsule. A comparatively small injury to the internal capsule results in a more severe paralysis than does a larger injury to the cortex itself.

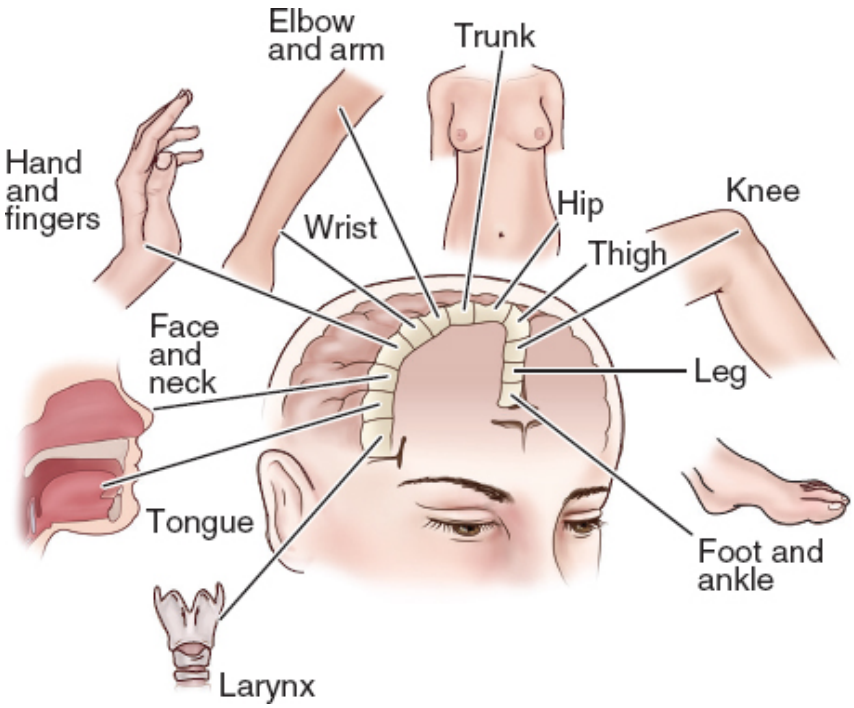

Figure 60-11 • Diagrammatic representation of the cerebrum showing locations for control of motor movement of various parts of the body.

At the medulla, the corticospinal tracts cross to the opposite side, continuing to the anterior horn of the spinal cord, in proximity to a motor nerve cell. Until this point, neurons are known as upper motor neurons. As they connect to motor fibers of the spinal nerves, they become lower motor neurons. The lower motor neurons receive the impulse in the posterior part of the cord and run to the myoneural junction located in the peripheral muscle.

Involuntary motor activity is also possible and is mediated through reflex arcs. Synaptic connections between anterior horn cells and sensory fibers that have entered adjacent or neighboring segments of the spinal cord serve as protective mechanisms. These connections are seen during deep tendon reflex testing.

Upper and Lower Motor Neurons

The voluntary motor system consists of two groups of neurons: upper motor neurons and lower motor neurons. Upper motor neurons originate in the cerebral cortex, the cerebellum, and the brain stem. Their fibers make up the descending motor pathways, are located entirely within the CNS, and modulate the activity of the lower motor neurons. Lower motor neurons are located either in the anterior horn of the spinal cord gray matter or within cranial nerve nuclei in the brain stem. Axons of lower motor neurons in both sites extend through peripheral nerves and terminate in skeletal muscle. Lower motor neurons are located in both the CNS and the peripheral nervous system.

The motor pathways from the brain to the spinal cord, as well as from the cerebrum to the brain stem, are formed by upper motor neurons. They begin in the cortex of one side of the brain, descend through the internal capsule, cross to the opposite side in the brain stem, descend through the corticospinal tract, and synapse with the lower motor neurons in the cord. The lower motor neurons receive the impulse in the posterior part of the cord and run to the myoneural junction located in the peripheral muscle. The clinical features of lesions of upper and lower motor neurons are discussed in the following sections and in Table 60-4.

TABLE 60-4 Comparison of Upper Motor Neuron and Lower Motor Neuron Lesions

Upper Motor Neuron Lesions	Lower Motor Neuron Lesions
Loss of voluntary control	Loss of voluntary control
Increased muscle tone	Decreased muscle tone
Muscle spasticity	Flaccid muscle paralysis
No muscle atrophy	Muscle atrophy
Hyperactive and abnormal reflexes	Absent or decreased reflexes

Adapted from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological and neurosurgical nursing* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Upper Motor Neuron Lesions

Upper motor neuron lesions can involve the motor cortex, the internal capsule, the spinal cord gray matter, and other structures of the brain through which the corticospinal tract descends. If the upper motor neurons are damaged or destroyed, as frequently occur with stroke or spinal cord injury, paralysis (loss of voluntary movement) results. However, because the inhibitory influences of intact upper motor neurons are impaired, **reflex** (involuntary) movements are uninhibited, and hence hyperactive deep tendon reflexes, diminished or absent superficial reflexes, and pathologic reflexes such as a Babinski response occur. Severe leg spasms can occur as the result of an upper motor neuron lesion; the spasms result from the preserved reflex arc, which lacks inhibition along the

spinal cord below the level of injury. There is little or no muscle atrophy, and muscles remain permanently tense, exhibiting spastic paralysis.

Paralysis associated with upper motor neuron lesions can affect a whole extremity, both extremities, or an entire half of the body. *Hemiplegia* (paralysis of an arm and leg on the same side of the body) can be the result of an upper motor neuron lesion. If hemorrhage, an embolus, or a thrombus destroys the fibers from the motor area in the internal capsule, the arm and the leg of the opposite side become stiff, weak, or paralyzed, and the reflexes are hyperactive. If both legs are paralyzed, the condition is called *paraplegia.* If all four extremities are paralyzed, the condition is called *tetraplegia* (quadriplegia). See Chapter 63 for additional discussion of these disorders.

Lower Motor Neuron Lesions

A patient is considered to have lower motor neuron damage if a motor nerve is damaged between the spinal cord and muscle. The result of lower motor neuron damage is muscle paralysis. Reflexes are lost, and the muscle becomes flaccid (limp) and atrophied from disuse. If the patient has injured the spinal trunk and it can heal, the use of muscles connected to that section of the spinal cord may be regained. However, if the anterior horn motor cells are destroyed, the nerves cannot regenerate, and the muscles are never useful again.

Flaccid paralysis and atrophy of the affected muscles are the principal signs of lower motor neuron disease. Lower motor neuron lesions can be the result of trauma, infection (poliomyelitis), toxins, vascular disorders, congenital malformations, degenerative processes, and neoplasms. Compression of nerve roots by herniated intervertebral discs is a common cause of lower motor neuron dysfunction.

Coordination of Movement

The motor system is complex, and motor function depends not only on the integrity of the corticospinal tracts but also on other pathways from the basal ganglia and cerebellum that control and coordinate voluntary motor function. The smoothness, accuracy, and strength that characterize the muscular movements of a normal person are attributable to the influence of the cerebellum and the basal ganglia.

Through the action of the cerebellum, the contractions of opposing muscle groups are adjusted in relation to each other to maximal mechanical advantage; muscle contractions can be sustained evenly at the desired tension and without significant fluctuation, and reciprocal movements can be reproduced at high and constant speed, in stereotyped fashion and with relatively little effort.

The basal ganglia play an important role in planning and coordinating motor movements and posture. Complex neural connections link the basal ganglia with the cerebral cortex. The major effect of these structures is to inhibit unwanted muscular activity.

Impaired cerebellar function, which may occur as a result of an intracranial injury or some type of an expanding mass (e.g., a hemorrhage, an abscess, or a tumor), results in loss of muscle tone, weakness, and fatigue. Depending on the area of the brain affected, the patient has different motor symptoms or responses. The patient may demonstrate abnormal flexion, abnormal extension, or flaccid posturing. **Flaccidity** (lack of muscle tone) preceded by abnormal posturing in a patient with cerebral injury indicates severe neurologic impairment, which may herald brain death (Klein & Stewart-Amidei, 2017; Posner, Saper, Schiff, et al., 2019). See Chapter 61, Figure 61-1 for further explanation of posturing.

Destruction or dysfunction of the basal ganglia leads not to paralysis but to muscle rigidity, disturbances of posture, and difficulty initiating or changing movement. The patient tends to have involuntary movements. These may take the form of coarse tremors, most often in the upper extremities, particularly in the distal portions; athetosis, which is movement of a slow, squirming, writhing, twisting type; or chorea, marked by spasmodic, purposeless, irregular, uncoordinated motions of the trunk and the extremities, and facial grimacing. Disorders affecting basal ganglia activity include Parkinson's and Huntington diseases (see Chapter 65).

Sensory System Function

Receiving Sensory Impulses

Afferent impulses travel from their points of origin to their destinations in the cerebral cortex via the ascending pathways directly, or they may cross at the level of the spinal cord or in the medulla, depending on the type of sensation carried. Knowledge of these pathways is important for neurologic assessment and for understanding symptoms and their relationship to various lesions.

Sensory impulses convey sensations of heat, cold, and pain; position; and vibration. The axons enter the spinal cord by way of the posterior root, specifically in the posterior gray columns of the spinal cord, where they connect with the cells of secondary neurons. Pain and temperature fibers (located in the spinothalamic tract) cross immediately to the opposite side of the cord and course upward to the thalamus. Fibers carrying sensations of touch, light pressure, and localization do not connect immediately with the second neuron but ascend the cord for a variable distance before entering the gray matter and completing this connection. The axon of the secondary neuron traverses the cord, crosses in the medulla, and proceeds upward to the thalamus.

Position and vibratory sensations are produced by stimuli arising from muscles, joints, and bones. These stimuli are conveyed, uncrossed, all the way to the brain stem by the axon of the primary neuron. In the medulla, synaptic

connections are made with cells of the secondary neurons, whose axons cross to the opposite side and then proceed to the thalamus.

Integrating Sensory Impulses

The thalamus integrates all sensory impulses except olfaction. It plays a role in the conscious awareness of pain and the recognition of variation in temperature and touch. The thalamus is responsible for the sense of movement and position as well as the ability to recognize the size, shape, and quality of objects. Sensory information is relayed from the thalamus to the parietal lobe for interpretation.

Sensory Losses

Destruction of a sensory nerve results in total loss of sensation in its area of distribution (see Fig. 60-9). Lesions affecting the posterior spinal nerve roots may impair tactile sensation, causing intermittent severe pain that is referred to their areas of distribution. Destruction of the spinal cord yields complete anesthesia below the level of injury. Selective destruction or degeneration of the posterior columns of the spinal cord is responsible for a loss of position and vibratory sense in segments distal to the lesion, without loss of touch, pain, or temperature perception. A cyst in the center of the spinal cord causes dissociation of sensation—loss of pain at the level of the lesion. This occurs because the fibers carrying pain and temperature cross within the cord immediately on entering; thus, any lesion that divides the cord longitudinally divides these fibers. Other sensory fibers ascend the cord for variable distances, some even to the medulla, before crossing, thereby bypassing the lesion and avoiding destruction. Lesions in the thalamus or parietal lobe result in impaired touch, pain, temperature, and proprioceptive sensations.

Assessment of the Nervous System

An assessment of the nervous system involves conducting a health history and physical assessment.

Health History

An important aspect of the neurologic assessment is the history of the present illness. The initial interview provides an excellent opportunity to systematically explore the patient's current condition and related events while simultaneously observing overall appearance, mental status, posture, movement, and affect. Depending on the patient's condition, the nurse may need to rely on yes-or-no answers to questions, a review of the medical record, input from witnesses or the family, or a combination of these.

Neurologic disorders may be stable or progressive, characterized by symptom-free periods as well as fluctuations in symptoms. The health history therefore includes details about the onset, character, severity, location, duration, and frequency of symptoms and signs; associated complaints; precipitating, aggravating, and relieving factors; progression, remission, and exacerbation; and the presence or absence of similar symptoms among family members.

Common Symptoms

The symptoms of neurologic disorders are as varied as the disease processes. Symptoms may be subtle or intense, fluctuating or permanent, inconvenient or devastating. This chapter discusses the most common signs and symptoms associated with neurologic disease; the relationship of specific signs and symptoms to a disorder is presented in later chapters in this unit.

Pain

Pain is considered an unpleasant sensory perception and emotional experience associated with actual or potential tissue damage or described in terms of such damage. Pain is therefore considered multidimensional and entirely subjective. Pain can be acute or chronic. In general, acute pain lasts for a relatively short period of time and remits as the pathology resolves. In neurologic disease, acute pain may be associated with brain hemorrhage, spinal disc disease (Jarvis, 2020), or trigeminal neuralgia. In contrast, chronic or persistent pain extends for long periods of time and may represent a broader pathology. This type of pain can occur with many degenerative and chronic neurologic conditions (e.g., multiple sclerosis). See Chapter 9 for a more detailed discussion of pain.

Seizures

Seizures are the result of abnormal electrical discharges in the cerebral cortex, which then manifest as an alteration in sensation, behavior, movement, perception, or consciousness. The alteration may be short, such as in a blank stare that lasts only a second, or of longer duration, such as a tonic–clonic grand mal seizure that can last several minutes. The seizure activity reflects the area of the brain affected. Seizures can occur as isolated events, such as when induced by a high fever, alcohol or drug withdrawal, or hypoglycemia. A seizure may also be the first obvious sign of a brain lesion (Hickey & Strayer, 2020).

Dizziness and Vertigo

Dizziness is an abnormal sensation of imbalance or movement. It is common in the older adult and a common complaint encountered by health

professionals (Jarvis, 2020). Dizziness can have a variety of causes, including viral syndromes, hot weather, roller-coaster rides, and middle ear infections, to name a few. One difficulty confronting health care providers when assessing dizziness is the vague and varied terms that patients use to describe the sensation.

About 50% of all patients with dizziness have **vertigo**, or the illusion of movement in which the individual or the surroundings are sensed as moving, usually as rotation (Jarvis, 2020). Vertigo is usually a manifestation of vestibular dysfunction. It can be so severe as to result in spatial disorientation, lightheadedness, loss of equilibrium (staggering), and nausea and vomiting.

Visual Disturbances

Visual defects that cause people to seek health care can range from the decreased visual acuity associated with aging to sudden blindness caused by glaucoma. Normal vision depends on functioning visual pathways through the retina and optic chiasm and the radiations into the visual cortex in the occipital lobes. Lesions of the eye itself (e.g., cataract), lesions along the pathway (e.g., tumor), or lesions in the visual cortex (e.g., stroke) interfere with normal visual acuity. Abnormalities of eye movement (as in the nystagmus associated with multiple sclerosis) can also compromise vision by causing diplopia or double vision. See Chapter 58 for a more detailed discussion of disorders that affect vision.

Muscle Weakness

Muscle weakness is a common manifestation of neurologic disease. It frequently coexists with other symptoms of disease and can affect a variety of muscles, causing a wide range of disability. Weakness can be sudden and permanent, as in stroke, or progressive, as in neuromuscular diseases such as amyotrophic lateral sclerosis. Any muscle group can be affected.

Abnormal Sensation

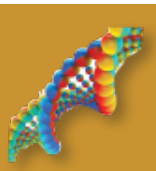
Abnormal sensation is a neurologic manifestation of both central and peripheral nervous system disease. Altered sensation can affect small or large areas of the body. It is frequently associated with weakness or pain and is potentially disabling. Lack of sensation places a person at risk for falls and injury.

Past Health, Family, and Social History

The nurse may inquire about any family history of genetic diseases (see Chart 60-1). A review of the medical history, including a system-by-system evaluation, is part of the health history. The nurse should be aware of any history of trauma or falls that may have involved the head or spinal cord.

Questions regarding the use of alcohol, medications, and illicit drugs are also relevant. The history-taking portion of the neurologic assessment is critical and, in many cases of neurologic disease, leads to an accurate diagnosis.

Physical Assessment 



The neurologic examination is a systematic process that includes a variety of clinical tests, observations, and assessments designed to evaluate the neurologic status of a complex system. Many neurologic rating scales exist (Herndon, 2006), and some of the more common ones are discussed in this chapter.

The brain and spinal cord cannot be examined as directly as other systems of the body. Therefore, much of the neurologic examination is an indirect evaluation that assesses the function of the specific body part or parts controlled by the nervous system. A neurologic assessment is divided into five components: consciousness and cognition, cranial nerves, motor system, sensory system, and reflexes. One or more components may become the priority assessment, depending on the patient's condition. For example, motor, sensory, and reflex assessments are the priority in patients with spinal injury, whereas in a patient who is comatose, the cranial nerves and level of consciousness become the priority.

Assessing Consciousness and Cognition

Cerebral abnormalities may cause disturbances in mental status, intellectual functioning, thought content, and emotional status. There may also be alterations in language abilities as well as lifestyle. The examiner must also be aware of the patient's overall level of consciousness and any changes over time (Posner et al., 2019).

The examiner records and reports specific observations regarding mental status, intellectual function, thought content, and emotional status, all of which permit comparison by others over time. Alterations should be described in specific and nonjudgmental terms. The use of terms such as "inappropriate" or "demented" is avoided, because they often mean different things to different people and are therefore not useful when describing behavior. Analysis and the conclusions that may be drawn from these findings usually depend on the examiner's knowledge of neuroanatomy, neurophysiology, and neuropathology.

Chart 60-1  GENETICS IN NURSING PRACTICE

Neurologic Disorders

Several neurologic disorders are associated with genetic abnormalities. Neurologic impairment is noted with many other genetic illnesses. Some examples include:

Autosomal Dominant:

- Cerebral arteriopathy
- Familial Alzheimer's disease
- Huntington disease
- Myotonic dystrophies
- Neurofibromatosis
- Von Hippel–Lindau syndrome

Autosomal Recessive:

- Canavan disease
- Familial dysautonomia
- Friedreich ataxia

X Linked:

- Duchenne muscular dystrophy
- Fragile X syndrome

Inheritance pattern is not distinct; however, there is a genetic predisposition for the disease:

- Amyotrophic lateral sclerosis (ALS)
- Epilepsy
- Neural tube defects (e.g., spina bifida, anencephaly)
- Parkinson's disease
- Tourette syndrome

Other genetic disorders that also impact the neurologic system:

- Bipolar disease
- Down syndrome
- Phenylketonuria (PKU)
- Schizophrenia
- Tay–Sachs disease
- Tuberous sclerosis complex

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Neurologic Disorders

- Assess for other similarly affected relatives with neurologic impairment.
- Inquire about age of onset (e.g., present at birth—spina bifida; developed in childhood—Duchenne muscular dystrophy; developed in adulthood—Huntington disease, Alzheimer's disease, ALS).
- Inquire about the presence of related conditions such as intellectual disability or learning disabilities (neurofibromatosis type 1).

Patient Assessment

- Assess for the presence of other physical features suggestive of an underlying genetic condition, such as skin lesions seen in neurofibromatosis (*café-au-lait* spots).
- Assess attention span, and the presence of hyperactivity or withdrawn behavior.
- Assess for other congenital abnormalities (e.g., cardiac, ocular).
- Inspect for presence of freckles in the axillary or inguinal areas.
- Assess for presence of uncoordinated movement of extremities, muscle twitching, or history of seizures.
- Assess for poor or hyperactive muscle tone.
- Assess for episodes of forgetfulness or uncharacteristic changes in behavior or mood.
- Inspect for disproportionate facial features (fragile X or Down syndrome).
- Observe for presence of "tics" or uncontrolled body movement.
- Ask about history of seizures or head trauma.

Mental Status

An assessment of mental status begins by observing the patient's appearance and behavior, noting dress, grooming, and personal hygiene. Posture, gestures, movements, and facial expressions often provide important information about the patient. Does the patient appear to be aware of and interact with the surroundings?

Assessing orientation to time, place, and person assists in evaluating mental status. Does the patient know what day it is, what year it is, and the name of the president of the United States? Is the patient aware of where they are? Is the patient aware of who the examiner is and of their purpose for being in the room? Assessment of immediate and remote memory is also important. Is the capacity for immediate memory intact?

Intellectual Function

A person with an average intelligence quotient (IQ) can repeat seven digits without faltering and can recite five digits backward. The examiner might ask the patient to count backward from 100 or to subtract 7 from 100, then 7 from that, and so forth (referred to as serial 7s). The capacity to interpret well-known proverbs tests abstract reasoning, which is a higher intellectual function —for example, does the patient know what is meant by "a stitch in time saves nine"? The intellectual function of patients with damage to the frontal cortex appears intact until one or more tests of intellectual capacity are performed. Questions designed to assess this capacity might include the ability to recognize similarities—for example, how are a mouse and dog or pen and pencil alike? Can the patient make judgments about situations—for example, if the patient arrives home without a house key, what alternatives are there?

Thought Content

During the interview, it is important to assess the patient's thought content. Are the patient's thoughts spontaneous, natural, clear, relevant, and coherent? Does the patient have any fixed ideas, illusions, or preoccupations? What are their insights into these thoughts? Preoccupation with death or morbid events, hallucinations, and paranoid ideation are examples of unusual thoughts or perceptions that require further evaluation.

Emotional Status

An assessment of consciousness and cognition also includes the patient's emotional status. Is the patient's affect (external manifestation of mood) natural and even, or irritable and angry, anxious, apathetic or flat, or euphoric? Does their mood fluctuate normally, or does the patient unpredictably swing from joy to sadness during the interview? Is affect appropriate to words and thought content? Are verbal communications consistent with nonverbal cues?

Language Ability

The person with normal neurologic function can understand and communicate in spoken and written language. Does the patient answer questions appropriately? Can they read a sentence from a newspaper and explain its meaning? Can the patient write their name or copy a simple figure that the examiner has drawn? A deficiency in language function is called *aphasia.* Different types of aphasia result from injury to different parts of the brain (see Table 60-5). See Chapter 62 for a detailed discussion of aphasia.

Impact on Lifestyle

The nurse assesses the impact of any impairment on the patient's lifestyle. Issues to consider include the limitations imposed on the patient by any

cognitive deficit and the patient's role in society, including family and community roles. The plan of care that the nurse develops needs to address and support adaptation to the neurologic deficit and continued function to the extent possible within the patient's support system.

Level of Consciousness

Consciousness is the patient's wakefulness and ability to respond to the environment. Level of consciousness is the most sensitive indicator of neurologic function. To assess level of consciousness, the examiner observes for alertness and ability to follow commands.

If the patient is not alert or able to follow commands, the examiner observes for eye opening; verbal response and motor response to stimuli, if any; and the type of stimuli needed to obtain a response. Noxious stimuli should be used first, then painful stimuli if no response is observed. In the patient with decreased level of consciousness, motor and cranial nerve functions become the priority assessments, because abnormalities can indicate the area of involvement in the absence of responsiveness. See Chapter 61 for further discussion of changes in level of consciousness.

TABLE 60-5 Types of Aphasia and Region of Brain Involved

Type of Aphasia	Brain Area Involved
Auditory receptive	Temporal lobe
Visual receptive	Parietal and occipital area
Expressive speaking	Inferior–posterior frontal areas
Expressive writing	Posterior frontal area

Unfolding Patient Stories: Marilyn Hughes • Part 2

Recall from Chapter 37 Marilyn Hughes, who came to the hospital after falling on icy stairs. She sustained a left midshaft tibia–fibula fracture, which requires surgery. Her husband informs the nurse that she also hit her head and did not respond to him for a short time after the fall. Describe the neurologic assessment performed by the nurse. Why should the nurse report this information promptly to the health care team?

Care for Marilyn and other patients in a realistic virtual environment: vSim(**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Examining the Cranial Nerves

Cranial nerves are assessed when level of consciousness is decreased, with brain stem pathology, or in the presence of peripheral nervous system disease (Weber & Kelley, 2018). Right and left cranial nerve functions are compared throughout the examination.

See Table 60-2 for methods of examining the cranial nerves.

Examining the Motor System

Motor Ability

A thorough examination of the motor system includes an assessment of muscle size and tone as well as strength, coordination, and balance. The patient is instructed to walk across the room, if possible, while the examiner observes posture and gait. The muscles are inspected, and palpated if necessary, for their size and symmetry. Any evidence of atrophy or involuntary movements (tremors, tics) is noted. Muscle tone (the tension present in a muscle at rest) is evaluated by palpating various muscle groups at rest and during passive movement. Resistance to these movements is assessed and documented. Abnormalities in tone include **spasticity** (increased muscle tone), **rigidity** (resistance to passive stretch), and flaccidity.

Muscle Strength

Assessing the patient's ability to flex or extend the extremities against resistance tests muscle strength. The function of an individual muscle or group of muscles is evaluated by placing the muscle at a disadvantage. The quadriceps, for example, is a powerful muscle responsible for straightening the leg. Once the leg is straightened, it is exceedingly difficult for the examiner to flex the knee. If the knee is flexed and the patient is asked to straighten the leg against resistance, weakness can be elicited. The evaluation of muscle strength compares the sides of the body to each other. For example, the right upper extremity is compared to the left upper extremity. Subtle differences in strength may be evaluated by testing for drift. For example, both arms are out in front of the patient with palms up; drift is seen as pronation of the palm, indicating a subtle weakness that may not have been detected on the resistance examination.

Clinicians use a 5-point scale to rate muscle strength. A 5 indicates full power of contraction against gravity and resistance or normal muscle strength; 4 indicates fair but not full strength against gravity and a moderate amount of resistance or slight weakness; 3 indicates just sufficient strength to overcome the force of gravity or moderate weakness; 2 indicates the ability to move but not to overcome the force of gravity or severe weakness; 1 indicates minimal contractile power (weak muscle contraction can be palpated but no movement is noted) or very severe weakness; and 0 indicates no movement (Jarvis, 2020).

Concept Mastery Alert

When recording muscle strength, a stick figure is used as a precise form to document findings. The five-point scale is used to rate and record distal and proximal strength in both upper and lower extremities. Figure 60-12 provides further details.

Assessment of muscle strength may be as detailed as necessary. One may quickly test the strength of the proximal muscles of the upper and lower extremities, always assessing both sides by comparing one side to the other. The strength of the finer muscles that control the function of the hand (hand grasp) and the foot (dorsiflexion and plantar flexion) can then be assessed.

Balance and Coordination

Cerebellar and basal ganglia influence on the motor system is reflected in balance control and coordination. Coordination in the hands and upper extremities is tested by having the patient perform rapid, alternating movements and point-to-point testing. First, the patient is instructed to pat their thigh as fast as possible with each hand separately. Then, the patient is instructed to alternately pronate and supinate the hand as rapidly as possible. Last, the patient is asked to touch each of the fingers with the thumb in a consecutive motion. Speed, symmetry, and degree of difficulty are noted. Point-to-point testing is accomplished by having the patient touch the examiner's extended finger and then their own nose. This is repeated several times.

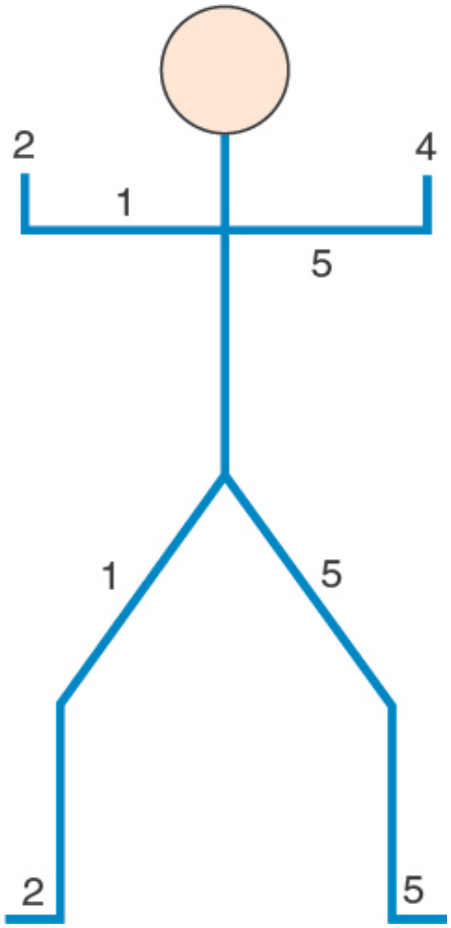

Figure 60-12 • A stick figure may be used to record muscle strength.

Coordination in the lower extremities is tested by having the patient run the heel down the anterior surface of the tibia of the other leg. Each leg is tested in turn. **Ataxia** is an incoordination of voluntary muscle action, particularly of the muscle groups used in activities such as walking or reaching for objects. Tremors (rhythmic, involuntary movements) noted at rest or during movement suggest a problem in the anatomic areas responsible for balance and coordination.

The **Romberg test** is a screening test for balance that can be done with the patient seated or standing. The patient can be seated or stand with feet together and arms at the side, first with eyes open and then with both eyes closed for 20 seconds (Weber & Kelley, 2018). The examiner stands close to support the standing patient if they begin to fall. Slight swaying is normal, but a loss of balance is abnormal and is considered a positive Romberg test. Additional cerebellar tests for balance in the patient who is ambulatory include hopping in place, alternating knee bends, and heel-to-toe walking (both forward and backward).

Examining the Sensory System

The sensory system is even more complex than the motor system, because sensory modalities are more widespread throughout the central and peripheral nervous systems. The sensory examination is largely subjective and requires the cooperation of the patient. The examiner should be familiar with dermatomes that represent the distribution of the peripheral nerves that arise from the spinal cord (see Fig. 60-9) (Jarvis, 2020).

Assessment of the sensory system involves tests for tactile sensation, superficial pain, temperature, vibration, and position sense (proprioception). During the sensory assessment, the patient's eyes are closed. Simple directions and reassurance that the examiner will not hurt or startle the patient encourage the cooperation of the patient.

Tactile sensation is assessed by lightly touching a cotton wisp or fingertip to corresponding areas on each side of the body. The sensitivity of proximal parts of the extremities is compared with that of distal parts, and the right and left sides are compared.

Pain and temperature sensations are transmitted together in the lateral part of the spinal cord, so it is unnecessary to test for temperature sense in most circumstances. Determining the patient's sensitivity to a sharp object can assess superficial pain perception. However, pain sensation is usually reserved for patients who do not respond to or cannot discriminate touch stimulation. The patient is asked to differentiate between the sharp and dull ends of a broken wooden cotton swab or tongue blade; using a safety pin is inadvisable because it breaks the integrity of the skin. Both the sharp and dull sides of the object are applied with equal intensity at all times, and the two sides are compared. In the patient with an altered level of consciousness alternative methods of assessing pain may need to be used (Poulsen, Brix, Andersen, et al., 2016).

Vibration and proprioception are transmitted together in the posterior part of the spinal cord. Vibration may be evaluated through the use of a low-frequency (128 or 256 Hz) tuning fork. The handle of the vibrating fork is placed against a bony prominence, and the patient is asked if a sensation is felt; the patient is then instructed to signal the examiner when the sensation ceases. Common locations used to test for vibratory sense include the distal joint of the great toe and the proximal thumb joint. If the patient does not perceive the vibrations at the distal bony prominences, the examiner progresses upward with the tuning fork until the patient perceives the vibrations. As with all measurements of sensation, a side-to-side comparison is made.

Position sense or proprioception may be determined by asking the patient to close both eyes and indicate, as the great toe or index finger is alternately moved up and down, in which direction movement has taken place. Vibration and position sense are often lost together, frequently in circumstances in which all other sensation remains intact.

Integration of sensation in the brain is evaluated by testing two-point discrimination. When the patient is touched with two sharp objects simultaneously, are they perceived as two or as one? If touched simultaneously on opposite sides of the body, the patient should normally report being touched in two places. If only one site is reported, the one not being recognized is said to demonstrate extinction. Another test of higher cortical sensory ability is tactile identification. The patient is instructed to close both eyes and identify an object (e.g., key, coin) that is placed in one hand by the examiner; inability to identify an object by touch is known as tactile agnosia or astereognosis. **Agnosia** is the general loss of ability to recognize objects through a particular sensory system. The patient can also be shown a familiar object and asked to identify it by name; inability to identify a visualized object is known as visual agnosia. Each of these dysfunctions implicates a different part of the brain (see Table 60-6).

Decreased or absent sensations occur with problems anywhere along the sensory pathway. Sensory deficits resulting from peripheral neuropathy or spinal cord injury follow anatomic dermatomes. Destructive lesions of the brain may affect sensation on an entire side of the body. Stroke affecting a portion of the sensory cortex will produce altered sensory discrimination.

TABLE 60-6 Types of Agnosia and Corresponding Sites of Lesions

Type of Agnosia	Affected Cerebral Area
Visual	Occipital lobe
Auditory	Temporal lobe (lateral and superior portions)
Tactile	Parietal lobe
Body parts and relationships	Parietal lobe (posteroinferior regions)

Examining the Reflexes

Reflexes are involuntary contractions of muscles or muscle groups in response to a stimulus. Reflexes are classified as deep tendon, superficial, or pathologic. Testing reflexes enables the examiner to assess involuntary reflex arcs that depend on the presence of afferent stretch receptors, spinal or brain stem synapses, efferent motor fibers, and a variety of modifying influences from higher levels.

Deep Tendon Reflexes

A reflex hammer is used to elicit a deep tendon reflex. The handle of the hammer is held loosely between the thumb and index finger, allowing a full swinging motion. The wrist motion is similar to that used during percussion. The extremity is positioned so that the tendon is slightly stretched. This

requires a sound knowledge of the location of muscles and their tendon attachments. The tendon is then struck briskly (see Fig. 60-13), and the response is compared with that on the opposite side of the body. A wide variation in reflex response may be considered normal; however, it is more important that the reflexes be symmetrically equivalent. When the comparison is made, both sides should be equivalently relaxed, and each tendon struck with equal force.

Valid findings depend on several factors: proper use of the reflex hammer, proper positioning of the extremity, and a patient who is relaxed (Jarvis, 2020). If the reflexes are symmetrically diminished or absent, the examiner may use isometric contraction of other muscle groups to increase reflex activity. For example, if lower extremity reflexes are diminished or absent, the patient is instructed to lock the fingers together and pull in opposite directions. Having the patient clench the jaw or press the heels against the floor or examining table may similarly elicit more reliable biceps, triceps, and brachioradialis reflexes.

The absence of reflexes is significant, although ankle jerks (Achilles reflex) may be normally absent in older adults. Deep tendon reflex responses are often graded on a scale of 0 to 4+, with 2+ considered normal (see Chart 60-2) but scale ratings are highly subjective. Findings can be recorded as a fraction, indicating the scale range (e.g., 2/4). Some examiners prefer to use the terms *present, absent,* and *diminished* when describing reflexes. As with muscle strength recording, a stick figure may be used to record numerical findings.

Biceps Reflex

The biceps reflex is elicited by striking the biceps tendon over a slightly flexed elbow (see Fig. 60-13A). The examiner supports the forearm at the elbow with one arm while placing the thumb against the tendon and striking the thumb with the reflex hammer. The normal response is flexion at the elbow and contraction of the biceps.

Triceps Reflex

To elicit a triceps reflex, the patient's arm is flexed at the elbow and hanging freely at the side. The examiner supports the patient's arm and identifies the triceps tendon by palpating 2.5 to 5 cm (1 to 2 inches) above the elbow. A direct blow on the tendon (see Fig. 60-13B) normally produces contraction of the triceps muscle and extension of the elbow.

Figure 60-13 • Techniques for eliciting major reflexes. **A.** Eliciting the biceps reflex. **B.** Eliciting the triceps reflex. **C.** Eliciting the patellar reflex. **D.** Eliciting the Achilles reflex. Parts **A**–**D** reprinted with permission from Weber, J., & Kelley, J. (2018). *Health assessment in nursing* (6th ed., Figs. 25-31, 25-32, 25-33A, 25-34A). Philadelphia, PA: Lippincott Williams & Wilkins.

Brachioradialis Reflex

With the patient's forearm resting on the lap or across the abdomen, the brachioradialis reflex is assessed. A gentle strike of the hammer 2.5 to 5 cm (1 to 2 inches) above the wrist results in flexion and supination of the forearm (Jarvis, 2020).

Patellar Reflex

The patellar reflex is elicited by striking the patellar tendon just below the patella. The patient may be in a sitting or a lying position. If the patient is supine, the examiner supports the legs to facilitate relaxation of the muscles (see Fig. 60-13C). Contractions of the quadriceps and knee extension are normal responses.

Achilles Reflex

To elicit an Achilles reflex, the foot is dorsiflexed at the ankle and the hammer strikes the stretched Achilles tendon (see Fig. 60-13D). This reflex normally produces plantar flexion. If the examiner cannot elicit the ankle reflex and suspects that the patient cannot relax, the patient is instructed to kneel on a chair or similar elevated, flat surface. This position places the ankles in dorsiflexion and reduces any muscle tension in the gastrocnemius. The Achilles tendons are struck in turn, and plantar flexion is usually demonstrated (Jarvis, 2020).

Clonus

When reflexes are hyperactive, a movement called **clonus** may be elicited. If the foot is abruptly dorsiflexed, it may continue to "beat" two or three times before it settles into a position of rest. Occasionally with CNS system disease, this activity persists, and the foot does not come to rest while the tendon is being stretched but persists in repetitive activity. The unsustained clonus associated with normal but hyperactive reflexes is not considered pathologic. Sustained clonus always indicates the presence of CNS disease and requires further evaluation.

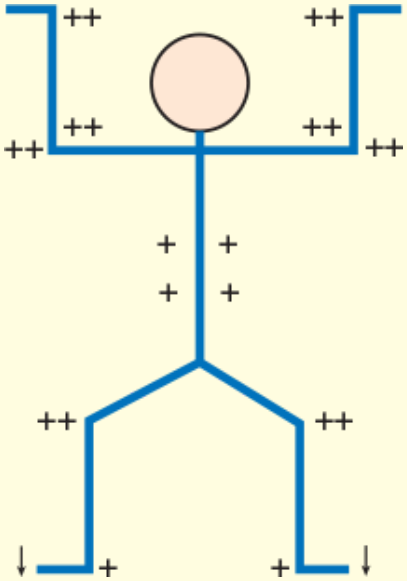

Chart 60-2

Documenting Reflexes

Deep tendon reflexes are graded on a scale of 0–4:

0 No response
1+ Diminished (hypoactive)
2+ Normal
3+ Increased (may be interpreted as normal)
4+ Hyperactive (hyperreflexia)

The deep tendon responses and plantar reflexes are commonly recorded on stick figures. The arrow points downward if the plantar response is normal and upward if the response is abnormal.

Superficial Reflexes

The major superficial reflexes include corneal, palpebral, gag, upper/lower abdominal, cremasteric (men only), and perianal. These reflexes are graded differently than the motor reflexes and are noted to be present (+) or absent (−). Of these, only the corneal, gag, and plantar reflexes are commonly tested.

The corneal reflex is tested carefully using a clean wisp of cotton and lightly touching the outer corner of each eye on the sclera. The reflex is present if the action elicits a blink. A stroke or brain injury might result in loss of this reflex, either unilaterally or bilaterally. Loss of this reflex indicates the need for eye protection and possible lubrication to prevent corneal damage.

The gag reflex is elicited by gently touching the back of the pharynx with a cotton-tipped applicator, first on one side of the uvula and then the other. Positive response is an equal elevation of the uvula and "gag" with stimulation. Absent response on one or both sides can be seen following a stroke and requires careful evaluation and treatment of the resultant swallowing dysfunction to prevent aspiration of food and fluids.

Pathologic Reflexes

Pathologic reflexes are seen in the presence of neurologic disease; they often represent emergence of earlier reflexes that disappeared with maturity of the nervous system. A pathologic reflex indicative of CNS disease affecting the corticospinal tract is the **Babinski reflex (sign)**. In a person with an intact CNS, if the lateral aspect of the sole of the foot is stroked, the toes contract and draw together. However, in a person who has CNS disease of the motor system, the toes fan out and draw back (Jarvis, 2020). This is normal in newborns but represents a serious abnormality in adults. Other pathologic reflexes include the suck (sucking motions in response to touching the lips), snout (lip pursing in response to touching the lips), palmar (grasp in response to stroking the palm), and palmomental (contraction of the facial muscle in response to stimulation of the thenar eminence near the thumb) reflexes in adults. These reflexes often signify progressive nervous system degeneration (Klein & Stewart-Amidei, 2017).

Gerontologic Considerations

During the normal aging process, the nervous system undergoes many changes and is more vulnerable to illness. Age-related changes in the nervous system vary in degree and must be distinguished from those due to disease. It is important for clinicians not to attribute abnormality or dysfunction to aging without appropriate investigation. For example, although diminished strength and agility are a normal part of aging, localized weakness can only be attributed to disease.

Structural and Physiologic Changes

As the brain ages, neurons are lost, leading to a decrease in the number of synapses and neurotransmitters. This results in slowed nerve conduction and response time. Brain weight decreases, and the ventricle size increases to maintain cranial volume leading to a decreased brain volume. These changes in brain volume accelerate even in healthy people between the ages of 60 and 70 years (Battaglini, Gentile, Luchetti, et al., 2019). Cerebral blood flow and metabolism are reduced, leading to slower mental functions. Temperature regulation becomes less efficient. In the peripheral nervous system, myelin is lost, resulting in a decrease in conduction velocity in some nerves. Visual and auditory nerves degenerate, leading to loss of visual acuity and hearing. Taste buds atrophy, and nerve cell fibers in the olfactory bulb degenerate (Jarvis, 2020). Nerve cells in the vestibular system of the inner ear, cerebellum, and proprioceptive pathways also degenerate, leading to balance difficulties. Deep tendon reflexes can be decreased or in some cases absent. Hypothalamic function is modified such that stage IV sleep is reduced. There is an overall

slowing of autonomic nervous system responses. Pupillary responses are reduced or may not appear at all in the presence of cataracts.

Motor Alterations

Reduced nerve input into muscle contributes to an overall reduction in muscle bulk, with atrophy most easily noted in the hands. Changes in motor function often result in decreased strength and agility, with increased reaction time. Gait is often slowed and wide based. These changes can create difficulties in maintaining balance, predisposing the older person to falls.

Sensory Alterations

Tactile sensation is dulled in the older adult due to a decrease in the number of sensory receptors. There may be difficulty in identifying objects by touch, because fewer tactile cues are received from the bottom of the feet and the person may become confused about body position and location.

Sensitivity to glare, decreased peripheral vision, and a constricted visual field occur due to degeneration of visual pathways, resulting in disorientation, especially at night when there is little or no light in the room. Because the older adult takes longer to recover visual sensitivity when moving from a light to dark area, nightlights and a safe and familiar arrangement of furniture are essential.

Loss of hearing can contribute to confusion, anxiety, disorientation, misinterpretation of the environment, feelings of inadequacy, and social isolation. A decreased sense of taste and smell may contribute to weight loss and disinterest in food. A decreased sense of smell may present a safety hazard, because older adults living alone may be unable to detect household gas leaks or fires. Smoke and carbon monoxide detectors—important in every residence—are critical for the older adult.

Temperature Regulation and Pain Perception

The older adult patient may feel cold more readily than heat and may require extra covering when in bed; a room temperature somewhat higher than usual may be desirable. Reaction to painful stimuli may be decreased with age. Because pain is an important warning signal, caution must be used when hot or cold packs are used. The older patient may be burned or suffer frostbite before being aware of any discomfort. Complaints of pain such as abdominal discomfort or chest pain may be more serious than the patient's perception might indicate and thus require careful evaluation. In older adults, two common pain syndromes that affect the neurologic system are diabetic and postherpetic neuropathies. These frequently occur due to the high rate of these comorbid conditions in older adults. See Chapter 46 for a discussion of diabetic neuropathy.

Mental Status

Although mental processing time decreases with age, memory, language, and judgment capacities remain intact. Change in mental status should never be assumed to be a normal part of aging. **Delirium** is an acute confused state that begins with disorientation and if not recognized and treated early can progress to changes in level of consciousness, irreversible brain damage, and sometimes death. Older age is a risk, but delirium is also seen in patients who have underlying CNS damage or are experiencing an acute condition such as infection, adverse medication reaction, or dehydration. Drug toxicity and depression may produce impairment of attention and memory and should be evaluated as a possible cause of mental status change. Assessment with validated screening tool leads to improved detection of delirium (Smulter, Lingehall, Gustafson, et al., 2019). The Confusion Assessment Method (CAM) is a commonly used screening tool (Inouye, van Dyck, Alessi, et al., 1990) (see Chapter 8, Chart 8-7). Delirium must be differentiated from dementia, which is a chronic and irreversible deterioration of cognitive status. See Chapter 61, Table 61-4 for further discussion of delirium and dementia.

Nursing Implications

Nursing care for patients with age-related changes to the nervous system and for patients with long-term neurologic disability who are aging should include the modifications described previously. In addition, the consequences of any neurologic deficit and its impact on overall function such as activities of daily living, the use of assistive devices, and individual coping should be assessed and considered in planning patient care. Fall risk must be evaluated and fall prevention measures instituted for the patient who is hospitalized as well as in the home.

The nurse must understand the altered responses and the changing needs of the older adult patient before providing education. Visual and hearing deficits require adaptations in activities such as preoperative education, diet therapy, and education about new medications. When using visual materials for education or menu selection, adequate lighting without glare, contrasting colors, and large print are used to offset visual difficulties caused by rigidity and opacity of the lens in the eye and slower pupillary reaction. Procedures and preparations needed for diagnostic tests are explained, taking into account the possibility of impaired hearing and slowed responses in the older adult. Even with hearing loss, the older adult patient often hears adequately if the speaker uses a low-pitched, clear voice; shouting only makes it harder for the patient to understand the speaker. Providing auditory and visual cues aids understanding; if the patient has a significant hearing or visual loss, assistive devices, a signer, an interpreter, or a translator may be needed.

Providing education at an unrushed pace and using reinforcement enhance learning and retention. Material should be short, concise, and concrete. Vocabulary is matched to the patient's ability, and terms are clearly defined. The older adult patient requires adequate time to receive and respond to stimuli, learn, and react. These measures allow comprehension, memory, and formation of association and concepts.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with altered neurologic function. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. Women who are premenopausal are advised to practice effective contraception before and for several days after any diagnostic procedure using contrast, and the woman who is breast-feeding is instructed to stop for the time period recommended by the nuclear medicine department (Pagana & Pagana, 2018). The nurse should note trends in results, because they provide information about disease progression as well as the patient's response to therapy.

Computed Tomography Scanning

Computed tomography (CT) scanning uses a narrow x-ray beam to scan body parts in successive layers. The images provide cross-sectional views of the brain, distinguishing differences in tissue densities of the skull, cortex, subcortical structures, and ventricles. An intravenous (IV) contrast agent may be used to highlight differences further. The brightness of each slice of the brain in the final image is proportional to the degree to which it absorbs x-rays. The image is displayed on an oscilloscope or television monitor and is photographed and stored digitally (Fischbach & Fischbach, 2018). CT scanning is usually performed first without contrast material and then with IV contrast, if needed. The patient lies on an adjustable table with the head in a headrest while the scanning system rotates around the head and produces cross-sectional images. The patient must lie with the head held perfectly still without talking or moving the face, because head motion distorts the image. CT scanning is quick and painless and uses a small amount of radiation to produce images; it has a high degree of sensitivity for detecting lesions.

Brain lesions have a different tissue density from the surrounding normal brain tissue. Abnormalities detected on brain CT include tumor or other masses, infarction, hemorrhage, displacement of the ventricles, and cortical atrophy (Fischbach & Fischbach, 2018). CT angiography allows visualization of blood vessels; in some situations, this eliminates the need for formal

angiography. Whole-body CT scanners allow cross-sections of the spinal cord to be visualized. The injection of a water-soluble iodinated contrast agent into the subarachnoid space through lumbar puncture improves the visualization of the spinal and intracranial contents on these images. The CT scan, along with magnetic resonance imaging (MRI), has largely replaced myelography as a diagnostic procedure for the diagnosis of herniated lumbar discs.

Nursing Interventions

Essential nursing interventions include preparation for the procedure and patient monitoring. Preparation includes educating the patient about the need to lie quietly throughout the procedure. A review of relaxation techniques may be helpful for patients with claustrophobia. Sedation can be used if agitation, restlessness, or confusion interferes with a successful study. Ongoing patient monitoring during sedation is necessary. If a contrast agent is used, the patient must be assessed before the CT scan for an iodine/shellfish allergy, because the contrast agent used may be iodine based. Kidney function must also be evaluated because the contrast material is cleared through the kidneys. A suitable IV line for contrast injection and a period of fasting (usually 4 hours) are required prior to the study. Patients who receive an IV contrast agent are monitored during and after the procedure for allergic reactions and changes in kidney function (Fischbach & Fischbach, 2018). Fluid intake is also encouraged after IV contrast to facilitate contrast clearance through the kidney.

Magnetic Resonance Imaging

MRI uses a powerful magnetic field to obtain images of different areas of the body. The magnetic field causes the hydrogen nuclei (protons) within the body to align like small magnets in a magnetic field. In combination with radiofrequency pulses, the protons emit signals, which are converted to images. An MRI scan can be performed with or without a contrast agent and can identify a cerebral abnormality earlier and more clearly than other diagnostic tests (Fischbach & Fischbach, 2018). It can provide information about the chemical changes within cells, allowing the clinician to monitor a tumor's response to treatment. It is particularly useful in the diagnosis of brain tumor, stroke, and multiple sclerosis and does not involve ionizing radiation. An MRI scan may take an hour or longer to complete, so its use in emergency situations is limited.

Several MRI applications allow imaging of brain blood flow and metabolism via special imaging techniques added to the MRI. Such techniques include diffusion-weighted imaging (DWI), perfusion-weighted imaging (PWI), magnetic resonance spectroscopy, and fluid attenuation inversion recovery (FLAIR) (Fischbach & Fischbach, 2018). Magnetic resonance angiography (MRA) allows separate visualization of the cerebral vasculature

without the administration of an arterial contrast agent. Both MRI and CT images are used as tools to plan and direct surgical intervention.

Nursing Interventions

Patient preparation includes providing education and obtaining an adequate history. Ferromagnetic substances in the body may become dislodged by the magnet, so history of working with metal fragments must be reviewed. Patients with any type of cardiac implantable electronic device need to be screened to see if it is safe for the patient to undergo any type of MRI (Indik, Gimbel, Abe, et al., 2017). The patient is assessed for implants containing metal (e.g., aneurysm clips, orthopedic hardware, artificial heart valves, intrauterine devices). These objects could malfunction, be dislodged, or heat up as they absorb energy. Cochlear implants will be inactivated by MRI; therefore, other imaging procedures are considered. A complete list of metal compatibility may be found on MRI manufacturer Web sites.

Before the patient enters the room where the MRI is to be performed, all metal objects and credit cards (the magnetic field can erase them) must be removed. This includes medication patches that have a metal backing and metallic lead wires; these can cause burns if not removed (Fischbach & Fischbach, 2018). No metal objects may be brought into the room where the MRI is located; this includes oxygen tanks, IV poles, ventilators, or even stethoscopes. The magnetic field generated by the unit is so strong that any metal-containing items will be strongly attracted and literally can be pulled away with such force that they fly like projectiles toward the magnet. There is a risk of severe injury and death. Further, damage to expensive equipment may occur.

Quality and Safety Nursing Alert

For patient safety, the nurse prevents any patient care equipment containing metal or metal parts (e.g., portable oxygen tanks, wheelchairs) from entering the room where the MRI is located. The nurse also assesses for and removes any medication patches with foil backing (such as nicotine patches) that may cause a burn while an MRI scan is being performed.

For the MRI, the patient lies with the head in a frame on a flat platform that is moved into a tube housing the magnet (see Fig. 60-14). The tube is narrow; people with a wide girth may not fit into the scanner. Patients who are unable to lie flat will not be able to tolerate an MRI. The scanning process is painless, but the patient hears loud thumping of the magnetic coils as the magnetic field is being pulsed. Patients may experience claustrophobia while inside the

narrow tube; sedation may be prescribed in these circumstances. “Open” MRI machines are less claustrophobic than the other devices and are available in many locations. However, the images produced on these machines are sometimes not so detailed, and traditional devices are preferred for accurate diagnosis. The patient may be educated about the use of relaxation techniques while in the scanner. The patient is informed that it will be possible to talk to the staff during the scan through a microphone inside the scanner (Fischbach & Fischbach, 2018).

Figure 60-14 • Technician explains what to expect during a magnetic resonance imaging procedure.

Positron Emission Tomography

PET is a computer-based nuclear imaging technique that produces images of actual organ functioning. The patient either inhales a radioactive gas or is injected with a radioactive substance that emits positively charged particles. When these positrons combine with negatively charged electrons (normally found in the body’s cells), the resultant gamma rays can be detected by a scanning device that produces a series of two-dimensional views at various levels of the brain. This information is integrated by a computer and gives a composite picture of the brain at work.

PET permits the measurement of blood flow, tissue composition, and brain metabolism and thus indirectly evaluates brain function. The brain is one of the most metabolically active organs, consuming 80% of the glucose the body

uses (Hickey & Strayer, 2020). PET measures this activity in specific areas of the brain and can detect changes in glucose use.

PET is useful in showing metabolic changes in the brain (Alzheimer's disease), locating lesions (brain tumor, epileptogenic lesions), identifying blood flow and oxygen metabolism in patients with strokes, distinguishing tumor from areas of necrosis, and revealing biochemical abnormalities associated with mental illness. The isotopes used have a very short half-life and are expensive to produce, requiring specialized equipment for production. Improvement in the scanning procedure and production of isotopes, as well as the advent of reimbursement by third-party payers, has increased the clinical applications of PET studies.

Nursing Interventions

Key nursing interventions include patient preparation, which involves explaining the test and educating the patient about inhalation techniques and the sensations (e.g., dizziness, lightheadedness, headache) that may occur. The IV injection of the radioactive substance produces similar side effects. Relaxation exercises may reduce anxiety during the test.

Single-Photon Emission Computed Tomography

SPECT is a three-dimensional imaging technique that uses radionuclides and instruments to detect single photons. It is a perfusion study that captures a moment of cerebral blood flow at the time of injection of a radionuclide. Gamma photons are emitted from a radiopharmaceutical agent given to the patient and are detected by a rotating gamma camera or cameras; the image is sent to a minicomputer. This approach allows areas behind overlying structures or background to be viewed, greatly increasing the contrast between normal and abnormal tissue. It is relatively inexpensive, and the duration is similar to that of a CT scan.

SPECT is useful in detecting the extent and location of abnormally perfused areas of the brain, thus allowing detection, localization, and sizing of stroke (before it is visible by CT scan); localization of seizure foci in epilepsy; detection of tumor progression (Fischbach & Fischbach, 2018); and evaluation of perfusion before and after neurosurgical procedures.

Nursing Interventions

The nursing interventions for SPECT primarily include patient preparation and patient monitoring. Providing education about what to expect before the test can allay anxiety and ensure patient cooperation during the test. Pregnancy and breast-feeding are contraindications to SPECT.

The nurse may need to accompany and monitor the patient during transport to the nuclear medicine department for the scan. Patients are monitored during and after the procedure for allergic reactions to the radiopharmaceutical agent.

Cerebral Angiography

Cerebral angiography is an x-ray study of the cerebral circulation with a contrast agent injected into a selected artery. A valuable tool in investigating vascular disease or anomalies, it is used to determine vessel patency, identify presence of collateral circulation, and provide detail on vascular anomalies that can be used in planning interventions. With the advent of additional imaging techniques, formal cerebral angiography is less frequently performed.

Cerebral angiograms are performed by threading a catheter through the femoral artery in the groin or the radial artery of the wrist and up to the desired vessel. Alternatively, direct puncture of the carotid artery may be performed. X-ray images are obtained as the contrast agent flows through the vessels; the carotid and vertebral arterial systems are visualized, as well as venous drainage. Arterial access may also be used for interventional procedures, such as placing coils in an aneurysm or arteriovenous malformation.

Nursing Interventions

Prior to the angiography, the patient's blood urea nitrogen and creatinine should be checked to ensure the kidneys will be able to excrete the contrast agent. The patient should be well hydrated, and clear liquids are usually permitted up to the time of the test. The patient is instructed to void immediately before the test, and locations of the appropriate peripheral pulses are marked with a felt-tip pen. The patient is instructed to remain immobile during the angiogram process and is told to expect a brief feeling of warmth in the face, behind the eyes, or in the jaw, teeth, tongue, and lips, and a metallic taste when the contrast agent is injected.

When the femoral artery is selected for access, the hair in the groin is clipped and prepared and a local anesthetic agent is given to minimize pain at the insertion site and to reduce arterial spasm. A catheter is introduced into the femoral artery, flushed with heparinized saline, and filled with contrast agent. When the radial artery is selected for access, the wrist will be prepared and accessed using medications to relax and dilate the vessel to allow the catheter to pass (Mason, Shah, Tamis-Holland, et al., 2018). Fluoroscopy is used to guide the catheter to the appropriate vessels. Neurologic assessment is conducted during and immediately following cerebral angiography to observe for embolism or arterial dissection that may occur during the test. Signs of these complications include new onset of alterations in the level of consciousness, weakness on one side of the body, motor or sensory deficits, and speech disturbances.

Nursing care after cerebral angiography includes observation of the injection site for bleeding or hematoma formation (a localized collection of blood). Because a hematoma at the puncture site or embolization to a distal artery affects peripheral pulses, the peripheral pulses that were marked prior to the test are monitored frequently. The color and temperature of the involved extremity are assessed to detect possible embolism (Fischbach & Fischbach, 2018; Mason et al., 2018). Fluids are encouraged to facilitate clearance of the contrast through the kidney. The nurse also monitors for an allergic reaction to the contrast agent, as well as hypotension if vasodilatory medications were used to facilitate a radial approach (Mason et al., 2018).

Myelography

A myelogram is an x-ray of the spinal subarachnoid space taken after the injection of a contrast agent into the spinal subarachnoid space through a lumbar puncture. The water-based contrast agent disperses upward through the CSF to outline the spinal subarachnoid space and shows any distortion of the spinal cord or spinal dural sac caused by tumors, cysts, herniated vertebral discs, or other lesions. Myelography is often followed by CT scanning (Fischbach & Fischbach, 2018).

Nursing Interventions

The patient is educated about what to expect during the procedure and made aware that changes in position may be made during the procedure. After myelography, the patient lies in bed with the head of the bed elevated 30 to 45 degrees. The patient is advised to remain in bed in the recommended position for 4 to 24 hours after testing. Drinking liberal amounts of fluid for rehydration and replacement of CSF may decrease the incidence of post–lumbar puncture headache. The blood pressure, pulse, respiratory rate, and temperature are monitored, as well as the patient's ability to void. Complications that may occur include nausea, vomiting, headache, fever, stiff neck, seizures, paralysis of one side of the body, and changes in level of consciousness (Fischbach & Fischbach, 2018).

Noninvasive Carotid Flow Studies

Noninvasive carotid flow studies use ultrasound imagery and Doppler measurements of arterial blood flow to evaluate carotid and deep orbital circulation. The graph produced indicates blood velocity. Increased blood velocity can indicate stenosis or partial obstruction. These tests are often obtained before more invasive tests such as arteriography or are used as screening tools. Carotid Doppler, carotid ultrasonography, oculoplethysmography, and ophthalmodynamometry are four common

noninvasive vascular techniques that permit evaluation of arterial blood flow and detection of arterial stenosis, occlusion, and plaques. These vascular studies allow noninvasive imaging of extra- and intracranial circulation (Fischbach & Fischbach, 2018).

Transcranial Doppler

Transcranial Doppler uses the same noninvasive techniques as carotid flow studies but records the blood flow velocities of the intracranial vessels. Arterial flow velocities can be measured through thin areas of the temporal and occipital bones of the skull. A handheld Doppler probe emits a pulsed beam; the signal is reflected by the moving red blood cells within the blood vessels. Transcranial Doppler is a noninvasive technique that is helpful in assessing vasospasm (a complication following subarachnoid hemorrhage), altered cerebral blood flow found in occlusive vascular disease, other cerebral pathologies, and brain death.

Nursing Interventions

When a carotid flow study or transcranial Doppler is scheduled, the procedure is described to the patient. The patient is informed that this is a noninvasive test, that a handheld transducer will be placed over the neck and the orbits of the eyes, and that a water-soluble gel or lubricant is used on the transducer (Fischbach & Fischbach, 2018). Either of these two low-risk tests can be performed at the patient's bedside.

Electroencephalography

An electroencephalogram (EEG) represents a record of the electrical activity generated in the brain (Hickey & Strayer, 2020). It is obtained through electrodes applied on the scalp or through microelectrodes placed within the brain tissue. It provides an assessment of cerebral electrical activity. It is useful for diagnosing and evaluating seizure disorders, coma, or organic brain syndrome. Tumors, brain abscesses, blood clots, and infection may cause abnormal patterns in electrical activity. The EEG is also used in making a determination of brain death.

Electrodes are applied to the scalp to record the electrical activity in various regions of the brain. The amplified activity of the neurons between any two of these electrodes is recorded on continuously moving paper; this record is called the *encephalogram.*

For a baseline recording, the patient lies quietly with both eyes closed. The patient may be asked to hyperventilate for 3 to 4 minutes or to look at a bright, flashing light for photic stimulation. These activation procedures are performed to evoke abnormal electrical discharges, such as seizure potentials.

A sleep EEG may be recorded after sedation because some abnormal brain waves are seen only when the patient is asleep. If the epileptogenic area is inaccessible to conventional scalp electrodes, nasopharyngeal electrodes may be used.

Chart 60-3  **NURSING RESEARCH PROFILE**

Electroencephalographic Patterns During Nursing Interventions in Neurointensive Care

Elf, K., Carlsson, T., Santeliz Rivas, L., et al. (2019). Electroencephalographic patterns during common nursing interventions in neurointensive care: A descriptive pilot study. *Journal of Neuroscience Nursing, 51*(1), 10–15.

Purpose

The purpose of this study was to identify changes on electroencephalography (EEG) during standard neurointensive nursing care.

Design

The study was a descriptive pilot study using a convenience sample of patients admitted to the neurointensive care unit with impaired consciousness due to a neurosurgical condition. The sample included 12 participants, with a mean age of 65 years with diagnoses of subarachnoid hemorrhage, intracerebral hemorrhage, acute subdural hematoma, meningitis, ischemic infarction, or traumatic brain injury. All participants were mechanically ventilated, with continuous sedations and intracranial monitoring. The study design included the monitoring of simultaneous continuous EEG and video recording. The nursing interventions monitored included airway suctioning, repositioning, and when professionally touched for assessment of hygienic interventions.

Findings

Four participants had seizure activity during four nursing interventions (0.4% of nursing interventions); one participant had stimulus-induced rhythmic discharges during an intervention. All 12 participants showed muscle artifacts during 353 nursing interventions (36.3%), which may be a sign of stress. Muscle artifacts happened during all types of nursing interventions but occurred most often when more than one intervention was performed.

Nursing Implications

Patients with neuroscience disorders in intensive care undergo many stressors, and the results of this study indicate that nursing interventions may cause stress in patients. Oral care, repositioning, suctioning, and hygienic care may cause stress. Nurses should be mindful of the comfort of the patient with a neuroscience disorder when delivering care at the bedside and consider shorter and fewer interventions in patients who are sensitive.

Depth recording of EEG is performed by introducing electrodes stereotactically (radiologically placed using instrumentation) into a target area of the brain, as indicated by the patient's seizure pattern and scalp EEG. It is used to identify patients who may benefit from surgical excision of epileptogenic foci. Special transsphenoidal, mandibular, and nasopharyngeal

electrodes can be used, and video recording combined with EEG monitoring and telemetry is used in hospital settings to capture epileptiform abnormalities and their sequelae. Some epilepsy centers provide long-term ambulatory EEG monitoring with portable recording devices. Some evidence suggests that continuous EEG may be a useful tool for nurses planning interventions in patients who are critically ill (Elf, Carlsson, Santeliz Rivas, et al., 2019). See the Nursing Research Profile in Chart 60-3.

Nursing Interventions

To increase the chances of recording seizure activity, it is sometimes recommended that the patient be deprived of sleep the night before the EEG. Anticonvulsant agents, tranquilizers, stimulants, and depressants should be withheld 24 to 48 hours before an EEG, because these medications can alter the EEG wave patterns or mask the abnormal wave patterns of seizure disorders (Pagana & Pagana, 2018). Coffee, tea, chocolate, and cola drinks are omitted from the meal before the test because of their stimulating effect. However, the meal itself is not omitted, because an altered blood glucose level can cause changes in brain wave patterns.

The patient is informed that the standard EEG takes 45 to 60 minutes; a sleep EEG requires 12 hours. The patient is assured that the procedure does not cause an electric shock and that the EEG is a diagnostic test, not a form of treatment. An EEG requires the patient to lie quietly during the test. Sedation is not advisable, because it may lower the seizure threshold in patients with a seizure disorder and it alters brain wave activity in all patients. The nurse needs to check the prescription regarding the administration of anticonvulsant medication prior to testing.

Routine EEGs use a water-soluble lubricant for electrode contact, which can be wiped off and removed by shampooing later. Sleep EEGs involve the use of collodion glue for electrode contact, which requires acetone for removal.

Electromyography

An electromyogram (EMG) is obtained by inserting needle electrodes into the skeletal muscles to measure changes in the electrical potential of the muscles (Pagana & Pagana, 2018). The electrical potentials are shown on an oscilloscope and amplified so that both the sound and appearance of the waves can be analyzed and compared simultaneously.

An EMG is useful in determining the presence of neuromuscular disorders and myopathies. It helps distinguish weakness due to neuropathy (functional or pathologic changes in the peripheral nervous system) from weakness resulting from other causes.

Nursing Interventions

The procedure is explained, and the patient is warned to expect a sensation similar to that of an intramuscular injection as the needle is inserted into the muscle. The muscles examined may ache for a short time after the procedure.

Nerve Conduction Studies

Nerve conduction studies are performed by stimulating a peripheral nerve at several points along its course and recording the muscle action potential or the sensory action potential that results. Surface or needle electrodes are placed on the skin over the nerve to stimulate the nerve fibers. This test is useful in the study of peripheral neuropathies and is often included as part of the EMG.

Evoked Potential Studies

Evoked potential studies involve application of an external stimulus to specific peripheral sensory receptors with subsequent measurement of the electrical potential generated. Electrical changes are detected with the aid of computerized devices that extract the signal, display it on an oscilloscope, and store the data on magnetic tape or disc. In neurologic diagnosis, they reflect nerve conduction times in the peripheral nervous system. In clinical practice, the visual, auditory, and somatosensory systems are most often tested.

In visual evoked responses, the patient looks at a visual stimulus (flashing lights, a checkerboard pattern on a screen). The average of several hundred stimuli is recorded by EEG leads placed over the occipital lobe. The transit time from the retina to the occipital area is measured using computer-averaging methods.

Brainstem auditory evoked responses (BAERs) are measured by applying an auditory stimulus (repetitive auditory click) and measuring the transit time via the brain stem into the cortex. Specific lesions in the auditory pathway modify or delay the response. BAERs may be used in the diagnosis of brain stem abnormalities and in determination of brain death.

In somatosensory evoked responses (SERs), the peripheral nerves are stimulated (electrical stimulation through skin electrodes) and the transit time along the spinal cord to the cortex is measured and recorded from scalp electrodes. SERs are used to detect deficits in spinal cord or peripheral nerve conduction and to monitor spinal cord function during surgical procedures. It is also useful in the diagnosis of demyelinating diseases, such as multiple sclerosis and polyneuropathies, where nerve conduction is slowed.

Nursing Interventions

The nurse explains the procedure and reassures the patient and encourages him or her to relax. The patient is advised to remain perfectly still throughout the recording to prevent artifacts (signals not generated by the brain) that interfere with the recording and interpretation of the test.

Lumbar Puncture and Examination of Cerebrospinal Fluid

A lumbar puncture (spinal tap) is carried out by inserting a needle into the lumbar subarachnoid space to withdraw CSF (Schreiber, 2019). The test may be performed to obtain CSF for examination, to measure and reduce CSF pressure, to determine the presence or absence of blood in the CSF, and to administer medications intrathecally (into the spinal canal).

The needle is inserted into the subarachnoid space in the widest intervertebral spaces; between the second and third, the third and fourth, or fourth and fifth lumbar vertebrae (Schreiber, 2019). Because the spinal cord ends at the first lumbar vertebra, insertion of the needle below the level of the second lumbar vertebra prevents puncture of the spinal cord.

A lumbar puncture may be risky in the presence of an intracranial mass lesion because intraspinal pressure is decreased by removal of CSF, and the brain may herniate downward through the foramen magnum. A successful lumbar puncture requires that the patient be relaxed; a patient who is anxious is tense, and this may artificially alter the pressure reading. The nurse may be asked to assist with a lumbar puncture.

For the procedural guidelines for assisting with a lumbar puncture, go to thepoint.lww.com/Brunner15e.

Cerebrospinal Fluid Analysis

The CSF should be clear and colorless. Pink, blood-tinged, or grossly bloody CSF may indicate a subarachnoid hemorrhage. The CSF may be bloody initially because of local trauma but becomes clearer as more fluid is drained (Hickey & Strayer, 2020; Schreiber, 2019). Specimens are obtained for cell count, culture, glucose, protein, and other tests as indicated. The specimens should be sent to the inhibitor laboratory immediately because changes will take place and alter the result if the specimens are allowed to stand. See Table A-5 in Appendix A on thePoint for the normal values of CSF.

Post–Lumbar Puncture Headache

A post–lumbar puncture headache, ranging from mild to severe, may occur a few hours to several days after the procedure. It is a throbbing bifrontal or occipital headache that is dull and deep in character. It is particularly severe on sitting or standing but lessens or disappears when the patient lies down.

The headache is caused by CSF leakage at the puncture site (Schreiber, 2019). The fluid continues to escape into the tissues by way of the needle track from the spinal canal. As a result of a leak, the supply of CSF in the cranium is depleted to a point at which it is insufficient to maintain proper mechanical stabilization of the brain. When the patient assumes an upright position, tension and stretching of the venous sinuses and pain-sensitive structures occur.

Post–lumbar puncture headache may be avoided if a small-gauge needle (22 gauge) is used (Hickey & Strayer, 2020). A post–lumbar puncture headache is usually managed with analgesic agents, encouraging hydration, ingestion of caffeine, and lying supine (Schreiber, 2019).

Other Complications of Lumbar Puncture

Herniation of the intracranial contents, spinal epidural abscess, spinal epidural hematoma, and meningitis are rare but serious complications of lumbar puncture. Other complications include temporary voiding problems, slight elevation of temperature, backache or spasms, and stiffness of the neck.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Many diagnostic tests are carried out in short-procedure units or outpatient testing settings or units. As a result, family members often provide the postprocedure care. Therefore, the patient and family must receive adequate education about precautions to take after the procedure, complications to watch for, and steps to take if complications occur. Because many patients undergoing neurologic diagnostic studies are older adults or have neurologic deficits, provisions must be made to ensure that transportation, postprocedure care, and appropriate monitoring are available.

Continuing and Transitional Care

Contacting the patient and family after diagnostic testing enables the nurse to determine whether they have any questions about the procedure or whether the patient had any untoward results. Education is reinforced and the patient and family are reminded to make and keep follow-up appointments. Patients,

family members, and health care providers are focused on the immediate needs, issues, or deficits that necessitated the diagnostic testing.

CRITICAL THINKING EXERCISES

1 pq Identify the priorities, approach, and techniques you would use to perform a neurologic assessment on a 32-year-old patient with headaches. How will your priorities, approaches, and techniques differ if the patient has a visual impairment, is hard of hearing, or has lower extremity weakness?

2 ebp A 60-year-old patient is scheduled for an MRI scan and tells you he has a pacemaker. What resources would you use to identify whether it is safe for this patient to undergo MRI? What is the evidence base for these practices? Identify the criteria used to evaluate the strength of the evidence for these practices.

61 Management of Patients with Neurologic Dysfunction

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the causes, clinical manifestations, and medical management of various neurologic dysfunctions.
2. Use the nursing process as a framework for care of the patient with altered level of consciousness.
3. Identify the early and late clinical manifestations of increased intracranial pressure and apply the nursing process as a framework for care of the patient with increased intracranial pressure.
4. Compare and contrast the indications for intracranial or transsphenoidal surgery and use the nursing process as a framework for care of the patient undergoing intracranial or transsphenoidal surgery.
5. Explain the various types and causes of seizures and develop a plan of care for the patient experiencing seizures.
6. Recognize the causes, clinical manifestations, and medical and nursing management of the patient experiencing various types of headaches.

NURSING CONCEPTS

Comfort
Development
Family
Health, Wellness, and Illness
Infection
Intracranial Regulation
Mobility
Patient Education

GLOSSARY

akinetic mutism: unresponsiveness to the environment; the patient makes no movement or sound but sometimes opens the eyes

altered level of consciousness (LOC): when a patient is not oriented, does not follow commands, or needs persistent stimuli to achieve a state of alertness

brain death: irreversible loss of all functions of the entire brain, including the brain stem

coma: prolonged state of unconsciousness

craniectomy: a surgical procedure that involves removal of a portion of the skull

craniotomy: a surgical procedure that involves entry into the cranial vault

Cushing's response: the brain's attempt to restore blood flow by increasing arterial pressure to overcome the increased intracranial pressure (*synonym:* Cushing's reflex)

decerebration: an abnormal body posture associated with severe brain injury, characterized by extreme extension of the upper and lower extremities

decortication: an abnormal posture associated with severe brain injury, characterized by abnormal flexion of the upper extremities and extension of the lower extremities

delirium: an acute, confused state that begins with disorientation and if not recognized and treated early can progress to changes in level of consciousness, irreversible brain damage, and sometimes death

dementia: broad term for a syndrome characterized by a general decline in higher brain functioning, such as reasoning, with a pattern of eventual decline in the ability to perform even basic activities of daily living, such as toileting and eating

epilepsy: at least two unprovoked seizures occurring more than 24 hours apart

herniation: abnormal protrusion of tissue through a defect or natural opening

intracranial pressure (ICP): pressure exerted by the volume of the intracranial contents within the cranial vault

locked-in syndrome: condition resulting from a lesion in the pons in which the patient lacks all distal motor activity (paralysis) but cognition is intact

migraine: a severe, unrelenting headache often accompanied by symptoms such as nausea, vomiting, and visual disturbances

minimally conscious state: a state in which the patient demonstrates awareness but cannot communicate thoughts or feelings

Monro–Kellie hypothesis: theory that states that due to limited space for expansion within the skull, an increase in any one of the cranial contents—brain tissue, blood, or cerebrospinal fluid (CSF)—causes a change in the volume of the others (*synonym:* Monro–Kellie doctrine)

persistent vegetative state: condition in which the patient is wakeful but devoid of conscious content, without cognitive or affective mental function

primary headache: a headache for which no specific organic cause can be found

pseudobulbar affect: emotional disturbance characterized by uncontrollable episodes of crying or laughing, or other emotional displays

secondary headache: headache identified as a symptom of another organic disorder (e.g., brain tumor, hypertension)

seizures: paroxysmal transient disturbance of the brain resulting from a discharge of abnormal electrical activity

status epilepticus: episode in which the patient experiences multiple seizures with no recovery time in between

Sudden Unexpected Death in Epilepsy (SUDEP): nontraumatic, nondrowning unexpected death of patient with epilepsy

transsphenoidal: surgical approach to the pituitary via the sphenoid sinuses

This chapter presents an overview of care of the patient with an altered level of consciousness (LOC); the patient with increased intracranial pressure (ICP); and the patient who is undergoing neurosurgical procedures, experiencing seizures, or experiencing headaches. Some of the disorders in this chapter, such as headaches and seizures, may be symptoms of dysfunction in another body system. Alternatively, headaches and seizures can be symptoms of a disruption of the neurologic system. These disorders can also be diagnosed at times as "idiopathic," or without an identifiable cause. The commonalities of these

disorders are often the behaviors and needs of the patient and the approaches nurses use to support the patient.

The central nervous system (CNS) contains a vast network of neurons that control the body's vital functions. However, this system is vulnerable, and its optimal function depends on several key factors. First, the neurologic system relies on its structural integrity for support and homeostasis, but this integrity may be disrupted. Examples of structural disruption include head injury, brain tumor, intracranial hemorrhage, infection, and stroke. As brain tissue expands in the inflexible cranium, **intracranial pressure (ICP)** (pressure exerted by the volume of the intracranial contents within the cranial vault) rises, and cerebral perfusion is impaired. Further expansion places pressure on vital centers, which can cause permanent neurologic deficits or lead to brain death.

Second, the neurologic system relies on the body's ability to maintain a homeostatic environment. It requires the delivery of the essential elements of oxygen and glucose, as well as filtration of substrates that are toxic to the neurons. The functions of the neurologic system may be decreased or absent because of the effect of toxic substrates or the body's inability to provide essential substrates. Sepsis, hypovolemia, myocardial infarction, cardiopulmonary arrest, hypoglycemia, electrolyte imbalance, drug and/or alcohol overdose, encephalopathy, and ketoacidosis are examples of such circumstances. Some conditions can be treated and reversed; others result in permanent neurologic deficits and disabilities.

Although the specialty of neuroscience nursing requires an understanding of neuroanatomy, neurophysiology, neurodiagnostic testing, critical-care nursing, and rehabilitation nursing, nurses in all settings care for patients with neurologic disorders (Hickey & Strayer, 2020). Ongoing assessment of the patient's neurologic function and health needs, identification of problems, mutual goal setting, development and implementation of care plans (including education, counseling, and coordinating activities), and evaluation of the outcomes of care are nursing actions integral to the recovery of the patient. The nurse also collaborates with other members of the health care team to provide essential care, offer a variety of solutions to problems, help the patient and family gain control of their lives, and explore the educational and supportive resources available in the community. The goals are to achieve as high a level of function as possible and to enhance the quality of life for the patient with neurologic impairment and their family.

ALTERED LEVEL OF CONSCIOUSNESS

An **altered level of consciousness (LOC)** is present when the patient is not oriented, does not follow commands, or needs persistent stimuli to achieve a state of alertness. LOC is gauged on a continuum, with a normal state of alertness and full cognition (consciousness) on one end and coma on the other end. **Coma** is a clinical state of unarousable unresponsiveness in which there are no purposeful responses to internal or external stimuli, although nonpurposeful responses to painful stimuli and brain stem reflexes may be present. The usual duration of coma is variable. **Akinetic mutism** is a state of unresponsiveness to the environment in which the patient makes no voluntary movement. **Persistent vegetative state** is a condition in which the patient who is unresponsive resumes sleep–wake cycles after coma but is devoid of cognitive or affective mental function. A **minimally conscious state** differs from persistent vegetative state in that the patient has inconsistent but reproducible signs of awareness (Rohaut, Eliseyev, & Claassen, 2019). **Locked-in syndrome** results from a lesion affecting the pons and results in paralysis and the inability to speak, but vertical eye movements and lid elevation remain intact and are used to indicate responsiveness. The level of responsiveness and consciousness is the most important indicator of the patient's condition (Owen, 2019).

Pathophysiology

Altered LOC is not a disorder itself; rather, it is a result of multiple pathophysiologic phenomena. The cause may be neurologic (head injury, stroke), toxicologic (drug overdose, alcohol intoxication), or metabolic (hepatic or kidney injury, diabetic ketoacidosis).

The underlying cause of neurologic dysfunction is disruption in the cells of the nervous system, neurotransmitters, or brain anatomy (see Chapter 60). Disruptions result from cellular edema or other mechanisms, such as disruption of chemical transmission at receptor sites by antibodies.

Intact anatomic structures of the brain are needed for normal function. The two hemispheres of the cerebrum must communicate, via an intact corpus callosum, and the lobes of the brain (frontal, parietal, temporal, and occipital) must communicate and coordinate their specific functions (see Chapter 60). Other

anatomic structures of importance are the cerebellum and the brain stem. The cerebellum has both excitatory and inhibitory actions and is largely responsible for coordination of movement. The brain stem contains areas that control the heart rate, respiration, and blood pressure. Disruptions in the anatomic structures result from trauma, edema, pressure from tumors, or other mechanisms, such as an increase or decrease in the circulation of blood or CSF.

Clinical Manifestations

Alterations in LOC occur along a continuum, and the clinical manifestations depend on where the patient is on this continuum. As the patient's state of alertness and consciousness decreases, changes occur in the pupillary response, eye opening response, verbal response, and motor response. However, initial alterations in LOC may be reflected by subtle behavioral changes, such as restlessness or increased anxiety. The pupils, normally round and quickly reactive to light, become sluggish (response is slower); as the patient becomes comatose, the pupils become fixed (no response to light). The patient in a coma does not open the eyes to voice or command, respond verbally, or move the extremities in response to a request to do so.

Assessment and Diagnostic Findings

The patient with an altered LOC is at risk for alterations in every body system. A complete assessment is performed, with particular attention to the neurologic system. The neurologic examination should be as complete as the LOC allows. It includes an evaluation of mental status, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function. LOC, a sensitive indicator of neurologic function, is assessed based on the criteria in the Glasgow Coma Scale: eye opening, verbal response, and motor response (Hickey & Strayer, 2020). The patient's responses are rated on a scale from 3 to 15. A score of 3 indicates severe impairment of neurologic function, brain death, or pharmacologic inhibition of the neurologic response. A score of 15 indicates that the patient is fully responsive (see Chapter 63, Chart 63-4).

If the patient is comatose and has localized signs such as abnormal pupillary and motor responses, it is assumed that neurologic disease is present until proven otherwise. If the patient is comatose but pupillary light reflexes are preserved, a toxic or metabolic disorder is suspected. Common diagnostic procedures used to identify the cause of unconsciousness include computed tomography (CT) scanning, perfusion CT (PCT), magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), and electroencephalography (EEG). Additional procedures include positron emission tomography (PET) and single-photon emission computed tomography (SPECT) (see Chapter 60). Ongoing research confirms EEG, MRI, and PET as important technologies in determining brain function through the evaluation of metabolic and electrical activity (Rohaut et al., 2019). Laboratory tests include analysis of blood glucose, electrolytes, serum ammonia, and liver function tests; blood urea nitrogen (BUN) levels; serum osmolality; calcium level; and partial thromboplastin and prothrombin times. Other studies may be used to evaluate serum ketones, alcohol and drug concentrations, and arterial blood gases.

Medical Management

The first priority of treatment for the patient with altered LOC is to obtain and maintain a patent airway. The patient may be orally or nasally intubated, or a tracheostomy may be performed. Until the ability of the patient to breathe is determined, a mechanical ventilator is used to maintain adequate oxygenation and ventilation. The circulatory status (blood pressure, heart rate) is monitored to ensure adequate perfusion to the body and brain. An intravenous (IV) catheter is inserted to provide access for IV fluids and medications. Neurologic care focuses on the specific neurologic pathology, if known. Nutritional support, via a feeding tube or a gastrostomy tube, is initiated as soon as possible. In addition to measures designed to determine and treat the underlying causes of altered LOC, other medical interventions are aimed at pharmacologic management and prevention of complications.

NURSING PROCESS

The Patient with an Altered Level of Consciousness

Assessment

Assessment of the patient with an altered LOC often starts with assessing the verbal response through determining the patient's orientation to time, person, and place. Patients are asked to identify the day, date, or season of the year, as well as where they are or the clinicians, family members, or visitors present. Other questions such as "Who is the president?" or "What is the next holiday?" may be helpful in determining the patient's processing of information. Verbal response cannot be evaluated if the patient is intubated or has a tracheostomy, and this should be clearly documented.

Alertness is measured by the patient's ability to open the eyes spontaneously or in response to a vocal or noxious stimulus (pressure or pain). Patients with severe neurologic dysfunction cannot do this. The nurse assesses for periorbital edema (swelling around the eyes) or trauma, which may prevent the patient from opening the eyes, and documents any such condition that interferes with eye opening.

Motor response includes spontaneous, purposeful movement (e.g., the awake patient can move all four extremities with equal strength on command), movement only in response to painful stimuli, or abnormal posturing. If the patient is not responding to commands, the motor response is tested by applying a painful stimulus (firm but gentle pressure) to the nail bed or by squeezing a muscle. If the patient attempts to push away or withdraw, the response is recorded as purposeful or appropriate ("Patient withdraws to painful stimulus"). This response is considered purposeful if the patient can cross the midline from one side of the body to the other in response to a painful stimulus. An inappropriate or nonpurposeful response is random and aimless. Posturing may be decorticate or decerebrate (see Fig. 61-1). The most severe neurologic impairment results in flaccidity. The motor response cannot be elicited or assessed when the patient has been given pharmacologic paralyzing agents (i.e., neuromuscular-blocking agents).

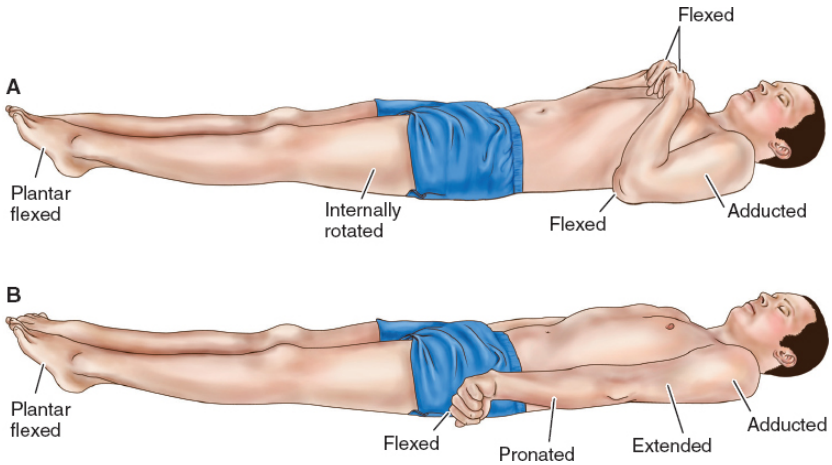

Figure 61-1 • Abnormal posture response to stimuli. **A.** Decorticate posturing and flexion of the upper extremities, internal rotation of the lower extremities, and plantar flexion of the feet. **B.** Decerebrate posturing, involving extension and outward rotation of upper extremities and plantar flexion of the feet. Adapted from Posner, J. B., Saper, C. B., Schiff, N. D., et al. (2007). *Plum and Posner's diagnosis of stupor and coma* (4th ed.). Oxford, UK: Oxford University Press.

In addition to LOC, the nurse monitors parameters such as respiratory status, eye signs, and reflexes on an ongoing basis. Table 61-1 summarizes the assessment and the clinical significance of the findings. Body functions (circulation, respiration, elimination, fluid and electrolyte balance) are examined in a systematic and ongoing manner.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired breathing due to neurologic impairment
- Risk for injury associated with lack of adaptive and defensive resources due to decreased LOC

- Risk for hypovolemia associated with inability to take fluids by mouth
- Risk for impaired nutritional intake associated with inability to ingest nutrients to meet metabolic needs
- Impaired oral mucous membrane integrity associated with mouth breathing, absence of pharyngeal reflex, and altered fluid intake
- Risk for impaired skin integrity associated with prolonged immobility
- Risk for injury associated with diminished or absent corneal reflex
- Impaired thermoregulation associated with damage to hypothalamic center
- Impaired urination associated with altered impairment in neurologic sensing and control
- Bowel incontinence associated with impairment in neurologic sensing and control and also associated with changes in nutritional delivery methods
- Impaired health maintenance associated with neurologic impairment
- Interrupted family process associated with health crisis

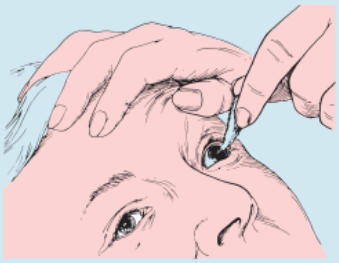
Collaborative Problems/Potential Complications

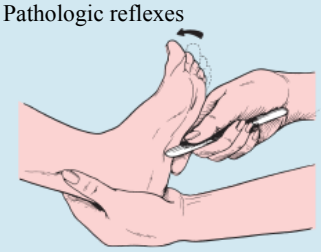
Potential complications may include the following:

- Respiratory distress or failure
- Pneumonia
- Aspiration
- Pressure injury
- Venous thromboembolism (VTE)
- Contractures

Planning and Goals

The patient with altered LOC is subject to all of the complications associated with immobility. Therefore, the goals of care for the patient with altered LOC include normalization of breathing, protection from injury, attainment of fluid volume balance, maintenance of nutritional needs, achievement of intact oral mucous membranes, maintenance of normal skin integrity, absence of corneal injury, attainment of effective thermoregulation, and effective urinary elimination. Additional goals include bowel continence, restoration of health maintenance, maintenance of intact family or support system, and absence of complications.





Because the protective reflexes of the patient who is unconscious are impaired, the quality of nursing care provided may mean the difference between life and death. The nurse must assume responsibility for the patient until the basic reflexes (coughing, blinking, and swallowing) return and the patient becomes conscious and oriented. Therefore, the major nursing goal is to compensate for the absence of these protective reflexes.

Nursing Interventions

Achieving an Adequate Breathing Pattern

The most important consideration in managing the patient with altered LOC is to establish an adequate airway and ensure normalization of the breathing pattern. Obstruction of the airway is a risk because the epiglottis and tongue may relax, occluding the oropharynx, or the patient may aspirate vomitus or nasopharyngeal secretions.

TABLE 61-1 Nursing Assessment of the Patient Who Is Unconscious

Examination	Clinical Assessment	Clinical Significance
Level of responsiveness or consciousness	Eye opening; verbal and motor responses; pupils (size, equality, reaction to light)	Obeying commands is a favorable response and demonstrates a return to consciousness
Pattern of respiration	Respiratory pattern Cheyne–Stokes respiration Hyperventilation Ataxic respiration with irregularity in depth/rate	Disturbances of respiratory center of brain may result in various respiratory patterns Suggests lesions deep in both hemispheres; area of basal ganglia and upper brain stem Suggests onset of metabolic problem or brain stem damage Ominous sign of damage to medullary center
Eyes		
Pupils (size, equality, reaction to light) 	Equal, normally reactive pupils Equal or unequal diameter Progressive dilation Fixed dilated pupils	Suggests that coma is toxic or metabolic in origin Helps determine location of lesion Indicates increasing intracranial pressure Indicates injury at level of midbrain
Eye movements	Normally, eyes should move from side to side	Functional and structural integrity of brain stem is assessed by inspection of extraocular movements; usually absent in deep coma
Corneal reflex 	When cornea is touched with a wisp of clean cotton, blink response is normal	Tests cranial nerves V and VII; helps determine location of lesion if unilateral; absent in deep coma
Facial symmetry	Asymmetry (sagging, decrease in wrinkles)	Sign of paralysis
Swallowing reflex	Drooling versus spontaneous swallowing	Absent in coma Paralysis of cranial nerves X and XII
Neck	Stiff neck Absence of spontaneous neck movement	Subarachnoid hemorrhage, meningitis Fracture or dislocation of cervical spine
Response of extremity to noxious stimuli	Firm pressure on a joint of the upper and lower extremities Observe spontaneous movements	Asymmetric response in paralysis Absent in deep coma
Deep tendon reflexes	Tap patellar and biceps tendons	Brisk response may have localizing value. Asymmetric response in paralysis Absent in deep coma
Pathologic reflexes 	Firm pressure with blunt object on sole of foot, moving along lateral margin and crossing to the ball of foot	Flexion of the toes, especially the great toe, is normal except in newborn Dorsiflexion of toes (especially great toe) indicates contralateral pathology of corticospinal tract (Babinski reflex) Helps determine location of lesion in brain
Abnormal posture	Observation for posturing (spontaneous or in response to noxious stimuli) Flaccidity with absence of motor response	Deep extensive brain lesion Seen with cerebral hemisphere pathology and metabolic depression of brain function Decerebrate posturing indicates deeper and more severe dysfunction than does

	Decorticate posture (flexion and internal rotation of forearms and hands) Decerebrate posture (extension and external rotation)	decorticate posturing; implies brain pathology; poor prognostic sign

The accumulation of secretions in the pharynx presents a serious problem. Because the patient cannot swallow and lacks pharyngeal reflexes, these secretions must be removed to eliminate the danger of aspiration. Elevating the head of the bed to 30 degrees helps prevent aspiration. Positioning the patient in a lateral or semiprone position also helps because it allows the jaw and tongue to fall forward, thus promoting drainage of secretions.

Positioning alone is not always adequate, however. Suctioning and oral hygiene may be required. Suctioning is performed to remove secretions from the posterior pharynx and upper trachea. Before and after suctioning, the patient is adequately ventilated to prevent hypoxia (Hickey & Strayer, 2020). Chest physiotherapy and postural drainage may be initiated to promote pulmonary hygiene, unless contraindicated by the patient's underlying condition. The chest should be auscultated at least every 8 hours to detect adventitious breath sounds or absence of breath sounds.

Despite these measures, or because of the severity of impairment, the patient with altered LOC often requires intubation and mechanical ventilation. Nursing actions for the patient who is mechanically ventilated include maintaining the patency of the endotracheal tube or tracheostomy, providing frequent oral care, monitoring arterial blood gas measurements, and maintaining ventilator settings (see Chapter 19).

Protecting the Patient

For the protection of the patient, side rails are padded. Two rails are kept in the raised position during the day and three at night; however, raising all four side rails is considered a restraint by The Joint Commission if the intent is to limit the patient's mobility. Care should be taken to prevent injury from invasive lines and equipment, and other potential sources of injury should be identified, such as restraints, tight dressings, environmental irritants, damp bedding or dressings, and tubes and drains.

Protection also includes ensuring the patient's dignity during altered LOC. Simple measures such as providing privacy and speaking to the patient during nursing care activities preserve the patient's dignity. Not speaking negatively about the patient's condition or prognosis is also important, because patients in a coma may be able to hear. The patient who is comatose has an increased need for advocacy, and the nurse is responsible for seeing that these advocacy needs are met.

Quality and Safety Nursing Alert

If the patient begins to emerge from unconsciousness, every measure that is available and appropriate for calming and quieting the patient should be used. Any form of restraint is likely to be countered with resistance, leading to self-injury or to a dangerous increase in ICP. Therefore, physical restraints are avoided, if possible; a written prescription must be obtained if their use is essential for the patient's well-being.

Maintaining Fluid Balance and Managing Nutritional Needs

Hydration status is assessed by examining tissue turgor and mucous membranes, assessing intake and output trends, and analyzing laboratory data. Fluid needs are met initially by administering the required IV fluids. However, IV solutions (and blood component therapy) for patients with intracranial conditions must be given slowly. If they are given too rapidly, they can increase ICP. The quantity of fluids given may be restricted to minimize the possibility of cerebral edema.

If the patient does not recover quickly and sufficiently enough to take adequate fluids and calories by mouth, a feeding or gastrostomy tube will be inserted for the administration of fluids and enteral feedings. Research suggests that patients fed within 48 hours of injury have improved outcomes over those in whom nutrition is delayed (Lucke-Wold, Logsdon, Nguyen, et al., 2018).

Providing Mouth Care

The mouth is inspected for dryness, inflammation, and crusting. The patient who is unconscious requires careful oral care, because there is a risk of parotitis if the mouth is not kept scrupulously clean. The mouth is cleansed and rinsed carefully to remove secretions and crusts and to keep the mucous membranes moist. A thin coating of petrolatum on the lips prevents drying, cracking, and encrustations.

If the patient has an endotracheal tube, the tube should be moved to the opposite side of the mouth daily to prevent ulceration of the mouth and lips. If the patient is intubated and mechanically ventilated, good oral care is also necessary. Research suggests that comprehensive mouth care with antiseptic such as chlorhexidine and head of bed elevation decreases ventilator-associated pneumonia and improves the oral health in patients who are intubated (Malhan, Usman, Trehan, et al., 2019).

Maintaining Skin and Joint Integrity

Preventing skin breakdown requires continuing nursing assessment and intervention. Special attention is given to patients who are unconscious, because they cannot respond to external stimuli. Assessment includes a regular schedule of turning to avoid pressure, which can cause breakdown and necrosis of the skin. Turning also provides kinesthetic (sensation of movement), proprioceptive (awareness of position), and vestibular (equilibrium) stimulation. After turning, the patient is carefully repositioned to prevent ischemic necrosis over pressure areas. Dragging or pulling the patient up in bed must be avoided, because this creates a shearing force and friction on the skin surface.

Maintaining correct body position is important; equally important is passive exercise of the extremities to prevent contractures. The use of splints or foam boots aids in the prevention of footdrop and eliminates the pressure of bedding on the toes. The use of trochanter rolls to support the hip joints keeps the legs in proper alignment. The arms are in abduction, the fingers lightly flexed, and the hands in slight supination. The heels of the feet are assessed for pressure areas. Specialty beds, such as fluidized or low–air-loss beds, may be used to decrease pressure on bony prominences (Hickey & Strayer, 2020).

Preserving Corneal Integrity

Some patients who are unconscious have their eyes open and have inadequate or absent corneal reflexes. The cornea may become irritated, dry, or scratched, leading to ulceration. The eyes may be cleansed with cotton balls moistened with sterile normal saline to remove debris and discharge. Artificial tears or methylcellulose may be prescribed to provide lubrication. Periorbital edema often occurs after cranial surgery. If cold compresses are prescribed, care must be exerted to avoid contact with the cornea. Eye patches should be used cautiously because of the potential for corneal abrasion from contact with the patch; eye shields may provide eye protection with less risk of injury.

Maintaining Body Temperature

High fever in the patient who is unconscious may be caused by infection of the respiratory or urinary tract, drug reactions, or damage to the hypothalamic temperature-regulating center. A slight elevation of temperature may be caused by dehydration. The environment can be adjusted, depending on the patient's condition, to promote a normal body temperature. If body temperature is elevated, a minimum amount of bedding is used. The room may be cooled to 18.3°C (65°F). However, if the patient is an older adult and does not have an elevated temperature, a warmer environment is needed.

Because of damage to the temperature-regulating center in the brain or severe intracranial infection, patients who are unconscious often develop very high temperatures. Such temperature elevations must be controlled, because the increased metabolic demands of the brain can exceed cerebral circulation and oxygen delivery, potentially resulting in cerebral deterioration (Hickey & Strayer, 2020). Studies suggest that hyperthermia may contribute to poor outcome after brain injury but not through a decreased brain oxygen level (Rincon, 2018). Persistent hyperthermia with no identified clinical source of infection indicates brain stem damage and a poor prognosis.

Quality and Safety Nursing Alert

The body temperature of a patient who is unconscious is never taken by mouth. Rectal, tympanic (if not contraindicated), or core temperature measurement is preferred to the less accurate axillary temperature.

Strategies for reducing fever include:

- Removing all bedding over the patient (with the possible exception of a light sheet, towel, or small drape)
- Administering acetaminophen or ibuprofen as prescribed
- Giving cool sponge baths
- Using a hypothermia blanket

- Monitoring temperature frequently to assess the patient's response to the therapy and to prevent an excessive decrease in temperature and shivering

Preventing Urinary Retention

The patient with an altered LOC is often incontinent or has urinary retention. The bladder is palpated or scanned at intervals to determine whether urinary retention is present, because a full bladder may be an overlooked cause of overflow incontinence. A portable bladder ultrasound instrument is a useful tool in bladder management and retraining programs.

If the patient is not voiding, a program of intermittent catheterization should be devised in order to reduce the patient's risk of urinary tract infection. A catheter may be inserted during the acute phase of illness to monitor urinary output. Because catheters are a major cause of urinary tract infection, the patient is observed for fever and cloudy urine. The area around the urethral orifice is inspected for drainage and cleansed routinely. The urinary catheter is usually removed if the patient has a stable cardiovascular system and if no diuresis, sepsis, or voiding dysfunction existed before the onset of coma. Although many patients who are unconscious urinate spontaneously after catheter removal, the bladder should be scanned with a portable bladder ultrasound device periodically for urinary retention (see Chapter 47, Fig. 47-8).

An external catheter (condom catheter) for the male patient and absorbent pads or female incontinence device for the female patient can be used for patients who are unconscious and can urinate spontaneously, although involuntarily. As soon as consciousness is regained, a bladder training program is initiated (Hickey & Strayer, 2020). The patient who is incontinent is monitored frequently for skin irritation and skin breakdown. Appropriate skin care is implemented to prevent these complications.

Promoting Bowel Function

The abdomen is assessed for distention by listening for bowel sounds and measuring the girth of the abdomen with a tape measure. There is a risk of diarrhea from infection, antibiotic agents, and hyperosmolar fluids. Frequent loose stools may also occur with fecal impaction. Commercial fecal collection bags are available for patients with fecal incontinence (see Chapter 41, Fig. 41-1).

Immobility and lack of dietary fiber can cause constipation. The nurse monitors the number and consistency of bowel movements and performs a rectal examination for signs of fecal impaction. Stool softeners may be prescribed and can be given with tube feedings. To facilitate bowel emptying, a glycerin suppository or bowel stimulant may be indicated. The patient may require an enema routinely to empty the lower colon.

Restoring Health Maintenance

Once increased ICP is not a problem, the nurse assists the patient and family to restore the health of the patient who is unconscious. This involves using auditory, visual, olfactory, gustatory, tactile, and kinesthetic activities to stimulate the patient emerging from coma (Gattuta, Coralo, Lo Buono, et al., 2018). Efforts are made to restore the sense of daily rhythm by maintaining usual day and night patterns for activity and sleep. The nurse touches and talks to the patient and encourages family members and friends to do so. Communication is extremely important and includes touching the patient and spending enough time with the patient to become sensitive to their needs. It is also important to avoid making any negative comments about the patient's status or prognosis in the patient's presence.

The nurse orients the patient to time and place at least once every 8 hours. Sounds from the patient's usual environment may be introduced using a recording. Family members can read to the patient from a favorite book and may suggest radio and television programs that the patient previously enjoyed as a means of enriching the environment and providing familiar input.

When arousing from coma, many patients experience a period of agitation, indicating that they are becoming more aware of their surroundings but still cannot react or communicate in an appropriate fashion. Although this is disturbing for many family members, it is actually a positive clinical sign. At this time, it is necessary to minimize stimulation by limiting background noises, having only one person speak to the patient at a time, giving the patient a longer period of time to respond, and allowing for frequent rest or quiet times. After the patient has regained consciousness, recordings of family or social events may assist the patient in recognizing family and friends and allow them to experience missed events.

Programs of sensory stimulation for patients with brain injury have been developed in an effort to improve outcomes. Although these are controversial programs with inconsistent results, some support the concept of providing structured neurostimulation (Hickey & Strayer, 2020).

Meeting the Family's Needs

The family of the patient with altered LOC may be thrown into a sudden state of crisis and go through the process of severe anxiety, denial, anger, remorse, grief, and reconciliation. Depending on the disorder that caused the altered LOC and the extent of the patient's recovery, the family may be unprepared for the changes in the cognitive and physical status of their loved one. If the patient has significant residual deficits, the family may require considerable time, assistance, and support to come to terms with these changes. To help family members mobilize resources and coping skills, the nurse reinforces and clarifies information about the patient's condition, encourages the family to be involved in care, and listens to and encourages sharing of feelings and concerns while supporting decision making about management and placement after hospitalization. Families may benefit from participation in support services offered through the hospital, rehabilitation facility, or community organizations.

The family may need to face the death of their loved one. The patient with a neurologic disorder is often pronounced brain dead before the heart stops beating. The term **brain death** describes irreversible loss of all functions of the entire brain and absence of brain stem reflexes (Milliken & Uveges, 2020). The term may be misleading to the family because, although brain function has ceased, the patient appears to be alive, with the heart rate and blood pressure sustained by vasoactive medications and breathing continued by mechanical ventilation. When discussing a patient who is brain dead with family members, it is important to provide accurate, timely, understandable, and consistent information. See Chapter 13 for discussion of end-of-life care.

Monitoring and Managing Potential Complications

Pneumonia, aspiration, and respiratory failure are potential complications in any patient who has a depressed LOC and who cannot protect the airway or turn, cough, and take deep breaths. The longer the period of unconsciousness, the greater the risk of pulmonary complications.

Vital signs and respiratory function are monitored closely to detect any signs of respiratory failure or distress. Complete blood count and arterial blood gas measurements are assessed to determine whether there are adequate red blood cells to carry oxygen and whether ventilation is effective. Chest physiotherapy and suctioning are initiated to prevent respiratory complications such as pneumonia. Oral care interventions are performed for patients receiving mechanical ventilation to maintain oral health and decrease the incidence of pneumonia (Malhan et al., 2019). If pneumonia develops, cultures are obtained to identify the organism so that appropriate antibiotic agents can be given.

The patient with altered LOC is monitored closely for evidence of impaired skin integrity, and strategies to prevent skin breakdown and pressure injuries are continued through all phases of care, including hospitalization, rehabilitation, and home care. Factors that contribute to impaired skin integrity (e.g., incontinence, inadequate dietary intake, pressure on bony prominences, edema) are addressed. If pressure injuries develop, strategies to promote healing are undertaken. Care is taken to prevent bacterial contamination of pressure injuries, which may lead to sepsis and septic shock. See Chapter 56 for assessment and management of pressure injuries.

The patient should also be monitored for signs and symptoms of VTE, which may manifest as a deep vein thrombosis (DVT) or pulmonary embolism (PE). Prophylaxis with subcutaneous heparin or low-molecular-weight heparin (dalteparin, danaparoid) as well as anti-embolism stockings or pneumatic compression devices are prescribed according to the patient's risk factors for thrombosis and bleeding (Galan, Egea-Guerrero, Diaz, et al., 2016). The nurse observes for signs and symptoms of DVT or PE.

Patients with a prolonged decrease in LOC are at risk for developing contractures. During acute care, the patient is turned every 2 hours and passive range of motion performed at least twice a day. Splints, provided by occupational therapy, are applied to the hands and feet in a rotating manner to maintain functional joint alignment. Hand splints have been reported to be safe and beneficial for patients in decreasing spasticity and improving hand opening (Khan, Amatya, Bensmail, et al., 2019).

Evaluation

Expected patient outcomes may include:

1. Attains optimal breathing pattern
2. Experiences no injuries
3. Attains or maintains adequate fluid balance and nutritional status
   a. Has no clinical signs or symptoms of dehydration
   b. Demonstrates normal range of serum electrolytes
   c. Has no clinical signs or symptoms of overhydration or malnutrition
4. Achieves healthy oral mucous membranes

5. Maintains intact skin
6. Has no corneal injury
7. Attains or maintains thermoregulation
8. Has no urinary retention
9. Has no diarrhea or fecal impaction
10. Receives appropriate sensory stimulation
11. Has family members who cope with crisis
    a. Verbalize fears and concerns
    b. Participate in patient's care and provide sensory stimulation by talking and touching
12. Is free of complications
    a. Has arterial blood gas values or oxygen saturation levels within normal range
    b. Displays no signs or symptoms of pneumonia
    c. Exhibits intact skin over pressure areas
    d. Does not develop VTE such as DVT or PE

INCREASED INTRACRANIAL PRESSURE

The rigid cranial vault contains brain tissue (1400 g), blood (75 mL), and CSF (75 mL). The volume and pressure of these three components are usually in a state of equilibrium and produce the ICP. ICP is usually measured in the lateral ventricles, with the normal pressure being 0 to 10 mm Hg, and 15 mm Hg being the upper limit of normal (Hickey & Strayer, 2020).

The **Monro–Kellie hypothesis,** also known as the Monro–Kellie doctrine, explains the dynamic equilibrium of cranial contents. The hypothesis states that because of the limited space for expansion within the skull, an increase in any one of the components causes a change in the volume of the others (Witherspoon & Ashby, 2017). Because brain tissue has limited space to expand, compensation typically is accomplished by displacing or shifting CSF, increasing the absorption or diminishing the production of CSF, or decreasing cerebral blood volume. Without such changes, ICP begins to rise. Under normal circumstances, minor changes in blood volume and CSF volume occur constantly as a result of alterations in intrathoracic pressure (coughing, sneezing, straining), posture, blood pressure, and systemic oxygen and carbon dioxide levels.

Pathophysiology

Increased ICP affects many patients with acute neurologic conditions because pathologic conditions alter the relationship between intracranial volume and ICP. Although elevated ICP is most commonly associated with head injury, it also may be seen as a secondary effect in other conditions, such as brain tumors, subarachnoid hemorrhage, and toxic and viral encephalopathies. Increased ICP from any cause decreases cerebral perfusion, stimulates further edema (swelling), and may shift brain tissue, resulting in herniation —a dire and frequently fatal event.

Decreased Cerebral Blood Flow

Increased ICP may reduce cerebral blood flow, resulting in ischemia and cell death. In the early stages of cerebral ischemia, the vasomotor centers are stimulated and the systemic pressure rises to maintain cerebral blood flow. Usually, this is accompanied by a slow bounding pulse and respiratory irregularities. These changes in blood pressure, pulse, and respiration are important clinically because they suggest increased ICP.

The concentration of carbon dioxide in the blood and in the brain tissue also plays a role in the regulation of cerebral blood flow. An increase in the partial pressure of arterial carbon dioxide ($PaCO_2$) causes cerebral vasodilation, leading to increased cerebral blood flow and increased ICP. A decrease in

$PaCO_2$ has a vasoconstrictive effect, limiting blood flow to the brain. Decreased venous outflow may also increase cerebral blood volume, thus raising ICP.

Cerebral Edema

Cerebral edema or swelling is defined as an abnormal accumulation of water or fluid in the intracellular space, extracellular space, or both, associated with an increase in the volume of brain tissue. Edema can occur in the gray, white, or interstitial matter. As brain tissue swells within the rigid skull, several mechanisms attempt to compensate for the increasing ICP. These compensatory mechanisms include autoregulation as well as decreased production and flow of CSF. **Autoregulation** refers to the brain's ability to change the diameter of its blood vessels to maintain a constant cerebral blood flow during alterations in systemic blood pressure. This mechanism can be impaired in patients who are experiencing a pathologic and sustained increase in ICP.

Cerebral Response to Increased Intracranial Pressure

As ICP rises, compensatory mechanisms in the brain work to maintain blood flow and prevent tissue damage. The brain can maintain a steady perfusion pressure if the arterial systolic blood pressure is 50 to 150 mm Hg and the ICP is less than 40 mm Hg. Changes in ICP are closely linked with cerebral perfusion pressure (CPP). The CPP is calculated by subtracting the ICP from the mean arterial pressure (MAP). For example, if the MAP is 100 mm Hg and the ICP is 15 mm Hg, then the CPP is 85 mm Hg. The normal CPP is 70 to 100 mm Hg (Hickey & Strayer, 2020). As ICP rises and the autoregulatory mechanism of the brain is overwhelmed, the CPP can increase to greater than 100 mm Hg or decrease to less than 50 mm Hg. Patients with a CPP of less than 50 mm Hg experience irreversible neurologic damage. Therefore, the CPP must be maintained at 70 to 80 mm Hg to ensure adequate blood flow to the brain. If ICP is equal to MAP, cerebral circulation ceases.

A clinical phenomenon known as the **Cushing's response** (also called Cushing's reflex) is seen when cerebral blood flow decreases significantly. When ischemic, the vasomotor center triggers an increase in arterial pressure in an effort to overcome the increased ICP. A sympathetically mediated response causes an increase in the systolic blood pressure with a widening of the pulse pressure and cardiac slowing. This response is seen clinically as an increase in systolic blood pressure, widening of the pulse pressure, and reflex slowing of the heart rate. It is a late sign requiring immediate intervention; however, perfusion may be recoverable if the Cushing's response is treated rapidly.

At a certain point, the brain's ability to autoregulate becomes ineffective and decompensation (ischemia and infarction) begins. When this occurs, the patient exhibits significant changes in mental status and vital signs. The bradycardia, hypertension, and bradypnea associated with this deterioration are known as Cushing's triad, which is a grave sign. At this point, herniation of the brain stem and occlusion of the cerebral blood flow occur if therapeutic intervention is not initiated. **Herniation** refers to the shifting of brain tissue from an area of high pressure to an area of lower pressure (see Fig. 61-2). The herniated tissue exerts pressure on the brain area into which it has shifted, which interferes with the blood supply in that area. Cessation of cerebral blood flow results in cerebral ischemia, infarction, and brain death.

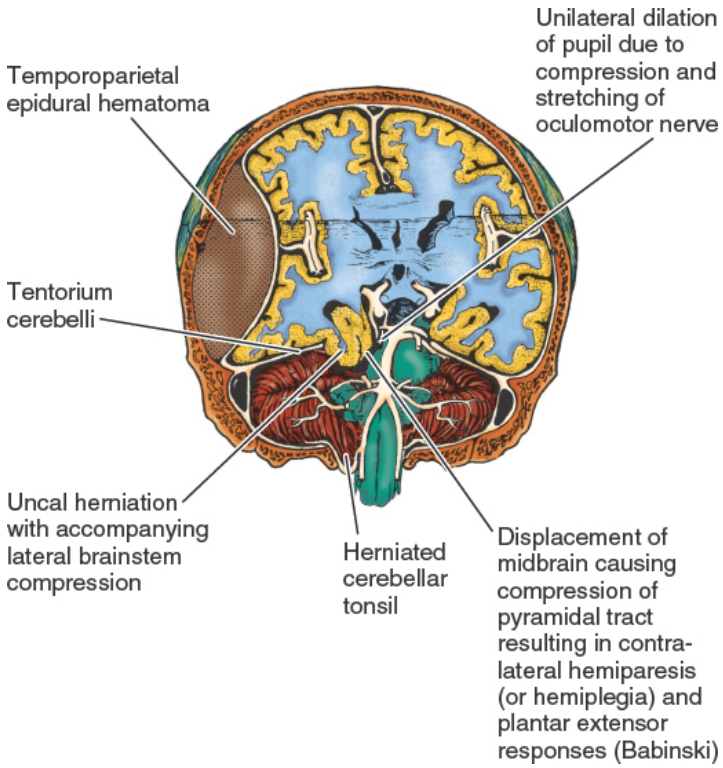


Figure 61-2 • Cross-section of the brain showing herniation of part of the temporal lobe through the tentorium as a result of a temporoparietal epidural hematoma. Reprinted with permission from Kintzel, K. C. (1977). *Advanced concepts in clinical nursing*. Philadelphia, PA: J. B. Lippincott.

Clinical Manifestations

If ICP increases to the point at which the brain's ability to adjust has reached its limits, neural function is impaired; this may be manifested at first by clinical changes in LOC and later by abnormal respiratory and vasomotor responses.

Quality and Safety Nursing Alert

The earliest sign of increasing ICP is a change in LOC. Agitation, slowing of speech, and delay in response to verbal suggestions may be early indicators.

Any sudden change in the patient's condition, such as restlessness (without apparent cause), confusion, or increasing drowsiness, has neurologic significance. These signs may result from compression of the brain due to swelling from hemorrhage or edema, an expanding intracranial lesion (hematoma or tumor), or a combination of both.

As ICP increases, the patient becomes stuporous, reacting only to loud or painful stimuli. At this stage, serious impairment of brain circulation is probably taking place, and immediate intervention is required. As neurologic function deteriorates further, the patient becomes comatose and exhibits abnormal motor responses in the form of **decortication** (abnormal flexion of the upper extremities and extension of the lower extremities), **decerebration** (extreme extension of the upper and lower extremities), or flaccidity (see Fig. 61-1). If the coma is profound and irreversible with no known confounding factors, brain stem reflexes are absent, and respirations are impaired or absent, the patient may be evaluated for brain death (Milliken & Uveges, 2020).

Assessment and Diagnostic Findings

The diagnostic studies used to determine the underlying cause of increased ICP are discussed in detail in Chapter 60. The most common diagnostic tests are CT scanning and MRI. The patient may also undergo

cerebral angiography, PET, or SPECT. Transcranial Doppler studies provide information about cerebral blood flow. The patient with increased ICP may also undergo electrophysiologic monitoring to observe cerebral blood flow indirectly. Evoked potential monitoring measures the electrical potentials produced by nerve tissue in response to external stimulation (auditory, visual, or sensory). Lumbar puncture is avoided in patients with increased ICP, because the sudden release of pressure in the lumbar area can cause the brain to herniate (Hickey & Strayer, 2020). See Chapter 60 for further discussion of lumbar puncture and other diagnostic tests.

Complications

Complications of increased ICP include brain stem herniation, diabetes insipidus, and syndrome of inappropriate antidiuretic hormone (SIADH).

Brain stem herniation results from an excessive increase in ICP in which the pressure builds in the cranial vault and the brain tissue presses down on the brain stem. This increasing pressure on the brain stem results in cessation of blood flow to the brain, leading to irreversible brain anoxia and brain death.

Neurogenic diabetes insipidus is the result of decreased secretion of antidiuretic hormone (ADH). The patient has excessive urine output, decreased urine osmolality, and serum hyperosmolarity (Tudor & Thompson, 2019). Therapy consists of administration of fluids, electrolyte replacement, and administration of a synthetic vasopressin (desmopressin). See Chapters 10 and 45 for a discussion of diabetes insipidus.

SIADH is the result of increased secretion of ADH. The patient becomes volume overloaded, urine output diminishes, and serum sodium concentration becomes dilute. Treatment of SIADH includes fluid restriction (less than 800 mL/day with no free water), which is usually sufficient to correct the hyponatremia. In severe cases, careful administration of a 3% hypertonic saline solution may be therapeutic (Hickey & Strayer, 2020). The change in serum sodium concentration should not exceed a correction rate of approximately 1.3 mEq/L/h. See Chapters 10 and 45 for further discussion of SIADH.

Medical Management

Increased ICP is a true emergency and must be treated promptly. Invasive monitoring of ICP is an important component of management. Immediate management to relieve increased ICP requires decreasing cerebral edema, lowering the volume of CSF, or decreasing cerebral blood volume while maintaining cerebral perfusion. These goals are accomplished by administering osmotic diuretics, restricting fluids, draining CSF, controlling fever, maintaining systemic blood pressure and oxygenation, and reducing cellular metabolic demands. See Chapter 63 for a discussion of the management of increased ICP.

Monitoring Intracranial Pressure and Cerebral Oxygenation

The purposes of ICP monitoring are to identify increased pressure early in its course (before cerebral damage occurs), to quantify the degree of elevation, to initiate appropriate treatment, to provide access to CSF for sampling and drainage, and to evaluate the effectiveness of treatment. ICP can be monitored with the use of an intraventricular catheter (ventriculostomy), a subarachnoid bolt, an epidural or subdural catheter, or a fiberoptic transducer–tipped catheter placed in the subdural space or in the ventricle (see Fig. 61-3).

When a ventriculostomy or intraventricular catheter monitoring device is used for monitoring ICP, a fine-bore catheter is inserted into a lateral ventricle, preferably in the nondominant hemisphere of the brain (Hickey & Strayer, 2020). The catheter is connected by a fluid-filled system to a transducer, which records the pressure in the form of an electrical impulse. In addition to obtaining continuous ICP recordings, the ventricular catheter allows CSF to drain, particularly during acute increases in pressure. The ventriculostomy can also be used to drain blood from the ventricle. Continuous drainage of CSF under pressure control is an effective method of treating intracranial hypertension. Another advantage of a ventricular catheter is access for the intraventricular administration of medications and the occasional instillation of air or a contrast agent for ventriculography. Complications associated with its use include infection, meningitis, ventricular collapse, occlusion of the catheter by brain tissue or blood, and problems with the monitoring system.

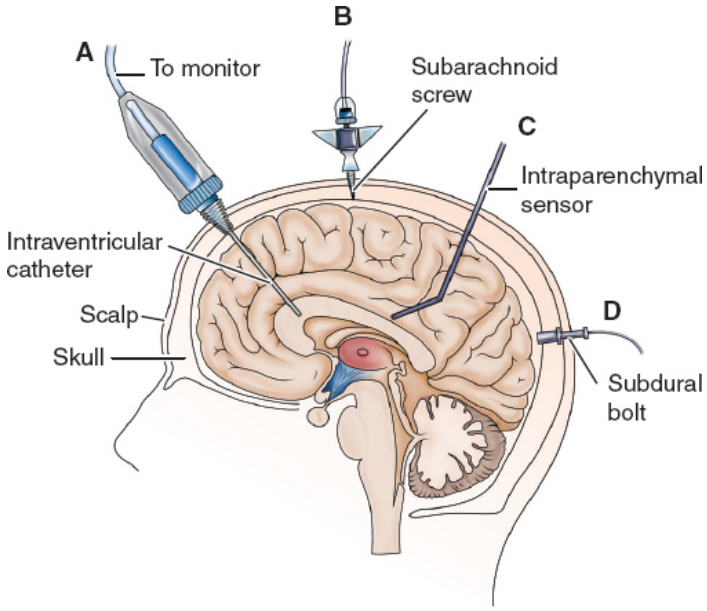

Figure 61-3 • Intracranial pressure monitoring. A device may be placed in the ventricle (**A**), the subarachnoid space (**B**), the intraparenchymal space (**C**), or the subdural space (**D**).

The subarachnoid screw or bolt is a hollow device that is inserted through the skull and dura mater into the cranial subarachnoid space (Hickey & Strayer, 2020). It has the advantage of not requiring a ventricular puncture. The subarachnoid screw is attached to a pressure transducer, and the output is recorded on an oscilloscope. The hollow screw technique also has the advantage of avoiding complications from brain shift and small ventricle size. Complications include infection and blockage of the screw by clot or brain tissue, which leads to a loss of pressure tracing and a decrease in accuracy at high ICP readings.

An epidural monitor uses a pneumatic flow sensor to detect ICP. The epidural ICP monitoring system has a low incidence of infection and complications and appears to read pressures accurately. Calibration of the system is maintained automatically, and abnormal pressure waves trigger an alarm system. One disadvantage of the epidural catheter is the inability to withdraw CSF for analysis.

A fiberoptic monitor, or transducer-tipped catheter, is an alternative to other intraventricular, subarachnoid, and subdural systems (Al-Mufti, Smith, Lander, et al., 2018). The miniature transducer reflects pressure changes, which are converted to electrical signals in an amplifier and displayed on a digital monitor. The catheter can be inserted into the ventricle, subarachnoid space, subdural space, or brain parenchyma or under a bone flap. If inserted into the ventricle, it can also be used in conjunction with a CSF drainage device.

Interpreting Intracranial Pressure Waveforms

Waves of high pressure and troughs of relatively normal pressure indicate changes in ICP. Waveforms are captured and recorded on an oscilloscope. These waves have been classified as A waves (plateau waves), B waves, and C waves (see Fig. 61-4). The plateau waves (A waves) are transient, paroxysmal, recurring elevations of ICP that may last 5 to 20 minutes and range in amplitude from 40 to 100 mm Hg (Al-Mufti et al., 2018). Plateau waves have clinical significance and indicate changes in vascular volume within the intracranial compartment that are beginning to compromise cerebral perfusion. The A waves may increase in amplitude and frequency, reflecting cerebral ischemia and brain damage that can occur before overt signs and symptoms of raised ICP are seen clinically. B waves are shorter (30 seconds to 2 minutes) and have smaller amplitude (up to 50 mm Hg). They have less clinical significance, but if seen in a series in a patient with depressed consciousness, they may precede the appearance of A waves. B waves may be seen in patients with intracranial hypertension and decreased intracranial compliance. C waves are small, rhythmic oscillations with frequencies of 4 to 8 per minute and appear to be related to rhythmic variations of the systemic arterial blood pressure and respirations (Hickey & Strayer, 2020).

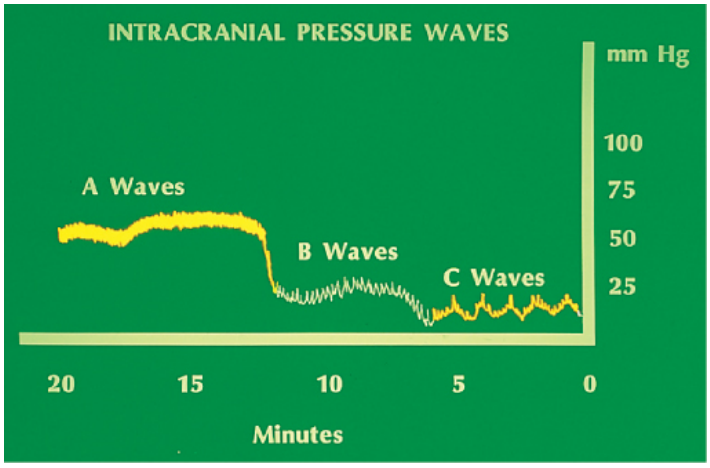

Figure 61-4 • Intracranial pressure waves. Composite diagram of A (plateau) waves, which indicate cerebral ischemia; B waves, which indicate intracranial hypertension and variations in the respiratory cycle; and C waves, which relate to variations in systemic arterial pressure and respirations.

Other Neurologic Monitoring Systems

Another trend in neurologic monitoring is microdialysis of the patient with a brain injury (Zhou & Kalanuria, 2018). Cortical probes are placed near the injured area and are used to measure levels of glutamate, lactate, pyruvate, and glucose, substances that reflect the metabolic function of the brain. Some researchers theorize that direct measurements of glucose and energy by-products in the brain will lead to better management of these patients. Although cerebral microdialysis has reduced the mortality of patients who are brain injured, more study is needed to link it to improved outcomes (Zhou & Kalanuria, 2018).

An additional trend is monitoring of cerebral oxygenation through monitoring of the oxygen saturation in the jugular venous bulb ($SjvO_2$) or via a catheter in the brain. Cerebral oxygenation is thought to be important because changes in cerebral perfusion may reflect an increase in ICP. Readings taken from a catheter residing in the jugular outflow tract allow for a comparison of arterial and venous oxygen saturation, and the balance of cerebral oxygen supply and demand is demonstrated. Venous jugular desaturations can reflect early cerebral ischemia, alerting the clinician before an increase in ICP occurs. Minimizing cerebral desaturations can potentially improve outcomes. This type of monitoring is now widely available and has been successfully used to identify secondary brain insults. A limiting factor is that this saturation reflects overall perfusion of the brain rather than that of a specific injured area (Al-Mufti et al., 2018).

Another method of measuring cerebral oxygenation and temperature is by inserting a fiberoptic catheter into the brain matter. The most common system is Licox (see Fig. 61-5). The system includes a monitor with a screen for the display of oxygen and temperature values and cables that connect to the monitoring probes in the brain (Hickey & Strayer, 2020).

Decreasing Cerebral Edema

Osmotic diuretics such as mannitol and hypertonic saline (3%) may be administered to decrease fluid in the brain tissue and reduce cerebral edema (Witherspoon & Ashby, 2017). These agents act by drawing water across intact membranes, thereby reducing the volume of the brain and extracellular fluid. An indwelling urinary catheter is usually inserted to monitor urinary output and to manage the resulting diuresis. If the patient is receiving osmotic diuretics, serum osmolality and electrolytes should be determined to assess hydration status. If a brain tumor is the cause of the increased ICP, corticosteroids (e.g., dexamethasone) help reduce the edema surrounding the tumor.

Figure 61-5 • The Licox brain tissue oxygen monitor. Permission granted by Integra LifeSciences Corporation, Princeton, New Jersey, USA.

Another method for decreasing cerebral edema is fluid restriction (Hickey & Strayer, 2020). Limiting overall fluid intake leads to dehydration and hemoconcentration, which draws fluid across the osmotic gradient and decreases cerebral edema. Conversely, overhydration of the patient with increased ICP is avoided, because it increases cerebral edema.

Researchers have long hypothesized that lowering body temperature would decrease cerebral edema by reducing the oxygen and metabolic requirements of the brain, thus protecting the brain from continued ischemia. If body metabolism can be reduced by lowering the body temperature, the collateral circulation in the brain may be able to provide an adequate blood supply to the brain. The effect of hypothermia on ICP requires more study; thus far, induced hypothermia has not consistently been shown to be beneficial for patients with brain injury. Inducing and maintaining hypothermia is a major clinical treatment and requires knowledge and skilled nursing observation and management. The type and length of rewarming techniques after hypothermia may also be factors in the outcome of patients with neurologic injuries (Rincon, 2018).

Maintaining Cerebral Perfusion

Cardiac output may be manipulated to provide adequate perfusion to the brain. Improvements in cardiac output are made using fluid volume and inotropic agents such as dobutamine and norepinephrine. The effectiveness of the cardiac output is reflected in the CPP, which is maintained at greater than 70 mm Hg. A lower CPP indicates that the cardiac output is insufficient to maintain adequate cerebral perfusion. $SjvO_2$ and Licox, described earlier, assist in monitoring cerebral perfusion.

Decompressive hemicraniectomy may also be considered as a surgical strategy to assist in the management of refractory intracranial hypertension. The removal of a part of the skull allows the brain to expand without the pressure constraints exerted by the cranial vault. Complications of this procedure include infection and increased potential for injury to the unprotected underlying brain structures. Once the patient is no longer at risk for increased ICP, the bone flap may be surgically replaced (Hutchinson, Kolias, Tajsic, et al., 2019).

Reducing Cerebrospinal Fluid and Intracranial Blood Volume

CSF drainage is frequently performed, because the removal of CSF with a ventriculostomy drain can dramatically reduce ICP and restore CPP. Caution should be used in draining CSF, however, because excessive drainage may result in collapse of the ventricles and herniation. The reduction in $PaCO_2$ may result in hypoxia, ischemia, and an increase in cerebral lactate levels. Maintaining the $PaCO_2$ at greater than 30 mm Hg may prove beneficial (Hickey & Strayer, 2020).

Controlling Fever

Preventing a temperature elevation is critical, because fever increases cerebral metabolism and the rate at which cerebral edema forms. Strategies to reduce body temperature include administration of antipyretic medications, as prescribed, and the use of a hypothermia blanket. Additional strategies for reducing fever were discussed previously in the Nursing Process section on altered LOC. The patient's temperature is monitored closely, and the patient is observed for shivering, which should be avoided because it is associated with increased oxygen consumption, increased levels of circulating catecholamines, and increased vasoconstriction. Shivering is associated with decreased levels of brain oxygenation; however, the association between shivering and neurologic outcome is unknown.

Maintaining Oxygenation and Reducing Metabolic Demands

Arterial blood gases and pulse oximetry are monitored to ensure that systemic oxygenation remains optimal. Metabolic demands may be reduced through the administration of high doses of barbiturates if the patient is unresponsive to conventional treatment. The mechanism by which barbiturates decrease ICP and protect the brain is uncertain, but the resultant comatose state is thought to reduce the metabolic requirements of the brain, thus providing cerebral protection.

Another method of reducing cellular metabolic demand and improving oxygenation is the administration of medications causing sedation. The patient who receives these agents cannot move; this decreases the metabolic demands and results in a decrease in cerebral oxygen demand. The patient cannot respond to or report pain either. The most common agents used for sedation are pentobarbital, thiopental, propofol, and dexmedetomidine (Opdenakker, Vanstraelen, De Sloovere, et al., 2019).

If sedative agents are used, the ability to perform serial neurologic assessments is lost. Therefore, other monitoring tools are needed to assess the patient's status and response to therapy. Important parameters that must be assessed include ICP, blood pressure, heart rate, respiratory rate, and the patient's response to ventilator therapy (e.g., patient-ventilator dyssynchrony; see Chapter 19). The level of pharmacologic paralysis is adjusted based on serum levels of the medications given and the assessed parameters. Potential complications of these medications include hypotension caused by decreased sympathetic tone and myocardial depression.

Patients receiving high doses of barbiturates or pharmacologic sedatives require continuous cardiac monitoring, endotracheal intubation, mechanical ventilation, and arterial pressure monitoring, as well as ICP monitoring.

NURSING PROCESS

The Patient with Increased Intracranial Pressure

Assessment

Initial assessment of the patient with increased ICP includes obtaining a history of events leading to the present illness and the pertinent past medical history. It is usually necessary to obtain this information from family or friends. The neurologic examination should be as complete as the patient's condition allows. It includes an evaluation of mental status, LOC, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function. Because the patient is critically ill, ongoing assessment is more focused, including pupil checks, assessment of selected cranial nerves, frequent measurements of vital signs and ICP, and the use of the Glasgow Coma Scale (see Table 61-1).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses include the following:

- Impaired breathing associated with neurologic dysfunction (brain stem compression, structural displacement)
- Risk for ineffective tissue perfusion associated with the effects of increased ICP
- Hypovolemia associated with fluid restriction
- Risk for infection associated with ICP monitoring system (fiberoptic or intraventricular catheter)

Other relevant nursing diagnoses are included in the earlier section on altered LOC.

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Brain stem herniation
- Diabetes insipidus
- SIADH

Planning and Goals

The goals for the patient include normalization of respiration, adequate cerebral tissue perfusion through reduction in ICP, restoration of fluid balance, absence of infection, and absence of complications.

Nursing Interventions

Achieving an Adequate Breathing Pattern

In order to normalize breathing it is essential to maintain the airway. The patency of the airway is assessed. Secretions that are obstructing the airway must be suctioned with care, because transient elevations of ICP occur with suctioning (Hickey & Strayer, 2020). Hypoxia caused by poor oxygenation leads to cerebral ischemia and edema. Coughing is discouraged because it increases ICP. The lung fields are auscultated at least every 8 hours to determine the presence of adventitious sounds or any areas of congestion. Elevating the head of the bed may aid in clearing secretions and improve venous drainage of the brain.

The patient must be monitored for respiratory irregularities. Increased pressure on the frontal lobes or deep midline structures may result in Cheyne–Stokes respirations, whereas pressure in the midbrain can cause hyperventilation. If the lower portion of the brain stem (the pons and medulla) is involved, respirations become irregular and eventually cease.

There is ongoing controversy about the use of hyperventilation therapy in traumatic brain injury. This therapy is used in some circumstances to reduce ICP by causing cerebral vasoconstriction and a decrease in cerebral blood volume. The nurse collaborates with the respiratory therapist in monitoring the $PaCO_2$, which is usually maintained at less than 30 mm Hg. Employing hyperventilation should follow guidelines for management of TBI as it involves risk of cerebral vasoconstriction and ischemia (Saherwala, Bader, Stutzman, et al., 2018). Patients undergoing hyperventilation therapy also benefit from multimodality monitoring to determine the overall effect of this therapy on brain perfusion (Hickey & Strayer, 2020).

A neurologic observation record (see Fig. 61-6) is maintained, and all observations are made in relation to the patient's baseline condition. Repeated assessments of the patient are made (sometimes minute by minute) so that improvement or deterioration may be noted immediately. If the patient's condition deteriorates, the primary provider is notified emergently and preparations are made for surgical intervention.

Optimizing Cerebral Tissue Perfusion

In addition to ongoing nursing assessment, strategies are initiated to reduce factors contributing to the elevation of ICP (see Table 61-2).

Proper positioning helps reduce ICP. The patient's head is kept in a neutral (midline) position, maintained with the use of a cervical collar if necessary, to promote venous drainage. Elevation of the head is maintained at 30 to 45 degrees unless contraindicated. Extreme rotation of the neck and flexion of the neck are avoided, because compression or distortion of the jugular veins increases ICP. Extreme hip flexion is also avoided, because this position causes an increase in intra-abdominal and intrathoracic pressures, which can produce an increase in ICP. Relatively minor changes in position can significantly affect ICP. If monitoring reveals that turning the patient raises ICP, rotating beds, turning sheets, and holding the patient's head during turning may minimize the stimuli that increase ICP. Research suggests that patient response to position change is highly variable and requires close hemodynamic monitoring and individualized care (Hickey & Strayer, 2020).

The Valsalva maneuver, which can be produced by straining at defecation or even moving in bed, raises ICP and is to be avoided. Stool softeners may be prescribed. If the patient is alert and able to eat, a diet high in fiber may be indicated. Abdominal distention, which increases intra-abdominal and intrathoracic pressure and ICP, should be noted. Enemas and cathartics are avoided if possible. When moving or being turned in bed, the patient can be instructed to exhale (which opens the glottis) to avoid the Valsalva maneuver.

Mechanical ventilation presents unique problems for the patient with increased ICP. Before suctioning, the patient should be preoxygenated and briefly hyperventilated using 100% oxygen on the ventilator. Suctioning should not last longer than 15 seconds. High levels of positive end-expiratory pressure (PEEP) must be utilized cautiously, because they may decrease venous return to the heart and decrease venous drainage from the brain through increased intrathoracic pressure (Hickey & Strayer, 2020).

Activities that increase ICP, as indicated by changes in waveforms, should be avoided if possible. Spacing of nursing interventions may prevent transient increases in ICP. During nursing interventions, the ICP should not increase above 25 mm Hg, and it should return to baseline levels within 5 minutes. Patients with increased ICP should not demonstrate a significant increase in pressure or change in the ICP waveform. Patients with the potential for a significant increase in ICP may need sedation before initiation of nursing activities (Hickey & Strayer, 2020).

Emotional stress and frequent arousal from sleep are avoided. A calm atmosphere is maintained. Environmental stimuli (e.g., noise, conversation) should be minimal.

Maintaining Negative Fluid Balance

The administration of osmotic and loop diuretics is part of the treatment protocol to reduce ICP. Corticosteroids may be used to reduce cerebral edema (except when it results from trauma), and fluids may be restricted. All of these treatment modalities promote dehydration.

Skin turgor, mucous membranes, urine output, and serum and urine osmolality are monitored to assess fluid status. If IV fluids are prescribed, the nurse ensures that they are given at a slow to moderate rate with an IV infusion pump, to prevent too-rapid administration and avoid overhydration. For the patient receiving mannitol, the nurse observes for the possible development of heart failure and pulmonary edema. The intent of treatment is to promote a shift of fluid from the intracellular to the intravascular compartment and to control cerebral edema. However, this shift of fluid volume to the intravascular compartment may overwhelm the ability of the myocardium to increase workload sufficient to meet these demands, which may cause failure and pulmonary edema.

For patients undergoing dehydrating procedures, vital signs, including blood pressure, must be monitored to assess fluid volume status. An indwelling urinary catheter is inserted to permit assessment of renal function and fluid status. During the acute phase, urine output is monitored hourly. An output greater than 200 mL/h for 2 consecutive hours may indicate the onset of diabetes insipidus (Hickey & Strayer, 2020). These patients need careful oral hygiene, because mouth dryness occurs with dehydration. Frequently rinsing the mouth with nondrying solutions, lubricating the lips, and removing encrustations relieve dryness and promote comfort.

TABLE 61-2 Increased Intracranial Pressure and Interventions

Factor	Physiology	Interventions	Rationale
Cerebral edema	Can be caused by contusion, tumor, or abscess; water intoxication (hypo-osmolality); alteration in the blood–brain barrier (protein leaks into the tissue, causing water to follow).	Administer osmotic diuretics as prescribed (monitor serum osmolality). Maintain head of bed elevation at 30 degrees. Maintain alignment of the head.	Promotes venous return. Prevents impairment of venous return through the jugular veins.
Hypoxia	A decrease in PaO_2 to <60 mm Hg causes cerebral vasodilation.	Maintain PaO_2 >60 mm Hg. Maintain oxygen therapy. Monitor arterial blood gas values. Suction when needed. Maintain a patent airway.	Prevents hypoxia and vasodilation.
Hypercapnia (elevated $PaCO_2$)	Causes vasodilation.	Maintain $PaCO_2$ (normally 35–45 mm Hg) by establishing ventilation.	Normalizing $PaCO_2$ minimizes vasodilation and thus reduces the cerebral blood volume.
Impaired venous return	Increases the cerebral blood volume.	Maintain head alignment. Elevate head of bed 30 degrees.	Hyperextension, rotation, or hyperflexion of the neck causes decreased venous return.
Increase in intrathoracic or abdominal pressure	An increase in these pressures due to coughing, PEEP, or Valsalva maneuver causes a decrease in venous return.	Monitor arterial blood gas values, and keep PEEP as low as possible. Provide humidified oxygen. Administer stool softeners as prescribed.	To keep secretions loose and easy to suction or expectorate. Soft bowel movements will prevent straining or Valsalva maneuver.

$PaCO_2$, partial pressure of arterial carbon dioxide; PaO_2, partial pressure of arterial oxygen; PEEP, positive end-expiratory pressure.

Preventing Infection

The risk of infection is greatest when ICP is monitored with an intraventricular catheter and increases with the duration of the monitoring. Most health care facilities have written protocols for managing these systems and maintaining their sterility; strict adherence to the protocols is essential.

Aseptic technique must be used when managing the system and changing the ventricular drainage bag. The drainage system is also checked for loose connections, because they can cause leakage and contamination of the CSF as well as inaccurate readings of ICP. The nurse observes the character of the CSF drainage and reports increasing cloudiness or blood. The patient is monitored for signs and symptoms of meningitis: fever, chills, nuchal (neck) rigidity, and increasing or persistent headache. See Chapter 64 for a discussion of meningitis.

Monitoring and Managing Potential Complications

The primary complication of increased ICP is brain herniation resulting in death (see Fig. 61-2). Nursing management focuses on detecting early signs of increasing ICP, because medical interventions are usually ineffective once later signs develop (Hickey & Strayer, 2020). Frequent neurologic

assessments and documentation and analysis of trends will reveal the subtle changes that may indicate increasing ICP.

Detecting Indications of Increasing Intracranial Pressure. The nurse assesses for and immediately reports any signs or symptoms of increasing ICP (see Chart 61-1). The focus is on detecting early signs of increasing ICP.

Monitoring Intracranial Pressure. Because clinical assessment is not always a reliable guide in recognizing increased ICP, especially in patients who are comatose, monitoring of ICP and cerebral oxygenation is an essential part of management. ICP is monitored closely for continuous elevation or significant increase over baseline. The trend of ICP measurements over time is an important indication of the patient's underlying status. Vital signs are assessed when an increase in ICP is noted (Hickey & Strayer, 2020).

Careful attention to aseptic technique is needed when handling any part of the monitoring system (Hickey & Strayer, 2020). The insertion site is inspected for signs of infection. Temperature, pulse, and respirations are closely monitored for systemic signs of infection (Rincon, 2018). All connections and stopcocks are checked for leaks, because even small leaks can distort pressure readings and lead to infection (Hickey & Strayer, 2020).

When ICP is monitored with a fluid system, the transducer is calibrated at a particular reference point, usually 2.5 cm (1 inch) above the ear with the patient in the supine position; this point corresponds to the level of the foramen of Monro (see Fig. 61-7). CSF pressure readings depend on the patient's position. For subsequent pressure readings, the head should be in the same position relative to the transducer. Fiberoptic catheters are calibrated before insertion and do not require further referencing; they do not require the head of the bed to be at a specific position to obtain an accurate reading.

Chart 61-1

Detecting Increasing Intracranial Pressure (ICP)

Early Signs and Symptoms of Increasing ICP

- *Disorientation, restlessness, increased respiratory effort, purposeless movements, and mental confusion.* These are early clinical indications of increasing ICP because the brain cells responsible for cognition are extremely sensitive to decreased oxygenation.
- *Pupillary changes and impaired extraocular movements.* These occur as the increasing pressure displaces the brain against the oculomotor and optic nerves (cranial nerves II, III, IV, and VI), which arise from the midbrain and brain stem (see Chapter 60).
- *Weakness in one extremity or on one side of the body.* This occurs as increasing ICP compresses the pyramidal tracts.
- *Headache that is constant, increasing in intensity, and aggravated by movement or straining.* This occurs as increasing ICP causes pressure and stretching of venous and arterial vessels in the base of the brain.

Later Signs and Symptoms of Increasing ICP

- The level of consciousness continues to deteriorate until the patient is comatose (Glasgow Coma Scale score ≤8).
- The pulse rate and respiratory rate decrease or become erratic, and the blood pressure and temperature increase. The pulse pressure (the difference between the systolic and diastolic pressures) widens. The pulse fluctuates rapidly, varying from bradycardia to tachycardia.
- Altered respiratory patterns develop, including Cheyne–Stokes breathing (rhythmic waxing and waning of rate and depth of respirations alternating with brief periods of apnea) and ataxic breathing (irregular breathing with a random sequence of deep and shallow breaths).
- Projectile vomiting may occur with increased pressure on the reflex center in the medulla.
- Hemiplegia or decorticate or decerebrate posturing may develop as pressure on the brain stem increases; bilateral flaccidity occurs before death.
- Loss of brain stem reflexes, including pupillary, corneal, gag, and swallowing reflexes, is an ominous sign of approaching death.

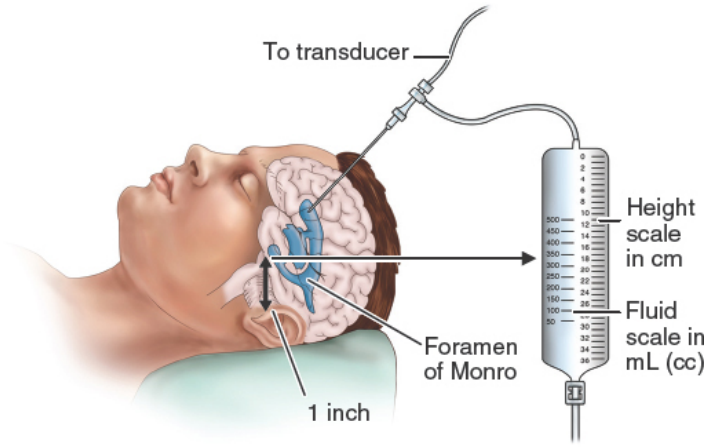

Figure 61-7 • Location of the foramen of Monro for calibration of the intracranial pressure monitoring system.

When technology is associated with patient management, the nurse must be certain that the technologic equipment is functioning properly and used correctly (Liu, Griffith, Jang, et al., 2020) (see the Nursing Research Profile in Chart 61-2). The most important concern must be the patient to whom equipment is attached. The patient and family must be informed about the technology and the goals of its use. The patient's response is monitored, and appropriate comfort measures are implemented to ensure that the patient's stress is minimized.

ICP measurement is only one parameter; repeated neurologic checks and clinical examinations remain important measures. Astute observation, comparison of findings with previous observations, and interventions can assist in preventing life-threatening ICP elevations.

Monitoring for secondary complications. The nurse also assesses for complications of increased ICP, including diabetes insipidus and SIADH (see Chapters 10 and 45). Urine output should be monitored closely. Diabetes insipidus requires fluid and electrolyte replacement, along with the administration of vasopressin, to replace and slow the urine output. Serum electrolyte levels are monitored for imbalances. SIADH requires fluid restriction and monitoring of serum electrolyte levels.

Chart 61-2  **NURSING RESEARCH PROFILE**

Aspects of Intracranial Pressure Monitoring

Liu, X., Griffith, M., Jang, H., et al. (2020). Intracranial pressure monitoring via external ventricular drain: Are we waiting long enough before recording the real value? *Journal of Neuroscience Nursing*, *52*(1), 37–42.

Purpose

The purpose of this study of intracranial pressure (ICP) recordings was to obtain an insight into how well the intermittent external ventricular drain (EVD) clamping procedure is performed for ICP documentation.

Design

This was a retrospective analysis of ICP recordings. For each recording of ICP, the mean and standard deviation were calculated. The duration of EVD closure, time interval between two adjacent EVD closures, and the total number of EVD closures were calculated for each patient. An algorithm to evaluate whether ICP reached a new equilibrium before the EVD was reopened for drainage was developed. The percentage of EVD closures that reached the equilibrium was calculated.

Findings

Data were obtained from 107 patients with subarachnoid hemorrhage who had 32,755 EVD closures in total. Only 65.9% of openings lasted less than 1 minute and 16.3% lasted longer than 5 minutes. The median duration of each EVD closure was 25 seconds. Only 22.9% of EVD closures reached ICP equilibrium before EVD reopening.

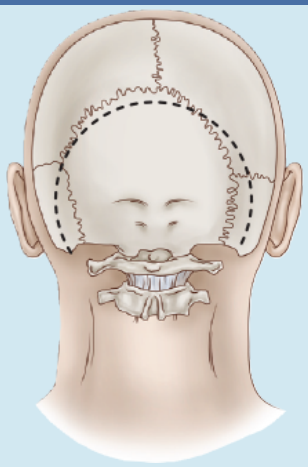
Nursing Implications

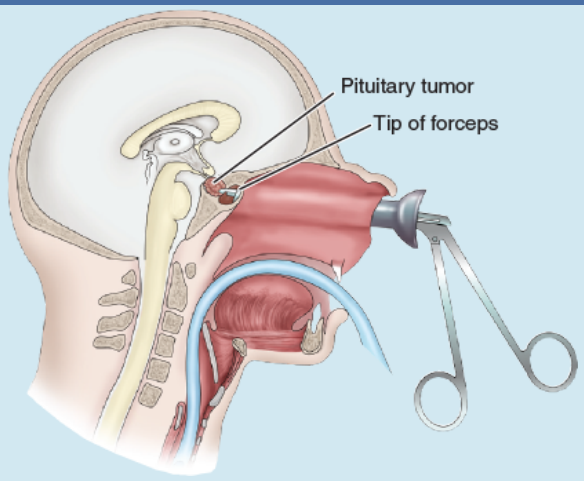
This research provides evidence for the need to properly train and provide a standard guideline for bedside nurses to correctly obtain and document ICP. Nurses working in settings where ICP is monitored need to work on clear guidelines that specify the need to wait the required time when opening and closing an EVD in order to get an accurate reading.

Evaluation

Expected patient outcomes may include:

1. Attains optimal breathing pattern
   a. Maintains patent airway
   b. Breathes in a regular pattern
   c. Attains or maintains arterial blood gas values within acceptable range
2. Demonstrates optimal cerebral tissue perfusion
   a. Increasingly oriented to time, place, and person
   b. Follows verbal commands; answers questions correctly
3. Attains desired fluid balance
   a. Maintains fluid restriction
   b. Demonstrates serum and urine osmolality values within acceptable range
4. Has no signs or symptoms of infection
   a. Has no fever
   b. Shows no redness, swelling, or drainage at arterial, IV, and urinary catheter sites
   c. Has no redness, swelling, or purulent drainage from invasive intracranial monitoring device
5. Absence of complications
   a. Has ICP values that remain within normal limits
   b. Demonstrates urine output and serum electrolyte levels within acceptable limits





INTRACRANIAL SURGERY

A **craniotomy** involves opening the skull surgically to gain access to intracranial structures. This procedure is performed to remove a tumor, relieve elevated ICP, evacuate a blood clot, or control

hemorrhage. The surgeon cuts the skull to create a bony flap, which can be repositioned after surgery and held in place by periosteal or wire sutures. One of two approaches through the skull is used: above the tentorium (supratentorial craniotomy) into the supratentorial compartment, or below the tentorium into the infratentorial (posterior fossa) compartment. A third approach, the **transsphenoidal** approach (through the mouth and nasal sinuses) is often used to gain access to the pituitary gland (Hickey & Strayer, 2020). Table 61-3 compares these three different surgical approaches.

Alternatively, intracranial structures may be approached through burr holes (see Fig. 61-8), which are circular openings made in the skull by either a hand drill or an automatic craniotome (which has a self-controlled system to stop the drill when the bone is penetrated). Burr holes may be used to determine the presence of cerebral swelling and injury and the size and position of the ventricles. They are also a means of evacuating an intracranial hematoma or abscess and for making a bone flap in the skull that allows access to the ventricles for decompression, ventriculography, or shunting procedures. Other cranial procedures include **craniectomy** (excision of a portion of the skull) and cranioplasty (repair of a cranial defect using a plastic or metal plate).

TABLE 61-3 Comparison of Cranial Surgical Approaches

Supratentorial	Infratentorial	Transsphenoidal
		
Site of Surgery		
Above the tentorium	Below the tentorium, brain stem	Sella turcica and pituitary region
Incision Location		
Incision is made above the area to be operated on; usually located behind the hairline.	Incision is made at the nape of the neck, around the occipital lobe.	Incision is made beneath the upper lip to gain access into the nasal cavity.
Select Nursing Interventions		
Maintain head of bed elevated at 30 degrees, with neck in neutral alignment.	Maintain neck in straight alignment. Avoid flexion of the neck to prevent possible tearing of the suture line.	Maintain nasal packing in place and reinforce as needed. Instruct patient to avoid blowing the nose. Provide oral care according to institutional procedure.
Position patient on either side or back. (Avoid positioning patient on operative side if a large tumor has been removed.)	Position the patient on either side. (Check surgeon's preference for positioning of patient.)	Keep head of bed elevated to promote venous drainage and drainage from the surgical site.

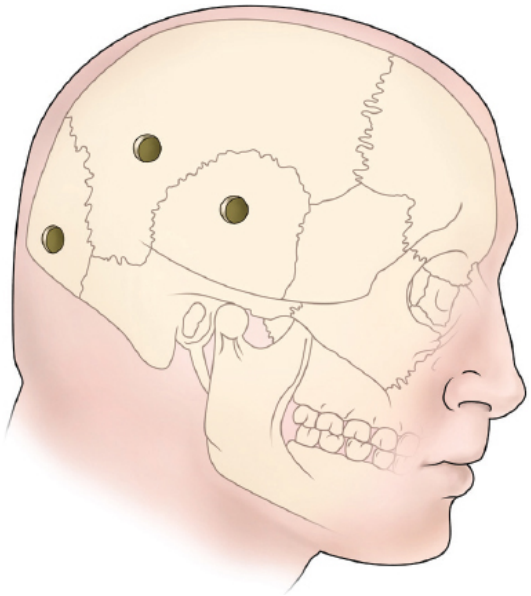


Figure 61-8 • Burr holes may be used in neurosurgical procedures to make a bone flap in the skull, to aspirate a brain abscess, or to evacuate a hematoma.

Supratentorial and Infratentorial Approaches

Preoperative Management

Medical Management

Preoperative diagnostic procedures may include a CT scan to demonstrate the lesion and show the degree of surrounding brain edema, the ventricular size, and the displacement. An MRI scan provides information similar to that of a CT scan with improved tissue contrast, resolution, and anatomic definition. Cerebral angiography may be used to study a tumor's blood supply or obtain information about vascular lesions. Transcranial Doppler flow studies are used to evaluate the blood flow within intracranial blood vessels.

Patients may be prescribed an anticonvulsant medication such as phenytoin, levetiracetam, or a phenytoin metabolite (fosphenytoin sodium) before surgery to reduce the risk of postoperative **seizures** (paroxysmal transient disturbance of the brain resulting from a discharge of abnormal electrical activity) (Comerford & Durkin, 2020). Recent research suggests that anticonvulsant medications should not be used routinely, but only when the patient experiences seizures (Mirian, Pedersen, Sabers, et al., 2019). Before surgery, corticosteroids such as dexamethasone may be given to reduce cerebral edema if the patient has a brain tumor. Fluids may be restricted. A hyperosmotic agent (mannitol) and a diuretic agent such as furosemide may be administered IV immediately before and sometimes during surgery if the patient tends to retain fluid, as do many who have intracranial dysfunction. Antibiotic agents may be given if there is a chance of cerebral contamination; diazepam or lorazepam may be prescribed before surgery to allay anxiety.

Nursing Management

The preoperative assessment serves as a baseline against which postoperative status and recovery are compared. This assessment includes evaluating the LOC and responsiveness to stimuli and identifying any neurologic deficits, such as paralysis, visual dysfunction, alterations in personality or speech, and bladder and bowel disorders. Baseline distal and proximal motor strength in both upper and lower extremities is tested and recorded. See Chapter 60 for a discussion of the testing of motor function.

The patient's and family's understanding of and reactions to the anticipated surgical procedure and its possible sequelae are assessed, as is the availability of support systems for the patient and family. Adequate preparation for surgery, with attention to the patient's physical and emotional status, can reduce the risk of

anxiety, fear, and postoperative complications. The patient is assessed for neurologic deficits and their potential impact after surgery. For motor deficits or weakness or paralysis of the arms or legs, trochanter rolls are applied to the extremities, and the feet are positioned against a footboard or the ankles are supported in a neutral position with orthotic boots. A patient who can ambulate is encouraged to do so. If the patient is aphasic, writing materials or picture and word cards showing the bedpan, glass of water, blanket, and other frequently used items may help improve communication.

Preparation of the patient and family includes providing education about what to expect during and after surgery. The patient should plan to shower and wash their hair prior to surgery using the preferred cleansing solution. Hair is removed with the use of clippers and the surgical site prepared immediately before surgery (usually in the operating room), and IV antibiotics are given 1 hour prior to the incision to decrease the chance of infection (American Association of Neuroscience Nurses [AANN], 2016b). An indwelling urinary catheter is inserted in the operating room to drain the bladder during the administration of diuretic agents and to permit monitoring of urinary output. The patient may have an arterial line placed for monitoring of pressures after surgery. The large head dressing applied after surgery may impair hearing temporarily. Vision may be limited if the eyes are swollen shut. If a tracheostomy or endotracheal tube remains in place, the patient will be unable to speak until the tube is removed, so an alternative method of communication must be established.

An altered cognitive state may make the patient unaware of the impending surgery. Even so, encouragement and attention to the patient's needs are necessary. Whatever the state of awareness of the patient, the family needs reassurance and support, because they usually recognize the seriousness of brain surgery.

Postoperative Management

Postoperatively, an arterial line may be in place to monitor and manage blood pressure. The patient may be intubated and may receive supplemental oxygen therapy. Ongoing postoperative management is aimed at detecting and reducing cerebral edema, relieving pain and preventing seizures, and monitoring ICP and neurologic status.

Reducing Cerebral Edema

Medications to reduce cerebral edema include mannitol, which increases serum osmolality and draws free water from areas of the brain (with an intact blood–brain barrier). The fluid is then excreted by osmotic diuresis. Dexamethasone may be administered IV every 6 hours for 24 to 72 hours; the route is changed to oral as soon as possible, and the dosage is typically tapered over 5 to 7 days; some patients may require an extended taper (Comerford & Durkin, 2020).

Relieving Pain and Preventing Seizures

Acetaminophen is usually prescribed for temperatures exceeding 37.5°C (99.6°F) (Rincon, 2018) and for mild pain. The patient usually has a headache after a craniotomy as a result of stretching and irritation of nerves in the scalp during surgery. Codeine, administered IV or orally, is often sufficient to relieve headache. Morphine sulfate may also be used in the management of postoperative pain in patients who have undergone a craniotomy with the goal of a patient reporting acceptable pain level (AANN, 2016b).

Anticonvulsant medication (phenytoin, levetiracetam) is often prescribed prophylactically for patients who have undergone supratentorial craniotomy because of the high risk of seizures after these procedures (Hickey & Strayer, 2020). Serum levels are monitored to check that the medication levels are within the therapeutic range.

Monitoring Intracranial Pressure

A patient undergoing intracranial surgery may have an ICP or cerebral oxygenation monitor inserted during surgery. Strict adherence to written protocols for managing these systems is essential, as discussed earlier, for preventing infection and managing ICP. The system is removed after the ICP or cerebral oxygenation is normal and stable. The neurosurgeon must be notified immediately if the system is not functioning.

NURSING PROCESS

The Patient Who Has Undergone Intracranial Surgery

Assessment

After surgery, the frequency of postoperative monitoring is based on the patient's clinical status. Assessing respiratory function is essential, because even a small degree of hypoxia can increase cerebral ischemia. The respiratory rate and pattern are monitored, and arterial blood gas values are assessed frequently. Fluctuations in vital signs are carefully monitored and documented, because they may indicate increased ICP. The patient's temperature is measured to assess for hyperthermia secondary to infection or damage to the hypothalamus. Neurologic checks are made frequently to detect increased ICP resulting from cerebral edema or bleeding. A change in LOC or response to stimuli may be the first sign of increasing ICP.

The surgical dressing is inspected for evidence of bleeding and CSF drainage. The incision is monitored for redness, tenderness, bulging, separation, or foul odor. Sodium retention may occur in the immediate postoperative period. Serum and urine electrolytes, BUN, blood glucose, weight, and clinical status are monitored. Intake and output are measured in view of losses associated with fever, respiration, and CSF drainage. The nurse must be alert to the development of complications; all assessments are carried out with these problems in mind. Seizures are a potential complication, and any seizure activity is carefully recorded and reported. Restlessness may occur as the patient becomes more responsive, or restlessness may be caused by pain, confusion, hypoxia, or other stimuli.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for ineffective tissue perfusion associated with cerebral edema
- Risk for impaired thermoregulation associated with damage to the hypothalamus, dehydration, and infection
- Impaired gas exchange associated with hypoventilation, aspiration, and immobility
- Difficulty coping associated with sensory perception changes due to periorbital edema, head dressing, endotracheal tube, and effects of ICP
- Disturbed body image associated with change in appearance or physical disabilities

Other nursing diagnoses may include impaired communication (aphasia) associated with insult to brain tissue and high risk for impaired skin integrity associated with immobility, pressure, and incontinence; impaired mobility associated with a neurologic deficit secondary to the neurosurgical procedure or to the underlying disorder may also occur.

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Increased ICP
- Bleeding and hypovolemic shock
- Fluid and electrolyte disturbances
- Infection
- CSF leak
- Seizures

Planning and Goals

The major goals for the patient include maintaining or restoring neurologic homeostasis to improve cerebral tissue perfusion, adequate thermoregulation, normal ventilation and gas exchange, ability to cope with sensory deprivation, adaptation to changes in body image, and absence of complications.

Nursing Interventions

Maintaining Cerebral Tissue Perfusion

Attention to the patient's respiratory status is essential, because even slight decreases in the oxygen level (hypoxia) or slight increases in the carbon dioxide level (hypercarbia) can affect cerebral perfusion, the clinical course, and the patient's outcome. The endotracheal tube is left in place until the patient shows signs of awakening and has adequate spontaneous ventilation, as evaluated clinically and by arterial blood gas analysis. Secondary brain damage can result from impaired cerebral oxygenation.

Some degree of cerebral edema occurs after brain surgery; it tends to peak 24 to 36 hours after surgery, potentially producing decreased responsiveness on the second postoperative day. The control of cerebral edema was discussed earlier. Nursing strategies used to control factors that may raise ICP were presented in the previous Nursing Process section on increased ICP. Intraventricular drainage is carefully monitored, using strict asepsis when any part of the system is handled.

Vital signs and neurologic status (LOC and responsiveness, pupillary and motor responses) are assessed every 15 to 60 minutes. Extreme head rotation is avoided, because this raises ICP. After supratentorial surgery, the patient is placed on their back or side (on the unoperated side if a large lesion was removed) with one pillow under the head. The head of the bed may be elevated 30 degrees, depending on the level of the ICP and the neurosurgeon's preference. After posterior fossa (infratentorial) surgery, the patient is kept flat on one side (off the back) with the head on a small, firm pillow. The patient may be turned on either side, keeping the neck in a neutral position. When the patient is being turned, the body should be turned as a unit to prevent placing strain on the incision and possibly tearing the sutures. The head of the bed may be elevated slowly as tolerated by the patient.

The patient's position is changed every 2 hours, and skin care is given frequently. During position changes, care is taken to prevent disruption of the ICP monitoring system. A turning sheet or lift sling placed under the patient's head to midthigh makes it easier to move and turn the patient safely.

Regulating Temperature

Moderate temperature elevation can be expected after intracranial surgery because of the reaction to blood at the operative site or in the subarachnoid space. Injury to the hypothalamic centers that regulate body temperature can occur during surgery. Fever is treated vigorously to combat the effect of an elevated temperature on brain metabolism and function.

Nursing interventions include monitoring the patient's temperature and using the following measures to reduce body temperature: removing blankets, placing ice packs, and administering prescribed antipyretics to reduce fever (Rincon, 2018).

Conversely, hypothermia may be seen after lengthy neurosurgical procedures. Therefore, frequent measurements of rectal temperatures are necessary. Rewarming should occur slowly to prevent shivering, which increases cellular oxygen demands.

Improving Gas Exchange

The patient undergoing neurosurgery is at risk for impaired gas exchange and pulmonary infections due to immobility, immunosuppression, decreased LOC, and fluid restriction. Immobility compromises the respiratory system by causing pooling and stasis of secretions in dependent areas and the development of atelectasis. The patient whose fluid intake is restricted may be more vulnerable to atelectasis as a result of inability to expectorate thickened secretions. Pneumonia can develop due to aspiration and restricted mobility.

Repositioning the patient every 2 hours helps to mobilize pulmonary secretions and prevent stasis. After the patient regains consciousness, additional measures to expand collapsed alveoli can be instituted, such as yawning, sighing, deep breathing, incentive spirometry, and coughing (unless contraindicated). If necessary, the oropharynx and trachea are suctioned to remove secretions that cannot be raised by coughing; however, coughing and suctioning increase ICP. Therefore, suctioning should be used cautiously. Increasing the humidity in the oxygen delivery system may help to loosen secretions. The nurse and the respiratory therapist work together to monitor the effects of chest physiotherapy.

Coping with Sensory Deprivation

Periorbital edema is a common consequence of intracranial surgery, because fluid drains into the dependent periorbital areas when the patient has been positioned in a prone position during surgery. A hematoma may form under the scalp and spread down to the orbit, producing an area of ecchymosis (black eye).

Before surgery, the patient and family should be informed that one or both eyes may be edematous temporarily after surgery. After surgery, elevating the head of the bed (if not contraindicated) and applying cold compresses over the eyes will help reduce the edema. The surgeon is notified if periorbital edema increases significantly, because this may indicate that a postoperative clot is developing or that there is increasing ICP and poor venous drainage. Health care personnel should announce their presence when entering the room to avoid startling the patient whose vision is impaired due to periorbital edema or neurologic deficits.

Additional factors that can affect sensation include a bulky head dressing, the presence of an endotracheal tube, and effects of increased ICP. The first postoperative dressing change is usually

performed by the neurosurgeon. In the absence of bleeding or a CSF leak, every effort is made to minimize the size of the head dressing. If the patient requires an endotracheal tube for mechanical ventilation, every effort is made to extubate the patient as soon as clinical signs indicate it is possible. The patient is monitored closely for the effects of elevated ICP.

Enhancing Self-Image

The patient is encouraged to verbalize feelings and frustrations about any change in appearance. Nursing support is based on the patient's reactions and feelings. Factual information may need to be provided if the patient has misconceptions about puffiness about the face, periorbital bruising, and hair loss. Attention to grooming, the use of the patient's own clothing, and covering the head with a turban (and later a wig until hair growth occurs) are encouraged. Social interaction with close friends, family, and hospital personnel may increase the patient's sense of self-worth.

The family and social support system can be of assistance while the patient recovers from surgery.

Monitoring and Managing Potential Complications

The nurse must be vigilant for complications that may develop within hours of surgery and require close collaboration with the neurosurgeon. These include increased ICP, bleeding and hypovolemic shock, altered fluid and electrolyte balance (e.g., water intoxication, diabetes insipidus), infection, identification of a CSF leak, and seizures.

Monitoring for Increased Intracranial Pressure and Bleeding. Increased ICP and bleeding are life-threatening to the patient who has undergone intracranial surgery. The following points must be kept in mind when caring for any patient who has undergone such surgery:

- An increase in blood pressure and decrease in pulse with respiratory failure may indicate increased ICP.
- An accumulation of blood under the bone flap (extradural, subdural, or intracerebral hematoma) may pose a threat to life. A clot must be suspected in any patient who does not awaken as expected or whose condition deteriorates. An intracranial hematoma is suspected if the patient has any new postoperative neurologic deficits (especially a dilated pupil on the operative side). In these circumstances, the patient is returned to the operating room immediately for evacuation of the clot, if indicated.
- Cerebral edema, infarction, metabolic disturbances, and hydrocephalus are conditions that may mimic the clinical manifestations of a clot.

The patient is monitored closely for indicators of complications, and early signs and trends in clinical status are reported to the surgeon. Treatments are initiated promptly, and the nurse assists in evaluating the patient's response to treatment. The nurse also provides support to the patient and family.

Quality and Safety Nursing Alert

If signs and symptoms of increased ICP occur, efforts to decrease the ICP are initiated: alignment of the head in a neutral position without flexion to promote venous drainage, elevation of the head of the bed to 30 degrees (when prescribed), administration of mannitol (an osmotic diuretic), and possible administration of pharmacologic paralyzing agents.

Managing Fluid and Electrolyte Disturbances. Fluid and electrolyte imbalances may occur because of the patient's underlying condition and its management or as complications of surgery. These disturbances can contribute to the development of cerebral edema.

The postoperative fluid regimen depends on the type of neurosurgical procedure and is determined on an individual basis. The volume and composition of fluids are adjusted based on daily serum electrolyte values, along with fluid intake and output. Fluids may have to be restricted in patients with cerebral edema.

Oral fluids are usually resumed after the first 24 hours. The presence of gag and swallowing reflexes must be checked before initiation of oral fluids. Some patients with posterior fossa tumors have impaired swallowing, so fluids may need to be given by alternative routes. The patient should be observed for signs and symptoms of nausea and vomiting as the diet is progressed (AANN, 2016b).

Patients undergoing surgery for brain tumors often receive large doses of corticosteroids and are at risk for hyperglycemia. Serum glucose levels are measured every 4 to 6 hours, and sliding scale insulin is prescribed as needed. These patients are prone to stress ulcers, so histamine-2 receptor antagonists

(H_2 blockers) or proton pump inhibitors are prescribed to suppress the secretion of gastric acid. Patients also are monitored for bleeding and assessed for gastric pain.

If the surgical site is near to (or causes edema to) the pituitary gland and hypothalamus, the patient may develop symptoms of diabetes insipidus, which is characterized by excessive urinary output, elevated serum osmolality, decreased urine osmolality, hypernatremia, and a low urine specific gravity. The urine specific gravity is measured hourly, and fluid intake and output are monitored. Fluid replacement must compensate for urine output, and serum potassium levels must be monitored.

SIADH, which results in water retention with hyponatremia and serum hypo-osmolality, occurs in a wide variety of CNS disorders (e.g., brain tumor, head trauma) causing fluid disturbances. Nursing management includes careful intake and output measurements, specific gravity determinations of urine, and monitoring of serum and urine electrolyte levels while following directives for fluid restriction. SIADH is usually self-limited.

Preventing Infection. The patient undergoing neurosurgery is at risk for infection associated with the neurosurgical procedure (brain exposure, bone exposure, wound hematomas) and the presence of IV and arterial lines for fluid administration and monitoring. Risk for infection is increased in patients who undergo lengthy intracranial operations and in those who have external ventricular drains in place.

The dressing is often stained with blood in the immediate postoperative period. Because blood is an excellent culture medium for bacteria, the dressing is reinforced with sterile pads so that contamination and infection are avoided. A heavily stained or displaced dressing should be reported immediately. A drain is sometimes placed in the craniotomy incision to facilitate drainage.

After suboccipital surgical procedures, CSF may leak through the incision. This complication is dangerous because of the possibility of meningitis. After a suboccipital craniotomy, the patient is instructed to avoid coughing, sneezing, or nose blowing, which can cause CSF leakage by creating increased pressure on the operative site.

Quality and Safety Nursing Alert

Any sudden discharge of fluid from a cranial incision is reported at once, because a large leak often requires surgical repair. Attention should be paid to the patient who complains of a salty taste or "postnasal drip," because this can be caused by CSF trickling down the throat.

Aseptic technique is used when handling dressings, drainage systems, and IV and arterial lines. The patient is monitored carefully for signs and symptoms of infection, and cultures are obtained if infection is suspected. Appropriate antibiotic agents are given as prescribed. Other causes of infection in the patient undergoing intracranial surgery, such as pneumonia and urinary tract infections, are similar to those in other patients postoperatively.

Monitoring for Seizure Activity. Seizures may occur as complications after any intracranial neurosurgical procedure. Preventing seizures is essential to avoid further cerebral edema. Administering the prescribed anticonvulsant medication before and after surgery may prevent the development of seizures in subsequent months and years. **Status epilepticus** (prolonged seizures without recovery of consciousness in the intervals between seizures) may occur after craniotomy and also may be related to the development of complications (hematoma, ischemia). The management of status epilepticus is described later in this chapter.

Monitoring and Managing Other Complications. Other complications may occur during the first 2 weeks or later and may compromise the patient's recovery. The most important of these are VTE (DVT, PE), pulmonary and urinary tract infection, and pressure injuries. Most of these complications may be avoided with frequent changes of position, adequate suctioning of secretions, thrombosis prophylaxis, early removal of indwelling urinary catheter, early ambulation, and skin care.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The recovery at home of a patient who has had neurosurgery depends on the extent of the surgical procedure and its success. The patient's strengths as well as limitations are assessed and explained to the family, along with the family's part in promoting recovery. Because administration of postoperative medication is a priority, the patient and family are

educated to use a check-off system, pill boxes, and alarms to ensure that the medication is taken as prescribed.

The patient and family are educated about what to expect after intracranial surgery (see Chart 61-3). Dietary restrictions usually are not required unless another health problem necessitates a special diet. Although showering or tub bathing is permitted, the scalp should be kept dry until all sutures have been removed, unless the primary provider has specific wound care instructions. A clean scarf or cap may be worn until a wig or hairpiece is purchased. If skull bone has been removed, a protective helmet may be prescribed. The patient may require rehabilitation, depending on the postoperative level of function. The patient may require physical therapy for residual weakness and mobility issues. An occupational therapist is consulted to assist with self-care issues. If the patient has aphasia, speech therapy may be necessary.

Continuing and Transitional Care. The patient is discharged from the hospital as soon as possible. Patients with severe motor deficits require extensive physical therapy and rehabilitation. Those with postoperative cognitive and speech impairments require psychological evaluation, speech therapy, and rehabilitation. The nurse collaborates with the primary provider and other health care professionals during hospitalization and home or transitional care to achieve as complete a rehabilitation as possible and to assist the patient in living with residual disability.

If tumor, injury, or disease makes the prognosis poor, care is directed toward making the patient as comfortable as possible. With return of the tumor or cerebral compression, the patient becomes less alert and aware. Other possible consequences include paralysis, blindness, and seizures. The home health nurse, hospice nurse, and social worker collaborate with the family to plan for additional services or placement of the patient in an extended care facility (see the Cerebral Metastases section in Chapter 65). The patient and family are encouraged to discuss end-of-life preferences for care; the patient's end-of-life preferences must be respected (see Chapter 13). The nurse involved in home and continuing care of patients after cranial surgery also should remind patients and family members of the need for health promotion activities and recommended health screening.

Evaluation

Expected patient outcomes may include:

1. Achieves optimal cerebral tissue perfusion
   a. Opens eyes on request; uses recognizable words, progressing to normal speech
   b. Obeys commands with appropriate motor responses
2. Maintains normal body temperature
   a. Registers normal body temperature
3. Has normal gas exchange
   a. Has arterial blood gas values within normal ranges
   b. Breathes easily; lung sounds clear without adventitious sounds
   c. Takes deep breaths and changes position as directed
4. Copes with sensory deprivation
5. Demonstrates improving self-concept
   a. Pays attention to grooming
   b. Visits and interacts with others

Chart 61-3  **HOME CARE CHECKLIST**

Discharge After Intracranial Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed, any complications that occurred, and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., durable medical equipment, adaptive equipment) used in recovery period.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., walking and breathing exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
- State the name, dose, side effects, frequency, and schedule for all medications.
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization.
- Describe signs and symptoms of complications.
- State time and date of follow-up appointments.
- Relate how to reach primary provider with questions or complications.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, stress management), disease prevention and screening activities.

ADL, activities of daily living; IADL, instrumental activities of daily living.

6. Exhibits absence of complications
   a. Exhibits ICP within normal range
   b. Has minimal bleeding at surgical site; surgical incision healing without evidence of infection
   c. Shows fluid balance and electrolyte levels within desired ranges
   d. Exhibits no evidence of seizures

Transsphenoidal Approach

Tumors within the sella turcica and small adenomas of the pituitary can be removed through a transsphenoidal approach (see Table 61-3). Although an otorhinolaryngologist may make the initial opening, the neurosurgeon completes the opening into the sphenoidal sinus and exposes the floor of the sella. Microsurgical techniques provide improved illumination, magnification, and visualization so that nearby vital structures can be avoided.

The transsphenoidal approach offers direct access to the sella turcica with minimal risk of trauma and hemorrhage (Hickey & Strayer, 2020). It avoids many of the risks of craniotomy, and the postoperative discomfort is similar to that of other transnasal surgical procedures. It may also be used for pituitary ablation (destruction) in patients with metastatic breast or prostatic cancer.

Complications

Manipulation of the posterior pituitary gland during surgery may produce transient diabetes insipidus of several days' duration (Hickey & Strayer, 2020). It is treated with vasopressin but occasionally persists. Other complications include CSF leakage, visual disturbances, postoperative meningitis, pneumocephalus (air in the intracranial cavity), and SIADH (see Chapter 45).

Preoperative Management

Medical Management

The preoperative evaluation includes a series of endocrine tests, rhinologic evaluation (to assess the status of the sinuses and nasal cavity), and neuroradiologic studies. Funduscopic examination and visual field determinations are performed, because the most serious effect of pituitary tumor is localized pressure on the optic nerve or chiasm. In addition, the nasopharyngeal secretions are cultured, because a sinus infection is a contraindication to an intracranial procedure using this approach. Corticosteroids may be given before and after surgery, because the surgery involves removal of the pituitary, which is the source of adrenocorticotropic hormone (ACTH). Antibiotic agents may or may not be given prophylactically.

Nursing Management

The patient is educated in deep breathing techniques before surgery. In addition, the patient is instructed that after the surgery, they will need to avoid vigorous coughing, blowing the nose, sucking through a straw, or sneezing, because these actions may place increased pressure at the surgical site and cause a CSF leak (Hickey & Strayer, 2020).

Postoperative Management

Medical Management

Because the procedure disrupts the oral and nasal mucous membranes, management focuses on preventing infection and promoting healing. Medications include antimicrobial agents (which are continued until the nasal packing inserted at the time of surgery is removed), corticosteroids, analgesic agents for discomfort, and agents for the control of diabetes insipidus, if necessary (Hickey & Strayer, 2020).

Nursing Management

Vital signs are measured to monitor hemodynamic, cardiac, and ventilatory status. Because of the anatomic proximity of the pituitary gland to the optic chiasm, visual acuity and visual fields are assessed at regular intervals. One method is to ask the patient to count the number of fingers held up by the nurse. Evidence of decreasing visual acuity suggests an expanding hematoma.

The head of the bed is raised to decrease pressure on the sella turcica and to promote normal drainage. The patient is cautioned against blowing the nose or engaging in any activity that raises ICP, such as bending over or straining during urination or defecation.

Intake and output are measured as a guide to fluid and electrolyte replacement and to assess for diabetes insipidus. The urine specific gravity, serum sodium, and serum osmolality are measured and evaluated regularly. Daily weight is monitored. Fluids are usually given after nausea ceases, and the patient then progresses to a regular diet.

The nasal packing inserted during surgery is checked frequently for blood or CSF drainage. The major discomfort is related to the nasal packing and to mouth dryness and thirst caused by mouth breathing. Oral care is provided every 4 hours or more frequently. Usually, the teeth are not brushed until the incision above the teeth has healed. Warm saline mouth rinses and the use of a cool mist vaporizer are helpful. Petrolatum is soothing when applied to the lips. The packing is removed in 3 to 4 days, and only then can the area around the nares be cleaned with the prescribed solution to remove crusted blood and moisten the mucous membranes (Hickey & Strayer, 2020).

Home care considerations include advising the patient to use a room humidifier to keep the mucous membranes moist and to soothe irritation. The head of the bed is elevated at 30 degrees for at least 2 weeks after surgery. The patient is cautioned against blowing the nose or sneezing for at least 1 month, or as directed by their surgeon (Hickey & Strayer, 2020).

OTHER NEUROLOGIC DYSFUNCTIONS

Three other types of neurologic dysfunctions the nurse should be aware of include delirium, dementia, and pseudobulbar affect.

Delirium

Delirium, often called *acute confusional state,* begins with disorientation and if not recognized and treated can progress to changes in LOC, irreversible brain damage, and sometimes death. In fact, up to 80% of patients in intensive care units are affected, and the presence of delirium triples in-hospital mortality rates (Mulkey, Hardin, Munro, et al., 2019). Delirium is disturbing for the affected patient and their family, associated with worse outcomes, and a significant increase in medical care costs (Devlin, Skrobik, Gelinas, et al., 2018; Mulkey et al., 2019).

Careful clinical assessment is essential because delirium is sometimes mistaken for dementia and the two conditions may overlap; Table 61-4 compares dementia and delirium. It helps to know an individual patient's usual mental status and whether the changes noted are long term, which probably represents dementia, or are abrupt in onset, which is more likely delirium.

There are numerous risk factors for delirium. Risk factors that are modifiable include the use of medications such as benzodiazepines and the administration of blood transfusions (Devlin et al., 2018). Nonmodifiable risk factors include age, presence of dementia, prior coma, as well as recent emergency surgery or trauma (Devlin et al., 2018). Older adults are particularly vulnerable to acute confusion if they are in a debilitated health state or take multiple medications.

Nurses must recognize the symptoms of delirium and report them immediately. The Confusion Assessment Method (CAM) is a commonly used screening tool (Devlin et al., 2018; Inouye, van Dyck, Alessi, et al., 1990). (See Chapter 8, Chart 8-7.) Because of the acute and unexpected onset of symptoms, it is recommended that all patients who are critically ill receive routine screening for delirium at prescribed intervals (Devlin et al., 2018). If the delirium goes unrecognized and the underlying cause is not treated, permanent, irreversible brain damage or death can follow.

The most effective approach is prevention. Strategies include providing therapeutic activities for cognitive impairment, reorienting the patient as needed, ensuring early mobilization, controlling pain, minimizing the use of psychoactive drugs, preventing sleep deprivation, enhancing communication methods (particularly eyeglasses and hearing aids) for vision and hearing impairment, maintaining oxygen levels and fluid and electrolyte balance, and preventing surgical complications (Eliopoulos, 2018). Including the family in therapeutic activities, as appropriate, is encouraged but more research is needed to validate the effect of families (Devlin et al., 2018). There is some research evidence for the use of bright light therapy to reduce delirium in patients who are critically ill (Devlin et al., 2018).

Once delirium occurs, treatment of the underlying cause is most important. Therapeutic interventions vary depending on the cause. Delirium increases the risk of falls; therefore, management of patient safety and behavioral problems is essential. Because medication interactions and toxicity are often implicated, the nurse should alert the prescriber about any nonessential medications that could be discontinued. Nutritional and fluid intake should be supervised and monitored. The environment should be quiet and calm. To increase function and comfort, the nurse provides familiar environmental cues and encourages family members or friends to touch and talk to the patient (see Fig. 61-9). The nurse should provide for sleep hygiene measures in addition to assessing for and managing pain (Bennett, 2019). Ongoing mental status assessments using prior mental cognitive status as a baseline are helpful in evaluating responses to treatment and upon admission to a hospital or extended care facility. If the underlying problem is adequately treated, the patient often returns to baseline within several days.

Dementia

The cognitive, functional, and behavioral changes that characterize dementia eventually destroy a person's ability to function. The symptoms are usually subtle in onset and often progress slowly until they are obvious and devastating. Dementia in older adults is typically caused by some degree of neurodegeneration (Gale, Acar, & Daffner, 2018). The most common type of **dementia** is Alzheimer's disease (AD) (see Chapter 8 for discussion of AD). AD alone or in conjunction with other dementing disorders accounts for up to 75% of older adults with dementia (Hickey & Strayer, 2020). Other non-Alzheimer's dementias include degenerative, vascular, neoplastic, demyelinating, infectious, inflammatory, toxic, metabolic, and psychiatric disorders. It is important to identify reversible dementia, which occurs when pathologic conditions masquerade as dementia.

Pseudobulbar Affect

The condition known as **pseudobulbar affect** involves inappropriate or exaggerated emotional expression, usually episodes of laughing or crying. It is associated with brain injury (e.g., stroke, traumatic brain injury, multiple sclerosis [MS], amyotrophic lateral sclerosis [ALS], AD, Parkinson's disease). The term "pseudobulbar" refers to damage that occurs in the corticobulbar tracts in the brain (see Chapter 60). The emotional outbursts can cause embarrassment, anxiety, and depression, and often impair quality of life (Hickey & Strayer, 2020).

Older adults with pseudobulbar affect can respond appropriately to treatment. Initial management involves evaluation and recognition that this condition can coexist with mood disorders, such as depression, although crying in these patients should not be considered indicative of depression. Pharmacology studies have reported effective management with dextromethorphan hydrobromide and quinidine sulfate in patients with ALS, MS, stroke, TBI, and dementia (Comerford & Durkin, 2020; Hakimi & Maurer, 2018).

SEIZURE DISORDERS

Seizures are episodes of abnormal motor, sensory, autonomic, or psychic activity (or a combination of these) that result from sudden excessive discharge from cerebral neurons (Hickey & Strayer, 2020). A localized area or all of the brain may be involved. The International League Against Epilepsy (ILAE) has defined **epilepsy** as more than one unprovoked seizure (Fisher, Cross, French, et al., 2017). The ILAE differentiates between three main seizure types: focal onset, generalized onset, and unknown onset seizures (see Chart 61-4). Focal (or partial) seizures are thought to originate within a localized area of the brain. Generalized seizures occur in and rapidly engage bilaterally distributed networks. Unknown onset seizures can be described as "unclassified," so termed because of incomplete data surrounding the event, but they may also be described from their clinical features (Fisher et al., 2017). Seizures may also be characterized as "provoked," or related to acute, reversible conditions such as structural, metabolic, immune, infectious, or unknown etiologies.

TABLE 61-4  Summary of Differences Between Dementia and Delirium

	Dementia		Delirium
	Alzheimer's Disease (AD)	Vascular (Multi-Infarct) Dementia	
Etiology	Early onset (familial, genetic [chromosomes 14, 19, 21]) Late-onset sporadic—etiology unknown	Cardiovascular (CV) disease Cerebrovascular disease Hypertension	Medication toxicity and interactions; acute disease; trauma; chronic disease exacerbation Fluid and electrolyte disorders
Risk factors	Advanced age; genetics	Preexisting CV disease	Preexisting cognitive impairment
Occurrence	75% of dementias	10–20% of dementias	Up to 80% among hospitalized people
Onset	Slow	Often abrupt Follows a stroke or transient ischemic attack	Rapid, acute onset A harbinger of acute medical illness
Age of onset	Early-onset AD: 40–65 yrs Late-onset AD: 65+ yrs Most commonly: 85+ yrs	Most commonly 50–70 yrs	Any age, although predominantly in older adults
Gender	Males and females equally	Predominantly males	Males and females equally
Course	Chronic, irreversible; progressive, regular, downhill	Chronic, irreversible Fluctuating, stepwise progression	Acute onset Hypoalert—hypoactive Hyperalert–hyperactive Mixed hypo–hyper
Duration	2–20 yrs	Variable; years	Lasts 1 day to 1 mo
Symptom progress	Onset insidious: *Early*—mild and subtle *Middle and late*—intensified Progression to death (infection or malnutrition)	Depends on location of infarct and success of treatment; death attributed to underlying CV disease	Symptoms are fully reversible with adequate treatment; can progress to chronicity or death if underlying condition is ignored
Mood	Depression common	Labile: mood swings	Variable
Speech/language	Speech remains intact until late in disease: *Early*—mild anomia (cannot name objects); deficits progress until speech lacks meaning; echoes and repeats words and sounds; mutism *Early*—no motor deficits	May have speech deficit/aphasia depending on location of lesion	Fluctuating; often cannot concentrate long enough to speak May be somnolent
Physical signs	*Middle*—apraxia (cannot perform purposeful movement) *Late*—Dysarthria (impaired speech) *End stage*—loss of all voluntary activity; positive neurologic signs	According to location of lesion: focal neurologic signs, seizures Commonly exhibits motor deficits	Signs and symptoms of underlying disease
Orientation	Becomes lost in familiar places (topographic disorientation) Has difficulty drawing three-dimensional objects (visual and spatial disorientation) Disorientation to time, place, and person—with disease progression		May fluctuate between lucidity and complete disorientation to time, place, and person
Memory	Loss is an early sign of dementia; loss of recent memory is soon followed by progressive decline in recent and remote memory		Impaired recent and remote memory; may fluctuate between lucidity and confusion
Personality	Apathy, indifference, irritability: *Early disease*—social behavior intact; hides cognitive deficits *Advanced disease*—disengages from activity and relationships; suspicious; paranoid delusions caused by memory loss; aggressive; catastrophic reactions		Fluctuating; cannot focus attention to converse; alarmed by symptoms (when lucid); hallucinations; paranoid
Functional status, activities of daily living	Poor judgment in everyday activities; has progressive decline in ability to handle money, use telephone, use computer and other electronic devices, function in home and workplace		Impaired
Attention span	Distractible; short attention span		Highly impaired; cannot maintain or shift attention
Psychomotor	Wandering, hyperactivity, pacing, restlessness, agitation		Variable; alternates between high

activity		agitation, hyperactivity, restlessness, and lethargy
Sleep–wake cycle	Often impaired; wandering and agitation at nighttime	Takes brief naps throughout day and night

Clinical practice guidelines for the prevention and management of pain, agitation/sedation, delirium, immobility, and sleep disruption in adult patients in the ICU. *Critical Care Medicine*, *46*(9), e825–e873; Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological & neurosurgical nursing* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Figure 61-9 • Talking to family members may increase the comfort of patients with delirium.

Pathophysiology

The underlying cause is an electrical disturbance (arrhythmia) in the nerve cells in one section of the brain; these cells emit abnormal, recurring, uncontrolled electrical discharges. The characteristic seizure is a manifestation of this excessive neuronal discharge. Associated loss of consciousness, excess movement or loss of muscle tone or movement, and disturbances of behavior, mood, sensation, and perception may also occur.

Chart 61-4

Classification of Seizures: 2017 Basic Scheme

Focal

- Motor

Adapted from Fisher, R., Cross, H., French, J., et al. (2017). Operational classification of seizure types by the International League Against Epilepsy (ILAE). Retrieved on 5/25/2020 at: www.ilae.org/files/dmfile/Operational-Classification–Fisher_et_al-2017-Epilepsia.pdf

The specific causes of seizures are varied and can be categorized as genetic, due to a structural or metabolic condition, or the cause may be yet unknown etiologies (Fisher et al., 2017).

Causes of seizures include:

- Allergies
- Brain tumor
- Cerebrovascular disease
- CNS infections
- Drug and alcohol withdrawal
- Fever (childhood)
- Head injury
- Hypertension
- Hypoxemia of any cause, including vascular insufficiency
- Metabolic and toxic conditions (e.g., kidney injury, hyponatremia, hypocalcemia, hypoglycemia, pesticide exposure)

Clinical Manifestations

Depending on the location of the discharging neurons, seizures may range from a simple staring episode (generalized absence seizure) to prolonged convulsive movements with loss of consciousness.

The initial pattern of the seizures indicates the region of the brain in which the seizure originates (see Chart 61-4). Only a finger or hand may shake, or the mouth may jerk uncontrollably. The person may talk unintelligibly; may be dizzy; and may experience unusual or unpleasant sights, sounds, odors, or tastes, but without loss of consciousness (Hickey & Strayer, 2020).

Generalized seizures often involve both hemispheres of the brain, causing both sides of the body to react. Intense rigidity of the entire body may occur, followed by alternating muscle relaxation and contraction (generalized tonic–clonic contraction). The simultaneous contractions of the diaphragm and chest muscles may produce a characteristic epileptic cry. The tongue is often chewed, and the patient can be incontinent of urine and feces. After 1 or 2 minutes, the convulsive movements begin to subside; the patient relaxes and lies in deep coma, breathing noisily. The respirations at this point are chiefly abdominal. In the postictal state (after the seizure), the patient is often confused and hard to arouse and

may sleep for hours. Many patients report headache, sore muscles, fatigue, and depression (AANN, 2016a). Other generalized seizures may be absence types of seizures (Hickey & Strayer, 2020).

Focal seizures are subdivided into events characterized by both motor and nonmotor symptoms. There may be an impairment of consciousness or awareness or other dyscognitive features, localization, and progression of symptoms (Fisher et al., 2017).

Assessment and Diagnostic Findings

The diagnostic assessment is aimed at determining the type of seizures, their frequency and severity, and the factors that precipitate them. A developmental history is taken, including events of pregnancy and childbirth, to seek evidence of preexisting injury. The patient is also questioned about illnesses or head injuries that may have affected the brain. In addition to physical and neurologic evaluations, diagnostic examinations include biochemical, hematologic, and serologic studies. MRI is used to detect structural lesions such as focal abnormalities, cerebrovascular abnormalities, and cerebral degenerative changes (AANN, 2016a).

The EEG furnishes diagnostic evidence for a substantial proportion of patients with epilepsy and assists in classifying the type of seizure. Abnormalities in the EEG usually continue between seizures or, if not apparent, may be elicited by hyperventilation or during sleep (AANN, 2016a). Microelectrodes (depth electrodes) can be inserted deep in the brain to probe the action of single brain cells. Some people with clinical seizures have normal EEGs, whereas others who have never had seizures have abnormal EEGs. Telemetry and computerized equipment are used to monitor electrical brain activity while the patient pursues their normal activities and to store the readings on computer tapes for analysis. Video recording of seizures taken simultaneously with EEG telemetry is useful in determining the type of seizure as well as its duration and magnitude (Hickey & Strayer, 2020).

SPECT is an additional tool that is sometimes used in the diagnostic workup. It is useful for identifying the epileptogenic zone so that the area in the brain giving rise to seizures can be removed surgically (AANN, 2016a).

Nursing Management

During a Seizure

A major responsibility of the nurse is to observe and record the sequence of signs. The nature of the seizure usually indicates the type of treatment required (AANN, 2016a). Before and during a seizure, the patient is assessed and the following items are documented:

- Circumstances before the seizure (visual, auditory, or olfactory stimuli; tactile stimuli; emotional or psychological disturbances; sleep; hyperventilation)
- Occurrence of an aura (a premonitory or warning sensation, which can be visual, auditory, or olfactory)
- First thing the patient does in the seizure—where the movements or the stiffness begins, conjugate gaze position, and the position of the head at the beginning of the seizure. This information gives clues to the location of the seizure origin in the brain. (In recording, it is important to state whether the beginning of the seizure was observed.)
- Type of movements in the part of the body involved
- Areas of the body involved (turn back bedding to expose patient)
- Size of both pupils and whether the eyes are open
- Whether the eyes or head are turned to one side
- Presence or absence of automatisms (involuntary motor activity, such as lip smacking or repeated swallowing)
- Incontinence of urine or stool
- Duration of each phase of the seizure
- Unconsciousness, if present, and its duration
- Any obvious paralysis or weakness of arms or legs after the seizure
- Inability to speak after the seizure
- Movements at the end of the seizure
- Whether or not the patient sleeps afterward
- Cognitive status (confused or not confused) after the seizure

In addition to providing data about the seizure, nursing care is directed at preventing injury and supporting the patient, not only physically but also psychologically. Consequences such as anxiety, embarrassment, fatigue, and depression can be devastating to the patient.

After a Seizure

After a patient has a seizure, the nurse's role is to document the events leading to and occurring during and after the seizure and to prevent complications (e.g., aspiration, injury). The patient is at risk for hypoxia, vomiting, and pulmonary aspiration. To prevent complications, the patient is placed in the side-lying position to facilitate drainage of oral secretions, and suctioning is performed, if needed, to maintain a patent airway and prevent aspiration (see Chart 61-5). Seizure precautions are maintained, including having available functioning suction equipment with a suction catheter. The bed is placed in a low position with two to three side rails up and padded, if necessary, to prevent injury to the patient. The floor may be padded as an additional safety measure. The patient may be drowsy and may wish to sleep after the seizure; they may not remember events leading up to the seizure and for a short time thereafter.

The Epilepsies

Epilepsy is a group of syndromes characterized by unprovoked, recurring seizures (AANN, 2016a). Epileptic syndromes are classified by specific patterns of clinical features, including age at onset, family history, and seizure type. Epilepsy can be primary (idiopathic) or secondary (when the cause is known and the epilepsy is a symptom of another underlying condition, such as a brain tumor).

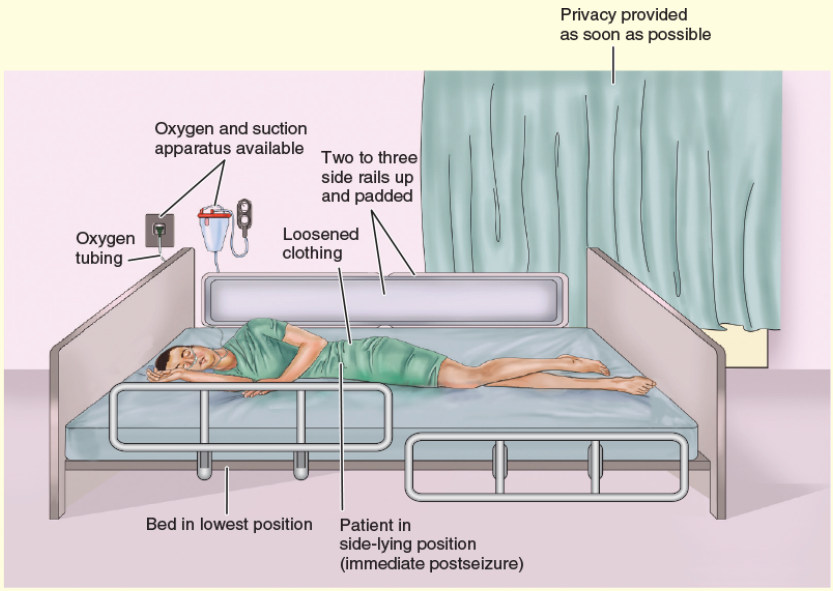
Epilepsy affects an estimated 3% of people during their lifetime, and most forms of epilepsy occur in children and older adults (Hickey & Strayer, 2020). The improved treatment for cerebrovascular disorders, head injuries, brain tumors, meningitis, and encephalitis has increased the number of patients at risk for seizures after recovery from these conditions. In addition, advances in EEG have aided in the diagnosis of epilepsy. The general public has been educated about epilepsy, which has reduced the stigma associated with it; as a result, more people are willing to acknowledge that they have epilepsy.

Although some evidence suggests that susceptibility to some types of epilepsy may be inherited, the cause of seizures in many people is idiopathic (unknown). Epilepsy can follow birth trauma, asphyxia neonatorum, head injuries, some infectious diseases (bacterial, viral, parasitic), toxicity (carbon monoxide and lead poisoning), circulatory problems, fever, metabolic and nutritional disorders, or drug or alcohol intoxication. It is also associated with brain tumors, abscesses, and congenital malformations.

Pathophysiology

Messages from the body are carried by the neurons (nerve cells) of the brain by discharges of electrochemical energy that sweep along them. These impulses occur in bursts whenever a nerve cell has a task to perform. Sometimes, these cells or groups of cells continue firing after a task is finished. During the period of unwanted discharges, parts of the body controlled by the errant cells may perform erratically. Resultant dysfunction ranges from mild to incapacitating and often causes loss of consciousness (Hickey & Strayer, 2020). If these uncontrolled, abnormal discharges occur repeatedly, a person is said to have an epileptic syndrome. Epilepsy is not associated with intellectual level. People who have epilepsy without other brain or nervous system disabilities fall within the same intelligence ranges as the overall population. Epilepsy is not synonymous with intellectual or developmental disabilities, but many people who have these types of disabilities, because of serious neurologic damage, also have epilepsy.

Chart 61-5



Care of the Patient During and After a Seizure

Nursing Care During a Seizure

- Provide privacy, and protect the patient from curious onlookers. (The patient who has an aura may have time to seek a safe, private place.)
- Ease the patient to the floor, if possible.
- Protect the head with a pad to prevent injury (from striking a hard surface).
- Loosen constrictive clothing and remove eyeglasses.
- Push aside any furniture that may injure the patient during the seizure.
- If the patient is in bed, remove pillows and raise side rails.
- *Do not attempt to pry open jaws that are clenched in a spasm or attempt to insert anything in the mouth during a seizure.* Broken teeth and injury to the lips and tongue may result from such an action.
- Do not attempt to restrain the patient during the seizure, because muscular contractions are strong and restraint can produce injury.
- If possible, place the patient on one side with head flexed forward, which allows the tongue to fall forward and facilitates drainage of saliva and mucus. If suction is available, use it if necessary to clear secretions.

Nursing Care After the Seizure

- Keep the patient on one side to prevent aspiration. Make sure the airway is patent.
- On awakening, reorient the patient to the environment.
- If the patient is confused or wandering, guide the patient gently to a bed or chair.
- If the patient becomes agitated after a seizure (postictal), stay a distance away, but close enough to prevent injury until the patient is fully aware.

Adapted from American Association of Neuroscience Nurses (AANN). (2016a). *Care of adults and children with seizures and epilepsy: AANN clinical practice guideline series*. Chicago, IL: Author.

Patients with epilepsy, particularly those with generalized events that are medically refractory, are at serious risk for **Sudden Unexpected Death in Epilepsy (SUDEP),** defined as nontraumatic, nondrowning unexpected death of a patient with epilepsy. These events may be witnessed or unwitnessed and postmortem examination reveals no anatomic or toxicologic cause of death. Cardiac and respiratory abnormalities have been implicated in these deaths. SUDEP may or may not be related to a seizure event (Barot & Nei, 2019).

Epilepsy in Women

More than one million American women have epilepsy, and they face particular needs associated with the syndrome. Women with epilepsy often note an increase in seizure frequency during menses; this has been

linked to the increase in sex hormones that alter the excitability of neurons in the cerebral cortex. The effectiveness of contraceptives is decreased by anticonvulsant medications. Therefore, patients should be encouraged to discuss family planning with their primary provider and to obtain preconception counseling if they are considering childbearing (Stephen, Harden, Tomson, et al., 2019).

Women of childbearing age who have epilepsy require special care and guidance before, during, and after pregnancy. Many women note a change in the pattern of seizure activity during pregnancy. The risk of congenital fetal anomaly is two to three times higher in women with epilepsy. Maternal seizures, anticonvulsant medications, and genetic predisposition all contribute to possible malformations. Women who take certain anticonvulsant medications for epilepsy are at risk and need careful monitoring, including blood studies to detect the level of anticonvulsant medications taken throughout pregnancy. Mothers who are at high risk (teenagers, women with histories of difficult deliveries, women who use illicit drugs [e.g., "crack" cocaine, heroin], and women with diabetes or hypertension) should be identified and monitored closely during pregnancy, because damage to the fetus during pregnancy and delivery can increase the risk of epilepsy. All of these issues need further study (Stephen et al., 2019).

Because of bone loss associated with the long-term use of anticonvulsant medications, patients receiving anticonvulsant agents should be assessed for low bone mass and osteoporosis. They should be educated about strategies to reduce their risks of osteoporosis (AANN, 2016a).

Gerontologic Considerations

Older adults have a high incidence of new-onset epilepsy (Hickey & Strayer, 2020). Cerebrovascular disease is the leading cause of seizures in the older adult but they are also associated with head injury, dementia, infection, alcoholism, and aging. Treatment depends on the underlying cause. Because many older adults have chronic health problems, they may be taking other medications that can interact with medications prescribed for seizure control. In addition, the absorption, distribution, metabolism, and excretion of medications are altered in the older adult as a result of age-related changes in renal and liver function. Therefore, older adult patients must be monitored closely for adverse and toxic effects of anticonvulsant medications and for osteoporosis.

Prevention

Society-wide efforts are the key to prevention of epilepsy. Head injury is one of the main causes of epilepsy that can be prevented. Through highway safety programs and occupational safety precautions, lives can be saved and epilepsy due to head injury prevented; these programs are discussed in Chapter 63.

Medical Management

The management of epilepsy is individualized to meet the needs of each patient and not just to manage and prevent seizures. Management differs from patient to patient, because some forms of epilepsy arise from brain damage and others result from altered brain chemistry.

Pharmacologic Therapy

Many medications are available to control seizures, although the exact mechanisms of action are unknown. The objective is to achieve seizure control with minimal side effects. Medication therapy controls—rather than cures—seizures. Medications are selected on the basis of the type of seizure being treated and the effectiveness and safety of the medications. If properly prescribed and taken, medications control seizures in 70% to 80% of patients with seizures. However, 20% of patients with generalized seizures and 30% of those with focal seizures do not demonstrate improvement with any prescribed medication or may be unable to tolerate the side effects of medications (AANN, 2016a). Table 61-5 lists select anticonvulsant medications.

Treatment usually starts with a single medication. The starting dose and the rate at which the dosage is increased depend on the occurrence of side effects. The medication levels in the blood are monitored, because the rate of drug absorption varies among patients. Changing to another medication may be necessary if seizure control is not achieved or if toxicity makes it impossible to increase the dosage. The medication may need to be adjusted because of concurrent illness, weight changes, or increases in stress. Side effects of anticonvulsant medications may be divided into three groups: idiosyncratic or allergic

disorders, which manifest primarily as skin reactions; acute toxicity, which may occur when the medication is initially prescribed; and chronic toxicity, which occurs late in the course of therapy.

The manifestations of drug toxicity are variable, and any organ system may be involved. For example, gingival hyperplasia (swollen and tender gums) can be associated with long-term use of phenytoin (Comerford & Durkin, 2020). Periodic physical and dental examinations and laboratory tests are performed for patients receiving medications that are known to have hematopoietic, genitourinary, or hepatic effects.

Surgical Management

Surgery is indicated for patients whose epilepsy results from intracranial tumors, abscesses, cysts, or vascular anomalies. Some patients have intractable seizure disorders that do not respond to medication. A focal atrophic process may occur secondary to trauma, inflammation, stroke, or anoxia. If the seizures originate in a reasonably well-circumscribed area of the brain that can be excised without producing significant neurologic deficits, the removal of the area generating the seizures may produce long-term control and improvement (AANN, 2016a).

This type of neurosurgery has been aided by several advances, including microsurgical techniques, EEGs with depth electrodes, improved illumination and hemostasis, and the introduction of neuroleptanalgesic agents (droperidol and fentanyl). These techniques, combined with the use of local anesthetic agents, enable the neurosurgeon to perform surgery on an alert and cooperative patient. Using special testing devices, electrocortical mapping, and the patient's responses to stimulation, the boundaries of the epileptogenic focus (i.e., abnormal area of the brain) are determined. Any abnormal epileptogenic focus is then excised (AANN, 2016a). Resection surgery significantly reduces the incidence of seizures in patients with refractory epilepsy.

TABLE 61-5 Select Anticonvulsant Medications

Medication	Dose-Related Side Effects	Toxic Effects
carbamazepine	Dizziness, drowsiness, unsteadiness, nausea and vomiting, diplopia, mild leukopenia	Severe skin rash, blood dyscrasias, hepatitis
clonazepam	Drowsiness, behavior changes, headache, hirsutism, alopecia, palpitations	Hepatotoxicity, thrombocytopenia, bone marrow failure, ataxia
ethosuximide	Nausea and vomiting, headache, gastric distress	Skin rash, blood dyscrasias, hepatitis, systemic lupus erythematosus
felbamate	Cognitive impairments, insomnia, nausea, headache, fatigue	Aplastic anemia, hepatotoxicity
gabapentin	Dizziness, drowsiness, somnolence, fatigue, ataxia, weight gain, nausea	Leukopenia, hepatotoxicity
lamotrigine	Drowsiness, tremor, nausea, ataxia, dizziness, headache, weight gain	Severe rash (Stevens–Johnson syndrome)
levetiracetam	Somnolence, dizziness, fatigue	Unknown
oxcarbazepine	Dizziness, somnolence, double vision, fatigue, nausea, vomiting, loss of coordination, abnormal vision, abdominal pain, tremor, abnormal gait	Hepatotoxicity
phenobarbital	Sedation, irritability, diplopia, ataxia	Skin rash, anemia
phenytoin	Visual problems, hirsutism, gingival hyperplasia, arrhythmias, dysarthria, nystagmus	Severe skin reaction, peripheral neuropathy, ataxia, drowsiness, blood dyscrasias
primidone	Lethargy, irritability, diplopia, ataxia, impotence	Skin rash
tiagabine	Dizziness, fatigue, nervousness, tremor, difficulty concentrating, dysarthria, weak or buckling knees, abdominal pain	Unknown
topiramate	Fatigue, somnolence, confusion, ataxia, anorexia, depression, weight loss	Nephrolithiasis
valproate	Nausea and vomiting, weight gain, hair loss, tremor, menstrual irregularities	Hepatotoxicity, skin rash, blood dyscrasias, nephritis
zonisamide	Somnolence, dizziness, anorexia, headache, nausea, agitation, rash	Leukopenia, hepatotoxicity

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

When seizures are refractory to medication in adolescents and adults with focal seizures, a vagal nerve stimulator (VNS) may be implanted under the clavicle. The device is connected to the vagus nerve in the

cervical area, where it delivers electrical signals to the brain to control and reduce seizure activity. An external programming system is used by the primary provider to change stimulator settings (Tzadok, Harush, Nissenkorn, et al., 2019). Patients can activate the stimulator with a magnet at the time of a seizure or aura. Some patients report that use of the VNS diminishes the severity or duration of the seizure. Complications such as infection, cardiac arrhythmias, hoarseness, cough, and laryngeal spasm can occur with the use of this device (AANN, 2016a).

Another surgical option for patients with refractory seizure activity is the responsive neurostimulation system (RNS). This is a surgically implanted device with electrodes that sense and record brain electrical activity. Electrodes deliver an electrical stimulation to the location of seizure origination within the brain. The RNS works by interrupting brainwave activity before a clinical seizure can occur (Wong, Mani, & Danish, 2019).

For patients with well-defined or anatomically deep epileptogenic lesions, MRI-guided stereotactic laser interstitial thermal therapy (LiTT) offers a less invasive treatment option. This treatment involves computer-assisted placement of a laser probe into the brain and delivery of heat therapy. Decisions about epilepsy surgery are complex, and these patients should be referred to epilepsy centers for further evaluation (Crepeau & Sirven, 2017).

More research is needed to determine the effects of the various surgical approaches on complication rates, quality of life, anxiety, and depression, all of which are issues for patients with epilepsy.

NURSING PROCESS

The Patient with Epilepsy

Assessment

The nurse elicits information about the patient's seizure history. The patient is asked about the factors or events that may precipitate the seizures. Alcohol intake is documented. The nurse determines whether the patient has an aura before an epileptic seizure, which may indicate the origin of the seizure (e.g., seeing a flashing light may indicate that the seizure originated in the occipital lobe). Observation and assessment during and after a seizure assist in identifying the type of seizure and its management.

The effects of epilepsy on the patient's lifestyle are assessed (AANN, 2016a). What limitations are imposed by the seizure disorder? Does the patient participate in any recreational activities? Have any social contacts? Is the patient working, and is it a positive or stressful experience? What coping mechanisms are used?

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for injury associated with seizure activity
- Fear associated with the possibility of seizures
- Difficulty coping associated with stresses imposed by epilepsy
- Lack of knowledge associated with epilepsy and anticonvulsant medications

Collaborative Problems/Potential Complications

The major potential complications for patients with epilepsy are status epilepticus and medication side effects (toxicity).

Planning and Goals

The major goals for the patient may include prevention of injury, control of seizures, achievement of a satisfactory psychosocial adjustment, acquisition of knowledge and understanding about the condition, and absence of complications.

Nursing Interventions

Preventing Injury

Injury prevention for the patient with seizures is a priority. Patients for whom seizure precautions are instituted should have pads applied to the side rails while in bed. Steps to prevent or minimize injury are presented in Chart 61-5.

Reducing Fear of Seizures

Fear that a seizure may occur unexpectedly can be reduced by the patient's adherence to the prescribed treatment regimen. Cooperation of the patient and family and their trust in the prescribed regimen are essential for control of seizures. The nurse emphasizes that the prescribed anticonvulsant medication must be taken on a continuing basis and that drug dependence or addiction does not occur. Periodic monitoring is necessary to ensure the adequacy of the treatment regimen, to prevent side effects, and to monitor for drug resistance (Hickey & Strayer, 2020).

In an effort to control seizures, factors that may precipitate them are identified, such as emotional disturbances, new environmental stressors, onset of menstruation in female patients, or fever (AANN, 2016a). The patient is encouraged to follow a regular and moderate routine in lifestyle, diet (avoiding excessive stimulants), exercise, and rest (sleep deprivation may lower the seizure threshold). Moderate activity is therapeutic, but excessive exercise should be avoided. An additional dietary intervention, referred to as the ketogenic diet or the Modified Atkins diet, may be helpful for control of seizures in some patients. This high-protein, low-carbohydrate, high-fat diet is most effective in children whose seizures have not been controlled with two anticonvulsant medications and has shown some success in adults with poor seizure control. Dietary therapy is not without risk and requires close monitoring and medical follow-up for possible side effects of therapy such as hyperlipidemia, malnutrition, weight loss, and osteoporosis (Crepeau & Sirven, 2017).

Photic stimulation (e.g., bright flickering lights, television viewing) may precipitate seizures; wearing dark glasses or covering one eye may be preventive. Tension states (anxiety, frustration) induce seizures in some patients. Classes in stress management may be of value. Because seizures are known to occur with alcohol intake, alcoholic beverages should be avoided.

Improving Coping Mechanisms

The social, psychological, and behavioral problems that frequently accompany epilepsy can be more of a disability than the actual seizures. Epilepsy may be accompanied by feelings of stigmatization, alienation, depression, and uncertainty (Hickey & Strayer, 2020). The patient must cope with the constant fear of a seizure and the psychological consequences (AANN, 2016a). Children with epilepsy may be ostracized and excluded from school and peer activities. These problems are compounded during adolescence and add to the challenges of dating, not being able to drive, and feeling different from other people. Adults face these problems in addition to the burden of finding employment, concerns about relationships and childbearing, insurance problems, and legal barriers. Substance use disorders may complicate matters. Family reactions may vary from outright rejection of the person with epilepsy to overprotection.

Counseling assists the patient and family to understand the condition and the limitations it imposes. Social and recreational opportunities are necessary for good mental health. Nurses can improve the quality of life for patients with epilepsy by educating them and their families about symptoms and their management (AANN, 2016a).

Providing Patient and Family Education

Perhaps the most valuable facets of care contributed by the nurse to the person with epilepsy are education and efforts to modify the attitudes of the patient and family toward the disorder. The person who experiences seizures may consider every seizure a potential source of humiliation and shame. This may result in anxiety, depression, hostility, and secrecy on the part of the patient and family. Ongoing education and encouragement should be given to patients to enable them to overcome these reactions. The patient with epilepsy should carry an emergency medical identification card or wear a medical information bracelet. The patient and family need to be educated about medications as well as care during a seizure.

Monitoring and Managing Potential Complications

Status epilepticus is the major potential complication and is described later in this chapter. Another complication is the toxicity of medications. The patient and family are educated about side effects and are given specific guidelines to assess and report signs and symptoms that indicate medication overdose. Anticonvulsant medications require careful monitoring for therapeutic levels. The patient should plan to have serum drug levels assessed at regular intervals. Many known drug interactions occur with anticonvulsant medications. A complete pharmacologic profile should be reviewed with the patient to avoid interactions that either potentiate or inhibit the effectiveness of the medications.

Quality and Safety Nursing Alert

Patients with epilepsy are at risk for status epilepticus from having their medication regimen interrupted.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Thorough oral hygiene after each meal, gum massage, daily flossing, and regular dental care are essential to prevent or control gingival hyperplasia in patients receiving phenytoin. The patient is also educated to inform all health care providers of the medication being taken, because of the possibility of drug interactions. An individualized comprehensive education plan is needed to assist the patient and family to adjust to this chronic disorder. Written patient education materials must be appropriate for the patient's reading level and must be provided in alternative formats if warranted.

Continuing and Transitional Care. Because epilepsy can be lifelong, health promotion is important. See Chart 61-6 for health promotion strategies for the patient with epilepsy.

For many patients with epilepsy, overcoming employment problems is a challenge. State vocational rehabilitation agencies can provide information about job training. The EFA has a training and placement service. If seizures are not well controlled, information about sheltered workshops or home employment programs may be obtained. Federal and state agencies and federal legislation may be of assistance to people with epilepsy who experience job discrimination. As a result of the Americans

With Disabilities Act, the number of employers who knowingly hire people with epilepsy is increasing, but barriers to employment still exist.

Chart 61-6 HEALTH PROMOTION

Strategies for the Patient with Epilepsy

- Take anticonvulsant medications daily as prescribed to keep the drug level constant to prevent seizures. Never discontinue medications, even if there is no seizure activity.
- Keep a medication and seizure record (in electronic or paper format), noting when medications are taken and any seizure activity.
- Notify the primary provider if unable to take medications due to illness.
- Have anticonvulsant medication serum levels checked regularly. When testing is prescribed, report to the laboratory for blood sampling before taking morning medication.
- Avoid activities that require alertness and coordination (driving, operating machinery) until after the effects of the medication have been evaluated.
- Report signs of toxicity so that dosage can be adjusted. Common signs include drowsiness, lethargy, dizziness, difficulty walking, hyperactivity, confusion, inappropriate sleep, and visual disturbances.
- Avoid over-the-counter medications unless approved by the primary provider.
- Carry a medical alert bracelet or identification card specifying the name of the anticonvulsant medication and primary provider.
- Avoid seizure triggers, such as alcoholic beverages, electrical shocks, stress, caffeine, constipation, fever, hyperventilation, and hypoglycemia.
- Take showers rather than tub baths to avoid drowning if seizure occurs; never swim alone.
- Exercise in moderation in a temperature-controlled environment to avoid excessive heat.
- Develop regular sleep patterns to minimize fatigue and insomnia.
- Be aware of and use the Epilepsy Foundation of America (EFA) special services, including help in obtaining medications, vocational rehabilitation, and coping with epilepsy.

Patients who have uncontrollable seizures accompanied by psychological and social difficulties should be referred as early as possible to a comprehensive epilepsy center where continuous audio–video and EEG monitoring, specialized treatment, and rehabilitation services are available (AANN, 2016a). Patients and their families need to be reminded of the importance of participating in health promotion activities and recommended health screenings to promote a healthy lifestyle. Genetic and preconception counseling is advised.

Evaluation

Expected patient outcomes may include:

1. Sustains no injury during seizure activity
   a. Adheres to treatment regimen and identifies the hazards of stopping the medication
   b. Can identify appropriate care during seizure; caregivers can do so as well
2. Indicates a decrease in fear
3. Displays effective individual coping
4. Exhibits knowledge and understanding of epilepsy
   a. Identifies the side effects of medications
   b. Avoids factors or situations that may precipitate seizures (e.g., flickering lights, hyperventilation, alcohol)

c. Follows a healthy lifestyle by getting adequate sleep and eating meals at regular times to avoid hypoglycemia

5. Absence of complications

Status Epilepticus

Status epilepticus (acute prolonged seizure activity) can be defined as a seizure lasting 5 minutes or longer or serial seizures occurring without full recovery of consciousness between attacks (Hickey & Strayer, 2020). The term has been broadened to include continuous clinical or electrical seizures (on EEG) lasting at least 30 minutes, even without impairment of consciousness. It is considered a medical emergency. Status epilepticus produces cumulative effects. Vigorous muscular contractions impose a heavy metabolic demand and can interfere with respirations. Some respiratory arrest at the height of each seizure produces venous congestion and hypoxia of the brain. Repeated episodes of cerebral anoxia and edema may lead to irreversible and fatal brain damage. Factors that precipitate status epilepticus include interruption of anticonvulsant medication, fever, concurrent infection, or other illness.

Medical Management

The goals of treatment are to stop the seizures as quickly as possible, to ensure adequate cerebral oxygenation, and to maintain the patient in a seizure-free state. An airway and adequate oxygenation are established. If the patient remains unconscious and unresponsive, an endotracheal tube is inserted. IV diazepam, lorazepam, or fosphenytoin is given slowly in an attempt to halt seizures immediately. Other medications (phenytoin, phenobarbital) are given later to maintain a seizure-free state.

An IV line is established, and blood samples are obtained to monitor serum electrolytes, glucose, and phenytoin levels. EEG monitoring may be useful in determining the nature of the seizure activity. Vital signs and neurologic signs are monitored on a continuing basis. An IV infusion of dextrose is given if the seizure is caused by hypoglycemia. If initial treatment is unsuccessful, general anesthesia with a short-acting barbiturate may be used. The serum concentration of the anticonvulsant medication is measured, because a low level suggests that the patient was not taking the medication or that the dosage was too low. Cardiac involvement or respiratory depression may be life-threatening. The potential for postictal cerebral edema also exists.

Nursing Management

The nurse initiates ongoing assessment and monitoring of respiratory and cardiac function because of the risk for delayed depression of respiration and blood pressure secondary to administration of anticonvulsant medications and sedatives to halt the seizures. Nursing assessment also includes monitoring and documenting the seizure activity and the patient's responsiveness.

The patient is turned to a side-lying position, if possible, to assist in draining pharyngeal secretions. Suction equipment must be available because of the risk of aspiration. The IV line is closely monitored, because it may become dislodged during seizures.

A person who has received long-term anticonvulsant therapy has a significant risk for fractures resulting from bone disease (osteoporosis, osteomalacia, and hyperparathyroidism), which is a side effect of therapy (Comerford & Durkin, 2020). Therefore, during seizures, the patient is protected from injury with the use of seizure precautions and is monitored closely. The patient having seizures can inadvertently injure nearby people, so nurses should protect themselves. Additional nursing interventions for the person having seizures are presented in Chart 61-5.

HEADACHE

Headache, or cephalalgia, is one of the most common of all human physical complaints. Headache is a symptom rather than a disease entity; it may indicate organic disease (neurologic or other disease), a stress response, vasodilation (migraine), skeletal muscle tension (tension headache), or a combination of factors. A **primary headache** is one for which no organic cause can be identified. This type of headache includes migraine, tension-type, and cluster headaches (Hickey & Strayer, 2020). Cranial arteritis is another

common cause of headache. A classification of headaches was issued first by the Headache Classification Committee of the International Headache Society (IHS) in 1988. The IHS revised the headache classification in 2018; an abbreviated list is shown in Chart 61-7.

Chart 61-7

International Headache Society Classification of Headache

- Migraine
- Tension-type headache
- Trigeminal autonomic cephalalgias
- Other primary disorders
- Headache attributed to trauma or injury to the head and/or neck
- Headache attributed to cranial or cervical vascular disorder
- Headache attributed to nonvascular intracranial disorder
- Headache attributed to a substance or its withdrawal
- Headache attributed to infection
- Headache attributed to disorder of homeostasis
- Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
- Headache attributed to psychiatric disorder
- Painful cranial neuropathies and other facial pains
- Other headache disorders

Adapted from Headache Classification Committee of the International Headache Society (IHS). (2018). *The International Classification of Headache Disorders*, 3rd edition. *Cephalalgia*, *38*(1), 1–211.

Migraine is a complex of symptoms characterized by periodic and recurrent attacks of severe headache lasting from hours to days in adults. The cause of migraine has not been clearly demonstrated, but it is primarily a vascular disturbance that has a strong familial tendency. The typical time of onset is at puberty, and the incidence is higher in women than men (Hickey & Strayer, 2020).

There are many subtypes of migraine headache, including migraine with and without aura. Most patients have migraine without an aura. *Tension-type headaches* tend to be chronic and less severe and are probably the most common type of headache. *Trigeminal autonomic cephalalgias* include cluster headaches and paroxysmal hemicrania. Cluster headaches are relatively uncommon and seen more frequently in men than in women (Norris, 2019). Types of headaches not subsumed under these categories fall into the *other primary headache* group and include headaches triggered by cough, exertion, and sexual activity (IHS, 2018).

Cranial arteritis is a cause of headache in the older population, reaching its greatest incidence in those older than 70 years of age. Inflammation of the cranial arteries is characterized by a severe headache localized in the region of the temporal arteries. The inflammation may be generalized (in which case cranial arteritis is part of a vascular disease) or focal (in which case only the cranial arteries are involved).

A **secondary headache** is a symptom associated with other causes, such as a brain tumor, an aneurysm, or lumbar puncture. Although most headaches do not indicate serious disease, persistent headaches require further investigation. Serious disorders related to headache include brain tumors, subarachnoid hemorrhage, stroke, severe hypertension, meningitis, and head injuries.

Pathophysiology

The cerebral signs and symptoms of migraine result from a hyperexcitable brain that is susceptible to a phenomenon known as cortical spreading depression, a wave of depolarization over the cerebral cortex, cerebellum, and hippocampus. This depolarization activates inflammatory neuropeptides and other neurotransmitters (including serotonin), resulting in the stimulation of meningeal nociceptors. Vascular changes, inflammation, and a continuation of pain signal stimulation occur (Goadsby & Holland, 2019). The initial phase of this process is known as the premonitory phase and may include light, sound, and smell sensitivity. If treatment is initiated at this point, the migraine may be fully terminated. As the attack progresses, central sensitization occurs, and the migraine becomes much harder to treat.

Attacks can be triggered by hormonal changes associated with menstrual cycles, bright lights, stress, depression, sleep deprivation, fatigue, or odors. Certain foods containing tyramine (aged cheese, red wine,

beer), monosodium glutamate, and chocolate may be food triggers (Hickey & Strayer, 2020). The use of oral contraceptives may be associated with increased frequency and severity of attacks in some women.

Emotional or physical stress may cause contraction of the muscles in the neck and scalp, resulting in tension headache. The pathophysiology of cluster headache is not fully understood. One theory is that it is caused by dilation of orbital and nearby extracranial arteries. Cranial arteritis is thought to represent an immune vasculitis in which immune complexes are deposited within the walls of affected blood vessels, producing vascular injury and inflammation. A biopsy may be performed on the involved artery to make the diagnosis.

Clinical Manifestations

Migraine

The migraine with aura can be divided into four phases: premonitory, aura, the headache, and recovery (headache termination and postdrome).

Premonitory Phase

The premonitory phase is experienced by more than 80% of adult migraine sufferers, with symptoms that occur hours to days before a migraine headache. Symptoms may include depression, irritability, feeling cold, food cravings, anorexia, change in activity level, increased urination, diarrhea, or constipation. Patients may experience the same prodrome with each migraine headache. A current theory regarding premonitory symptoms is that they involve the neurotransmitter dopamine.

Aura Phase

An aura may be a variable feature for patients who experience migraines and can be seen in about 30% of patients (Goadsby & Holland, 2019). An aura is characterized by focal neurologic symptoms. Visual disturbances (i.e., light flashes and bright spots) are most common and may be hemianopic (affecting only half of the visual field). Other symptoms that may follow include numbness and tingling of the lips, face, or hands; mild confusion; slight weakness of an extremity; drowsiness; and dizziness.

This period of aura was thought to correspond to the phenomenon of cortical spreading depression that is associated with reduced metabolic demand in abnormally functioning neurons. This can be associated with decreased blood flow; however, cerebral blood flow studies performed during migraine headaches demonstrate that although changes in blood vessels occur during phases of migraine, cerebral blood flow is not the main abnormality. In fact, some studies suggest that the aura and headache phases may occur simultaneously (Goadsby & Holland, 2019).

Headache Phase

Migraine headache is severe and incapacitating and is often associated with photophobia (light sensitivity), phonophobia (sound sensitivity), or allodynia (abnormal perception of innocuous stimuli) (Goadsby & Holland, 2019). Research differs in the role of vascular changes (either vasodilatory or vasoconstrictive) with respect to migraine pathophysiology and the experience of migraine headache. Symptoms of migraine can also include nausea and vomiting.

Postdrome Phase

In the postdrome phase, the pain gradually subsides, but patients may experience tiredness, weakness, cognitive difficulties, and mood changes for hours to days. Muscle contraction in the neck and scalp is common, with associated muscle ache and localized tenderness. Physical exertion may exacerbate the headache pain. During this postheadache phase, patients may sleep for extended periods.

Other Headache Types

The tension-type headache is characterized by a steady, constant feeling of pressure that usually begins in the forehead, temple, or back of the neck. It is often bandlike or may be described as “a weight on top of my head.”

Cluster headaches are unilateral and come in clusters of one to eight daily, with excruciating pain localized to the eye and orbit and radiating to the facial and temporal regions. The pain is accompanied by watering of the eye and nasal congestion. Each attack lasts 15 minutes to 3 hours and may have a crescendo–decrescendo pattern (Hickey & Strayer, 2020). The headache is often described as penetrating.

Cranial arteritis often begins with general manifestations, such as fatigue, malaise, weight loss, and fever. Clinical manifestations associated with inflammation (heat, redness, swelling, tenderness, or pain over the involved artery) usually are present. Sometimes a tender, swollen, or nodular temporal artery is visible. Visual problems are caused by ischemia of the involved structures.

Assessment and Diagnostic Findings

The diagnostic evaluation includes a detailed history, a physical assessment of the head and neck, and a complete neurologic examination. Headaches may manifest differently in the same person over the course of a lifetime, and the same type of headache may manifest differently from patient to patient. The health history focuses on assessing the headache itself, with emphasis on the factors that precipitate or provoke it. The patient is asked to describe the headache in their own words.

Because headache is often the presenting symptom of a wider variety of physiologic and psychological disturbances, a general health history is an essential component of the patient database. Therefore, questions addressed in the health history should cover major medical and surgical illness as well as a body systems review.

The medication history can provide insight into the patient's overall health status and indicate medications that may be provoking headaches. Antihypertensive agents, diuretic medications, anti-inflammatory agents, and monoamine oxidase (MAO) inhibitors are a few of the categories of medications that can provoke headaches. Daily use of over-the-counter or prescribed pain medications for 8 to 10 days out of a month can lead to a chronic headache due to medication overuse (Comerford & Durkin, 2020). Emotional factors can play a role in precipitating headaches. Stress is thought to be a major initiating factor in migraine headaches; therefore, sleep patterns, level of stress, recreational interests, appetite, emotional problems, and family stressors are relevant. There is a strong familial tendency for headache disorders, and a positive family history may help in making a diagnosis.

A direct relationship may exist between exposure to toxic substances and headache. Careful questioning may uncover chemicals to which a worker has been exposed. Under the Right-to-Know Law, employees have access to the material safety data sheets (commonly referred to as MSDSs) for all substances with which they come in contact in the workplace (see Chapter 68). The occupational history also includes assessment of the workplace as a possible source of stress and for a possible ergonomic basis of muscle strain and headache.

A complete description of the headache itself is crucial. The nurse reviews the age at onset of headaches; this particular headache's frequency, location, and duration; the type of pain; factors that relieve and precipitate the event; and associated symptoms (Starling, 2018). The data obtained should include the patient's own words about the headache in response to the following questions:

- What is the location? Is it unilateral or bilateral? Does it radiate?
- What is the quality—dull, aching, steady, boring, burning, intermittent, continuous, paroxysmal?
- How many headaches occur during a given period of time?
- What are the precipitating factors, if any—environmental (e.g., sunlight, weather change), foods, exertion, other?
- What makes the headache worse (e.g., coughing, straining)?
- What time (day or night) does it occur?
- How long does a typical headache last?
- Are there any associated symptoms, such as facial pain, lacrimation (excessive tearing), or scotomas (blind spots in the field of vision)?
- What usually relieves the headache (aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs], ergot preparation, food, heat, rest, neck massage)?
- Does nausea, vomiting, weakness, or numbness in the extremities accompany the headache?
- Does the headache interfere with daily activities?
- Do you have any allergies?
- Do you have insomnia, poor appetite, loss of energy?
- Is there a family history of headache?
- What is the relationship of the headache to your lifestyle or physical or emotional stress?
- What medications are you taking?

Diagnostic testing often is not helpful in the investigation of headache, because usually there are few objective findings. In patients who demonstrate abnormalities on the neurologic examination, CT scan, cerebral angiography, or MRI scan may be used to detect underlying causes, such as tumor or aneurysm.

Electromyography (EMG) may reveal a sustained contraction of the neck, scalp, or facial muscles. Laboratory tests may include complete blood count, erythrocyte sedimentation rate, electrolytes, glucose, creatinine, and thyroid hormone levels.

Prevention

Prevention begins by having the patient avoid specific triggers that are known to initiate the headache syndrome. Preventive medical management of migraine involves the daily use of one or more agents that are thought to block the physiologic events leading to an attack. Treatment regimens vary greatly, as do patient responses; therefore, close monitoring is indicated.

Alcohol, nitrites, vasodilators, and histamines may precipitate cluster headaches. Elimination of these factors helps prevent the headaches.

Medical Management

Therapy for migraine headache is divided into abortive (symptomatic) and preventive approaches. The abortive approach, best used in those patients who have less frequent attacks, is aimed at relieving or limiting a headache at the onset or while it is in progress. The preventive approach is used in patients who experience more frequent attacks at regular or predictable intervals and may have a medical condition that precludes the use of abortive therapies (Starling, 2018). Medical management of migraine during pregnancy and lactation includes nonpharmacologic strategies in addition to safe medication practices. Nonpharmacologic treatments include mainly avoidance of triggers (Hickey & Strayer, 2020) (see Chart 61-8). Noninvasive neuromodulation devices may also provide some relief with minimal side effects (Tepper, 2019).

The triptans, which are serotonin receptor agonists, are the most specific antimigraine agents available. These agents cause vasoconstriction, reduce inflammation, and may reduce pain transmission. The triptans in routine clinical use include sumatriptan, naratriptan, rizatriptan, zolmitriptan, almotriptan, eletriptan, and frovatriptan (Comerford & Durkin, 2020). Many of the triptan medications are available in a variety of formulations, such as nasal sprays, inhalers, conventional tablet, disintegrating tablet, suppositories, or injections. The nasal sprays may be useful for patients experiencing nausea and vomiting (Tepper, 2019).

Chart 61-8 PATIENT EDUCATION

Migraine Headaches

The nurse instructs the patient to:

- Be aware of the definition of migraine headaches along with the characteristics and manifestations.
- Recognize triggers of migraine headaches and how to avoid such triggers as:
  - Foods that contain tyramine, such as chocolate, cheese, coffee, dairy products
  - Dietary habits that result in long periods between meals
  - Menstruation and ovulation (caused by hormone fluctuation)
  - Alcohol (causes vasodilation of blood vessels)
  - Fatigue and fluctuations in sleep patterns
- Develop and use a paper or electronic headache diary.
- Implement stress management and lifestyle changes to minimize the frequency of headaches.
- Ensure correct pharmacologic management: acute therapy and prophylaxis to include medication regimen and side effects.
- Use comfort measures during headache attacks, such as resting in a quiet and dark environment, applying cold compresses to the painful area, and elevating the head.
- Seek out resources for education and support, such as the National Headache Foundation.

The triptans are considered first-line treatment of the management of moderate to severe migraine pain. Best results are achieved with early use of triptans; oral dosing takes effect within 20 to 60 minutes of taking the drug and if needed may be repeated in 2 to 4 hours. Triptans are contraindicated in patients with ischemic heart disease. Careful administration and dosing instructions to patients are important to prevent

adverse reactions such as increased blood pressure, drowsiness, muscle pain, sweating, and anxiety. Interactions are possible if the medication is taken in conjunction with St. John's wort (Comerford & Durkin, 2020).

Ergotamine preparations (taken orally, sublingually, subcutaneously, intramuscularly, by rectum, or by inhalation) may be effective in aborting the headache if taken early in the migraine process. They are low in cost. Ergotamine tartrate acts on smooth muscle, causing prolonged constriction of the cranial blood vessels. Each patient's dosage is based on individual needs. Side effects include aching muscles, paresthesias (numbness and tingling), nausea, and vomiting. Pretreatment with antiemetic agents may be required. None of the triptan medications should be taken concurrently with medications containing ergotamine because of the potential for a prolonged vasoactive reaction (Comerford & Durkin, 2020).

Other nonspecific medications are also used in the treatment of migraine and include NSAIDs, antispasmodic agents, and neuroleptics. Neuroleptic agents can be used alone or in conjunction with triptans and/or NSAIDs (Tepper, 2019).

Prophylactic treatment of migraine includes the use of beta-blockers, antiepileptics, antidepressants, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers. Calcitonin gene–related peptides (CGRPs) have been found in increased levels in patients with migraine, and three CGRP monoclonal antibodies have been approved by the U.S. Food and Drug Administration (FDA) for migraine prevention: erenumab, fremanezumab, and galcanezumab (Hickey & Strayer, 2020).

The medical management of an acute attack of cluster headaches may include 100% oxygen by facemask for 15 minutes, subcutaneous sumatriptan, or intranasal zolmitriptan (Hickey & Strayer, 2020).

The medical management of cranial arteritis consists of early administration of a corticosteroid to prevent the possibility of loss of vision due to vascular occlusion or rupture of the involved artery (Starling, 2018). The patient is instructed not to stop the medication abruptly, because this can lead to relapse. Analgesic agents are prescribed for comfort.

Nursing Management

When migraine or the other types of headaches have been diagnosed, the goal of nursing management is pain relief. It is reasonable to try nonpharmacologic interventions first, but the use of medications should not be delayed. The first priority is to treat the acute event of the headache and the second is to prevent recurrent episodes. Prevention involves patient education regarding precipitating factors, possible lifestyle or habit changes that may be helpful, and pharmacologic measures.

Relieving Pain

Individualized treatment depends on the type of headache and differs for migraine, cluster headaches, cranial arteritis, and tension headache. Nursing care is directed toward treatment of the acute episode. A migraine or a cluster headache in the early phase requires abortive medication therapy instituted as soon as possible. Some headaches can be prevented if the appropriate medications are taken before the onset of pain. Nursing care during an attack includes comfort measures such as a quiet, dark environment; elevation of the head of the bed to 30 degrees; and symptomatic treatment (i.e., administration of antiemetic medication) (Hickey & Strayer, 2020).

Symptomatic pain relief for tension headache may be obtained by application of local heat or massage. Additional strategies may include administration of analgesic agents, antidepressant medications, and muscle relaxants.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Headaches, especially migraines, are more likely to occur when the patient is ill, overly tired, or stressed. Nonpharmacologic therapies are important and include patient education about the type of headache, its mechanism (if known), and appropriate changes in lifestyle to avoid triggers. Regular sleep, meals, exercise, relaxation, and avoidance of dietary triggers may be helpful in avoiding headaches (Starling, 2018).

The patient with tension headaches needs education and reassurance that the headache is not the result of a brain tumor or other intracranial disorder. Stress reduction techniques, such as biofeedback, exercise programs, and meditation, are examples of nonpharmacologic therapies that may prove helpful. The patient

and family need to be educated about the importance of following the prescribed treatment regimen for headache and keeping follow-up appointments. In addition, the patient is reminded of the importance of participating in health promotion activities and recommended health screenings to promote a healthy lifestyle. Chart 61-8 presents educational topics for the patient with migraine headaches.

Continuing and Transitional Care

The National Headache Foundation (see the Resources section) provides a list of clinics in the United States and the names of primary providers who specialize in headache and who are members of the American Headache Society.

CRITICAL THINKING EXERCISES

1 pq A patient is admitted to your unit for a supratentorial cranial procedure. Identify the nursing priorities before, during, and after the procedure. What are the priorities for patient and caregiver education in preparation for discharge?

2 ebp As a member of your unit's practice council, you are working on identifying interventions to assess and manage delirium. Using your knowledge of evidence-based practice guidelines, list the most important assessments and interventions for nurses to implement. Compare and contrast the options supported by the guidelines.

3 ipc You are a nurse working in an outpatient neurology clinic. A 28-year-old woman is newly diagnosed with epilepsy. What nursing and interprofessional assessments are indicated? What interventions, including patient education, will you implement? What interprofessional referrals would be appropriate?

62 Management of Patients with Cerebrovascular Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the incidence of, risk factors and preventive measures for, and impact of cerebrovascular disorders.
2. Compare the various types of cerebrovascular disorders: their causes, clinical manifestations, and medical management.
3. Explain the principles of nursing management as they relate to the care of a patient in the acute stage of an ischemic stroke.
4. Use the nursing process as a framework for care of the patient recovering from an ischemic stroke or from a hemorrhagic stroke.
5. Discuss essential elements for family education and preparation for home care of the patient who has had a stroke.

NURSING CONCEPTS

Family
Functional Ability
Intracranial Regulation
Patient Education
Perfusion
Sensory Perception

GLOSSARY

agnosia: loss of ability to recognize objects through a particular sensory system; may be visual, auditory, or tactile

aneurysm: a weakening or bulge in an arterial wall

aphasia: inability to express oneself or to understand language

apraxia: inability to perform previously learned purposeful motor acts on a voluntary basis

dysarthria: defects of articulation due to neurologic causes

dysphagia: difficulty swallowing

expressive aphasia: inability to express oneself; often associated with damage to the left frontal lobe area

hemianopsia: blindness of half of the field of vision in one or both eyes

hemiparesis: weakness of one side of the body, or part of it, due to an injury in the motor area of the brain

hemiplegia: paralysis of one side of the body, or part of it, due to an injury in the motor area of the brain

infarction: tissue necrosis in an area deprived of blood supply

penumbra region: area of low cerebral blood flow

receptive aphasia: inability to understand what someone else is saying; often associated with damage to the temporal lobe area

Cerebrovascular disorder is an umbrella term that refers to a functional abnormality of the central nervous system (CNS) that occurs when the blood supply to the brain is disrupted. Stroke is the primary cerebrovascular disorder in the United States, and while it dropped from

the fourth to the fifth leading cause of death, it is still a leading cause of serious, long-term disability. Approximately 795,000 people experience a stroke each year in the United States. Approximately 610,000 of these are new strokes, and 185,000 are recurrent strokes (Virani, Alonso, Benjamin, et al., 2020). About 7 million Americans over the age of 20 who have survived a stroke are alive today. The financial impact of stroke is profound, with estimated direct and indirect costs of $45.5 billion from 2014 to 2015 (Virani et al., 2020).

Strokes can be divided into two major categories: ischemic (approximately 87%), in which vascular occlusion and significant hypoperfusion occur, and hemorrhagic (approximately 13%), in which there is extravasation of blood into the brain or subarachnoid space (Hickey & Strayer, 2020; Virani et al., 2020). Although there are some similarities between the two types of stroke, differences exist in etiology, pathophysiology, medical management, surgical management, and nursing care. Table 62-1 compares ischemic and hemorrhagic strokes.

TABLE 62-1 Comparison of Major Types of Stroke

Types of Stroke	Causes	Main Presenting Symptoms	Functional Recovery
Ischemic	• Large artery thrombosis • Small penetrating artery thrombosis • Cardiogenic embolic • Cryptogenic (no known cause) • Other	• Numbness or weakness of the face, arm, or leg, especially on one side of the body, aphasia, vision loss (homonymous hemianopsia)	Majority of recovery made in the first 3–6 mo, slower steps toward recovery may be made up to 1 yr and beyond with therapy.
Hemorrhagic	• Intracerebral hemorrhage • Subarachnoid hemorrhage • Cerebral aneurysm • Arteriovenous malformation	• "Worst headache of my life" • Decreased level of consciousness • Seizure	Slower recovery, typically left with more disability.

Adapted from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological & neurosurgical nursing* (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Ischemic Stroke

An ischemic stroke, formerly referred to as a cerebrovascular accident or "brain attack," is a sudden loss of function resulting from disruption of the blood supply to a part of the brain. The term *brain attack* has been used to suggest to health care practitioners and the public that a stroke is an urgent health care issue similar to a heart attack. The only U.S. Food and Drug Administration (FDA)-approved thrombolytic therapy has a treatment window of 3 hours after the onset of a stroke, and scientific statements have endorsed its expanded use for up to 4.5 hours (Del Zoppo, Saver, Jauch, et al., 2009; Powers, Rabinstein, Ackerson, et al., 2019). Although the time frame for treatment has expanded, urgency is

needed on the part of the public and health care practitioners for rapid transport of the patient to a hospital for assessment and administration of the medication.

Ischemic strokes are subdivided into five different types based on the cause: large artery thrombotic strokes (20%), small penetrating artery thrombotic strokes (25%), cardiogenic embolic strokes (20%), cryptogenic strokes (30%), and others (5%) (see Table 62-1). Large artery thrombotic strokes are caused by atherosclerotic plaques in the large blood vessels of the brain. Thrombus formation and occlusion at the site of the atherosclerosis result in ischemia and **infarction** (tissue necrosis in an area deprived of blood supply) (Hickey & Strayer, 2020).

Small penetrating artery thrombotic strokes affect one or more vessels and are a common type of ischemic stroke. Small artery thrombotic strokes are also called *lacunar strokes* because of the cavity that is created after the death of infarcted brain tissue (Hickey & Strayer, 2020).

Cardiogenic embolic strokes are associated with cardiac arrhythmias, usually atrial fibrillation. Embolic strokes can also be associated with valvular heart disease and thrombi in the left ventricle. Emboli originate from the heart and circulate to the cerebral vasculature, most commonly the left middle cerebral artery, resulting in a stroke. Embolic strokes may be prevented by the use of anticoagulation therapy in patients with atrial fibrillation.

The last two classifications of ischemic strokes are cryptogenic strokes, which have no known cause, and strokes from other causes, such as illicit drug use (cocaine), coagulopathies, migraine/vasospasm, or spontaneous dissection of the carotid or vertebral arteries.

COVID-19 Considerations

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is a community-acquired coronavirus whose primary pathologic evolution occurs within the respiratory system; however, due to abnormal blood clotting, one of the manifestations of coronavirus disease 2019 (COVID-19) can be ischemic stroke (Wadman, Couzin-Frankel, Kaiser, et al., 2020). The increase in blood clots in patients with COVID-19 is associated with laboratory findings of high D-dimer levels (Wadman et al., 2020). Case reports of patients who have had strokes and COVID-19 reveal that many are younger than 50 years of age and that the strokes occur in the large blood vessels of the brain, resulting in severe

neurologic deficits (see later discussion) (Oxley, Mocco, Majidi, et al., 2020).

Pathophysiology

In an ischemic brain attack, there is disruption of the cerebral blood flow due to obstruction of a blood vessel. This disruption in blood flow initiates a complex series of cellular metabolic events referred to as the ischemic cascade (see Fig. 62-1).

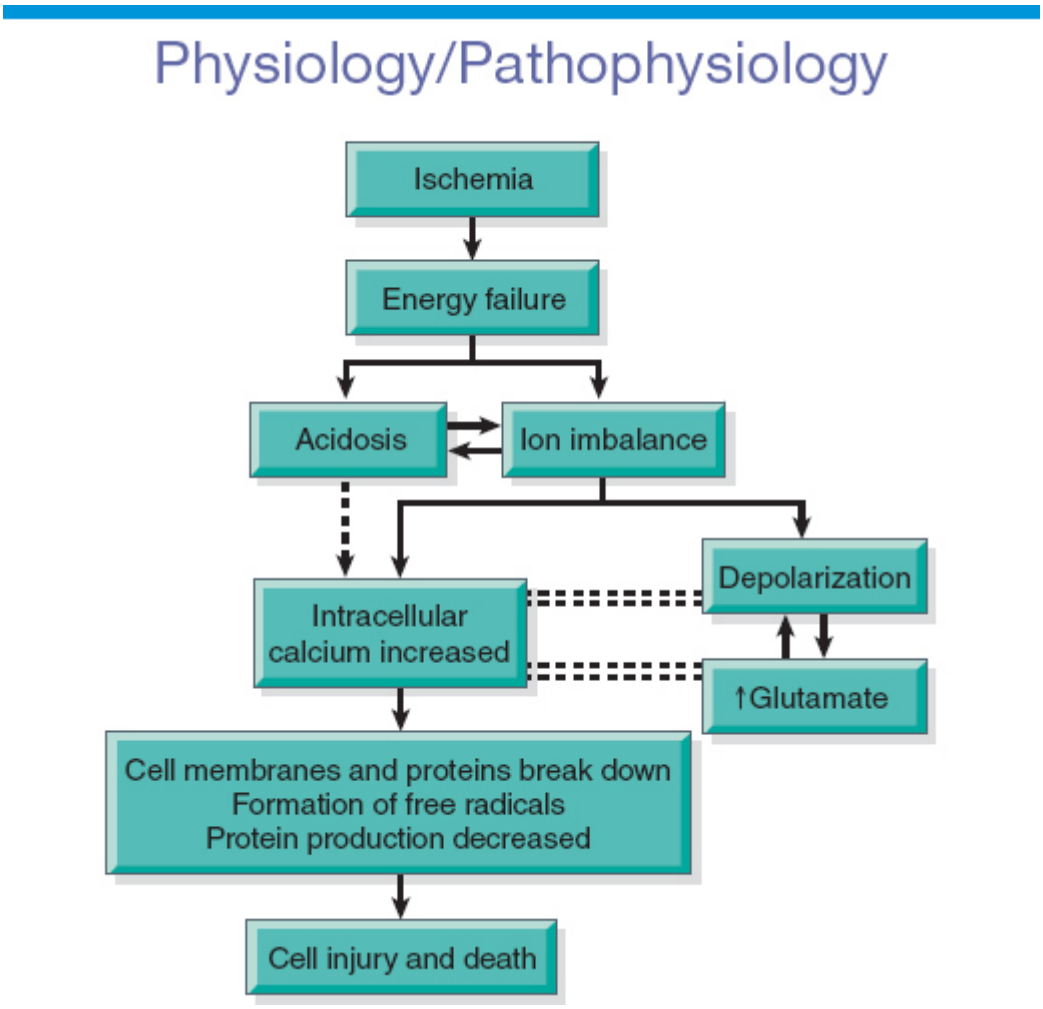

Figure 62-1 • Some of the processes contributing to ischemic brain cell injury.

The ischemic cascade begins when cerebral blood flow decreases to less than 25 mL per 100 g of blood per minute. At this point, neurons are no longer able to maintain aerobic respiration. The mitochondria must then switch to anaerobic respiration, which generates large amounts of

lactic acid, causing a change in the pH. This switch to the less efficient anaerobic respiration also renders the neuron incapable of producing sufficient quantities of adenosine triphosphate (ATP) to fuel the depolarization processes. The membrane pumps that maintain electrolyte balance begin to fail, and the cells cease to function.

Early in the cascade, an area of low cerebral blood flow, referred to as the **penumbra region**, exists around the area of infarction. The penumbra region is ischemic brain tissue that may be salvaged with timely intervention. The ischemic cascade threatens cells in the penumbra because membrane depolarization of the cell wall leads to an increase in intracellular calcium and the release of glutamate. The influx of calcium and the release of glutamate, if continued, activate a number of damaging pathways that result in the destruction of the cell membrane, the release of more calcium and glutamate, vasoconstriction, and the generation of free radicals. These processes enlarge the area of infarction into the penumbra, extending the stroke. A person experiencing a stroke typically loses 1.9 million neurons each minute that a stroke is not treated, and the ischemic brain ages 3.6 years each hour without treatment (Saver, 2006).

Each step in the ischemic cascade represents an opportunity for intervention to limit the extent of secondary brain damage caused by a stroke. The penumbra area may be revitalized by administration of tissue plasminogen activator (t-PA). Medications that protect the brain from secondary injury are called *neuroprotectants.* A number of clinical trials have focused on neuroprotective medications and strategies to improve stroke recovery and survival; so far, none have shown positive results (Powers et al., 2019).

Clinical Manifestations

An ischemic stroke can cause a wide variety of neurologic deficits, depending on the location of the lesion (which blood vessels are obstructed), the size of the area of inadequate perfusion, and the amount of collateral (secondary or accessory) blood flow. See Chapter 60 for discussion of anatomy and brain blood supply. The patient may present with any of the following signs or symptoms:

- Numbness or weakness of the face, arm, or leg, especially on one side of the body
- Confusion or change in mental status
- Trouble speaking or understanding speech

- Visual disturbances
- Difficulty walking, dizziness, or loss of balance or coordination
- Sudden severe headache

Motor, sensory, cranial nerve, cognitive, and other functions may be disrupted. Table 62-2 reviews the neurologic deficits frequently seen in patients with stroke. Table 62-3 compares the symptoms and behaviors seen in right hemispheric stroke with those seen in left hemispheric stroke.

Motor Loss

A stroke is an upper motor neuron lesion and results in loss of voluntary control over motor movements. Because the upper motor neurons decussate (cross), a disturbance of voluntary motor control on one side of the body may reflect damage to the upper motor neurons on the opposite side of the brain. The most common motor dysfunction is **hemiplegia** (paralysis of one side of the body, or part of it) caused by a lesion of the opposite side of the brain. **Hemiparesis**, or weakness of one side of the body, or part of it, is another sign. The concept of upper and lower motor neuron lesions is described in more detail in Chapter 60, Table 60-4.

In the early stage of stroke, the initial clinical features may be flaccid paralysis and loss of or decrease in the deep tendon reflexes. When these deep reflexes reappear (usually by 48 hours), increased tone is observed along with spasticity (abnormal increase in muscle tone) of the extremities on the affected side.

Communication Loss

Other brain functions affected by stroke are language and communication. In fact, stroke is the most common cause of **aphasia** (inability to express oneself or to understand language). The following are dysfunctions of language and communication:

- **Dysarthria** (difficulty in speaking) or dysphasia (impaired speech), caused by paralysis of the muscles responsible for producing speech
- Aphasia, which can be **expressive aphasia** (inability to express oneself), **receptive aphasia** (inability to understand language), or global (mixed) aphasia (see Chapter 60, Table 60-5)
- **Apraxia** (inability to perform a previously learned action), as may be seen when a patient makes verbal substitutions for

desired syllables or words

Perceptual Disturbances

Perception is the ability to interpret sensation. Stroke can result in visual–perceptual dysfunctions, disturbances in visual–spatial relations, and sensory loss.

Visual–perceptual dysfunctions are caused by disturbances of the primary sensory pathways between the eye and visual cortex. Homonymous **hemianopsia** (blindness in half of the visual field in one or both eyes) may occur from stroke and may be temporary or permanent. The affected side of vision corresponds to the paralyzed side of the body.

Disturbances in visual–spatial relations (perceiving the relationship of two or more objects in spatial areas) are frequently seen in patients with right hemispheric damage.

Sensory Loss

Sensory losses from stroke may be mild, such as a slight impairment of touch, or more severe, with loss of proprioception (ability to perceive the position and motion of body parts) as well as difficulty in interpreting visual, tactile, and auditory stimuli. An **agnosia** is the loss of the ability to recognize objects through a particular sensory system; it may be visual, auditory, or tactile (see Chapter 60, Table 60-6).

Cognitive Impairment and Psychological Effects

If damage has occurred to the frontal lobe, learning capacity, memory, or other higher cortical intellectual functions may be impaired. Such dysfunction may be reflected in a limited attention span, difficulties in comprehension, forgetfulness, and a lack of motivation. These changes can cause the patient to become easily frustrated during rehabilitation. Depression is common and may be exaggerated by the patient's natural response to this catastrophic event. Emotional lability, hostility, frustration, resentment, lack of cooperation, and other psychological problems may occur.

TABLE 62-2 Neurologic Deficits of Stroke: Manifestations and Nursing Implications

Neurologic Deficit	Manifestation	Nursing Implications/Patient Education Applications
Visual Field Deficits		
Homonymous hemianopsia (loss of half of the visual field)	• Unaware of persons or objects on side of visual loss • Neglect of one side of the body • Difficulty judging distances	Place objects within intact field of vision. Approach the patient from side of intact field of vision. Instruct/remind the patient to turn head in the direction of visual loss to compensate for loss of visual field. Encourage the use of eyeglasses if available. When educating the patient, do so within patient's intact visual field.
Loss of peripheral vision	• Difficulty seeing at night • Unaware of objects or the borders of objects	Place objects in center of patient's intact visual field. Encourage the use of a cane or other object to identify objects in the periphery of the visual field. Ensure that the patient's driving ability is evaluated.
Diplopia	• Double vision	Explain to the patient the location of an object when placing it near the patient. Consistently place patient care items in the same location.
Motor Deficits		
Hemiparesis	• Weakness of the face, arm, and leg on the same side (due to a lesion in the opposite hemisphere)	Place objects within the patient's reach on the nonaffected side. Instruct the patient to exercise and increase the strength on the unaffected side.
Hemiplegia	• Paralysis of the face, arm, and leg on the same side (due to a lesion in the opposite hemisphere)	Encourage the patient to provide range-of-motion exercises to the affected side. Reposition the patient every 2 h. Maintain body alignment in functional position. Exercise unaffected limb to increase mobility, strength, and use.
Ataxia		Support patient during the initial

	• Staggering, unsteady gait • Unable to keep feet together; needs a broad base to stand	ambulation phase. Provide supportive device for ambulation (walker, cane). Instruct the patient not to walk without assistance or supportive device.
Dysarthria	• Difficulty in forming words	Provide the patient with alternative methods of communicating. Allow the patient sufficient time to respond to verbal communication. Support patient and family to alleviate frustration related to difficulty in communicating.
Dysphagia	• Difficulty in swallowing	Test the patient's pharyngeal reflexes before offering food or fluids. Assist the patient with meals. Place food on the unaffected side of the mouth. Allow ample time to eat.
Sensory Deficits		
Paresthesia (occurs on the side opposite the lesion)	• Sensation of numbness, tingling, or a "pins and needles" sensation • Difficulty with proprioception	Instruct patient that sensation may be altered. Provide range of motion to affected areas and apply corrective devices as needed. If numbness is present, protect the affected areas from injury and burns.
Verbal Deficits		
Expressive aphasia	• Unable to form words that are understandable; may be able to speak in single-word responses	Encourage patient to repeat sounds of the alphabet. Explore the patient's ability to write as an alternative means of communication.
Receptive aphasia	• Unable to comprehend the spoken word; can speak but may not make sense	Speak clearly and in an unhurried manner to assist the patient in forming the sounds. Explore the patient's ability to read as an alternative means of communication.
Global (mixed) aphasia	• Combination of both receptive and	Speak clearly and in simple sentences; use gestures or pictures

	expressive aphasia	when able. Establish alternative means of communication.
Cognitive Deficits	• Short- and long-term memory loss • Decreased attention span • Impaired ability to concentrate • Poor abstract reasoning • Altered judgment	Reorient patient to time, place, and situation frequently. Use verbal and auditory cues to orient patient. Provide familiar objects (family photographs, favorite objects). Use noncomplicated language. Match visual tasks with a verbal cue; holding a toothbrush, simulate brushing of teeth while saying, "I would like you to brush your teeth now." Minimize distracting noises and views when providing education to the patient. Repeat and reinforce instructions frequently.
Emotional Deficits	• Loss of self-control • Emotional lability • Decreased tolerance to stressful situations • Depression • Withdrawal • Fear, hostility, and anger • Feelings of isolation	Support patient during uncontrollable outbursts. Discuss with the patient and family that the outbursts are due to the disease process. Encourage patient to participate in group activity. Provide stimulation for the patient. Control stressful situations, if possible. Provide a safe environment. Encourage patient to express feelings and frustrations related to disease process.

TABLE 62-3 Comparison of Left and Right Hemispheric Strokes

Left Hemispheric Stroke	Right Hemispheric Stroke
Paralysis or weakness on right side of body	Paralysis or weakness on left side of body
Right visual field deficit	Left visual field deficit
Aphasia (expressive, receptive, or global)	Spatial–perceptual deficits
Altered intellectual ability	Increased distractibility
Slow, cautious behavior	Impulsive behavior and poor judgment Lack of awareness of deficits

Adapted from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological & neurosurgical nursing* (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Assessment and Diagnostic Findings

Any patient with neurologic deficits needs a careful history eliciting the last time the patient was seen well and a rapid focused physical and neurologic examination. Initial assessment focuses on airway patency, which may be compromised by loss of gag or cough reflexes and altered respiratory pattern; cardiovascular status (including blood pressure, cardiac rhythm and rate, carotid bruit); and gross neurologic deficits.

Patients may present to the acute care facility with temporary neurologic symptoms. A transient ischemic attack (TIA) is a neurologic deficit that completely resolves in 24 hours (most last less than 1 hour). A TIA is manifested by a sudden loss of motor, sensory, or visual function. The symptoms result from temporary ischemia (impairment of blood flow) to a specific region of the brain; however, when brain imaging is performed, there is no evidence of ischemia. A TIA may serve as a warning of impending stroke. Approximately 3% to 15% of all strokes are preceded by a TIA and occur within the first 90 days after the TIA (Hickey & Strayer, 2020; Johnston, Easton, Farrant, et al., 2018). Lack of evaluation and treatment of a patient who has experienced previous TIAs may result in a stroke and irreversible deficits.

The initial diagnostic test for a stroke is a noncontrast computed tomography (CT) scan. This should be initiated within 20 minutes from the time the patient presents to the emergency department (ED) to determine if the event is ischemic or hemorrhagic, as the type of stroke determines treatment (Powers et al., 2019). Some cities now have mobile stroke units (an ambulance with a CT scanner) that can rapidly make this important distinction and can begin acute medical management. Further

diagnostic workup for ischemic stroke involves attempting to identify the source of the thrombi or emboli and to determine if the patient would benefit from mechanical intervention (clot removal). Studies may include CT angiography or CT perfusion; magnetic resonance imaging (MRI) and magnetic resonance angiography of the brain and neck vessels; transcranial Doppler flow studies; and transthoracic or transesophageal echocardiography (Hickey & Strayer, 2020; Powers et al., 2019). A 12-lead electrocardiogram (ECG) and a carotid ultrasound are other standard tests.

Prevention

Primary prevention of ischemic stroke remains the best approach. A healthy lifestyle including not smoking, engaging in physical activity (at least 40 minutes a day, 3 to 4 days a week), maintaining a healthy weight, and following a healthy diet (including modest alcohol consumption), can reduce the risk of having a stroke (Virani et al., 2020). Specific diets that have decreased risk of stroke include the Dietary Approaches to Stop Hypertension (DASH) diet (high in fruits and vegetables, moderate in low-fat dairy products, and low in animal protein), the Mediterranean diet (supplemented with nuts), and overall diets that are rich in fruits and vegetables. Research findings suggest that low-dose aspirin may lower the risk of a first stroke for those who are at risk (Meschia, Bushnell, Boden-Albala, et al., 2014).

Stroke risk screenings are an ideal opportunity to lower stroke risk by identifying people or groups of people who are at high risk for stroke and by educating patients and the community about recognition and prevention of stroke. Stroke screenings are usually coordinated and run by nurses. Age, gender, and race are well-known nonmodifiable risk factors for stroke. High-risk groups include people older than 55 years, and the incidence of stroke more than doubles in each successive decade. Men have a higher age-adjusted rate of stroke than that of women in younger and middle age, but that difference narrows in the oldest age groups, in which the rate in women is almost equal to or sometimes even higher than in men. Each year, 55,000 more women than men have a stroke. Compared to Caucasian Americans, African Americans and some Hispanic/Latino Americans have a higher incidence of stroke and higher mortality (Virani et al., 2020).

There are many risk factors for ischemic stroke (see Chart 62-1). For people who are at high risk, interventions that alter modifiable factors,

such as treating hypertension and stopping smoking, reduce stroke risk (Meschia et al., 2014).

Chart 62-1 MODIFIABLE RISK FACTORS

Ischemic Stroke

- Asymptomatic carotid stenosis
- Atrial fibrillation
- Diabetes (associated with accelerated atherogenesis)
- Dyslipidemia
- Excessive alcohol consumption
- Hypercoagulable states
- Hypertension (controlling hypertension, the major risk factor, is the key to preventing stroke)
- Migraine
- Obesity
- Sedentary lifestyle
- Sleep apnea
- Smoking

Adapted from Meschia, J. F., Bushnell, C., Boden-Albala, B., et al. (2014). Guidelines for the primary prevention of stroke: A statement for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke*, *45*(12), 3754–3832.

Additional treatable conditions that increase risk of stroke include sickle cell diseases, cardiomyopathy (ischemic and nonischemic), and valvular heart disease (e.g., endocarditis, prosthetic heart valves). Lesser known and potentially modifiable risk factors for stroke are migraine (especially migraine with aura), sleep apnea, and inherited and acquired hypercoagulable states. Chronic inflammatory conditions that have been associated with an increased risk of stroke are systemic lupus erythematosus and rheumatoid arthritis (Norris, 2019).

Several methods of preventing recurrent stroke have been identified for patients with TIAs or ischemic stroke. Patients with moderate to severe carotid stenosis are treated with carotid endarterectomy (CEA) or

carotid angioplasty and stenting. In patients with atrial fibrillation, which increases the risk of emboli, administration of an anticoagulant that inhibits clot formation may prevent both thrombotic and embolic strokes (Kernan, Ovbiagele, Black, et al., 2014).

Medical Management

Patients who have experienced a TIA or stroke should have medical management for secondary prevention. Those with atrial fibrillation (or cardioembolic strokes) are treated with dose-adjusted warfarin with a target international normalized ratio (INR) of 2 to 3. Other anticoagulants that may be prescribed as alternative drugs include dabigatran, apixaban, edoxaban, or rivaroxaban, unless they are contraindicated. These drugs are also known as direct oral anticoagulants (DOACs). If anticoagulants are contraindicated, aspirin alone is the best option, although the addition of clopidogrel to aspirin is also a reasonable therapy (Kernan et al., 2014).

Platelet-inhibiting medications, including aspirin, extended-release dipyridamole plus aspirin, and clopidogrel decrease the incidence of cerebral infarction in patients who have experienced TIAs and stroke from suspected embolic or thrombotic causes. The specific medication that is used is based on the patient's health history. If the patient has had a minor ischemic stroke or what is considered a TIA with a high risk of having stroke, and they did not receive thrombolytic therapy, they may receive two platelet-inhibiting medications (dual antiplatelet therapy). Typically this is clopidogrel and aspirin, and can be taken for a period of 21 to 90 days after the stroke or TIA (Powers et al., 2019).

Research suggests that medications known as statins reduce coronary events and ischemic strokes. The most current stroke prevention guideline now includes the recommendation of a statin even if the low-density lipoprotein (LDL) cholesterol is below 100 mg/dL and there is no evidence of atherosclerotic cardiovascular disease (coronary artery disease/myocardial infarction, hypertensive heart disease and peripheral arterial disease) (Kernan et al., 2014). The FDA has included indications for statin medications, such as atorvastatin and simvastatin, to include secondary stroke prevention.

After the acute stroke period, antihypertensive medications are also used, if indicated, for secondary stroke prevention. Preferred drugs include angiotensin-converting enzyme (ACE) inhibitors and diuretics, or a combination of both (Kernan et al., 2014).

Medical management of acute ischemic stroke needs to include consideration for endovascular treatment (Powers et al., 2019). The FDA has approved several devices that open the blocked artery and restore blood flow to the brain. These devices are used by specialists in the endovascular suite.

Thrombolytic Therapy

Thrombolytic agents are used to treat ischemic stroke by dissolving the blood clot that is blocking blood flow to the brain. Recombinant t-PA is a genetically engineered form of t-PA (a thrombolytic substance made naturally by the body) (Comerford & Durkin, 2020). It works by binding to fibrin and converting plasminogen to plasmin, which stimulates fibrinolysis of the clot. Rapid diagnosis of stroke and initiation of thrombolytic therapy (within 3 hours) in patients with ischemic stroke leads to a decrease in the size of the stroke and an overall improvement in functional outcome after 3 months (National Institute of Neurological Disorders and Stroke [NINDS], 1995). The goal is for intravenous (IV) t-PA to be given within 45 minutes of the patient arriving to the ED (Powers et al., 2019).

Mechanical intervention (e.g., mechanical thrombectomy, endovascular thrombectomy, intra-arterial mechanical thrombectomy) can be used with t-PA or as an alternative to IV administration (Amatangelo & Thomas, 2019). Intra-arterial mechanical thrombectomy allows for higher concentrations of the drug to be given directly to the clot, and the time window for treatment may be extended up to 24 hours in patients that meet specific criteria (Powers et al., 2019). Those not eligible for IV delivery may be eligible for intra-arterial delivery, and these methods may also be combined. Treatment using intra-arterial delivery must occur in specialized centers with access to emergent cerebral angiogram and interventional operating rooms/suites (Powers et al., 2019). Ongoing clinical trials continue to investigate the efficacy of other thrombolytic agents.

To realize the full potential of early intervention, community education directed at recognizing the symptoms of stroke and obtaining appropriate emergency care is necessary to ensure rapid transport to a hospital and initiation of therapy within the recommended 3-hour period (which may be extended up to 4.5 hours) (Del Zoppo et al., 2009; Powers et al., 2019). Delays make the patient ineligible for therapies, because revascularization of necrotic tissue (which develops after 3 hours) increases the risk of cerebral edema and hemorrhage.

Endovascular Therapy

It is now recommended that patients with acute ischemic stroke receive endovascular therapy and medical management with a stent retriever if they meet specific criteria (Powers et al., 2019). All of the following criteria need to be met:

- Prestroke status of no deficits
- Acute ischemic stroke receiving IV t-PA within 4.5 hours of onset according to guidelines from professional medical societies
- Causative occlusion of the internal carotid artery or middle cerebral artery segment
- Age ≥18 years
- National Institutes of Health Stroke Scale (NIHSS) score of ≥6 (see later discussion)
- An Alberta Stroke Program Evaluation of Computed Tomography (ASPECT) score of ≥6 (a radiologic assessment of the CT scan), and treatment can be initiated (groin puncture) within 6 hours of symptom onset

Patients eligible for t-PA should receive IV t-PA even if endovascular treatments are being considered (Powers et al., 2019). Thrombolytic therapy should not be delayed.

Enhancing Prompt Diagnosis

After being notified by emergency medical service personnel, the ED contacts the appropriate staff (neurologist, neuroradiologist, radiology department, nursing staff, ECG, and laboratory technicians) and informs them of the patient's imminent arrival at the hospital. Many institutions have acute stroke teams that respond rapidly, ensuring that treatment occurs within the allotted period. This may be called a Code Stroke.

Initial management requires the definitive diagnosis of an ischemic stroke by brain imaging and a careful history to determine whether the patient meets the criteria for t-PA therapy (see Chart 62-2). The goal is that diagnostic results from imaging are completed within 25 minutes of the patient's arrival to the ED. Some of the contraindications for thrombolytic therapy include symptom onset greater than 3 hours before admission (expanded to 4.5 hours), a patient who is anticoagulated (with an INR above 1.7), or a patient who has recently had any type of

significant intracranial pathology (e.g., previous stroke, head injury, trauma) in the last 3 months.

Before receiving t-PA, the patient is assessed using the NIHSS, a standardized assessment tool that helps evaluate stroke severity (see Table 62-4). Total NIHSS scores range from 0 (normal) to 42 (severe stroke). Certification in the administration of the scale is recommended and is available for nurses and other health care professionals.

Chart 62-2

Eligibility Criteria for Tissue Plasminogen Activator Administration

- Age ≥18 years
- Clinical diagnosis of ischemic stroke
- Systolic blood pressure ≤185 mm Hg; diastolic ≤110 mm Hg
- No minor (nondisabling) stroke
- Prothrombin time ≤15 seconds or international normalized ratio ≤1.7 (if taking an anticoagulant, the same guidance is used)
- Not received low-molecular weight heparin during the past 24 hours
- Platelet count ≥100,000/mm^3
- No symptoms consistent with infective endocarditis
- No prior intracranial hemorrhage
- No subarachnoid hemorrhage
- No stroke, serious head trauma, or intracranial surgery within 3 months
- No gastrointestinal bleeding within 21 days, or gastrointestinal malignancy

Some of these are relative contraindications (the provider administering the medication needs to weigh the risks and benefits of the therapy). There are more stringent t-PA administration guidelines for patients with stroke symptoms that began 3 to 4.5 hours ago and also for those whose symptoms began longer than 4.5 hours ago or for whom time of onset is unclear, coupled with specific MRI findings. Specific guidance also exists for patients taking thrombin inhibitors or factor Xa inhibitors.

Adapted from Powers, W. J., Rabinstein, A. A., Ackerson, T., et al. (2019). Guidelines for the early management of patients with acute ischemic stroke: 2019 update to the 2018 guidelines for the early management of acute ischemic stroke: A guideline for healthcare professionals from the American Heart association/American Stroke Association. *Stroke*, *50*(12), e344–e418.

Dosage and Administration

The patient is weighed to determine the dose of t-PA. Typically, two or more IV sites are established prior to administration of t-PA (one for the t-PA and the other for administration of IV fluids). The dosage for t-PA is 0.9 mg/kg, with a maximum dose of 90 mg. Ten percent of the calculated dose is given as an IV bolus over 1 minute. The remaining

dose (90%) is given IV over 1 hour via an infusion pump (Comerford & Durkin, 2020; Hickey & Strayer, 2020; Powers et al., 2019).

The patient is admitted to the intensive care unit or an acute stroke unit, where continuous cardiac monitoring and frequent neurologic assessments are conducted (Amatangelo & Thomas, 2019). Vital signs are obtained frequently, with particular attention to blood pressure (with the goal of lowering the risk of intracranial hemorrhage) and temperature. An example of a standard protocol would be to obtain vital signs every 15 minutes for the first 2 hours, every 30 minutes for the next 6 hours, then every hour until 24 hours after treatment. Blood pressure should be maintained with the systolic pressure less than 185 mm Hg and the diastolic pressure less than 110 mm Hg (Powers et al., 2019). Fever needs to be treated. Airway management is instituted based on the patient's clinical condition and arterial blood gas values.

Side Effects

Once it is determined that the patient is a candidate for t-PA therapy, no anticoagulant or platelet inhibiting medications (e.g., aspirin, clopidogrel) are given for the next 24 hours. Bleeding is the most common side effect of t-PA administration, and the patient is closely monitored for any bleeding (IV insertion sites, urinary catheter site, endotracheal tube, nasogastric tube, urine, stool, emesis, other secretions). A 24-hour delay in placement of nasogastric tubes, urinary catheters, and intra-arterial pressure catheters is recommended. Intracranial bleeding is a major complication that occurred in approximately 6.4% of patients in the initial t-PA study (NINDS, 1995). A number of factors are associated with the occurrence of symptomatic intracranial bleeding: age greater than 70 years, baseline NIHSS score greater than 20, serum glucose concentration 300 mg/dL or higher, and edema or mass effect observed on the patient's initial CT scan (NINDS, 1995).

Therapy for Patients with Ischemic Stroke Not Receiving Tissue Plasminogen Activator

Not all patients are candidates for t-PA therapy. In some centers, other treatments may include anticoagulant administration (IV heparin or low–molecular-weight heparin). Because of the risks associated with urgent anticoagulation, their general use is not recommended for patients with acute ischemic stroke (Powers et al., 2019).

Careful maintenance of cerebral hemodynamics to maintain cerebral perfusion is extremely important after a stroke. Increased intracranial pressure (ICP) from brain edema and associated complications may occur after a large ischemic stroke. Interventions during this period include measures to reduce ICP, such as administering an osmotic diuretic (e.g., mannitol) to those that are declining clinically. Other treatment measures include the following (Powers et al., 2019):

TABLE 62-4 Summary of National Institutes of Health Stroke Scale (NIHSS)

Category	Description	Score
1a. LOC	Alert	0
	Arousable by minor stimulation	1
	Obtunded, strong stimulation to attend	2
	Unresponsive, or reflexive responses only	3
1b. LOC questions (month, age)	Answers both correctly	0
	Answers one correctly	1
	Both incorrect	2
1c. LOC commands (open, close eyes; make fist, let go)	Obeys both correctly	0
	Obeys one correctly	1
	Both incorrect	2
2. Best gaze (eyes open—patient follows examiner's finger or face)	Normal	0
	Partial gaze palsy	1
	Forced deviation	2
3. Visual (introduce visual stimulus/threat to patient's visual field quadrants)	No visual loss	0
	Partial hemianopsia	1
	Complete hemianopsia	2
	Bilateral hemianopsia	3
4. Facial palsy (show teeth, raise eyebrows, and squeeze eyes shut)	Normal	0
	Minor	1
	Partial	2
	Complete	3
5a. Motor; arm—left (elevate extremity to 90 degrees and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
	Amputation, joint fusion (explain)	N/A
5b. Motor; arm—right (elevate extremity to 90 degrees and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
	Amputation, joint fusion (explain)	N/A
6a. Motor; leg—left (elevate extremity to 30 degrees and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
	Amputation, joint fusion (explain)	N/A
6b. Motor; leg—right (elevate	No drift	0

extremity to 30 degrees and score drift/movement)	Drift but maintains in air Unable to maintain in air No effort against gravity No movement Amputation, joint fusion (explain)	1 2 3 4 N/A
7. Limb ataxia (finger-to-nose and heel-to-shin testing)	Absent Present in one limb Present in two limbs	0 1 2
8. Sensory (pinprick to face, arm, trunk, and leg—compare side to side)	Normal Mild to moderate loss Severe to total loss	0 1 2
9. Best language (name items, describe a picture, and read sentences)	No aphasia Mild to moderate aphasia Severe aphasia Mute	0 1 2 3
10. Dysarthria (evaluate speech clarity by having patient repeat words)	Normal Mild to moderate dysarthria Severe dysarthria, mostly unintelligible or worse Intubated or other physical barrier	0 1 2 N/A
11. Extinction and inattention (use information from prior testing to score)	No abnormality Visual, tactile, auditory, or other extinction to bilateral simultaneous stimulation Profound hemiattention or extinction to more than one modality	0 1 2
Total score		___

LOC, level of consciousness; N/A, not applicable.

Adapted from the version available at the National Institute of Neurological Disorders and Stroke (NINDS). (n.d.). *NIH stroke scale*. Bethesda, MD: National Institutes of Health. Retrieved on 3/8/2020 at: www.ninds.nih.gov/sites/default/files/NIH_Stroke_Scale_Booklet.pdf. It is recommended that the full scale with all instructions be used.

- Providing supplemental oxygen if oxygen saturation is below 95%
- Elevation of the head of the bed to 30 degrees to assist the patient in handling oral secretions and decrease ICP
- Possible hemicraniectomy for increased ICP from brain edema in a very large stroke
- Intubation with an endotracheal tube to establish a patent airway, if necessary

- Continuous hemodynamic monitoring (the goals for blood pressure in the first 24 hours after a stroke remain controversial for a patient who has not received thrombolytic therapy; antihypertensive treatment may be given to lower the blood pressure by 15% if the systolic blood pressure exceeds 220 mm Hg or the diastolic blood pressure exceeds 120 mm Hg)
- Frequent neurologic assessments to determine if the stroke is evolving and if other acute complications are developing (such complications may include seizures, bleeding from anticoagulation, or medication-induced bradycardia, which can result in hypotension and subsequent decreases in cardiac output and cerebral perfusion pressure)
- Monitoring for the development of fever (elevated temperature in the first 24 hours after stroke has been associated with increased in-hospital mortality)
- Monitoring of blood glucose and management with sliding scale insulin to keep levels in the range of 140 to 180 mg/dL

Managing Potential Complications

Adequate cerebral blood flow is essential for cerebral oxygenation. If cerebral blood flow is inadequate, the amount of oxygen supplied to the brain will decrease, and tissue ischemia will result. Adequate oxygenation begins with pulmonary care, maintenance of a patent airway, and administration of supplemental oxygen as needed. The importance of adequate gas exchange in these patients cannot be overemphasized, because many patients are at risk for aspiration pneumonia.

Other potential complications after a stroke include urinary tract infections, cardiac arrhythmias (ventricular ectopy, tachycardia, and heart blocks), and complications of immobility. Hyperglycemia has been associated with poor neurologic outcomes in acute stroke; therefore, blood glucose levels are monitored and hypoglycemia avoided as well (Powers et al., 2019).

Surgical Prevention of Ischemic Stroke

One surgical procedure for select patients with TIAs and mild stroke is CEA. A CEA is the removal of an atherosclerotic plaque or thrombus from the carotid artery to prevent stroke in patients with occlusive disease of the extracranial cerebral arteries (see Fig. 62-2). This surgery

is indicated for patients with symptoms of TIA or mild stroke (or those without symptoms) who are found to have severe (70% to 99%) carotid artery stenosis or moderate (50% to 69%) stenosis with other significant risk factors.

Carotid artery stenting (CAS), with or without angioplasty, is a less invasive procedure that is used for treatment of carotid stenosis. This procedure has less discomfort for the patient and a shorter recovery time than CEA. Age can be considered when deciding which procedure will be best for the patient. For patients older than 70 years, CEA demonstrated improved outcomes in research studies; for those who were younger, outcomes between CAS and CEA were similar when comparing procedure complications (Kernan et al., 2014).

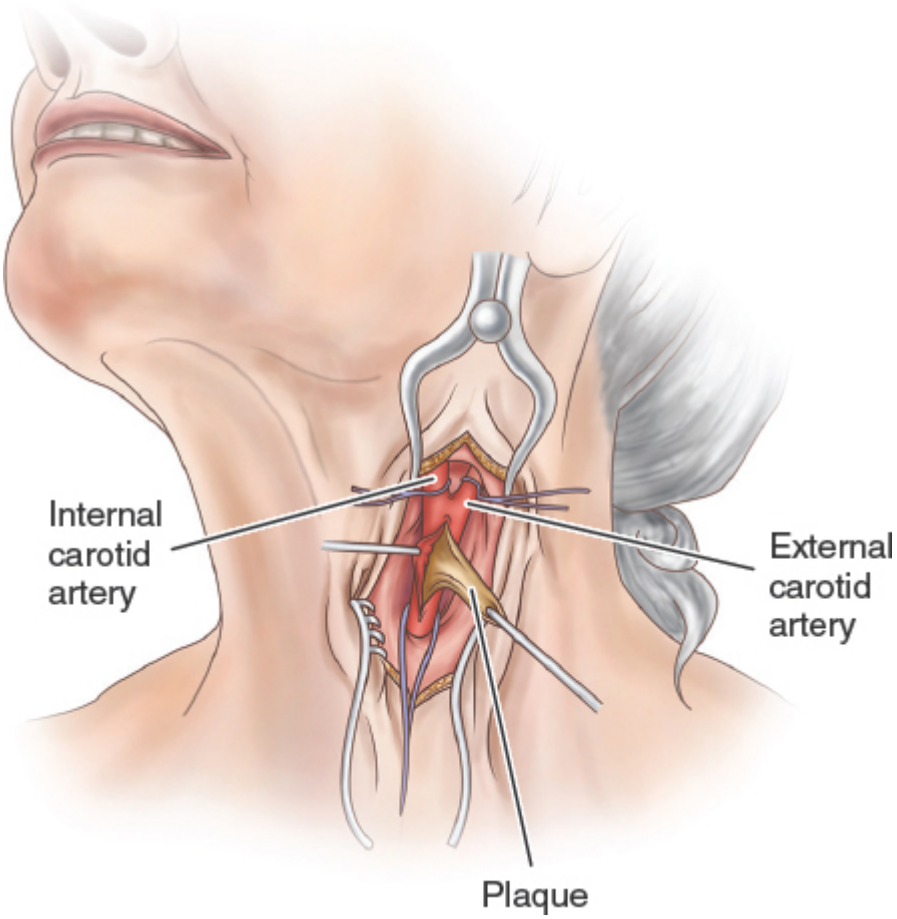

Figure 62-2 • Plaque, a potential source of emboli in transient ischemic attack and stroke, is surgically removed from the carotid artery.

Nursing Management

The main complications of CEA are stroke, cranial nerve injuries, infection or hematoma at the incision, and carotid artery disruption. It is important to maintain adequate blood pressure levels in the immediate postoperative period. Blood pressure instability is common, and lasts 12 to 24 hours after the procedure (Hickey & Strayer, 2020). Hypotension is avoided to prevent cerebral ischemia and thrombosis. Uncontrolled hypertension may precipitate cerebral hemorrhage, edema, hemorrhage at the surgical incision, or disruption of the arterial reconstruction. Medications are used to reduce the blood pressure to previous levels. Close cardiac monitoring is necessary, because these patients frequently have concomitant coronary artery disease.

After CEA, a neurologic observation record (see Chapter 61, Fig. 61-6) is used to monitor and document assessment parameters for all body systems, with particular attention to neurologic status. The primary provider is notified immediately if a neurologic deficit develops. Formation of a thrombus at the site of the endarterectomy is suspected if there is a sudden new onset of neurologic deficits, such as weakness on one side of the body. The patient should be prepared for repeat endarterectomy.

Difficulty in swallowing, hoarseness, or other signs of cranial nerve dysfunction must be assessed. Cranial nerve injury is the most common complication following CEA. The nurse focuses on assessment of the following cranial nerves: facial (VII), glossopharyngeal (IX), vagus (X), spinal accessory (XI), and hypoglossal (XII). Some edema in the neck after surgery is expected; however, extensive edema and hematoma formation can obstruct the airway. Emergency airway supplies, including those needed for a tracheostomy, must be available (Rich, Treat-Jacobson, DeVeaux, et al., 2017). Table 62-5 provides more information about potential complications of carotid surgery.

Management after carotid stenting also requires monitoring of neurologic status and evaluation for hematoma formation (at the catheterization site). Cardiac monitoring is necessary with assessment for bilateral pulses distal to the catheterization site. Typically, patients are discharged the day after stenting if there are no complications (Rich et al., 2017).

TABLE 62-5 Select Complications of Carotid Endarterectomy (CEA) and Nursing Interventions

Complication	Characteristics	Nursing Interventions
Incision hematoma	Large or rapidly expanding hematomas require emergency treatment. Risks include tracheal deviation and airway compromise. If the airway is obstructed by the hematoma, the incision may be opened at the bedside.	Monitor neck discomfort and wound expansion. Report swelling, subjective feelings of pressure in the neck, difficulty breathing.
Hypertension	Poorly controlled hypertension increases the risk of postoperative complications, including hematoma and hyperperfusion syndrome. There is an increased incidence of neurologic impairment and death due to intracerebral hemorrhage. May be related to surgically induced abnormalities (manipulation) of carotid baroreceptor sensitivity.	Keep in mind that risk is highest in the first 48 h after surgery. Check blood pressure frequently, and report deviations from baseline. Administer medications, as prescribed, to reduce hypertension. Observe for and report new onset of neurologic deficits.
Postoperative hypotension	Treated with fluids (if suspected to be related to hypovolemia) and low-dose phenylephrine infusion (if occurs in normovolemia). Usually resolves in 24–48 h. Patients with hypotension should have serial electrocardiograms to rule out myocardial infarction.	Monitor blood pressure and observe for signs and symptoms of hypotension.
Hyperperfusion syndrome	Occurs when cerebral vessel autoregulation fails. Arteries accustomed to diminished blood flow may be permanently dilated; increased blood flow after endarterectomy coupled with insufficient vasoconstriction leads to capillary bed damage, edema, and hemorrhage. Typically occurs within 2 wks of surgery.	Observe for severe unilateral headache improved by sitting upright or standing. Monitor for any changes in level of consciousness or confusion.
Intracerebral hemorrhage	Occurs infrequently but is often fatal or results in serious neurologic impairment. Can occur secondary to	Monitor neurologic status, and report any changes in mental status or

	hyperperfusion syndrome. Increased risk with advanced age, hypertension, presence of high-grade stenosis, poor collateral flow, and slow flow in the region of the middle cerebral artery.	neurologic functioning immediately.

NURSING PROCESS

The Patient Recovering from an Ischemic Stroke

The acute phase of an ischemic stroke may last 1 to 3 days, but ongoing monitoring of all body systems is essential as long as the patient requires care. The patient who has had a stroke is at risk for multiple complications, including deconditioning and other musculoskeletal problems, swallowing difficulties, bowel and bladder dysfunction, inability to perform self-care, and skin breakdown. Nursing management focuses on the prompt initiation of rehabilitation for any deficits.

Assessment

During the acute phase, a neurologic flow sheet is maintained to provide data about the following important measures of the patient's clinical status:

- Decrease in level of consciousness or responsiveness as evidenced by movement, resistance to changes of position, and response to stimulation; orientation to time, place, and person
- Change in vital signs with particular attention to blood pressure and temperature; maintenance of both within desired parameters
- Presence or absence of voluntary or involuntary movements of the extremities, muscle tone and strength, body posture, and position of the head
- Eye opening, comparative size of pupils and pupillary reactions to light, and ocular position
- Color of the face and extremities; temperature and moisture of the skin
- Quality and rates of pulse and respiration; arterial blood gas values as indicated, body temperature, and arterial pressure
- Ability to speak
- Volume of fluids ingested or given; volume of urine excreted each 24 hours
- Presence of bleeding
- Monitoring of continuous oxygen saturation
- Monitoring blood glucose

After the acute phase, the nurse assesses mental status (memory, attention span, perception, orientation, affect, speech/language), sensation/perception (the patient may have decreased awareness of pain and temperature), motor control (upper and lower extremity movement), swallowing ability, nutritional and hydration status, skin integrity, activity tolerance, and bowel and bladder function. Ongoing nursing assessment continues to focus on any impairment of function in the patient's daily activities, because the quality of life after stroke is closely related to the patient's functional status.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired mobility associated with hemiparesis, loss of balance and coordination, spasticity, and brain injury
- Acute pain (painful shoulder) associated with hemiplegia and disuse
- Impaired ability to perform hygiene, impaired self-toileting, impaired ability to dress, impaired self-feeding associated with stroke sequelae
- Discomfort associated with altered sensory reception, transmission, or integration
- Impaired swallowing
- Impaired urination associated with flaccid bladder, detrusor instability, confusion, or difficulty in communicating
- Constipation associated with change in mental status or difficulty communicating
- Acute confusion associated with brain infarction
- Impaired verbal communication associated with brain damage
- Risk for impaired skin integrity associated with to hemiparesis, hemiplegia, or decreased mobility
- Impaired family process associated with catastrophic illness and caregiving burdens
- Impaired sexual functioning associated with neurologic deficits or fear of failure

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Decreased cerebral blood flow due to increased ICP
- Inadequate oxygen delivery to the brain
- Pneumonia
- Seizure

Planning and Goals

Although rehabilitation begins on the day the patient has the stroke, the process is intensified during convalescence and requires a coordinated team effort. It is helpful for the team to know what the patient was like before the stroke: their illnesses, abilities, mental and emotional state, behavioral characteristics, and activities of daily living. It is also helpful for clinicians to be knowledgeable about the relative importance of predictors of stroke outcome (age, NIHSS score, and level of consciousness at the time of admission) in order to provide survivors of stroke and their families with realistic goals (Powers et al., 2019).

The major goals for the patient (and family) may include improved mobility, avoidance of shoulder pain, achievement of self-care, relief of discomfort, prevention of aspiration, continence of bowel and bladder, decreasing confusion, achieving a form of communication, maintaining skin integrity, restored family functioning, improved sexual function, and absence of complications.

Nursing Interventions

Nursing care has a significant impact on the patient's recovery. Often, many body systems are impaired as a result of the stroke, and conscientious care and timely interventions can prevent debilitating complications. During and after the acute phase, nursing interventions focus on the whole person. In addition to providing physical care, the nurse encourages and fosters recovery by listening to the patient and asking questions to elicit the meaning of the stroke experience.

Improving Mobility and Preventing Joint Deformities

A patient with hemiplegia has unilateral paralysis (paralysis on one side). When control of the voluntary muscles is lost, the strong flexor muscles exert control over the extensors. The arm tends to adduct (adductor muscles are stronger than abductors) and rotate internally. The elbow and the wrist tend to flex, the affected leg tends to rotate externally at the hip joint and flex at the knee, and the foot at the ankle joint supinates and tends toward plantar flexion.

Correct positioning is important to prevent contractures; measures are used to relieve pressure, assist in maintaining good body alignment, and prevent compressive neuropathies, especially of the ulnar and peroneal nerves. Because flexor muscles are stronger than extensor muscles, a splint applied at night to the affected extremity may prevent flexion and maintain correct positioning during sleep.

Preventing Shoulder Adduction. To prevent adduction of the affected shoulder while the patient is in bed, a pillow is placed in the axilla when there is limited external rotation; this keeps the arm away from the chest. A pillow is placed under the arm, and the arm is placed in a neutral (slightly flexed) position, with distal joints positioned higher than the more proximal joints (i.e., the elbow is positioned higher than the shoulder and the wrist higher than the elbow). This helps to prevent edema and the resultant joint fibrosis that will limit range of motion if the patient regains control of the arm (see Fig. 62-3).

Positioning the Hand and Fingers. The fingers are positioned so that they are barely flexed. The hand is placed in slight supination (palm faces upward), which is its most functional position. If the upper extremity is flaccid, a splint can be used to support the wrist and hand in a functional position. If the upper extremity is spastic, a hand roll is not used, because it stimulates the grasp reflex. In this instance, a dorsal wrist splint is useful in allowing the palm to be free of pressure. Every effort is made to prevent hand edema.

Figure 62-3 • Correct positioning to prevent shoulder adduction.

Spasticity, particularly in the hand, can be a disabling complication after stroke. Botulinum toxin type A injected intramuscularly into wrist and finger muscles has been shown to be effective in reducing this spasticity (although the effect is temporary, typically lasting 2 to 4 months). This treatment is also effective for treating lower limb spasticity (Sun, Chen, Fu, et al., 2019). Other treatments for spasticity may include stretching, splinting (in select patients), and oral medications such as baclofen and tizanidine (Teasell, Salbach, Foley, et al., 2020).

Changing Positions. The patient's position should be changed every 2 hours. To place a patient in a lateral (side-lying) position, a pillow is placed between the legs before the patient is turned. To promote venous return and prevent edema, the upper thigh should not be acutely flexed. The patient may be turned from side to side, but if sensation is impaired, the amount of time spent on the affected side should be limited.

If possible, the patient is placed in a prone position for 15 to 30 minutes several times a day. A small pillow or a support is placed under the pelvis, extending from the level of the umbilicus to the upper third of the thigh (see Fig. 62-4). This position helps promote hyperextension of the hip joints, which is essential for normal gait and helps prevent knee and hip flexion contractures. The prone position also helps drain bronchial secretions and prevents contractural deformities of the shoulders and knees. During positioning, it is important to reduce pressure and change position frequently to prevent pressure injuries.

Establishing an Exercise Program. The affected extremities are exercised passively and put through a full range of motion four or five times a day to maintain joint mobility, regain motor control, prevent contractures in the paralyzed extremity, prevent further deterioration of the neuromuscular system, and enhance circulation. Exercise is helpful in preventing venous stasis, which may predispose the patient to venous thromboembolism (VTE). VTE includes deep vein thrombosis (DVT) and pulmonary embolism (PE).

Repetition of an activity forms new pathways in the CNS and therefore encourages new patterns of motion. At first, the extremities are usually flaccid. If tightness occurs in any area, the range-of-motion exercises should be performed more frequently.

The patient is observed for signs and symptoms that may indicate PE or excessive cardiac workload during exercise; these include

shortness of breath, chest pain, cyanosis, and increasing pulse rate with exercise. Frequent short periods of exercise always are preferable to longer periods at infrequent intervals. Regularity in exercise is most important. Improvement in muscle strength and maintenance of range of motion can be achieved only through daily exercise.

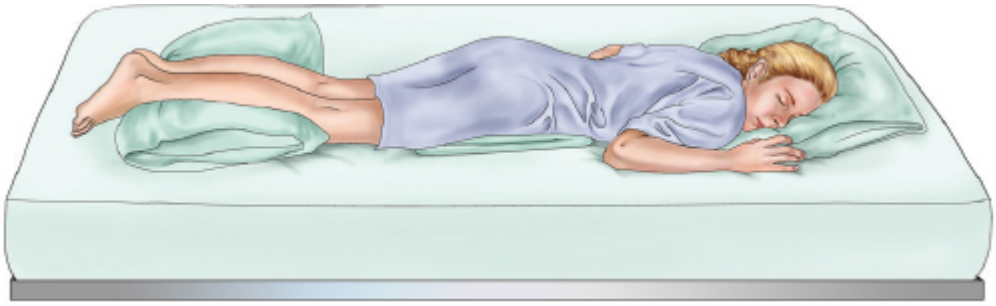

Figure 62-4 • Prone position with pillow support helps prevent hip flexion.

The patient is encouraged and reminded to exercise the unaffected side at intervals throughout the day. It is helpful to develop a written schedule to remind the patient of the exercise activities. The nurse supervises and supports the patient during these activities. The patient can be instructed to put the unaffected leg under the affected one to assist in moving it when turning and exercising. Flexibility, strengthening, coordination, endurance, and balancing exercises prepare the patient for ambulation. Quadriceps muscle setting and gluteal setting exercises (see Chapter 37, Chart 37-4) are started early to improve the muscle strength needed for walking; these are performed at least five times daily for 10 minutes at a time.

Preparing for Ambulation. As soon as possible, the patient is assisted out of bed and an active rehabilitation program is started. The patient is first educated to maintain balance while sitting and then to learn to balance while standing. If the patient has difficulty in achieving standing balance, a tilt table, which slowly brings the patient to an upright position, can be used. Tilt tables are especially helpful for patients who have been on bed rest for prolonged periods and have orthostatic blood pressure changes.

If the patient needs a wheelchair, the folding type with hand brakes is the most practical because it allows the patient to manipulate the chair. The chair should be low enough to allow the patient to propel it with the uninvolved foot and narrow enough to permit it to be used at

home. When the patient is transferred from the wheelchair, the brakes must be applied and locked on both sides of the chair.

The patient is usually ready to walk as soon as standing balance is achieved. Parallel bars are useful in these first efforts. A chair or wheelchair should be readily available in case the patient suddenly becomes fatigued or feels dizzy.

The training periods for ambulation should be short and frequent. As the patient gains strength and confidence, an adjustable cane can be used for support. In general, a three- or four-pronged cane provides a stable support in the early phases of rehabilitation.

Preventing Shoulder Pain

The incidence of shoulder pain after stroke can vary widely, but has been measured to be as high as 84% (Zhou, Li, Lu, et al., 2018). That pain may prevent patients from learning new skills and affect their quality of life. Shoulder function is essential in achieving balance and performing transfers and self-care activities. Problems that can occur include rotator cuff disorders, spasticity of the shoulder muscles, painful shoulder, subluxation of the shoulder, and shoulder–hand syndrome. Development of a condition known as central pain syndrome may also contribute to the development of shoulder pain after a stroke.

A flaccid shoulder joint may be overstretched by the use of excessive force in turning the patient or from overstrenuous arm and shoulder movement. To prevent shoulder pain, the nurse should never lift the patient by the flaccid shoulder or pull on the affected arm or shoulder. Overhead pulleys should also be avoided. If the arm is paralyzed, subluxation (incomplete dislocation) at the shoulder can occur as a result of overstretching of the joint capsule and musculature by the force of gravity when the patient sits or stands in the early stages after a stroke. This results in severe pain. Shoulder–hand syndrome (painful shoulder and generalized swelling of the hand) can cause a frozen shoulder and ultimately atrophy of subcutaneous tissues. When a shoulder becomes stiff, it is usually painful.

Many shoulder problems can be prevented by proper patient movement and positioning. The flaccid arm is positioned on a table or with pillows while the patient is seated. A sling maybe worn on the flaccid arm when the patient first becomes ambulatory, to prevent the paralyzed upper extremity from dangling without support. Range-of-

motion exercises are important in preventing painful shoulder. Overstrenuous arm movements are avoided. The patient is instructed to interlace the fingers, place the palms together, and push the clasped hands slowly forward to bring the scapulae forward; the patient then raises both hands above the head. This is repeated throughout the day. The patient is instructed to flex the affected wrist at intervals and move all the joints of the affected fingers. The patient is encouraged to touch, stroke, rub, and look at both hands. Pushing the heel of the hand firmly down on a surface is useful. Elevation of the arm and hand is also important in preventing dependent edema of the hand. Patients with continuing pain after attempted movement and positioning may require the addition of analgesia to their treatment program. Other treatments may include injections to the shoulder joint with corticosteroid medications or botulinum toxin type A, shoulder taping/strapping, acupuncture, electrical stimulation, heat or ice, and soft tissue massage (Teasell et al., 2020; Treister, Hatch, Cramer, et al., 2017).

Medications are often helpful in the management of poststroke pain. The medications that are used include amitriptyline, gabapentin, lamotrigine, and pregabalin (Teasell et al., 2020; Treister et al., 2017).

Enhancing Self-Care

As soon as the patient can sit up, they are encouraged to participate in personal hygiene activities. The patient is helped to set realistic goals; if feasible, a new task is added daily. The first step is to carry out all self-care activities on the unaffected side. Such activities as combing the hair, brushing the teeth, shaving with an electric razor, bathing, and eating can be carried out with one hand and should be encouraged. Although the patient may feel awkward at first, these motor skills can be learned by repetition, and the unaffected side will become stronger with use. The nurse must be sure that the patient does not neglect the affected side. Assistive devices will help make up for some of the patient's deficits (see Chart 62-3). A small towel is easier to control while drying after bathing, and boxed paper tissues are easier to use than a roll of toilet tissue.

Return of functional ability is important to the patient recovering after a stroke. An early baseline assessment of functional ability with an instrument such as the Functional Independence Measure (FIM™) is important in team planning and goal setting for the patient. The FIM™ is a widely used instrument in stroke rehabilitation and

provides valuable information about motor, social, and cognitive function. The patient's morale may improve if ambulatory activities are carried out in street clothes. The family is instructed to bring in clothing that is preferably a size larger than that usually worn. Clothing fitted with front or side fasteners or Velcro closures is the most suitable. The patient has better balance if most of the dressing activities are carried out while seated.

Chart 62-3

Assistive Devices to Enhance Self-Care After Stroke

Bathing and Grooming Devices

- Electric razors with head at 90 degrees to handle
- Grab bars, nonskid mats, handheld shower heads
- Long-handled bath sponge
- Shower and tub seats, stationary or on wheels

Dressing Aids

- Elastic shoelaces
- Long-handled shoehorn
- Velcro closures

Eating Devices

- Nonskid mats to stabilize plates
- Plate guards to prevent food from being pushed off plate
- Wide-grip utensils to accommodate a weak grasp

Mobility Aids

- Canes, walkers, wheelchairs
- Transfer devices such as transfer boards and belts

Toileting Aids

- Grab bars next to toilet
- Raised toilet seat

Perceptual problems may make it difficult for the patient to dress without assistance because of an inability to match the clothing to the body parts. To assist the patient, the nurse can take steps to keep the

environment organized and uncluttered, because the patient with a perceptual problem is easily distracted. The clothing is placed on the affected side in the order in which the garments are to be put on. The use of a large mirror while dressing promotes the patient's awareness of what they are putting on the affected side. The patient has to make many compensatory movements when dressing; these can produce fatigue and painful twisting of the intercostal muscles. Support and encouragement are provided to prevent the patient from becoming overly fatigued and discouraged. Even with intensive training, not all patients can achieve independence in dressing.

Adjusting to Physical Changes

Patients with a decreased field of vision should be approached on the side where visual perception is intact. All visual stimuli (e.g., clock, calendar, television) should be placed on this side. The patient can be educated to turn the head in the direction of the defective visual field to compensate for this loss. The nurse should make eye contact with the patient and draw their attention to the affected side by encouraging the patient to move the head. The nurse may also want to stand at a position that encourages the patient to move or turn to visualize who is in the room. Increasing the natural or artificial lighting in the room and providing eyeglasses are important aids to increasing vision.

The patient with homonymous hemianopsia turns away from the affected side of the body and tends to neglect that side and the space on that side; this is known as amorphosynthesis. In such instances, the patient cannot see food on half of the tray, and only half of the room is visible. It is important for the nurse to constantly remind the patient of the other side of the body; to maintain alignment of the extremities; and, if possible, to place the extremities where the patient can see them.

Assisting With Nutrition

Stroke can result in **dysphagia** (difficulty swallowing) due to impaired function of the mouth, tongue, palate, larynx, pharynx, or upper esophagus. Patients must be observed for paroxysms of coughing, food dribbling out of or pooling in one side of the mouth, food retained for long periods in the mouth, or nasal regurgitation when swallowing liquids. Swallowing difficulties place the patient at risk for aspiration, pneumonia, dehydration, and malnutrition.

A swallow assessment should be performed as soon as possible after the patient's arrival to the ED (preferably within 4 to 24 hours). This is done before allowing any oral intake. A speech therapist will evaluate the patient's swallowing ability, but an assessment may also be done by the nurse using a validated and reliable assessment tool (Stroke Foundation, 2019).

If swallowing function is partially impaired, it may return over time, or the patient may be educated in alternative swallowing techniques, advised to take smaller boluses of food, and educated about types of foods that are easier to swallow. The patient may be started on a thick liquid or pureed diet, because these foods are easier to swallow than thin liquids. Having the patient sit upright, preferably out of bed in a chair, and instructing them to tuck the chin toward the chest as they swallow will help prevent aspiration. The diet may be advanced as the patient becomes more proficient at swallowing. If the patient cannot resume oral intake, a gastrointestinal feeding tube is placed for ongoing tube feedings and medication administration.

Enteral tubes can be either nasogastric (placed in the stomach) or nasoenteral (placed in the duodenum) to reduce the risk of aspiration. Nursing responsibilities in feeding include elevating the head of the bed at least 30 degrees to prevent aspiration, checking the position of the tube before feeding, ensuring that the cuff of the tracheostomy tube (if in place) is inflated, and giving the tube feeding slowly. The feeding tube is aspirated periodically to ensure that the feedings are passing through the gastrointestinal tract. Retained or residual feedings increase the risk of aspiration. Patients with retained feedings may benefit from the placement of a gastrostomy tube or a percutaneous endoscopic gastrostomy (PEG) tube. In a patient with a feeding tube, the tube should be placed in the duodenum to reduce the risk of aspiration. For long-term feedings, a gastrostomy tube is preferred (see Chapter 39).

Attaining Bladder and Bowel Control

After a stroke, the patient may have transient urinary incontinence due to confusion, inability to communicate needs, and inability to use the urinal or bedpan because of impaired motor and postural control. Occasionally after a stroke, the bladder becomes atonic, with impaired sensation in response to bladder filling. Sometimes, control of the external urinary sphincter is lost or diminished. During this period, intermittent catheterization with sterile technique is carried

out. After muscle tone increases and deep tendon reflexes return, bladder tone increases and spasticity of the bladder may develop. Because the patient's sense of awareness is clouded, persistent urinary incontinence or urinary retention may be symptomatic of bilateral brain damage. The voiding pattern is analyzed, and the urinal or bedpan is offered on this pattern or schedule. The upright posture and standing position are helpful for male patients during this aspect of rehabilitation.

Patients may have problems with bowel control, particularly constipation. Unless contraindicated, a high-fiber diet and adequate fluid intake (2 to 3 L/day) should be provided, and a regular time (usually after breakfast) should be established for toileting.

Improving Thought Processes

After a stroke, the patient may have problems with cognitive, behavioral, and emotional deficits related to brain damage. However, in many instances, a considerable degree of function can be recovered, because not all areas of the brain are equally damaged; some remain more intact and functional than others.

After assessment that delineates the patient's deficits, the neuropsychologist, in collaboration with the primary provider, psychiatrist, nurse, and other professionals, structures a training program using cognitive-perceptual retraining, visual imagery, reality orientation, and cueing procedures to compensate for losses. Specific techniques used maybe conventional, computer-assisted, or virtual reality based.

The role of the nurse is supportive. The nurse reviews the results of neuropsychological testing; observes the patient's performance and progress; gives positive feedback; and, most importantly, conveys an attitude of confidence and hope. Interventions capitalize on the patient's strengths and remaining abilities while attempting to improve performance of affected functions. Other interventions are similar to those for improving cognitive functioning after a head injury (see Chapter 63).

Improving Communication

Aphasia, which impairs the ability to express oneself and to understand what is being said, may become apparent in various ways. The cortical area that is responsible for integrating the myriad pathways required for the comprehension and formulation of language is called *Broca area.* It is located in a convolution adjoining

the middle cerebral artery. This area is responsible for control of the combinations of muscular movements needed to speak each word. Broca area is so close to the left motor area that a disturbance in the motor area often affects the speech area. This is why so many patients who are paralyzed on the right side (due to damage or injury to the left side of the brain) cannot speak, whereas those paralyzed on the left side are less likely to have speech disturbances.

The speech therapist assesses the communication needs of the patient who has had a stroke, describes the precise deficit, and suggests the best overall method of communication. Most language intervention strategies can be tailored for the individual patient. The patient is expected to take an active part in establishing goals.

A person with aphasia may become depressed. The inability to talk on the telephone, text, answer a question, or participate in conversation often causes anger, frustration, fear of the future, and hopelessness. Nursing interventions include strategies to make the atmosphere conducive to communication. This includes being sensitive to the patient's reactions and needs and responding to them in an appropriate manner while always treating the patient as an adult. The nurse provides strong emotional support and understanding to allay anxiety and frustration.

A common pitfall is for the nurse or other health care team member to complete the thoughts or sentences of the patient. This should be avoided, because it causes the patient to become more frustrated at not being allowed to speak and may deter efforts to practice putting thoughts together and completing sentences. A consistent schedule, routines, and repetition help the patient to function despite significant deficits. A written copy of the daily schedule, a folder of personal information (birth date, address, names of relatives), checklists, and recorded lists help improve the patient's memory and concentration. The patient may also benefit from a communication board (electronic or written), which has pictures of common needs and phrases. The board may be translated into any language.

When talking with the patient, it is important for the nurse to gain the patient's attention, speak slowly, and keep the language of instruction consistent. One instruction is given at a time, and time is allowed for the patient to process what has been said. The use of gestures may enhance comprehension. Speaking is thinking out loud, and the emphasis is on thinking. Listening and sorting out incoming

messages require mental effort; the patient must struggle against mental inertia and needs time to organize a response.

In working with the patient with aphasia, the nurse must remember to talk to the patient during care activities. This provides social contact for the patient. Chart 62-4 describes points to keep in mind when communicating with the patient with aphasia.

Maintaining Skin Integrity

The patient who has had a stroke may be at risk for skin and tissue breakdown because of altered sensation and inability to respond to pressure and discomfort by turning and moving. Preventing skin and tissue breakdown requires frequent assessment of the skin, with emphasis on bony areas and dependent parts of the body. During the acute phase, a specialty bed (e.g., low air-loss bed) may be used until the patient can move independently or assist in moving.

Chart 62-4

Communicating with the Patient with Aphasia

- Face the patient and establish eye contact.
- Speak in a clear, unhurried manner, and normal tone of voice.
- Use short phrases, and pause between phrases to allow the patient time to understand what is being said.
- Limit conversation to practical and concrete matters.
- Use gestures, pictures, objects, and writing.
- As the patient uses and handles an object, say what the object is. It helps to match the words with the object or action.
- Be consistent in using the same words and gestures each time you give instructions or ask a question.
- Keep extraneous noises and sounds to a minimum. Too much background noise can distract the patient or make it difficult to sort out the message being spoken.

A regular turning schedule (e.g., every 2 hours) is adhered to, even if pressure-relieving devices are used to prevent tissue and skin breakdown. When the patient is positioned or turned, care must be used to minimize shear and friction forces, which cause damage to tissues and predispose the skin to breakdown.

The patient's skin must be kept clean and dry; gentle massage of healthy (nonreddened) skin and adequate nutrition are other factors that help to maintain skin and tissue integrity.

Improving Family Coping

Family members play an important role in the patient's recovery. Family members are encouraged to participate in counseling and to use support systems that will help with the emotional and physical stress of caring for the patient. Involving others in the patient's care and providing education about stress management techniques and methods for maintaining personal health also facilitate family coping.

The family may have difficulty accepting the patient's disability and may be unrealistic in their expectations. They are given information about the expected outcomes and are counseled to avoid doing activities that the patient is able to do. They are assured that their love and interest are part of the patient's therapy.

The family needs to be informed that the rehabilitation of the patient with hemiplegia requires many months and that progress may be slow. The gains made by the patient in the hospital or rehabilitation unit must be maintained. All caregivers should approach the patient with a supportive and optimistic attitude, focusing on the patient's remaining abilities. The rehabilitation team, the medical and nursing team, the patient, and the family must all be involved in developing attainable goals for the patient at home.

Most relatives of patients with stroke handle the physical changes better than the emotional aspects of care. The family should be prepared to expect occasional episodes of emotional lability. The patient may laugh or cry easily or without cause (pseudobulbar affect) and may be irritable and demanding or depressed and confused. The nurse can explain to the family that the patient's laughter does not necessarily connote happiness, nor does crying reflect sadness, and that emotional lability usually improves with time.

Family-centered care involves seeing patients and family caregivers as a one unit. Nurses can assess caregivers' strengths and ability to provide care. This assessment should be a continual process because needs change throughout the hospitalization period and rehabilitation stay. Providing information about community resources, respite care and adult day care, and mental health issues (for the patient who has had a stroke and for caregivers) will help with the transition to home.

Helping the Patient Cope with Sexual Dysfunction

Sexual functioning can be profoundly altered by stroke. Although research in this area of stroke management is limited, it appears that patients who have had a stroke consider sexual function important, and many have sexual dysfunction. Sexual dysfunction after stroke is multifactorial. There may be medical reasons for the dysfunction (neurologic and cognitive deficits, previous diseases, medications) as well as various psychosocial factors, including depression. A stroke is such a catastrophic illness that the patient experiences loss of self-esteem and value as a sexual being. These psychosocial factors play an important role in determining sexual drive, activity, and satisfaction after a stroke.

Nurses in the rehabilitation setting play a crucial role in beginning a dialogue between the patient and their partner about sexuality after a stroke. In-depth assessments to determine sexual history before and after the stroke should be followed by appropriate interventions. Interventions for the patient and partner focus on providing relevant information, education, reassurance, adjustment of medications, counseling regarding coping skills, suggestions for alternative sexual positions, and a means of sexual expression and satisfaction.

Monitoring and Managing Potential Complications

Decreased cerebral blood flow due to increased ICP, leading to inadequate oxygen delivery to the brain, seizures, and pneumonia are potential complications in any patient who has had an ischemic stroke. The more severe the stroke (i.e., the higher the NIHSS), the greater the risk of complications.

During the acute phase of care, a neurologic flow sheet (see Chapter 61, Fig. 61-6) is used to monitor and document assessment parameters. Changes in blood pressure, pulse, and respiration are important clinically because they suggest increased ICP and are reported immediately. If signs and symptoms of pneumonia develop, cultures are obtained to identify the organism so that appropriate antibiotic agents can be given.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Patient and family education is a fundamental component of stroke recovery. The nurse provides education about stroke, its causes and prevention, and the

rehabilitation process. In both acute care and rehabilitation facilities, the focus is on educating the patient to resume as much self-care as possible. This may entail using assistive devices or modifying the home environment to help the patient live with a disability.

An occupational therapist may be helpful in assessing the home environment and recommending modifications to help the patient become more independent. For example, a shower is more convenient than a tub for the patient with hemiplegia because most patients do not gain sufficient strength to get up and down from a tub. Sitting on a stool of medium height with rubber suction tips allows the patient to wash with greater ease. A long-handled bath brush with a soap container is helpful to the patient who has only one functional hand. If a shower is not available, a stool may be placed in the tub and a portable shower hose attached to the faucet. Hand rails may be attached alongside the bathtub and the toilet. Other assistive devices include special utensils for eating, grooming, dressing, and writing (see Chart 62-3).

A program of physical therapy can be beneficial, whether it takes place in the home or in an outpatient program. Constraint-induced movement therapy has been used in stroke rehabilitation and involves constraint of the less affected upper limb, and intensely training the more affected limb. Robotic-assisted therapy uses sensorimotor training of the upper limb. This method allows patients to train without the presence of a therapist. Other techniques may include using virtual reality and video game applications, functional/neuromuscular/transcutaneous electrical nerve stimulation, transcranial magnetic stimulation, and ambulation with body weight support and treadmill training to assist with recovery (Veteran's Administration/Department of Defense, The Management of Stroke Rehabilitation Work Group, 2019).

Continuing and Transitional Care

A variety of transitional care models are being used in patients with stroke. Some evidence supports positive outcomes using transitional care but more research and standardization of interventions is needed for confirmation. One model currently being investigated is a person-centered model. This model includes a telephone call at 2, 30, and 60 days after discharge. Calls are conducted either by a nurse or an advanced practice provider. Patients are also seen in the outpatient clinic within 2 weeks after discharge (Bushnell, Duncan, Lycan, et al.,

2018). Depending on the specific neurologic deficits resulting from the stroke, the patient at home may require the services of a number of health care professionals. The nurse often coordinates the care of the patient at home and considers the many educational needs of caregivers and patients. The family (often the spouse) requires education as well as assistance in planning and providing care.

The family is advised that the patient may tire easily, may become irritable and upset by small events, and may be less interested in events than expected. Emotional problems associated with stroke are often related to speech dysfunction and the frustrations of being unable to communicate. A speech therapist allows the family to be involved and gives the family practical instructions to help the patient between therapy sessions.

Depression is a common and serious problem (increases mortality) in the patient who has had a stroke. Approximately one third of patients who have had a stroke will suffer from depression (Virani et al., 2020). Risk factors include gender (more prevalent in women), a history of depression, cognitive or physical impairment, anxiety, aphasia and stroke severity (Villa, Ferrari, & Moretti, 2018). Because the length of hospital stays has shortened, depression may not be identified in the acute setting. Nurses in all care settings should identify patients who may be at risk for depression or who show depressive symptoms. In the home or in the rehabilitation setting, nurses may be involved in coordinating care and referring patients and family to appropriate resources. The family can help by continuing to support the patient and by giving positive reinforcement for the progress that is being made. Antidepressant therapy may be prescribed, and may help with recovery from stroke (Elzib, Pawloski, Ding, et al., 2019).

Community-based stroke support groups may allow the patient and family to learn from others with similar problems and to share their experiences. Support groups take the form of in-person meetings as well as Internet-based support programs. The patient is encouraged to continue hobbies and recreational and leisure interests and to maintain contact with friends to prevent social isolation. All nurses coming in contact with the patient should encourage the patient to keep active, adhere to the exercise program, and remain as self-sufficient as possible.

Chart 62-5  NURSING RESEARCH PROFILE

Early Identification of Depression in Caregivers of Stroke Survivors

Byun, E., Evans, L., Sommers, M., et al. (2019). Depressive symptoms in caregivers immediately after stroke. *Topics in Stroke Rehabilitation*, *26*(3), 187–194.

Purpose

In the early weeks post stroke, caregivers face many challenges and increased stress related to caring for a stroke survivor. Recognizing those caregivers most at risk for developing depression early after hospital discharge may lead to decreased symptoms and improved health and quality of life for caregivers. The long-term health of caregivers of stroke survivors is significant; poor health can impact their ability to serve in the capacity of caregiver. The purpose of this study was to identify characteristics of caregivers and stroke survivors associated with caregiver depressive symptoms in the early weeks following a family member's stroke.

Design

This study used a prospective, longitudinal exploratory design. The participants were a convenience sample of 63 caregivers of older adult stroke survivors who had been diagnosed with a new or recurrent ischemic or hemorrhagic stroke within the past 2 weeks. They were recruited from urban acute care settings. Caregivers were enrolled in the study by 2 weeks post stroke (T1) and then revisited 4 weeks later (T2). Symptoms of depression were measured using the Patient Health Questionnaire (PHQ-9). The PHQ-9 is a 9-item scale used as a screening tool for major and minor depression. Uncertainty, stress, coping capacity, social support, chronic illness, and sociodemographic information were measured. Perceived stress was measured with the Perceived Stress Scale. Physiologic stress was measured by salivary cortisol levels measured upon waking and in the evening. The stroke survivor's functional status was measured using the Barthel Index, a 10-item scale measuring functional status. Sociodemographic information and clinical characteristics (severity of stroke, description of stroke, presence of communication disability, and days post stroke) of the stroke survivors were also collected.

Findings

This study began with 63 caregivers enrolled. By the second time point evaluation (T2), 13 stroke survivors had died, 3 caregivers

withdrew from the study, and 7 more were lost to follow-up. A total of 40 caregivers completed the second time point evaluation (T2). Ages of caregivers ranged from 30 to 89 years (mean 56.92 years). Ages of stroke survivors ranged from 65 to 95 years (mean 75.92 years). More than half (57%) of caregivers had at least mild depressive symptoms in the early weeks of caregiving. Six weeks after the stroke, 40% continued to have depressive symptoms. About 30% had at least moderate depressive symptoms at both time points (T1 and T2). Greater depressive symptoms were correlated with elevated salivary cortisol levels in the evening but not with levels upon waking. Characteristics associated with more depressive symptoms across the first 6 weeks post stroke included caregiver uncertainty, perceived stress, coping, social support, race, income, time spent in caregiving, and stroke survivor race and functional status.

Nursing Implications

This study found that depressive symptoms in this sample of caregivers were common in the early weeks of caregiving. It is important for nurses to understand the caregiving experience and the risk in both patients and caregivers for developing depression. Clearly identifying characteristics that are associated with caregivers developing depression can help with earlier recognition of those at risk. If these caregivers receive appropriate interventions and additional support soon after hospital discharge, they may experience decreased depressive symptoms and improved quality of life. Nurses should be involved in the discharge process to home and can help caregivers adjust and be prepared for their new role and challenges.

The nurse should recognize the potential effects of caregiving on the family. Not all families have the adaptive coping skills and adequate psychological functioning necessary for the long-term care of another person. The patient's spouse may be older, with their own health concerns; in some instances, the patient may have been the provider of care to the spouse. A spouse may have to take on new roles and responsibilities in the relationship and around the home. Spouses may also feel a sense of loss (of freedom and leisure time as well as of the marital relationship) and may experience social isolation and financial burdens. Depression is common in caregivers of patients who have survived a stroke, with rates globally documented as approximately 40% (Loh, Tan, Zhang, et al., 2017).

Nurses should assess caregivers for signs and symptoms of depression (Byun, Evans, Sommers, et al., 2019). See the Nursing Research Profile in Chart 62-5.

Caregivers may require reminders to attend to their own health concerns and well-being. Even healthy caregivers may find it difficult to maintain a schedule that includes being available around the clock. The nurse encourages the family to arrange for respite care services (planned short-term care to relieve the family from having to provide continuous 24-hour care), which may be available from an adult day care center. Some hospitals also offer weekend respite care that can provide caregivers with needed time for themselves. The nurse involved in home and continuing care also needs to remind the patient and family of the need for respite care as well as continuing health promotion and screening practices.

Evaluation

Expected patient outcomes may include:

1. Achieves improved mobility
    a. Avoids deformities (contractures and footdrop)
    b. Participates in prescribed exercise program
    c. Achieves sitting balance
    d. Uses unaffected side to compensate for loss of function of hemiplegic side
2. Reports absence of shoulder pain
    a. Demonstrates shoulder mobility; exercises shoulder
    b. Elevates arm and hand at intervals
3. Achieves self-care; performs hygiene care; uses adaptive equipment
4. Demonstrates techniques to compensate for the discomfort of sensory deficits, such as turning the head to see people or objects
5. Demonstrates safe swallowing
6. Achieves usual pattern of bowel and bladder elimination
7. Participates in cognitive improvement program
8. Demonstrates improved communication
9. Maintains intact skin without breakdown

a. Demonstrates skin turgor within normal limits
b. Participates in turning and positioning activities

10. Family members demonstrate a positive attitude and coping mechanisms
    a. Encourage patient in exercise program
    b. Take an active part in rehabilitation process
    c. Contact respite care programs or arrange for other family members to assume some responsibilities for care
11. Develops alternative approaches to sexual expression
12. Absence of complications
    a. Has ICP values that remain within normal limits
    b. Has no signs and symptoms of pneumonia

Hemorrhagic Stroke

Hemorrhagic strokes are primarily caused by intracerebral (10%) and subarachnoid hemorrhage (3%) and are caused by bleeding into the brain tissue, the ventricles, or the subarachnoid space (Norris, 2019). Primary intracerebral hemorrhage from a spontaneous rupture of small vessels accounts for approximately 80% of hemorrhagic strokes and is caused chiefly by uncontrolled hypertension. Subarachnoid hemorrhage results from a ruptured intracranial aneurysm (discussed later in this chapter) (Hickey & Strayer, 2020; Virani et al., 2020).

A common cause of primary intracerebral hemorrhage in the older adult is cerebral amyloid angiopathy, which involves damage caused by the deposit of beta-amyloid protein in the small- and medium-sized blood vessels of the brain. Cerebral amyloid angiopathy makes these blood vessels fragile and prone to bleeding. Secondary intracerebral hemorrhage is associated with arteriovenous malformations (AVMs), trauma, intracranial neoplasms, or certain medications (e.g., anticoagulants, cocaine, or amphetamines). The mortality rate has been reported to be as high as 50% after an intracranial hemorrhage (Hickey & Strayer, 2020; Norris, 2019). Patients who survive the acute phase of

care usually have more severe deficits and a longer recovery phase compared to those with ischemic stroke.

Pathophysiology

The pathophysiology of hemorrhagic stroke depends on the cause and underlying type of cerebrovascular disorder. Symptoms are produced when a primary hemorrhage, aneurysm, or AVM presses on nearby cranial nerves or brain tissue or, more dramatically, when an aneurysm or AVM ruptures, causing subarachnoid hemorrhage (hemorrhage into the cranial subarachnoid space). Normal brain metabolism is disrupted by the brain's exposure to blood; by an increase in ICP resulting from the sudden entry of blood into the subarachnoid space, which compresses and injures brain tissue; or by secondary ischemia of the brain resulting from the reduced perfusion pressure and vasospasm that frequently accompany subarachnoid hemorrhage.

Intracerebral Hemorrhage

An intracerebral hemorrhage, or bleeding into the brain tissue, is most common in patients with hypertension and cerebral atherosclerosis, because degenerative changes from these diseases cause rupture of the blood vessel. An intracerebral hemorrhage may also result from certain types of arterial pathology, trauma, brain tumors, and the use of medications (e.g., anticoagulants, amphetamines, and cocaine).

Bleeding related to hypertension occurs most commonly in the deeper structures of the brain (basal ganglia and thalamus); it occurs less frequently in the brainstem (mostly the pons) and cerebellum (Hickey & Strayer, 2020). Bleeding in the outer cerebral lobes (lobar hemorrhages) in those 75 or older can be related to cerebral amyloid angiopathy and is frequently in the frontal and parietal lobes. Occasionally, the bleeding ruptures the wall of the lateral ventricle and causes intraventricular hemorrhage, which is associated with poor outcomes and death (Hickey & Strayer, 2020)).

Intracranial (Cerebral) Aneurysm

An intracranial (cerebral) **aneurysm** is a dilation of the walls of a cerebral artery that develops as a result of weakness in the arterial wall. The cause of aneurysms is unknown, although research is ongoing. An

aneurysm may be due to atherosclerosis, which results in a defect in the vessel wall with subsequent weakness of the wall; a congenital defect of the vessel wall; hypertensive vascular disease; head trauma; or advancing age.

Any artery within the brain can be the site of a cerebral aneurysm, but these lesions usually occur at the bifurcations of the large arteries at the circle of Willis (see Fig. 62-5). The cerebral arteries most commonly affected by an aneurysm are the internal carotid artery, anterior cerebral artery, anterior communicating artery, posterior communicating artery, posterior cerebral artery, and middle cerebral artery. Multiple cerebral aneurysms are not uncommon.

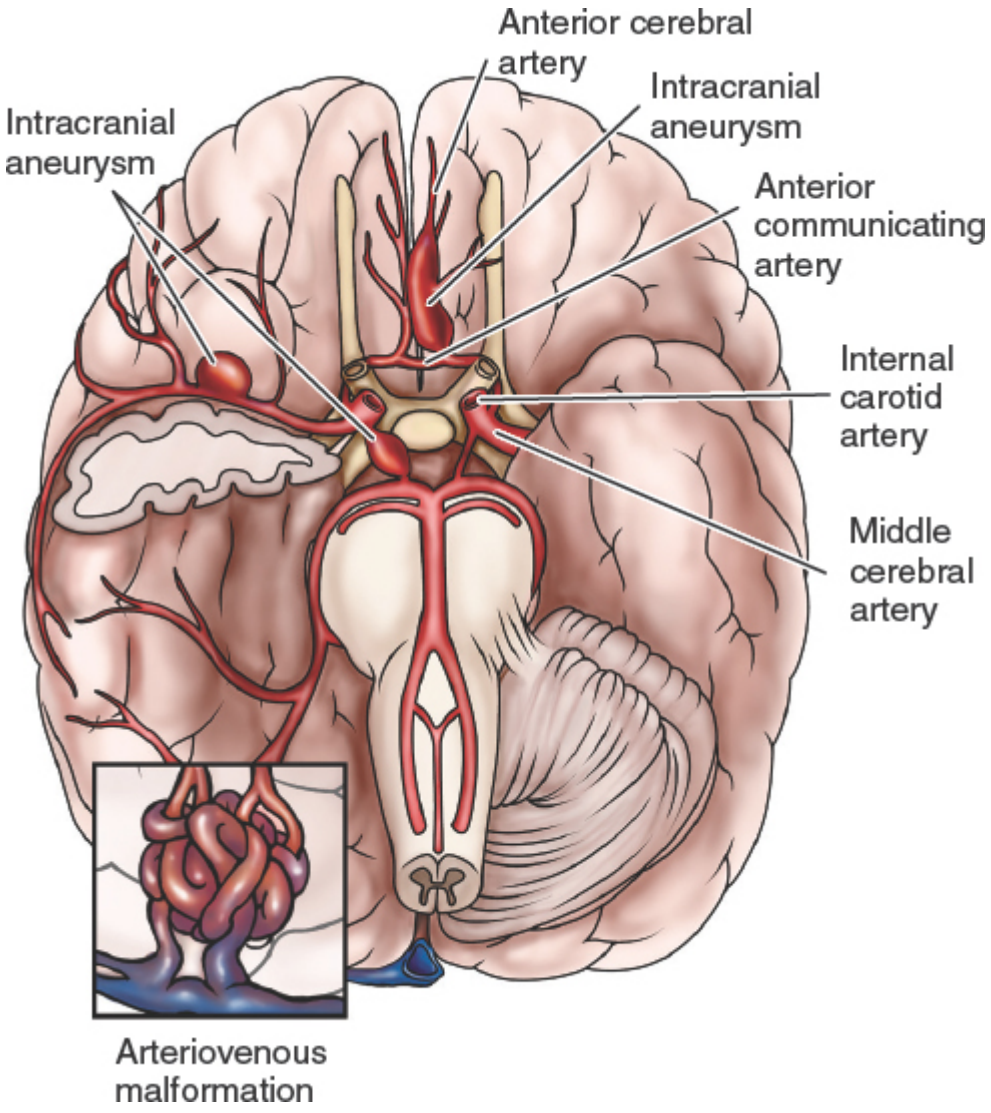

Figure 62-5 • Common sites of intracranial aneurysms and an arteriovenous malformation.

Arteriovenous Malformations

Most AVMs are caused by an abnormality in embryonal development that leads to a tangle of arteries and veins in the brain that lacks a capillary bed (see Fig. 62-5). The absence of a capillary bed leads to dilation of the arteries and veins and eventual rupture. AVM is a common cause of hemorrhagic stroke in young people (Hickey & Strayer, 2020).

Subarachnoid Hemorrhage

A subarachnoid hemorrhage (hemorrhage into the subarachnoid space) may occur as a result of an AVM, intracranial aneurysm, trauma, or hypertension. The most common causes are a leaking aneurysm in the area of the circle of Willis and a congenital AVM of the brain (Hickey & Strayer, 2020).

Clinical Manifestations

The patient with a hemorrhagic stroke can present with a wide variety of neurologic deficits, similar to the patient with ischemic stroke. The conscious patient most commonly reports a severe headache. A comprehensive assessment reveals the extent of the neurologic deficits. Many of the same motor, sensory, cranial nerve, cognitive, and other functions that are disrupted after ischemic stroke are also altered after a hemorrhagic stroke. Table 62-2 reviews the neurologic deficits frequently seen in patients who have had a stroke. Table 62-3 compares the symptoms seen in right hemispheric stroke with those seen in left hemispheric stroke. Other symptoms that may be observed more frequently in patients with acute intracerebral hemorrhage (compared with ischemic stroke) are nausea or vomiting, headache, an early sudden change in level of consciousness (confusion to coma), and possibly seizures.

In addition to the neurologic deficits (similar to those of ischemic stroke), the patient with an intracranial aneurysm or AVM may have some unique clinical manifestations. Rupture of an aneurysm or AVM usually produces a sudden, unusually severe headache and often loss of consciousness for a variable period of time. There may be pain and rigidity of the back of the neck (nuchal rigidity) and spine due to meningeal irritation. Visual disturbances (visual loss, diplopia, ptosis) occur if the aneurysm is adjacent to the oculomotor nerve. Tinnitus,

dizziness, photophobia (visual intolerance of light), nausea or vomiting, and hemiparesis may also occur.

At times, an aneurysm or AVM leaks blood, leading to the formation of a clot that seals the site of rupture. In this instance, the patient may show little neurologic deficit. In other cases, severe bleeding occurs, resulting in cerebral damage, followed rapidly by coma and death.

Prognosis depends on the neurologic condition of the patient, the patient's age, associated diseases, and the extent and location of the hemorrhage or intracranial aneurysm. Subarachnoid hemorrhage from an aneurysm is a catastrophic event with significant morbidity and mortality.

Assessment and Diagnostic Findings

Any patient with suspected stroke should undergo a CT scan or MRI scan to determine the type of stroke, the size and location of the hematoma, and the presence or absence of ventricular blood and hydrocephalus. Because hemorrhagic stroke is an emergency, CT scan is usually obtained first because it can be done rapidly. Cerebral angiography using the conventional method or a CT angiography confirms the diagnosis of an intracranial aneurysm or AVM. These tests show the location and size of the lesion and provide information about the affected arteries, veins, adjoining vessels, and vascular branches. Lumbar puncture may be performed if there is no evidence of increased ICP, the CT scan results are negative, and subarachnoid hemorrhage must be confirmed. Lumbar puncture in the presence of increased ICP could result in brainstem herniation or rebleeding.

For the procedural guidelines for assisting with a lumbar puncture, go to thepoint.lww.com/Brunner15e.

When diagnosing a hemorrhagic stroke in a patient younger than 40 years, some clinicians obtain a toxicology screen for illicit drug use.

Prevention

Primary prevention of hemorrhagic stroke is the best approach and includes managing hypertension and ameliorating other significant risk factors. Control of hypertension can reduce the risk of hemorrhagic stroke. Additional risk factors are increased age, male gender, certain ethnicities (Latino, African American, and Japanese) and moderate or excessive alcohol intake (Hickey & Strayer, 2020). Stroke risk screenings provide an ideal opportunity to lower hemorrhagic stroke risk by identifying individuals or groups at high risk and educating patients and the community about recognition and prevention.

Complications

Potential complications of hemorrhagic stroke include rebleeding or hematoma expansion; cerebral vasospasm resulting in cerebral ischemia; acute hydrocephalus, which results when free blood obstructs the reabsorption of cerebrospinal fluid (CSF) by the arachnoid villi; and seizures.

Cerebral Hypoxia and Decreased Blood Flow

Immediate complications of a hemorrhagic stroke include cerebral hypoxia, decreased cerebral blood flow, and extension of the area of injury. Providing adequate oxygenation of blood to the brain minimizes cerebral hypoxia. Brain function depends on delivery of oxygen to the tissues. Administering supplemental oxygen and maintaining the hemoglobin and hematocrit at acceptable levels will assist in maintaining tissue oxygenation.

Cerebral blood flow depends on the blood pressure, cardiac output, and integrity of cerebral blood vessels. Adequate hydration (IV fluids) must be ensured to reduce blood viscosity and improve cerebral blood flow. Extremes of hypertension or hypotension need to be avoided to prevent changes in cerebral blood flow and the potential for extending the area of injury.

A seizure can also compromise cerebral blood flow, resulting in further injury to the brain. Observing for seizure activity and initiating appropriate treatment are important components of care after a hemorrhagic stroke.

Vasospasm

The development of cerebral vasospasm (narrowing of the lumen of the involved cranial blood vessel) is a serious complication of subarachnoid hemorrhage and is a leading cause of morbidity and mortality in those who survive the initial subarachnoid hemorrhage. The mechanism responsible for vasospasm is not clear, but it is associated with increasing amounts of blood in the subarachnoid cisterns and cerebral fissures, as visualized by CT scan. Monitoring for vasospasm may be performed through the use of bedside transcranial Doppler ultrasonography or follow-up cerebral angiography (Connolly, Rabinstein, Carhuapoma, et al., 2012; Wilson, Ashcroft, & Troiani, 2019).

Vasospasm most frequently occurs 7 to 8 days after initial hemorrhage (American Association of Neuroscience Nurses [AANN], 2018), when the clot undergoes lysis (dissolution), and the chance of rebleeding is increased. It leads to increased vascular resistance, which impedes cerebral blood flow and causes brain ischemia (delayed cerebral ischemia) and infarction. Vasospasm can also occur 3 to 14 days after subarachnoid hemorrhage (Hickey & Strayer, 2020). Vasospasm is likely not the only factor that plays a role in the development of delayed cerebral ischemia. The signs and symptoms reflect the areas of the brain involved. Vasospasm is often heralded by a worsening headache, a decrease in level of consciousness (confusion, lethargy, and disorientation), or a new focal neurologic deficit (aphasia, hemiparesis).

Management of vasospasm remains difficult and controversial. It is believed that early surgery to clip the aneurysm prevents rebleeding and that removal of blood from the basal cisterns around the major cerebral arteries may prevent vasospasm.

Medication may be effective in the treatment and prevention of vasospasm. Based on the theory that vasospasm is caused by an increased influx of calcium into the cell, medication therapy may be used either to block or antagonize this action, or to prevent or reverse the action of vasospasm if already present. Nimodipine is the most studied calcium channel blocker for prevention of vasospasm in subarachnoid hemorrhage. Current guidelines recommend that nimodipine be prescribed for all patients with subarachnoid hemorrhage (Connolly et al., 2012). This is currently the only drug approved by the FDA for the prevention and treatment of vasospasm in subarachnoid hemorrhage.

Another therapy for vasospasm and the resulting delayed cerebral ischemia, referred to as triple-H therapy, is aimed at minimizing the deleterious effects of the associated cerebral ischemia and includes (1)

fluid volume expanders (hypervolemia), (2) induced arterial hypertension, and (3) hemodilution. However, current research and guidelines now endorse euvolemia to prevent delayed cerebral ischemia and induced arterial hypertension for treatment of delayed cerebral ischemia (Connolly et al., 2012).

Increased Intracranial Pressure

An increase in ICP can occur after either an ischemic or a hemorrhagic stroke but almost always follows a subarachnoid hemorrhage, usually because of disturbed circulation of CSF caused by blood in the basal cisterns. Neurologic assessments are performed frequently, and if there is evidence of deterioration from increased ICP (due to cerebral edema, herniation, hydrocephalus, or vasospasm), CSF drainage may be instituted by ventricular catheter drainage (Hemphill, Greenberg, Anderson, et al., 2015). Mannitol may be administered to reduce ICP. When mannitol is used as a long-term measure to control ICP, dehydration and disturbances in electrolyte balance (hyponatremia or hypernatremia; hypokalemia or hyperkalemia) may occur. Mannitol pulls water out of the brain tissue by osmosis and reduces total body water through diuresis. The patient's fluid balance is monitored continuously and is assessed for signs of dehydration and for rebound elevation of ICP. Other interventions may include elevating the head of the bed to 30 to 45 degrees, avoidance of hyperglycemia and hypoglycemia, sedation, and use of hypertonic saline in a variety of concentrations (e.g., 3%, 7.5%, or 23%) (Hickey & Strayer, 2020).

Hypertension

Hypertension is the most common cause of intracerebral hemorrhage, and its treatment is critical. Specific goals for blood pressure management, which are individualized for each patient, remain controversial. Blood pressure goals may depend on the presence of increased ICP. Guidelines for management of intracerebral hemorrhage recommend early blood pressure lowering (if the systolic blood pressure is between 150 and 220 mm Hg) to a goal systolic of 140 mm Hg, and report that lowering blood pressure can be effective for improving patient outcomes. If systolic blood pressure is above 220 mm Hg, IV continuous infusions of antihypertensive agents may be prescribed (Hemphill et al., 2015). Nicardipine is one agent that may be used as a continuous IV infusion. Labetalol and hydralazine are other examples of

medications that may be given as an IV bolus. During the administration of antihypertensive agents, hemodynamic monitoring is important to detect and avoid a precipitous drop in blood pressure, which can produce brain ischemia. Stool softeners are used to prevent straining, which can elevate the blood pressure.

Medical Management

The goals of medical treatment for hemorrhagic stroke are to allow the brain to recover from the initial insult (bleeding), to prevent or minimize the risk of rebleeding, and to prevent or treat complications. Management may consist of bed rest with sedation to prevent agitation and stress, management of vasospasm, and surgical or medical treatment to prevent rebleeding. If the bleeding is caused by anticoagulation with warfarin, the INR may be corrected with fresh-frozen plasma and vitamin K or prothrombin complex concentrations. Reversing the anticoagulation effect of DOACs requires use of an antidote. Idarucizumab is a medication that was approved for reversing dabigatran and andexanet alfa; it is an antidote for patients treated with rivaroxaban and apixaban; both are factor Xa inhibitors (Cordonnier, Demchuk, Ziai, et al., 2018). If seizures occur, they are treated with anti-epileptic drugs such as levetiracetam or phenytoin. Hyperglycemia should also be treated, and hypoglycemia is avoided. Intermittent pneumatic compression devices should be used starting on the first day of the hospital admission to prevent DVT. If the patient is not mobile after 1 to 4 days from the onset of the hemorrhage and there is documentation of the bleeding ceasing, then DVT prevention medications (low-molecular-weight heparin or unfractionated heparin) may be prescribed (Hemphill et al., 2015). Analgesic agents may be prescribed for head and neck pain. Fever should be treated with acetaminophen and devices such as cooling blankets. After discharge, most patients will require antihypertensive medications to decrease their risk of another intracerebral hemorrhage.

Surgical Management

In many cases, a primary intracerebral hemorrhage is not treated surgically. However, if the patient is showing signs of worsening neurologic examination, increased ICP, or signs of brainstem compression, then surgical evacuation is recommended for the patient with a cerebellar hemorrhage (Hemphill et al., 2015). Surgical evacuation is most frequently accomplished via a craniotomy (see

Chapter 61). Minimally invasive surgical techniques have also been investigated.

The patient with an intracranial aneurysm is prepared for surgical intervention as soon as their condition is considered stable. Surgical treatment of the patient with an unruptured aneurysm is an option. The goal of surgery is to prevent bleeding in an unruptured aneurysm or further bleeding in an already ruptured aneurysm. This objective is accomplished by isolating the aneurysm from its circulation or by strengthening the arterial wall. An aneurysm may be excluded from the cerebral circulation by means of a ligature or a clip across its neck. If this is not anatomically possible, the aneurysm can be reinforced by wrapping it with some substance to provide support and induce scarring.

Advances in technology have led to the introduction of interventional neuroradiology for the treatment of aneurysms. These techniques are now being used more frequently. Endovascular techniques may be used in select patients to occlude the blood flow from the artery that feeds the aneurysm with coils, liquid embolic agents, or other techniques to occlude the aneurysm itself. If the aneurysm is very large or very wide at its neck, a stent-like device made of a very fine mesh may be used to divert the blood flow away from the aneurysm. The determination of which technique should be used is based on many factors (characteristics of the patient and aneurysm) and is made by experienced endovascular specialists (Connolly et al., 2012; Thompson, Brown, Amin-Hanjani, et al., 2015).

Postoperative complications are rare but can occur. Potential complications include psychological symptoms (disorientation, amnesia, Korsakoff syndrome), intraoperative embolization or artery rupture, postoperative artery occlusion, fluid and electrolyte disturbances (from dysfunction of the neurohypophyseal system), and gastrointestinal bleeding. Complications post procedurally may also include bleeding, hematoma, vascular complications, allergic reactions, and stroke.

NURSING PROCESS

The Patient with a Hemorrhagic Stroke

Assessment

A complete neurologic assessment is performed initially and includes evaluation for the following:

- Altered level of consciousness
- Sluggish pupillary reaction
- Motor and sensory dysfunction
- Cranial nerve deficits (extraocular eye movements, facial droop, presence of ptosis)
- Speech difficulties and visual disturbance
- Headache and nuchal rigidity or other neurologic deficits

All patients should be monitored in the intensive care unit after an intracerebral or subarachnoid hemorrhage. Neurologic assessment findings are documented and reported as indicated. The frequency of these assessments varies depending on the patient's condition. Any changes in the patient's condition require reassessment and thorough documentation; changes should be reported immediately.

Concept Mastery Alert

Alteration in level of consciousness often is the earliest sign of deterioration in a patient with a hemorrhagic stroke. Because nurses have the most frequent contact with patients, they are in the best position to detect subtle changes. Drowsiness and slight slurring of speech may be early signs that the level of consciousness is deteriorating.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for ineffective tissue perfusion associated with bleeding or vasospasm
- Anxiety associated with illness or medically imposed restrictions (aneurysm precautions)

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Vasospasm
- Seizures
- Hydrocephalus
- Rebleeding
- Hyponatremia

Planning and Goals

The goals for the patient may include improved cerebral tissue perfusion, relief of anxiety, and the absence of complications.

Nursing Interventions

Optimizing Cerebral Tissue Perfusion

The patient is closely monitored for neurologic deterioration resulting from recurrent bleeding, increasing ICP, or vasospasm. A neurologic flow record is maintained. The blood pressure, pulse, level of consciousness (an indicator of cerebral perfusion), pupillary responses, and motor function are checked hourly. Respiratory status is monitored, because a reduction in oxygen in areas of the brain with impaired autoregulation increases the chances of a cerebral infarction. Any changes are reported immediately.

Implementing Aneurysm Precautions. Cerebral aneurysm precautions are implemented for the patient with a diagnosis of aneurysm (prior to any intervention) to provide a nonstimulating environment, prevent increases in ICP, and prevent further bleeding. The patient is placed on bed rest in a quiet, nonstressful environment, because activity, pain, and anxiety are thought to elevate the blood pressure, which may increase the risk for bleeding. Visitors may be restricted (AANN, 2018).

The head of the bed is elevated 30 to 45 degrees to promote venous drainage and decrease ICP. Any activity that suddenly increases the blood pressure or obstructs venous return is avoided. This includes the Valsalva maneuver, straining, forceful sneezing, pushing oneself up in bed, and acute flexion or rotation of the head and neck (which compromises the jugular veins). Stool softeners and mild laxatives are prescribed. Both prevent constipation, which can cause an increase in ICP. Dim lighting is helpful, because photophobia is common. The purpose of aneurysm precautions should be thoroughly explained to both the patient (if possible) and

family. Intermittent pneumatic compression devices and unfractionated heparin or low-molecular weight heparin are prescribed to decrease the incidence of DVT resulting from immobility. The legs are observed for signs and symptoms of DVT (tenderness, redness, swelling, warmth, and edema), and abnormal findings are reported.

Relieving Anxiety

Sensory stimulation is kept to a minimum for patients on aneurysm precautions. For patients who are awake, alert, and oriented, an explanation of the restrictions helps reduce the patient's sense of isolation. Reality orientation is provided to help maintain orientation.

Keeping the patient well informed of the plan of care provides reassurance and helps minimize anxiety. Appropriate reassurance also helps relieve the patient's fears and anxiety. The family also requires information and support.

Monitoring and Managing Potential Complications

Vasospasm. The patient is assessed for signs of possible vasospasm: intensified headaches, a decrease in level of responsiveness (confusion, disorientation, lethargy), or evidence of aphasia or partial paralysis. These signs may develop several days after surgery or on the initiation of treatment and must be reported immediately. The calcium channel blocker nimodipine should be given for prevention of vasospasm, and fluid volume expanders in the form of triple-H therapy may be prescribed as well (Connolly et al., 2012).

Seizures. Seizure precautions are maintained for every patient who may be at risk for seizure activity. Should a seizure occur, maintaining the airway and preventing injury are the primary goals. Medication therapy is initiated at this time (see Chapter 61).

Hydrocephalus. Blood in the subarachnoid space or ventricles impedes the circulation of CSF, resulting in hydrocephalus. A CT scan that indicates dilated ventricles confirms the diagnosis. Hydrocephalus can occur within the first 24 hours (acute) after subarachnoid hemorrhage or several days (subacute) to several weeks (delayed) later. Symptoms vary according to the time of onset and may be nonspecific. Acute hydrocephalus is characterized by sudden onset of stupor or coma and is managed with a ventriculostomy drain to decrease ICP. Symptoms of subacute and delayed hydrocephalus include gradual onset of drowsiness, behavioral changes, and ataxic

gait. A ventriculoperitoneal shunt is surgically placed to treat chronic hydrocephalus. Changes in patient responsiveness are reported immediately.

Rebleeding. The rate of recurrent hemorrhage is approximately 1% to 5% per patient per year after intracerebral hemorrhage (Hemphill et al., 2015). Hypertension is the most serious and modifiable risk factor, which shows the importance of appropriate antihypertensive treatment.

Aneurysm rebleeding is the highest during the first 2 to 12 hours after the initial hemorrhage (Connolly et al., 2012) and is considered a major complication. Symptoms of rebleeding include sudden severe headache, nausea, vomiting, decreased level of consciousness, and neurologic deficit. Rebleeding is confirmed by CT scan. Blood pressure is carefully maintained with medications. The most effective preventive treatment is to secure the aneurysm if the patient is a candidate for surgery or endovascular treatment.

Hyponatremia. After subarachnoid hemorrhage, hyponatremia is found in 30% to 50% of patients (Wilson et al., 2019). Hyponatremia has been found to be associated with the onset of vasospasm (Connolly et al., 2012). Laboratory data must be checked frequently, and hyponatremia (defined as a serum sodium concentration less than 135 mEq/L) must be identified as early as possible. The patient's primary provider needs to be notified of a low serum sodium level that has persisted for 24 hours or longer. The patient is then evaluated for syndrome of inappropriate antidiuretic hormone (SIADH) or cerebral salt-wasting syndrome. SIADH is described in Chapter 10. Cerebral salt-wasting syndrome occurs when the kidneys are unable to conserve sodium and volume depletion results. The treatment most often is the use of IV hypertonic 3% saline.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The patient and family are provided with education that will enable them to cooperate with the care and restrictions required during the acute phase of hemorrhagic stroke and to prepare them to return home. Patient and family education includes information about the causes of hemorrhagic stroke and its possible consequences. In addition, the patient and family are informed about the medical treatments that are implemented, including surgical intervention if warranted, and the

importance of interventions taken to prevent and detect complications (i.e., aneurysm precautions, close monitoring of the patient). Depending on the presence and severity of neurologic impairment and other complications resulting from the stroke, the patient may be transferred to a rehabilitation unit or center for additional patient and family education about strategies to regain self-care ability. Education addresses the use of assistive devices or modification of the home environment to help the patient live with the disability. Modifications of the home may be required to provide a safe environment.

Chart 62-6  **HOME CARE CHECKLIST**

The Patient Recovering from a Stroke

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the stroke on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State names, dose, side effects, frequency and schedule for all medications.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, rehabilitation team, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., diet, ADLs, IADLs, activity) necessary for recovery and health maintenance as applicable.
  - Demonstrate environmental modifications and adaptive techniques for accomplishing activities of daily living.
  - Demonstrate home exercises, the use of splints or orthotics, proper positioning, and frequent repositioning.
  - Identify safety measures to prevent falls.
  - Identify holistic interventions for pain management (e.g., positioning, distraction).
  - Describe procedures for maintaining skin integrity.
  - Demonstrate indwelling catheter care, if applicable. Describe a bowel and bladder elimination program as appropriate.
  - Verbalize dietary adjustments (e.g., thickened liquids, pureed diet, small frequent meals) during recovery.
  - Demonstrate swallowing techniques or care of enteral feeding tube.
- Identify psychosocial consequences of stroke (e.g., depression, emotional lability, frustration, fatigue) and appropriate interventions.
- Discuss measures to prevent subsequent strokes.
- Identify potential complications and discuss measures to prevent them (blood clots, aspiration, pneumonia, urinary tract infection, fecal impaction, skin breakdown, contracture).
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.

- Identify resources and other sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.
- Identify appropriate recreational or diversional activities.

Resources

See Chapter 2, Chart 2-6 for additional information about durable medical equipment and Chapter 7, Chart 7-6: Home Care Checklist: Managing Chronic Illness and Disability at Home.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care. The acute and rehabilitation phase of care focuses on obvious needs, issues, and deficits for the patient with a hemorrhagic stroke. The patient and family are reminded of the importance of following recommendations to prevent further hemorrhagic stroke and keeping follow-up appointments with health care providers for monitoring of risk factors. Referral for home, community-based, or transitional care may be warranted to assess the home environment and the ability of the patient and to ensure that the patient and family are able to manage at home. Home visits provide opportunities to monitor the physical and psychological status of the patient and the ability of the family to cope with any alterations in the patient's status. In addition, the home health nurse reminds the patient and family of the importance of continuing health promotion and screening practices. Chart 62-6 lists education for the patient recovering from a stroke.

Evaluation

Expected patient outcomes may include:

1. Demonstrates stable neurologic status and vital signs and respiratory patterns within normal limits
   a. Is alert and oriented to time, place, and person
   b. Demonstrates understandable speech patterns and stable cognitive processes
   c. Demonstrates usual and equal strength, movement, and sensation of all four extremities

d. Exhibits deep tendon reflexes and pupillary responses within normal limits

2. Exhibits reduced anxiety level
   a. States rationale for aneurysm precautions
   b. Exhibits clear thought processes
   c. Is less restless
   d. Exhibits absence of physiologic indicators of anxiety (e.g., has vital signs within normal limits; usual respiratory rate; absence of excessive, fast speech)
3. Is free of complications
   a. Exhibits absence of vasospasm
   b. Exhibits vital signs within normal limits and is without seizures
   c. Verbalizes understanding of seizure precautions
   d. Exhibits intact mental, motor, and sensory status
   e. Reports no visual changes

Veterans Considerations

Each year, an estimated 15,000 veterans are hospitalized with a stroke-related diagnosis; of these, between 15% and 30% have severe impairment while 40% have some type of functional limitation (Veteran's Administration/Department of Defense, The Management of Stroke Rehabilitation Work Group, 2019). Care for the veteran who has had a stroke takes place in a variety of settings. There are 33 primary stroke centers, 32 limited hours stroke centers, 43 supporting stroke facilities, and 45 acute rehabilitation facilities within the Department of Veterans Affairs. Nurses who work with patients who have had strokes should be aware of these systems as they may need to assist the veteran and their family to facilitate transfer or referral to facilities that can best meet their health care needs.

CRITICAL THINKING EXERCISES

1 pq A 61-year-old woman arrived in the ED and is being evaluated for suspected stroke. Her family reports that they last saw her normal 2 hours ago. What steps can you take to ensure rapid evaluation and treatment? What are your priorities for her care? If she is found to be eligible for t-PA and/or intra-arterial thrombolysis, how will your priorities change?

2 ipc You are caring for a patient who experienced an ischemic stroke and now has visual loss (homonymous hemianopsia). What nursing interventions can be implemented at the bedside to assist the patient with this visual deficit? What education can be provided to the patient when they are ready for discharge, and what other disciplines would you collaborate with to ensure that the patient is safely discharged to home? What are the specific roles and responsibilities of those other professionals?

3 ebp A 74-year-old male patient has experienced a large left hemispheric ischemic stroke. He has just arrived to the nursing unit from the ED and you are his nurse. Your initial assessment reveals that he has a fever, and a finger stick is performed and shows an elevated blood glucose. Evaluate the strength of the evidence surrounding elevated temperature and elevated blood glucose in acute stroke. Is there any evidence supporting the use of hypothermia in acute stroke?

63 Management of Patients with Neurologic Trauma

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the mechanisms of injury, clinical signs and symptoms, diagnostic testing, and treatment options for patients with traumatic brain and spinal cord injury.
2. Use the nursing process as a framework for care of the patient with traumatic brain injury.
3. Identify the population at risk for spinal cord injury and explain the clinical features and management of the patient with neurogenic shock.
4. Discuss the pathophysiology of autonomic dysreflexia and describe the appropriate nursing interventions.
5. Apply the nursing process as a framework for care of the patient with spinal cord injury and the patient with tetraplegia or paraplegia.

NURSING CONCEPTS

Family
Fluids and Electrolytes
Functional Ability
Infection
Intracranial Regulation
Medical Emergencies
Nutrition
Sensory Perception

GLOSSARY

autonomic dysreflexia: a life-threatening emergency in patients with spinal cord injury that causes a hypertensive emergency (*synonym:* autonomic hyperreflexia)

complete spinal cord lesion: a condition that involves total loss of sensation and voluntary muscle control below the lesion

concussion: a temporary loss of neurologic function with no apparent structural damage to the brain

contusion: bruising of the brain surface

incomplete spinal cord lesion: a condition in which there is preservation of the sensory or motor fibers, or both, below the lesion

neurogenic bladder: bladder dysfunction that results from a disorder or dysfunction of the nervous system; may result in either urinary retention or bladder overactivity

paraplegia: paralysis of the lower extremities with dysfunction of the bowel and bladder from a lesion in the thoracic, lumbar, or sacral region of the spinal cord

primary injury: initial damage to the brain that results from the traumatic event

secondary injury: an insult to the brain subsequent to the original traumatic event

spinal cord injury (SCI): an injury to the spinal cord, vertebral column, supporting soft tissue, or intervertebral discs caused by trauma

tetraplegia: varying degrees of paralysis of both arms and legs, with dysfunction of bowel and bladder from a lesion of the cervical segments of the spinal cord; formerly called *quadriplegia*

transection: severing of the spinal cord; transection can be complete (all the way through the cord) or incomplete (partially through)

traumatic brain injury: an injury to the skull or brain that is severe enough to interfere with normal functioning (*synonym:* craniocerebral trauma)

traumatic brain injury, closed (blunt): occurs when the head accelerates and then rapidly decelerates or collides with another object and brain tissue is damaged, but there is no opening through the skull and dura

traumatic brain injury, open (penetrating): occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path (penetrating injury), or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain

Trauma involving the central nervous system can be life-threatening. Even if not life-threatening, brain and spinal cord injury (SCI) may result in major physical and psychological dysfunction and can alter the patient's life completely. Neurologic trauma affects the patient, the family, the health care system, and the society as a whole because of its major sequelae and the costs of acute and long-term care of patients with trauma to the brain and spinal cord.

Head Injuries

Head injury is a broad classification that encompasses any damage to the head as a result of trauma. A head injury does not necessarily mean a brain injury is present. **Traumatic brain injury** (TBI) or craniocerebral trauma describes an injury that is the result of an external force and is of sufficient magnitude to interfere with daily life and prompts the seeking of treatment.

The Centers for Disease Control and Prevention (CDC) estimates that there are 2.9 million emergency department (ED) visits in the United States each year, the majority of which are for a mild TBI (CDC, 2019). As a result of TBI, approximately 56,800 people die (contributing to about 30% of all injury-related deaths), 288,000 are hospitalized, and 80,000 to 90,000 will have long-term disability (CDC, 2019; Hickey & Strayer, 2020). Approximately 78% of patients are treated in the ED and released (Williamson & Rajajee, 2018). The most common causes of TBIs are falls (48%), motor vehicle crashes (14%), being struck by objects (15%), and assaults (10%). Children up to 4 years of age, adolescents 15 to 19 years, and adults 65 years and older are most likely to sustain a TBI. In every age group, TBI rates are higher for males than for females (Hickey & Strayer, 2020). An estimated 5.3 million people are living with a TBI-related disability, producing an annual economic impact of approximately $76.5 billion due to medical expenses and the cost of lost productivity (CDC, 2019). The best approach to head injury is prevention (see Chart 63-1).

Chart 63-1  **HEALTH PROMOTION**

Preventing Head and Spinal Cord Injuries

- Advise drivers to obey traffic laws and to avoid speeding or driving when under the influence of drugs or alcohol.
- Advise all drivers and passengers to wear seat belts and shoulder harnesses. Children younger than 12 years should use an age/size-appropriate system in the back seat.
- Caution passengers against riding in the back of pickup trucks.
- Advise motorcyclists, scooter riders, bicyclists, skateboarders, and roller skaters to wear helmets.
- Promote educational programs that are directed toward violence and suicide prevention in the community.
- Provide water safety instruction.
- Educate patients about steps that can be taken to prevent falls, particularly in older adults.
- Advise athletes to use protective devices. Recommend that coaches be educated in proper coaching techniques.
- Advise owners of firearms to keep them locked in a secure area where children cannot access them.

Pathophysiology

Damage to the brain from traumatic injury takes two forms: primary injury and secondary injury. **Primary injury** is defined as the consequence of direct contact to the head/brain during the instant of initial injury, causing extracranial focal injuries (e.g., contusions, lacerations, external hematomas, and skull fractures), as well as possible focal brain injuries from sudden movement of the brain within the cranial vault (e.g., subdural hematomas [SDHs], concussion, diffuse axonal injury [DAI]). The greatest opportunity for decreasing TBI is the implementation of prevention strategies (see Chart 63-1).

Secondary injury evolves over the ensuing hours and days after the initial injury and results from inadequate delivery of glucose and oxygen to the cells. Identification, prevention, and treatment of secondary injury are the main foci of early management of severe TBI. Contributors to this process include intracranial pathologic processes such as intracranial hemorrhage, cerebral edema, intracranial hypertension, hyperemia, seizures, and vasospasm (Hickey & Strayer, 2020; Kaur & Sharma, 2018). Systemic effects from hypotension, hyperthermia, hypoxia, hypercarbia, infection, electrolyte imbalances, and anemia can also be factors which add to the complex biochemical, metabolic, and inflammatory changes that further compromise an injured brain (Hickey & Strayer, 2020).

The Monro–Kellie hypothesis, also known as the Monro–Kellie doctrine, explains the dynamic equilibrium of cranial contents. The cranial vault contains three main components: brain, blood, and cerebrospinal fluid (CSF). According to

the Monro–Kellie hypothesis, the cranial vault is a closed system, and if one of the three components increases in volume, at least one of the other two must decrease in volume or the pressure will increase. Any bleeding or swelling within the skull increases the volume of contents within the skull and therefore causes increased intracranial pressure (ICP) (see Chapter 61). If the pressure increases enough, it can cause displacement of the brain through or against the rigid structures of the skull. This causes restriction of blood flow to the brain, decreasing oxygen delivery and waste removal. Cells within the brain become anoxic and cannot metabolize properly, producing ischemia, infarction, irreversible brain damage, and eventually brain death (see Fig. 63-1).

Scalp Injury

Isolated scalp trauma is generally classified as a minor injury. Because its many blood vessels constrict poorly, the scalp bleeds profusely when injured. Trauma may result in an abrasion (brush wound), contusion, laceration, or subgaleal hematoma (hematoma beneath the layers of tissue of the scalp) (Hickey & Strayer, 2020). A large avulsion (tearing away) of the scalp may be potentially life-threatening and is a true emergency. Diagnosis of a scalp injury is based on physical examination, inspection, and palpation. Scalp wounds are potential portals of entry for organisms that cause intracranial infections. Therefore, the area is irrigated before the laceration is sutured to remove foreign material and to reduce the risk for infection (Hollander, 2019). Subgaleal hematomas usually reabsorb and do not require any specific treatment.

Skull Fractures

A skull fracture is a break in the continuity of the skull caused by forceful trauma. It may occur with or without damage to the brain. Skull fractures are classified by type and location. Types include linear, comminuted, and depressed skull fractures, whereas location fractures include frontal, temporal, and basal skull fractures. A simple (linear) fracture is a break in the continuity of the bone. A comminuted skull fracture refers to a splintered or multiple fracture line. Depressed skull fractures occur when the bones of the skull are forcefully displaced downward and can vary from a slight depression to bones of the skull being splintered and embedded within brain tissue. A fracture of the base of the skull is referred to as a basal skull fracture (Hickey & Strayer, 2020). A fracture may be open, indicating a scalp laceration or tear in the dura (e.g., from a bullet or an ice pick), or closed, in which case the dura is intact.

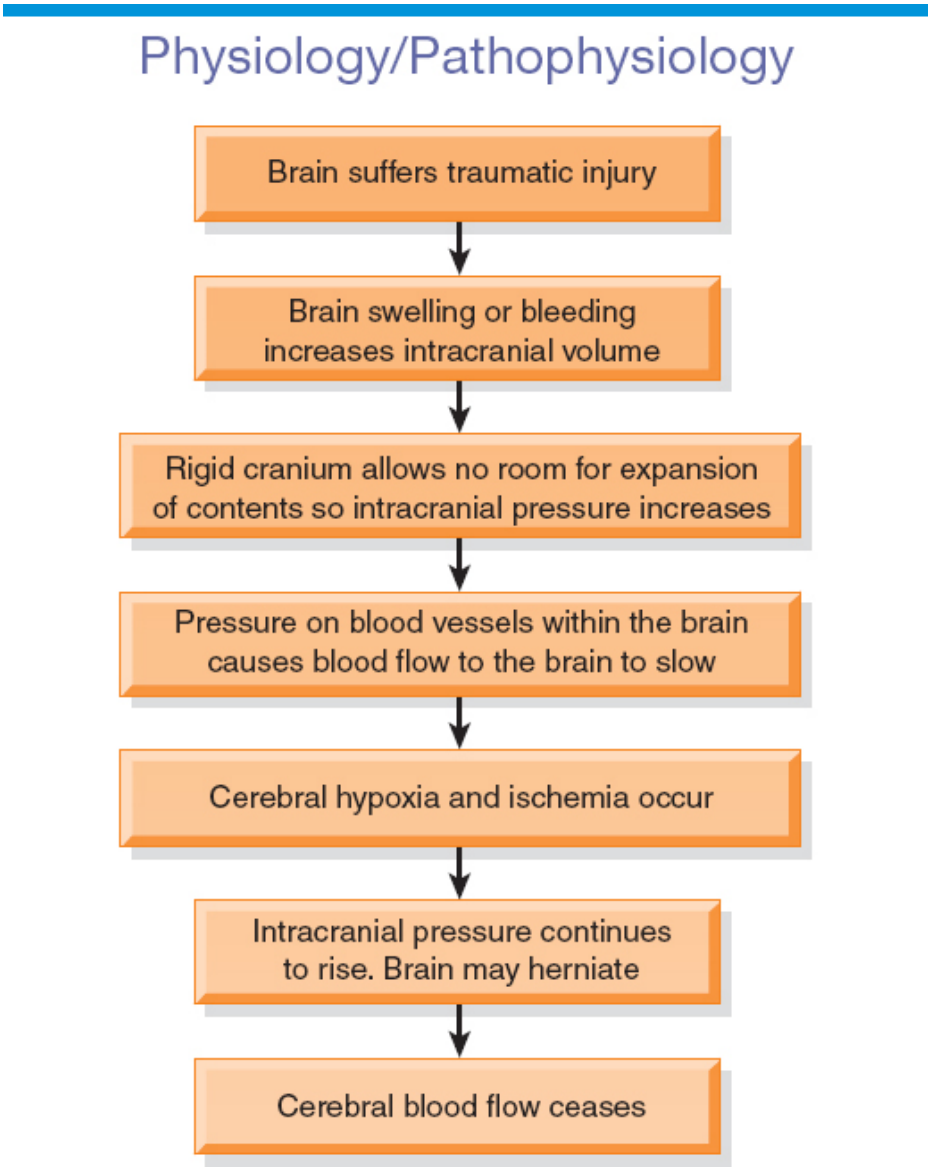

Figure 63-1 • Pathophysiology of traumatic brain injury.

Clinical Manifestations

Symptoms, apart from those of the local injury, depend on the severity and the anatomic location of the underlying brain injury. Persistent, localized pain usually suggests that a fracture is present. Fractures of the cranial vault may or may not produce swelling in the region of the fracture. Fractures of the base of the skull tend to traverse the paranasal sinus of the frontal bone or the middle ear located in the temporal bone. Therefore, they frequently produce hemorrhage from the nose, pharynx, or ears, and blood may appear under the conjunctiva. An area of ecchymosis (bruising) may be seen over the mastoid (Battle sign). Basal skull fractures are suspected when CSF escapes from the ears (CSF otorrhea) and the nose (CSF rhinorrhea). Drainage of CSF is a serious problem, because meningeal infection can occur if organisms gain access to the cranial contents via the nose, ear, or sinus through a tear in the dura.

Veterans Considerations

Military personnel in combat roles are at increased risk for TBI, with a prevalence rate ranging from 15% to 23% (Turgoose & Murphy, 2018). A common cause of TBI in a veteran is a combat-related blast injury from various forms of improvised explosive devices. Unlike TBI in the civilian population, which causes a primary and secondary injury, TBI in the military population causes four levels of injury (Chapman & Diaz-Arrastia, 2014). The primary injury is due to the atmospheric overpressure followed by underpressure or vacuum. The secondary injury occurs when objects are placed in motion (shrapnel) by the blast, hitting the service member. Tertiary injury occurs when the service member is thrown by the blast and hits their head against the ground, a wall, or other solid surface. Quaternary injury involves other injuries from the blast, such as burns and crush injuries. At this time, there is no evidence to suggest significant differences between a blast injury and a blunt brain injury. Magnetic resonance imaging (MRI) studies do not indicate any microstructural differences. It appears there are no cognitive differences either. Treatment options for a veteran with TBI are the same as those for a civilian with TBI; however, veterans can have complex needs, especially those with multiple injuries.

Assessment and Diagnostic Findings

A computed tomography (CT) scan can be used to diagnose a skull fracture. The ease with which a diagnosis of skull fracture is made depends on the site of the fracture. If a fracture is found on CT scan, there is always the question of associated brain injury, and an MRI scan provides better resolution and clearer pictures of the injured area (Hickey & Strayer, 2020).

Gerontologic Considerations

Older patients with head injuries differ from those who are younger in terms of etiology of injury, higher mortality rates, longer lengths of hospital stay, and worse functional outcomes (Thompson, Rivara, & Wang, 2020) (see the Nursing Research Profile in Chart 63-2). Neurologic assessment can be challenging, as the older adult patient with a TBI can have hearing or visual deficits or preexisting dementia or cognitive issues, making establishment of a neurologic baseline difficult. The most common causes of injury in older adult patients are falls and motor vehicle crashes. Approximately 81% of all TBIs among adults aged 65 years and older result from falls (CDC, 2019). Physiologic changes related to aging may place the older adult at increased risk for injury, alter the type and severity of injury that occurs, or lead to complications.

Several factors place older adults at increased risk for hematomas. Brain weight decreases, the dura becomes more adherent to the skull, and reaction times slow with increasing age (Battaglini, Gentile, Luchetti, et al., 2019). Also, many

older adults take aspirin and anticoagulant agents as part of routine management of chronic conditions.

Medical Management

Nondepressed skull fractures generally do not require surgical treatment; however, close observation of the patient is essential. Nursing personnel may observe the patient in the hospital, but if no underlying brain injury is present, the patient may be allowed to return home. If the patient is discharged home, specific instructions must be given to the family (see later discussion of concussion).

Chart 63-2  **NURSING RESEARCH PROFILE**

Head Injury in Older Adults

Thompson, H. J., Rivara, F. P., & Wang, J. (2020). Symptoms, function, and outcomes in the first year after mild-moderate traumatic brain injury. *Journal of Neuroscience Nursing*, *52*(2), 46–52.

Purpose

Older adults have higher rates of emergency department (ED) visits, hospitalization, and death for traumatic brain injury (TBI) compared to younger adults. The purpose of this study was to describe and compare the injury trajectory at 1 year for older and younger adults who had a TBI.

Design

This was a prospective longitudinal cohort study of 33 adults who had a mild to moderate TBI. Participants were recruited in the ED and followed for 1 year. Data were collected on symptoms, function using the Glasgow Outcome Scale-Extended Functional Status Examination, and health-related quality of life (HRQOL) for 1 week, then at 1, 3, 6, and 12 months after the injury.

Findings

The total number of symptoms did not differ when younger and older adults were compared, but the symptoms clusters were different. Older adults reported more physical symptoms such as fatigue, balance and coordination problems, and being bothered by noise. Younger adults reported more psychological symptoms such as anxiety. Function measured on the Glasgow Outcome Scale-Extended Functional Status Examination was lower in older adults at 1 year post injury compared to younger adults. Physical HRQOL was lower in older adults consistently over the year compared to younger adults. In contrast, mental HRQOL was higher in older adults.

Nursing Implications

Nurses working with older adults, who have had a TBI should know that they report different symptoms clusters compared to younger adults. Nursing interventions with older adults who have had a TBI should focus on balance, coordination, as well as energy conservation measures to minimize fatigue and other measures to reduce environmental noises.

Depressed skull fractures usually require surgery with elevation of the skull and débridement, usually within 24 hours of injury. Skull fractures can be a combination of open, compound, closed, or simple. Associated injuries include concurrent scalp laceration, dural tears, and brain injury directly below the fracture from compression of the tissue below the bony injury and from lacerations produced by the bony fragments (Hickey & Strayer, 2020).

Brain Injury

The most important consideration in any head injury is whether the brain is injured. Even seemingly minor injury can cause significant brain damage secondary to obstructed blood flow and decreased tissue perfusion. The brain cannot store oxygen or glucose to any significant degree. Because the cerebral cells need an uninterrupted blood supply to obtain these nutrients, irreversible brain damage and cell death occur if the blood supply is interrupted for even a few minutes. A **traumatic brain injury, closed (blunt)** occurs when the head accelerates and then rapidly decelerates or collides with another object (e.g., a wall, the dashboard of a car) and brain tissue is damaged but there is no opening through the skull and dura. A **traumatic brain injury, open (penetrating)** occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain.

Types of Brain Injury

Injuries to the brain can be focal or diffuse. Focal injuries include contusions and several types of hematomas. Concussions and DAI are the major diffuse injuries (Hickey & Strayer, 2020).

Contusion

In cerebral **contusion**, the brain is bruised and damaged in a specific area because of severe acceleration–deceleration force or blunt trauma. The impact of the brain against the skull leads to a contusion. Clinical manifestations of a contusion are dependent upon size, location, and the extent of surrounding cerebral edema. Although a contusion may occur in any area of the brain, most are usually located in the anterior portions of the frontal and temporal lobes, around the sylvian fissure, and at the orbital areas; less commonly, contusions are located at the parietal and occipital areas.

Contusions can be characterized by loss of consciousness associated with stupor and confusion. The effects of injury, particularly hemorrhage and edema, peak after about 18 to 36 hours. These effects, which can cause secondary effects resulting in an increased ICP and possible herniation syndromes, are most pronounced in temporal lobe contusions. Patients are most often managed medically with interventions directed toward prevention of additional insults. Deep contusions are more often associated with hemorrhage and destruction of the reticular activating fibers, altering arousal (Hickey & Strayer, 2020).

Intracranial Hemorrhage

Hematomas are collections of blood in the brain that may be epidural (above the dura), subdural (below the dura), or intracerebral (within the brain) (see Fig. 63-2). Major symptoms are frequently delayed until the hematoma is large enough to cause distortion of the brain and increased ICP. The signs and symptoms of cerebral ischemia resulting from compression by a hematoma are variable and

depend on the speed with which vital areas are affected and the area that is injured. A rapidly developing hematoma, even if small, may be fatal, whereas a larger but slowly developing one may allow compensation for increases in ICP.

Epidural Hematoma

After a head injury, blood may collect in the epidural (extradural) space between the skull and the dura mater. This can result from a skull fracture that causes a rupture or laceration of the middle meningeal artery, the artery that runs between the dura and the skull inferior to a thin portion of temporal bone. Hemorrhage from this artery causes rapid pressure in the brain. Epidural hematomas (EDHs) account for approximately 2.7% to 4% of traumatic head injuries (Hickey & Strayer, 2020).

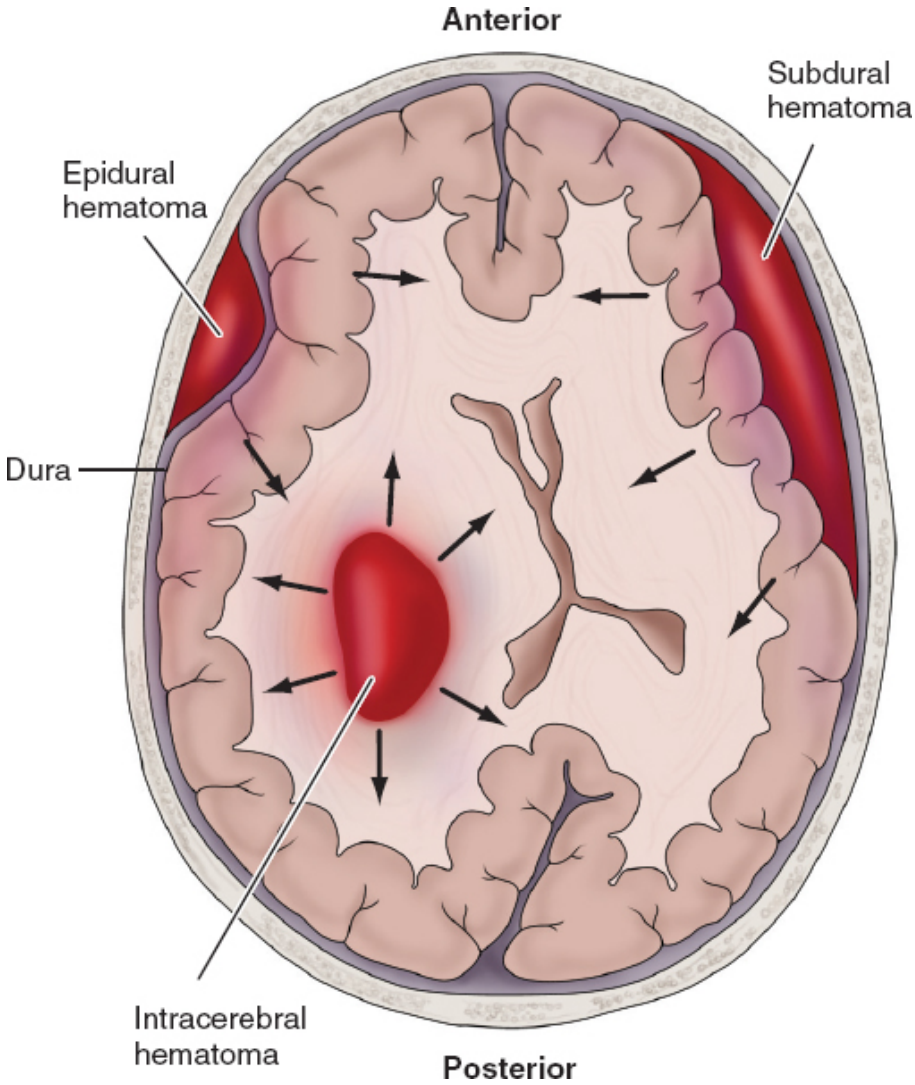

Figure 63-2 • Location of epidural, subdural, and intracerebral hematomas.

Symptoms are caused by the expanding hematoma. EDHs are often characterized by a brief loss of consciousness, followed by a lucid interval in

which the patient is awake and conversant. During this lucid interval, compensation for the expanding hematoma takes place by rapid absorption of CSF and decreased intravascular volume, both of which help to maintain the ICP within normal limits. When these mechanisms can no longer compensate, even a small increase in the volume of the blood clot produces a marked elevation in ICP. The patient then becomes increasingly restless, agitated, and confused as the condition progresses to coma. Then, often suddenly, signs of herniation appear (usually deterioration of consciousness and signs of focal neurologic deficits, such as dilation and fixation of a pupil or paralysis of an extremity), and the patient's condition deteriorates rapidly. The most common type of herniation syndrome associated with an EDH is uncal herniation causing pressure on the midbrain (Hickey & Strayer, 2020).

An EDH is considered an extreme emergency; marked neurologic deficit or even respiratory arrest can occur within minutes. Treatment consists of making openings through the skull (burr holes; see Chapter 61, Fig. 61-8) to decrease ICP emergently, remove the clot, and control the bleeding. A craniotomy may be required to remove the clot and control the bleeding. A drain is usually inserted after creation of burr holes or a craniotomy to prevent reaccumulation of blood.

Subdural Hematoma (SDH)

An SDH is a collection of blood between the dura and the brain, a space normally occupied by a thin cushion of fluid. The most common cause is trauma, but it can also occur as a result of coagulopathies or rupture of an aneurysm. An SDH is more frequently venous in origin and is caused by the rupture of small vessels that bridge the subdural space (Vacca & Argento, 2018). SDHs may be acute or chronic depending on the size of the involved vessel and the amount of bleeding in the CT scan.

Acute SDH

An acute SDH is usually caused by some kind of head injury, typically a fall. Signs and symptoms include changes in the level of consciousness (LOC), pupillary signs, and hemiparesis. There may be minor or even no symptoms with small collections of blood. Coma, increasing blood pressure, decreasing heart rate, and slowing respiratory rate are all signs of a rapidly expanding mass requiring immediate intervention.

If the patient can be transported rapidly to the hospital, an immediate craniotomy is performed to open the dura, allowing the subdural clot to be evacuated. Successful outcome also depends on the control of ICP and careful monitoring of respiratory function (see Chapter 61). The mortality rate for patients with acute SDH is high because of associated brain damage (Hickey & Strayer, 2020).

Chronic SDH

A chronic SDH can develop from seemingly minor head injuries and is seen most frequently in older adults who are prone to this type of head injury due to brain atrophy, which is a consequence of the aging process (Vacca & Argento, 2018).

Seemingly minor head trauma may produce enough impact to shift the brain contents abnormally. The time between injury and onset of symptoms can be lengthy (e.g., 3 weeks to months), so the actual injury may be forgotten.

A chronic SDH can resemble other conditions—for example, it may be mistaken for a stroke. The bleeding is less profuse, but compression of the intracranial contents still occurs. The blood within the brain changes in character in 2 to 4 days, becoming thicker and darker. In a few weeks, the clot breaks down and has the color and consistency of motor oil. Eventually, calcification or ossification of the clot takes place. The brain adapts to this foreign body invasion, and the clinical signs and symptoms fluctuate. Symptoms include severe headache, which tends to come and go; alternating focal neurologic signs; personality changes; mental deterioration; and focal seizures (Vacca & Argento, 2018).

The treatment for a chronic SDH consists of surgical evaluation for evacuation of the clot. Consideration must be made for reversal of coagulopathies and iatrogenic anticoagulation (Vacca & Argento, 2018). The operative procedure may be carried out through multiple burr holes, or a craniotomy may be performed for a sizable subdural mass that cannot be suctioned or drained through burr holes.

Intracerebral Hemorrhage and Hematoma

Intracerebral hemorrhage is bleeding into the parenchyma of the brain. It is commonly seen in head injuries when force is exerted to the head over a small area (e.g., missile injuries, bullet wounds, stab injuries). These hemorrhages within the brain may also result from the following:

- Systemic hypertension, which causes degeneration and rupture of a vessel
- Rupture of an aneurysm
- Vascular anomalies
- Intracranial tumors
- Bleeding disorders such as leukemia, hemophilia, aplastic anemia, and thrombocytopenia
- Complications of anticoagulant therapy

Nontraumatic causes of intracerebral hemorrhage are discussed in Chapter 62.

The onset may be insidious, beginning with the development of neurologic deficits, followed by headache. Management includes supportive care; control of ICP; and careful administration of fluids, electrolytes, and antihypertensive medications. Surgical intervention by craniotomy or craniectomy permits removal of the blood clot and control of hemorrhage but may not be possible because of the inaccessible location of the bleeding or the lack of a clearly circumscribed area of blood that can be removed.

Concussion

A **concussion** is a temporary loss of neurologic function with no apparent structural damage to the brain. Of the 1.7 million TBIs that occur in the United States each year, it is estimated that approximately 80% of them are concussions, also referred to as "mild TBI" (CDC, 2019). The mechanism of injury is usually blunt trauma from an acceleration–deceleration force, a direct blow, or a blast injury. If brain tissue in the frontal lobe is affected, the patient may exhibit bizarre irrational behavior, whereas involvement of the temporal lobe can produce temporary amnesia or disorientation.

The duration of mental status abnormalities is an indicator of the grade of the concussion. The patient is discharged from the hospital or ED once they return to baseline after a concussion. Monitoring includes observing the patient for a decrease in LOC, worsening headache, dizziness, seizures, abnormal pupil response, vomiting, irritability, slurred speech, and numbness or weakness in the arms or legs (Silverberg, Iaccarino, Panenka, et al., 2020). The occurrence of these symptoms is a red flag indicating the need for further intervention. Recovery may appear complete, but long-term sequelae are possible and repeat injuries are common.

Repeated concussive incidents can lead to a syndrome known as chronic traumatic encephalopathy. This syndrome has been recognized in those participating in contact sports such as football and boxing. The presentation is similar to Alzheimer's disease, characterized by personality changes, memory impairment, and speech and gait disturbances. Imaging findings show gross cerebral, particularly temporal lobe, atrophy (Hickey & Strayer, 2020; Turk & Budson, 2019).

Diffuse Axonal Injury (DAI)

DAI results from widespread shearing and rotational forces that produce damage throughout the brain—to axons in the cerebral hemispheres, corpus callosum, and brain stem. The injured area may be diffuse with no identifiable focal lesion. DAI is associated with prolonged traumatic coma; it is more serious and is associated with a poorer prognosis than a focal lesion. The patient with DAI in severe head trauma experiences no lucid interval, immediate coma, decorticate and decerebrate posturing (see Chapter 61, Fig. 61-1), and global cerebral edema. Diagnosis is made by clinical signs in conjunction with a CT or MRI scan (Schweitzer, Niogi, Whitlow, et al., 2019). Recovery depends on the severity of the axonal injury.

Medical Management

Assessment and diagnosis of the extent of injury are accomplished by the initial physical and neurologic examinations. CT and MRI scans are the main neuroimaging diagnostic tools and are useful in evaluating the brain structure (Schweitzer et al., 2019). Positron emission tomography (PET) is available in some trauma centers for assessing brain function.

Any patient with a head injury is presumed to have a cervical spine injury until proven otherwise. The patient is transported from the scene of the injury on a board with the head and neck maintained in alignment with the axis of the body. A cervical collar should be applied and maintained until cervical spine x-rays have been obtained and the absence of cervical SCI documented.

All therapy is directed toward preserving brain homeostasis and preventing secondary brain injury, which is injury to the brain that occurs after the original traumatic event. Common causes of secondary injury are cerebral edema, hypotension, and respiratory depression that may lead to hypoxemia and electrolyte imbalance. Treatments to prevent secondary injury include stabilization of cardiovascular and respiratory function to maintain adequate cerebral perfusion, control of hemorrhage and hypovolemia, and maintenance of optimal blood gas values.

Acute TBI treatment guidelines have been developed by the Brain Trauma Foundation. Adherence to these treatment guidelines may subsequently improve patient care and outcomes (Saherwala, Bader, Stutzman, et al., 2018).

Treatment of Increased Intracranial Pressure

As the damaged brain swells with edema or as blood collects within the brain, an increase in ICP occurs; this requires aggressive treatment (see Chapter 61 for a discussion on the relationship between ICP and cerebral perfusion pressure [CPP]). If the ICP remains elevated, it can decrease the CPP. Initial management is based on preventing secondary injury and maintaining adequate cerebral oxygenation (Sacco & Delibert, 2018).

Surgery is required for evacuation of blood clots, débridement and elevation of depressed fractures of the skull, and suture of severe scalp lacerations. ICP is monitored closely; if increased, it is managed by maintaining adequate oxygenation, elevating the head of the bed, and maintaining normal blood volume (McCafferty, Neal, Marshall, et al., 2018). Devices to monitor ICP or drain CSF can be inserted during surgery or at the bedside using aseptic technique. The patient is cared for in the intensive care unit (ICU), where expert nursing care and medical treatment are readily available.

Supportive Measures

Treatment also includes ventilatory support, seizure prevention, fluid and electrolyte maintenance, nutritional support, and management of pain and anxiety. Patients who are comatose are intubated and mechanically ventilated to ensure adequate oxygenation and protect the airway.

Because seizures can occur after head injury and can cause secondary brain damage from hypoxia, anticonvulsant agents may be given. If the patient is very agitated, benzodiazepines are the most commonly used sedative agents which do not affect cerebral blood flow or ICP. Lorazepam and midazolam are frequently

used but have active metabolites that may cause prolonged sedation, making it difficult to conduct a neurologic assessment. Propofol, a sedative–hypnotic agent that is supplied in an intralipid emulsion for intravenous (IV) use, is the sedative of choice. It is an ultrashort-acting, rapid-onset drug with elimination half-life of less than an hour. It has a major advantage of being titratable to its desired clinical effect but still provides the opportunity for an accurate neurologic assessment (Hickey & Strayer, 2020). A nasogastric tube may be inserted, because reduced gastric motility and reverse peristalsis are associated with head injury, making regurgitation and aspiration common in the first few hours.

Chart 63-3  **ETHICAL DILEMMA**

How Can Advocacy Be Assured for a Patient Who Is Undocumented and Incapacitated?

Case Scenario

J.S. is a 24-year-old man who is undocumented and undomiciled. He was brought to the hospital by ambulance after falling from a 20-foot-high scaffold at a construction site 2 days ago. You are J.S.'s nurse in the intensive care unit (ICU). According to J.S.'s assigned medical social worker, a coworker on the work site where J.S. fell followed him to the hospital post injury. Information gathered from the coworker included that J.S. was working as a day laborer and was sending money to his parents in Honduras. J.S. reportedly speaks no English and only some Spanish; his primary language is native Honduran Moskitu. Despite aggressive interventions, including emergent craniotomy, ventriculostomy placement, and endotracheal intubation and mechanical ventilation, J.S. has remained unresponsive to all stimuli since admission to the ICU, with a current Glasgow Coma Scale score of 3. The consulting neurologist has opined that J.S. will not recover from his traumatic brain injury, and that he will either succumb to his injuries or remain in a persistent vegetative state (see Chapter 61). The state where you work has a provision that two physicians may decide to withdraw life-sustaining therapy for patients who are unbefriended (i.e., without next of kin/surrogates) and decisionally incapacitated such as J.S. The attending physician intensivist assigned to J.S. tells you during her rounds that she intends to consult with another intensivist colleague so that J.S. is extubated, and wants you to prepare to assist them. You ask the intensivist if attempts should be made to find J.S.'s parents to get their permission to withdraw treatment. The intensivist says to you "How are we supposed to find them? And even if we do locate them, they do not speak English, and maybe they do not understand Spanish, either. How can we tell them what has happened and get them on board? For heaven's sake, we are not doing this man any favors by letting him linger like this!"

Discussion

People from socioeconomically disadvantaged groups and those who are racial and ethnic minorities are at greater risk for morbidity and mortality than those who are socioeconomically secure and White. No group is at greater risk for suffering health disparities than those who are undocumented and undomiciled. Patients who are undocumented will typically forego seeking treatment for anything other than a dire health emergency, as they typically are uninsured, not eligible for assistance programs, and risk deportation by seeing a health care provider.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Assume that the intensivist believes she is advocating for what is best for J.S. by withdrawing life support. What dangers might be inherent in this type of paternalistic attitude (i.e., *I know what is best for the patient*)?

- How might it be possible to ascertain what J.S.'s wishes would be if he were not incapacitated? Is trying to determine this futile and needlessly prolonging his suffering?
- What resources might you mobilize to be of assistance to you, to J.S., and to J.S.'s parents in Honduras? Do J.S.'s parents have the right to know what has happened to their son? What if his parents are found, and want J.S. to continue life-sustaining treatments? Can they legitimately make that decision on his behalf?

Brain Death

When a patient has sustained a severe head injury incompatible with life, the patient is a potential organ donor. The nurse may assist in the clinical examination for determination of brain death and in the process of organ procurement. The three cardinal signs of brain death on clinical examination are coma, the absence of brain stem reflexes, and apnea. Adjunctive tests, such as cerebral blood flow studies, electroencephalogram (EEG), transcranial Doppler, and brain stem auditory-evoked potential, are often used to confirm brain death (Hickey & Strayer, 2020). The health care team provides information to the family and assists them with the decision-making process about end-of-life care (see the section Supporting Family Coping and Chart 63-3).

NURSING PROCESS

The Patient with a Traumatic Brain Injury

Assessment

Depending on the patient's neurologic status, the nurse may elicit information from the patient, from the family, or from witnesses or emergency rescue personnel. Although all usual baseline data may not be collected initially, the immediate health history should include the following questions:

- When did the injury occur?
- What caused the injury? A high-velocity missile? An object striking the head? A fall?
- What was the direction and force of the blow?

A history of unconsciousness or amnesia after a head injury indicates a significant degree of brain damage, and changes that occur minutes to hours after the initial injury can reflect recovery or indicate the development of secondary brain damage. The nurse should determine if there was a loss of consciousness, the duration of the unconscious period, and if the patient could be aroused.

In addition to asking questions that establish the nature of the injury and the patient's condition immediately after the injury, the nurse examines the patient thoroughly. This assessment includes determining the patient's LOC using the Glasgow Coma Scale (GCS) and assessing the patient's response to tactile stimuli (if unconscious), pupillary response to light, corneal and gag reflexes, and motor function (Teasdale & Jennett, 1974). The GCS (see Chart 63-4) is based on the three criteria of eye opening, verbal responses, and motor responses to verbal commands or painful stimuli. It is particularly useful for monitoring changes during the acute phase, the first few days after a head injury. It does not take the place of an indepth neurologic assessment.

Detailed assessments are made initially and at frequent intervals throughout the acute phase of care (Hickey & Strayer, 2020). Monitoring of ICP is crucial to decision making for patients with neurologic injuries, yet research findings indicate that proper training and a standard guideline is necessary to correctly document ICP (Liu, Griffith, Jang, et al., 2020) (see the Nursing Research Profile in Chapter 61, Chart 61-2). Baseline and ongoing assessments are critical in nursing assessment of the patient with brain injury, whose condition can worsen dramatically and irrevocably if subtle signs are overlooked (Sacco & Davis, 2019; Urden, Stacy, & Lough, 2018). More information on assessment is provided in the following sections and in Figure 63-3 and Table 63-1.

Chart 63-4  **ASSESSMENT**

Glasgow Coma Scale

The Glasgow Coma Scale is a tool for assessing a patient's response to stimuli. Scores range from 3 (deep coma) to 15 (normal).

Eye-opening response	Spontaneous	4
	To voice	3
	To pain	2
	None	1
Best verbal response	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Best motor response	Obeys command	6
	Localizes pain	5
	Withdraws	4
	Flexion	3
	Extension	2
	None	1
Total		3 to 15

Figure 63-3 • Assessment parameters for the patient with a head injury include eye opening and responsiveness (**A**), vital signs (**B**), and motor response reflected in hand strength or response to painful stimulus (**C, D**). Photos by B. Proud.

TABLE 63-1  Multisystem Assessment Measures for the Patient with Traumatic Brain Injury

System-Specific Considerations	Assessment Data
Neurologic System	
• Severe TBI results in unconsciousness and alters many neurologic functions. • All body functions must be supported. • Increased ICP and herniation syndromes are life-threatening. • Measures are instituted to control elevated ICP.	• Assessment of neurologic status • Assessment for signs and symptoms of ICP elevation • Calculation of cerebral perfusion pressure if ICP monitor is in place • Monitoring of anticonvulsant medication blood levels
Respiratory System	
• Complete or partial airway obstruction will compromise the oxygen supply to the brain. • An altered respiratory pattern can result in cerebral hypoxia. • A short period of apnea at the moment of impact can result in spotty atelectasis. • Systemic disturbances from head injury can cause hypoxemia. • Brain injury can alter brain stem respiratory function. • Shunting of blood to the lungs as a result of a sympathetic discharge at the time of injury can cause neurogenic pulmonary edema.	• Assessment of respiratory function: • Auscultate chest for breath sounds • Note the respiratory pattern, if possible (not possible if a ventilator is being used) • Note the respiratory rate • Note whether the cough reflex is intact • Arterial blood gas levels • Complete blood count • Chest x-ray studies • Sputum cultures • Oxygen saturation using pulse oximetry
Cardiovascular System	
• The patient may develop cardiac arrhythmias, tachycardia, or bradycardia. • The patient may develop hypotension or hypertension. • Because of immobility and unconsciousness, the patient is at high risk for DVT and PE. • Fluid and electrolyte imbalance can be related to several problems including alterations in antidiuretic hormone secretion, the stress response, or fluid restriction. • Specific conditions may occur: • Diabetes insipidus • Syndrome of inappropriate secretion of antidiuretic hormone • Electrolyte imbalance • Hyperglycemic hyperosmolar syndrome.	• Assessment of vital signs • Monitoring for cardiac arrhythmias • Assessment for venous thromboembolism including PE and DVT • Electrocardiogram • Electrolyte studies • Blood coagulation studies • Blood glucose level • Blood acetone level • Blood osmolality • Urine-specific gravity
Gastrointestinal System	

• Injury to the GI tract can result in paralytic ileus. • Constipation can result from bed rest, NPO status, fluid restriction, and opioids given for pain control. • Bowel incontinence is related to the patient's unconscious state or altered mental state.	• Assessment of abdomen for bowel sounds and distention • Monitoring for decreased hemoglobin
Metabolic (Nutritional) System	
• The patient receives all fluids IV for the first few days until the GI tract is functioning. • A nutritional consultation is initiated within the first 24–48 h; parenteral or enteral nutrition may be started.	• Assessment of fluid and electrolyte balance • Recording of weight, if possible • Hematocrit • Electrolyte studies
Genitourinary System	
• Fluid restriction or the use of diuretic agents can alter the amount of urinary output. • Urinary incontinence is related to the patient's unconscious state.	• Intake and output record
Musculoskeletal System	
• Immobility contributes to musculoskeletal changes. • Decerebrate or decorticate posturing makes proper positioning difficult (see Chapter 61, Fig. 61-1).	• Assessment of range of motion of joints and development of deformities or spasticity
Integumentary System (Skin and Mucous Membranes)	
• Immobility secondary to TBI and unconsciousness contributes to the development of pressure areas and skin breakdown. • Intubation causes irritation of the mucous membrane and deterioration of oral health.	• Assessment of skin integrity and character • Assessment of oral mucous membrane and oral health of the skin
Psychological/Emotional Response	
• The patient with TBI is unconscious. • The family needs emotional support to deal with the crisis.	• Alternative methods of assessment for pain are indicated in the patient who is unconscious • Collection of information about the family and the role within the family of the person with head injury • Assessment of the family to determine how functional it was before the injury occurred

DVT, deep vein thrombosis; GI, gastrointestinal; ICP, intracranial pressure; IV, intravenous; NPO, nothing by mouth; PE, pulmonary embolism; TBI, traumatic brain injury.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired airway clearance and impaired gas exchange associated with brain injury
- Risk for ineffective tissue perfusion associated with increased ICP, decreased CPP, and possible seizures
- Hypovolemia associated with decreased LOC and hormonal dysfunction
- Impaired nutritional status associated with increased metabolic demands, fluid restriction, and inadequate intake
- Risk for injury (self-directed and directed at others) associated with seizures, disorientation, restlessness, or brain damage
- Risk for impaired thermoregulation associated with damaged temperature-regulating mechanisms in the brain
- Risk for impaired skin integrity associated with bed rest, hemiparesis, hemiplegia, immobility, or restlessness
- Difficulty coping associated with brain injury
- Impaired sleep associated with brain injury and frequent neurologic checks
- Risk for impaired family coping associated with unresponsiveness of patient, unpredictability of outcome, prolonged recovery period, and the patient's residual physical disability and emotional deficit
- Lack of knowledge about brain injury, recovery, and the rehabilitation process

The nursing diagnoses for the patient who is unconscious and the patient with increased ICP also apply (see Chapter 61).

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Decreased cerebral perfusion
- Cerebral edema and herniation
- Impaired oxygenation and ventilation
- Impaired fluid, electrolyte, and nutritional balance
- Risk for posttraumatic seizures

Planning and Goals

The goals for the patient may include maintenance of a patent airway, adequate CPP, fluid and electrolyte balance, adequate nutritional status, prevention of secondary injury, maintenance of body temperature within normal limits, maintenance of skin integrity, improvement of coping, prevention of sleep deprivation, effective family coping, increased knowledge about the rehabilitation process, and absence of complications.

Nursing Interventions

The nursing interventions for the patient with a TBI are extensive and diverse. They include making nursing assessments, setting priorities for nursing interventions, anticipating needs and complications, and initiating rehabilitation.

Maintaining the Airway

One of the most important nursing goals in the management of head injury is to establish and maintain an adequate airway. The brain is extremely sensitive to hypoxia, and a neurologic deficit can worsen if the patient is hypoxic. Therapy is directed toward maintaining optimal oxygenation to preserve cerebral function. An obstructed airway causes carbon dioxide retention and hypoventilation, which can produce cerebral vessel dilation and increased ICP (Urden et al., 2018).

Interventions to ensure an adequate exchange of air are discussed in Chapter 61 and include the following (Hickey & Strayer, 2020):

- Maintaining the patient who is unconscious in a position that facilitates drainage of oral secretions, with the head of the bed elevated about 30 degrees to decrease intracranial venous pressure
- Establishing effective suctioning procedures (pulmonary secretions produce coughing and straining, which increase ICP)
- Guarding against aspiration and respiratory insufficiency
- Closely monitoring arterial blood gas values to assess the adequacy of ventilation. The goal is to keep blood gas values within normal limits to ensure adequate cerebral blood flow
- Monitoring the patient who is receiving mechanical ventilation for pulmonary complications such as acute respiratory distress syndrome and pneumonia

The patient who is intubated is at high risk for ventilator-associated pneumonia and providing good oral hygiene can help prevent this complication (Gallagher, 2017).

Monitoring Neurologic Function

Patients with severe TBI are admitted to the ICU for close assessment and monitoring (cardiac monitoring, pulse oximetry, invasive arterial blood pressure monitoring, end-tidal CO_2, and temperature monitoring). Parameters are assessed initially and as frequently as the patient's condition requires. As soon as the initial assessment is made, the use of a neurologic observational

flow record is started and maintained. The importance of ongoing assessment and monitoring of the patient with brain injury cannot be overstated.

Level of Consciousness. The GCS is used to assess LOC at regular intervals, because changes in the LOC precede all other changes in vital and neurologic signs. The patient's best responses to predetermined stimuli are recorded (see Chart 63-4). Each response is scored (the greater the number, the better the functioning), and the sum of these scores gives an indication of the severity of coma and a prediction of possible outcome. The lowest score is 3 (least responsive); the highest is 15 (most responsive). A GCS score between 3 and 8 is generally accepted as indicating a severe head injury (Hickey & Strayer, 2020).

Concept Mastery Alert

The GCS is considered the most sensitive indicator of a lapse in neurologic functioning in patients with TBI and is often the earliest sign of acute change in ICP.

Vital Signs. Although a change in LOC is the most sensitive neurologic indication of deterioration of the patient's condition, vital signs are also monitored at frequent intervals to assess the intracranial status. Table 63-1 depicts the general assessment parameters for the patient with a head injury.

Signs of increasing ICP include bradycardia (slowing of the heart rate), increasing systolic blood pressure, and widening pulse pressure (Cushing's reflex). As brain compression increases, respirations become rapid, the blood pressure may decrease, and the pulse slows further. This is an ominous development, as is a rapid fluctuation of vital signs (Hickey & Strayer, 2020). The temperature is maintained at less than 38°C (100.4°F) (Young & Prescott, 2019). Tachycardia and arterial hypotension may indicate that bleeding is occurring elsewhere in the body.

Concept Mastery Alert

In a patient with a head injury, a rapid increase in body temperature is regarded as unfavorable because hyperthermia increases the metabolic demands of the brain and may indicate brain stem damage—a poor prognostic sign.

Motor Function. Motor function is assessed frequently by observing spontaneous movements, asking the patient to raise and lower the extremities, and comparing the strength and equality of the upper and lower extremities at periodic intervals. To assess upper extremity strength, the nurse instructs the patient to squeeze the examiner's fingers tightly. The nurse assesses lower extremity motor strength by placing the hands on the soles of the patient's feet and asking the patient to push down against the examiner's hands. Examination of the motor system is discussed in more detail in Chapter 60.

The presence or absence of spontaneous movement of each extremity is also noted, and speech and eye signs are assessed.

If the patient does not demonstrate spontaneous movement, responses to painful stimuli are assessed (Hickey & Strayer, 2020). Motor response to pain is assessed by applying a central stimulus, such as pinching the pectoralis major muscle, to determine the patient's best response. Peripheral stimulation may provide inaccurate assessment data because it may result in a reflex movement rather than a voluntary motor response. Abnormal responses (lack of motor response; extension responses) are associated with a poorer prognosis.

Other Neurologic Signs. The size and equality of the pupils and their reaction to light need to be continuously assessed. A unilaterally dilated and poorly responding pupil may indicate a developing hematoma, with subsequent pressure on the third cranial nerve due to shifting of the brain. If both pupils become fixed and dilated, this indicates acute injury and intrinsic damage to the upper brain stem and is a poor prognostic sign (Hickey & Strayer, 2020).

The patient with a head injury may develop deficits such as anosmia (lack of sense of smell), eye movement abnormalities, aphasia, memory deficits, and posttraumatic seizures or epilepsy. Patients may be left with residual psychological deficits (impulsiveness; emotional lability; or uninhibited, aggressive behaviors) and, as a consequence of the impairment, may lack insight into their emotional responses.

Monitoring Fluid and Electrolyte Balance

Brain damage can produce metabolic and hormonal dysfunctions. The monitoring of serum electrolyte levels is important, especially in patients receiving osmotic diuretics, those with syndrome of inappropriate antidiuretic hormone (SIADH) secretion, and those with posttraumatic diabetes insipidus.

Serial studies of blood and urine electrolytes and osmolality are carried out because head injuries may be accompanied by disorders of sodium regulation. Hyponatremia is common after head injury due to shifts in extracellular fluid, electrolytes, and volume. Hyperglycemia, for example, can cause an increase in extracellular fluid that lowers sodium. Hypernatremia may also occur as a result of sodium retention that may last several days, followed by sodium diuresis. Increasing lethargy, confusion, and seizures may be the result of electrolyte imbalance.

Endocrine function is evaluated by monitoring serum electrolytes, blood glucose values, and intake and output. Urine is tested regularly for acetone. A record of daily weights is maintained, especially if the patient has hypothalamic involvement and is at risk for the development of diabetes insipidus.

Promoting Adequate Nutrition

Head injury results in metabolic changes that increase calorie consumption and nitrogen excretion. Protein demand increases. Early initiation of nutritional

therapy has been shown to improve outcomes in patients with head injury. Patients with brain injury are assumed to be catabolic, and nutritional support consultation should be considered as soon as the patient is admitted. Parenteral nutrition via a central line or enteral feedings given via a nasogastric or nasojejunal feeding tube should be considered, though enteral is the preferred route (Hickey & Strayer, 2020). If CSF rhinorrhea occurs or if there is any suspicion of disruption to the skull base, an oral feeding tube should be inserted instead of a nasal tube.

Laboratory values should be monitored closely in patients receiving parenteral nutrition. Elevating the head of the bed can help prevent distention, regurgitation, and aspiration. A continuous-drip infusion or pump may be used to regulate the feeding. Enteral or parenteral feedings are usually continued until the swallowing reflex returns and the patient can meet caloric requirements orally. See Chapter 39 for the principles and technique of enteral feedings.

Preventing Injury

Often, as the patient emerges from coma, a period of lethargy and stupor is followed by a period of agitation. Each phase is variable and depends on the person, the location of the injury, the depth and duration of coma, and the patient's age. Restlessness may be caused by hypoxia, fever, pain, or a full bladder. It may indicate injury to the brain but may also be a sign that the patient is regaining consciousness. (Some restlessness may be beneficial because the lungs and extremities are exercised.) Agitation may also be the result of discomfort from catheters, IV lines, restraints, and repeated neurologic checks. Alternatives to restraints must be used whenever possible.

Strategies to prevent injury include the following:

- Assessing the patient to ensure that oxygenation is adequate, and the bladder is not distended. Dressings and casts are checked for constriction
- Using padded side rails or wrapping the patient's hands in mitts to protect the patient from self-injury and dislodging of tubes. Restraints are used judiciously because straining against them can increase ICP or cause other injury. Enclosed or floor-level specialty beds may be indicated
- Avoiding opioids as a means of controlling restlessness, because they depress respiration, constrict the pupils, and alter responsiveness
- Reducing environmental stimuli by keeping the room quiet, limiting visitors, speaking calmly, and providing frequent orientation information (e.g., explaining where the patient is and what is being done)
- Providing adequate lighting to prevent visual hallucinations
- Minimizing disruption of the patient's sleep–wake cycles
- Lubricating the patient's skin with oil or emollient lotion to prevent irritation due to rubbing against the sheet

- Using an external sheath catheter for a male patient if incontinence occurs. Because prolonged use of an indwelling catheter inevitably produces infection, the patient may be placed on an intermittent catheterization schedule.

Maintaining Thermoregulation

Fever in the patient with a TBI can be the result of damage to the hypothalamus, cerebral irritation from hemorrhage, or infection. The nurse monitors the patient's temperature every 2 to 4 hours. If the temperature increases, efforts are made to identify the cause and to control it using acetaminophen and cooling devices to maintain normothermia. Cooling devices should be used with caution so as not to induce shivering, which increases ICP. If infection is suspected, potential sites of infection are cultured, and antibiotic agents are prescribed and administered. Research about therapeutic hypothermia for patients with TBI suggests there is no clear evidence to guide therapy (Watson, Shepherd, Rhodes, et al., 2018; Weng, Yang, Huang, et al., 2018).

Maintaining Skin Integrity

Patients with TBI often require assistance in turning and positioning because of immobility or unconsciousness. Prolonged pressure on the tissues decreases circulation and leads to tissue necrosis. Potential areas of breakdown need to be identified early to avoid the development of pressure injuries. Specific nursing measures include the following:

- Assessing all body surfaces and documenting skin integrity every 8 hours
- Turning and repositioning the patient every 2 hours
- Providing skin care every 4 hours
- Assisting the patient to get out of bed to a chair three times a day

Improving Coping

Although many patients with head injury survive because of resuscitative and supportive technology, they frequently have ineffective coping due to cognitive sequelae. Cognitive impairment includes memory deficits; decreased ability to focus and sustain attention to a task (distractibility); impulsivity; egocentricity; and slowness in thinking, perceiving, communicating, reading, and writing. Psychiatric, emotional, and relationship problems develop in many patients after head injury. Resulting psychosocial, behavioral, emotional, and cognitive impairments are devastating to the family as well as to the patient (Oyesanya, Arulselvam, Thompson, et al., 2019).

These problems require collaboration among many disciplines. A neuropsychologist (specialist in evaluating and treating cognitive problems) plans a program and initiates therapy or counseling to help the patient reach maximal potential. Cognitive rehabilitation activities help the patient devise new problem-solving strategies. The retraining is carried out over an extended period and may include the use of sensory stimulation and reinforcement,

behavior modification, reality orientation, computer training programs, and video games. Assistance from many disciplines is necessary during this phase of recovery. Even if intellectual ability does not improve, social and behavioral abilities may improve.

The patient recovering from a TBI may experience fluctuations in the level of cognitive function, with orientation, attention, and memory frequently affected. Many types of sensory stimulation programs have been tried, and research on these programs is ongoing (Hickey & Strayer, 2020). When pushed to a level greater than the impaired cortical functioning allows, the patient may show symptoms of fatigue, anger, and stress (headache, dizziness). The Rancho Los Amigos Scale: Levels of Cognitive Functioning is frequently used to assess cognitive function and evaluate ongoing recovery from head injury. Progress through the levels of cognitive function can vary widely for individual patients (Hagen, Malkmus, & Durham, 1972). Nursing management and a description of each level are included in Table 63-2.

Preventing Sleep Pattern Disturbance

Patients who require frequent monitoring of neurologic status may experience sleep deprivation as they are awakened hourly for assessment of LOC. To allow the patient longer times of uninterrupted sleep and rest, the nurse can group nursing care activities so that the patient is disturbed less frequently. Environmental noise is decreased, and the room lights are dimmed. Measures to increase comfort may promote sleep and rest (Giusti, Tuteri, & Mirella, 2016).

Supporting Family Coping

Having a loved one sustain a TBI produces a great deal of stress in the family. This stress can result from the patient's physical and emotional deficits, the unpredictable outcome, and altered family relationships. Families report difficulties in coping with changes in the patient's temperament, behavior, and personality (Oyesanya et al., 2019). Such changes are associated with disruption in family cohesion, loss of leisure pursuits, and loss of work capacity, as well as social isolation of the caretaker. The family may experience marital disruption, anger, grief, guilt, and denial in recurring cycles.

To promote effective coping, the nurse can ask the family how the patient is different now, what has been lost, and what is most difficult about coping with this situation. Helpful interventions include providing family members with accurate and honest information and encouraging them to continue to set well-defined short-term goals. Family counseling helps address the family members' acute feelings of loss and helplessness and gives them guidance for the management of inappropriate behaviors. Support groups help the family members share problems, develop insight, gain information, network, and gain assistance in maintaining realistic expectations, hope, and a good quality of life (Oyesanya et al., 2019).

The Brain Injury Association of America (see the Resources section) serves as a clearinghouse for information and resources for patients with head injuries

and their families, including specific information on coma, rehabilitation, behavioral consequences of head injury, and family issues. This organization can provide names of facilities and professionals who work with patients with head injuries and can assist families in organizing local support groups.

TABLE 63-2 Rancho Los Amigos Scale: Levels of Cognitive Function

Cognitive Level	Description	Nursing Management
For levels I–III, the key approach is to *provide stimulation*.		
I: No response	Completely unresponsive to all stimuli, including painful stimuli	Multiple modalities of sensory input should be used. Examples are listed here, but management should be individualized and expanded based on available materials and patient preferences (determined by obtaining information from the family).
II: Generalized response	Nonpurposeful response; responds to pain but in a nonpurposeful manner	*Olfactory*: Perfumes, flowers, shaving lotion. *Visual*: Family pictures, card, personal items.
III: Localized response	Responses more focused—withdraws to pain; turns toward sound; follows moving objects that pass within the visual field; pulls on sources of discomfort (e.g., tubes, restraints); may follow simple commands but inconsistently and in a delayed manner	*Auditory*: Radio, television, recordings of family voices or favorite recordings, talking to patient (nurse, family members). The nurse should tell patient what is going to be done, discuss the environment, provide encouragement. *Tactile*: Touching of skin, rubbing various textures on skin. *Movement*: Range-of-motion exercises, turning, repositioning, the use of water mattress.
For levels IV–VI, the key approach is to *provide structure.*		
IV: Confused, agitated response	Alert, hyperactive state in which patient responds to internal confusion/agitation; behavior nonpurposeful in relation to the environment; aggressive, bizarre behavior common	For level IV, which lasts 2–4 wks, interventions are directed at decreasing agitation, increasing environmental awareness, and promoting safety.

		• Approach patient in a calm manner, and use a soft voice. • Screen patient from environmental stimuli (e.g., sounds, sights); provide a quiet, controlled environment. • Remove devices that contribute to agitation (e.g., tubes), if possible. • Functional goals cannot be set because the patient is unable to cooperate.
V: Confused, inappropriate response	When agitation occurs, it is the result of external rather than internal stimuli; focused attention is difficult; memory is severely impaired; responses are fragmented and inappropriate to the situation; there is no carryover of learning from one situation to the other	For levels V and VI, interventions are directed at decreasing confusion, improving cognitive function, and improving independence in performing ADLs. • Provide supervision. • Use repetition and cues to educate about ADLs. Focus the patient's attention, and help to increase their concentration. • Help the patient organize activities. • Clarify misinformation and reorient when confused. • Provide a consistent, predictable schedule (e.g., post daily

		schedule on large poster board).
VI: Confused, appropriate response	Follows simple directions consistently but is inconsistently oriented to time and place; short-term memory worse than long-term memory; can perform some ADLs	
For levels VII–X, the key approach is *integration into the community*.		
VII: Automatic, appropriate response	Appropriately responsive and oriented within the hospital setting; needs little supervision in ADLs; some carryover of learning; patient has superficial insight into disability; has decreased judgment and problem-solving abilities; lacks realistic planning for future	For levels VII–X, interventions are directed at increasing the patient's ability to function with minimal or no supervision in the community. • Reduce environmental structure. • Help the patient plan for adapting ADLs for self into the home environment. • Discuss and adapt home-living skills (e.g., cleaning, cooking) to patient's ability. • Provide standby assistance, as needed, for ADLs and home-living skills.
VIII: Purposeful, appropriate	Alert, oriented, intact memory; has realistic goals for the future. Able to complete familiar tasks for 1 h in a distracting environment; overestimates or underestimates abilities, argumentative, easily frustrated, self-centered; uncharacteristically dependent/independent	
IX: Purposeful, appropriate	Independently shifts back and forth between tasks and completes them accurately for at least 2 consecutive hours; uses assistive memory devices to recall schedule and activities; aware of and acknowledges impairments and disability when they interfere with task completion; depression may continue; may be easily irritable and have a low frustration tolerance	• Provide assistance on request for adapting ADLs and home-living skills.
X: Purposeful,	Able to handle multiple tasks simultaneously	• Monitor for signs

appropriate	in all environments but may require periodic breaks; independently initiates and carries out familiar and unfamiliar tasks but may require more than usual amount of time or compensatory strategies to complete them; accurately estimates abilities and independently adjusts to task demands; periodic periods of depression may occur; irritability and low frustration tolerance when sick, fatigued, or under stress	and symptoms of depression. • Help the patient plan, anticipate concerns, and solve problems.

ADLs, activities of daily living.

Adapted from Los Amigos Research and Education Institute, Inc., & Downey, C. A. (2002). Used with permission.

Many patients with severe head injury die of their injuries, and many of those who survive experience long-term disability that prevents them from resuming their previous roles and functions. During the most acute phase of injury, family members need factual information and support from the health care team.

Many patients with severe head injuries that result in brain death are young and otherwise healthy and are therefore considered for organ donation. Family members of patients with such injuries need support during this extremely stressful time and assistance in making decisions to end life support and permit donation of organs. They need to know that the patient who is brain dead and whose respiratory and cardiovascular systems are maintained through life support is not going to survive and that the severe head injury, not the removal of the patient's organs or the removal of life support, is the cause of the patient's death. Bereavement counselors and members of the organ procurement team are often immensely helpful to family members in making decisions about organ donation and in helping them cope with stress.

Monitoring and Managing Potential Complications

Decreased Cerebral Perfusion Pressure. Maintenance of adequate CPP is important to prevent serious complications of head injury due to decreased cerebral perfusion. Adequate CPP is greater than 50 mm Hg. If CPP falls below a patient's threshold, a vasodilating cascade occurs, causing the volume of blood to increase inside the brain, which causes ICP to increase. Measures to maintain adequate CPP are essential because a decrease in CPP can impair cerebral perfusion and cause brain hypoxia and ischemia, leading to permanent brain damage. Once the threshold CPP is reached, vasoconstriction of the cerebral blood vessels occurs, causing ICP to decrease. Therapy (e.g., elevation of the head of the bed, increased IV fluids, CSF drainage) is directed toward decreasing cerebral edema and increasing venous outflow from the brain. Systemic hypotension, which causes vasoconstriction and a significant decrease in CPP, is treated with increased IV fluids or vasopressors (Livesay, McNett, Keller, et al., 2017).

Cerebral Edema and Herniation. The patient with a head injury is at risk for additional complications such as increased ICP and brain stem herniation. Cerebral edema is the most common cause of increased ICP in the patient with a head injury, with the swelling peaking approximately 48 to 72 hours after injury. Bleeding also may increase the volume of contents within the rigid, closed compartment of the skull, causing increased ICP and herniation of the brain stem and resulting in irreversible brain anoxia and brain death (Hickey & Strayer, 2020; Vijay & Jaison, 2019). ICP is measured continuously and nursing interventions such as turning and suctioning have been associated with variation in the ICP (Olson, Parcon, Santos, et al., 2017). Measures to control ICP are listed in Chart 63-5 and discussed in Chapter 61.

Impaired Oxygenation and Ventilation. Impaired oxygenation and ventilation may require mechanical ventilatory support. The patient must be monitored for a patent airway, altered breathing patterns, and hypoxemia and pneumonia. Interventions may include endotracheal intubation, mechanical ventilation, and positive end-expiratory pressure. See Chapters 19 and 61 for a detailed discussion on these topics.

Chart 63-5

Controlling ICP in Patients with Severe Brain Injury

- Elevate the head of the bed as prescribed.
- Maintain the patient's head and neck in neutral alignment (no twisting or flexing the neck).
- Initiate measures to prevent the Valsalva maneuver (e.g., stool softeners).
- Maintain body temperature within normal limits.
- Administer oxygen (O_2) to maintain partial pressure of arterial oxygen (PaO_2) >90 mm Hg.
- Maintain fluid balance with normal saline solution.
- Avoid noxious stimuli (e.g., excessive suctioning, painful procedures).
- Administer sedation to reduce agitation.
- Maintain cerebral perfusion pressure of 60–70 mm Hg.

Adapted from Hickey, J. V., & Strayer, A. (2020). *The clinical practice of neurological & neurosurgical nursing*. (8th ed.). Philadelphia, PA: Wolters Kluwer.

Impaired Fluid, Electrolyte, and Nutritional Balance. Fluid, electrolyte, and nutritional imbalances are common in the patient with a head injury. Common imbalances include hyponatremia, which is often associated with SIADH (see Chapters 10 and 45), hypokalemia, and hyperglycemia. Modifications in fluid intake with tube feedings or IV fluids, including hypertonic saline, may be necessary to treat these imbalances (Hickey & Strayer, 2020). Insulin

administration may be prescribed to treat hyperglycemia; blood glucose levels are maintained between 80 and 160 mg/dL (Vijay & Jaison, 2019).

Undernutrition is also a common problem in response to the increased metabolic needs associated with severe head injury. Decisions about early feeding should be individualized; options include IV hyperalimentation or placement of a feeding tube (jejunal or gastric). Caloric expenditure can increase up to 120% to 140% with TBI, requiring close monitoring of nutritional status, with a higher concentration of protein if tolerated (Quintard & Ichai, 2018).

Posttraumatic Seizures. Patients with head injury are at an increased risk for posttraumatic seizures. Posttraumatic seizures are classified as immediate (within 24 hours after injury), early (within 1 to 7 days after injury), or late (more than 7 days after injury) (Hickey & Strayer, 2020). Seizure prophylaxis is the practice of administering anticonvulsant medications to patients with head injury to prevent seizures. It is important to prevent posttraumatic seizures, especially in the immediate and early phases of recovery, because seizures may increase ICP and decrease oxygenation (Chartrain, Yaeger, Feng, et al., 2017; Zaman, Dubiel, Driver, et al., 2017). However, many anticonvulsant medications impair cognitive performance and can prolong the duration of rehabilitation. Therefore, the overall benefits of these medications must be weighed against their side effects. Research evidence supports the use of prophylactic anticonvulsant agents to prevent immediate and early seizures after head injury, but not for prevention of late seizures (Chartrain et al., 2017; Zaman et al., 2017). See Chapter 61 for the nursing management of seizures.

Chart 63-6  **HOME CARE CHECKLIST**

The Patient with a TBI

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of TBI and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, rehabilitation team, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., ADLs, IADLs, activity) necessary for recovery and health maintenance, as applicable.
  - Demonstrate safe techniques to assist patient with self-care, hygiene, and ambulation.
  - Demonstrate safe techniques for eating, feeding patient, or assisting patient with eating.
  - Identify the need for close monitoring of behavior due to changes in cognitive functioning.
  - Describe strategies for reinforcing positive behaviors.
  - Describe household modifications needed to ensure safe environment for the patient.
- Explain the need for monitoring for changes in neurologic status and for complications.
- Identify changes in neurologic status and signs and symptoms of complications (e.g., pneumonia, urinary tract infection, meningitis) that should be reported to the neurosurgeon or nurse.
- Relate how to reach primary provider with questions or complications.
- State the importance of continuing follow-up by health care team.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health-promotion, disease prevention, and screening activities.

Resources

See Chapter 7, Chart 7-6 Home Care Checklist: Managing Chronic Illness and Disability at Home.

ADL, activities of daily living; IADL, instrumental activities of daily living; TBI, traumatic brain injury.

Educating Patients About Self-Care. Education early in the course of head injury often focuses on reinforcing information given to the family about the patient's condition and prognosis. As the patient's status and expected outcome change over time, family education may focus on interpretation and explanation of changes in the patient's physical and psychological responses.

Once the patient's physical status allows discharge to home, a rehabilitation center, or a subacute care facility, the patient and family are educated about limitations that can be expected and complications that may occur. The nurse explains to the patient and family, verbally and in writing, how to monitor for complications that merit contacting the primary provider. Depending on the patient's prognosis and physical and cognitive status, the patient may be included in education about self-care management strategies.

If the patient is at risk for late posttraumatic seizures, anticonvulsant medications may be prescribed at discharge. The patient and family require education about the side effects of these medications and the importance of continuing to take them as prescribed.

Continuing and Transitional Care. The rehabilitation phase of care for the patient with a TBI begins at hospital admission. Admission to the rehabilitation unit is a milestone in a patient's recovery and requires intense work by the patient to complete the daily schedule of therapies. The goals of rehabilitation are to maximize the patient's ability to return to their highest level of functioning and to their home and the community, address concerns before discharge for a smooth transition to home or rehabilitation, and promote independence with adaptation to deficits. The patient is encouraged to continue the rehabilitation program after discharge, because improvement in status may continue 3 or more years after injury. Changes in the patient with a TBI and the effects of long-term rehabilitation on the family and their coping abilities need ongoing assessment. Continued education and support of the patient and family are essential as their needs and the patient's status change. Education to address with the family of the patient who is about to return home is described in Chart 63-6.

Depending on status, the patient is encouraged to return to usual activities gradually. Referral to support groups and to the Brain Injury Association of America may be warranted (see the Resources section).

During the acute and rehabilitation phases of care, the focus of education is on obvious needs, issues, deficits, and complications. Complications after TBI include infections (e.g., pneumonia, urinary tract infection [UTI], sepsis, wound infection, osteomyelitis, meningitis, ventriculitis, brain abscess) and heterotopic ossification (painful bone overgrowth in weight-bearing joints).

The nurse reminds the patient and family of the need for continuing health promotion and screening practices after the initial phase of care. Patients who

have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers.

Evaluation

Expected patient outcomes may include:

1. Attains or maintains effective airway clearance, ventilation, and brain oxygenation
   a. Achieves blood gas values within normal limits and has breath sounds clear on auscultation
   b. Mobilizes and clears secretions
2. Achieves satisfactory fluid and electrolyte balance
   a. Demonstrates serum electrolytes within normal limits
   b. Has no clinical signs of dehydration or overhydration
3. Attains adequate nutritional status
   a. Is free of gastric distention and vomiting
   b. Shows minimal weight loss
4. Avoids injury
   a. Shows lessening agitation and restlessness
   b. Is oriented to person, place, and time
5. Maintains body temperature within normal limits
   a. Absence of fever
   b. Absence of hypothermia
6. Demonstrates intact skin integrity
   a. Exhibits no redness or breaks in skin integrity
   b. Exhibits no pressure injuries
7. Shows improvement in coping
8. Demonstrates usual sleep–wake cycle
9. Family demonstrates adaptive family processes
   a. Joins support group
   b. Shares feelings with appropriate health care personnel
   c. Makes end-of-life decisions, if needed
10. Demonstrates absence of complications
    a. Demonstrates ICP within normal limits
    b. Exhibits vital signs and body temperature within normal limits and increases orientation to person, place, and time
11. Experiences no posttraumatic seizures
    a. Takes anticonvulsant medications as prescribed
    b. Identifies side effects/adverse effects of anticonvulsant medications

12. Participates in rehabilitation process as indicated for patient and family members
    a. Takes active role in identifying rehabilitation goals and participating in recommended patient care activities
    b. Prepares for discharge

Spinal Cord Injury (SCI)

Spinal cord injury (SCI), an injury to the spinal cord, vertebral column, supporting soft tissue, or intervertebral discs caused by trauma is a major health disorder. In the United States, approximately 294,000 persons are living with an SCI. An estimated 17,810 new cases occur annually; common causes are motor vehicle crashes, falls, violence (predominantly gunshot wounds), and sports-related injuries (National Spinal Cord Injury Statistical Center [NSCISC], 2020). Males account for 78% of patients with SCI. The average age of injury is 43 years of age (NSCISC, 2020). The indirect cost for the care of patients with SCI averages about $77,701 per patient per year in 2019 dollars (NSCISC, 2020).

The predominant risk factors for SCI include younger age, male gender, and alcohol and illicit drug abuse. The frequency with which these risk factors are associated with SCI serves to emphasize the importance of primary prevention. The same interventions suggested earlier in this chapter for head injury prevention help decrease the incidence of SCI (see Chart 63-1). Life expectancy continues to increase for people with SCI because of improved health care but remains slightly lower than for those without SCI. The major causes of death are pneumonia, pulmonary embolism (PE), and sepsis (Hickey & Strayer, 2020).

Paraplegia (paralysis of the lower body) and **tetraplegia** (paralysis of all four extremities; formerly called *quadriplegia*) can occur, with incomplete tetraplegia being the most frequently occurring injury, followed by complete paraplegia, complete tetraplegia, and incomplete paraplegia.

Pathophysiology

Damage in SCI ranges from transient concussion (from which the patient fully recovers) to contusion, laceration, and compression of the spinal cord tissue (either alone or in combination), to complete **transection** (severing) of the spinal cord (which renders the patient paralyzed below the level of the injury). The vertebrae most frequently involved are the fifth, sixth, and seventh cervical vertebrae (C5–C7), the 12th thoracic vertebra (T12), and the first lumbar vertebra (L1). These vertebrae are most susceptible because there is a greater range of mobility in the vertebral column in these areas (Hickey & Strayer, 2020).

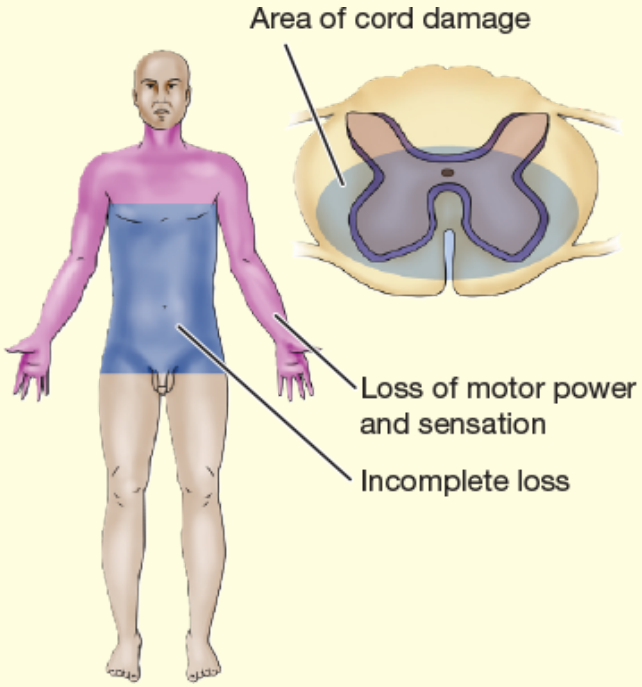
SCI can be separated into two categories: primary injuries and secondary injuries. Primary injuries are the result of the initial insult or trauma and are usually permanent. Secondary injuries resulting from SCI include edema and

hemorrhage (Venkatesh, Ghosh, Mullick, et al., 2019). The secondary injury is a major concern for critical-care nurses. Early treatment is essential to prevent partial damage from becoming total and permanent.

Veterans Considerations

Veterans account for a large proportion of those living with SCI (Gary, Cao, Burns, et al., 2020). Veterans who have suffered an SCI are significantly older and predominantly male compared to civilians with SCI (Furlan, Kurban, & Craven, 2019). However, the level of injury, severity, mechanisms of injury, and need for mechanical ventilation after the SCI are all similar to civilians (Furlan et al., 2019). Veterans with war-related SCIs are predominantly young, White, and male; they have commonly sustained thoracic, severe, SCI caused by gunshot or explosion; and they often have at least one other bodily injury in addition to SCI (Furlan, Gulasingam, & Craven, 2017). Differences between veterans and civilians with SCI may influence adjustment and functional outcomes. For example, factors such as the high rates of posttraumatic stress syndrome, the need to accommodate to civilian life, and the burden of not being able to serve increase the risk for poorer health and unhealthy behaviors, mental health problems, and substance use disorder (Gary et al., 2020). Veterans with SCI have higher cognitive function, social integration, self-perceived independence, and social support, as well as less pain and fewer secondary impairments than civilians with SCI. They also have better physical independence and mobility (Gary et al., 2020). Among civilians, there is a greater likelihood of employment post SCI for non-Hispanic White men with a college education. However, veterans with SCI lesions higher in the spinal cord are less likely to be employed.

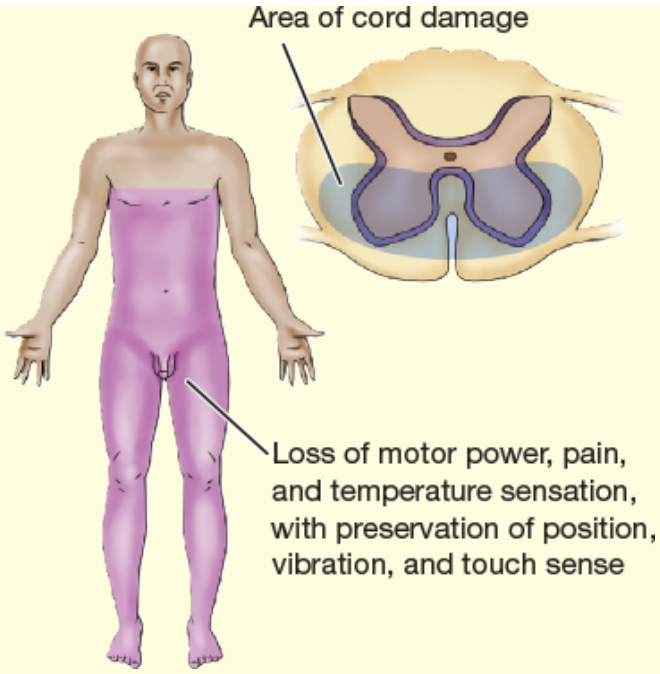
Clinical Manifestations



Manifestations of SCI depend on the type and level of injury (see Chart 63-7). The type of injury refers to the extent of injury to the spinal cord itself. A **complete spinal cord lesion** signifies loss of both sensory and voluntary motor communication from the brain to the periphery, resulting in paraplegia or tetraplegia. **Incomplete spinal cord lesion** denotes that the ability of the spinal cord to relay messages to and from the brain is not completely absent. Sensory and/or motor fibers are preserved below the lesion. Injuries are classified according to the area of spinal cord damage: central, lateral, anterior, or peripheral (see Chart 63-7).

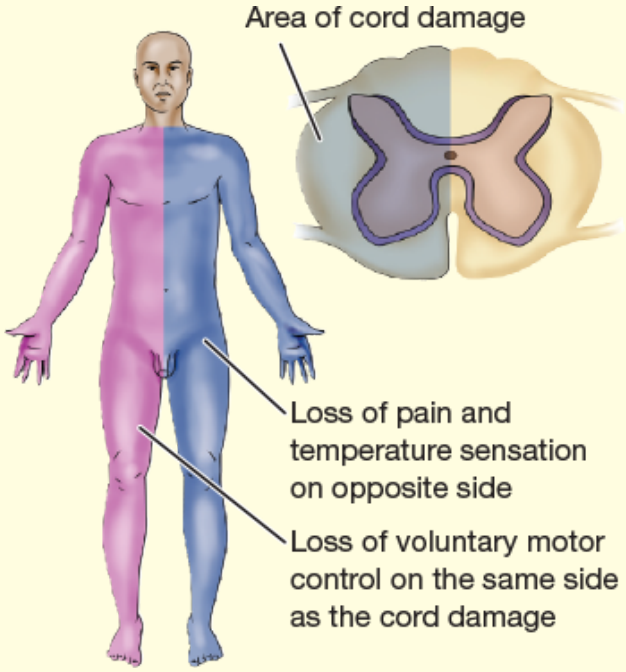
Chart 63-7

Effects of Spinal Cord Injuries



Central Cord Syndrome

- *Characteristics*: Motor deficits (in the upper extremities compared to the lower extremities; sensory loss varies but is more pronounced in the upper extremities); bowel/bladder dysfunction is variable, or function may be completely preserved.
- *Cause*: Injury or edema of the central cord, usually of the cervical area. May be caused by hyperextension injuries.



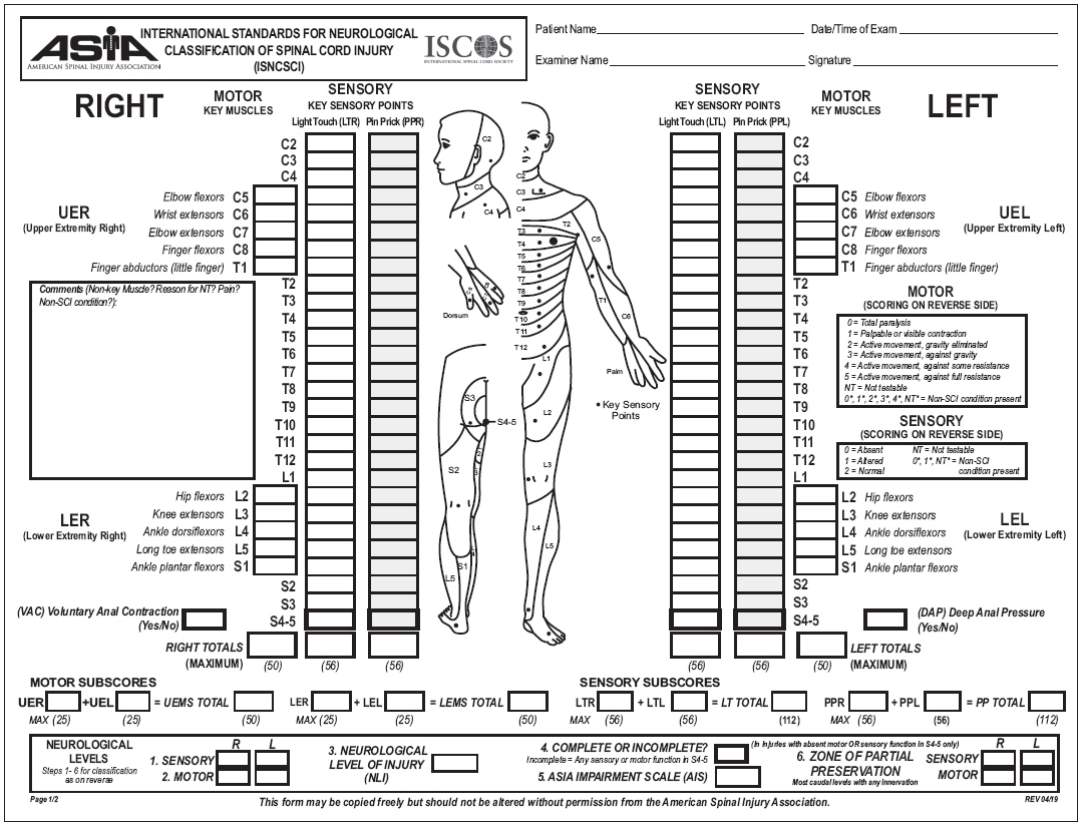
Anterior Cord Syndrome

- *Characteristics*: Loss of pain, temperature, and motor function is noted below the level of the lesion; light touch, position, and vibration sensation remain intact.
- *Cause*: The syndrome may be caused by acute disc herniation or hyperflexion injuries associated with fracture/dislocation of vertebra. It may also occur as a result of injury to the anterior spinal artery, which supplies the anterior two thirds of the spinal cord.

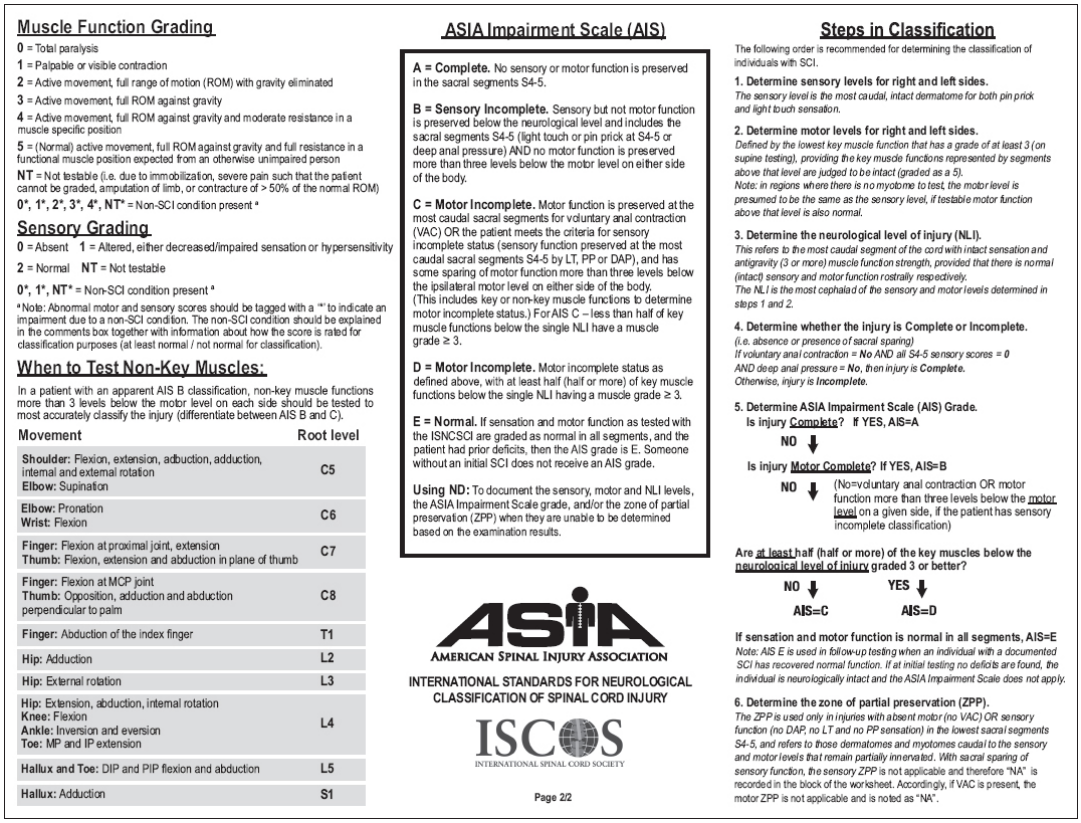
Lateral Cord Syndrome (Brown-Séquard Syndrome)

- *Characteristics*: Ipsilateral paralysis or paresis is noted, together with ipsilateral loss of touch, pressure, and vibration and contralateral loss of pain and temperature.
- *Cause*: The lesion is caused by a transverse hemisection of the cord (half of the cord is transected from north to south), usually as a result of a knife or missile injury, fracture/dislocation of a unilateral articular process, or possibly an acute ruptured disc.

Adapted from Hickey, J. V., & Strayer, A. (2020). *The clinical practice of neurological & neurosurgical nursing* (8th ed.). Philadelphia, PA: Wolters Kluwer.



The American Spinal Injury Association (ASIA) provides classification of SCI according to the degree of sensory and motor function present after injury (ASIA, 2019; see Fig. 63-4). The neurologic level refers to the lowest level at which sensory and motor functions are intact. Below the neurologic level, there may be total or partial, sensory and/or motor paralysis (dependent upon affected tracts), loss of bladder and bowel control (usually with urinary retention and bladder distention), loss of sweating and vasomotor tone, and marked reduction of blood pressure from loss of peripheral vascular resistance.



If conscious, the patient usually complains of acute pain in the back or neck, which may radiate along the involved nerve. However, absence of pain does not rule out spinal injury, and a careful assessment of the spine should be conducted if there has been a significant force and mechanism of injury (i.e., concomitant head injury).

Respiratory dysfunction is related to the level of injury. The muscles contributing to respiration are the diaphragm (C4), intercostals (T1–T6), and abdominals (T6–T12). Injuries at C4 or above (causing paralysis of the diaphragm) often will require ventilator support, since acute respiratory failure is a leading cause of death (Hickey & Strayer, 2020). Injuries of T12 and above will have impact on respiratory function. Functional abilities by level of injury are described in Table 63-3.

Assessment and Diagnostic Findings

A detailed neurologic examination is performed. Diagnostic x-rays (lateral cervical spine x-rays) and CT scanning are usually performed initially. An MRI scan may be ordered as a further workup if a ligamentous injury is suspected, because significant spinal cord damage may exist even in the absence of bony injury (Hickey & Strayer, 2020). If an MRI scan is contraindicated, a myelogram may be used to visualize the spinal axis. An assessment is made for other injuries because spinal trauma often is accompanied by concomitant injuries, commonly to the head and chest. Continuous electrocardiographic monitoring may be indicated if an SCI is suspected, because bradycardia (slow heart rate) and asystole (cardiac standstill) are common in patients with acute spinal cord injuries.

Muscle Function Grading

0 = Total paralysis
1 = Palpable or visible contraction
2 = Active movement, full range of motion (ROM) with gravity eliminated
3 = Active movement, full ROM against gravity
4 = Active movement, full ROM against gravity and moderate resistance in a muscle specific position
5 = (Normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person
NT = Not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of > 50% of the normal ROM)
0*, 1*, 2*, 3*, 4*, NT* = Non-SCI condition present [a]

Sensory Grading

0 = Absent **1** = Altered, either decreased/impaired sensation or hypersensitivity
2 = Normal **NT** = Not testable
0*, 1*, NT* = Non-SCI condition present [a]

[a] Note: Abnormal motor and sensory scores should be tagged with a "*" to indicate an impairment due to a non-SCI condition. The non-SCI condition should be explained in the comments box together with information about how the score is rated for classification purposes (at least normal / not normal for classification).

When to Test Non-Key Muscles:

In a patient with an apparent AIS B classification, non-key muscle functions more than 3 levels below the motor level on each side should be tested to most accurately classify the injury (differentiate between AIS B and C).

Movement	Root level
Shoulder: Flexion, extension, adbuction, adduction, internal and external rotation **Elbow:** Supination	C5
Elbow: Pronation **Wrist:** Flexion	C6
Finger: Flexion at proximal joint, extension **Thumb:** Flexion, extension and abduction in plane of thumb	C7
Finger: Flexion at MCP joint **Thumb:** Opposition, adduction and abduction perpendicular to palm	C8
Finger: Abduction of the index finger	T1
Hip: Adduction	L2
Hip: External rotation	L3
Hip: Extension, abduction, internal rotation **Knee:** Flexion **Ankle:** Inversion and eversion **Toe:** MP and IP extension	L4
Hallux and Toe: DIP and PIP flexion and abduction	L5
Hallux: Adduction	S1

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments S4-5 by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body. (This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade ≥ 3.

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3.

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

AMERICAN SPINAL INJURY ASSOCIATION

INTERNATIONAL STANDARDS FOR NEUROLOGICAL CLASSIFICATION OF SPINAL CORD INJURY

INTERNATIONAL SPINAL CORD SOCIETY

Page 2/2

Steps in Classification

The following order is recommended for determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.

2. Determine motor levels for right and left sides.
Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5).
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.

3. Determine the neurological level of injury (NLI).
This refers to the most caudal segment of the cord with intact sensation and antigravity (3 or more) muscle function strength, provided that there is normal (intact) sensory and motor function rostrally respectively.
The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.

4. Determine whether the injury is Complete or Incomplete.
(i.e. absence or presence of sacral sparing)
*If voluntary anal contraction = **No** AND all S4-5 sensory scores = **0** AND deep anal pressure = **No**, then injury is **Complete**.*
*Otherwise, injury is **Incomplete**.*

5. Determine ASIA Impairment Scale (AIS) Grade.
Is injury Complete? If YES, AIS=A
NO
Is injury Motor Complete? If YES, AIS=B
NO (No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?
NO → **AIS=C** **YES** → **AIS=D**

If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact and the ASIA Impairment Scale does not apply.

6. Determine the zone of partial preservation (ZPP).
The ZPP is used only in injuries with absent motor (no VAC) OR sensory function (no DAP, no LT and no PP sensation) in the lowest sacral segments S4-5, and refers to those dermatomes and myotomes caudal to the sensory and motor levels that remain partially innervated. With sacral sparing of sensory function, the sensory ZPP is not applicable and therefore "NA" is recorded in the block of the worksheet. Accordingly, if VAC is present, the motor ZPP is not applicable and is noted as "NA".

Emergency Management

The immediate management at the scene of the injury is critical because improper handling of the patient can cause further damage and loss of neurologic function. Any patient who is involved in a motor vehicle crash, a diving or contact sports injury, a fall, or any direct trauma to the head and neck must be considered to have SCI until such an injury is ruled out. Initial care must include a rapid assessment, immobilization, extrication, and stabilization or control of life-threatening injuries, and transportation to the most appropriate medical facility. Immediate transportation to a trauma center with the capacity to manage major neurologic trauma is then necessary (Hickey & Strayer, 2020).

At the scene of the injury, the patient must be immobilized on a spinal (back) board, with the head and neck maintained in a neutral position, to prevent an incomplete injury from becoming complete. One member of the team must assume control of the patient's head to prevent flexion, rotation, or extension; this is done by placing the hands on both sides of the patient's head at about ear level to limit movement and maintain alignment while a spinal board and cervical

immobilizing device is applied. If possible, at least four people should slide the patient carefully onto a board for transfer to the hospital. Head blocks should also be considered, as they will further limit any neck movement. Any twisting movement may irreversibly damage the spinal cord by causing bony fragment or disc movement or exacerbating ligamentous injury, causing further instability.

The patient is referred to a regional spinal injury or trauma center because of the multidisciplinary personnel and support services required to counteract the destructive changes that occur in the first 24 hours after injury. During treatment in the emergency and x-ray departments, the patient is kept on the transfer board. The patient must always be maintained in an extended position. No part of the body should be twisted or turned, and the patient is not allowed to sit up. Once the extent of the injury has been determined, the patient may be placed on a rotating specialty bed or in a cervical collar (see Fig. 63-5). Later, if SCI and bone instability have been ruled out, the patient may be moved to a conventional bed or the collar may be removed without harm. If a specialty bed is needed but not available, the patient should be placed in a cervical collar and on a firm mattress.

TABLE 63-3 Functional Abilities by Level of Spinal Cord Injury

Injury Level	Segmental Sensorimotor Function	Dressing, Eating	Elimination	Mobility[a]
C1	Little or no sensation or control of head and neck; no diaphragm control; requires continuous ventilation	Dependent	Dependent	Limited. Voice or sip-n-puff controlled electric wheelchair
C2–C3	Head and neck sensation; some neck control; independent of mechanical ventilation for short periods	Dependent	Dependent	Same as for C1
C4	Good head and neck sensation and motor control; some shoulder elevation; diaphragm movement	Dependent; may be able to eat with adaptive sling	Dependent	Limited to voice, mouth, head, chin, or shoulder-controlled electric wheelchair
C5	Full head and neck control; shoulder strength; elbow flexion	Independent with assistance	Maximal assistance	Electric or modified manual wheelchair, needs transfer assistance
C6	Fully innervated shoulder; wrist extension or dorsiflexion	Independent or with minimal assistance	Independent or with minimal assistance	Independent in transfers and wheelchair
C7–C8	Full elbow extension; wrist plantar flexion; some finger control	Independent	Independent	Independent; manual wheelchair
T1–T5	Full-hand and finger control; use of intercostal and thoracic muscles	Independent	Independent	Independent; manual wheelchair
T6–T10	Abdominal muscle control, partial to good balance with trunk muscles	Independent	Independent	Independent; manual wheelchair
T11–L5	Hip flexors, hip abductors (L1–L3); knee extension (L2–L4); knee flexion; and ankle dorsiflexion (L4–L5)	Independent	Independent	Short distance to full ambulation with assistance
S1–S5	Full leg, foot, and ankle control; innervation of perineal muscles for bowel, bladder, and sexual function (S2–S4)	Independent	Normal to impaired bowel and bladder function	Ambulate independently with or without assistance

[a]Assistance refers to adaptive equipment, setup, or physical assistance.

Medical Management (Acute Phase)

The goals of management are to prevent secondary injury, to observe for symptoms of progressive neurologic deficits, and to prevent complications. The patient is resuscitated as necessary, and oxygenation and cardiovascular stability are maintained. SCI is a devastating event; new treatment methods and medications are continually being investigated for the acute and chronic phases of care (Venkatesh et al., 2019).

Pharmacologic Therapy

Administration of high-dose IV corticosteroids (methylprednisolone sodium succinate) in the first 24 or 48 hours is controversial. The validity of studies has been questioned based on critical analysis of the original and additional data. As a result, there is now a consensus that corticosteroids may offer only a slight benefit. Corticosteroids are no longer considered the standard of care for acute SCI, although some centers continue to use corticosteroid protocols (Hickey & Strayer, 2020).

Respiratory Therapy

Oxygen is given to maintain a high partial pressure of arterial oxygen (PaO_2), because hypoxemia can create or worsen a neurologic deficit of the spinal cord. If endotracheal intubation is necessary, extreme care is taken to avoid flexing or extending the patient's neck, which can result in extension of a cervical injury.

In high cervical spine injuries, spinal cord innervation to the phrenic nerve, which stimulates the diaphragm, is lost. Diaphragmatic pacing (electrical stimulation of the phrenic nerve) attempts to stimulate the diaphragm to help the patient breathe. Intramuscular diaphragmatic pacing is currently in the clinical trial phase for the patient with a high cervical injury. This is implanted via laparoscopic surgery, usually after the acute phase.

Skeletal Fracture Reduction and Traction

Management of SCI requires immobilization and reduction of dislocations (restoration of preinjury position) and stabilization of the vertebral column. This can be accomplished by surgical or nonsurgical interventions; both aim to prevent new or worsening neurologic damage.

Cervical fractures can be reduced, and the cervical spine aligned with some form of skeletal traction, such as with skeletal tongs or with the use of the halo device. Traction is applied to the skeletal traction device by weights (ensuring the weights are unencumbered); the amount depends on the size of the patient and the degree of fracture displacement. The traction force is exerted along the longitudinal axis of the vertebral bodies, with the patient's neck in a neutral position. The traction is then gradually increased by adding more weights. As the amount of traction is increased, the spaces between the intervertebral discs widen and the vertebrae are given a chance to slip back into position. Reduction usually occurs after correct alignment has been restored. Once reduction is achieved, as verified by cervical spine x-rays and neurologic examination, the weights are gradually removed until the amount of weight needed to maintain the alignment is identified. Traction is sometimes supplemented with manual manipulation of the neck by a surgeon, to help achieve realignment of the vertebral bodies.

A halo device may be used initially with traction or may be applied after removal of the tongs. It consists of a titanium or stainless-steel halo ring that is fixed to the skull by four pins, which are inserted into the outer table of the skull. The ring is attached to a removable halo vest, a device that suspends the weight of the unit circumferentially around the chest. A frame connects the ring to the chest. Halo devices provide immobilization of the cervical spine while allowing early ambulation (see Fig. 63-6) for patients with adequate function.

Thoracic and lumbar injuries are usually treated with surgical intervention, followed by immobilization with a fitted brace. Traction is often not indicated either before or after surgery, due to the relative stability of the spine in these regions.

Quality and Safety Nursing Alert

The patient's vital organ functions and body defenses must be supported and maintained until spinal and neurogenic shock abates and the neurologic system has recovered from the traumatic insult; this can take up to 4 months.

Figure 63-6 • Halo and vest for cervical and thoracic injuries. Adapted from Schwartz, E. D., Adam, E., & Flander, S. (2007). *Spinal trauma: Imaging, diagnosis, and management*. Philadelphia, PA: Lippincott Williams & Wilkins.

Surgical Management

Surgery is indicated in any of the following situations:

- Compression of the cord is evident.
- The injury results in a fragmented or unstable vertebral body.
- The injury involves a wound that penetrates the cord.
- Bony fragments are in the spinal canal.
- The patient's neurologic status is deteriorating.

Early surgical stabilization may improve the clinical outcome of patients compared to surgery performed later during the clinical course. The goals of surgical treatment are to preserve neurologic function by removing pressure from the spinal cord and to provide stability.

Management of Acute Complications of Spinal Cord Injury

Spinal and Neurogenic Shock

The spinal shock associated with SCI reflects a sudden depression of reflex activity in the spinal cord, called areflexia, that occurs below the level of injury. The muscles innervated by the part of the spinal cord segment below the level of the lesion are without sensation, paralyzed, and flaccid, and the reflexes are absent. Blood pressure may be decreased, and the patient may be bradycardic. Hypotension and shock can further damage the spinal cord; therefore, the mean arterial pressure (MAP) should be maintained at 85 mm Hg or higher during the hyperacute phase. The reflexes that initiate bladder and bowel function are affected. Bowel distention and paralytic ileus can be caused by depression of the reflexes and are treated with intestinal decompression by insertion of a nasogastric tube. A paralytic ileus most often occurs within the first 2 to 3 days after SCI and resolves within 3 to 7 days.

Neurogenic shock develops as a result of the loss of autonomic nervous system function below the level of the lesion. The vital organs are affected, causing decreases in blood pressure, heart rate, and cardiac output, as well as venous pooling in the extremities and peripheral vasodilation (Volski & Ackerman, 2020). In addition, the patient does not perspire in the paralyzed portions of the body, because sympathetic activity is blocked; therefore, close observation is required for early detection of an abrupt onset of fever. See Chapter 11 for further discussion on neurogenic shock.

With injuries to the cervical and upper thoracic spinal cord, innervation to the major accessory muscles of respiration is lost and respiratory problems develop. These include decreased vital capacity, retention of secretions, increased partial pressure of arterial carbon dioxide ($PaCO_2$) levels and decreased oxygen levels, respiratory failure, and pulmonary edema.

Venous Thromboembolism

The risk for venous thromboembolism (VTE) is a potential complication of immobility and occurs in patients with SCI at the same rate as those having had other types of traumatic injuries (Wang, Strayer, Harris, et al., 2017). Patients who develop VTE are at high risk for both deep vein thrombosis (DVT) and PE due to immobility, flaccidity, and decreased vasomotor tone (Wang et al., 2017).

Manifestations of PE include pleuritic chest pain, anxiety, shortness of breath, and abnormal blood gas values (increased $PaCO_2$ and decreased PaO_2). A fatal PE

has been reported in up to 2% of patients with SCI within the first 3 months after injury (Hickey & Strayer, 2020).

Low-dose anticoagulation therapy usually is initiated to prevent DVT and PE, along with the use of anti-embolism stockings or sequential pneumatic compression devices (SCDs). In some cases, permanent indwelling filters may be placed prophylactically in the vena cava to prevent emboli (dislodged clots) from migrating to the lungs and causing PE. Prevention continues into the rehabilitation and chronic phases of SCI care (Abrams & Wakasa, 2019). See Chapter 26 for further discussion on VTE.

Quality and Safety Nursing Alert

The calves or thighs of a patient who is immobile should never be massaged because of the danger of dislodging an undetected thromboembolus.

Other Complications

In addition to the respiratory complications (respiratory failure, pneumonia) and autonomic dysreflexia, other complications that may occur include pressure injuries and infection (urinary, respiratory, and local infection at the skeletal traction pin sites).

NURSING PROCESS

The Patient with Acute Spinal Cord Injury

Assessment

The patient's breathing pattern and the strength of the cough are assessed, and the lungs are auscultated, because paralysis of the diaphragm, in addition to abdominal and respiratory muscles, diminishes coughing and makes clearing of bronchial and pharyngeal secretions difficult. Reduced excursion of the chest also results.

The patient is monitored closely for any changes in motor or sensory function and for symptoms of progressive neurologic damage. In the early stages of SCI, determining whether the cord has been severed may not be possible, because signs and symptoms of cord edema are indistinguishable from those of cord transection. Edema of the spinal cord may occur with any severe cord injury and may further compromise spinal cord function.

Motor and sensory functions are assessed through careful neurologic examination. These findings are recorded on a flow sheet so that changes in the baseline neurologic status can be monitored closely and accurately. The ASIA classification is commonly used to describe the level of function for patients with SCI (see Fig. 63-4). Chart 63-7 also gives examples of the effects of altered spinal cord function. At the minimum:

- Motor ability is tested by asking the patient to spread the fingers, squeeze the examiner's hand, and move the toes or turn the feet.
- Sensation is evaluated by gently pinching the skin or touching it lightly with an object such as a tongue blade, starting at shoulder level and working down both sides of the extremities. The patient should have both eyes closed so that the examination reveals true findings, not what the patient hopes to feel. The patient is asked where the sensation is felt.
- Any decrease in neurologic function is reported immediately.

The patient is also assessed for spinal shock, which is a complete loss of all reflex, motor, sensory, and autonomic activity below the level of the lesion that causes bladder paralysis and distention. The lower abdomen is palpated for signs of urinary retention and overdistention of the bladder. Further assessment is made for gastric dilation and paralytic ileus caused by an atonic bowel, a result of autonomic disruption.

Temperature is monitored because the patient may have periods of hyperthermia as a result of altered temperature control, which is due to the inability to perspire related to autonomic disruption. Body temperature becomes dependent on surroundings (poikilothermia).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired breathing associated with weakness or paralysis of diaphragm, abdominal, and intercostal muscles
- Impaired airway clearance associated with muscle weakness and inability to clear secretions
- Impaired mobility in bed and impaired mobility associated with motor and sensory impairments
- Risk for injury associated with motor and sensory impairment
- Risk for impaired skin integrity associated with immobility and sensory loss
- Urinary retention associated with inability to void spontaneously
- Constipation associated with presence of atonic bowel as a result of autonomic disruption
- Acute pain associated with treatment and prolonged immobility
- Autonomic dysreflexia associated with uninhibited sympathetic response of the nervous system following SCI

Collaborative Problems/Potential Complications

Potential complications may include the following:

- VTE
- Orthostatic hypotension

Planning and Goals

The goals for the patient may include improved breathing pattern and airway clearance, improved mobility, prevention of injury due to sensory impairment, maintenance of skin integrity, relief of urinary retention, improved bowel function, decreasing pain, early recognition of autonomic dysreflexia, and absence of complications.

Nursing Interventions

Promoting Adequate Breathing and Airway Clearance

Possible impending respiratory failure is detected by observing the patient, measuring vital capacity, monitoring oxygen saturation through pulse oximetry, and monitoring arterial blood gases. Early and vigorous attention to clearing bronchial and pharyngeal secretions can prevent retention of secretions and atelectasis. Suctioning may be indicated but should be used with caution to avoid stimulating the vagus nerve and producing bradycardia and cardiac arrest.

If the patient cannot cough effectively because of decreased inspiratory volume and inability to generate sufficient expiratory pressure, chest physiotherapy and assisted coughing may be indicated. Specific breathing exercises are supervised by the nurse to increase the strength and endurance of the inspiratory muscles, particularly the diaphragm. Assisted coughing

promotes clearing of secretions from the upper respiratory tract and is similar to the use of abdominal thrusts to clear an airway. Assisted coughing can be more effective than traditional suctioning because traditional suctioning clears the right mainstem bronchus, whereas sites for atelectasis and pneumonia are most commonly in the left lower lung lobe (Wang et al., 2017). Proper humidification and hydration are important to prevent secretions from becoming thick and difficult to remove even with coughing. The patient is assessed for signs of respiratory infection (e.g., cough, fever, dyspnea). Ascending edema of the spinal cord in the acute phase may cause respiratory difficulty that requires immediate intervention. Therefore, the patient's respiratory status must be monitored closely.

Improving Mobility

Proper body alignment is maintained at all times. If not on a specialized rotating bed, the patient should not be turned until the primary provider has indicated that it is safe to do so. Once safe for movement, the patient is repositioned frequently and is assisted out of bed as soon as the spinal column is stabilized. Various types of splints are used to prevent footdrop, which can often occur. When used, the splints are removed and reapplied every 2 hours. Trochanter rolls, applied from the crest of the ilium to the midthigh of both legs, help prevent external rotation of the hip joints. Patients with lesions above the midthoracic level have loss of sympathetic control of peripheral vasoconstrictor activity, leading to hypotension. These patients may tolerate changes in position poorly and require monitoring of blood pressure when positions are changed.

Contractures can develop rapidly with immobility and muscle paralysis. A joint that is immobilized too long becomes fixed as a result of contractures of the tendon and joint capsule. Atrophy of the extremities results from disuse. Contractures and other complications may be prevented by range-of-motion exercises that help preserve joint motion and stimulate circulation. Passive range-of-motion exercises should be implemented as soon as possible after the injury. Toes, metatarsals, ankles, knees, and hips should be put through a full range of motion at least four, or ideally five, times daily.

For most patients who have a cervical fracture without neurologic deficit, reduction in traction followed by rigid immobilization for 6 to 8 weeks restores skeletal integrity. These patients are allowed to move gradually to an erect position. A neck brace or molded collar is applied when the patient is mobilized after traction is removed (see Fig. 63-5).

Preventing Injury due to Sensory and Perceptual Alterations

The nurse assists the patient to compensate for sensory and perceptual alterations that occur with SCI. The intact senses above the level of the injury are stimulated through touch, aromas, flavorful food and beverages, conversation, and music. Additional strategies include the following:

- Providing glasses to enable the patient to see from the supine position

- Encouraging the use of hearing aids, if indicated, to enable the patient to hear conversations and environmental sounds
- Providing emotional support to the patient and family
- Educating the patient and family about strategies to compensate for, or cope with, sensory deficits

Maintaining Skin Integrity

Pressure injuries are a significant complication of SCI. They may begin within hours of an acute SCI where pressure is continuous and where the peripheral circulation is inadequate as a result of spinal shock and a recumbent position. It is important to move the patient from the backboard as soon as possible and inspect the skin. In addition, patients who wear cervical collars for prolonged periods may develop breakdown from the pressure of the collar under the chin, on the shoulders, and at the occiput. Pressure injury can add substantially to the personal and economic costs of living with SCI.

The most effective approach to addressing this costly complication of SCI is prevention. The patient's position is changed at least every 2 hours. Turning not only assists in the prevention of pressure injuries but also prevents pooling of blood and edema in the dependent areas. Careful inspection of the skin is made each time the patient is turned. The skin over the pressure points is assessed for redness or breaks; the perineum is checked for soilage, and the catheter is observed for adequate drainage. The patient's general body alignment and comfort are assessed. Special attention should be given to pressure areas in contact with the transfer board.

In addition, the patient's skin should be kept clean by washing with a mild soap, rinsing well, and blotting dry. Pressure-sensitive areas should be kept well lubricated and soft with oil or emollient lotion. The patient is educated about the danger of pressure injuries and is encouraged to take control and make decisions about appropriate skin care. See Chapter 56 for other aspects of care and prevention of pressure injuries.

Maintaining Urinary Elimination

Immediately after SCI, the urinary bladder becomes atonic and cannot contract by reflex activity. Urinary retention is the immediate result. During the initial acute phase, a urinary catheter is inserted; however, prompt discontinuation is advised due to high risk for catheter-associated urinary tract infection (CAUTI). Once discontinued, the patient has no sensation of bladder distention and overstretching of the bladder and detrusor muscle may occur, delaying the return of bladder function.

Intermittent catheterization is carried out to avoid overdistention of the bladder and high risk for UTI due to retention of urine. At an early stage, family members are shown how to carry out intermittent catheterization and are encouraged to participate in this facet of care, because they will be involved in long-term follow-up and must be able to recognize complications so that treatment can be instituted.

The patient is educated to record fluid intake, voiding pattern, amounts of residual urine after voiding, characteristics of urine, and any unusual sensations that may occur. The management of a **neurogenic bladder** (bladder dysfunction that results from a disorder or dysfunction of the nervous system) is addressed during the rehabilitation phase of care. The types of neurogenic bladder differ according to which motor or sensory pathways are disrupted (Hickey & Strayer, 2020).

External catheters (condom catheters) and leg bags to collect spontaneous voidings are useful for male patients with reflex or total incontinence. The appropriate design and size must be chosen for maximal success, and the patient or caregiver must be taught how to apply the condom catheter and how to provide daily hygiene including skin inspection. Instruction on emptying the leg bag must also be provided, and modifications can be made for patients with limited hand dexterity.

Improving Bowel Function

Immediately after SCI, a paralytic ileus usually develops as a result of neurogenic paralysis of the bowel; therefore, a nasogastric tube is often required to relieve distention and to prevent vomiting and aspiration (Stoffel, Van der Aa, Wittmann, et al., 2018).

Bowel activity usually returns within the first week. With the intake of nutrition, it is important to establish a bowel program. A bowel program can help to control bowel movements by establishing a pattern of planned evacuation. The nurse administers prescribed combinations of stool softeners, stimulant laxatives, bulking laxatives, and rectal laxatives along with rectal stimulation, to counteract the effects of immobility and analgesic agents (Stoffel et al., 2018).

Providing Comfort Measures: The Patient in Traction with Tongs or Halo Vest

A patient who has had pins, tongs, or calipers placed for cervical stabilization may have a headache or discomfort for several days after the pins are inserted. Patients initially may be bothered by the rather startling appearance of these devices, but usually they readily adapt to it because the device provides comfort for the unstable neck (see Fig. 63-6). The patient may complain of being caged in and of noise created by any object coming in contact with the frame of a halo device, but they can be reassured that adaptation will occur.

The areas around the four pin sites of a halo device are cleaned at least daily and observed for redness, drainage, and pain. The pins are observed for loosening, which may contribute to infection. If one of the pins becomes detached, the head is stabilized in a neutral position by one person, while another notifies the primary provider. A torque screwdriver should be readily available in case the screws on the frame need tightening.

The skin under the halo vest is inspected for excessive perspiration, redness, and skin blistering, especially on the bony prominences. The vest is opened at the sides to allow the torso to be washed. The liner of the vest should not

become wet, because dampness causes skin excoriation. Powder is not used inside the vest, because it may contribute to the development of pressure injuries. The liner should be changed periodically to promote hygiene and good skin care. If the patient is to be discharged with the vest, detailed instructions must be given to the family, with time allowed for them to demonstrate the necessary skills of halo vest care (see Chart 63-8).

Recognizing Autonomic Dysreflexia

Autonomic dysreflexia, also known as autonomic hyperreflexia, is an acute life-threatening emergency that occurs as a result of exaggerated autonomic responses to stimuli that are harmless in people without SCI. It occurs only after spinal shock has resolved. This syndrome is characterized by a severe, pounding headache with paroxysmal hypertension, profuse diaphoresis above the spinal level of the lesion (most often of the forehead), nausea, nasal congestion, and bradycardia. It occurs among patients with cord lesions above T6 (the sympathetic visceral outflow level) after spinal shock has subsided. The sudden increase in blood pressure may cause retinal hemorrhage, hemorrhagic stroke, myocardial infarction, or seizures (Hickey & Strayer, 2020). A number of stimuli may trigger this reflex: distended bladder (the most common cause); distention or contraction of the visceral organs, especially the bowel (from constipation, impaction); or stimulation of the skin (tactile, pain, thermal stimuli, pressure injury). Because this is an emergency situation, the objectives are to remove the triggering stimulus and to avoid the possibility of serious complications (Eldahan & Rabchevsky, 2018).

The following measures are carried out:

- The patient is placed immediately in a sitting position to lower the blood pressure.

Chart 63-8  **HOME CARE CHECKLIST**

The Patient with a Halo Vest

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
  - Describe the rationale for the use of the halo vest.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, rehabilitation team, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., diet, ADLs, IADLs, activity) necessary for recovery and health maintenance, as applicable.
  - Demonstrate safe techniques to assist the patient with self-care, hygiene, and ambulation.
  - Demonstrate assessment of frame, traction, tongs, and pins.
  - Demonstrate pin care using correct technique.
  - Demonstrate care of skin, including assessment (e.g., reddened or irritated areas, breakdown).
  - Identify signs and symptoms of infection.
  - Explain the reasons for and the method for changing the vest liner.
  - Identify holistic measures of pain management.
- Identify signs and symptoms of complications (e.g., venous thromboembolism, respiratory impairment, urinary tract infection).
- Describe emergency measures if respiratory or other complications develop while the patient is in the halo vest or if the frame becomes dislodged.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health-promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

- Rapid assessment is performed to identify and alleviate the cause.
- The bladder is emptied immediately via a urinary catheter. If an indwelling catheter is not patent, it is irrigated or replaced with another catheter.
- The rectum is examined for a fecal mass. If present, a topical anesthetic agent is inserted 10 to 15 minutes before the mass is

removed, because visceral distention or contraction can cause autonomic dysreflexia.

- The skin is examined for any areas of pressure, irritation, or broken skin.
- Any other stimulus that could be the triggering event, such as an object next to the skin or a draft of cold air, must be removed.
- If these measures do not relieve the hypertension and excruciating headache, antihypertensive medications may be prescribed and given slowly by the IV route.
- The medical record is labeled with a clearly visible indicator concerning the risk for autonomic dysreflexia.
- The patient is instructed about prevention and management measures.
- Any patient with a lesion above the T6 segment is informed that such an episode is possible and may occur even many years after the initial injury.

Monitoring and Managing Potential Complications

Patients are at high risk for VTE after SCI. The patient must be assessed for symptoms of VTE including DVT and PE. Chest pain, shortness of breath, and changes in arterial blood gas values must be reported promptly to the primary provider. The circumferences of the thighs and calves are measured and recorded daily; further diagnostic studies are performed if a significant increase is noted. Patients remain at high risk for thrombophlebitis for several months after the initial injury. Patients with paraplegia or tetraplegia are at increased risk for the rest of their lives. Immobilization and the associated venous stasis, as well as varying degrees of autonomic disruption, contribute to the high risk and susceptibility for DVT.

Anticoagulation should be initiated within 72 hours of injury and continued for at least 3 months (Abrams & Wakasa, 2019). The use of low-molecular-weight heparin or low-dose unfractionated heparin may be followed by long-term oral anticoagulation (i.e., warfarin). Additional measures such as range-of-motion exercises, anti-embolism stockings, and adequate hydration are important preventive measures. SCDs may also be used to reduce venous pooling and promote venous return. It is also important to avoid external pressure on the lower extremities that may result from flexion of the knees while the patient is in bed.

Orthostatic Hypotension. For the first 2 weeks after SCI, the blood pressure tends to be unstable and can be quite low. It gradually returns to preinjury levels, but periodic episodes of severe orthostatic hypotension frequently interfere with efforts to mobilize the patient. Interruption in the reflex arcs that normally produce vasoconstriction in the upright position, coupled with vasodilation and pooling in abdominal and lower extremity vessels, can result in hypotension. Orthostatic hypotension is a particularly common problem for patients with lesions above T7. In some patients with tetraplegia, even slight elevations of the head can result in blood pressure dysregulation.

A number of techniques can be used to reduce the frequency of hypotensive episodes. Close monitoring of vital signs before and during position changes is essential. Optimization of fluid status and vasopressor medication can be used to treat the profound vasodilation. Anti-embolism stockings should be applied to improve venous return from the lower extremities. Abdominal binders may also be used to encourage venous return and provide diaphragmatic support when the patient is upright (Abrams & Wakasa, 2019). Activity should be planned in advance, and adequate time should be allowed for a slow progression of position changes from recumbent to sitting and upright. Tilt tables frequently are helpful in assisting patients to make this transition.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. In most cases, patients with SCI (i.e., patients with tetraplegia or paraplegia) need long-term rehabilitation. The process begins during hospitalization as acute symptoms begin to subside or come under better control and the overall deficits and long-term effects of the injury become clear. The goals begin to shift from merely surviving the injury to learning strategies necessary to cope with the alterations that the injury imposes on activities of daily living (ADLs). The emphasis shifts from ensuring that the patient is stable and free of complications to specific assessment and planning designed to meet the patient's rehabilitation needs. Patient education may initially focus on the injury and its effects on mobility; dressing; and bowel, bladder, and sexual function. As the patient and family acknowledge the consequences of the injury and the resulting disability, the focus of education broadens to address issues necessary for carrying out the tasks of daily living and taking charge of their lives. Education must begin in the acute phase and continue throughout rehabilitation and the patient's entire life as changes occur, the patient ages, and problems arise.

Caring for the patient with SCI at home may at first seem a daunting task to the family. They will require dedicated nursing support to gradually assume full care of the patient. Although maintaining function and preventing complications will remain important, goals regarding self-care and preparation for discharge will assist in a smooth transition to rehabilitation and eventually to the community.

Continuing and Transitional Care. The goal of the rehabilitation process is independence. The nurse becomes a support to both the patient and the family, assisting them to assume responsibility for increasing aspects of patient care and management. Care for the patient with SCI involves members of all health care disciplines, which may include nursing, medicine, rehabilitation, respiratory therapy, physical and occupational therapy, case management, and social services. The nurse often serves as a coordinator of the management team and as a liaison with rehabilitation centers and home care agencies.

There are many challenges in providing care to the patient with SCI; meeting their psychological needs can be particularly challenging (Bibi,

Rasmussen, & McLiesh, 2018). The patient and family often require assistance in dealing with the psychological impact of the injury and its consequences; referral to a psychiatric clinical nurse specialist or other mental health care professional often is helpful. Therapeutic horseback riding may help increase balance, muscle strength, and self-esteem (Stergiou, Tzoufi, Ntzani, et al., 2017).

The nurse should reassure female patients with SCI that pregnancy is not contraindicated and fertility is relatively unaffected, but that pregnant women with acute or chronic SCI pose unique management challenges. The normal physiologic changes of pregnancy may predispose women with SCI to many potentially life-threatening complications, including autonomic dysreflexia, pyelonephritis, respiratory insufficiency, thrombophlebitis, PE, and unattended delivery. Preconception assessment and counseling are strongly recommended to ensure that the woman is in optimal health and to increase the likelihood of an uneventful pregnancy and healthy outcomes (Crane, Doody, Schiff, et al., 2019).

As more patients survive acute SCI, they face the changes associated with aging with a disability. Three common secondary health problems experienced by persons living with SCI include chronic pain, spasticity, and depression (Abrams & Wakasa, 2019). Education in the home and community focuses on health promotion and addresses the need to minimize risk factors (e.g., tobacco use, substance use disorder, obesity). Routine health-screening and preventive services are needed for the older adult with SCI for early detection of secondary health problems. Home health nurses and others who have contact with patients with SCI are in a position to educate patients about healthy lifestyles, remind them of the need for health screenings, and make referrals as appropriate. Assisting patients to identify accessible health care providers, clinical facilities, and imaging centers may increase the likelihood that they will participate in health screening.

Evaluation

Expected patient outcomes may include:

1. Demonstrates improvement in gas exchange and clearance of secretions, as evidenced by normal breath sounds on auscultation
    a. Breathes easily without shortness of breath
    b. Performs hourly deep breathing exercises, coughs effectively, and clears pulmonary secretions
    c. Is free of respiratory infection (e.g., has temperature, respiratory rate, and pulse within normal limits; breath sounds clear to auscultation; absence of purulent sputum)
2. Moves within limits of the dysfunction and demonstrates completion of exercises within functional limitations
3. Avoids injury due to sensory, motor, and perceptual alterations

a. Uses assistive devices (e.g., glasses, hearing aids, electronic devices) as indicated
b. Describes sensory, motor, and perceptual alterations as a consequence of injury

4. Demonstrates optimal skin integrity
   a. Exhibits normal skin turgor; skin is free of reddened areas or breaks
   b. Participates in skin care and monitoring procedures within functional limitations
5. Regains urinary bladder function
   a. Exhibits no signs of UTI (e.g., has temperature within normal limits; voids clear, dilute urine)
   b. Has adequate fluid intake
   c. Participates in bladder training program within functional limitations
6. Regains bowel function
   a. Reports regular pattern of bowel movement
   b. Consumes adequate dietary fiber and oral fluids
   c. Participates in bowel training program within functional limitations
7. Reports absence of pain and discomfort
8. Recognizes manifestations of autonomic dysreflexia if they occur (e.g., headache, diaphoresis, nasal congestion, bradycardia, or diaphoresis)
9. Is free of complications
   a. Demonstrates no signs of thrombophlebitis, DVT, or PE
   b. Maintains blood pressure within normal limits
   c. Reports no lightheadedness with position changes

Medical Management of Long-Term Complications of SCI

The patient faces a lifetime disability, requiring ongoing follow-up and care. The expertise of a number of health professionals including physicians (specifically a physiatrist), rehabilitation nurses, occupational therapists, physical therapists, psychologists, social workers, rehabilitation engineers, and vocational counselors, is necessary at different times as the need arises.

The patient with an SCI has a shorter life expectancy compared to those who have not had an SCI (Abrams & Wakasa, 2019). As patients with SCI age, they have many of the same medical problems as others. In addition, they face the threat of complications associated with their disability (Hickey & Strayer, 2020). Usually, patients are encouraged to follow-up at an outpatient spinal cord clinic when complications and other issues arise. Lifetime care includes assessment of the urinary tract at prescribed intervals because there is the likelihood of continuing alteration in detrusor and sphincter function, and the patient is prone to UTI (Abrams & Wakasa, 2019).

Long-term problems and complications of SCI include disuse syndrome, autonomic dysreflexia (discussed earlier), bladder and kidney infections, spasticity, and depression (Abrams & Wakasa, 2019). Pressure injuries with potential complications of sepsis, osteomyelitis, and fistulas occur in about 10% of patients. Spasticity may be particularly disabling. Heterotopic ossification (overgrowth of bone) in the hips, knees, shoulders, and elbows occurs in many patients after SCI. Spasticity and heterotopic ossification are painful and can produce a loss of range of motion (Abrams & Wakasa, 2019). Management includes observing for and addressing any alteration in physiologic status and psychological outlook, as well as the prevention and treatment of long-term complications. The nursing role involves emphasizing the need for vigilance in self-assessment and care.

NURSING PROCESS

The Patient with Tetraplegia or Paraplegia

Assessment

Assessment focuses on the patient's general condition, complications, and how the patient is managing at that particular point in time. A head-to-toe assessment and review of systems should be part of the database, with emphasis on the areas that are prone to problems in this population. A thorough inspection of all areas of the skin for redness or breakdown is critical. The nurse reviews the established bowel and bladder program with the patient, because the program must continue uninterrupted. Patients with tetraplegia or paraplegia have varying degrees of loss of motor power, deep and superficial sensation, vasomotor control, bladder and bowel control, and sexual function. They are faced with potential complications related to immobility, skin breakdown and pressure injuries, recurring UTIs, and contractures. Knowledge about these particular issues can further guide the assessment in any setting. Nurses in all settings, including home care, must be aware of these potential complications in the lifetime management of these patients.

An understanding of the emotional and psychological responses to tetraplegia or paraplegia is achieved by observing the responses and behaviors of the patient and family and by listening to their concerns (Bailey, Gammage, van Ingen, et al., 2017). Documenting these assessments and reviewing the plan with the entire team on a regular basis provide insight into how both the patient and the family are coping with the changes in lifestyle and body functioning. Additional information frequently can be gathered from the social worker or psychiatric/mental health worker.

It takes time for the patient and family to comprehend the magnitude of the disability. They may go through stages of grief, including shock, disbelief, denial, anger, depression, and acceptance. During the acute phase of the injury, denial can be a protective mechanism to shield the patient from the acute reality of what has happened. As the patient realizes the permanent nature of paraplegia or tetraplegia, the grieving process may be prolonged and all-encompassing because of the recognition that long-held plans and expectations are interrupted or permanently altered. A period of depression often follows as the patient experiences a loss of self-esteem in areas of self-identity, sexual functioning, and social and emotional roles. Exploration and assessment of these issues can assist in developing a meaningful plan of care.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired mobility in bed and impaired mobility associated with loss of motor function

- Risk for disuse
- Risk for impaired skin integrity associated withpermanent sensory loss and immobility
- Urinary retention associated with level of injury
- Constipation associated with effects of spinal cord disruption
- Impaired sexual functioning associated with neurologic dysfunction
- Difficulty coping associated with impact of disability on daily living
- Lack of knowledge about requirements for long-term management

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Spasticity
- Infection and sepsis

Planning and Goals

The goals for the patient may include attainment of some form of mobility; maintenance of healthy, intact skin; achievement of bladder management without infection; achievement of bowel control; achievement of sexual expression; strengthening of coping mechanisms; knowledge of long-term management; and absence of complications.

Nursing Interventions

The patient requires extensive rehabilitation, which is less difficult if appropriate nursing management has been carried out during the acute phase of the injury or illness. Nursing care is one of the key factors determining the success of the rehabilitation program. The main objective is for the patient to live as independently as possible in the home and community.

Increasing Mobility

Exercise Programs. The unaffected parts of the body are built up to optimal strength to promote maximum self-care. The muscles of the hands, arms, shoulders, chest, spine, abdomen, and neck must be strengthened in the patient with paraplegia, because they must bear full weight on these muscles to ambulate. The triceps and the latissimus dorsi are important muscles used in crutch walking. The muscles of the abdomen and the back also are necessary for balance and for maintaining the upright position.

To strengthen these muscles, the patient can do push-ups when in a prone position and sit-ups when in a sitting position. Extending the arms while holding weights (traction weights can be used) also develops muscle strength. Squeezing rubber balls or crumbling newspaper promotes hand strength.

With encouragement from all members of the rehabilitation team, the patient with paraplegia can develop the increased exercise tolerance needed for gait training and ambulation activities. The importance of maintaining cardiovascular fitness is stressed to the patient. Alternative exercises to increase the heart rate to target levels must be designed within the patient's abilities.

Mobilization. After the spine is stable enough to allow the patient to assume an upright posture, mobilization activities are initiated. A brace or vest may be used, depending on the level of the lesion. The sooner muscles are used, the less chance there is of disuse atrophy. The earlier the patient is brought to a standing position, the less opportunity there is for osteoporotic changes to take place in the long bones. Weight bearing also reduces the possibility of renal calculi and enhances many other metabolic processes.

Braces and crutches enable some patients with paraplegia to ambulate for short distances. Ambulation using crutches requires a high expenditure of energy. Motorized wheelchairs and specially equipped vans can provide greater independence and mobility for patients with high-level SCI or other lesions. Every effort should be made to encourage the patient to be as mobile and active as possible.

Long-term risks include altered body composition, a decrease in lean body mass, decreased bone mineral density, and increased body mass index (BMI). Patients are at high risk for obesity due to high fat intake combined with decreased physical activity (Silveira, Winter, Clark, et al., 2019). This puts patients at higher risk for developing comorbid conditions such as diabetes and cardiovascular diseases. Patients benefit from nutrition counseling to prevent these secondary complications. For those who are overweight or who have obesity, weight-loss programs must be designed to accommodate the dietary and physical activity barriers that are unique to this population.

Preventing Disuse Syndrome

Patients are at high risk for development of contractures as a result of disuse syndrome due to the musculoskeletal system changes (atrophy) brought about by the loss of motor and sensory functions below the level of injury. Range-of-motion exercises must be provided at least four times a day, and care is taken to stretch the Achilles tendon with exercises, to prevent footdrop. The patient is repositioned frequently and is maintained in proper body alignment whether in bed or in a wheelchair.

Contractures can complicate day-to-day care, increasing the difficulty of positioning and decreasing mobility. A number of surgical procedures have been tried, with varying degrees of success. These techniques are used if more conservative approaches fail, but the best treatment is prevention.

Promoting Skin Integrity

Because these patients spend a great portion of their lives in wheelchairs, pressure injuries are an ever-present threat. Contributing factors are permanent sensory loss over pressure areas; immobility, which makes relief of pressure difficult; trauma from bumps (against the wheelchair, toilet, furniture, and so forth) that cause unnoticed abrasions and wounds; loss of protective function of the skin from excoriation and maceration due to excessive perspiration and possible incontinence; and poor general health (anemia, diabetes), leading to

poor tissue perfusion. See Chapter 56 for discussion on the prevention and management of pressure injuries.

The person with tetraplegia or paraplegia must take responsibility for monitoring (or directing monitoring) of their skin status. This involves relieving pressure and not remaining in any position for longer than 2 hours, in addition to ensuring that the skin receives meticulous attention and cleansing. The patient is educated that pressure injuries develop over bony prominences that are exposed to unrelieved pressure in the sitting and lying positions. The most vulnerable areas are identified. The patient with paraplegia is instructed to use mirrors, if possible, to inspect these areas morning and night, observing for redness, slight edema, or any abrasions. While in bed, the patient should turn at 2-hour intervals and then inspect the skin again for redness that does not fade on pressure. The bottom sheet should be checked for wetness and for creases. The patient with tetraplegia or paraplegia, who cannot perform these activities, is encouraged to direct others to check these areas and prevent pressure injuries from developing.

The patient is educated to relieve pressure while in the wheelchair by doing push-ups, leaning from side to side to relieve ischial pressure, and tilting forward while leaning on a table. The caregiver for the patient with tetraplegia will need to perform these activities if the patient cannot do so independently. A wheelchair cushion is prescribed to meet individual needs, which may change in time with changes in posture, weight, and skin tolerance. A referral can be made to a rehabilitation engineer, who can measure pressure levels while the patient is sitting and then tailor the cushion and other necessary aids and assistive devices to the patient's needs.

The diet for the patient with tetraplegia or paraplegia should be high in protein, vitamins, and calories to ensure minimal wasting of muscle and the maintenance of healthy skin, and high in fluids to maintain well-functioning kidneys. Excessive weight gain and obesity should be avoided because they further limit mobility.

Improving Bladder Management

The effect of the spinal cord lesion on the bladder depends on the level of injury, the degree of cord damage, and the length of time after injury. A patient with tetraplegia or paraplegia usually has either a reflex or a nonreflex bladder. Both bladder types increase the risk for UTI.

The nurse emphasizes the importance of maintaining an adequate flow of urine by encouraging a fluid intake of about 2.5 L daily. The patient should empty the bladder frequently so that there is minimal residual urine and should pay attention to personal hygiene, because infection of the bladder and kidneys almost always occurs by the ascending route. The perineum must be kept clean and dry, and attention must be given to the perianal skin after defecation. Underwear should be cotton (which is more absorbent) and should be changed at least once a day.

If an external catheter (condom catheter) is used, the sheath is removed nightly; the penis is cleansed to remove urine and is dried carefully, because warm urine on the periurethral skin promotes the growth of bacteria. Attention also is given to the collection bag. The nurse emphasizes the importance of monitoring for signs of UTI: cloudy, foul-smelling urine or hematuria (blood in the urine); fever; or chills.

The female patient who cannot achieve reflex bladder control or self-catheterization may need to wear pads or waterproof undergarments. Surgical intervention may be indicated in some patients to create a urinary diversion.

Establishing Bowel Control

The objective of a bowel training program is to establish bowel evacuation through reflex conditioning. If the SCI occurs above the sacral segments or nerve roots and there is reflex activity, the anal sphincter may be massaged (digital stimulation) to stimulate defecation. If the cord lesion involves the sacral segment or nerve roots, anal massage is not performed because the anus may be relaxed and lack tone. Massage is also contraindicated if there is spasticity of the anal sphincter. The anal sphincter is massaged by inserting a gloved finger (which has been adequately lubricated) 2.5 to 3.7 cm (1 to 1.5 inches) into the rectum and moving it in a circular motion or from side to side. It soon becomes apparent which area triggers the defecation response. This procedure should be performed at regular time intervals (usually every 48 hours), after a meal, and at a time that will be convenient for the patient at home (Schmelzer, Daniels, & Baird, 2018). The patient is educated about the symptoms of impaction (frequent loose stools; constipation) and is cautioned to watch for hemorrhoids. A diet with sufficient fluids and fiber is essential to developing a successful bowel training program, avoiding constipation, and decreasing the risk for autonomic dysreflexia.

Counseling on Sexual Expression

Many patients with tetraplegia and paraplegia can have some form of meaningful sexual relationship, although modifications are necessary. The patient and partner benefit from counseling about the range of sexual expression possible, special techniques and positions, exploration of body sensations offering sensual feelings, and urinary and bowel hygiene as related to sexual activity. For men with erectile failure, penile prostheses enable them to have and sustain an erection, and medications for erectile dysfunction may be helpful. Sildenafil, vardenafil, and tadalafil, for example, are oral smooth muscle relaxants that cause blood to flow into the penis, resulting in an erection (see Chapter 53). Patients who are sexually active should undergo counseling in birth control methods, as some methods (e.g., oral contraceptives) may increase risks for complications such as VTE (Hickey & Strayer, 2020).

Sexual education and counseling services are included in the rehabilitation services at spinal centers. Small group meetings in which patients can share

their feelings, receive information, and discuss sexual concerns and practical aspects are helpful in producing effective attitudes and adjustments.

Enhancing Coping Mechanisms

The impact of the disability and loss becomes marked when the patient returns home. Each time something new enters the patient's life (e.g., a new relationship, going to work), the patient is reminded anew of their limitations. Grief reactions and depression are common.

To work through depression, the patient must have some hope for relief in the future. The nurse can encourage the patient to feel confident in their ability to achieve self-care and relative independence. The role of the nurse ranges from caretaker during the acute phase to educator, counselor, and facilitator as the patient gains mobility and independence.

The patient's disability affects not only the patient but also the entire family. In many cases, family therapy is helpful in working through issues as they arise. Adjustment to the disability leads to the development of realistic goals for the future, making the best of the abilities that are left intact, and reinvesting in other activities and relationships. Rejection of the disability causes self-destructive neglect and nonadherence to the therapeutic program, which leads to more frustration and depression. Crises for which interventions may be sought include social, psychological, marital, sexual, and psychiatric problems. The family usually requires counseling, social services, and other support systems to help them cope with the changes in their lifestyle and socioeconomic status.

A major goal of nursing management is to help the patient overcome their sense of futility and to encourage the patient in the emotional adjustment that must be made before they are willing to venture into the outside world. However, an excessively sympathetic attitude on the part of the nurse may cause the patient to develop an overdependence that defeats the purpose of the entire rehabilitation program. The patient is educated and assisted when necessary, but the nurse should avoid performing activities that the patient can do independently with a little effort. This approach to care more than repays itself in the satisfaction of seeing a patient, who is completely demoralized and helpless, become independent and find meaning in a newly emerging lifestyle.

Monitoring and Managing Potential Complications

Spasticity. Muscle spasticity can be a problematic complication of tetraplegia and paraplegia. Flexor or extensor spasms occur below the level of the spinal cord lesion and can interfere with the rehabilitation process, ADLs, and quality of life (Abrams & Wakasa, 2019). Spasticity results from an imbalance between the facilitatory and inhibitory effects on neurons that exist normally. The area of the cord distal to the site of injury or lesion becomes disconnected from the higher inhibitory centers located in the brain, so facilitatory impulses, which originate from muscles, skin, and ligaments, predominate.

Spasticity is defined as a condition of increased muscle tone in a muscle that is weak. Initial resistance to stretching is quickly followed by sudden relaxation. The stimulus that precipitates spasm can be obvious, such as movement or a position change, or subtle, such as a slight jarring of the wheelchair. Most patients with tetraplegia or paraplegia have some degree of spasticity. Because it increases muscle tone, some degree of spasticity can be beneficial in patients who are weak (Abrams & Wakasa, 2019). With SCI, the onset of spasticity usually occurs from a few weeks to 6 months after the injury. The same muscles that are flaccid during the period of spinal shock develop spasticity during recovery. The intensity of spasticity tends to peak approximately 2 years after the injury, after which the spasms tend to regress.

Management of spasticity is based on the severity of symptoms and the degree of incapacitation. Botulinum toxin injections, as well as the antispasmodic medication baclofen, available in an oral and an intrathecal form, may be indicated (Comerford & Durkin, 2020). Oral medications such as diazepam, dantrolene, and tizanidine help control spasms by decreasing sympathetic outflow from the central nervous system. Other forms of adjunctive therapy include oral and transdermal forms of clonidine (Hickey & Strayer, 2020). All of the antispasmodic medications cause drowsiness, weakness, and vertigo in some patients. Passive range-of-motion exercises and frequent turning and repositioning are helpful, because stiffness tends to increase spasticity. These activities also are essential in the prevention of contractures, pressure injuries, and bowel and bladder dysfunction.

Infection and Sepsis. Patients with tetraplegia and paraplegia are at increased risk for infection and sepsis from a variety of sources: urinary tract, respiratory tract, and pressure injuries. Sepsis remains a major cause of complications and death in these patients. Prevention of infection and sepsis is essential through maintenance of skin integrity, complete emptying of the bladder at regular intervals, and prevention of urinary and fecal incontinence. The risk for respiratory infection can be decreased by avoiding contact with people who have symptoms of respiratory infection, performing coughing and deep breathing exercises to prevent pooling of respiratory secretions, receiving yearly influenza vaccines, and giving up smoking. A high-protein diet is important in maintaining an adequate immune system, as is avoiding factors that may reduce immune system function, such as excessive stress, drug abuse, and excessive alcohol intake.

If infection occurs, the patient requires thorough assessment and prompt treatment. Antibiotic therapy and adequate hydration, in addition to local measures (depending on the site of infection), are initiated immediately.

UTIs are minimized or prevented by aseptic technique in catheter management, adequate hydration, a bladder training program, and prevention of overdistention of the bladder and urinary stasis.

Skin breakdown and infection are prevented by the maintenance of a turning schedule; frequent back care; regular assessment of all skin areas; regular cleaning and lubrication of the skin; passive range-of-motion exercise

to prevent contractures; pressure relief over broken skin areas, bony prominences, and heels; and wrinkle-free bed linen.

Pulmonary infections are managed and prevented by frequent coughing, turning, and deep breathing exercises and chest physiotherapy; aggressive respiratory care and suctioning of the airway if a tracheostomy is present; assisted coughing as needed; and adequate hydration.

Infections of any kind can be life-threatening. Aggressive nursing interventions are key to prevention, detection, and early management.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Patients with tetraplegia or paraplegia are at risk for complications for the rest of their lives. Therefore, a major aspect of nursing care is educating the patient and family about these complications and about strategies to minimize risks. UTIs, contractures, infected pressure injuries, and sepsis may necessitate hospitalization. Other late complications that may occur include lower extremity edema, joint contractures, respiratory dysfunction, and pain. To avoid these and other complications, the patient and family members are educated about skin care, catheter care, range-of-motion exercises, breathing exercises, and other care techniques. Education is initiated as soon as possible and extends into the rehabilitation or long-term care facility and home. In all aspects of care, it is important for the nurse and patient to set mutual goals and discuss the tasks the patient is capable of doing independently and which tasks the patient needs assistance to complete. See Chart 63-9 for a summary of education points for managing a therapeutic regimen at home.

Continuing and Transitional Care. Referral for home care is often appropriate for assessment of the home setting, patient education, and evaluation of the patient's physical and emotional status. During visits by the nurse, education about strategies to prevent or minimize potential complications is reinforced. The home environment is assessed for adequacy of care and for safety. Environmental modifications are made, and specialized equipment is obtained, ideally before the patient goes home.

The nurse also assesses the patient's and the family's adherence to recommendations and their use of coping strategies. The use of inappropriate coping strategies (e.g., drug and alcohol use) is assessed, and referrals to counseling are made for the patient and family. Appropriate and effective coping strategies are reinforced. The nurse reviews previous education and determines the need for further physical or psychological assistance. The patient's self-esteem and body image may be extremely poor at this time. Because people with high levels of social support often report feelings of well-being despite major physical disability, it is beneficial for the nurse to assess and promote further development of the support system and effective coping strategies for each patient. Caregivers and peer mentors play a critical role in

helping patients feel less dependent, experience feelings of freedom, and reintegrate into the community (Gassaway, Jones, Sweatman, et al., 2017).

Chart 63-9  **HOME CARE CHECKLIST**

Avoiding Complications of SCI

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of SCI and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- State what types of environmental and safety changes or supports are needed for optimum functioning in the home.
- Demonstrate skin care:
  - Inspect bony prominences every morning and evening.
  - Identify stage I pressure injury and actions to take if present.
  - Change dressings for stage II to IV pressure injuries.
  - State dietary requirements to promote healing of pressure injuries.
  - Demonstrate pressure relief at prescribed intervals.
  - State sitting schedule and demonstrate weight lifts in wheelchair.
  - Demonstrate adherence to bed turning schedule, bed positioning, and the use of bridging techniques.
  - Apply and wear protective boots at prescribed times.
  - Demonstrate correct wheelchair sitting posture.
  - Demonstrate techniques to avoid friction and shear in bed.
  - Demonstrate proper hygiene to maintain skin integrity.
- Demonstrate bladder care:
  - State schedule for voiding, toileting, and catheterization.
  - Identify relationship of fluid intake to voiding and catheterization schedule.
  - Demonstrate clean self-intermittent catheterization and care of catheterization equipment.
  - Demonstrate indwelling catheter care.
  - Demonstrate application of external condom catheter.
  - Demonstrate application, emptying, and cleaning of urinary drainage bag.
  - Demonstrate application of incontinence pads and performance of perineal hygiene.
  - State signs and symptoms of urinary tract infection.
  - State signs and symptoms of urinary catheter blockage.
- Demonstrate bowel care:
  - State optimum dietary intake to promote evacuation.
  - Describe medication regimen for bowel care (drug names, schedule, and dosage).

- Identify schedule for optimum bowel evacuation.
- Demonstrate techniques to increase intraabdominal pressure; Valsalva maneuver; abdominal massage; leaning forward.
- Demonstrate techniques to stimulate bowel movements: ingesting warm liquids; digital stimulation; insertion of suppositories.
- Demonstrate optimum position for bowel evacuation: on toilet with knees higher than hips; left side in bed with knees flexed and head of bed elevated 30 to 45 degrees.
- Identify complications and corrective strategies for bowel retraining: constipation, impaction, diarrhea, hemorrhoids, rectal bleeding, anal tears.

- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify contact details of support services for people with disability and their caregivers/families.
- Demonstrate how to access transportation:
  - Identify locations of wheelchair accessibility for public buses or trains.
  - Identify contact details for private wheelchair van.
  - Contact Division of Motor Vehicles for handicapped parking permit.
  - Contact Division of Motor Vehicles for driving test when appropriate.
  - Identify resources for adapting private vehicle with hand controls or wheelchair lift.
- Identify vocational rehabilitation resources:
  - State the contact details for vocational rehabilitation services.
  - Identify educational opportunities that may lead to future employment.
- Identify community resources for recreation:
  - State local recreation centers that offer programs for people with disability.
  - Identify leisure activities that can be pursued in the community.
  - State how to reach primary provider with questions or if complications arise.
  - State follow-up schedule.
  - Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, instrumental activities of daily living; SCI, spinal cord injury.

The patient requires continuing, lifelong follow-up by the primary provider, physical therapist, and other rehabilitation team members, because the neurologic deficit is usually permanent and new deficits, complications, and secondary conditions can develop. These require prompt attention before they take their toll in additional physical impairment, time, morale, and financial

costs. Research suggests that education and peer mentoring may decrease complications following SCI (Abrams & Wakasa, 2019; Gassaway et al., 2017). The local counselor for the Office of Vocational Rehabilitation works with the patient with respect to job placement or additional educational or vocational training. The nurse is in a good position to remind patients and family members of the need for continuing health promotion and screening practices. Referral to accessible health care providers and imaging centers is important in health promotion and health screening. See Chapter 7 for more information on chronic illness and disability.

Evaluation

Expected patient outcomes may include:

1. Attains maximum form of mobility
2. Contractures do not develop
3. Maintains healthy, intact skin
4. Achieves bladder control, absence of UTI
5. Achieves bowel control
6. Reports sexual satisfaction
7. Shows improved adaptation to environment and others
8. Exhibits reduction in spasticity
    a. Reports understanding of the precipitating factors
    b. Uses measures to reduce spasticity
9. Describes long-term management required
10. Exhibits absence of complications

CRITICAL THINKING EXERCISES

1 ebp You are caring for a 27-year-old woman who was involved in a motor vehicle crash. Her CT scan of the head revealed a left subdural hematoma. The Glasgow Coma Scale was 10, pupils were reactive bilaterally, and she moved all four extremities. She had no difficulties with airway control or respirations. What evidence-based nursing interventions will you implement in your care of this patient? Identify the criteria used to evaluate the strength of the evidence for these practices.

2 pq A 32-year-old man fell off his 10-speed bicycle, hitting the side of his head on the pavement, losing consciousness. He woke up in the emergency department confused and complained of a headache. His CT scan of the head revealed a right epidural hematoma. He was taken to the operating room for a craniotomy. What are your priority neurological assessments for this patient postoperatively? What are your priority nursing interventions to control intracranial pressure?

3 ipc A 22-year-old man, on a dare from his friends, attempted a backward flip from a 20-feett-high rocky cliff into shallow water that was less than 6-feet deep. He struck his back on a large protruding rock before entering the water and sustained a C-5 hyperextension injury to his neck. Upon arrival to the ED, his vital signs are stable but he is flaccid in all extremities with no sensation below nipple line. Which members of the interdisciplinary team do you anticipate will provide care for this patient? What steps will the interdisciplinary team take to address the patient's health care needs?

64 Management of Patients with Neurologic Infections, Autoimmune Disorders, and Neuropathies

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Differentiate among the infectious disorders of the nervous system according to causes, manifestations, medical care, and nursing management.
2. Describe the pathophysiology, clinical manifestations, and medical and nursing management of multiple sclerosis, myasthenia gravis, and Guillain–Barré syndrome.
3. Use the nursing process as a framework for care of the patient with multiple sclerosis or Guillain–Barré syndrome.
4. Explain disorders of the cranial nerves, their manifestations, and indicated nursing interventions.
5. Apply the nursing process as a framework for care of the patient with a cranial nerve disorder.

NURSING CONCEPTS

Family
Functional Ability
Immunity
Infection
Inflammation
Mobility
Nutrition
Patient Education
Sensory Perception

GLOSSARY

ataxia: impaired coordination of movement during voluntary movement
diplopia: the awareness of two images of the same object occurring in one or both eyes (*synonym*: double vision)
dysphagia: difficulty swallowing
dysphonia: voice impairment or altered voice production
hemiparesis: weakness of one side of the body, or part of it, due to an injury in the motor area of the brain
hemiplegia: paralysis of one side of the body, or part of it, due to an injury in the motor area of the brain
neuropathy: general term indicating a disorder of the nervous system
paresthesia: numbness, tingling, or a “pins and needles” sensation
prion: a pathogen smaller than a virus that is resistant to standard sterilization procedures
ptosis: drooping of the eyelids
spasticity: muscular hypertonicity with increased resistance to stretch often associated with weakness, increased deep tendon reflexes, and diminished superficial reflexes

The diverse group of neurologic disorders that make up infectious and autoimmune disorders and cranial and peripheral neuropathies presents unique challenges for nursing care. The nurse who cares for patients with these disorders must have a clear understanding of the pathophysiology, diagnostic testing, medical and nursing care, and rehabilitation processes. Some of the issues nurses must help patients and families confront include adaptation to the effects of the disease, potential changes in family dynamics, and end-of-life issues.

INFECTIOUS NEUROLOGIC DISORDERS

The infectious disorders of the nervous system include meningitis, brain abscesses, various types of encephalitis, Creutzfeldt–Jakob disease (CJD), and variant Creutzfeldt–Jakob disease (vCJD). The clinical manifestations, assessment and diagnostic findings, as well as the medical and nursing management, are related to the specific infectious process.

Meningitis

Meningitis is inflammation of the meninges, which cover and protect the brain and spinal cord. The two main types of meningitis are bacterial and viral (Norris, 2019). Meningitis can be the main reason a patient is hospitalized, or it can develop during hospitalization; it is classified as septic or aseptic. Septic meningitis is caused by bacteria. The bacteria *Streptococcus pneumoniae* and *Neisseria meningitidis* are responsible for 80% to 90% of cases of bacterial meningitis in adults (Hickey & Strayer, 2020). In aseptic meningitis, the cause is viral or secondary to cancer or having a weakened immune system, such as in human immunodeficiency virus (HIV). The most common causative agents are the enteroviruses (Norris, 2019). Aseptic meningitis occurs more frequently in the summer and early fall.

First-year college students and members of the military who have not been vaccinated are at higher risk for meningococcal meningitis. Although infections occur year-round, the peak incidence is in the winter and early spring. Factors that increase the risk of bacterial meningitis include tobacco use and viral upper respiratory infection, because they increase the amount of droplet production. Otitis media and mastoiditis increase the risk of bacterial meningitis, because the bacteria can cross the epithelial membrane and enter the subarachnoid space. People with immune system deficiencies are also at greater risk for development of bacterial meningitis (Norris, 2019).

Pathophysiology

Meningeal infections generally originate in one of two ways: through the bloodstream as a consequence of other infections or by direct spread, such as might occur after a traumatic injury to the facial bones or secondary to invasive procedures.

Once the causative organism enters the bloodstream, it crosses the blood–brain barrier and proliferates in the cerebrospinal fluid (CSF). The host immune response stimulates the release of cell wall fragments and lipopolysaccharides, facilitating inflammation of the subarachnoid and pia mater. Because the cranial vault contains little room for expansion, the

inflammation may cause increased intracranial pressure (ICP). CSF circulates through the subarachnoid space, where inflammatory cellular materials from the affected meningeal tissue enter and accumulate.

The prognosis for bacterial meningitis depends on the causative organism, the severity of the infection and illness, and the timeliness of treatment. The *N. meningitidis* bacterium results in an acute fulminant presentation approximately 10% of the time. This presentation may include adrenal damage, circulatory collapse, and widespread hemorrhages (Waterhouse–Friderichsen syndrome) (Hickey & Strayer, 2020). This syndrome is the result of endothelial damage and vascular necrosis caused by the bacteria.

Clinical Manifestations

Headache along with fever and chills are frequent initial symptoms. Fever tends to remain high throughout the course of the illness. The headache is usually either steady or throbbing and very severe as a result of meningeal irritation. Older adults may have mental status changes and focal neurologic deficits (Mount & Boyle, 2017). Meningeal irritation results in a number of other well-recognized signs common to all types of meningitis (Norris, 2019; Weber & Kelley, 2018):

- *Neck immobility:* Nuchal rigidity (a stiff and painful neck) can be an early sign, and any attempts at flexion of the head are difficult because of spasms in the muscles of the neck. Usually, the neck is supple, and the patient can easily bend the head and neck forward.
- *Positive Kernig sign:* When the patient is lying with the thigh flexed on the abdomen, the leg cannot be completely extended (see Fig. 64-1A). When Kernig sign is bilateral, meningeal irritation is suspected.
- *Positive Brudzinski sign:* When the patient's neck is flexed (after ruling out cervical trauma or injury), flexion of the knees and hips is produced; when the lower extremity of one side is passively flexed, a similar movement is seen in the opposite extremity (see Fig. 64-1B). Brudzinski sign is a more sensitive indicator of meningeal irritation than Kernig sign.
- *Photophobia (extreme sensitivity to light):* This finding is common due to irritation of the meninges, especially around the diaphragm sellae.
- A rash can be a striking feature of *meningococcal meningitidis* infection, occurring in about half of patients with this type of meningitis. Skin lesions develop, ranging from a petechial rash with purpuric lesions to large areas of ecchymosis.

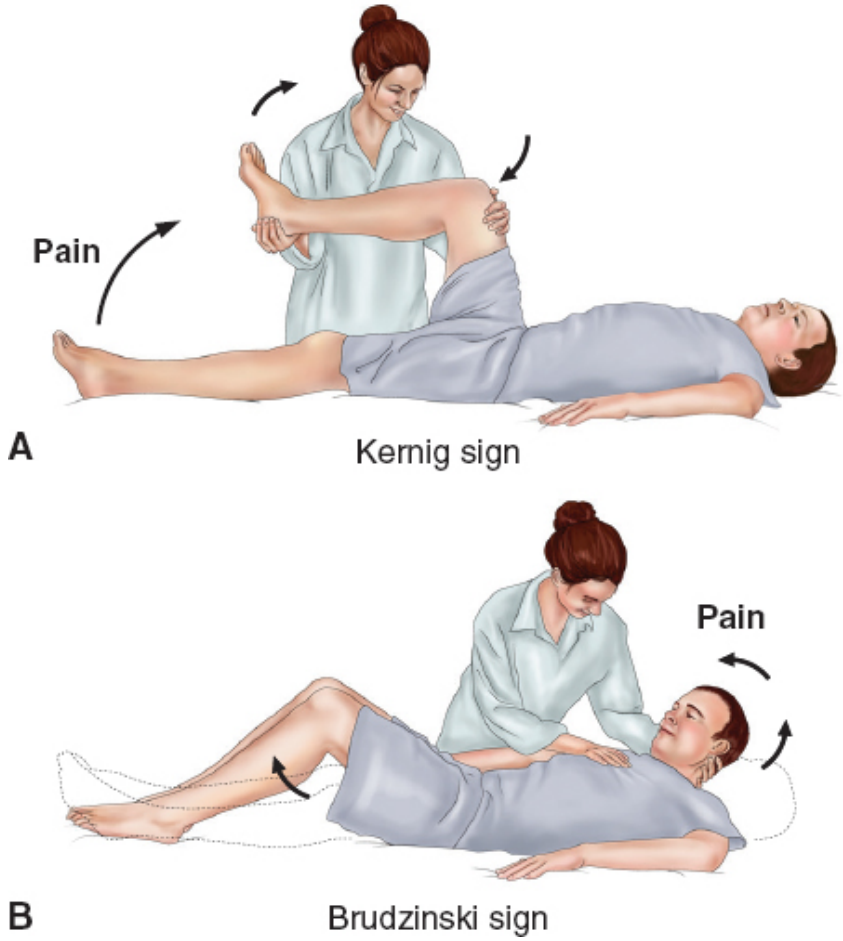

Figure 64-1 • Testing for meningeal irritation. **A.** Kernig sign. Flex the patient's leg at both the hip and knee and then straighten the knee. **B.** Brudzinski sign. As the neck is flexed, watch the hips and knees for a reaction.

Disorientation and memory impairment are common early in the course of the illness. The changes depend on the severity of the infection as well as the individual response to the physiologic processes. Behavioral manifestations are also common. As the illness progresses, lethargy, unresponsiveness, and coma may develop.

Seizures can occur and are the result of areas of irritability in the brain. ICP increases secondary to diffuse brain swelling or hydrocephalus (Hickey & Strayer, 2020). The initial signs of increased ICP include decreased level of consciousness (LOC) and focal motor deficits. If ICP is not controlled, the uncus of the temporal lobe may herniate through the tentorium, causing pressure on the brainstem. Brainstem herniation is a life-threatening event that causes cranial nerve dysfunction and depresses the centers of vital functions, such as the medulla. See Chapter 61 for discussion of the patient with a change in LOC or increased ICP.

An acute fulminant infection produces signs of sepsis: an abrupt onset of high fever, extensive purpuric lesions (over the face and extremities), shock,

and signs of disseminated intravascular coagulation (see Chapter 29). Death may occur within a few hours after onset of the infection.

Assessment and Diagnostic Findings

If the clinical presentation suggests meningitis, diagnostic testing is conducted to identify the causative organism. A computed tomography (CT) scan is used to detect a shift in brain contents (which may lead to herniation) prior to a lumbar puncture in patient with altered LOC, papilledema, neurologic deficits, new onset of seizure, immunocompromised state, or history of central nervous system (CNS) disease. Bacterial culture and Gram staining of CSF and blood are key diagnostic tests (Hickey & Strayer, 2020). An overview of CSF values and alterations in bacterial, viral, and fungal meningitis is presented in Table 64-1. Gram staining allows for rapid identification of the causative bacteria and initiation of appropriate antibiotic therapy.

Prevention

The Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC) recommends that the meningococcal conjugated vaccine be given to youth at 11 to 12 years of age, with a booster dose at 16 years of age (CDC, 2020).

People in close contact with patients with meningococcal meningitis should be treated with antimicrobial chemoprophylaxis using rifampin, ciprofloxacin, or ceftriaxone. Therapy should be started within 24 hours after exposure because a delay limits the effectiveness of the prophylaxis. Vaccination should also be considered as an adjunct to antibiotic chemoprophylaxis for anyone living with a person who develops meningococcal infection. Vaccination against *Haemophilus influenzae* and *S. pneumoniae* should be encouraged for children and adults who are at-risk (CDC, 2020).

Medical Management

Successful outcomes depend on the early administration of an antibiotic agent that crosses the blood–brain barrier into the subarachnoid space in sufficient concentration to halt the multiplication of bacteria. Penicillin G in combination with one of the cephalosporins (e.g., ceftriaxone, cefotaxime) is most often administered intravenously (IV), emergently with suspected bacterial meningitis (Hickey & Strayer, 2020).

Dexamethasone has been shown to be beneficial as adjunct therapy in the treatment of acute bacterial meningitis and in pneumococcal meningitis if it is given before or concurrently with the first dose of antibiotic and every 6 hours for the next 4 days. Research suggests that dexamethasone improves the

outcome in adults and does not increase the risk of gastrointestinal bleeding (Hickey & Strayer, 2020).

Dehydration and shock are treated with fluid volume expanders. Seizures, which may occur early in the course of the disease, are treated with anticonvulsant medications. Increased ICP is treated as necessary (see Chapter 61).

Nursing Management

The patient with meningitis is critically ill; therefore, many of the nursing interventions are collaborative with the physician, respiratory therapist, and other members of the health care team. The patient's safety and well-being depend on sound nursing judgment. Most patients will need the following nursing interventions:

- Instituting infection control precautions until 24 hours after initiation of antibiotic therapy (oral and nasal discharge is considered infectious)
  - Assisting with pain management due to overall body aches and neck pain
  - Assisting with getting rest in a quiet, darkened room
  - Implementing interventions to treat the elevated temperature, such as antipyretic agents and cooling blankets
  - Encouraging the patient to stay hydrated either orally or peripherally
  - Ensuring close neurologic monitoring (see Chapter 61)

Neurologic status and vital signs are continually assessed. Pulse oximetry and arterial blood gas values are used to quickly identify the need for respiratory support if increasing ICP compromises the brainstem. Insertion of a cuffed endotracheal tube (or tracheotomy) and mechanical ventilation may be necessary to maintain adequate tissue oxygenation.

Blood pressure (usually monitored using an arterial line) is assessed for early manifestations of shock, which precedes cardiac or respiratory failure. Rapid IV fluid replacement may be prescribed, but care is taken to prevent fluid overload. Fever also increases the workload of the heart and cerebral metabolism. ICP will increase in response to increased cerebral metabolic demands. Therefore, measures are taken to reduce body temperature as quickly as possible.

TABLE 64-1 Cerebrospinal Fluid Values Diagnostic for Meningitis

Parameter	Normal CSF	Bacterial Meningitis	Viral Meningitis
Opening pressure (mm H_2O)	100–180	Elevated >180	Variable
Leukocyte count (white blood cell/mm^3)	0–5	Increased 100–5000	Increased 50–1000
Neutrophils (%)	0	≥80	<40
Protein (mg/dL)	15–50	Elevated 100–500	Normal or slightly increased
Glucose (mg/dL)	40–80; 0.6 times blood glucose level	<40; <0.4 times blood glucose level	Normal

CSF, cerebrospinal fluid.

Adapted from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological & neurosurgical nursing* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Other important components of nursing care include the following measures:

- Protecting the patient from injury secondary to seizure activity or altered LOC
  - Monitoring daily body weight; serum electrolytes; and urine volume, specific gravity, and osmolality, especially if syndrome of inappropriate antidiuretic hormone (SIADH) is suspected
  - Preventing complications associated with immobility, such as pressure injury and pneumonia

Any sudden, critical illness can be devastating to the family. Because the patient's condition is often critical and the prognosis guarded, the family needs to be informed about the patient's condition. Periodic family visits are essential to facilitate coping of the patient and family. An important aspect of the nurse's role is to support the family and assist them in identifying others who can be supportive to them during the crisis (Hickey & Strayer, 2020).

Promoting Home, Community-Based, and Transitional Care

After the patient has achieved physiologic homeostasis and has demonstrated achievement of major health care goals, rehabilitation continues either in a rehabilitation facility, skilled nursing facility, or at home. Continued support and evaluation by the nurse are essential.

Because patients may have been critically ill and focused on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices, such as regular physical examinations and appropriate diagnostic screening tests.

Brain Abscess

Brain abscesses account for less than 1% of space-occupying brain lesions in the United States (Hickey & Strayer, 2020). Brain abscesses are rare in people who are immunocompetent; they are more frequently diagnosed in people who are immunosuppressed as a result of an underlying disease or the use of immunosuppressive medications.

Pathophysiology

A brain abscess is a collection of infectious material within the tissue of the brain. Bacteria are the most common causative organisms. The most common predisposing conditions for abscesses among adults who are immunocompetent are otitis media and rhinosinusitis. It is estimated that 40% of brain abscesses are otogenic in origin (Hickey & Strayer, 2020). An abscess can result from intracranial surgery, penetrating head injury, or tongue piercing. Organisms causing brain abscess may reach the brain by hematologic spread from the lungs, gums, tongue, or heart, or from a wound or intra-abdominal infection.

Clinical Manifestations

The clinical manifestations of a brain abscess result from alterations in intracranial dynamics (edema, brain shift), infection, or the location of the abscess. Headache, usually worse in the morning, is the most prevalent symptom. Mental status changes may occur. Fever is present 53% of the time (Sonneville, Ruimy, Benzonana, et al., 2017). Vomiting and focal neurologic deficits occur as well. Focal deficits including weakness and decreasing vision reflect the area of brain that is involved. As the abscess expands, symptoms of increased ICP such as decreasing LOC and seizures occur (Hickey & Strayer, 2020).

Assessment and Diagnostic Findings

The baseline neurologic examination may reveal a variety of signs and symptoms based on the location of the abscess (see Chart 64-1). Neuroimaging with CT scanning with contrast is used most often to identify the size and location of the abscess. Cerebritis is a small infection in the brain that can progress to an abscess if not detected or treated. Aspiration of the abscess, guided by CT or MRI, is often used to culture and identify the infectious organism. MRI is the preferred study, because it provides higher resolution of the lesion and assists with identification of additional lesions if present

(Sonneville et al., 2017). Blood cultures are obtained if the abscess is believed to arise from a distant source.

Medical Management

Treatment is aimed at controlling increased ICP, draining the abscess, and providing antimicrobial therapy directed at the abscess and the main source of infection. Large IV doses of antibiotic agents are given to penetrate the blood–brain barrier and reach the abscess. The choice of the specific antibiotic medication is based on culture and sensitivity testing and directed at the causative organism. Antibiotics should be started as soon as possible; the initial antibiotic started typically is ceftriaxone combined with metronidazole, which will be adjusted based on the culture and sensitivity results (Brouwer & van de Beek, 2017). A stereotactic guided aspiration may be used to drain the abscess and identify the causative organism. Surgical excision is not the preferred method, except in cases where the abscess is large and multi-lobulated (Sonneville et al., 2017). Corticosteroids may be prescribed to help reduce the inflammatory cerebral edema if the patient shows evidence of an increasing neurologic deficit. Anticonvulsant medications may be prescribed to prevent or treat seizures (see Chapter 61).

Chart 64-1  **ASSESSMENT**

Assessing for Brain Abscesses

Be alert to the following signs and symptoms of brain abscess:

Frontal Lobe

- Expressive aphasia (inability to express oneself)
- Frontal headache
- Hemiparesis (weakness on one side of the body)
- Seizures

Temporal Lobe

- Changes in vision
- Facial weakness
- Localized headache
- Receptive aphasia (inability to understand language)

Cerebellar Abscess

- Ataxia
- Nystagmus (rhythmic, involuntary movements of the eye)
- Occipital headache

Nursing Management

Nursing care focuses on continuing to assess the neurologic status, administering medications, assessing the response to treatment, and providing supportive care.

Ongoing neurologic assessment alerts the nurse to changes in ICP, which may indicate a need for more aggressive intervention. The nurse also assesses and documents the responses to medications. Blood laboratory test results, specifically blood glucose and serum potassium levels, are closely monitored when corticosteroids are prescribed (Comerford & Durkin, 2020). Administration of insulin or electrolyte replacement may be required to return these values to within normal limits.

Patient safety is another key nursing responsibility. Injury may result from decreased LOC or falls related to motor weakness or seizures.

The patient with a brain abscess is very ill, with neurologic deficits, such as **hemiplegia** (paralysis of one side of the body, or part of it), **hemiparesis** (weakness of one side of the body, or part of it), seizures, visual deficits, and cranial nerve palsies that may persist after treatment. The nurse must assess the family's ability to express distress at the patient's condition, cope with the patient's illness and deficits, and obtain support. Treatment has improved and

70% of patients have no or minimal permanent neurologic deficits, but more research is needed on long-term function (Brouwer & van de Beek, 2017).

Herpes Simplex Encephalitis

Encephalitis is an acute inflammatory process of the brain tissue. The herpes simplex virus (HSV) is the most common cause of acute encephalitis in the United States, accounting for 10% to 15% of cases of encephalitis (Hickey & Strayer, 2020).

Pathophysiology

The pathology of encephalitis involves local necrotizing hemorrhage that becomes more generalized, followed by edema. There is also progressive deterioration of nerve cell bodies (Norris, 2019).

Clinical Manifestations

The initial symptoms of herpes simplex encephalitis include fever, headache, confusion, and hallucinations. Focal neurologic symptoms reflect the areas of cerebral inflammation and necrosis and include fever, headache, behavioral changes, focal seizures, dysphasia, hemiparesis, and altered LOC (Norris, 2019).

Assessment and Diagnostic Findings

Neuroimaging studies, such as electroencephalography (EEG), and CSF examination are used to diagnose encephalitis. MRI is used to detect inflammation that shows up as hyperintense (bright) areas (see Fig. 64-2). The EEG shows diffuse slowing or focal changes in the temporal lobe in the majority of patients. Lumbar puncture often reveals a high opening pressure, glucose within normal limits, and high protein levels in CSF samples (see Table 64-1). The polymerase chain reaction (PCR) is the standard test for early diagnosis of herpes simplex encephalitis. PCR identifies the deoxyribonucleic acid (DNA) bands of HSV-1 in the CSF with 95% sensitivity and 99% specificity rates (Hickey & Strayer, 2020).

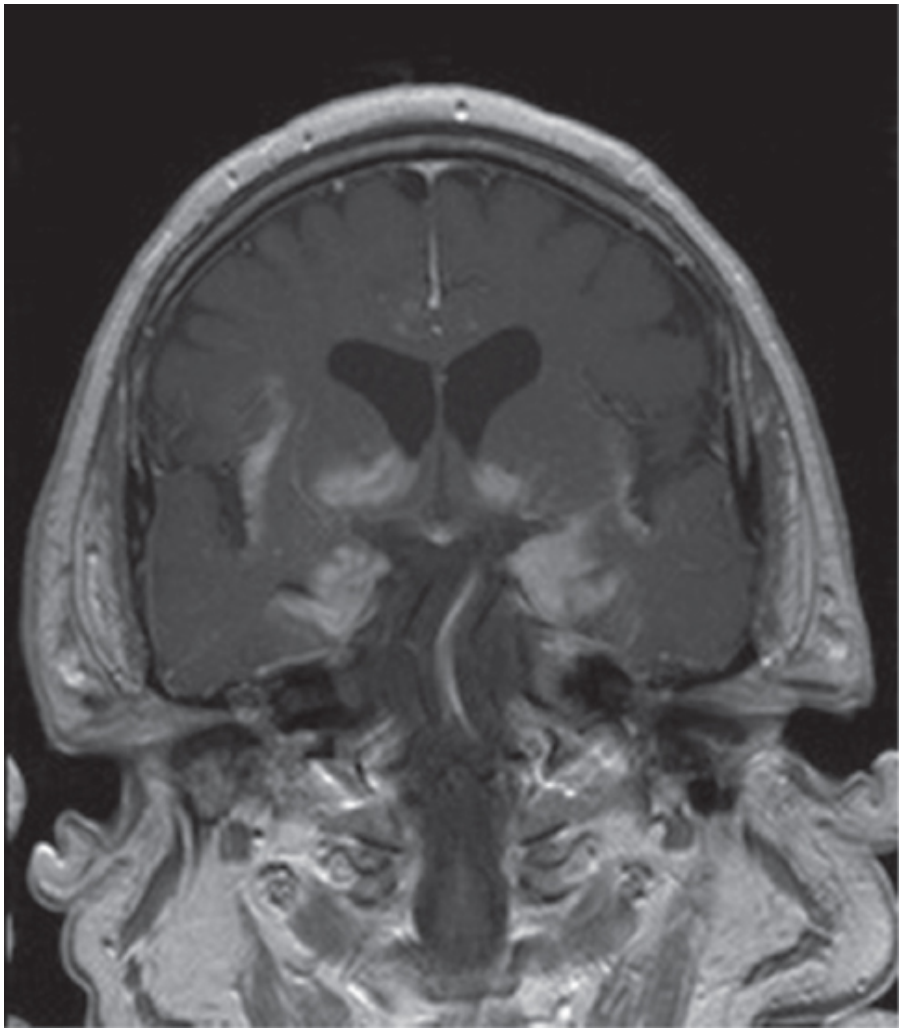

Figure 64-2 • Herpes simplex virus encephalitis. Coronal view, MRI scan. Note bilateral hyperintensity (bright) areas indicative of inflammation. Reprinted with permission from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological & neurosurgical nursing* (8th ed., Fig. 28-4C). Philadelphia, PA: Wolters Kluwer.

Medical Management

The antiviral agent acyclovir is the medication of choice in the treatment for HSV (Hickey & Strayer, 2020). Early administration of an antiviral agent (usually well tolerated) improves the prognosis associated with HSV. The mode of action is inhibition of viral DNA replication. To prevent relapse, treatment should continue for up to 3 weeks. Slow IV administration over 1 hour prevents crystallization of the medication in the urine. The usual dose of acyclovir is decreased if the patient has a history of renal insufficiency.

Nursing Management

Assessment of neurologic function is key to monitoring the progression of disease. Comfort measures to reduce headache include dimming the lights, limiting noise and visitors, grouping nursing interventions, and administering analgesic agents. Opioid analgesic medications may mask neurologic symptoms; therefore, they are used cautiously. Seizures and altered LOC require care directed at injury prevention and safety. Nursing care addressing patient and family anxieties is ongoing throughout the illness. Monitoring of blood chemistry test results and urinary output alert the nurse to the presence of renal complications related to antiviral therapy.

Arthropod-Borne Virus Encephalitis

Arthropod-borne viruses, or arboviruses, are maintained in nature through biologic transmission between susceptible vertebrate hosts by blood feeding arthropods (mosquitoes, psychodids, ceratopogonids, and ticks). Arthropod vectors transmit several types of viruses that cause encephalitis. The main vector in North America is the mosquito. Arbovirus infection (transmitted by arthropod vectors) occurs in specific geographic areas during the summer and fall. In the United States, there are five main arboviral encephalitides: eastern equine encephalitis, western equine encephalitis, St. Louis encephalitis, La Crosse encephalitis, and West Nile virus encephalitis (Hickey & Strayer, 2020).

Pathophysiology

Viral replication occurs at the site of the mosquito bite. The host immune response attempts to control viral replication. If the immune response is inadequate, viremia will ensue. The virus gains access to the CNS via the olfactory tract, resulting in encephalitis. It spreads from neuron to neuron, predominantly affecting the cortical gray matter, the brainstem, and the thalamus. Meningeal exudates compound the clinical presentation by irritating the meninges and increasing ICP.

Clinical Manifestations

St. Louis and West Nile virus encephalitis most commonly affect adults. An arboviral encephalitis occurs along a continuum with some cases having only flulike symptoms (i.e., headache and fever) but others progressing to specific neurologic manifestations that vary depending on the viral type (Hickey & Strayer, 2020). A unique clinical feature of arboviral encephalitis is SIADH with hyponatremia. Onset of symptoms is abrupt with fever, headache, dizziness, nausea, and malaise. If the disease spreads to the CNS, symptoms

include stiff neck, confusion, dizziness, and tremors. Coma can occur in severe cases, and mortality increases with age. Eastern equine encephalitis has the highest mortality rate at 50% (Hickey & Strayer, 2020).

Assessment and Diagnostic Findings

Arboviral infections are seasonal. Preliminary diagnosis is based on clinical presentation and location and dates of recent travel because certain viruses are endemic to certain geographic locales. Neuroimaging and CSF evaluation are useful in the diagnosis of encephalitis. The MRI scan demonstrates inflammation of the basal ganglia in cases of St. Louis encephalitis and inflammation in the periventricular area in cases of West Nile encephalitis. EEG can identify abnormal brain waves, which can help identify some viral infections.

Medical Management

No specific medication for arboviral encephalitis exists; therefore, treatment is supportive and symptom management is key (Hickey & Strayer, 2020). Controlling elevated ICP is a critical component of care in cases with neurologic manifestations.

Nursing Management

Many patients, particularly those with only fever and headache, are treated on an outpatient basis. If the patient is very ill, hospitalization may be required. The nurse carefully assesses neurologic status and identifies improvement or deterioration in the patient's condition. See Chapter 61 for management of the patient with increased ICP. Injury prevention is key in light of the potential for falls or seizures. Any encephalitis that progresses may result in death or lifelong residual health issues such as neurologic deficits and seizures. The family will need support and education to cope with these residual issues. The nurse may need to mobilize community support services for the patient and family, because the recovery may be long.

Public education addressing the prevention of arboviral encephalitis is a key nursing role. Clothing that provides coverage and insect repellents containing 20% to 35% diethyltoluamide (DEET) should be used on exposed clothing and skin in high-risk areas to decrease mosquito and tick bites (Hickey & Strayer, 2020). Remaining indoors at dawn and dusk when mosquito activity is highest is recommended. Screens should be in good repair in the home, and standing water should be removed. All cases of arboviral encephalitis must be reported to the local health department.

Creutzfeldt–Jakob and Variant Creutzfeldt–Jakob Diseases

CJD and vCJD belong to a group of degenerative, infectious neurologic disorders called *transmissible spongiform encephalopathies* (TSE). CJD is rare and has no identifiable cause. vCJD, the human variation of bovine spongiform encephalopathy (BSE) (mad cow disease), results from ingesting meat infected with prions. **Prions,** which cause TSEs, are pathogens smaller than a virus that are resistant to standard methods of disinfection and sterilization (Garcia, 2019). Although CJD and vCJD have distinct clinical features, one characteristic they share is a lack of CNS inflammation. CJD may lie dormant for decades before causing neurologic degeneration. The incubation period of vCJD seems to be shorter (less than 10 years). In both diseases, the symptoms are progressive, there is no definitive treatment, and the outcome is fatal often within 1 year of symptom onset (Hickey & Strayer, 2020).

Almost all cases of vCJD have been reported in the United Kingdom, with a smaller number of cases being identified in 10 other countries worldwide. The risk of vCJD in the United States is thought to be low, because cattle are fed primarily with soy-derived feed as opposed to feed containing animal parts.

Pathophysiology

The prion is a unique pathogen because it lacks nucleic acid, which enables the organism to withstand conventional means of disinfection and sterilization (Garcia, 2019). In both CJD and vCJD, the prion crosses the blood–brain barrier and is deposited in brain tissue and causes degeneration of brain tissue (Hickey & Strayer, 2020). Cell death occurs, and spongiform changes (spongy vacuoles) are produced in the brain. The spongiform vacuoles are surrounded by amyloid plaque.

There are three major forms of CJD (Manthorpe & Simcock, 2019). Approximately 85% of cases appear sporadically, hence this form is called sporadic CJD. The incidence is 1 case per 1 million people. Sporadic CJD occurs spontaneously with no risk factors. The second form is familial or hereditary CJD, and this type accounts for 5% to 10% of cases. The third type is acquired CJD. This form is transmitted by contaminated brain, tissue, or neurosurgical instruments and accounts for less than 1% of cases (World Health Organization [WHO]. n.d.).

The prion exists in lymphoid tissue and blood in both vCJD and CJD. Both prion diseases are believed to be bloodborne. No method is available to screen blood for infectivity. For this reason, the American Red Cross does not accept blood donation from anyone who has stayed more than 3 months in the United Kingdom (UK) between 1980 and 1996 or has received a blood transfusion in

France or the UK at any time between 1980 and the present (Miller, Grima, & Plonowski, 2020).

Clinical Manifestations

CJD and vCJD have several clinically distinct features. Psychiatric symptoms occur early in vCJD, whereas they are a late symptom in CJD. The mean age at onset of vCJD is 27 years, whereas the mean age for CJD onset is 65 years. The presenting symptoms of vCJD include affective symptoms (i.e., behavioral changes), sensory disturbance, and limb pain. Muscle spasms and rigidity, dysarthria (difficulty speaking), incoordination, cognitive impairment, and sleep disturbances follow. Patients with sporadic CJD present with mental deterioration, **ataxia** (inability to coordinate movements), and visual disturbance. Memory loss, involuntary movement, paralysis, and mutism occur as the disease progresses. After clinical presentation, people with vCJD survive an average of 14 months; those with CJD survive for less than 1 year (Manthorpe & Simcock, 2019).

Assessment and Diagnostic Findings

Brain biopsy, the only way to confirm diagnosis, is not recommended (Hickey & Strayer, 2020). The three diagnostic tests currently used in suspicious clinical presentations to support the diagnosis of CJD are immunologic assessment, EEG, and MRI scanning. Immunologic assessment of CSF detects a protein kinase inhibitor referred to as 14–3–3 (Hickey & Strayer, 2020). The presence of this inhibitor indicates neuronal cell death, which is not specific to CJD but does support the diagnosis. The EEG reveals a characteristic pattern over the duration of the disease. After initial slowing, the EEG shows periodic activity. Later in the course of the disease, the EEG shows burst suppressions characterized by periodic spikes alternating with slow periods. The MRI scan demonstrates symmetric or unilateral hyperintense signals arising from the basal ganglia.

Medical Management

After the onset of specific neurologic symptoms, progression of disease occurs quickly. There is no effective treatment for CJD or vCJD. The care of the patient is supportive and palliative. Goals of the interprofessional care team include prevention of injury related to immobility and dementia, promotion of patient comfort, and provision of support and education for the family.

Nursing Management

The nursing care of patients is primarily supportive and palliative. Psychological and emotional support of the patient and family throughout the course of the illness is needed. Care extends to providing for a dignified death and supporting the family through the processes of grief and loss. Hospice services are appropriate either at home or at an inpatient facility. See Chapter 13 for an in-depth discussion of end-of-life issues.

Prevention of disease transmission is an important part of nursing care. Although patient isolation is not necessary, the use of standard precautions is important. Institutional protocols are followed for handling of brain, spinal cord, pituitary gland, and eye tissue; and for exposure and decontamination of equipment. If surgery is necessary, it is recommended that disposable instruments be used and then incinerated, because conventional methods of sterilization do not destroy the prion (Hickey & Strayer, 2020). If disposable instruments cannot be used, stringent sterilization methods such as the use of bleach for cleaning and extended sterilization time for instruments should be used (Garcia, 2019).

AUTOIMMUNE PROCESSES

Autoimmune nervous system disorders include multiple sclerosis (MS), myasthenia gravis, and Guillain–Barré syndrome (GBS).

Multiple Sclerosis

MS is an immune-mediated, progressive demyelinating disease of the CNS. Demyelination refers to the destruction of myelin—the fatty and protein material that surrounds certain nerve fibers in the brain and spinal cord; it results in impaired transmission of nerve impulses (see Fig. 64-3). MS affects nearly 400,000 people in the United States (Hickey & Strayer, 2020; Norris, 2019). MS may occur at any age, but the age of peak onset is between 20 and 50 years; it affects women three times more than men (Hickey & Strayer, 2020).

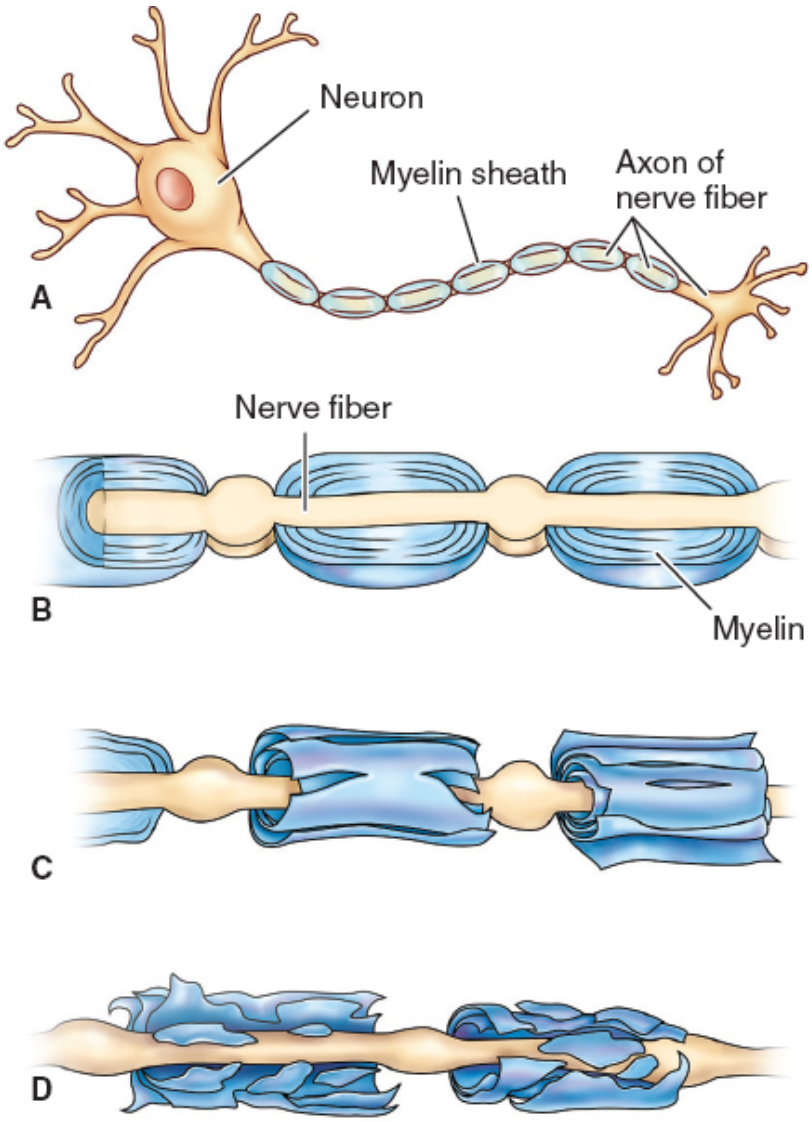

Figure 64-3 • The process of demyelination. **A, B.** A normal nerve cell and axon with myelin. **C, D.** The slow disintegration of myelin, resulting in a disruption in axon function.

The cause of MS is unknown and is an area of ongoing research. Autoimmune activity results in demyelination, but the sensitized antigen has not been identified. Multiple factors play a role in the initiation of the immune process. Geographic prevalence is highest in Europe, New Zealand, southern Australia, the northern United States, and southern Canada. MS is less prevalent in Asians. There is a greater frequency in northern colder latitudes (Hickey & Strayer, 2020).

MS is considered to have many risks, including genetic factors. It has not been found to be genetically transmitted but there have been 200 genetic variations related to MS (Hickey & Strayer, 2020). A specific virus capable of initiating the autoimmune response has not been identified. It is believed that DNA on the virus mimics the amino acid sequence of myelin, resulting in an

immune system cross-reaction in the presence of a defective immune system. Environmental risks include obesity, lack of vitamin D exposure, and a high salt diet in the teenage years (Hickey & Strayer, 2020).

There are several acute and subacute forms of MS. Less severe forms include radiologically isolated syndrome (RIS) and clinically isolated syndrome (CIS). RIS consists of MS-like lesions that are identified on MRI in the absence of clinical signs and symptoms. Approximately one third of patients are diagnosed with MS within 5 years of the identification of an incidental lesion on MRI (Coyle, 2019). CIS is the presence of acute or subacute clinical findings for at least 24 hours (Coyle, 2019).

The four main clinical forms are remitting-relapsing (RRMS), secondary progressive, primary progressive (PPMS), and progressive-relapsing (Bradshaw & Houtchens, 2018).

Pathophysiology

Sensitized T and B lymphocytes cross the blood–brain barrier; their function is to check the CNS for antigens and then leave. In MS, sensitized T cells remain in the CNS and promote the infiltration of other agents that damage the immune system. The immune system attack leads to inflammation that destroys mostly the white matter of the CNS myelin (which insulates the axon and speeds the conduction of impulses along the axon) and the oligodendroglial cells that produce myelin in the CNS (Norris, 2019).

Demyelination interrupts the flow of nerve impulses and results in a variety of manifestations, depending on the nerves affected. Plaques appear on demyelinated axons, further interrupting the transmission of impulses. Demyelinated axons are scattered irregularly throughout the CNS. The areas most frequently affected are the optic nerves, chiasm, and tracts; the cerebrum; the brainstem and cerebellum; and the spinal cord (Norris, 2019). The axons themselves begin to degenerate, resulting in permanent and irreversible damage.

Clinical Manifestations

The course of MS assumes many different patterns. In some patients, the disease follows a benign course, and symptoms are so mild that the patient does not seek health care or treatment. The patient with RIS will have no symptoms, while the typical presentation of CIS includes unilateral optic neuritis, focal symptoms, or partial myelopathy (Coyle, 2019).

Approximately 85% of patients have RRMS (Coyle, 2019). With each relapse, recovery is usually complete; however, residual deficits may occur and accumulate over time, contributing to functional decline. Over time, most patients with RRMS move to the secondary progressive form, in which disease

progression occurs with or without relapses. Approximately 15% of patients have PPMS, in which disabling symptoms steadily increase, with rare plateaus and temporary minor improvement. PPMS may result in quadriparesis, cognitive dysfunction, visual loss, and brainstem syndromes (Coyle, 2019). The least common presentation (about 5% of cases) is progressive-relapsing, which is characterized by relapses with continuous disabling progression between exacerbations (Coyle, 2019; Norris, 2019). The signs and symptoms of MS are varied and multiple, reflecting the location of the lesion (plaque) or combination of lesions. Physical, emotional, and cognitive symptoms impact the quality of life (Debska, Milaniak, & Skorupska-Krol, 2020; Kalb, Feinstein, Rohrig, et al., 2019). Fatigue, depression, weakness, numbness, difficulty in coordination, loss of balance, spasticity, and pain are all common (Norris, 2019). Visual disturbances due to lesions in the optic nerves or their connections may include blurring of vision, **diplopia** (double vision, or the awareness of two images of the same object occurring in one or both eyes), scotoma (patchy blindness), and total blindness.

Fatigue affects most people with MS and is often the most disabling symptom (Newland, Lorenz, Smith, et al., 2019). Heat, depression, anemia, deconditioning, and medication may contribute to fatigue. Avoiding hot temperatures, effective treatment of depression and anemia, a change in medication, as well as occupational and physical therapies may help manage fatigue (Coyle, 2019).

Pain is another common symptom of MS. Lesions on the sensory pathways cause pain. Additional sensory manifestations include paresthesias, dysesthesias, and proprioception loss. Many people with MS need daily analgesic medications. In some cases, pain is managed with opioids, anticonvulsant medications, or antidepressants. Rarely, surgery may be needed to interrupt pain pathways.

Among women who are perimenopausal, those with MS are more likely to have pain related to osteoporosis. In addition to estrogen loss, immobility and corticosteroid therapy play a role in the development of osteoporosis among women with MS. Bone mineral density testing is recommended for this high-risk group. See Chapter 36 for a discussion of the diagnosis of and treatment for osteoporosis.

Spasticity is characterized by muscle hypertonicity with increased resistance to stretch often associated with weakness, increased deep tendon reflexes, and diminished superficial reflexes. It occurs in 90% of patients with MS, most often in the lower extremities, and can include loss of the abdominal reflexes. Spasticity results from involvement of the pyramidal tracts, the main motor pathways of the spinal cord. Cognitive and psychosocial problems may reflect frontal or parietal lobe involvement. Some degree of cognitive change (e.g., memory loss, decreased concentration) occurs in about half of patients,

but severe cognitive changes with dementia (progressive organic mental disorder) are rare.

Involvement of the cerebellum or basal ganglia can produce ataxia and tremor. Loss of the control connections between the cortex and the basal ganglia may occur and cause emotional lability and euphoria. Bladder, bowel, and sexual dysfunctions are common. Additional complications include urinary tract infections (UTIs), constipation, pressure injury, contracture deformities, dependent pedal edema, pneumonia, and osteoporosis. Emotional, social, marital, economic, and vocational problems may also occur.

Exacerbations and remissions are characteristic of MS. During exacerbations, new symptoms appear and existing ones worsen; during remissions, symptoms decrease or disappear. Relapses may be associated with emotional and physical stress.

Gerontologic Considerations

The life expectancy for patients with MS is 7 to 14 years shorter than patients without MS (Coyle, 2019). Those diagnosed with secondary progressive disease live an average of 38 years after onset. Older adult patients with MS have specific physical and psychosocial challenges. They may have chronic health problems, for which they may be taking additional medications that could interact with medications prescribed for MS. The absorption, distribution, metabolism, and excretion of medications are altered in the older adult as a result of age-related changes in kidney and liver functions. Therefore, older adult patients must be monitored closely for adverse and toxic effects of MS medications and for osteoporosis (particularly if corticosteroids have been used frequently to treat exacerbations). The cost of medications may lead to poor adherence to the prescribed regimen in older adult patients on fixed incomes.

Older adult patients with MS are particularly concerned about increasing disability, family burden, marital concern, and the possible future need for nursing home care. Immobility resulting in fewer social opportunities contributes to loneliness and depression. In addition to functional loss, the physical challenges experienced by older adults with MS include spasticity, pain, bladder dysfunction, impaired sleep, and an increased need for assistance with self-care.

Assessment and Diagnostic Findings

The diagnosis of MS is based on clinical, imaging, and laboratory findings. An important component is the presence of plaques in the CNS disseminated in space and over time observed on MRI scans with no better explanation for the clinical presentation (Thompson, Banwell, Barkhof, et al., 2018). Additional

criteria are detailed in Table 64-2. Electrophoresis of CSF identifies the presence of oligoclonal banding (several bands of immunoglobulin G bonded together, indicating an immune system abnormality) (Thompson et al., 2018). Evoked potential studies can help define the extent of the disease process and monitor changes (Coyle, 2019). Underlying bladder dysfunction is diagnosed by urodynamic studies. Neuropsychological testing may be indicated to assess cognitive impairment. A sexual history helps identify changes in sexual function.

Medical Management

There is no cure for MS. An individual treatment program is indicated to relieve symptoms and provide continuing support, particularly for patients with cognitive changes, who may need more structure and support. The goals of treatment are to delay the progression of the disease, manage chronic symptoms, and treat acute exacerbations. Common symptoms requiring intervention include ataxia, bladder dysfunction, depression, fatigue, and spasticity. Management includes pharmacologic and nonpharmacologic strategies.

TABLE 64-2 The 2017 McDonald Criteria for Diagnosis of Multiple Sclerosis in Patients with an Attack at Onset

	Number of Lesions with Objective Clinical Evidence	Additional Data Needed for a Diagnosis of Multiple Sclerosis
≥2 clinical attacks	≥2	None[a]
≥2 clinical attacks	1 (as well as clear-cut historical evidence of a previous attack involving a lesion in a distinct anatomical location[b])	None[a]
≥2 clinical attacks	1	Dissemination in space demonstrated by an additional clinical attack implicating a different CNS site or by MRI
1 clinical attack	≥2	Dissemination in time demonstrated by an additional clinical attack or by MRI OR demonstration of CSF-specific oligoclonal bands[c]
1 clinical attack	1	Dissemination in space demonstrated by an additional clinical attack implicating a different CNS site or by MRI AND Dissemination in time demonstrated by an additional clinical attack or by MRI OR demonstration of CSF-specific oligoclonal bands[c]

If the 2017 McDonald Criteria are fulfilled and there is no better explanation for the clinical presentation, the diagnosis is multiple sclerosis. If multiple sclerosis is suspected by virtue of a clinically isolated syndrome but the 2017 McDonald Criteria are not completely met, the diagnosis is possible multiple sclerosis. If another diagnosis arises during the evaluation that better explains the clinical presentation, the diagnosis is not multiple sclerosis.

[a]No additional tests are required to demonstrate dissemination in space and time. However, unless MRI is not possible, brain MRI should be obtained in all patients in whom the diagnosis of multiple sclerosis is being considered. In addition, spinal cord MRI or CSF examination should be considered in patients with insufficient clinical and MRI evidence supporting multiple sclerosis, with a presentation other than a typical clinically isolated syndrome, or with atypical features. If imaging or other tests (e.g., CSF) are undertaken and are negative, caution needs to be taken before making a diagnosis of multiple sclerosis, and alternative diagnoses should be considered.

[b]Clinical diagnosis based on objective clinical findings for two attacks is most secure. Reasonable historical evidence for one past attack, in the absence of documented objective neurologic findings, can include historical events with symptoms and evolution characteristic for a previous inflammatory demyelinating attack; at least one attack, however, must be supported by objective findings. In the absence of residual objective evidence, caution is needed.

[c]The presence of CSF-specific oligoclonal bands does not demonstrate dissemination in time per se but can substitute for the requirement for demonstration of this measure.

Pharmacologic Therapy

Medications prescribed for MS include those for disease modification and those for symptom management. Disease-modifying therapies delay disease progression in many forms of MS (Rae-Grant, Day, Marrie, et al., 2018). Many types of medications are used for symptom management in MS.

Disease-Modifying Therapies

In the past decade, the number of disease-modifying therapies has increased dramatically (Bradshaw & Houtchens, 2018). The key concept of disease-modifying therapies is to reduce the frequency of relapse, the duration of relapse, and the number and size of plaques observed on MRI in RRMS; however, these therapies are not effective in PPMS (Hickey & Strayer, 2020). There is debate about whether to use disease-modifying therapies in patients with RIS to prevent future disease progression to MS (Coyle, 2019; Rae-Grant et al., 2018).

Interferon beta-1a and interferon beta-1b are administered subcutaneously every other day. Another preparation of interferon beta-1a may be given intramuscularly once a week and pegylated interferon beta-1a can be given subcutaneously every 14 days. Side effects of all interferon-beta medications include flulike symptoms, increased liver function tests, leukopenia, headache, depression, and skin necrosis (Coyle, 2019). For optimal control of disability, disease-modifying medications should be started early in the course of the disease (Rae-Grant et al., 2018).

Glatiramer acetate also reduces the rate of relapse in RRMS and is administered subcutaneously daily. It has some adverse effects, such as injection-site reactions and flushing, but these are usually self-limiting to a few minutes. There are no monitoring parameters (Bradshaw & Houtchens, 2018).

Teriflunomide, fingolimod, and dimethyl fumarate are oral disease-modifying therapies that may be better tolerated by the patient who has difficulty with injection reactions. These medications have significantly reduced relapse rates in several types of MS (Bradshaw & Houtchens, 2018). Ocrelizumab has a 6% annual relapse reduction rate in patients with PPMS (Bradshaw & Houtchens, 2018).

IV methylprednisolone, used to treat acute exacerbations, shortens the duration of relapse but has not been found to have long-term benefit (Bradshaw & Houtchens, 2018). It exerts anti-inflammatory effects by acting on T cells and cytokines. The medication is given as 1 g IV daily for 3 to 5

days, followed by an oral taper of prednisone. Side effects include mood swings, weight gain, and electrolyte imbalances (Comerford & Durkin, 2020).

The medication mitoxantrone is given via IV infusion every 3 months. Mitoxantrone can reduce the frequency of clinical relapses in patients with secondary progressive or worsening RRMS. Patients must be very closely monitored for side effects (i.e., cardiac toxicity), and there is a maximum lifetime dose that can be given (Hickey & Strayer, 2020).

Symptom Management

Medications are also prescribed for management of specific symptoms. Baclofen, a gamma-aminobutyric acid agonist, is the medication of choice for treating spasticity. It can be given orally or by intrathecal injection for severe spasticity (Hickey & Strayer, 2020). Benzodiazepines (e.g., diazepam), tizanidine, and dantrolene may also be used to treat spasticity and improve motor function (Hickey & Strayer, 2020). Patients with disabling spasms and contractures may require nerve blocks or surgical intervention. Fatigue that interferes with activities of daily living (ADLs) may be treated with amantadine, pemoline, or dalfampridine. Ataxia is a chronic problem most resistant to treatment. Medications used to treat ataxia include beta-adrenergic blockers (e.g., propranolol), the anticonvulsant agent gabapentin, and benzodiazepines (e.g., clonazepam).

Bladder and bowel problems are often difficult for patients, and a variety of medications (anticholinergic agents, alpha-adrenergic blockers, antispasmodic agents) may be prescribed. Nonpharmacologic strategies also assist in establishing effective bowel and bladder elimination.

UTI may be superimposed on the underlying neurologic dysfunction. Increased fluid intake and good perineal care help reduce the risk of UTI. Antibiotic agents are prescribed when appropriate. See Chapter 49 for further discussion of UTI management.

NURSING PROCESS

The Patient with MS

Assessment

Nursing assessment addresses neurologic deficits and the impact of the disease on the patient and family. The patient's mobility and balance are observed to determine whether there is risk of falling. Assessment of function is carried out both when the patient is well rested and when fatigued. The patient is assessed for weakness, spasticity, visual impairment, incontinence, and disorders of swallowing and speech. Additional areas of assessment include how MS has affected the patient's quality of life, how the patient is coping, adherence to the prescribed medication regimen, and what the patient would like to improve (Debska et al., 2020; Newland et al., 2019).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired mobility associated with weakness, muscle paresis, spasticity, increased weight
- Risk for fall associated with sensory and visual impairment, lower extremity weakness
- Fatigue associated with insufficient energy
- Difficulty coping associated with uncertainty of course of MS

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Constipation or fecal incontinence (see Chapter 41)
- Communication issues and potential for aspiration related to cranial nerve involvement (see cranial nerve discussion later in this chapter)
- Cognitive changes
- Managing therapies at home related to physical, psychological, and social limits imposed by MS
- Changes in sexuality
- Urinary incontinence (see Chapter 49)

Planning and Goals

The major goals for the patient may include promotion of physical mobility, avoidance of falls, decreasing fatigue, development of coping strategies, and absence of complications.

Nursing Interventions

An individualized program of physical, occupational, and speech-language therapy, rehabilitation, and education is combined with emotional support. An educational plan of care is developed to enable the person with MS to deal with the physiologic, social, and psychological problems that accompany chronic disease. The presence of depression, pain, fatigue, and walking difficulty all decrease physical activity. Assisting patients with management of these symptoms may help increase the level of physical activity and overall sense of well-being.

Promoting Physical Mobility

Relaxation and coordination exercises promote muscle efficiency. Progressive resistive exercises are used to strengthen weak muscles, because diminishing muscle strength is often significant in MS.

Exercise. Walking improves the gait, particularly the problem of loss of position sense of the legs and feet. If certain muscle groups are irreversibly affected, other muscles can be trained to compensate. Instruction in the use of assistive devices may be needed to ensure their safe and correct use.

Minimizing Spasticity and Contractures. Muscle spasticity is common and, in its later stages, is characterized by severe adductor spasm of the hips with flexor spasm of the hips and knees. Without relief, fibrous contractures of these joints occur. Warm packs may be beneficial, but hot baths should be avoided because of risk of burn injury secondary to sensory loss and increasing symptoms that may occur with elevation of the body temperature. Exposure to extreme cold is avoided as this may increase spasticity.

Daily exercises for muscle stretching are prescribed to minimize joint contractures. Special attention is given to the hamstrings, gastrocnemius muscles, hip adductors, biceps, and wrist and finger flexors. Muscle spasticity is common and interferes with usual function. Application of prescribed orthotics may help maintain a functional position and reduce contractures. A stretch–hold–relax routine is helpful for relaxing and treating muscle spasticity. Swimming and stationary bicycling are useful, and progressive weight bearing can relieve spasticity in the legs. The patient should not be hurried in any of these activities, because this often increases spasticity.

Activity and Rest. The patient is encouraged to work and exercise to a point just short of fatigue. Very strenuous physical exercise is not advisable, because it raises the body temperature and may aggravate symptoms. The patient is advised to take frequent short rest periods. Exposure to heat increases fatigue and muscle weakness, so air conditioning is recommended in at least one room.

Nutrition. Similar to the population at large, many patients with MS are overweight or have obesity. Contributing factors include the use of corticosteroids for exacerbations of symptoms and mobility

impairments as a result of the disease. Interventions to promote healthy eating and weight reduction need to take into account that fatigue and mobility impairments are barriers to engagement in nutritional behaviors for people with MS. Nurses also need to be certain to include family members in interventions and nutrition education, because they are often the gatekeepers for food preparation and selection. Additional strategies include avoidance of alcohol and cigarette smoking.

Preventing Falls

If motor dysfunction causes problems of incoordination and clumsiness, or if ataxia is apparent, then the patient is at risk for falls. To overcome this risk, the patient is instructed to walk with feet apart to widen the base of support and to increase walking stability. If loss of position sense occurs, the patient is instructed to watch their feet while walking. Gait training may require assistive devices (walker, cane, braces, crutches, parallel bars) and instruction about their use by a physical therapist. If the gait remains inefficient, a wheelchair or motorized scooter may be the solution. The occupational therapist is a valuable resource person in suggesting and securing aids to promote independence. If incoordination is a problem and tremor of the upper extremities occurs when voluntary movement is attempted (intention tremor), weighted wrist weights or neuromodulation devices may be used. The patient is trained in transfer and ADLs.

Because sensory loss may occur in addition to motor loss, pressure injuries are a continuing threat to skin integrity. The need to use a wheelchair continuously increases the risk. See Chapter 56 for a discussion of the prevention and treatment of pressure injury.

Managing Fatigue

Fatigue is a common symptom reported in 60% to 90% of those with MS, but the etiology remains unclear. It is often the most disabling symptom and the most common reason patients cease employment (Hickey & Strayer, 2020; Newland et al., 2019). Many factors contribute to fatigue and the nurse helps the patient identify risks and ameliorate those that lead to fatigue. Research that identified the relationships among MS-related symptoms, sleep hygiene behaviors, and sleep quality in adults with MS who report fatigue suggests that decreasing the use of electronic devices prior to sleep can improve sleep quality and lessen fatigue (Newland et al., 2019). See the Nursing Research Profile in Chart 64-2.

Strengthening Coping Mechanisms

The diagnosis of MS is distressing to the patient and family. They need to know that no two patients with MS have identical symptoms or courses of illness. Although some patients do experience significant disability, others have a near-normal lifespan with minimal disability. Some families, however, face acute frustrations and problems. MS affects people who are

often in an early stage of life and concerned about career and family responsibilities. Family conflict, disintegration, separation, and divorce are not uncommon. Often, young family members assume the responsibility of caring for a parent with MS. Nursing interventions in this area include assisting patients and families to manage or reduce stress and making appropriate referrals for counseling and support to minimize the adverse effects of dealing with chronic illness.

Chart 64-2  NURSING RESEARCH PROFILE

The Relationship Between MS and Sleep

Newland, P., Lorenz, R. A., Smith, J. M., et al. (2019). The relationship among multiple sclerosis-related symptoms, sleep quality, and sleep hygiene behaviors. *Journal of Neuroscience Nursing*, *51*(1), 37–42.

Purpose

Fatigue is common among those with MS and has a negative impact on many aspects of their lives. The purpose of this study was to examine the relationships among MS-related symptoms, sleep hygiene behaviors, and sleep quality in adults with MS who report fatigue.

Design

This was a descriptive correlational study with a convenience sample of 39 community dwelling adults with MS. Data were collected about demographic characteristics. Measures used to collect data included the revised MS-Related Symptom Scale, the patient self-report version of the Expanded Disability Status Scale, a single item sleep quality scale, the Pittsburgh Sleep Quality Index (PSQI), and a sleep behavior self-rating scale.

Findings

The mean age of participants was 45 years; 80% reported having RRMS and 20% reported PPMS. High levels of forgetfulness, anxiety, and difficulty concentrating were significantly correlated with poor sleep quality. Fatigue was higher in those who used electronic devices around bedtime and practiced poor sleep hygiene behaviors. Pain, a frequent symptom in those with MS, was not significantly related to sleep quality.

Nursing Implications

Nurses working with patients with MS should incorporate interventions for symptoms, particularly forgetfulness, anxiety, and difficulty concentrating, as they significantly impact sleep. Education should include the recommendation to remove electronic devices from the bedroom, and to restrict the use of technology in the hours prior to sleep.

The nurse, mindful of these complex problems, initiates home care and coordinates a network of services, including social services, speech therapy, physical therapy, and homemaker services. To strengthen the patient's coping skills, as much information as possible is provided. Patients need a list of available assistive devices, services, and resources.

Coping through problem solving involves helping the patient define the problem and develop alternatives for its management. Planning carefully, maintaining flexibility, and preserving a hopeful attitude are useful for psychological and physical adaptation.

Monitoring and Managing Potential Complications

Complications that can occur with MS are caused by damage to the myelin in the CNS. The nurse monitors for the presence of cognitive changes, how the patient is able to manage at home, or changes in sexuality. Cognitive changes or inability to manage prescribed therapies at home may be due to psychological effects of MS. The patient is monitored for the risk of suicide as 50% of patients with MS experience major depression and the suicide rate is twice that of the general population (Kalb et al., 2019).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. As the disease progresses, the patient and family need to learn new strategies to maintain optimal independence. Educating about self-care techniques may be initiated in the hospital or clinic setting and reinforced in the home. Self-care education may address the use of assistive devices, self-catheterization, and administration of medications that affect the course of the disease or treat complications. An education plan that addresses intramuscular or subcutaneous administration of medications (including side effects) is developed for the patient and their family or caregiver. The patient and family are educated about exercises that enable the patient to continue some form of activity or that maintain or improve function (see Chart 64-3).

Continuing and Transitional Care. After discharge, the nurse often provides education and reinforcement of new interventions in the patient's home. Nurses in the home setting assess for changes in the patient's physical and emotional status; provide physical care to the patient if required; coordinate outpatient services and resources; and encourage health promotion, appropriate health screenings, and adaptation. Modifications that allow independence in the home should be implemented (e.g., assistive eating devices, raised toilet seat, bathing aids, telephone modifications, long-handled comb, tongs, modified clothing).

If changes in the disease or its course are noted, the nurse encourages the patient to contact the primary provider, because treatment of an acute exacerbation or new problem may be indicated. Continuing health care and follow-up are recommended.

The patient with MS is encouraged to contact the local chapter of the National MS Society for services, publications, and contact with others who have MS (see the Resources section). Local chapters also provide direct services to patients. Through group interaction, the patient has an opportunity to meet others with similar problems, share experiences, and learn self-help methods.

Evaluation

Expected patient outcomes may include:

1. Improves physical mobility
    a. Participates in gait training and rehabilitation program
    b. Establishes a balanced program of rest and exercise
    c. Uses assistive devices correctly and safely
2. Is free of falls
    a. Monitors self and environment for falls risk factors
    b. Asks for assistance when necessary
3. Reports decreased level of fatigue
    a. Identifies strategies to decrease fatigue
    b. Maintains appropriate sleep hygiene behaviors

Chart 64-3  HOME CARE CHECKLIST

The Patient with MS

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of MS and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications.
    - Demonstrate correct techniques of administering injectable medications, if prescribed.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., exercise, activity) necessary to maintain health.
    - Demonstrate environmental modifications and adaptive techniques for accomplishing activities of daily living.
    - Identify strategies to manage symptoms (pain, cognitive responses, dysphagia, tremors, visual disturbances).
    - State how to prevent complications (e.g., pressure injury, pneumonia, depression).
    - Identify coping strategies.
    - Identify ways to minimize fatigue.
    - Explain how to prevent injury.
    - Identify optimal nutritional intake; consider weight reduction as indicated if patient is overweight or has obesity.
    - State ways to promote sexual function.
    - Discuss ways to manage bowel and bladder function.
    - Name benefits of exercise and physical activity.
    - Identify ways to minimize immobility and spasticity.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families (e.g., National MS Society, MS support services).
- Identify the need for health promotion, disease prevention, and screening activities.

Resources

See Chapter 7, Chart 7-9: Home Care Checklist: Managing Chronic Illness for additional information.

ADLs, activities of daily living; IADLs, instrumental activities of daily living; MS, multiple sclerosis.

4. Demonstrates effective coping strategies
   a. Maintains sense of control
   b. Modifies lifestyle to fit goals and limitations
   c. Verbalizes desire to pursue goals and developmental tasks of adulthood
   d. Demonstrates healthy social interactions
   e. Participates in meaningful activities
5. Understands ways to avoid complications and is free of complications
6. Explains reasons for measures to prevent complications

Myasthenia Gravis

Myasthenia gravis, an autoimmune disorder affecting the myoneural junction, is characterized by varying degrees of weakness of the voluntary muscles. It is uncommon, with an incidence between 9 and 30 in 1 million people in the United States (Hickey & Strayer, 2020). It occurs more often in women during the second and third decades of life; however, after age 50, it is more common in men (Hickey & Strayer, 2020).

Pathophysiology

Normally, a chemical impulse precipitates the release of acetylcholine from vesicles on the nerve terminal at the myoneural junction. The acetylcholine attaches to receptor sites on the motor endplate and stimulates muscle contraction. Continuous binding of acetylcholine to the receptor site is required for muscular contraction to be sustained.

In myasthenia gravis, antibodies directed at the acetylcholine receptor sites impair transmission of impulses across the myoneural junction. Therefore, fewer receptors are available for stimulation, resulting in voluntary muscle weakness that escalates with continued activity (see Fig. 64-4). These antibodies are found in 85% of people with myasthenia gravis (Hickey & Strayer, 2020). Of people with myasthenia gravis, most have either thymic hyperplasia or a thymic tumor, and the thymus gland is believed to be the site of antibody production. In patients who are acetylcholine receptor antibody negative, other antibodies appear to target a protein in the myoneural junction (Hickey & Strayer, 2020).

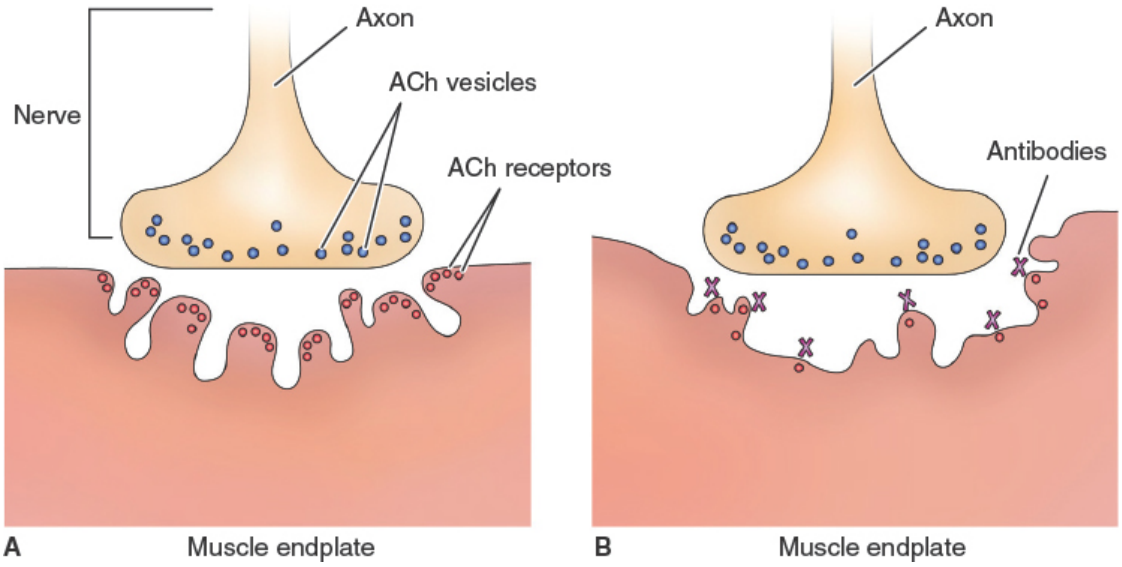

Figure 64-4 • Myasthenia gravis. **A.** Usual acetylcholine (ACh) receptor site. **B.** ACh receptor site in myasthenia gravis.

Clinical Manifestations

The clinical manifestation of myasthenia gravis is highly variable. There are two clinical types: ocular and generalized. In the ocular form, only the eye muscles are involved. Diplopia and **ptosis** (drooping of the eyelids) are common (Hickey & Strayer, 2020). In the generalized form, patients experience weakness of the muscles of the face and throat (bulbar symptoms), limbs, and respiratory weakness. Weakness of the facial muscles results in a bland facial expression. Laryngeal involvement produces **dysphonia** (voice impairment) and **dysphagia** (difficulty swallowing), which increases the risk of choking and aspiration. Generalized weakness affects all extremities and may involve the intercostal muscles, resulting in decreasing vital capacity and respiratory failure. When this occurs, the patient is in a myasthenic crisis (National Institute of Neurological Disorders and Stroke [NINDS], 2020). Myasthenia gravis is purely a motor disorder with no effect on sensation or coordination.

Assessment and Diagnostic Findings

A common test used to diagnose myasthenia gravis is the acetylcholinesterase inhibitor test. It is performed by administering edrophonium chloride IV; 30 seconds after injection, facial muscle weakness and ptosis should resolve for about 5 minutes (Hickey & Strayer, 2020). Immediate improvement in muscle strength after administration of this agent represents a positive test and usually confirms the diagnosis. Atropine should be available to control potential side

effects of this medication, which include bradycardia, asystole, bronchoconstriction, sweating, and cramping.

Another study, the ice test, is indicated in patients who have cardiac conditions or asthma. With this test, an ice pack is held over the patient's eyes for 1 minute; the ptosis should temporarily resolve in a patient with myasthenia gravis (Hickey & Strayer, 2020).

Several blood tests for acetylcholine antibodies are also used to confirm the diagnosis (Hickey & Strayer, 2020). Repetitive nerve stimulation (RNS) demonstrates a decrease in successive action potentials. A single-fiber electromyography (EMG) detects a delay or failure of neuromuscular transmission and is about 99% sensitive in confirming the diagnosis of myasthenia gravis (Hickey & Strayer, 2020). This is an uncomfortable test for the patient.

The thymus gland, a site of acetylcholine receptor antibody production, may be enlarged in myasthenia gravis and may be identified by MRI scan.

Medical Management

Management of myasthenia gravis is directed at improving function and reducing and removing circulating antibodies. Therapeutic modalities include administration of anticholinesterase medications and immunosuppressive therapy, intravenous immune globulin (IVIG), therapeutic plasma exchange, and thymectomy. There is no cure for myasthenia gravis; treatments do not stop the production of the acetylcholine receptor antibodies.

Pharmacologic Therapy

Pyridostigmine bromide, an anticholinesterase medication, is the first line of therapy (Hickey & Strayer, 2020). It provides symptomatic relief by inhibiting the breakdown of acetylcholine and increasing the relative concentration of available acetylcholine at the neuromuscular junction. The dosage is gradually increased to a daily maximum and is given in divided doses (usually four times a day). Adverse effects of anticholinesterase medications include diarrhea, abdominal cramps, and/or excessive saliva (Comerford & Durkin, 2020). Pyridostigmine tends to have fewer side effects than other anticholinesterase medications.

If pyridostigmine bromide does not improve muscle strength and control fatigue, the next agents used are the immunomodulating drugs. The goal of immunosuppressive therapy is to reduce production of the antibody. Corticosteroids suppress the patient's immune response, decreasing the amount of antibody production, and this correlates with clinical improvement. An initial dose of prednisone is given daily and maintained for 1 to 2 months; as symptoms improve, the medication is tapered (Hickey & Strayer, 2020). As the corticosteroid medications take effect, the dosage of anticholinesterase

medication can usually be lowered. Cytotoxic medications are used to treat myasthenia gravis if there is inadequate response to steroids. Azathioprine inhibits T lymphocytes and B-cell proliferation and reduces acetylcholine receptor antibody levels. Therapeutic effects may not be evident for 3 to 12 months. Leukopenia and hepatotoxicity are serious adverse effects, so monthly evaluation of liver enzymes and white blood cell count is necessary.

IVIG can be used to treat exacerbations; however, in select patients, it is used on a long-term adjunctive basis. IVIG treatment involves the administration of pooled human gamma-globulin and improvement occurs in a few days to a week (Hickey & Strayer, 2020). The effects of IVIG typically last only about 28 days after infusion, and complications include headache, migraine exacerbation, aseptic meningitis, and flulike symptoms (Vitiello, Emmi, Silvestri, et al., 2019).

A number of medications are contraindicated for patients with myasthenia gravis because they exacerbate the symptoms. The primary provider and the patient should weigh risks and benefits before any new medications are prescribed. Procaine should be avoided, and the patient's dentist is informed of the diagnosis of myasthenia gravis.

Therapeutic Plasma Exchange

A technique called therapeutic plasma exchange, formerly referred to as plasmapheresis, is used to treat exacerbations. The patient's plasma and plasma components are removed through a centrally placed large-bore double-lumen catheter. The blood cells and antibody-containing plasma are separated, after which the cells and a plasma substitute are reinfused. Temporary reduction in the level of circulating antibodies is provided with therapeutic plasma exchange. A typical course consists of daily or alternate-day treatment, and the number of treatments is determined by the patient's response (Hickey & Strayer, 2020)

Surgical Management

Thymectomy (surgical removal of the thymus gland) can produce antigen-specific immunosuppression and result in clinical improvement. Optimal outcomes of the surgery are in patients younger than 60 years who have had myasthenia gravis diagnosed within the past 3 years. It is the only treatment that can result in complete remission, which occurs in approximately 35% of patients (Hickey & Strayer, 2020). A course of preoperative IVIG or therapeutic plasma exchange decreases the time needed for postoperative mechanical ventilation. The entire thymus gland must be removed for optimal clinical outcomes.

A thymectomy should be performed at a designated center with a surgical and anesthesia staff experienced in the perioperative management of those with myasthenia gravis (Hickey & Strayer, 2020). After surgery, the patient is monitored in an intensive care unit, with special attention to respiratory function. The patient is weaned from mechanical ventilation after thorough respiratory assessment. After the thymus gland is removed, it may take up to 3 years for the patient to benefit from the procedure because of the long life of circulating T cells. Thymectomy is considered an elective surgery and best performed when the clinical course of the disease is stable for optimal outcomes (Hickey & Strayer, 2020).

Complications

A myasthenic crisis is an exacerbation of the disease process characterized by severe generalized muscle weakness and respiratory and bulbar weakness that may result in respiratory failure. Crisis may result from disease exacerbation or a specific precipitating event. The most common precipitator is respiratory infection; others include medication change, surgery, pregnancy, and medications that exacerbate myasthenia. A cholinergic crisis caused by overmedication with cholinesterase inhibitors is rare (Hickey & Strayer, 2020).

Neuromuscular respiratory failure is the critical complication in myasthenic and cholinergic crises. Respiratory muscle and bulbar weakness combine to cause respiratory compromise. Weak respiratory muscles do not support inhalation. An inadequate cough and an impaired gag reflex, caused by bulbar weakness, result in poor airway clearance. A downward trend of two respiratory function tests, the negative inspiratory force and vital capacity, is the first clinical sign of respiratory compromise.

Endotracheal intubation and mechanical ventilation may be needed (see Chapter 19). Noninvasive positive-pressure ventilation uses an external device in the form of a vest that provides respiratory support without endotracheal intubation. Cholinesterase inhibitors are stopped when respiratory failure occurs and gradually restarted after the patient demonstrates improvement with a course of therapeutic plasma exchange or IVIG. Nutritional support may be needed if the patient is intubated for a long period or swallowing ability is affected (see Chapter 39).

Nursing Management

Because myasthenia gravis is a chronic disease and most patients are seen on an outpatient basis, much of the nursing care focuses on patient and family education. Educational topics for outpatient self-care include medication

management, energy conservation, strategies to help with ocular manifestations, and prevention and management of complications.

Medication management is a crucial component of ongoing care. Understanding the actions of the medications and taking them on schedule is emphasized, as are the consequences of delaying medication and the signs and symptoms of myasthenic and cholinergic crises. The patient can determine the best times for daily dosing by keeping a diary to determine fluctuation of symptoms and to learn when the medication is wearing off. The medication schedule can then be manipulated to maximize strength throughout the day.

Quality and Safety Nursing Alert

Maintenance of stable blood levels of anticholinesterase medications is imperative to stabilize muscle strength. Therefore, the anticholinesterase medications must be given on time. Any delay in administration of medications may exacerbate muscle weakness and make it impossible for the patient to take medications orally.

Regular administration of IVIG or subcutaneous immunoglobulin may be prescribed. The patient and family are educated about managing immunoglobulin therapy.

For the procedural guidelines for management of IVIG, go to thepoint.lww.com/Brunner15e.

The patient is also educated about strategies to conserve energy. To do this, the nurse helps the patient identify the optimal times for rest throughout the day. If the patient lives in a two-story home, the nurse can suggest that frequently used items (e.g., hygiene products, cleaning products, snacks) be kept on each floor to minimize travel between floors. The patient is encouraged to apply for a handicapped license plate to minimize walking from parking spaces and to schedule activities to coincide with peak energy and strength levels. Using consistent routines, scheduling periods of rest, monitoring for depression, maintaining good sleep patterns, and incorporating interventions to conserve energy are all strategies to reduce fatigue (Hickey & Strayer, 2020).

To minimize the risk of aspiration, mealtimes should coincide with the peak effects of anticholinesterase medication. In addition, rest before meals is encouraged to reduce muscle fatigue. The patient is advised to sit upright during meals, with the neck slightly flexed to facilitate swallowing. Soft foods

in gravy or sauces can be swallowed more easily. Eating larger meals in the morning and smaller meals in the evening is another good strategy. Supplemental feedings may be helpful to ensure adequate nutrition.

If choking occurs frequently, the patient should be evaluated by a speech-language pathologist for formal dietary and mechanical techniques to avoid aspiration. Suction should be available at home, with the patient and family instructed in its use.

Impaired vision results from ptosis of one or both eyelids, decreased eye movement, or double vision. To prevent corneal damage when the eyelids do not close completely, the patient is instructed to tape the eyes closed for short intervals and to regularly instill artificial tears. Patients who wear eyeglasses can have "crutches" attached to help lift the eyelids. Patching of one eye or wearing prism glasses can help with double vision.

The patient is reminded of the importance of maintaining health promotion practices and following health care screening recommendations. Factors that exacerbate symptoms and potentially cause crisis should be noted and avoided: emotional stress, infections (particularly respiratory infections), vigorous physical activity, some medications, and high environmental temperature. The Myasthenia Gravis Foundation of America provides support services and educational materials for patients, families, and health care providers (see the Resources section).

Myasthenic Crisis

Respiratory distress and varying degrees of dysphagia, dysarthria, eyelid ptosis, diplopia, and prominent muscle weakness are symptoms of myasthenic crisis. The patient is placed in an intensive care unit for constant monitoring because of associated intense and sudden fluctuations in clinical condition.

Providing ventilatory assistance takes precedence in the immediate management of the patient with myasthenic crisis. Ongoing assessment for respiratory failure is essential. The nurse assesses the respiratory rate, depth, and breath sounds and monitors pulmonary function parameters (vital capacity and negative inspiratory force) to detect pulmonary problems before respiratory dysfunction progresses. Blood is drawn for arterial blood gas analysis. Endotracheal intubation and mechanical ventilation may be needed (see Chapter 19).

If the abdominal, intercostal, and pharyngeal muscles are severely weak, the patient cannot cough, take deep breaths, or clear secretions. Chest physiotherapy, including postural drainage to mobilize secretions and suctioning to remove secretions, may have to be performed frequently. (Postural drainage should not be performed for 30 minutes after feeding.)

Assessment strategies and supportive measures include the following:

- Arterial blood gases, serum electrolytes, input and output, and daily weight are monitored.
- If the patient cannot swallow, enteral tube feedings may be prescribed (see Chapter 39).
- Sedative and tranquilizing agents are avoided, because they aggravate hypoxia and hypercapnia and can cause respiratory and cardiac depression.

Guillain–Barré Syndrome

Guillain–Barré Syndrome (GBS), also known as acute idiopathic polyneuritis, is an autoimmune attack on the peripheral nerve myelin. The result is acute, rapid segmental demyelination of peripheral nerves and some cranial nerves, producing ascending weakness with dyskinesia (inability to execute voluntary movements), hyporeflexia, and **paresthesias** (a sensation of numbness, tingling, or a "pins and needles" sensation). An antecedent event (most often a viral infection) precipitates clinical presentation in approximately 60% to 70% of cases (CDC, 2019). *Campylobacter jejuni* (implicated in 40% of cases in the United States), cytomegalovirus, Epstein–Barr virus, *Mycoplasma pneumoniae, H. influenzae,* and Zika virus are the most common infectious agents that are associated with the development of GBS.

There are several subtypes of GBS (Malek & Salameh, 2019). With the most well-known type, the patient experiences weakness in the lower extremities, which progresses upward and has the potential for respiratory failure. The second type is purely motor with no altered sensation. A third type, called descending GBS, is much more difficult to diagnose; it mostly affects the head and neck muscles. The rarest type is the Miller–Fisher variant (see discussion later in this chapter) (NINDS, 2018b).

The annual incidence of GBS is 1 to 2 cases per 100,000 people, and it affects males and females equally. Death occurs in 5% to 10% of cases, resulting from respiratory failure, autonomic dysfunction, sepsis, or pulmonary embolism (PE) (Hickey & Strayer, 2020). Seventy percent of patients with GBS experience full recovery. The remaining 30% can have disability ranging from minor to major (NINDS, 2018b).

Pathophysiology

GBS is the result of a cell-mediated and humoral immune attack on peripheral nerve myelin proteins that causes inflammatory demyelination. The best-accepted theory of cause is molecular mimicry, in which an infectious organism contains an amino acid that mimics the peripheral nerve myelin protein. The immune system cannot distinguish between the two proteins and

attacks and destroys peripheral nerve myelin. The exact location of the immune attack within the peripheral nervous system is the ganglioside GM1b. With the autoimmune attack, there is an influx of macrophages and other immune-mediated agents that attack myelin and cause inflammation and destruction, interruption of nerve conduction, and axonal loss (NINDS, 2018b).

Myelin is a complex substance that covers nerves, providing insulation and speeding the conduction of impulses from the cell body to the dendrites. The cell that produces myelin in the peripheral nervous system is the Schwann cell. In GBS, the Schwann cell can be spared, allowing for remyelination in the recovery phase of the disease. If damage has occurred to the axons, then regrowth is required and takes months or years and is often incomplete (NINDS, 2018b).

Clinical Manifestations

GBS typically begins with muscle weakness and diminished reflexes of the lower extremities. Hyporeflexia and weakness may progress to tetraplegia. Demyelination of the nerves that innervate the diaphragm and intercostal muscles results in neuromuscular respiratory failure. Sensory symptoms include paresthesias of the hands and feet and pain related to the demyelination of sensory fibers.

The antecedent event usually occurs 1 to 3 weeks before symptoms begin. Weakness usually begins in the legs and may progress upward. Maximum weakness (the plateau) varies in length but usually includes neuromuscular respiratory failure and bulbar weakness. GBS progresses to peak severity typically within 2 weeks and no longer than 4 weeks. If progression is longer, then the patient is classified as having chronic inflammatory demyelinating polyneuropathy (Hickey & Strayer, 2020). Any residual symptoms are permanent and reflect axonal damage from demyelination.

Cranial nerve demyelination can result in a variety of clinical manifestations. Optic nerve demyelination may result in blindness. Bulbar muscle weakness related to demyelination of the glossopharyngeal and vagus nerves results in the inability to swallow or clear secretions. Vagus nerve demyelination results in autonomic dysfunction, manifested by instability of the cardiovascular system. The presentation is variable and may include tachycardia, bradycardia, hypertension, or orthostatic hypotension. The symptoms of autonomic dysfunction occur and resolve rapidly. GBS does not affect cognitive function or LOC.

Although the classic clinical features include areflexia and ascending weakness, variations in the clinical presentation occurs. There may be a sensory presentation, with progressive sensory symptoms; an atypical axonal

destruction; or the Miller–Fisher variant, which includes paralysis of the ocular muscles, ataxia, and areflexia (Malek & Salameh, 2019; NINDS, 2018b).

Assessment and Diagnostic Findings

The patient presents with symmetric weakness, diminished reflexes, and upward progression of motor weakness. A history of a viral illness in the previous few weeks suggests the diagnosis. Changes in vital capacity and negative inspiratory force are assessed to identify impending neuromuscular respiratory failure. Serum laboratory tests are not useful in the diagnosis. However, elevated protein levels are detected in CSF evaluation, without an increase in other cells. Electrophysiology studies demonstrate a progressive loss of nerve conduction velocity (Malek & Salameh, 2019).

Medical Management

Because of the possibility of rapid progression and neuromuscular respiratory failure, GBS is a medical emergency that may require management in an intensive care unit. After baseline values are identified, assessment of changes in muscle strength and respiratory function alert the clinician to the physical and respiratory needs of the patient. Respiratory therapy or mechanical ventilation may be necessary to support pulmonary function and adequate oxygenation. Some clinicians recommend elective intubation before the onset of extreme respiratory muscle fatigue. Emergent intubation may result in autonomic dysfunction, and mechanical ventilation may be required for an extended period. The patient is weaned from mechanical ventilation after the respiratory muscles can again support spontaneous respiration and maintain adequate tissue oxygenation.

Other interventions are aimed at preventing the complications of immobility. These may include the use of anticoagulant agents and sequential compression boots to prevent venous thromboembolism (VTE), including deep vein thrombosis (DVT) and PE.

Therapeutic plasma exchange and IVIG are used to directly affect the peripheral nerve myelin antibody level. Both therapies decrease circulating antibody levels and reduce the amount of time the patient is immobilized and dependent on mechanical ventilation. The cardiovascular risks posed by autonomic dysfunction require continuous electrocardiographic (ECG) monitoring. Tachycardia and hypertension are treated with short-acting medications such as alpha-adrenergic blocking agents. The use of short-acting agents is important, because autonomic dysfunction is very labile. Hypotension is managed by increasing the amount of IV fluid administered.

NURSING PROCESS

The Patient with GBS

Assessment

Ongoing assessment for disease progression is critical. The patient is monitored for life-threatening complications (respiratory failure, cardiac arrhythmias, VTE [including DVT or PE]) so that appropriate interventions can be initiated. Because of the threat to the patient in this sudden, potentially life-threatening disease, the nurse must assess the patient's and family's ability to cope and their use of coping strategies.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired breathing associated with rapidly progressive weakness and impending respiratory failure
- Impaired mobility associated with paralysis
- Impaired nutritional intake associated with inability to swallow
- Impaired verbal communication associated with cranial nerve dysfunction
- Anxiety associated with loss of control and paralysis
- Fatigue associated with physical deconditioning and stressors

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Respiratory failure
- Autonomic dysfunction

Planning and Goals

The major goals for the patient may include improved respiratory function, increased mobility, improved nutritional status, effective communication, decreased anxiety, decreased fatigue, and absence of complications.

Nursing Interventions

Maintaining Respiratory Function

Respiratory function can be maximized with incentive spirometry and chest physiotherapy. Monitoring for changes in vital capacity and negative inspiratory force is key to early intervention for neuromuscular respiratory failure. Mechanical ventilation is required if the vital capacity falls, making spontaneous breathing impossible and tissue oxygenation inadequate.

The potential need for mechanical ventilation should be discussed with the patient and family on admission to provide time for psychological

preparation and decision making. Intubation and mechanical ventilation result in less anxiety if they are initiated on a nonemergency basis to a patient who has been well informed. The patient may require mechanical ventilation for a long period. See Chapter 19 for the nursing management of the patient requiring mechanical ventilation.

Bulbar weakness that impairs the ability to swallow and clear secretions is another factor in the development of respiratory failure in the patient with GBS. Suctioning may be needed to maintain a clear airway.

The nurse assesses the blood pressure and heart rate frequently to identify autonomic dysfunction so that interventions can be initiated quickly if needed. Medications are given or a temporary pacemaker placed for clinically significant bradycardia.

Enhancing Physical Mobility

Nursing interventions to enhance physical mobility and prevent the complications of immobility are key to the function and survival of patients. The paralyzed extremities are supported in functional positions, and passive range-of-motion exercises are performed at least twice daily. DVT and PE are threats to the patient who is paralyzed. Nursing interventions are aimed at preventing VTE. Range-of-motion exercises, position changes, anticoagulation, the use of anti-embolism stockings and sequential compression boots, and adequate hydration decrease the risk of VTE.

Padding may be placed over bony prominences, such as the elbows and heels, to reduce the risk of pressure injury. The need for frequent position changes cannot be overemphasized. The nurse evaluates laboratory test results that may indicate malnutrition or dehydration, both of which increase the risk of pressure injury and decrease mobility. The nurse collaborates with the primary provider and dietitian to develop a plan to meet the patient's nutritional and hydration needs.

Providing Adequate Nutrition

Paralytic ileus may result from insufficient parasympathetic activity. In this event, the nurse administers IV fluids and parenteral nutrition as a supplement and monitors for the return of bowel sounds. If the patient cannot swallow because of bulbar paralysis (immobility of muscles), a gastrostomy tube may be placed to administer nutrients. The nurse carefully assesses the return of the gag reflex and bowel sounds before resuming oral nutrition.

Improving Communication

Because of paralysis, the patient cannot talk, laugh, or cry and therefore has no method for communicating needs or expressing emotion. Although the patient may be unable to speak, cognition is completely intact. Establishing some form of communication with picture cards or an eye blink system

provides a means of communication. Collaboration with the speech therapist may be helpful in developing a communication mechanism that is most effective for a specific patient.

Decreasing Anxiety

The patient and family are faced with a sudden, potentially life-threatening disease; therefore, their levels of anxiety may be high. The impact of disease on the family depends on the patient's role within the family. Referral to a support group may provide information and support to the patient and family.

The family may feel helpless in caring for the patient. Mechanical ventilation and monitoring devices may frighten and intimidate them. Family members often want to participate in physical care; with education and support by the nurse, they should be allowed and encouraged to do so.

In addition the patient may experience isolation, loneliness, lack of control, and fear. Nursing interventions that increase the patient's sense of control include providing information about the condition, emphasizing a positive appraisal of coping resources, and providing education about relaxation exercises and distraction techniques. The positive attitude and atmosphere of the multidisciplinary team are important to promote a sense of well-being.

Diversional activities are encouraged to decrease loneliness and isolation. Encouraging visitors (when possible), engaging visitors or volunteers to read to the patient, listening to musical recordings or audiobooks, assisting with audio visual communication with friends and family through a phone or electronic device, and watching television or movies are ways to alleviate the patient's sense of isolation.

Reducing Fatigue

The disease process increases disability and dependence on others for simple activities of living. As the patient begins to recover and regains the ability to perform activities on their own, they will find increased rest is needed to maintain this independence. The patient may need only a little help at the beginning of the day, but as the day progresses may require more assistance. Too much exertion will result in fatigue. The patient will need assistance learning how to pace their daily activities to incorporate periods of rest, both physically and mentally. The nurse can help identify activities that are physically demanding, assess the amount of sleep the patient is getting and needs, assist the patient and family to ensure time for self-care, and provide education about healthy eating to maintain strength.

Monitoring and Managing Potential Complications

Thorough assessment of respiratory function at regular and frequent intervals is essential, because respiratory insufficiency and subsequent failure due to weakness or paralysis of the intercostal muscles and

diaphragm may develop quickly. Respiratory failure is the major cause of mortality, although rare. In addition to the respiratory rate and the quality of respirations, vital capacity is monitored frequently and at regular intervals so that respiratory insufficiency can be anticipated. Decreasing vital capacity with associated muscle weakness indicates impending respiratory failure. Signs and symptoms include breathlessness while speaking, shallow and irregular breathing, the use of accessory muscles, tachycardia, weak cough, and changes in respiratory pattern.

Other complications include cardiac arrhythmias (which necessitate ECG monitoring), transient hypertension, orthostatic hypotension, DVT, PE, urinary retention, and other threats to any patient who is immobilized and paralyzed. These complications require monitoring and attention to prevent them and prompt treatment if indicated.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Patients with GBS and their families are usually frightened by the sudden onset of life-threatening symptoms and their severity. Therefore, educating the patient and family about the disorder and its generally favorable prognosis is important (see Chart 64-4).

During the acute phase of the illness, the patient and family are educated about strategies that can be implemented to minimize the effects of immobility and other complications. As function begins to return, family members and other home care providers are educated about care of the patient and their role in the rehabilitation process. Preparation for discharge is an interdisciplinary effort requiring family or caregiver education by all team members, including the nurse, physician, occupational and physical therapists, speech therapist, and respiratory therapist.

Chart 64-4  **HOME CARE CHECKLIST**

The Patient with GBS

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of GBS and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- State what types of environmental and safety changes or supports are needed for optimum functioning in the home.
  - State changes in lifestyle (e.g., nutrition, skin care, exercise, activity) necessary during recovery period and to maintain health as indicated.
  - Demonstrate environmental modifications and adaptive techniques for accomplishing ADLs (e.g., bathing, hygiene, grooming, dressing) and safely managing self-care.
  - Manage respiratory needs—tracheostomy care, suctioning.
  - Verbalize dietary adjustments and optimum nutrition during recovery.
  - Demonstrate proper body mechanics regarding lifting and transfers.
  - Practice gait training and strength endurance.
  - Perform range-of-motion exercises.
  - Discuss bowel and bladder management.
  - Operate and explain function of medical equipment and mobility aids—walkers, wheelchairs, bedside commodes, tub transfer benches, adaptive devices.
  - Describe coping mechanisms and diversional activities appropriately.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families (e.g., GBS Foundational International).
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; GBS, Guillain–Barré syndrome: IADLs, instrumental activities of daily living.

Continuing and Transitional Care. Most patients with GBS experience complete recovery. Patients who have experienced total or prolonged paralysis require intensive rehabilitation; the extent depends on the patient's needs. Approaches include a comprehensive inpatient program if deficits are significant, an outpatient program if the patient can travel by car, or a home program of physical and occupational therapy. The recovery phase may be long and requires patience as well as involvement on the part of the patient and family.

During acute care, the focus is on immediate issues and deficits. The nurse needs to remind or educate patients and family members of the need for continuing health promotion and screening practices after this initial phase of care.

Evaluation

Expected patient outcomes may include the following:

1. Maintains effective respirations and airway clearance
   a. Has clear breath sounds on auscultation
   b. Demonstrates gradual improvement in respiratory function
   c. Breathes spontaneously
   d. Has vital capacity within normal range
   e. Exhibits arterial blood gases and pulse oximetry within normal limits
2. Shows increasing mobility
   a. Regains use of extremities
   b. Participates in rehabilitation program
   c. Demonstrates no contractures and minimal muscle atrophy
3. Receives adequate nutrition and hydration
   a. Consumes diet adequate to meet nutritional needs
   b. Swallows without aspiration
4. Demonstrates recovery of speech
   a. Communicates needs through alternative strategies
   b. Practices exercises recommended by the speech therapist
5. Shows less anxiety
6. Experiences fewer episodes of fatigue
   a. Verbalizes a plan to reduce fatigue and increase energy
   b. Takes rest periods during the day
   c. Identifies activities with higher importance during periods of high energy
7. Has absence of complications

a. Maintains intact skin integrity
b. Does not develop VTE
c. Voids without difficulty

CRANIAL NERVE DISORDERS

Because the brainstem and cranial nerves involve vital motor, sensory, and autonomic functions of the body, these nerves may be affected by conditions arising primarily within these structures or in secondary extension from adjacent disease processes. The cranial nerves are examined separately and in sequence (see Chapter 60, Table 60-2). Some cranial nerve deficits can be detected by observing the patient's face, eye movements, speech, and swallowing. EMG is used to investigate motor and sensory dysfunction. An MRI scan is used to obtain images of the cranial nerves and brainstem. An overview of disorders that may affect each of the cranial nerves, including clinical manifestations and nursing interventions, is presented in Table 64-3. The following discussion centers on the most common disorders of the cranial nerves: trigeminal neuralgia, a condition affecting the fifth cranial nerve, and Bell palsy, caused by involvement of the seventh cranial nerve.

TABLE 64-3 Disorders of Cranial Nerves

Disorder	Clinical Manifestations	Nursing Interventions
Olfactory Nerve—I		
Head trauma Intracranial tumor Intracranial surgery	Unilateral or bilateral anosmia (temporary or persistent) Diminished taste for food	Assess sense of smell Assess for cerebrospinal fluid rhinorrhea if patient has sustained head trauma
Optic Nerve—II		
Optic neuritis Increased intracranial pressure Pituitary tumor	Lesions of optic tract producing homonymous hemianopsia	Assess visual acuity Restructure environment to prevent injuries Educate patient to accommodate for visual loss
Oculomotor Nerve—III		Assess extraocular movement and for nonreactive pupil
Trochlear Nerve—IV		Assess extraocular movement and for nonreactive pupil
Abducens Nerve—VI		
Vascular Brainstem ischemia Hemorrhage and infarction Neoplasm Trauma Infection	Dilation of pupil with loss of light reflex on one side Impairment of ocular movement Diplopia Gaze palsies Ptosis of eyelid	Assess extraocular movement and for nonreactive pupil
Trigeminal Nerve—V		
Trigeminal neuralgia Head trauma Cerebellopontine lesion Sinus tract tumor and metastatic disease Compression of trigeminal root by tumor or blood vessel	Pain in face Diminished or loss of corneal reflex Chewing dysfunction	Assess for pain and triggering mechanisms for pain Assess for difficulty in chewing Discuss trigger zones and pain precipitants with patient Protect cornea from abrasion Ensure good oral hygiene Educate patient about medication regimen
Facial Nerve—VII		
Bell palsy Facial nerve tumor Intracranial lesion Herpes zoster	Facial dysfunction; weakness and paralysis Hemifacial spasm Diminished or absent taste Pain	Recognize facial paralysis as emergency; refer for treatment as soon as possible Discuss protective care for eyes Select easily chewed foods; patient should eat and drink from unaffected side of mouth Emphasize importance of oral hygiene

		Provide emotional support for changed appearance of face
Vestibulocochlear Nerve—VIII		
Tumors and acoustic neuroma Vascular compression of nerve Ménière syndrome	Tinnitus Vertigo Hearing difficulties	Assess pattern of vertigo Provide for safety measures to prevent falls Ensure that patient can maintain balance before ambulating Caution patient to change positions slowly Assist with ambulation Encourage the use of assistive devices
Glossopharyngeal Nerve—IX		
Glossopharyngeal neuralgia from neurovascular compression of cranial nerves IX and X Trauma Inflammatory conditions Tumor Vertebral artery aneurysms	Pain at base of tongue Difficulty in swallowing Loss of gag reflex Palatal, pharyngeal, and laryngeal paralysis	Assess for paroxysmal pain in throat, decreased or absent swallowing, and gag and cough reflexes Monitor for dysphagia, aspiration, and nasal dysarthric speech. Position patient upright for eating or tube feeding
Vagus Nerve—X		
Spastic palsy of larynx; bulbar paralysis; high vagal paralysis Guillain–Barré syndrome Vagal body tumors Nerve paralysis from malignancy, surgical trauma such as carotid endarterectomy	Voice changes (temporary or permanent hoarseness) Vocal paralysis Dysphagia	Assess for airway obstruction/provide airway management Prevent aspiration Support patient having voice reconstruction procedures
Spinal Accessory Nerve—XI		
Spinal cord disorder Amyotrophic lateral sclerosis Trauma Guillain–Barré syndrome	Drooping of affected shoulder with limited shoulder movement Weakness or paralysis of head rotation, flexion, extension; shoulder elevation	Support patient undergoing diagnostic tests
Hypoglossal Nerve—XII		
Medullary lesions	Abnormal movements of	Observe swallowing ability

Amyotrophic lateral sclerosis Polio and motor system disease, which may destroy hypoglossal nuclei Multiple sclerosis Trauma	tongue Weakness or paralysis of tongue muscles Difficulty in talking, chewing, and swallowing	Observe speech pattern Be aware of swallowing or vocal difficulties Prepare for alternative feeding methods (tube feeding) to maintain nutrition

Adapted from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological & neurosurgical nursing* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Trigeminal Neuralgia

Trigeminal neuralgia, formerly known as *tic douloureux*, is a condition of the fifth cranial nerve that is characterized by paroxysms of sudden pain in the area innervated by any of the three branches of the nerve (Hickey & Strayer, 2020; see Fig. 64-5). The pain ends as abruptly as it starts and is described as a unilateral shooting and stabbing or burning sensation. The unilateral nature of the pain is an important feature. Associated involuntary contraction of the facial muscles can cause sudden closing of the eye or twitching of the mouth, hence the former name *tic douloureux* (painful twitch). Although the cause is not certain, it is thought to be demyelination of axons in the trigeminal ganglion, root, and nerve by pressing vessels or a demyelinating disease such as MS (Hickey & Strayer, 2020).

Trigeminal neuralgia occurs most often as people age, most commonly between the fifth and sixth decade of life. It is more common in women and in people with MS compared to the general population (Hickey & Strayer, 2020). Patients who develop trigeminal neuralgia before age 50 years should be evaluated for the coexistence of MS, because trigeminal neuralgia occurs more often in patients with MS (Hickey & Strayer, 2020). Pain-free intervals may be measured in terms of minutes, hours, days, or longer. With advancing years, the painful episodes tend to become more frequent and agonizing. The patient lives in constant fear of attacks.

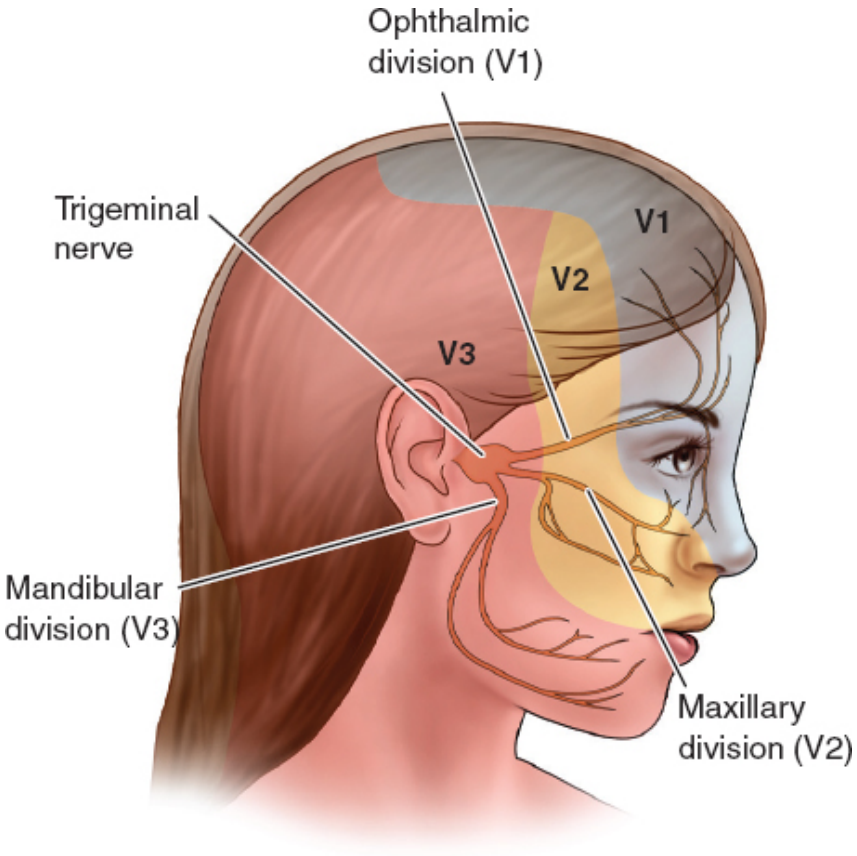

Figure 64-5 • Distribution of trigeminal nerve branches—the fifth cranial nerve.

Paroxysms can occur with any stimulation of the terminals of the affected nerve branches, such as washing the face, shaving, brushing the teeth, eating, and drinking. A draft of cold air or direct pressure against the nerve trunk may also cause pain. Certain areas are called *trigger points* because the slightest touch immediately starts a paroxysm or episode. To avoid stimulating these areas, patients with trigeminal neuralgia try not to touch or wash their faces, shave, chew, or do anything else that might cause an attack. These behaviors are a clue to the diagnosis.

Medical Management

Pharmacologic Therapy

Anticonvulsant agents, such as carbamazepine, relieve pain in most patients with trigeminal neuralgia by reducing the transmission of impulses at certain nerve terminals. Carbamazepine is taken with meals. Serum levels must be monitored to avoid toxicity in patients who require high doses to control the pain. Side effects include nausea, dizziness, drowsiness, and aplastic anemia (Hickey & Strayer, 2020). The patient is monitored for bone marrow depression during long-term therapy. Gabapentin and baclofen are also used

for pain control. If pain control is still not achieved, phenytoin may be used as adjunctive therapy.

Surgical Management

If pharmacologic management fails to relieve pain, a number of surgical options are available. Although these procedures may relieve facial pain for a few years, recurrence is possible (Hickey & Strayer, 2020). The choice of procedure depends on the patient's preference and health status. The procedures are designed to either decompress the nerve and save nerve function, or to damage the nerve and destroy nerve function to keep it from malfunctioning (Hickey & Strayer, 2020).

Microvascular Decompression of the Trigeminal Nerve

An intracranial approach is used to relieve the contact between the cerebral vessel and the trigeminal nerve root entry. With the aid of an operating microscope, the artery loop is lifted from the nerve to relieve the pressure, and a small prosthetic device is inserted to prevent recurrence of impingement on the nerve. The postoperative management is the same as for other intracranial surgeries (see Chapter 61).

Radiofrequency Thermal Coagulation

Percutaneous radiofrequency produces a thermal lesion on the trigeminal nerve. Although immediate pain relief is experienced, dysesthesia of the face and loss of the corneal reflex may occur. MRI is used for identification of the trigeminal nerve followed by gamma knife radiosurgery. Gamma knife radiosurgery is a noninvasive method of delivering focused radiation to the trigeminal nerve (Obermann, 2019).

Percutaneous Balloon Microcompression

Percutaneous balloon microcompression disrupts large myelinated fibers in all three branches of the trigeminal nerve. After its placement, the balloon is filled with a contrast material for fluoroscopic identification. The balloon compresses the nerve root for 1 minute and provides microvascular decompression (Hickey & Strayer, 2020).

Nursing Management

Preventing Pain

Preoperative management of a patient with trigeminal neuralgia occurs mostly on an outpatient basis and includes recognizing factors that may aggravate excruciating facial pain, such as food that is too hot or too cold or jarring of the patient's bed or chair. Even washing the face, combing the hair, or brushing

the teeth may produce acute pain. The nurse can assist the patient in preventing or reducing this pain by providing education about preventive strategies. Providing cotton pads and room temperature water for washing the face, instructing the patient to rinse with mouthwash after eating if toothbrushing causes pain, and performing personal hygiene during pain-free intervals are all effective strategies. The patient is instructed to take food and fluids at room temperature, to chew on the unaffected side, and to ingest soft foods. The nurse recognizes that anxiety, depression, and insomnia often accompany chronic painful conditions and uses appropriate interventions and referrals. See Chapter 9 for management of patients with chronic pain.

Providing Postoperative Care

Postoperative neurologic assessments are conducted to evaluate the patient for facial motor and sensory deficits in each of the three branches of the trigeminal nerve. If the surgery results in sensory deficits to the affected side of the face, the patient is instructed not to rub the eye because the pain of a resulting injury will not be detected. The eye is assessed for irritation or redness. Artificial tears may be prescribed to prevent dryness in the affected eye. The patient is cautioned not to chew on the affected side until numbness has diminished. The patient is observed carefully for any difficulty in eating or swallowing foods of different consistencies.

Bell's Palsy

Bell's palsy (idiopathic facial paralysis) is caused by unilateral inflammation of the seventh cranial nerve, which results in weakness or paralysis of the facial muscles on the affected side (see Fig. 64-6). Although the cause is unknown, theories include reactivation of a dormant viral infection (herpes simplex, herpes zoster) or autoimmune syndromes (NINDS, 2018a). Those most commonly affected with Bell's palsy are between the ages of 15 and 45 years (Hickey & Strayer, 2020).

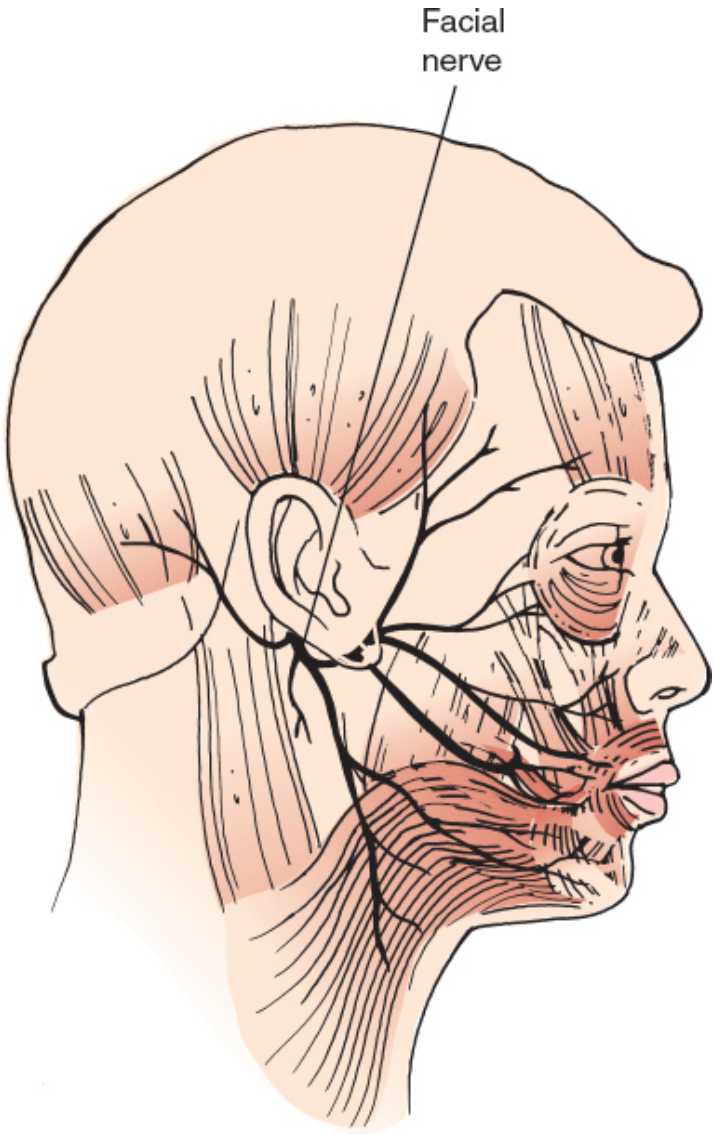

Figure 64-6 • Distribution of the facial nerve—the seventh cranial nerve.

Bell's palsy may be a type of pressure paralysis. The inflamed, edematous nerve becomes compressed to the point of damage, or its blood supply is occluded, producing ischemic necrosis of the nerve. The face is distorted from paralysis of the facial muscles which ranges in severity. Other symptoms may include drooping of the mouth, drooling, excessive lacrimation (tearing), and the patient may experience painful sensations in the face, behind the ear, and in the eye (NINDS, 2018a). The patient may also experience speech difficulties and may be unable to eat on the affected side because of weakness or paralysis of the facial muscles. The majority of patients recover completely and Bell's palsy rarely recurs (Somasundara, Sullivan, & Cheesbrough, 2017).

Medical Management

The objectives of treatment are to maintain the muscle tone of the face and to prevent or minimize denervation. The patient should be reassured that no stroke has occurred and that spontaneous recovery occurs within 3 to 5 weeks in most patients.

Corticosteroid therapy (prednisone) may be prescribed to reduce inflammation and edema; this reduces vascular compression and permits restoration of blood circulation to the nerve. Early administration of corticosteroid therapy, started within 72 hours of symptom onset, is highly effective in diminishing the severity of the disease, relieving the pain, and preventing or minimizing denervation (NINDS, 2018a).

Facial pain is controlled with analgesic agents. Electrical stimulation may be applied to the face to prevent muscle atrophy. Although most patients recover with conservative treatment, surgical decompression of the facial nerve is controversial as there is minimal evidence that this is helpful (NINDS, 2018a; Somasundara et al., 2017).

Nursing Management

While the paralysis is present, nursing care involves protection of the eye from injury. Frequently, the eyelid does not close completely and the blink reflex is diminished, so the eye is vulnerable to injury from dust and foreign particles. Corneal irritation and ulceration may occur. Distortion of the lower lid alters the proper drainage of tears. To prevent injury, the eye should be covered with a protective shield at night. The eye patch may abrade the cornea, however, because there is some difficulty in keeping the partially paralyzed eyelids closed. Moisturizing eye drops during the day and eye ointment at bedtime may help prevent injury (Somasundara et al., 2017). The patient can be educated to close the paralyzed eyelid manually before going to sleep. Wraparound sunglasses or goggles may be worn during the day to decrease evaporation from the eye.

After the sensitivity of the nerve to touch decreases and the patient can tolerate touching the face, the nurse can suggest massaging the face several times daily, using a gentle upward motion, to maintain muscle tone. Facial exercises, such as wrinkling the forehead, blowing out the cheeks, and whistling, may be performed with the aid of a mirror to prevent muscle atrophy. Exposure of the face to cold and drafts is avoided.

DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM

Peripheral Neuropathies

A peripheral **neuropathy** (disorder of the nervous system) is a disorder affecting the peripheral motor and sensory nerves. Peripheral nerves connect the spinal cord and brain to all other organs. They transmit motor impulses from the brain and relay sensory impulses to the brain. Peripheral neuropathies are characterized by bilateral and symmetric disturbance of function, usually beginning in the feet and hands. The most common cause of peripheral neuropathy is diabetes with poor glycemic control (Hickey & Strayer, 2020). Many drugs, such as antineoplastic agents, also cause peripheral neuropathies (Hickey & Strayer, 2020). The major symptoms of peripheral nerve disorders are loss of sensation, muscle atrophy, weakness, diminished reflexes, pain, and paresthesia of the extremities.

Peripheral nerve disorders are diagnosed by history, physical examination, and electrodiagnostic studies such as EEG. The diagnosis of peripheral neuropathy in the older adult population is challenging because many symptoms, such as decreased reflexes, can be associated with the normal aging process (Eliopoulos, 2018).

No specific treatment exists for peripheral neuropathy. Elimination or control of the cause may slow progression. Patients with peripheral neuropathy are at risk for falls, thermal injuries, and skin breakdown. The plan of care includes inspection of the lower extremities for skin breakdown. Assistive devices such as a walker or cane may decrease the risk of falls. Bathwater temperature is checked to avoid thermal injury. Footwear should be accurately sized. Driving may be limited or eliminated, thereby disrupting the patient's sense of independence.

Mononeuropathy

Mononeuropathy is limited to a single peripheral nerve and its branches. It arises when the trunk of the nerve is compressed or entrapped (as in carpal tunnel syndrome), traumatized (as when bruised by a blow), overstretched (as in joint dislocation), punctured by a needle used to inject a drug or damaged by the drugs thus injected, or inflamed because an adjacent infectious process extends to the nerve trunk. Mononeuropathy is frequently seen in patients with diabetes.

Pain is seldom a major symptom of mononeuropathy when the condition is due to trauma, but in patients with complicating inflammatory conditions such as arthritis, pain is prominent. Pain is increased with all body movements that tend to stretch, strain, or cause pressure on the injured nerve and sudden jarring of the body (e.g., from coughing or sneezing). The skin in the areas supplied by nerves that are injured or diseased may become reddened and glossy, the subcutaneous tissue may become edematous, and the nails and hair

in this area are altered. Chemical injuries to a nerve trunk, such as those caused by drugs injected into or near it, are often permanent.

The objective of treatment of mononeuropathy is to remove the cause, if possible (e.g., freeing the compressed nerve). Local corticosteroid injections may reduce inflammation and the pressure on the nerve. Aspirin or codeine may be used to relieve pain. Chronic pain can be treated with neuropathic pain medications such as gabapentin (Comerford & Durkin, 2020).

Nursing care involves protection of the affected limb or area from injury, as well as appropriate patient education about mononeuropathy and its treatment. The nurse assesses the impact of pain and weakness on the patient's quality of life and suggests interventions to cope with concerns the patient expresses (Girach, Julian, Varrassi, et al., 2019). Referrals to physical therapy for exercises to prevent muscle wasting and to occupational therapy to evaluate for splints that may help with appropriate positioning may be warranted.

CRITICAL THINKING EXERCISES

1 ipc You are participating in morning rounds in the ICU where you work. The team is discussing a patient who has been assigned to you for the day, a 20-year-old woman admitted last night with meningitis. What members of the interprofessional care team are essential to include in the care of this patient? How will you, as this patient's nurse, facilitate an interprofessional discussion to help facilitate her recovery?

2 pq You are caring for a 60-year-old man with a recent diagnosis of CJD. His wife of 30 years visits every day. What are the priorities for care of this patient? What will be your priorities when educating this patient and his wife?

3 ebp In the outpatient clinic where you work, a woman with a new diagnosis of MS received treatment and is back to her baseline function. She tells you that she has been "cured." What evidence-based education would you provide the patient about potential triggers that may cause a return of symptoms?

65 Management of Patients with Oncologic or Degenerative Neurologic Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe brain and spinal cord tumors: their classification, pathophysiology, clinical manifestations, diagnosis, and medical and nursing management.
2. Use the nursing process as a framework for care of the patient with nervous system metastases or primary brain tumor.
3. Explain the pathophysiologic processes responsible for various neurodegenerative disorders.
4. Apply the nursing process as a framework for care of the patient with Parkinson's disease or the patient who has had a cervical discectomy.

NURSING CONCEPTS

Family
Fluids and Electrolytes
Infection
Intracranial Regulation
Mobility
Nutrition
Patient Education
Sensory Perception
Stress and Coping

GLOSSARY

bradykinesia: abnormally slow voluntary movements and speech
chorea: rapid, jerky, involuntary, purposeless movements of the extremities or facial muscles, including facial grimacing
dementia: broad term for a syndrome characterized by a general decline in higher brain functioning, such as reasoning, with a pattern of eventual decline in ability to perform even basic activities of daily living, such as toileting and eating
dyskinesia: impaired ability to execute voluntary movements
dysphonia: voice impairment or altered voice production
neurodegenerative: deterioration of cells or function of the nervous system
papilledema: edema of the optic nerve usually due to increased intracranial pressure (ICP)
paresthesia: numbness, tingling, or a “pins and needles” sensation
sciatica: pain and tenderness that radiates along the sciatic nerve that runs through the thigh and leg
spondylosis: degenerative changes occurring in a disc and adjacent vertebral bodies; can occur in the cervical or lumbar vertebrae

The occurrence of oncologic or degenerative disease processes in the neurologic system produces a unique set of nursing challenges. Thus, nurses who care for patients with these disorders must have a clear understanding of the pathophysiology, diagnostic testing, medical and nursing care, and rehabilitation processes. Nurses provide care for patients with oncologic or degenerative disease processes in many inpatient and outpatient settings. Oncologic disorders include brain and spinal cord tumors. Degenerative neurologic disorders include Parkinson’s disease (PD), Huntington disease,

amyotrophic lateral sclerosis (ALS), muscular dystrophies, and degenerative disc disease. Post-polio syndrome (PPS) is thought to be degenerative in nature and is included in this chapter.

ONCOLOGIC DISORDERS OF THE BRAIN AND SPINAL CORD

There are many types of brain and spinal cord tumors, each with its own biology, prognosis, and treatment options. Because of the unique anatomy and physiology, tumors of the central nervous system (CNS) are challenging to diagnose and treat.

Brain Tumors

A brain tumor occupies space within the skull, growing as a spherical mass or diffusely infiltrating tissue. The effects of brain tumors are caused by inflammation, compression, and infiltration of tissue. A variety of physiologic changes result, causing any or all of the following pathophysiologic events (Hickey & Strayer, 2020):

- Increased intracranial pressure (ICP) and cerebral edema
  - Focal neurologic signs such as headache
  - Seizure activity
  - Hydrocephalus
  - Altered pituitary function

Neoplastic lesions in the brain ultimately cause death by increasing ICP and impairing vital functions, such as respiration.

There are over 100 types of brain tumors with an estimated 78,000 new cases each year. These include 25,000 malignant and 53,000 nonmalignant brain tumors (American Association of Neuroscience Nurses [AANN], 2016). Brain tumors are classified as primary or secondary. Primary brain tumors originate from cells within the brain. In adults, most primary brain tumors originate from glial cells (cells that make up the structure and support system of the brain and spinal cord) and are supratentorial (located above the covering of the cerebellum). Primary tumors progress locally, rarely metastasize outside the CNS, and have a 5-year survival rate of 33.4% (Garcia, Slone, Dolecek, et al., 2019).

Developed countries have a higher incidence of primary brain tumors, with rates of 5.1 per 100,000 compared to 3.0 per 100,000 in less developed countries. This is most likely due to more frequent diagnosis with improved imaging modalities. Although many risk factors have been investigated,

exposure to ionizing radiation is the only known modifiable risk factor (AANN, 2016). Many genetic factors and genetic syndromes (such as neurofibromatosis) are associated with brain tumor risk in families (AANN, 2016).

Secondary, or metastatic, brain tumors develop from structures outside the brain and are twice as common as primary brain tumors (AANN, 2016). Metastatic lesions to the brain can occur from the lung, breast, lower gastrointestinal tract, pancreas, kidney, and skin (melanomas) neoplasms. Single or multiple metastases may occur, and brain metastases may be found at any time during the disease course, even at initial diagnosis of the primary disease. Patient survival rates from primary brain cancers are improving, however, the incidence of brain metastases is increasing (AANN, 2016).

The highest incidence of brain tumors in adults occurs in the fifth through seventh decades of life (Young, Chmura, Wainwright, et al., 2017). There is a slight male predominance in the incidence of malignant brain tumors.

Types of Primary Brain Tumors

Brain tumors may be classified into several groups: those arising from the coverings of the brain (e.g., dural meningioma), those developing in or on the cranial nerves (e.g., acoustic neuroma), those originating within brain tissue (e.g., glioma), and metastatic lesions originating elsewhere in the body. Tumors of the pituitary and pineal glands and of cerebral blood vessels are also types of brain tumors. Relevant clinical considerations include the location and the histologic character of the tumor. About 70% of the time tumors are benign but even benign tumors, such as colloid cysts, can occur in vital areas and can grow large enough to have serious effects (Hickey & Strayer, 2020). See Chart 65-1 for the classification of brain tumors.

Chart 65-1

Classification of Brain Tumors in Adults

I. Intracerebral Tumors
- **A.** Gliomas—infiltrate any portion of the brain; most common type of brain tumor
  1. Astrocytomas (grades I and II)
  2. Glioblastoma (astrocytoma grades III and IV)
  3. Oligodendroglioma (low and high grades)
  4. Ependymoma (grades I to IV)
  5. Medulloblastoma

II. Tumors Arising From Supporting Structures
- **A.** Meningiomas
- **B.** Neuromas (acoustic neuroma, schwannoma)
- **C.** Pituitary adenomas

III. Developmental Tumors
- **A.** Angiomas
- **B.** Dermoid, epidermoid, teratoma, craniopharyngioma

IV. Metastatic Lesions

Adapted from Hickey, J. V., & Strayer, A. L. (2020). *The clinical practice of neurological and neurosurgical nursing* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Gliomas

In adults, gliomas (principally astrocytoma) account for approximately 25% of symptomatic primary brain tumors. Glial tumors, the most common type of intracerebral brain neoplasm, are divided into many categories (McFaline-Figueroa & Lee, 2018). Astrocytomas, arising from astrocytic cells, are the most common type of glioma and are graded from I to IV, indicating the degree of malignancy (McFaline-Figueroa & Lee, 2018). The grade is based on cellular density, cell mitosis, and degree of differentiation from the original cell type. Grades III and IV tumors are known as glioblastomas and have little resemblance to the original cell type. Astrocytomas infiltrate into the surrounding neural connective tissue and therefore cannot be totally removed without causing considerable damage to vital structures.

Oligodendroglial tumors, arising from oligodendroglial cells, represent about 1.4% of gliomas (Hickey & Strayer, 2020). Most oligodendrogliomas occur in adults aged 50 to 60, are found in men more often than in women, and are categorized as low or high grade (anaplastic) (Young et al., 2017). The histologic distinction between astrocytomas and oligodendrogliomas is difficult to make but is important, because oligodendrogliomas are more sensitive than astrocytomas to chemotherapy. Tumors originating from

ependymal cells, another type of glial cell, are known as ependymomas and are more common in children than adults. Glial tumors may be treated with a combination of surgery, radiation therapy, and chemotherapy, depending on specific cell and patient characteristics as well as the location of the tumor (Young et al., 2017).

Meningiomas

Meningiomas, which represent 37% of all primary brain tumors, are common benign encapsulated tumors of arachnoid cells on the meninges (McFaline-Figueroa & Lee, 2018). They are slow growing, occur most often in middle-aged adults, and are more common in women. Meningiomas often occur in areas proximal to the venous sinuses. Manifestations depend on the area involved and are often the result of compression rather than invasion of brain tissue. Preferred treatment for symptomatic lesions is surgery with complete removal or partial dissection, although radiation therapy may be useful for some patients. Metastasis is rare with meningiomas but benign meningiomas may be challenging to remove surgically without causing neurologic deficits if the tumor is located at the base of the skull or surrounds the optic nerve, or in the rare case if the tumor is invasive. Multiple meningiomas may occur with neurofibromatosis type 2 (Euskirchen & Peyre, 2018).

Acoustic Neuromas

Acoustic neuromas account for 16% of brain tumors, with men and women equally affected, and occur most commonly in the fifth decade of life (Hong & Moliterno, 2019).

An acoustic neuroma is a tumor of the eighth cranial nerve—the cranial nerve most responsible for hearing and balance. It usually arises just within the internal auditory meatus, where it frequently expands before filling the cerebellopontine recess. An acoustic neuroma may grow slowly and attain considerable size before it is diagnosed. The patient usually experiences loss of hearing, tinnitus, and episodes of vertigo and staggering gait. As the tumor becomes larger, painful sensations of the face may occur on the same side as a result of the tumor's compression of the fifth cranial nerve (Hong & Moliterno, 2019). Many acoustic neuromas are benign and can be managed conservatively. Many that continue to grow can be surgically removed and have a good prognosis (see Chapter 59). Some acoustic neuromas may be suitable for stereotactic radiotherapy rather than open craniotomy. Stereotactic radiotherapy is discussed later in this chapter.

Pituitary Adenomas

Pituitary tumors account for about 16% of all primary brain tumors (AANN, 2016). They can occur at any age but are more common in older adults.

Women are affected more often than men, particularly during the childbearing years. Pituitary tumors are rarely malignant but cause symptoms as a result of pressure on adjacent structures or hormonal changes (Jang, Oh, Lee, et al., 2020).

Pressure Effects of Pituitary Adenomas

Pressure from a pituitary adenoma may be exerted on the optic nerves, optic chiasm, or optic tracts or on the hypothalamus or the third ventricle if the tumor invades the cavernous sinuses or expands into the sphenoid bone. These pressure effects produce headache, visual dysfunction, hypothalamic disorders (disorders of sleep, appetite, temperature, and emotions), increased ICP, and enlargement and erosion of the sella turcica (Donovan & Welch, 2018; Jang et al., 2020; Molitch, 2017).

Hormonal Effects of Pituitary Adenomas

Functioning pituitary tumors can produce one or more hormones normally produced by the anterior pituitary. Hormonal hypersecretion is caused only by pituitary adenomas (Molitch, 2017). Many adenomas (50%) secrete an excess amount of hormone including prolactin (prolactinomas), growth hormone (GH) producing acromegaly in adults, adrenocorticotropic hormone (ACTH) resulting in Cushing's disease, or thyroid-stimulating hormone (TSH) (Molitch, 2017). Adenomas that secrete TSH or follicle-stimulating hormone and luteinizing hormone occur infrequently, whereas adenomas that produce both GH and prolactin are relatively common.

The female patient whose pituitary gland is secreting excessive quantities of prolactin presents with amenorrhea or galactorrhea (excessive or spontaneous flow of milk). Male patients with prolactinomas may present with impotence and hypogonadism. Acromegaly, caused by excess GH, produces enlargement of the hands and feet, distortion of the facial features, and pressure on peripheral nerves (entrapment syndromes). The clinical features of Cushing's disease, a condition associated with prolonged overproduction of cortisol, occur with excessive production of ACTH. Manifestations include a form of obesity with redistribution of fat to the facial, supraclavicular, and abdominal areas; hypertension; purple striae and ecchymoses; osteoporosis; elevated blood glucose levels; and emotional disorders. See Chapter 45 for a discussion of endocrine disorders resulting from these tumors.

Gerontologic Considerations

The incidence of all brain tumors increases with age (Young et al., 2017). Intracranial tumors can produce personality changes, confusion, speech dysfunction, or disturbances of gait. In older adult patients, early signs and symptoms of intracranial tumors can be easily overlooked or incorrectly

attributed to cognitive and neurologic changes associated with normal aging (Eliopoulos, 2018). Neurologic signs and symptoms in the older adult must be carefully evaluated, because brain metastases occur in patients with a history of prior cancer. Regardless of the age of the patient or the decision to proceed or not with treatment, the nurse provides supportive care. Researchers have reported that the degree of frailty influences clinical outcomes of older adult patients undergoing surgery for brain tumor resection (Harland, Wang, Gunaydin, et al., 2020). Patients identified as moderately frail or frail are at increased risk for a longer length of hospital stay and tend to require discharge to a long-term care facility rather than home (Harland et al., 2020).

Clinical Manifestations

Brain tumors can produce both focal or generalized neurologic signs and symptoms. Generalized symptoms reflect increased ICP, and the most common focal or specific signs and symptoms result from tumors that interfere with functions in specific brain regions. Figure 65-1 indicates common brain tumor sites.

Increased Intracranial Pressure

As discussed in Chapter 61, the skull is a rigid compartment containing essential noncompressible contents: brain matter, intravascular blood, and cerebrospinal fluid (CSF). The Monro-Kellie hypothesis or doctrine explains the dynamic equilibrium of the cranial contents. According to this hypothesis, if any one of these skull components increases in volume, ICP increases unless one of the other components decreases in volume. Consequently, any change in volume occupied by the brain (as occurs with disorders such as brain tumor or cerebral edema) produces signs and symptoms of increased ICP (Witherspoon & Ashby, 2017).

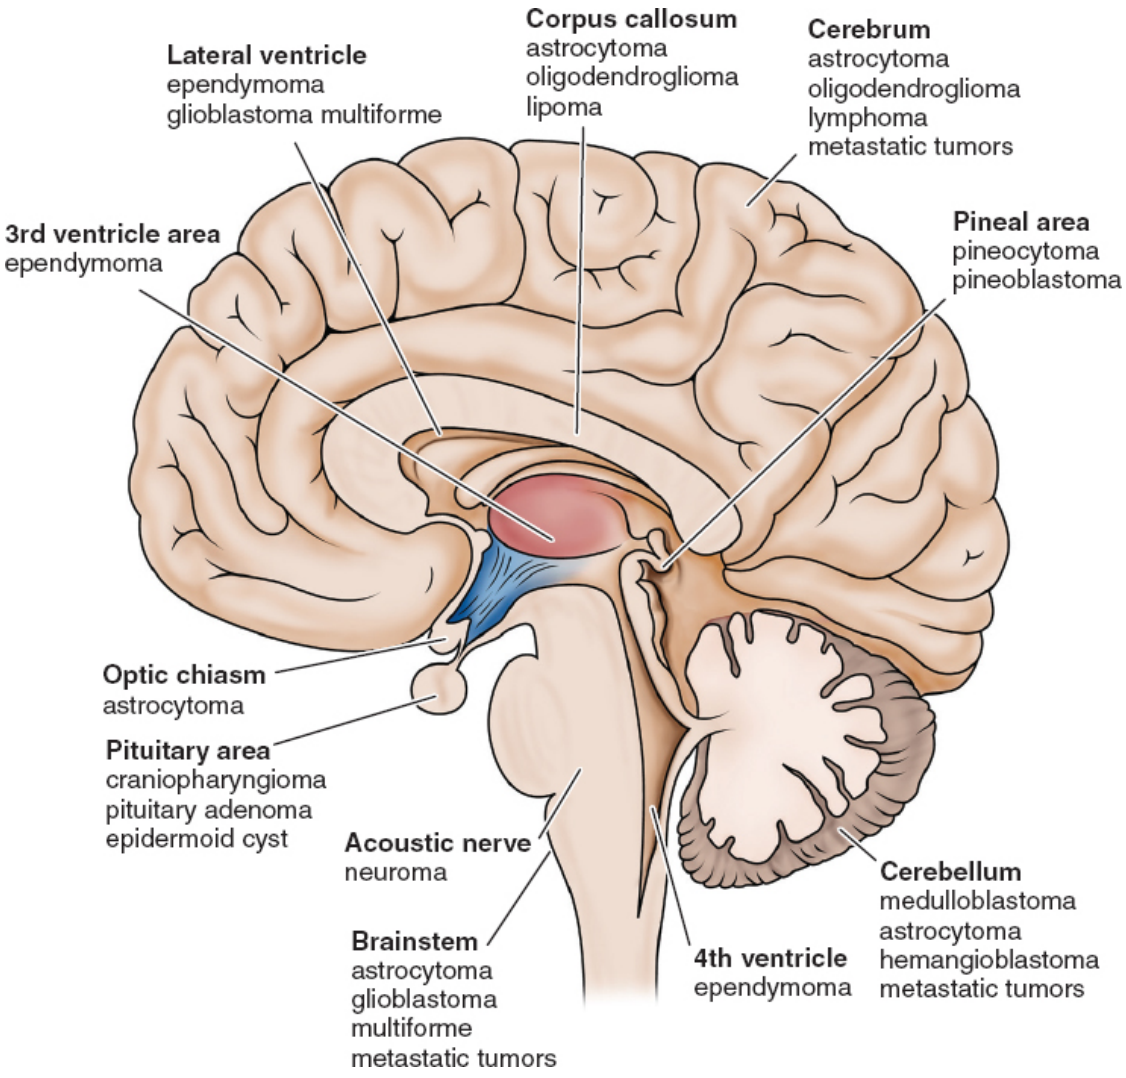

Figure 65-1 • Common brain tumor sites.

The enlarging tumor and its associating edema disrupts the equilibrium between the brain, blood, and CSF. As the tumor grows, compensatory adjustments may occur through compression of intracranial veins, reduction of CSF volume (by increased absorption or decreased production), a modest decrease in cerebral blood flow, or reduction of intra- and extracellular brain tissue mass. When these compensatory mechanisms fail, the patient develops signs and symptoms of increased ICP, most often including headache, nausea with or without vomiting, and **papilledema** (swelling of the optic nerve) (Hickey & Strayer, 2020). Personality changes and a variety of focal deficits, including motor, sensory, and cranial nerve dysfunction, are common.

Headache

One third of patients with brain tumors report headache as an early symptom (Hickey & Strayer, 2020). Headache is most commonly reported in the early morning and is made worse by coughing, straining, or sudden movement

(Norris, 2019). It is thought to be caused by the tumor invading, compressing, or distorting the pain-sensitive structures or by edema that accompanies the tumor. The headaches may be generalized or localized to the site of the tumor. As the edema increases, headache is generally bifrontal or bioccipital regardless of the tumor location (Hickey & Strayer, 2020).

Vomiting

Vomiting, seldom related to food intake, is usually the result of irritation of the vagal centers in the medulla (Hickey & Strayer, 2020). Forceful vomiting is described as projectile vomiting. Headache may be relieved by vomiting.

Visual Disturbances

The tumor itself or the surrounding edema can compress the third cranial nerve, causing optic disc swelling or papilledema. This limits the visual acuity along the visual pathway, mildly or profoundly, as diplopia (double vision), hemianopsia (visual field deficits), or varying levels of blindness (Jang et al., 2020).

Seizures

Seizures are common in patients with brain tumors either initially or throughout their disease process (McFaline-Figueroa & Lee, 2018). Seizures may be focal or generalized. Tumors of the frontal, parietal, and temporal lobes carry the greatest risk of seizures; seizures are unusual with brainstem or cerebellar tumors. See Chapter 61 for discussion about seizures and related management.

If not the initial presentation, seizures can be a result of metabolic factors (electrolyte imbalances, liver failure or kidney disease, radiation or chemotherapy side effects), structural causes (parenchymal metastases, leptomeningeal disease, dural metastases) or a new hemorrhage, thrombosis, or development of meningitis (Hickey & Strayer, 2020). If the patient presents with a seizure, then anticonvulsant drugs are prescribed. Medications with the best evidence for controlling seizure activity include levetiracetam, carbamazepine, phenytoin, and zonisamide (Comerford & Durkin, 2020).

Localized Symptoms

When specific regions of the brain are affected, local signs and symptoms occur, such as sensory or motor abnormalities, visual alterations, alterations in cognition, or language disturbances (e.g., aphasia). Identifying the signs and symptoms is important, because it can help identify tumor location. Some tumors are not easily localized because they lie in so-called silent areas of the brain (i.e., areas in which functions are not well defined). Many tumors can be

localized by correlating the signs and symptoms to specific areas in the brain, as follows (Hickey & Strayer, 2020):

- A tumor in the motor cortex of the frontal lobe produces hemiparesis and partial seizures on the opposite side of the body or generalized seizures. A frontal lobe tumor may also produce changes in emotional state and behavior, as well as an apathetic mental attitude. The patient often becomes impulsive, inappropriate in speech, gestures, and behavior.
- A parietal lobe tumor may cause decreased sensation on the opposite side of the body or generalized seizures.
- A temporal lobe tumor may cause seizures as well as psychological disorders.
- An occipital lobe tumor produces visual manifestations: contralateral homonymous hemianopsia (visual loss in half of the visual field on the opposite side of the tumor) and visual hallucinations.
- A cerebellar tumor causes dizziness; an ataxic or staggering gait with a tendency to fall toward the side of the lesion; marked muscle incoordination; and nystagmus (involuntary rhythmic eye movements), usually in the horizontal direction.
- A cerebellopontine angle tumor usually originates in the sheath of the acoustic nerve and gives rise to a characteristic sequence of symptoms. Tinnitus and vertigo appear first, soon followed by progressive nerve deafness (eighth cranial nerve dysfunction). Numbness and tingling of the face and tongue occur (due to involvement of the fifth cranial nerve). Later, weakness or paralysis of the face develops (seventh cranial nerve involvement). Finally, because the enlarging tumor presses on the cerebellum, abnormalities in motor function may be present.
- Brainstem tumors may be associated with cranial nerve deficits along with complex motor and sensory function impairments (see Chapter 64, Table 64-3).

Assessment and Diagnostic Findings

The history of the illness, the manner, and the time frame in which the symptoms evolved are key components in the diagnosis of brain tumors. A neurologic examination indicates the involved areas of the CNS. To assist in the precise localization of the lesion, a battery of tests is performed. Computed tomography (CT) scans, enhanced by a contrast agent, can give specific information concerning the number, size, and density of the lesions, and the extent of secondary cerebral edema. CT can provide information about the ventricular system. A magnetic resonance imaging (MRI) scan is the most

helpful diagnostic tool for detecting brain tumors, particularly smaller lesions, and tumors in the brainstem and pituitary regions, where bone is thick. MRI is also useful in monitoring response to treatment.

Computer-assisted stereotactic (three-dimensional) biopsy is used to diagnose deep-seated brain tumors and to provide a basis for treatment and prognosis. Stereotactic approaches involve the use of a three-dimensional frame that allows very precise localization of the tumor; a stereotactic frame and multiple imaging studies (x-rays, CT scans, or MRIs) are used to localize the tumor and verify its position (see Fig. 65-2). Brain-mapping technology helps determine the proximity of diseased areas of the brain to structures essential for normal brain function.

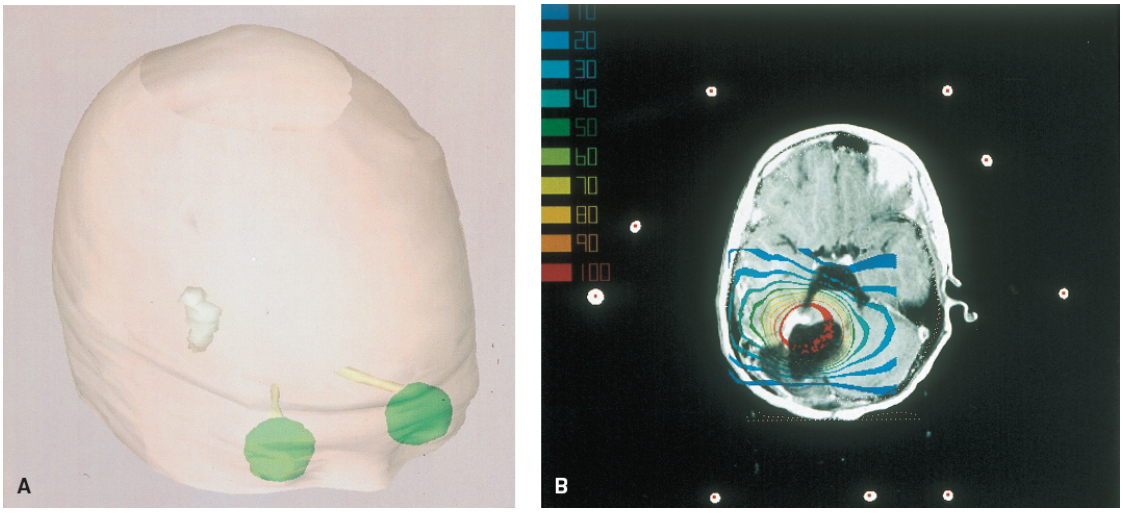

Figure 65-2 • A. Using stereotactic or "brain-mapping" guided approach, a three-dimensional computer image fuses the computed tomography image and magnetic resonance image to pinpoint the exact location of the brain tumor. This low-grade astrocytoma is localized adjacent to the brainstem, is inoperable, and is treated with radiation. Note the optic chasm and optic nerves. **B.** Computerized image of the prescribed radiation dose.

Positron emission tomography (PET) is used to supplement MRI scanning in many centers. On PET scans, low-grade tumors are associated with hypometabolism, and high-grade tumors show hypermetabolism. This information can be useful in making treatment decisions (Achrol, Rennert, Anders, et al., 2019). An electroencephalogram can detect abnormal brain waves in regions occupied by or adjacent to tumor; it is used to evaluate temporal lobe seizures and to assist in ruling out other disorders. Cytologic studies of the CSF may be performed to detect malignant cells as CNS tumors can shed cells into the CSF resulting in metastasis.

Medical Management

A variety of medical management approaches, including surgery, chemotherapy, and external-beam radiation therapy, are used alone or in combination (AANN, 2016; Hickey & Strayer, 2020). A relatively new treatment option for glioblastomas is tumor-treating fields. This device provides alternating electric field therapy that disrupts the mitotic process and is worn on the head (McFaline-Figueroa & Lee, 2018). The main side effect is skin irritation.

Secreting tumors may be treated with medications that suppress hormones. Nonfunctioning tumors may have no effect on pituitary function or may suppress hormone production and release. Hormone replacement may be necessary for these patients to restore normal endocrine function. The management of brain tumors is complex and requires an interdisciplinary approach to care to optimize patient outcomes (Achrol et al., 2019).

Surgical Management

The objective of surgical management is to remove as much tumor as possible without increasing the neurologic deficit (paralysis, blindness), or to relieve symptoms by partial removal (decompression). Surgery also provides the opportunity to biopsy tissue to establish a definitive diagnosis. A variety of surgical approaches may be used; the specific approach depends on the type of tumor, its location, and its accessibility. Conventional surgical approaches require a craniotomy (incision into the skull). See Chapter 61 for a discussion of care of the patient who has undergone a craniotomy. This approach is used in patients with meningiomas, acoustic neuromas, cystic astrocytomas of the cerebellum, colloid cysts of the third ventricle, congenital tumors such as dermoid cyst, and some of the granulomas. With improved imaging techniques and the availability of the operating microscope and microsurgical instrumentation, even large tumors can be removed through a relatively small craniotomy. For patients with malignant glioma, complete removal of the tumor and cure are not possible, but the rationale for resection includes relief of ICP, removal of any necrotic tissue, and reduction in the bulk of the tumor, which theoretically leaves behind fewer cells to become resistant to radiation or chemotherapy. Most pituitary adenomas are treated by transsphenoidal microsurgical removal (see Chapter 61), and the remainder of tumors that cannot be removed completely are treated by radiation (Hickey & Strayer, 2020).

Radiation Therapy

Radiation therapy—the cornerstone of treatment for many brain tumors—decreases the incidence of recurrence of incompletely resected tumors (AANN, 2016). Gamma radiation is delivered via an external beam to the

tumor in multiple fractions. Brachytherapy (the surgical implantation of radiation sources to deliver high doses at a short distance) is an option for some types of tumors depending on their location. It is usually used as an adjunct to conventional radiation therapy or as a rescue measure for recurrent disease. Radioisotopes such as iodine 131 (^{131}I) are used to minimize effects on surrounding brain tissue.

Stereotactic procedures may be performed using a linear accelerator or gamma knife to perform radiosurgery (Hickey & Strayer, 2020). These procedures allow treatment of deep, inaccessible tumors, often in a single session. Precise localization of the tumor is accomplished by the stereotactic approach and by minute measurements and precise positioning of the patient. Multiple narrow beams then deliver a very high dose of radiation. An advantage of this method is that no surgical incision is needed. Disadvantages include the lag time between treatment and the desired result as well as the potential for developing radiation necrosis (AANN, 2016).

Chemotherapy

Chemotherapy may be used in conjunction with radiation therapy, or as the sole therapy, with the goal of increasing survival time. The greatest challenge in chemotherapy of brain tumors is that the blood–brain barrier prevents drugs from getting to the tumor in effective doses without causing systemic toxicity (AANN, 2016).

Malignant glioma is usually treated with 6 weeks of oral temozolomide during radiation therapy, followed by 6 to 12 months of oral temozolomide. Low-grade gliomas may be treated with 6 months of oral temozolomide alone. Temozolomide is an oral chemotherapy that crosses the blood–brain barrier (McFaline-Figueroa & Lee, 2018). Several other chemotherapy agents are used alone or in combination depending on the type of tumor.

Autologous bone marrow transplantation is used in some patients who will receive chemotherapy or radiation therapy, because it can “rescue” the patient from the bone marrow toxicity associated with high doses of chemotherapy and radiation. A fraction of the patient’s bone marrow is aspirated, usually from the iliac crest, and stored. The patient receives large doses of chemotherapy or radiation therapy to destroy large numbers of malignant cells. The marrow is then reinfused intravenously after treatment is completed. See Chapter 12 for discussion of bone marrow transplant.

Pharmacologic Therapy

Corticosteroids are useful in relieving headache and alterations in level of consciousness. Corticosteroids such as dexamethasone are thought to reduce inflammation and edema around tumors (AANN, 2016). Other medications used include osmotic diuretics (e.g., mannitol and hypertonic saline) to

decrease the fluid content of the brain, which leads to a decrease in ICP. Anticonvulsant medications are used to treat and control seizures (Comerford & Durkin, 2020).

Nursing Management

The characteristics of headache, when present, should be assessed. Upright positioning and pain medications may be useful in managing pain; nurses should evaluate the effectiveness of pain management interventions (Ijzerman-Korevaar, Snijers, Saskia, et al., 2018). Even if seizure history is absent, the patient and family should be educated about the possibility of seizure and the need to adhere to prophylactic anticonvulsant medications, if prescribed. The patient with a brain tumor may be at increased risk for aspiration as a result of cranial nerve dysfunction. Medications to alleviate nausea and to prevent vomiting should be considered (Ijzerman-Korevaar et al., 2018). Preoperatively, the gag reflex and ability to swallow are evaluated. In patients with diminished gag response, care includes educating the patient to direct food and fluids toward the unaffected side, having the patient sit upright to eat, offering a semisoft diet, and having suction readily available. The effects of increased ICP caused by the tumor mass are reviewed in Chapter 61. The nurse performs neurologic checks; monitors vital signs; maintains a neurologic observation record (see Chapter 61, Fig. 61-6); spaces nursing interventions to prevent rapid increase in ICP; and reorients the patient when necessary to person, time, and place. The use of corticosteroids to control headache and neurologic symptoms requires astute nursing assessment and intervention because many adverse effects can occur, including hyperglycemia, electrolyte abnormalities, and muscle weakness (see Chapter 45, Table 45-3). Patients with changes in cognition caused by their lesion require frequent reorientation and the use of orienting devices (e.g., personal possessions, photographs, lists, a clock), supervision of and assistance with self-care, and ongoing monitoring and intervention for prevention of injury. Patients with seizures are carefully monitored and protected from injury. Motor function is checked at intervals because specific motor deficits may occur, depending on the tumor's location. When muscle weakness is present, an interprofessional approach, including the nurse and physical and occupational therapists, can be used to preserve muscle strength, promote range of motion, and facilitate independence in self-care. Sensory disturbances are assessed and any area of numbness should be protected from injury. Speech is evaluated, and patients with speech deficits can be educated to use alternative forms of communication. Eye movement and pupillary size and reaction may be affected by cranial nerve involvement. Fatigue is common during therapy; efforts should be made to conserve energy and promote rest.

The psychosocial effects on family caregivers of a family member who has brain metastases may be significant (Ketcher, Otto, & Reblin, 2020). Caregivers should be included in the plan of care.

The nursing process for patients undergoing neurosurgery is discussed in Chapter 61. The patient's functional abilities should be reassessed postoperatively, because changes can occur.

Cerebral Metastases

A significant number of patients with cancer experience neurologic deficits caused by metastasis to the nervous system, which can include the brain, CSF, and meninges. Metastatic lesions to the brain are more common than primary brain tumors and have an associated 2-year survival rate of less than 10% (Achrol et al., 2019). The high number of metastatic brain tumors is clinically important, as more patients with all forms of cancer live longer because of improved therapies. Neurologic signs and symptoms include headache, gait disturbances, visual impairment, personality changes, altered mentation (memory loss and confusion), focal weakness, paralysis, aphasia, and seizures (McFaline-Figueroa & Lee, 2018). These signs and symptoms can be devastating to both patient and family. Metastases to the CSF and meninges, known as leptomeningeal metastases, can produce symptoms of headache and isolated cranial nerve deficits.

Medical Management

The treatment of metastatic nervous system cancer is palliative and involves eliminating or reducing serious symptoms. Even when palliation is the goal, distressing signs and symptoms can be relieved, thereby improving the quality of life for both patient and family (McFaline-Figueroa & Lee, 2018). Patients with intracerebral metastases who are not treated have a poor prognosis with a limited survival time. The therapeutic options include whole brain radiation therapy (the foundation of treatment) for multiple metastases or stereotactic radiosurgery for up to three sites of metastases. Surgery may be considered for a single symptomatic metastasis. Systemic chemotherapy directed at the primary cancer may be ineffective in crossing the blood–brain barrier, but chemotherapy that crosses this barrier may be added. Intrathecal chemotherapy, with direct injection of chemotherapy agents into the CSF of the brain or spinal canal, may be useful in persons with metastases (Song, Li, Yin, et al., 2018). Some combination of these treatments is usually the optimal method.

Pain can be a significant problem and is managed by means of a stepped progression in the doses and type of analgesic agents needed for relief. If the

patient has severe pain, morphine can be infused into the epidural or subarachnoid space through a spinal needle and a catheter placed as near as possible to the spinal segment where the pain is projected. Small doses of morphine are given at prescribed intervals (see Chapter 9).

NURSING PROCESS

The Patient with Nervous System Metastases or Primary Brain Tumor

Assessment

The nursing assessment includes a baseline neurologic examination and focuses on how the patient is functioning, moving, and walking; adapting to weakness or paralysis and to loss of vision and speech; and dealing with seizures. Assessment addresses symptoms that cause distress to the patient and affect the quality of life, including pain, respiratory problems, bowel and bladder disorders, and sleep disturbances, as well as impairment of skin integrity, fluid balance, and temperature regulation (Hickey & Strayer, 2020). Nutritional status is assessed, because cachexia and cancer-related anorexia-cachexia syndrome are common (see Chapter 12).

The nurse takes a dietary history to assess food intake, intolerance, and preferences. Calculation of body mass index can confirm the loss of subcutaneous fat and lean body mass (see Chapter 4). Biochemical measurements are reviewed to assess the degree of malnutrition, impaired cellular immunity, and electrolyte balance (normal laboratory values are found in Appendix A on thePoint). A dietitian assists in determining the caloric needs of the patient.

The nurse works with other members of the health care team to assess the impact of the illness on the family in terms of home care, altered relationships, financial problems, time pressures, and family problems. This information is important in helping family members cope with the diagnosis and the changes associated with it.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired self-feeding, impaired ability to perform hygiene, impaired ability to dress, and impaired self-toileting associated with loss or impairment of motor and sensory functions and decreased cognitive abilities
- Impaired nutritional status associated with cachexia due to treatment and tumor effects, decreased nutritional intake, and malabsorption
- Impaired nutritional status associated with increased nutritional intake and impaired metabolism
- Anxiety associated with uncertainty, change in appearance, or altered lifestyle

- Interrupted family process associated with situational crisis imposed by the care of the person with a terminal illness

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Seizures (see Chapter 61)
- Headaches (see Chapter 61)

Planning and Goals

The goals for the patient include compensating for self-care deficits, improving nutrition, reducing anxiety, enhancing family coping skills, and absence of complications.

Nursing Interventions

Compensating for Self-Care Deficits

The patient may have difficulty participating in goal setting depending on the tumor location and if cognitive function is affected. The nurse encourages the family to assist the patient to be as independent as possible for as long as possible (Hickey & Strayer, 2020). Increasing assistance with self-care activities is to be expected. Because the patient with nervous system metastasis and the family live with uncertainty, they are encouraged to plan for each day and to make the most of each day. The tasks and challenges are to assist the patient to find useful coping mechanisms, adaptations, and compensations for solving problems that arise. Use of an interprofessional health care team is helpful. An individualized exercise program helps maintain strength, endurance, and range of motion. Eventually, referral for home or hospice care may be necessary (see Chapter 13).

Improving Nutrition

Patients with nausea, vomiting, diarrhea, breathlessness, and pain are rarely interested in eating. These symptoms are managed or controlled through assessment, planning, and care. The nurse educates the family about how to position the patient for comfort and safety during meals. A dietician may help with alternative food choices that are easily tolerated. Meals are planned for times when the patient is rested and in less distress from pain or the effects of treatment.

The patient needs to be clean, comfortable, and free of pain for meals in an environment that is as attractive as possible. Oral hygiene before meals helps to improve appetite. Offensive sights, sounds, and odors are eliminated. Creative strategies may be required to make food more palatable, provide enough fluids, and increase opportunities for socialization during meals. The family may be asked to keep a log of daily weights and to record the quantity of food eaten to determine the daily calorie count. Dietary supplements, if acceptable to the patient, can be

provided to meet increased caloric needs. If the patient is not interested in most usual foods, those foods preferred by the patient should be offered. When the patient shows marked deterioration as a result of tumor growth and effects, some other form of nutritional support (e.g., tube feeding, parenteral nutrition) may be indicated if consistent with the patient's end-of-life preferences (AANN, 2016) (see Chapter 39 for discussion of tube feeding and Chapter 41 for discussion of parenteral nutrition). Nursing interventions include assessing the patency of the central and intravenous lines or feeding tube, monitoring the insertion site for infection, checking the infusion rate, monitoring intake and output, and changing the intravenous tubing and dressing. Family members are instructed in these techniques if they will be providing care at home. Parenteral nutrition can be provided at home if indicated. The patient's quality of life may guide the selection, initiation, maintenance, and discontinuation of nutritional support. The nurse and family should not place too much emphasis on eating or on discussions about food, because the patient may not desire aggressive nutritional intervention. The subsequent course of action must be congruent with the wishes and choices of the patient and family.

Increased appetite may occur in patients receiving steroids and may result in weight gain as well as hyperglycemia. Patients and family members should be instructed to monitor weight and blood glucose (if appropriate), as well as maintain a healthy diet with caloric intake appropriate to patient needs.

Relieving Anxiety

Patients may be restless, with changing moods that may include intense depression, euphoria, paranoia, and severe anxiety. The patient's response to a life-threatening illness reflects their pattern of reaction to other crisis situations. Serious illness imposes additional strains that often bring other unresolved problems to light. The patient's own coping strategies can help deal with anxious and depressed feelings. Health care providers need to be sensitive to the patient and caregivers' concerns and fears (Ketcher et al., 2020).

Patients need the opportunity to exercise some control over their situation. A sense of mastery can be gained as they learn to understand the disease and its treatment and how to deal with their feelings. Researchers have reported that resilience positively influences problem-based coping strategies (Liang, Liu, Lu, et al., 2020). The presence of family, friends, a spiritual advisor, and health care professionals may be supportive. Brain tumor support services may provide a feeling of meaning and strength (see the Resources section).

Spending time with patients allows them time to talk and to communicate their fears and concerns. Open communication and acknowledgment of fears are often therapeutic. Touch is also a form of

communication. These patients need reassurance that continuing care will be provided and that they will not be abandoned. If a patient's emotional reactions are very intense or prolonged, additional help from a spiritual advisor, social worker, or mental health professional may be indicated.

Enhancing Family Processes

The family needs to be reassured that their loved one is receiving optimal care and that attention will be paid to the patient's changing symptoms and concerns. If the patient can no longer carry out self-care, the family and additional support systems (social worker, home health aide, home health nurse, hospice nurse) may be needed. Assessment and education of family caregivers about neurologic and cognitive symptoms is necessary, acute, and challenging (Boele, Terhorst, Prince, et al., 2019). Investigating resources that are available may decrease the burden on the caregivers. These efforts improve the psychosocial well-being of the patient and family caregivers (Boele et al., 2019; Ketcher et al., 2020).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The patient and family often have major responsibility for care at home. Caregivers may struggle with a new "normal" while their support systems fluctuate as their relationship with the patient they are caring for is strengthened, maintained, or strained (Ketcher et al., 2020). In addition to the psychological aspect, education includes pain management strategies, prevention of complications related to treatment strategies, and methods to ensure adequate fluid and food intake (see Chart 65-2). Educational needs of the patient and family regarding care priorities are likely to change as the disease progresses; the nurse should assess the changing needs of the patient and the family and inform them about resources and services early and frequently to assist them (see the Resources section).

Continuing and Transitional Care. Home health services are valuable resources that should be made available to the patient and the family early in the course of an illness. Anticipating needs before they occur can assist in smooth initiation of services. Home health focuses on the areas of symptom and pain control, assistance in self-care, control of treatment complications, and administration of specific forms of treatment (e.g., parenteral nutrition). The nurse assesses pain management, respiratory status, complications of the disorder and its treatment, and the patient's cognitive and emotional status. In addition, the nurse assesses the family's ability to perform necessary care and notifies the primary provider about changing needs or complications, if indicated.

Steps to initiate hospice care, including discussion of hospice care as an option, should not be postponed until death is imminent for the patient with a metastasis or high-grade tumor. Exploration of hospice care as an option

should be initiated at a time when hospice services can provide support and care to the patient and family consistent with their end-of-life decisions and can assist in allowing death with dignity. See Chapter 13 for in-depth discussion of end-of-life care.

Evaluation

Expected patient outcomes may include:

1. Engages in self-care activities to extent possible
   a. Uses assistive devices or accepts assistance as needed
   b. Schedules periodic rest periods to permit maximal participation in self-care
2. Maintains as optimal a nutritional status as possible
   a. Eats and accepts food within limits of condition and preferences

Chart 65-2  HOME CARE CHECKLIST

The Patient with Nervous System Metastases or Primary Brain Tumor

At the completion of education, the patient and/or caregiver will be able to:

- State effects of the tumor according to its type and location in the brain or spinal cord.
- State the impact of the tumor and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
  - Describe goals and side effects of treatment and suggested management approaches.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - When indicated, use nonpharmacologic pain management techniques in addition to prescribed pharmacologic methods.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., nutritional needs, ADL assistance) necessary to maintain health.
- Identify coping strategies, such as:
  - Taking control, setting daily goals, and staying positive
  - Participating in rehabilitation to improve self-care
  - Engaging in relaxation techniques
  - Utilizing family support
  - Contacting support services (e.g., American Brain Tumor Association)
  - Participating in faith community/religious practices
- Identify community resources, including palliative care, home health service, or hospice, as appropriate.
- List complications of medications/therapeutic regimen necessitating a call to the nurse or primary provider.
- List complications of medications/therapeutic regimen necessitating a visit to the emergency department.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.

Resources

See Chapter 12, Chart 12-10: Home Care Checklist: The Patient Receiving Care for an Oncologic Disorder.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

b. Accepts alternative methods of providing nutrition if indicated

3. Reports being less anxious
   a. Is less restless and is sleeping better
   b. Verbalizes concerns and fears
   c. Participates in activities of personal importance
4. Family members seek help as needed
   a. Demonstrate ability to bathe, feed, and care for the patient and participate in pain management and prevention of complications
   b. Express feelings and concerns to appropriate health professionals
   c. Discuss and seek hospice care as needed
5. Understands ways to avoid complications and is free of complications
   a. Explains reasons for measures to prevent complications
   b. Seizures and headaches are controlled to the extent possible

Spinal Cord Tumors

Tumors within the spinal canal are classified according to their anatomic relation to the spinal cord (Hickey & Strayer, 2020). They include intramedullary lesions (within the spinal cord), extramedullary-intradural lesions (within or under the spinal dura), and extramedullary-extradural lesions (outside the dural membrane). Primary tumors are usually intramedullary, consisting of astrocytoma or ependymoma; meningiomas can occur as extramedullary-intradural lesions (Epstein, 2018). Secondary tumors are far more common and are usually extramedullary-extradural lesions. Tumors that occur within the spinal canal or exert pressure on it cause symptoms ranging from localized or shooting pains, weakness, and loss of reflexes below the tumor level to progressive loss of motor function and paralysis. Usually, sharp pain occurs in the area innervated by the spinal roots that arise from the cord in the region of the tumor. In addition, increasing sensory deficits develop below the level of the lesion. Loss of bowel and bladder function is common.

Assessment and Diagnostic Findings

Neurologic examination and diagnostic studies are used to make the diagnosis. Neurologic examination focuses on assessing pain and identifying loss of reflexes, sensation, or motor function. Helpful diagnostic studies include CT scans, MRI scans, and biopsy. The MRI scan is the most commonly used and the most sensitive diagnostic tool (Hickey & Strayer, 2020) and it is

particularly helpful in detecting epidural spinal cord compression and metastases (Kaplow & Iyere, 2016).

Medical Management

Treatment of specific intraspinal tumors depends on the type and location of the tumor, the presenting symptoms, and the patient's physical status. Surgical intervention is the primary treatment for most spinal cord tumors followed by chemotherapy and radiation therapy.

Extramedullary-extradural spinal cord compression occurs in 5% to 7% of patients who die of cancer and is considered a neurologic emergency (Kaplow & Iyere, 2016). For the patient with spinal cord compression resulting from metastatic cancer (most commonly from breast, prostate, or lung), high-dose dexamethasone combined with radiation therapy is effective in relieving pain (see Chapter 12 for a discussion of care of the patient with spinal cord compression). Palliative care may be an option for the medical management of some patients. Chemotherapy specific to the tumor type may be considered (AANN, 2016).

Surgical Management

Tumor removal is desirable but not always possible. The goal is to remove as much tumor as possible while sparing uninvolved portions of the spinal cord. Sudden decrease or loss of motor, sensory, and bowel and bladder function indicates the need for emergent surgery to reestablish function and protect the cord from further damage (Hickey & Strayer, 2020). Microsurgical techniques have improved the prognosis for patients with intramedullary tumors. Extramedullary-intradural tumors may be completely resected. Prognosis is related to the degree of neurologic impairment at the time of surgery, the speed with which symptoms occurred, and the origin of the tumor. Patients with extensive neurologic deficits before surgery are less likely to regain full functional recovery after successful tumor removal.

Nursing Management

Providing Preoperative Care

The objectives of preoperative care include recognition of neurologic changes through ongoing assessments, pain control, and management of altered activities of daily living (ADLs) resulting from sensory and motor deficits and bowel and bladder dysfunction. The nurse assesses for weakness, muscle wasting, spasticity, sensory changes, bowel and bladder dysfunction, and potential respiratory problems, especially if a cervical tumor is present. The patient is also evaluated for coagulation deficiencies. A history of

anticoagulation medication use is obtained and reported, because the use of these may impede hemostasis postoperatively. The patient is educated about breathing exercises, and they are demonstrated preoperatively. Postoperative pain management strategies are discussed with the patient before surgery.

Assessing the Patient After Surgery

The patient is monitored for deterioration in status with frequent and targeted assessments of vital signs and neurologic examinations (Hickey & Strayer, 2020). A sudden onset of neurologic deficit is an ominous sign and may be due to spinal cord ischemia or infarction. Frequent neurologic checks are carried out, with emphasis on movement, strength, and sensation of the upper and lower extremities. Assessment of sensory function involves pinching the skin of the arms, legs, and trunk to determine if there is loss of feeling and, if so, at what level. Vital signs are monitored at regular intervals to detect and treat potential complications early (Hemmer, 2018).

Managing Pain

The prescribed pain medication should be given in adequate amounts and at appropriate intervals to relieve pain and prevent its recurrence. Pain is the hallmark of spinal metastasis. Patients with sensory root involvement may suffer excruciating pain, which requires effective pain management.

The bed is usually kept flat initially. The nurse turns the patient as a unit, keeping shoulders and hips aligned and the back straight (also referred to as logrolling) (see discussion later in chapter). The side-lying position is usually the most comfortable, because this position imposes the least pressure on the surgical site. Placement of a pillow between the knees of the patient in a side-lying position helps to prevent extreme knee flexion.

Monitoring and Managing Potential Complications

If the tumor was in the cervical area, respiratory compromise due to postoperative edema may occur (Kaplow & Iyere, 2016). The nurse monitors the patient for asymmetric chest movement, abdominal breathing, and abnormal breath sounds. For a high cervical lesion, the endotracheal tube remains in place until adequate respiratory function is ensured. The patient is encouraged to perform deep-breathing and coughing exercises.

The area over the bladder is palpated or a bladder scan performed to assess for urinary retention (see Chapter 47, Fig. 47-8). The nurse also monitors for incontinence, because urinary dysfunction usually implies significant decompensation of spinal cord function. An intake and output record is maintained. In addition, the abdomen is auscultated for bowel sounds.

Staining of the dressing may indicate leakage of CSF from the surgical site, which may lead to serious infection or to an inflammatory reaction in the

surrounding tissues that can cause severe pain in the postoperative period. Bulging at the incision may indicate contained CSF leak. The site should be monitored for increasing bulging, known as pseudomeningocele, which may require surgical repair (Alattar, Hirshman, McCutcheon, et al., 2018; Hickey & Strayer, 2020).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

In preparation for discharge, the patient is assessed for the ability to function independently in the home and for the availability of resources such as family members to assist in caregiving. Patients with residual sensory involvement are cautioned about the dangers of extremes in temperature. They should be educated about the dangers of heating devices (e.g., hot water bottles, heating pads, space heaters) as their sensory integration may be impaired, causing them to lose the ability to detect dangerous stimulations and to react appropriately. The patient is educated to check skin integrity daily. Patients with impaired motor function related to motor weakness or paralysis may require training in ADLs and safe use of assistive devices, such as a cane, walker, or wheelchair. The patient and family members are educated about pain management strategies, bowel and bladder management, and assessment for signs and symptoms that should be reported promptly (see Chart 65-2).

Continuing and Transitional Care

Referral for inpatient or outpatient rehabilitation may be warranted to improve self-care abilities. A consultation for home, community-based, or transitional care may be indicated and provides the nurse with the opportunity to assess the patient's physical and psychological status and the patient's and family's ability to adhere to recommended management strategies. During the home visit, the nurse determines whether changes in neurologic function have occurred. The patient's respiratory status and nutritional status are assessed. The adequacy of pain management is assessed, and modifications are made to ensure adequate pain relief. The need for hospice services or placement in an extended care facility is discussed with the patient and family if warranted, and the patient is asked about preferences for end-of-life care. In addition, social workers may be consulted to assist the patient and family members in identifying support services that can provide help in coping with the disease process (Hickey & Strayer, 2020).

DEGENERATIVE DISORDERS

Disorders of the central and peripheral nervous system that are **neurodegenerative** (leading to deterioration of normal cells or function of the nervous system) are characterized by the slow onset of signs and symptoms. Patients are managed at home for as long as possible and are admitted to the acute care setting for exacerbations, treatments, and surgical interventions as needed.

Parkinson's Disease

PD is a slowly progressing neurologic movement disorder that eventually leads to disability. It affects about 1 million patients who are hospitalized in the United States each year (Moore, Smith, & Cho, 2017). The disease affects men more often than women. Symptoms usually first appear in the fifth decade of life; however, cases have been diagnosed as early as 30 years of age. The degenerative or idiopathic form of PD is the most common; there is also a secondary form with a known or suspected cause. Although the cause of most cases is unknown, research suggests a multifactorial combination of age, environment, and heredity (AANN, 2019).

Pathophysiology

PD is associated with decreased levels of dopamine resulting from degeneration of dopamine storage cells in the substantia nigra in the basal ganglia region of the brain (see Fig. 65-3). Fibers or neuronal pathways project from the substantia nigra to the corpus striatum, where neurotransmitters are vital to the control of complex body movements. Through the neurotransmitters acetylcholine (excitatory) and dopamine (inhibitory), striatal neurons relay messages to the higher motor centers that control and refine motor movements. The loss of dopamine stores in this area of the brain results in more excitatory neurotransmitters than inhibitory neurotransmitters, leading to an imbalance that affects voluntary movement (Hickey & Strayer, 2020).

Clinical symptoms do not appear until 60% of the pigmented neurons are lost and the striatal dopamine level is decreased by 80%. Cellular degeneration impairs the extrapyramidal tracts that control semiautomatic functions and coordinated movements; motor cells of the motor cortex and the pyramidal tracts are not affected. Researchers are working on uncovering the exact mechanism of neurodegeneration. Current theories suggest a combined and complicated interweaving of both environmental and genetic factors that affect numerous fundamental cellular processes. Fifteen percent of early PD cases are associated with multiple genetic mutations (Poewe, Seppi, Tanner, et al., 2017). Ongoing research includes recognition of biomarkers and development of individualized treatment options (Poewe et al., 2017).

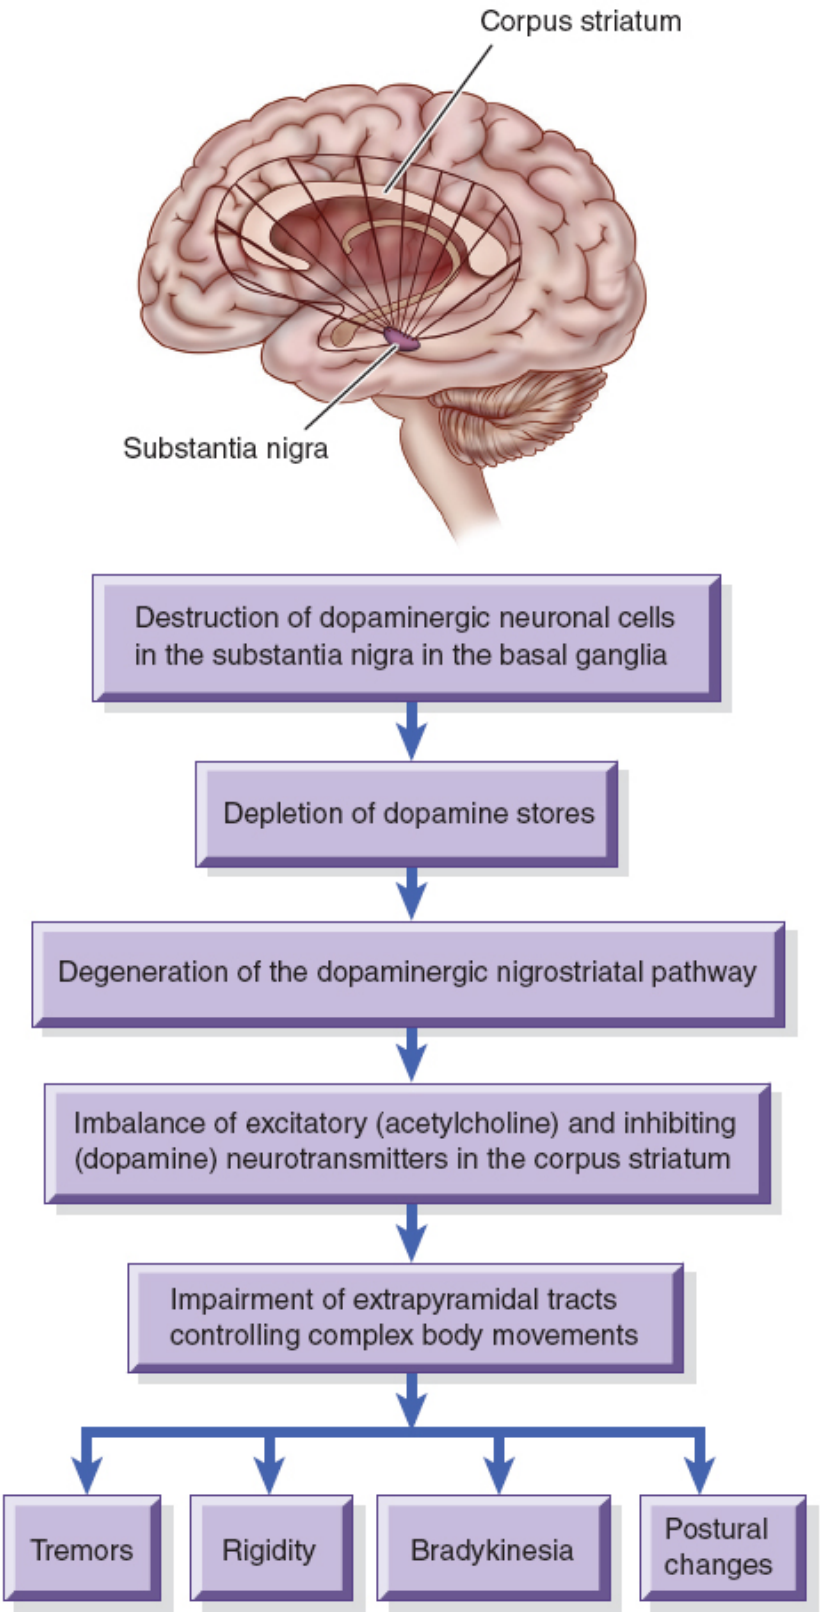

Figure 65-3 • Pathophysiology of Parkinson's disease. The nuclei in the substantia nigra project fibers to the corpus striatum. The

nerve fibers carry dopamine to the corpus striatum. The loss of dopamine nerve cells from the brain's substantia nigra is thought to be responsible for the symptoms of Parkinson's disease.

Clinical Manifestations

PD has a gradual onset, and symptoms progress slowly over a chronic, prolonged course. The cardinal signs are tremor, rigidity, bradykinesia/akinesia, and postural instability (Hickey & Strayer, 2020). Two major subtypes of PD are tremor dominant (most other symptoms are absent) and nontremor dominant (akinetic-rigid and postural instability).

Tremor

Although symptoms are variable, a slow, unilateral resting tremor is present in the majority of patients at the time of diagnosis. Resting tremor characteristically disappears with purposeful movement and during sleep but is evident when the extremities are motionless or at rest. The tremor may manifest as a rhythmic, slow turning motion (pronation–supination) of the forearm and the hand and a motion of the thumb against the fingers as if rolling a pill between the fingers.

Rigidity

Resistance to passive limb movement characterizes muscle rigidity. Passive movement of an extremity may cause the limb to move in jerky increments, referred to as lead-pipe or cogwheel movements. Involuntary stiffness of the passive extremity increases when another extremity is engaged in voluntary active movement. Stiffness of the arms, legs, face, and posture are common. Early in the disease, the patient may complain of shoulder pain due to rigidity (Hickey & Strayer, 2020).

Bradykinesia

A common feature of PD is **bradykinesia**, which refers to the overall slowing of active movement (Bronner & Korczyn, 2017). Patients may also take longer to complete activities and have difficulty initiating movement, such as rising from a sitting position or turning in bed.

Postural Instability

The patient commonly develops postural and gait problems. Due to a loss of postural reflexes, the patient stands with the head bent forward and walks with a propulsive gait. The posture is caused by the forward flexion of the neck, hips, knees, and elbows. The patient may walk faster and faster, trying to move the feet forward under the body's center of gravity (shuffling gait). Difficulty

in pivoting causes loss of balance, either forward (propulsion) or backward (retropulsion). Gait impairment and postural instability place the patient at increased risk for falls (Hickey & Strayer, 2020).

Other Manifestations

The effect of PD on the basal ganglia often produces autonomic symptoms that include excessive and uncontrolled sweating, drooling, paroxysmal flushing, orthostatic hypotension, gastric and urinary retention, constipation, and sexual dysfunction (Bronner & Korczyn, 2017). Dysphagia is a substantial problem, with more than 50% of patients reporting choking as well as vision and olfactory changes (AANN, 2019). Neurogenic orthostatic hypotension occurs in 30% to 50% of patients with PD (Sin & Khemani, 2020).

Psychiatric changes include depression, anxiety, dementia, delirium, hallucinations, and psychosis. Depression and anxiety are common; whether these are reactions to the disorder or related to a biochemical abnormality is uncertain (AANN, 2019). Stress, medications, and depression contribute to the cognitive changes of diminished executive functions, attention difficulties, decreased thinking, and word-finding challenges. More than 80% of patients with a 20-year disease duration of PD experience **dementia,** a broad term for a syndrome characterized by a general decline in higher brain functioning, such as reasoning, with a pattern of eventual decline in ability to perform even basic ADLs, such as toileting and eating (Gale, Acar, & Daffner, 2018). In addition, auditory and visual hallucinations have been reported in people with PD and may be associated with depression, dementia, lack of sleep, or adverse effects of medications.

Hypokinesia (abnormally diminished movement) is also common and may appear after the tremor. The freezing phenomenon refers to a transient inability to perform active movement and is thought to be an extreme form of bradykinesia. The patient tends to shuffle and exhibits a decreased arm swing as well. As dexterity declines, micrographia (small handwriting) develops. The face becomes increasingly masklike and expressionless, and the frequency of blinking decreases. **Dysphonia** (voice impairment or altered voice production) may occur as a result of weakness and incoordination of the muscles responsible for speech. In many cases, the patient develops dysphagia, begins to drool, and is at risk for choking and aspiration (AANN, 2019).

Complications associated with PD are common and are typically related to disorders of movement. As the disease progresses, patients are at risk for respiratory and urinary tract infection, skin breakdown, and injury from falls. The adverse effects of medications used to treat the symptoms are associated with numerous complications such as **dyskinesia** (impaired ability to execute voluntary movements) or orthostatic hypotension.

Assessment and Diagnostic Findings

Although laboratory tests and imaging studies are not helpful to the provider in diagnosing PD, ongoing research with PET and single-photon emission CT scanning has been helpful in understanding the disease and advancing treatment. Currently, the disease is diagnosed clinically from the patient's history and the presence of two of the four cardinal manifestations: tremor, rigidity, bradykinesia, and postural changes.

Early diagnosis can be challenging because patients rarely are able to pinpoint when the symptoms started. Often, a family member notices a change such as stooped posture; a stiff arm; a slight limp; tremor; or slow, small handwriting. The medical history, presenting symptoms, neurologic examination, and response to pharmacologic management are carefully evaluated when making the diagnosis. Diagnosis is often confirmed by a positive response to a levodopa trial (Hickey & Strayer, 2020).

The Revised Movement Disorder Society Unified Parkinson Disease Rating Scale (MDS-UPDRS) is a helpful assessment tool as it measures the disease progression including motor and nonmotor symptoms, and includes treatment complications (AANN, 2019).

Medical Management

Treatment is directed toward controlling symptoms and maintaining functional independence, because no medical or surgical approaches in current use prevent disease progression (AANN, 2019). Care is individualized for each patient based on presenting symptoms and social, occupational, and emotional needs. Pharmacologic management is the mainstay of treatment, although advances in research have led to more surgical options. Patients are usually cared for at home and are admitted to the hospital only for complications or to initiate new treatments.

Pharmacologic Therapy

Antiparkinsonian medications act by increasing striatal dopaminergic activity; reducing the excessive influence of excitatory cholinergic neurons on the extrapyramidal tract, thereby restoring a balance between dopaminergic and cholinergic activities; or acting on neurotransmitter pathways other than the dopaminergic pathway.

Levodopa is the most effective agent and the mainstay of treatment. Levodopa is converted to dopamine in the basal ganglia, producing symptom relief. Carbidopa is often added to levodopa to avoid metabolism of levodopa before it can reach the brain. The beneficial effects of levodopa therapy are most pronounced in the first year or two of treatment. Benefits begin to wane and adverse effects become more severe over time (Hickey & Strayer, 2020).

Within 5 to 10 years, most patients develop a response to the medication characterized by dyskinesia including facial grimacing, rhythmic jerking movements of the hands, head bobbing, chewing and smacking movements, and involuntary movements of the trunk and extremities. The patient may experience an on–off syndrome in which sudden periods of near immobility ("off effect") are followed by a sudden return of effectiveness of the medication ("on effect"). Changing the drug dosing regimen or switching to other drugs may be helpful in minimizing the on–off syndrome. Other potential adverse effects include nausea, vomiting, appetite loss, decreased BP, dystonia, dyskinesia, and confusion (Comerford & Durkin, 2020). To minimize adverse effects of levodopa over time, current practice includes delaying use of levodopa-containing drugs as long as possible, with the use of other drugs for symptom control in the interim. Table 65-1 provides a summary of select medications used in PD.

Surgical Management

The limitations of levodopa therapy, improvements in surgical techniques, and new approaches in transplantation have renewed interest in the surgical treatment of PD. In patients with disabling tremor, rigidity, or severe levodopa-induced dyskinesia, surgery may be considered. Although surgery provides symptom relief in select patients, it has not been shown to alter the course of the disease or to produce permanent improvement.

Stereotactic Procedures

Thalamotomy and pallidotomy are ablative procedures that were formerly used to relieve symptoms of PD such as tremors. However, these procedures permanently destroy brain tissue and are rarely used today. Deep brain stimulation (DBS) has largely replaced ablative procedures in the surgical treatment of PD. DBS involves surgical implantation of an electrode into the brain in either the globus pallidus or subthalamic nucleus. Stimulation of these areas may increase dopamine release or block anticholinergic release, thereby improving tremor and rigidity. Levodopa medication dose may be able to be reduced, thus improving dyskinesias.

Patients eligible for DBS are those who have responded to levodopa but are impaired by dyskinesias, have had the disease for at least 5 years, and are disabled by tremor. Patients with dementia and atypical PD are usually not considered for surgical procedures. PD rating scales and specific neurologic tests are used to identify patients who are eligible. Surgical treatment typically occurs 10 to 13 years after diagnosis (AANN, 2019).

TABLE 65-1 Select Medications Used to Treat Parkinson's Disease

Medications	Indications and Therapeutic Effects	Common Side Effects
Anticholinergic Agents		
trihexyphenidyl hydrochloride	Control of tremor in patients with early-onset disease	Blurred vision, flushing, rash, constipation, urinary retention, and acute confusional states
benztropine mesylate	Counteract the action of acetylcholine	Contraindicated in patients with narrow-angle glaucoma
Antiviral Agent		
amantadine hydrochloride	Reduce rigidity, tremor, bradykinesia, and postural changes in early Parkinson's disease (PD)	Psychiatric disturbances (mood changes, confusion, depression, hallucinations), lower extremity edema, nausea, epigastric distress, urinary retention, headache, and visual impairment
Dopamine Agonists		
bromocriptine mesylate pergolide	Early PD as well as secondary drug therapy after carbidopa or levodopa loses effectiveness	Nausea, vomiting, diarrhea, lightheadedness, hypotension, impotence, and psychiatric effects
Nonergot Derivatives		
ropinirole hydrochloride pramipexole	Early stages of PD	May cause drowsiness or dizziness
Monoamine Oxidase-Inhibitors		
selegiline rasagiline	Inhibit dopamine breakdown	Agitation, dizziness, nausea, headache, rhinitis, back pain, stomatitis, orthostatic hypotension, insomnia
Catechol-O-Methyltransferase Inhibitors		
entacapone	Increase the duration of action of carbidopa or levodopa	Abdominal pain, back pain, constipation, nausea, diarrhea, blood in urine
tolcapone	Reduce motor fluctuations in patients with advanced PD	

Adapted from Moore, D. J., Smith, B. M., & Cho, M. H. (2017). Managing meditations for hospital patients with Parkinson disease. *American Nurse Today*, *12*(1), 9–12.

A CT or MRI scan is used to localize the appropriate surgical site in the brain. Then, the patient's head is positioned in a stereotactic frame (see Fig. 65-4). After the surgeon makes an incision in the skin and a burr hole, an electrode is passed through to the target area to the subthalamic nuclei or globus pallidus. The desired response of the patient to the electrical stimulation (i.e., a decrease in rigidity) is used to confirm electrode placement. Electrode placement is completed on one side of the brain at a time; bilateral electrodes are usually placed (AANN, 2019). Electrodes are then connected to a pulse generator that is implanted in a subcutaneous subclavicular or abdominal pouch (see Fig. 65-5). The battery-powered pulse generator sends high-frequency electrical impulses through a wire placed under the skin to a lead anchored to the skull (see Fig. 65-6). These devices are not without complications that can result from both the surgical procedure needed for implantation (e.g., weakness, paresthesias, confusion, hemorrhage) and the device itself (e.g., infection, lead leakage) (Hickey & Strayer, 2020).

Figure 65-4 • A stereotactic frame is applied to a patient's head in preparation for deep brain stimulation. The frame provides external points of reference.

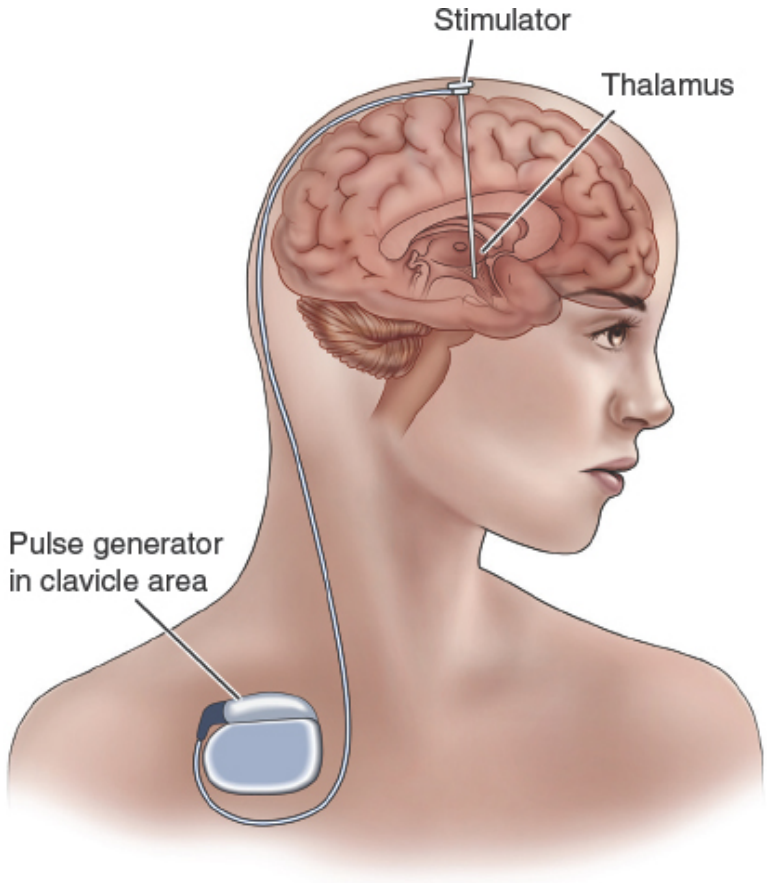

Figure 65-5 • Deep brain stimulation is provided by a pulse generator surgically implanted in a pouch beneath the clavicle. The generator sends high-frequency electrical impulses to the thalamus, thereby blocking the nerve pathways associated with tremors in Parkinson's disease.

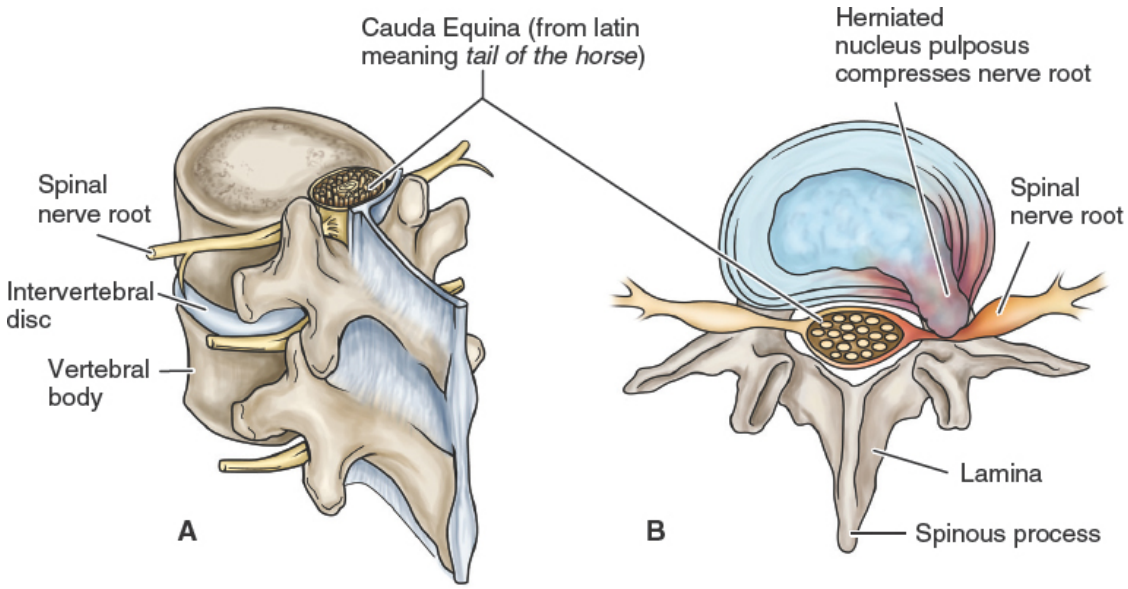

Figure 65-6 • **A.** Normal lumbar spine vertebrae, invertebral discs, and spinal nerve root. **B.** Ruptured vertebral disc.

Neural Transplantation

Ongoing research is exploring transplantation of porcine neuronal cells, human fetal cells, and stem cells to replace degenerated striatal cells (Kirkeby, Parmar, & Barker, 2017). Legal, ethical, and political concerns surrounding the use of fetal brain cells and stem cells have limited the exploration of these procedures.

NURSING PROCESS

The Patient with Parkinson's Disease

Assessment

The nurse gathers information focusing on how the disease has affected the patient's ADLs and functional abilities. The patient is observed for degree of disability and functional changes that occur throughout the day, such as responses to medication. Almost every patient with a movement disorder has some functional alteration and may have some type of behavioral dysfunction. The following questions may be useful to assess alterations:

- Do you have leg or arm stiffness?
- Have you experienced any irregular jerking of your arms or legs?
- Have you ever been "frozen" or rooted to the spot and unable to move?
- Does your mouth water excessively? Have you (or others) noticed yourself grimacing or making faces or chewing movements?
- What specific activities do you have difficulty doing?
- Have you had any recent falls?

During this assessment, the nurse observes the patient for quality of speech, loss of facial expression, swallowing deficits (drooling, poor head control, coughing), tremors, slowness of movement, weakness, forward posture, rigidity, evidence of mental slowness, and confusion. PD symptoms, as well as side effects of medications, put these patients at high risk for falls; therefore, a fall risk assessment should be conducted (Hickey & Strayer, 2020).

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired mobility associated with muscle rigidity and postural impairment
- Impaired self-feeding, impaired ability to dress, impaired ability to perform hygiene, impaired self-toileting associated with tremor and muscle rigidity
- Constipation associated with medication and reduced activity
- Impaired nutritional intake associated with tremor, slowness in eating, difficulty in chewing and swallowing
- Impaired verbal communication associated with decreased speech volume, slowness of speech, inability to move facial muscles
- Difficulty coping associated with depression and dysfunction due to disease progression

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Sleep disturbances
- Psychiatric disturbances

Planning and Goals

The goals for the patient may include improving functional mobility, maintaining independence in ADLs, achieving adequate bowel elimination, attaining and maintaining acceptable nutritional status, achieving effective communication, and developing positive coping mechanisms.

Nursing Interventions

Improving Mobility

A progressive program of daily exercise will increase muscle strength, improve coordination and dexterity, reduce muscular rigidity, and prevent contractures that occur when muscles are not used (Hickey & Strayer, 2020). Walking, riding a stationary bicycle, swimming, and gardening are all exercises that help maintain joint mobility. Stretching (stretch–hold–relax) and range-of-motion exercises promote joint flexibility. Postural exercises are important to counter the tendency of the head and neck to be drawn forward and down. A physical therapist may be helpful in developing an individualized exercise program and can provide instruction to the patient and caregiver on exercising safely. Faithful adherence to an exercise and walking program helps delay the progress of the disease. Warm baths and massage, in addition to passive and active exercises, help relax muscles and relieve painful muscle spasms that accompany rigidity.

Balance may be adversely affected because of the rigidity of the arms (arm swinging is necessary in normal walking). Special walking techniques must be learned to offset the shuffling gait and the tendency to lean forward. The patient is educated to concentrate on walking erect, to watch the horizon, and to use a wide-based gait (i.e., walking with the feet separated). A conscious effort must be made to swing the arms, raise the feet while walking, and use a heel–toe placement of the feet with long strides. The patient is advised to practice walking to marching music or to the sound of a ticking metronome, because this provides sensory reinforcement. Performing breathing exercises while walking provides additional movement of the ribcage and aerates larger parts of the lungs. Frequent rest periods aid in preventing frustration and fatigue.

Enhancing Self-Care Activities

Encouraging, educating, and supporting the patient during ADLs promote self-care (Hickey & Strayer, 2020). Environmental modifications are necessary to compensate for functional disability. Patients may have severe mobility problems that make normal activities impossible. Adaptive or assistive devices may be useful. A hospital bed at home with bedside rails,

an over-bed frame with a trapeze, or a rope tied to the foot of the bed can provide assistance in pulling up without help. An occupational therapist can evaluate the patient's needs in the home, make recommendations regarding adaptive devices, and educate the patient and caregiver how to improvise.

Improving Bowel Elimination

The patient may have severe problems with constipation. Among the factors causing constipation are weakness of the muscles used in defecation, lack of exercise, inadequate fluid intake, and decreased autonomic nervous system activity. The medications used for the treatment of the disease also inhibit normal intestinal secretions. A regular bowel routine may be established by encouraging the patient to follow a regular time pattern, consciously increase fluid intake, and eat foods with moderate fiber content. Laxatives should be avoided. Psyllium, for example, decreases constipation but carries the risk of bowel obstruction (Comerford & Durkin, 2020). A raised toilet seat is useful because the patient has difficulty in moving from a standing to a sitting position. Additional time may be needed for the patient to navigate to the toilet due to gait disturbances.

Improving Nutrition

Patients may have difficulty maintaining their weight. Eating becomes a very slow process, requiring concentration due to a dry mouth from medications and difficulty chewing and swallowing. These patients are at risk for aspiration because of impaired swallowing and the accumulation of saliva. They may be unaware that they are aspirating; subsequently, pneumonia may develop (Aslam, Simpson, Baugh, et al., 2019).

Monitoring weight on a weekly basis indicates whether caloric intake is adequate. Supplemental feedings increase caloric intake. As the disease progresses, a nasogastric or percutaneous endoscopic gastrostomy (PEG) tube may be necessary to maintain adequate nutrition. A consultation with dietitian may be indicated.

Enhancing Swallowing

Swallowing difficulties and choking are common in PD, leading to aspiration and pneumonia. To offset the aspiration risk, the patient should sit in an upright position during mealtime (Aslam et al., 2019). A semisolid diet with thick liquids is easier to swallow than solids; thin liquids should be avoided. The patient is instructed to think through the swallowing sequence, place the food on the tongue, close the lips and teeth, lift the tongue up and then back, and swallow. The patient is encouraged to chew first on one side of the mouth and then on the other. To control the buildup of saliva, the patient is reminded to hold the head upright and make a conscious effort to swallow. Massaging the facial and neck muscles before meals may be beneficial.

Encouraging the Use of Assistive Devices

An electric warming tray keeps food hot and allows the patient to rest during the prolonged time that it may take to eat. Special utensils also assist at mealtime. A plate that is stabilized, a nonspill cup, and eating utensils with built-up handles are useful self-help devices. The occupational therapist can assist in identifying appropriate adaptive devices.

Improving Communication

Speech disorders are present in most patients with PD. The low-pitched, monotonous, soft speech of patients requires that they make a conscious effort to speak slowly, with deliberate attention to what they are saying. The patient is reminded to face the listener, exaggerate the pronunciation of words, speak in short sentences, and take a few deep breaths before speaking. A speech therapist may be helpful in designing speech improvement exercises and assisting the family and health care personnel to develop and use a method of communication that meets the patient's needs. A small electronic amplifier is helpful if the patient has difficulty being heard.

Supporting Coping Abilities

Support can be given by encouraging the patient and pointing out that activities will be maintained through active participation. Patients with PD can become socially and emotionally withdrawn. It is best if patients are active participants in their therapeutic program, including social and recreational events.

Patients often feel embarrassed, apathetic, inadequate, bored, and lonely. In part, these feelings may result from physical slowness and the great effort that even small tasks require. The patient is assisted and encouraged to set achievable goals (e.g., improvement of mobility). Every effort should be made to encourage patients to carry out the tasks involved in meeting their own daily needs and to remain independent. Doing things for the patient merely to save time undermines the basic goal of improving coping abilities and promoting a positive self-concept.

Monitoring and Managing Potential Complications

A planned program of activity throughout the day prevents too much daytime sleeping as well as disinterest and apathy. When sleep disturbances occur, several interventions can improve sleep, including limiting caffeine intake before bedtime and assessing for nocturia.

The patient with PD is monitored regularly for signs and symptoms of depression. An interprofessional approach with a combination of physiotherapy, psychotherapy, medication therapy, and support group participation is used to treat depression when diagnosed (Hickey & Strayer, 2020).

The patient in late stages of PD is particularly at risk for psychiatric disturbances such as hallucinations, psychosis, and paranoid delusions (Hickey & Strayer, 2020). Interventions to manage psychiatric disturbances include low doses of antipsychotic drugs, minimizing medications with psychiatric side effects (see Table 65-1), and avoidance of dopamine depleting medications (Hickey & Strayer, 2020). Patients and their caregivers benefit from an interprofessional approach to care when psychiatric disturbances are present.

Promoting Home, Community-Based, or Transitional Care

Educating Patients About Self-Care. Patient and family education is important in the management of PD. The needs depend on the severity of symptoms and the stage of the disease. Care must be taken not to overwhelm the patient and family with too much information early in the disease process. Ongoing assessment, intervention, and evaluation of the patient and family's adaptations and education requirements are necessary with every encounter. The strategies to promote health include a clear explanation of the disease and the goal of assisting the patient to remain functionally independent as long as possible (see Chart 65-3). The patient and family must be educated about the effects and side effects of medications and about the importance of reporting side effects to the primary provider. Nurses in the home help patients and their families enhance self-management and quality of life.

Continuing and Transitional Care. Family members and partners often serve as caregivers, with home, community-based, or transitional services available to assist in meeting health care needs as the disease progresses. The caregiver may be under considerable stress from living with and caring for a person with a significant disability. Providing information about treatment and care helps anticipate future needs. The caregiver is included in the plan and may be advised to learn stress reduction techniques, to include others in the caregiving process, to obtain periodic relief from responsibilities, and to have a yearly health assessment. Allowing family members and partners to express feelings of frustration, anger, and guilt is often helpful to them.

The patient should be evaluated in the home for adaptation and safety needs and adherence to the plan of care. In the advanced stages, patients usually enter long-term care facilities. Periodically, admission to an acute care facility may be necessary for changes in medical management or treatment of complications. Nurses provide support, education, and monitoring of patients over the course of the illness.

Chart 65-3  HEALTH PROMOTION

Strategies for the Patient with PD

To promote optimal health, the nurse works closely with the patient and family to ensure that they understand:

- How PD and its treatment impact physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality
- The importance of adhering to the prescribed medication regimen; including knowing the purpose, dose, route, schedule, side effects, and precautions for all medications
- How and when to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendors)
- Specific types of environmental and safety changes or support that will allow optimum functioning in the home
- The risk of falls/injury and how to implement fall prevention and adaptive measures in the home

In addition, the nurse advises the patient and family about lifestyle changes that are necessary to maintain health and promote self-care and independence. These include:

- Ensuring nutritional needs, including adhering to dietary restrictions, managing dysphagia, and preventing aspiration
- Promoting speech and communication skills: speech exercises, communication techniques, breathing exercises
- Managing constipation: fluid intake, bowel routine
- Managing urinary problems: functional incontinence, retention (indwelling urinary catheter care, suprapubic catheter care)
- Avoiding the effects of immobility and promoting the advantages of preventive care: skin breakdown (frequent turning, pressure release, skin care), pneumonia (deep breathing, movement), contractures (range-of-motion exercises)
- Promoting the benefits of a daily exercise program
- Ensuring safe walking and balancing
- Using appropriate coping mechanisms and diversional activities

ADLs, activities of daily living; IADLs, instrumental activities of daily living; PD, Parkinson's disease.

The nurse involved in home and continuing care educates the patient and family members about the importance of addressing health promotion needs such as screening for hypertension and stroke risk assessments in this predominantly older adult population. Patients are referred to appropriate health care providers. Information is available from both the Parkinson's Foundation and the American Parkinson Disease Association (see the Resources section).

Evaluation

Expected patient outcomes may include:

1. Strives toward improved mobility
   a. Participates in exercise program daily
   b. Walks with wide base of support; exaggerates arm swinging when walking
   c. Takes medications as prescribed
2. Progresses toward self-care
   a. Allows time for self-care activities
   b. Uses self-help devices
3. Maintains bowel function
   a. Consumes adequate fluid
   b. Increases dietary intake of fiber
   c. Reports regular pattern of bowel function
4. Attains improved nutritional status
   a. Swallows without aspiration
   b. Takes time while eating
5. Achieves a method of communication
   a. Communicates needs
   b. Practices speech exercises
6. Copes with effects of PD
   a. Sets realistic goals
   b. Demonstrates persistence in meaningful activities
   c. Verbalizes feelings to appropriate person

Huntington Disease

Huntington disease is a chronic, progressive, hereditary disease of the nervous system that results in progressive involuntary choreiform movement and dementia. The disease affects approximately 1 in 10,000 men or women of all races at midlife. Every person has the gene that causes Huntington disease;

however, only those who inherit the expansion of the gene will develop the disease and pass it onto their children. Because it is transmitted by an autosomal dominant gene, each child of a parent with Huntington disease has a 50% risk of inheriting the disorder (Smedley & Coulson, 2019).

A genetic mutation in Huntington disease, the presence of a repeat in the Huntington gene (*HTT*), has been identified (Smedley & Coulson, 2019). Genetic testing can identify people who will develop this disease but cannot predict timing of disease onset. Although the gene was mapped in 1983, patients may choose not to be tested because of concerns about employment and health care discrimination. People of childbearing age with a family history of Huntington disease often seek information about their risk of disease transmission. Genetic counseling is crucial, and patients and their families may require long-term psychological counseling and emotional, financial, and legal support (see Chapter 6).

Pathophysiology

The basic pathology involves premature death of cells in the striatum (caudate and putamen) of the basal ganglia, the region deep within the brain that is involved in the control of movement. Cells also are lost in the cortex, the region of the brain associated with thinking, memory, perception, judgment, and behavior, and in the cerebellum, the area that coordinates voluntary muscle activity. Why the protein destroys only certain brain cells is unknown, but several theories have been proposed to explain the phenomenon. One possible theory is that glutamine, a building block for protein, abnormally collects in the cell nucleus, causing cell death (McColgan & Tabrizi, 2017).

Clinical Manifestations

This condition is characterized by a triad of symptoms that includes motor dysfunction (the most prominent is **chorea**, or rapid, jerky, involuntary, purposeless movements); cognitive impairment (problems with attention and emotion recognition); and behavioral features, such as apathy and blunted affect (McColgan & Tabrizi, 2017). As the disease progresses, constant writhing, twisting, and uncontrollable movements may involve the entire body. These motions are devoid of purpose or rhythm, although patients may try to turn them into purposeful movement. All of the body musculature is involved. Facial movements produce tics and grimaces. Speech becomes slurred, hesitant, often explosive, and eventually unintelligible. Chewing and swallowing are difficult, and there is a constant danger of choking and aspiration. Choreiform movements persist during sleep but are diminished (Mestre & Shannon, 2017).

As with speech, the gait becomes disorganized to the point that ambulation eventually is impossible. Although independent ambulation should be encouraged for as long as possible, a wheelchair usually becomes necessary. Eventually, the patient is confined to bed when the chorea interferes with walking, sitting, and all other activities. Bladder and bowel control are lost.

Cognitive impairment, such as problems with attention or recognizing emotions, occurs early on; in later stages, marked dementia is present. Initially, the patient is aware that the disease is responsible for the myriad dysfunctions that are occurring.

The behavioral changes may be more devastating to the patient and family than the abnormal movements. Personality changes may result in nervous, irritable, or impatient behaviors. In the early stages, patients are particularly subject to uncontrollable fits of anger, profound and often suicidal depression, apathy, anxiety, psychosis, or euphoria. Judgment and memory are impaired, and dementia eventually ensues (Mestre & Shannon, 2017). Hallucinations, delusions, and paranoid thinking may precede the appearance of disjointed movements. Emotional and cognitive symptoms often become less acute as the disease progresses (Mestre & Shannon, 2017).

Onset usually occurs between 35 and 45 years of age, although about 10% of patients are children. The disease progresses slowly. Despite a ravenous appetite, patients usually become emaciated and exhausted. Patients succumb in 10 to 20 years to heart failure, pneumonia, or infection, or as a result of a fall or choking (Mestre & Shannon, 2017).

Assessment and Diagnostic Findings

The diagnosis is made based on the clinical presentation of characteristic symptoms, a positive family history, and the known presence of the genetic marker cytosine-adenine-guanine (CAG) repeating on the Huntington gene (HTT)(Smedley & Coulson, 2019). CT or MRI scans show symmetrical striatal atrophy before motor symptoms appear (Urrutia, 2019).

Medical Management

No treatment halts or reverses the underlying process; therefore, the focus is on optimizing quality of life with available medication and supportive treatment. Patients experience the most benefit when they have integrated expertise of a Huntington disease multidisciplinary team (Urrutia, 2019). The only medication that is approved by the U.S. Food and Drug Administration to treat the symptom of chorea is tetrabenazine (Comerford & Durkin, 2020).

Benzodiazepines and neuroleptic drugs have also been reported to control chorea. Motor signs must be assessed and evaluated on an ongoing basis so that optimal therapeutic drug levels can be reached. Akathisia (motor

restlessness) in the patient who is overmedicated is dangerous because it may be mistaken for the restless fidgeting of the illness and consequently may be overlooked. In certain types of the disease, hypokinetic motor impairment resembles PD. In patients who present with rigidity, some temporary benefit may be obtained from antiparkinson medications, such as levodopa.

Selective serotonin reuptake inhibitors and tricyclic antidepressants have been recommended for control of psychiatric symptoms. The threat of suicide is present particularly early in the course of the disease. Psychotic symptoms usually respond to antipsychotic medications. Psychotherapy aimed at allaying anxiety and reducing stress may be beneficial. Nurses must look beyond the disease to focus on the patient's needs and capabilities (see Chart 65-4).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The needs of the patient and family for education depend on the nature and severity of the physical, cognitive, and psychological changes experienced by the patient. The patient and family members are educated about the medications prescribed and about signs indicating a need for change in medication or dosage. The educational plan addresses strategies to manage symptoms such as chorea, swallowing problems, limitations in ambulation, memory loss, irritability, depression, and loss of bowel and bladder function. Consultation with a speech therapist may be indicated to assist in identifying alternative communication strategies if speech is affected. A PEG tube may be considered for nutritional support later in the disease (Eliopoulos, 2018).

Continuing and Transitional Care

A program combining medical, nursing, psychological, social, occupational, speech, and physical rehabilitation services and palliative care is needed to help the patient and family cope with this severely disabling illness. Huntington disease exacts enormous emotional, physical, social, and financial tolls on every member of the family. The family needs supportive care as they adjust to the impact of the illness. Regular follow-up visits help allay the fear of abandonment.

Chart 65-4

Care of the Patient with Huntington Disease

Nursing Diagnosis: Risk for injury from falls and possible skin breakdown (pressure injury abrasions), resulting from constant movement

Nursing Interventions

- Pad the sides and head of the bed; ensure that the patient can see over the sides of bed.
- Use padded heel and elbow protectors.
- Keep the skin meticulously clean.
- Apply emollient cleansing agent and skin lotion as needed.
- Use soft sheets and bedding.
- Have patient wear football padding or other forms of padding.
- Encourage ambulation with assistance to maintain muscle tone.
- Secure the patient (only if necessary) in bed or chair with padded protective devices, making sure that they are loosened frequently.

Nursing Diagnosis: Impaired nutritional intake due to inadequate ingestion and dehydration resulting from swallowing or chewing disorders and danger of choking or aspirating food

Nursing Interventions

- Administer phenothiazines (chlorpromazine) as prescribed before meals (calms some patients).
- Talk to the patient before mealtime to promote relaxation; use mealtime for social interaction. Provide undivided attention and help the patient enjoy the mealtime experience.
- Use a warming tray to keep food warm.
- Learn the position that is best for *this* patient. Keep patient as close to upright as possible while feeding. Stabilize patient's head gently with one hand while feeding.
- Show the food, explain what the foods are, and temperature (e.g., whether hot or cold).
- Encircle the patient with one arm and get as close as possible to provide stability and support while feeding. Use pillows and wedges for additional support.
- Do not interpret stiffness, turning away, or sudden turning of the head as rejection; these are uncontrollable choreiform movements.
- For feeding, use a long-handled spoon (iced tea spoon). Place spoon on middle of tongue and exert slight pressure.
- Place bite-sized food between patient's teeth. Serve stews, casseroles, and thick liquids.
- Disregard messiness, and treat the person with dignity.
- Wait for the patient to chew and swallow before introducing another spoonful. Make sure that bite-sized food is small.
- Give between-meal feedings. Constant movement expends more calories. Patients often have voracious appetites, particularly for sweets.

Use blenderized meals if patient cannot chew; do not repeatedly give the same strained baby foods. Gradually introduce increased textures and consistencies to the diet.

For swallowing difficulties:

Apply gentle deep pressure around the patient's mouth.

Rub fingers in circles on the patient's cheeks and then down each side of the patient's throat.

Develop skill in the abdominal thrust (to be used in the event of choking).

Nursing Diagnosis: Impaired verbal communication from excessive grimacing and unintelligible speech

Nursing Interventions

Read to the patient.

Employ biofeedback and relaxation therapy to reduce stress.

Consult with speech therapist to help maintain and prolong communication abilities.

Try to devise a communication system, perhaps using cards with words or pictures of familiar objects, before verbal communication becomes too difficult. Patients can indicate correct card by hitting it with hand, grunting, or blinking the eyes.

Learn how this particular patient expresses needs and wants—particularly nonverbal messages (widening of eyes, responses).

Patients can understand even if unable to speak. Do not isolate patients by ceasing to communicate with them.

Nursing Diagnosis: Acute confusion and impaired socialisation

Nursing Interventions

Reorient the patient after awakening.

Have clock, calendar, and wall posters in view to assist in orientation.

Use every opportunity for one-to-one contact.

Use music for relaxation.

Have the patient wear a medical identification bracelet.

Keep the patient in the social mainstream.

Recruit and train volunteers for social interaction. Role-model appropriate and creative interactions.

Do not abandon a patient because the disease is terminal. Patients are *living* until the end.

Home care assistance, day care centers, respite care, and eventually skilled long-term care can assist the patient and family in coping with the constant strain of the illness. Although the relentless progression of the disease cannot be halted, families can benefit from supportive care. Planning for end-of-life care should occur early in the disease (see Chapter 13).

Voluntary organizations can be major aids to families and have been largely responsible for bringing the illness to national attention. The Huntington Disease Society of America helps patients and families by providing information, referrals, family and public education, and support for research (see the Resources section).

Amyotrophic Lateral Sclerosis

ALS is a disease of unknown cause in which there is a loss of motor neurons (nerve cells controlling muscles) in the anterior horns of the spinal cord and the motor nuclei of the lower brainstem. It is often referred to as Lou Gehrig disease, after the famous baseball player who suffered from the disease. As motor neuron cells die, the muscle fibers that they supply undergo atrophic changes. Neuronal degeneration may occur in both the upper and lower motor neuron systems (see Chapter 60). The leading theory held by researchers is that overexcitation of nerve cells by the neurotransmitter glutamate results in cell injury and neuronal degeneration. Risk factors are noted in Chart 65-5.

ALS most commonly occurs between 40 and 60 years of age and affects all social, racial, and ethnic backgrounds, with men being affected at slightly higher rates than women. The majority of cases of ALS arise sporadically, but 5% to 10% of cases are familial ALS resulting from an autosomal dominant trait carried by one parent. Familial ALS occurs 10 years earlier than the ALS average, and those afflicted tend to have a shorter life span (Hardiman, Al-Chalabi, Chio, et al., 2017).

Clinical Manifestations

Clinical manifestations depend on the location of the affected motor neurons, because specific neurons activate specific muscle fibers. The chief symptoms are fatigue, progressive muscle weakness, cramps, fasciculations (twitching), and lack of coordination. Loss of motor neurons in the anterior horns of the spinal cord results in progressive weakness and atrophy of the muscles of the arms, trunk, or legs. Spasticity usually is present, and the deep tendon stretch reflexes become brisk and overactive. Usually, the function of the anal and bladder sphincters remains intact, because the spinal nerves that control muscles of the rectum and urinary bladder are not affected.

Chart 65-5 RISK FACTORS

Amyotrophic Lateral Sclerosis

- Age
- Autoimmune disease
- Environmental exposures to toxins
- Family history
- Smoking
- Viral infections

Adapted from Vacca, V. M. (2020). Amyotrophic lateral sclerosis: Nursing care and considerations. *Nursing, 50*(6), 32–39.

In about 25% of patients, weakness starts in the muscles supplied by the cranial nerves, and difficulty in talking, swallowing, and ultimately breathing occurs (Conde, Martin, & Winck, 2019; Vacca, 2020). When the patient ingests liquids, soft palate and upper esophageal weakness cause the liquid to be regurgitated through the nose. Weakness of the posterior tongue and palate impairs the ability to laugh, cough, or even blow the nose. If bulbar muscles are impaired, speaking and swallowing are progressively difficult, and aspiration becomes a risk. The voice assumes a nasal sound, and articulation becomes so disrupted that speech is unintelligible. Some emotional lability may be present. It was traditionally believed that ALS spared cognitive function, but it is now recognized that some patients experience cognitive impairment.

The prognosis generally is based on the area of CNS involvement and the speed with which the disease progresses. Eventually, respiratory function is compromised (Conde et al., 2019). Death usually occurs as a result of infection, respiratory insufficiency, or aspiration.

Assessment and Diagnostic Findings

ALS is diagnosed on the basis of the signs and symptoms, because no clinical or laboratory tests are specific to this disease. Electromyography and muscle biopsy studies of the affected muscles indicate reduction in the number of functioning motor units. An MRI scan may show high signal intensity in the corticospinal tracts; this differentiates ALS from a multifocal motor neuropathy. Neuropsychological testing can assist in assessment and diagnosis (Hickey & Strayer, 2020).

Management

No cure exists for ALS (Vacca, 2020). The main focus of medical and nursing management is on interventions to maintain or improve function, well-being, and quality of life. Because ALS is a progressive disease, the therapeutic needs

are different than those of patients with acute processes. Insurance carriers tend to limit the number of therapy sessions, but with early integration into ALS clinics, alliances are developed for future contact with therapists familiar with the disease process (Hogden, Foley, Henderson, et al., 2017).

Two drugs are used to treat ALS, riluzole and edaravone (Vacca, 2020). The precise action of these drugs is not clear, but both are considered disease modifying treatments for ALS (Vacca, 2020).

Symptomatic treatment and rehabilitative measures are used to support the patient and improve the quality of life. Baclofen, dantrolene sodium, or diazepam may be useful for patients troubled by spasticity, which causes pain and interferes with self-care. Modafinil may be used for fatigue, and additional medications may be added to manage the pain, depression, drooling, and constipation that often accompany the disease. Research suggests that greater functional impairment is associated with greater depressive symptoms; consequently, managing depression helps to maintain a better quality of life (Soofi, Bello-Haas, Kho, et al., 2018). Many clinical trials and an ALS registry contribute to the ongoing study of this devastating disease (Vacca, 2020).

Most patients with ALS are managed at home and in the community, with hospitalization for acute problems. The most common reasons for hospitalization are dehydration and malnutrition, pneumonia, and respiratory failure; recognizing these problems at an early stage in the illness allows for the development of preventive strategies. End-of-life issues include pain, dyspnea, and delirium (Hickey & Strayer, 2020).

Mechanical ventilation (using negative-pressure ventilators) is an option if alveolar hypoventilation develops. Noninvasive positive-pressure ventilation is also an option. The use of noninvasive positive-pressure ventilation is particularly helpful at night and postpones the decision about whether to undergo a tracheotomy for long-term mechanical ventilation (Conde et al., 2019). A patient experiencing aspiration and swallowing difficulties may require enteral feeding. A PEG tube is inserted before the forced vital capacity drops below 50% of the predicted value. The tube can be safely placed in patients who are using noninvasive positive-pressure ventilation for ventilatory support (Hickey & Strayer, 2020).

Decisions about life support measures are made by the patient and family and should be based on a thorough understanding of the disease, the prognosis, and the implications of initiating such therapy. Patients are encouraged to complete an advance directive to preserve their autonomy in decision making. See Chapter 13 for additional discussion of end-of-life care.

The ALS Association has broad programs of research funding, patient and clinical services, patient information and support, and medical and public information (see the Resources section). The *ALS Association Newsletter* is a source of practical information.

Muscular Dystrophies

The muscular dystrophies are a group of incurable muscle disorders characterized by progressive weakening and wasting of the skeletal or voluntary muscles with 30 different types to date. Most of these diseases are inherited. Duchenne muscular dystrophy, the most common and severe type, occurs in 1 of every 3500 male births (Norris, 2019). The pathologic features include degeneration and loss of muscle fibers, variation in muscle fiber size, phagocytosis and regeneration, and replacement of muscle tissue by connective tissue. The common characteristics of these diseases include varying degrees of muscle wasting and weakness and abnormal elevation in serum levels of muscle enzymes. Differences among these diseases center on the genetic pattern of inheritance, the muscles involved, the age at onset, and the rate of disease progression. The symptoms can be diverse and may include muscle stiffness or weakness, decreased respiratory reserve, or cardiomyopathy. Prognosis depends on the type of muscular dystrophy. Regardless of age of onset, this disease varies in progression (Birnkrant, Bushby, Bann, et al., 2018b). The unique needs of these patients, who in the past did not live to adulthood, must be addressed, as they are living longer because of better supportive care and the emergence of disease modifying therapies (Birnkrant et al., 2018b; Trout, Case, Clemens, et al., 2018).

Medical Management

Treatment of the muscular dystrophies focuses on supportive care and prevention of complications in the absence of a cure (Birnkrant et al., 2018b). The goal of supportive management is to keep the patient active and functioning as normally as possible and to minimize functional deterioration. An individualized therapeutic exercise program is prescribed to prevent muscle tightness, contractures, and disuse atrophy. Night splints and stretching exercises are used to delay contractures of the joints, especially the ankles, knees, and hips. Braces may compensate for muscle weakness.

Spinal deformity is a severe problem. Weakness of trunk muscles and spinal collapse occur almost routinely in patients with severe neuromuscular disease. To help prevent spinal deformity, the patient is fitted with an orthotic jacket to improve sitting stability and reduce trunk deformity. This measure also supports cardiovascular status. In time, spinal fusion is performed to maintain spinal stability. Other procedures may be carried out to correct deformities.

Compromised pulmonary function may result either from progression of the disease or from deformity of the thorax secondary to severe scoliosis (Norris, 2019; Trout et al., 2018). Upper respiratory infections and fractures from falls must be vigorously treated in a way that minimizes immobilization because

joint contractures become worse when the patient's activities are more restricted than usual.

Other difficulties may manifest in relation to the underlying disease. Weakness of the facial muscles makes it difficult to attend to dental hygiene and to speak clearly, and impairs the ability to swallow safely (Birnkrant, Bushby, Bann, et al., 2018a). Gastrointestinal tract problems may include gastric dilation, rectal prolapse, and fecal impaction. Finally, cardiomyopathy appears to be a common complication in all forms of muscular dystrophy (Birnkrant et al., 2018a).

Genetic counseling is advised for parents and siblings of the patient because of the genetic nature of this disease. The Muscular Dystrophy Association (MDA) works to combat neuromuscular disease through research, programs of patient services and clinical care, and professional and public education (see the Resources section).

Nursing Management

The goals of the patient and the nurse are to maintain function at optimal levels and to enhance the quality of life. Therefore, the patient's physical requirements, which are considerable, are addressed without losing sight of emotional and developmental needs. The patient and family are actively involved in decision making, including end-of-life decisions (see Chapter 13).

During hospitalization for treatment of complications, the knowledge and expertise of the patient and family members responsible for caregiving in the home are assessed. Because the patient and family caregivers often have developed caregiving strategies that work effectively for them, these strategies need to be acknowledged and accepted, and provisions must be made to ensure that they are maintained during hospitalization (Birnkrant et al., 2018b).

Families of adolescents and young adults with muscular dystrophy need assistance to shift the focus of care from pediatric to adult care and to understand the usual disease course (Lindsay, Cagliostro, & McAdam, 2019; Trout et al., 2018). Nursing goals include assisting the adolescent to make the transition to adult values and expectations while providing age-appropriate ongoing care. The nurse may need to help build the confidence of an older adolescent or adult patient by encouraging them to pursue job training to become economically independent. Other nursing interventions might include guidance in accessing adult health care and finding appropriate programs in sex education.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Management goals are addressed in special rehabilitation programs or in the patient's home and community. Therefore, the patient and family require information and education about the disorder, its anticipated course, and care and management strategies that will optimize the patient's growth and development and physical and psychological status. Members of a variety of health-related disciplines are involved in patient and family education; recommendations are communicated to all members of the health care team so that they may work toward common goals.

Continuing and Transitional Care

Both the neuromuscular disease and the associated deformities may progress in adolescence and adulthood. Self-help and assistive devices can aid in maintaining maximum independence. These devices, recommended by physical and occupational therapists, often become necessary as more muscle groups are affected.

The family is instructed to monitor the patient for respiratory problems, because respiratory infection and cardiac failure are the most common causes of death. As respiratory difficulties develop, patients and their families need information regarding respiratory support. Options currently exist that can provide ventilatory support (e.g., negative-pressure devices, positive-pressure ventilators) while allowing mobility (Birnkrant et al., 2018a). Patients can remain relatively independent in a wheelchair, for example, while being maintained on a ventilator at home for many years.

The patient is encouraged to continue with range-of-motion exercises to prevent contractures, which are particularly disabling. Practical adaptations must be made, however, to cope with the effects of chronic neuromuscular disability. The patient at various stages of the disease may require a manual or an electric wheelchair, gait aids, upper and lower extremity and spinal orthotics, seating systems, bathroom equipment, lifts, ramps, and additional assistive devices, all of which require a team approach. The nurse assesses how the patient and family are managing, makes referrals, and coordinates the activities of the physical therapist, occupational therapist, and social services.

Patients who express concerns about increasing disability and dependence on others, as well as significant deterioration in health-related quality of life, benefit from an interprofessional approach to care (Trout et al., 2018). The patient is faced with a progressive loss of function, leading eventually to death. Feelings of helplessness and powerlessness are common. Each functional loss is accompanied by grief and mourning. The patient and family are assessed for depression, anger, or denial. The patient and family are assisted and encouraged to address decisions about end-of-life options before their need arises (see Chapter 13).

A psychiatric nurse clinician or other mental health professional may assist the patient to cope and adapt to the disease. By understanding and addressing

clinical concerns that are important for patients and their families, while at the same time assessing caregiver knowledge and burden during every encounter, the nurse provides a hopeful, supportive, and nurturing environment.

Degenerative Disc Disease

Low back pain is the second most common neurologic disorder in the United States, with one quarter of all adults reporting recent (within 3 months) back pain (Hickey & Strayer, 2020). It is frequently associated with depression, anxiety, smoking, alcohol abuse, obesity, and stress; and it is the most common reason for missed work and decreased productivity while at work (Ramanathan, Hibbert, Wiles, et al., 2018). Low back pain results in significant economic costs to patients, their families, and society. Acute pain lasts less than 3 months, whereas chronic pain has a duration of 3 months or longer. Approximately 90% of patients with low back pain recover spontaneously within 4 to 6 weeks (Hickey & Strayer, 2020). See Chapter 36, Chart 36-2 for further discussion of strategies to prevent acute low back pain.

Pathophysiology

The intervertebral disc is a cartilaginous plate that forms a cushion between the vertebral bodies (see Fig. 65-6A). This tough, fibrous material is incorporated in a capsule. A ball-like cushion in the center of the disc is called the *nucleus pulposus*. In herniation of the intervertebral disc (ruptured disc), the nucleus of the disc protrudes into the annulus (the fibrous ring around the disc), with subsequent nerve compression (Norris, 2019). Protrusion or rupture of the nucleus pulposus usually is preceded by degenerative changes that occur with aging. Loss of protein polysaccharides in the disc decreases the water content of the nucleus pulposus. The development of radiating cracks in the annulus weakens resistance to nucleus herniation. After trauma (falls and repeated minor stresses such as lifting incorrectly), the cartilage may be injured.

For most patients, the immediate symptoms of trauma are short-lived, and those resulting from injury to the disc do not appear for months or years. Disc degeneration pushes the capsule back into the spinal canal. It could also rupture and allow the nucleus pulposus to be pushed back against the dural sac or against a spinal nerve as it emerges from the spinal column (see Fig. 65-6B). This disease of the spinal root produces pain and extreme sensitivity to touch due to radiculopathy (pressure in the area of distribution of the involved nerve endings). Continued pressure may produce degenerative changes in the involved nerve, such as changes in sensation and deep tendon reflexes.

Gerontologic Considerations

Low back pain is commonly reported in older adults (Eliopoulos, 2018). Degenerative disc disease is also prevalent among older adults, but age alone should not exclude a patient from undergoing lumbar fusion if indicated (Badhiwala, Karmur, Hachem, et al., 2019). Researchers studied a group of 2238 patients (n = 1119, age <70; n = 1119, age ≥70) who underwent spinal fusion. The groups were balanced for factors including sex, race, diabetes, hypertension, congestive heart failure, smoking, chronic steroid use, type of fusion, and number of levels (see later discussion). Rates of all complications were similar between younger and older age groups, except urinary tract infection, which was more frequent among the ≥70 age group (OR 2.32, p = .009). Those in the older age group were more likely to be discharged to a rehabilitation or skilled care facility, rather than directly home (Badhiwala et al., 2019).

Clinical Manifestations

A herniated disc with accompanying pain may occur in any portion of the spine: cervical, thoracic (rare), or lumbar. The clinical manifestations depend on the location, the rate of development (acute or chronic), and the effect on the surrounding structures. Functional limitations are the main manifestation reported by patients. Researchers also report that pain intensity in patients with low back pain has a direct effect on ADLs and sleep quality (Kose, Tastan, Temiz, et al., 2019).

Assessment and Diagnostic Findings

A thorough health history and physical examination are important to rule out potentially serious conditions that may manifest as low back pain, including fracture, tumor, infection, or cauda equina syndrome (Hickey & Strayer, 2020).

The MRI scan has become the diagnostic tool of choice for localizing even small disc protrusions, particularly for lumbar spine disease. If the clinical symptoms are not consistent with the pathology seen on MRI, CT scanning and myelography are performed. A neurologic examination is carried out to determine whether reflex, sensory, or motor impairment from root compression is present and to provide a baseline for future assessment. Electromyography may be used to localize the specific spinal nerve roots involved. See Chapter 36, Chart 36-1 for a summary of additional diagnostic studies that may be used to evaluate low back pain.

Medical Management

Herniations of the cervical and the lumbar discs occur most commonly and are usually managed conservatively with medication and physical therapy or exercise (Hickey & Strayer, 2020). Surgery is sometimes necessary.

Surgical Management

Surgical excision of a herniated disc is performed if there is evidence of a progressing neurologic deficit (muscle weakness and atrophy, loss of sensory and motor function, loss of sphincter control) and radicular pain (pain that follows the dermatomal distribution [see Chapter 60, Fig. 60-9] of the compressed nerve) that are unresponsive to conservative management. The goal of surgical treatment is to reduce the pressure on the nerve root to relieve pain and reverse neurologic deficits. Microsurgical techniques make it possible to remove only the amount of tissue that is necessary, which preserves the integrity of normal tissue better and imposes less trauma on the body. During these procedures, spinal cord function can be monitored electrophysiologically.

Some of the surgical techniques available include (Hickey & Strayer, 2020):

- *Microdiscectomy:* Removal of herniated or extruded fragments of intervertebral disc material
- *Laminectomy:* Removal of the bone between the spinal process and facet pedicle junction to expose the neural elements in the spinal canal; this allows the surgeon to inspect the spinal canal, identify and remove pathologic tissue, and relieve compression of the cord and roots
- *Hemilaminectomy:* Removal of part of the lamina and part of the posterior arch of the vertebra
- *Partial laminectomy or laminotomy:* Creation of a hole in the lamina of a vertebra
- *Discectomy with fusion:* Fusion of the vertebral spinous process with a bone graft (from iliac crest or bone bank), with the object of spinal fusion being to bridge over the defective disc to stabilize the spine and reduce the rate of recurrence
- *Foraminotomy:* Enlargement of the intervertebral foramen to increase the space for exit of a spinal nerve, resulting in reduced pain, compression, and edema

Herniation of a Cervical Intervertebral Disc

The cervical spine is subjected to stresses that result from disc degeneration (due to aging, improper body mechanics) and **spondylosis** (degenerative changes occurring in a disc and adjacent vertebral bodies). Cervical disc

degeneration may lead to lesions that can cause damage to the spinal cord and its roots (Hickey & Strayer, 2020).

Clinical Manifestations

A cervical disc herniation usually occurs at the C5–C6 or C6–C7 interspaces and compresses a unilateral nerve root (Hickey & Strayer, 2020). Pain and stiffness may occur in the neck, the top of the shoulders, and the region of the scapulae. Patients sometimes interpret these signs as symptoms of heart trouble or bursitis. Pain may also occur in the arm and hand, accompanied by **paresthesia** (numbness, tingling, or a "pins and needles" sensation) of the upper extremity. Cervical MRI usually confirms the diagnosis. Occasionally, the disc herniates centrally onto the spinal cord, causing Lhermitte syndrome, an electriclike shock sensation in the extremities or spine with neck flexion or straining, and myelopathy (bilateral arm and leg weakness). Myelopathy indicates compression of the spinal cord. The patient may exhibit a decrease in fine motor skills, difficulty with ambulation, difficulty with bowel and bladder control, and respiratory impairment if compression has occurred high in the cervical spine (Hemmer, 2018).

Medical Management

The goals of treatment are to rest and immobilize the cervical spine to give the soft tissues time to heal and to reduce inflammation in the supporting tissues and the affected nerve roots in the cervical spine (Hickey & Strayer, 2020). It also reduces inflammation and edema in soft tissues around the disc, relieving pressure on the nerve roots. Proper positioning on a firm mattress may bring dramatic relief from pain.

The cervical spine may be rested and immobilized by a cervical collar, cervical traction, or a brace. A collar allows maximal opening of the intervertebral foramina and holds the head in a neutral or slightly flexed position. The patient may have to wear the collar 24 hours a day during the acute phase. The skin under the collar is inspected for irritation. After the patient is free of pain, cervical isometric exercises are started to strengthen the neck muscles.

Pharmacologic Therapy

Analgesic agents (nonsteroidal anti-inflammatory drugs [NSAIDs], acetaminophen/oxycodone, or acetaminophen/hydrocodone) are prescribed during the acute phase to relieve pain, and sedative agents may be given to control the anxiety that is often associated with cervical disc disease. Muscle relaxants (cyclobenzaprine, methocarbamol, metaxalone) are prescribed for less than 1 week to interrupt muscle spasm and to promote comfort (Hickey &

Strayer, 2020). NSAIDs (aspirin, ibuprofen, naproxen) or corticosteroids are prescribed to treat the inflammation and swelling that usually occurs in the affected nerve roots and supporting tissues. Occasionally, a corticosteroid is injected into the epidural space for relief of radicular pain. NSAIDs are given with food to prevent gastrointestinal irritation (Comerford & Durkin, 2020). Hot, moist compresses (for 10 to 20 minutes) applied to the back of the neck several times daily increase blood flow to the muscles and help relax the patient and reduce muscle spasm.

Surgical Management

Surgical excision of the herniated disc may be necessary if there is a significant neurologic deficit, progression of the deficit, evidence of cord compression, or pain that either worsens or fails to improve. A cervical discectomy, with or without fusion, may be performed to alleviate symptoms. An anterior surgical approach may be used through a transverse incision to remove disc material that has herniated into the spinal canal and foramina, or a posterior approach may be used at the appropriate level of the cervical spine. Potential complications with the anterior approach include carotid or vertebral artery injury, recurrent laryngeal nerve dysfunction, esophageal perforation, and airway obstruction (Hickey & Strayer, 2020). Complications of the posterior approach include damage to the nerve root or the spinal cord due to retraction or contusion of either of these structures, resulting in weakness of muscles supplied by the nerve root or cord.

Microsurgery, such as endoscopic microdiscectomy, may be performed in select patients through a small incision, using magnification techniques. This usually results in less tissue trauma and pain, and patients consequently have a shorter length of hospital stay compared with those who have conventional surgery (Hickey & Strayer, 2020).

NURSING PROCESS

The Patient Undergoing a Cervical Discectomy

Assessment

The patient is asked about past injuries to the neck, such as whiplash injury, because unresolved trauma can cause persistent discomfort, pain and tenderness, and symptoms of arthritis in the injured joint of the cervical spine. Assessment includes determining the onset, location, and radiation of pain and assessing for paresthesias, limited movement, and diminished function of the neck, shoulders, and upper extremities. It is important to determine whether the symptoms are bilateral; with large herniations, bilateral symptoms may be caused by cord compression. The area around the cervical spine is palpated to assess muscle tone and tenderness. Range of motion in the neck and shoulders is evaluated.

The patient is asked about any health issues that may influence the postoperative course and quality of life. It is also important to assess mood and stress levels. The nurse determines the patient's need for information about the surgical procedure and reinforces what the primary provider has explained. Strategies for pain management are discussed with the patient (Hickey & Strayer, 2020).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Acute pain associated with the surgical procedure
- Impaired mobility associated with the postoperative surgical regimen
- Lack of knowledge about the postoperative course and home care management

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hematoma at the surgical site, resulting in cord compression and neurologic deficit
- Recurrent or persistent pain after surgery

Planning and Goals

The goals for the patient may include relief of pain, improved mobility, increased knowledge and self-care ability, and prevention of complications.

Nursing Interventions

Relieving Pain

Incisional pain is expected. Radicular pain improves over time as the nerve recovers. If the patient has had a bone fusion with bone removed from the iliac crest, considerable pain may be experienced at the donor site. Interventions consist of monitoring the donor site for hematoma formation, administering the prescribed postoperative analgesic agent, positioning for comfort, and reassuring the patient that the pain can be relieved. If the patient experiences a sudden increase in pain, extrusion of the graft may have occurred, requiring reoperation. A sudden increase in pain should be promptly reported to the surgeon (Lall, 2018).

The patient may experience a sore throat, hoarseness, and dysphagia due to temporary edema. These symptoms are relieved by throat lozenges, voice rest, and humidification. A pureed diet may be given if the patient has dysphagia.

Improving Mobility

Postoperatively, a cervical collar (neck orthosis) may be worn, which contributes to limited neck motion and altered mobility. The patient is instructed to turn the body instead of the neck when looking from side to side. The neck should be kept in a neutral (midline) position. The patient is assisted during position changes to make sure that the head, shoulders, and thorax are kept aligned. When assisting the patient to a sitting position, the nurse supports the patient's neck and shoulders. To increase stability, the patient should wear shoes when ambulating. The patient is encouraged not to lift more than 10 pounds.

Monitoring and Managing Potential Complications

The patient is evaluated for bleeding and hematoma formation by assessing for swelling, excessive pressure in the neck, or severe pain in the incision area. The dressing is inspected for serosanguineous drainage, which suggests a dural leak. If this occurs, meningitis is a threat. A complaint of headache requires careful evaluation. Neurologic checks are made for swallowing deficits and upper and lower extremity weakness, because cord compression may produce rapid or delayed onset of paralysis (Hickey & Strayer, 2020). The patient who has had an anterior cervical discectomy is also assessed for a sudden return of radicular (spinal nerve root) pain, which may indicate instability of the spine (Hemmer, 2018).

Throughout the postoperative course, the patient is monitored frequently to detect any signs of respiratory difficulty, because retractors used during surgery may injure the laryngeal nerve, resulting in hoarseness and the inability to cough effectively and clear pulmonary secretions. In addition, the blood pressure and pulse are monitored to evaluate cardiovascular status and optimal circulation to the surgical site.

Bleeding at the surgical site and subsequent hematoma formation may occur. Severe localized pain not relieved by analgesic agents should be

reported. A change in neurologic status (motor or sensory function) should be reported promptly, because it suggests hematoma formation that may necessitate surgery to prevent irreversible motor and sensory deficits (Hickey & Strayer, 2020).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The patient's length of hospital stay is likely to be short; therefore, the patient and family should understand the care that is important for a smooth recovery. A cervical collar, if prescribed, is usually worn for about 6 weeks. The patient is educated in the use and care of the cervical collar. The patient will need to alternate tasks that involve minimal body movement (e.g., reading) with tasks that require greater body movement.

The patient is educated about strategies to manage the incision and to manage pain, and about signs and symptoms that may indicate complications that should be reported to the primary provider. The nurse assesses the patient's understanding of these management strategies, limitations, and recommendations. In addition, the nurse assists the patient in identifying strategies to cope with ADLs (e.g., self-care, child care) and minimize risks to the surgical site (see Chart 65-6). A discharge educational plan is developed collaboratively by members of the health care team to decrease the risk of recurrent disc herniation. Topics include those previously discussed as well as proper body mechanics, maintenance of optimal weight, proper exercise techniques, and modifications in activity.

Continuing and Transitional Care. The patient is instructed to see the primary provider at prescribed intervals so that the provider can document the disappearance of old symptoms and assess the range of motion of the neck. Recurrent or persistent pain may occur despite removal of the offending disc or disc fragments. Patients who undergo discectomy usually have consented to surgery after prolonged pain; they have often undergone repeated courses of ineffective conservative management and previous surgeries to relieve the pain. Therefore, the recurrence or persistence of symptoms postoperatively, including pain and sensory deficits, is often discouraging for the patient and family. The patient who experiences recurrence of symptoms requires emotional support and understanding. In addition, the patient is assisted in modifying activities and in considering options for subsequent treatment. The nurse educates the patient and family members about the need to participate in health-promotion and health-screening practices.

Evaluation

Expected patient outcomes may include:

1. Reports decreasing frequency and severity of pain

2. Demonstrates improved mobility
   a. Demonstrates progressive participation in self-care activities
   b. Identifies prescribed activity limitations and restrictions
   c. Demonstrates proper body mechanics
3. Is knowledgeable about postoperative course, medications, and home care management
   a. Lists the signs and symptoms to be reported postoperatively
   b. Identifies dose, action, and potential side effects of medications
   c. Identifies appropriate home care management activities and any restrictions
4. Has absence of complications
   a. Reports no increase in incision pain or sensory symptoms
   b. Demonstrates normal findings on neurologic assessment

Herniation of a Lumbar Disc

Most lumbar disc herniations occur at the L5–S1 region (Hickey & Strayer, 2020). A herniated lumbar disc produces low back pain accompanied by varying degrees of sensory and motor impairment.

Chart 65-6  **HOME CARE CHECKLIST**

The Patient with Cervical Discectomy and Cervical Collar

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., durable medical equipment, adaptive equipment) used in adapting to any permanent changes in structure or function to promote safety and optimum functioning.
  - Use adequate mattress and chair support.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - Describe nonpharmacologic interventions for pain relief used in conjunction to prescribed pain relief preparations.
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., exercises) and to limit or avoid (e.g., lifting, stair climbing, driving a car) during rehabilitation.
- Describe care for the surgical incision site.
  - Keep staples or sutures clean and dry and cover with dry dressing.
- Demonstrate proper body mechanics and prescribed exercise techniques.
  - Describe how to modify activity for optimum functioning.
  - Avoid sitting or standing for more than 30 minutes.
  - Avoid twisting, flexing, extending, or rotating the neck.
  - Avoid sleeping in a prone position or the use of pillows to minimize neck flexion in bed; keep head in a neutral position.
  - Wear low-heeled shoes.
  - Place a wrinkle-free silk scarf under the collar to increase comfort.
  - **For men:** Shave without twisting or moving the neck. This may be done with help while lying flat or sitting. Remove only the front part of the collar for shaving.
- Practice stress reduction and relaxation techniques.
- Care of the cervical collar:
  - Wear the collar at all times until directed otherwise by the primary provider.
  - Wash the neck under the collar twice a day with mild soap.
  - Keep the neck still while the collar is open.

    - With the assistance of a helper, wash the neck in steps.
    - Lie flat and supine.
    - Open the Velcro tabs on each side of the collar and remove its front portion.
    - Gently wash and dry the neck.
    - Replace the front part of the collar and refasten the tabs.
    - Turn to one side with a thin pillow under the head.
    - Open one tab.
    - Gently wash and dry the back of the neck. Refasten the tab.
    - Turn to the other side and wash and dry this side. Refasten the tab.
- Notify primary provider if any signs or symptoms of infection occur, such as fever, redness or irritation, drainage, increased pain.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support for patient and caregivers (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Clinical Manifestations

The patient complains of low back pain with muscle spasm and **sciatica** (pain and tenderness that radiates along the sciatic nerve that runs through the thigh and leg). Pain is aggravated by actions that increase intraspinal fluid pressure, such as bending, lifting, or straining (as in sneezing or coughing), and usually is relieved by bed rest. There is often some type of postural deformity, because pain causes an alteration of the normal spinal mechanics. If the patient lies on the back and attempts to raise a leg in a straight position, pain radiates into the leg; this maneuver, called the *straight-leg raising test,* stretches the sciatic nerve. Additional signs include muscle weakness, alterations in tendon reflexes, and sensory loss.

Assessment and Diagnostic Findings

The diagnosis of lumbar disc disease is based on the history and physical findings, specifically the location, quality, severity of pain, and the use of imaging techniques such as MRI and CT scans as well as myelography.

Medical Management

The objectives of treatment are to relieve pain, slow disease progression, and increase the patient's functional ability. Bed rest is discouraged because it may weaken muscles, but activities that exacerbate pain should be avoided.

Because muscle spasm is prominent during the acute phase, muscle relaxants are used. NSAIDs and systemic corticosteroids may be given to counter the inflammation and swelling that usually occurs in the supporting tissues and the affected nerve roots. Moist heat and massage help relax muscles. Strategies for increasing the patient's functional ability include weight reduction, physical therapy, and biofeedback. Exercises, prescribed by physical therapy, can help strengthen back muscles and decrease pain (Hickey & Strayer, 2020). See Chapter 9 for descriptions of nursing interventions for the patient with pain.

Surgical Management

In the lumbar region, surgical treatment includes lumbar disc excision through a posterolateral laminotomy and the techniques of microdiscectomy and percutaneous discectomy. In microdiscectomy, an operating microscope is used to visualize the offending disc and compressed nerve roots; it permits a small incision (2.5 cm [1 inch]) and minimal blood loss and takes about 30 minutes of operating time. In general, the length of hospital stay is short, and the patient makes a rapid recovery. Several minimally invasive techniques in spinal surgery have led to improved patient outcomes and lower hospital costs (Hickey & Strayer, 2020).

A patient undergoing a disc procedure at one level of the vertebral column may have a degenerative process at other levels. A herniation relapse may occur at the same level or elsewhere, so the patient may become a candidate for another disc procedure. Arachnoiditis (inflammation of the arachnoid membrane) may occur after surgery (and after myelography); it involves an insidious onset of diffuse, frequently burning pain in the lower back, radiating into the buttocks. Disc excision can leave adhesions and scarring around the spinal nerves and dura, which then produce inflammatory changes that create chronic neuritis and neurofibrosis. Disc surgery may relieve pressure on the spinal nerves, but it does not reverse the effects of neural injury and scarring and the pain that results. Failed disc syndrome (recurrence of sciatica after lumbar discectomy) remains a cause of disability (Hickey & Strayer, 2020).

Nursing Management

Providing Preoperative Care

Most patients fear surgery on any part of the spine and therefore need explanations about the surgery and reassurance that it will not weaken the back. When data are being collected for the health history, any reports of pain,

paresthesia, or muscle spasm are recorded to provide a baseline for comparison after surgery. Health issues that may influence the postoperative course and quality of life (e.g., fatigue, mood, stress, patient expectations, smoking) are important to assess. Preoperative assessment also includes an evaluation of movement of the extremities as well as bladder and bowel function (Hickey & Strayer, 2020). To facilitate the postoperative turning procedure, the patient is instructed to turn as a unit (called logrolling) as part of the preoperative preparation. Before surgery, the patient is also encouraged to take deep breaths, cough, and perform muscle setting exercises to maintain muscle tone.

Research suggests that the use of motivational interviewing helps build self-confidence with self-care management of symptoms in the postoperative period (Scheffel, Amidei, & Fitzgerald, 2019). See the Nursing Research Profile in Chart 65-7.

Assessing the Patient After Surgery

After lumbar disc excision, vital signs are checked frequently and the wound is inspected for hemorrhage, because vascular injury is a complication of disc surgery. Because postoperative neurologic deficits may occur from nerve root injury, the sensation and motor strength of the lower extremities are evaluated at specified intervals, along with the color and temperature of the legs and sensation of the toes. It is important to assess for urinary retention, which is another sign of neurologic deterioration (Hickey & Strayer, 2020). In discectomy with fusion, the patient has an additional surgical incision if bone fragments were taken from the iliac crest or fibula to serve as wedges in the spine. The recovery period is longer for patients who undergo discectomy with spinal fusion, because bony union must take place.

Positioning the Patient

To position the patient, a pillow is placed under the head, and the knee rest is elevated slightly to relax the back muscles. When the patient is lying on one side, however, extreme knee flexion must be avoided. The patient is encouraged to move from side to side to relieve pressure and is reassured that no injury will result from moving. When the patient is ready to turn, the bed is placed in a flat position and a pillow is placed between the patient's legs. The patient turns as a unit (logrolls) without twisting the back.

Chart 65-7  **NURSING RESEARCH PROFILE**

Improving Confidence with Self-Care Management

Scheffel, K., Amidei, C., & Fitzgerald, K. A. (2019). Motivational interviewing: Improving confidence with self-care management in postoperative thoracolumbar spine patients. *Journal of Neuroscience Nursing, 51*(3), 113–117.

Purpose

Patients undergoing spine surgery often lack confidence in self-care management of symptoms such as pain, lack of sleep, depression, and immobility. The purpose of this study was to examine whether a targeted motivational interview would improve confidence with self-care management of symptoms following spine surgery.

Design

This pilot study used a quasi-experimental, one group, pretest–posttest design with 15 participants who were undergoing spine surgery. The two main instruments used to gather data included the 10-item Oswestry Disability Index (ODI) and the Health Confidence Index (HCI).

Findings

Paired sample *t*-tests of the pre- and postintervention scores on both the ODI and HCI showed statistically significant differences. The HCI showed a statistically significant increase in scores with mean preintervention scores of 6.73 (SD = 2.12) and mean postintervention scores of 8.73 (SD = 1.43) indicating a significant increase in confidence in self-care of symptom-related disability.

Nursing Implications

Motivational interviewing is an effective strategy for implementing health promoting behaviors. This study adds evidence that motivational interviewing is a strategy nurses can use to improve patients' confidence in self-care management of symptoms following spine surgery.

To get out of bed, the patient lies on one side while pushing up to a sitting position. At the same time, the nurse or family member eases the patient's legs over the side of the bed. Coming to a sitting or standing posture is accomplished in one long, smooth motion. Most patients walk to the bathroom on the same day as the surgery. Sitting is discouraged except for defecation.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The patient is instructed to increase activity gradually, as tolerated, because it takes up to 6 weeks for the ligaments to heal. Excessive activity may result in spasm of the paraspinal muscles (Hickey & Strayer, 2020).

Activities that produce flexion strain on the spine (e.g., driving a car) should be avoided until healing has taken place. Heat may be applied to the back to relax muscle spasms. Scheduled rest periods are important, and the patient is advised to avoid heavy work for 2 to 3 months after surgery. Exercises are prescribed to strengthen the abdominal and erector spinal muscles. A back brace or corset may be necessary if back pain persists.

Continuing and Transitional Care

Referral for inpatient or outpatient rehabilitation may be warranted to improve self-care abilities after medical or surgical treatment for herniation of a lumbar disc. A home care referral may be indicated and provides the nurse with the opportunity to assess the patient's physical and psychological status, as well as their ability to adhere to recommended management strategies. During the home visit, the nurse determines whether changes in neurologic function have occurred. The adequacy of pain management is assessed, and modifications are made to ensure adequate pain relief (Hickey & Strayer, 2020).

Post-Polio Syndrome

Polio has mostly been eradicated globally due to concerted vaccination efforts. However, people who survived the polio epidemic of the 1940s and 1950s, many of whom are now older adults, are developing new symptoms of weakness, fatigue, and musculoskeletal pain identified as PPS. This phenomenon, which occurs at least 15 years after the polio exposure, affects 15 to 20 million people worldwide (Shing, Chipika, Finegan, et al., 2019). Men and women appear to be equally at risk for this condition.

Pathophysiology

The exact cause of PPS is not known, but researchers suspect that with aging or muscle overuse, the neurons not destroyed by the poliovirus continue generating axon sprouts (Shing et al., 2019). These new terminal axon sprouts reinnervate the affected muscles after the initial insult but may become more vulnerable as the body ages.

Assessment and Diagnostic Findings

No specific diagnostic test exists for PPS. Clinical diagnosis is made on the basis of the history and physical examination and exclusion of other medical

conditions that could be causing the new symptoms. Patients report a history of paralytic poliomyelitis followed by partial or complete recovery of function, with a plateau of function and then the recurrence of symptoms. Signs and symptoms may occur decades after the original onset of poliomyelitis (Shing et al., 2019).

Management

No specific medical or surgical treatment is available for this syndrome, and therefore nurses play a pivotal role in the team approach to assisting patients and families in dealing with the symptoms of progressive loss of muscle strength and significant fatigue (Shing et al., 2019; Pastuszak, Stepien, Tomczykiewicz, et al., 2017). Pain and weakness may be improved with infusion of intravenous immunoglobulin (Shing et al., 2019).

For the procedural guidelines for managing immunoglobulin therapy, go to thepoint.lww.com/Brunner15e.

Nursing interventions are aimed at maintaining the patient's strength as well as physical, psychological, and social well-being. Other health care professionals who may assist in patient care include physical, occupational, speech, and respiratory therapists; social workers; and chaplains.

The patient needs to plan and coordinate activities to conserve energy and reduce fatigue. Rest periods should be planned and assistive devices used to reduce weakness and fatigue. Important activities should be planned for the morning, because fatigue often increases in the afternoon and evening.

Pain in muscles and joints may be a problem. Nonpharmacologic techniques such as the application of heat and cold are appropriate, because older adults may not tolerate or may react to medications, particularly when they are taking multiple medications (Eliopoulos, 2018).

Maintaining a balance between adequate nutritional intake and avoiding excess calories that can lead to obesity is a challenge in this group of patients who are sedentary. Pulmonary hygiene and adequate fluid intake can help with airway management. Several interventions can improve sleep, including limiting caffeine intake before bedtime and assessing for nocturia. The patient may need to be evaluated for obstructive sleep apnea. Supportive ventilation may be appropriate, with continuous positive airway pressure if sleep apnea is a problem (see Chapter 18).

Bone density testing in patients with PPS has revealed low bone mass and osteoporosis. Therefore, the importance of identifying risks, preventing falls,

and treating osteoporosis must be discussed with patients and families. Families also need to be made aware of the possibility of changes in individual and family relationships due to the many symptoms of PPS. The nurse also needs to remind patients and family members of the need for health-promotion activities and health screening (Shing et al., 2019).

CRITICAL THINKING EXERCISES

1 ebp A 64-year-old man has been admitted to the unit where you work after having a seizure and has been newly diagnosed with a brain tumor. Identify the evidence-based practices for the management of brain tumors. Describe the evidence base for the practices that you have identified and the criteria used to evaluate the strength of that evidence. Identify the health-promotion activities you would recommend to this patient and the rationale for your recommendations.

2 pq You are caring for a 55-year-old woman newly diagnosed with Parkinson's disease. Assess and prioritize the patient's physiologic and psychosocial needs. What nursing interventions and actions would you suggest to assist in managing the treatment of and coping with Parkinson's disease? How would this be different if the patient lives alone?

3 ipc You are participating in morning rounds on the surgery unit where you work. The team is discussing one of the patients who has been assigned to you for the day, a 75-year-old man admitted yesterday following a lumbar disc excision. What members of the interprofessional care team should be included in the care of this patient? How will you, as this patient's nurse, facilitate an interprofessional discussion to assist with his discharge?

UNIT 16 Acute Community-Based Challenges

Case Study

USING EVIDENCE-BASED PRACTICES FOR EFFECTIVE CARE DURING A NOVEL VIRUS OUTBREAK

You are a home health nurse in an urban community. The Centers for Disease Control and Prevention (CDC) has informed

the agency where you work that there is an outbreak within your community of a novel respiratory virus that is implicated in causing pneumonia and acute respiratory failure. You know that when a novel virus begins to circulate among a population that universally has no immunity, some groups will be at greater risk of contracting the virus than others. You are worried about the patients you routinely care for as they have multiple comorbidities, likely placing them at higher risk. How will you find and integrate the best current evidence with clinical expertise, while also respecting patient and family preferences and values for delivery of optimal health care during a novel virus outbreak?

QSEN Competency Focus: **Evidence-Based Practice**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Evidence-Based Practice Definition: Integrate best current evidence with clinical expertise and patient/family preferences and values for delivery of optimal health care.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Explain the role of evidence in determining best clinical practice Describe how the strength and relevance of available evidence influences the choice of interventions in provision of patient-centered care	Which federal, state, and local sources will you use to identify an evolving evidence base around an outbreak of a novel virus? How will you judge the strength and the relevance of the evidence you locate? Describe how utilizing evidence-based education will help to increase the knowledge that a given patient will have regarding care during a pandemic.
Skills	
Read original research and evidence reports related to area of practice Locate evidence reports related to clinical practice topics and guidelines	Discuss what evidence you would use to guide your practice during an outbreak of a novel virus. According to the evidence-based literature, what are effective infection control techniques for patients of different ages and with various comorbidities during a novel viral outbreak?
Attitudes	
Acknowledge own limitations in knowledge and clinical expertise before determining when to deviate from evidence-based best practices	Reflect on how it would feel to have a novel viral outbreak impose restrictions on your life. How does a novel viral outbreak have the potential to impact the daily lives of patients with comorbidities?

66 Management of Patients with Infectious Diseases

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Differentiate between the concepts of colonization, infection, and disease.
2. Identify federal, state, and local resources available to the nurse seeking information about infectious diseases and discuss the benefits of recommended vaccines for health care workers and patients.
3. Compare and contrast standard and transmission-based precautions and discuss the elements of each of these prevention methods.
4. Describe the concept and the nursing management of patients with emerging infectious diseases.
5. Use the nursing process as a framework for care of the patient with a sexually transmitted infection or with an infectious disease.

Cellular Regulation
Family
Fluids and Electrolytes
Infection
Patient Education
Safety
Sexuality
Thermoregulation

GLOSSARY

bacteremia: laboratory-confirmed presence of bacteria in the bloodstream

carrier: person who has a pathogen without apparent signs and symptoms; one who is able to transmit an infection to others

colonization: the presence of microorganisms in or on a host, without host interference or interaction and without eliciting symptoms in the host

coronavirus disease 2019 (COVID-19): a disease caused by the virus SARS-CoV-2

emerging infectious diseases: human infectious diseases with an increased incidence within the past two decades, or with a potential to increase in the near future

epidemic: a widespread outbreak of a specific infectious disease from a single source within a community or population that exceeds anticipated levels of impact

health care–associated infection (HAI): an infection not present or incubating at the time of admission to the health care setting; this term has replaced the term *nosocomial infection*

host: an organism that provides living conditions to support a microorganism

immune: person with protection from a previous infection or vaccination who resists reinfection when re-exposed to the same agent

incubation period: time between contact and onset of signs and symptoms

infection: condition in which the host interacts physiologically and immunologically with a microorganism

infectious disease: any disease caused by the growth of pathogenic microbes in the body that may or may not be communicable

latency: time interval after primary infection when a microorganism lives within the host without producing clinical evidence of disease

methicillin-resistant *Staphylococcus aureus* (MRSA): *Staphylococcus aureus* bacterium that is not susceptible to extended-penicillin antibiotic formulas, such as methicillin, oxacillin, or nafcillin; MRSA may occur in a health care or community setting

normal flora: persistent nonpathogenic organisms colonizing a host

outbreak: the occurrence of a disease within a population that exceeds normal expectations

pandemic: an epidemic that spreads across multiple countries or continents

reservoir: any person, plant, animal, substance, or location that provides living conditions for microorganisms and that enables further dispersal of the organism

severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2): the virus that causes COVID-19

standard precautions: strategy of assuming all patients may carry infectious agents and using appropriate barrier precautions for all health care worker–patient interactions

susceptible: not possessing immunity to a particular pathogen

transient flora: organisms that have been recently acquired and are likely to be shed in a relatively short period

transmission-based precautions: precautions used in addition to standard precautions when contagious or epidemiologically significant organisms are recognized; the three types of transmission-based precautions are airborne, droplet, and contact precautions

vancomycin-resistant *Enterococcus* (VRE): *Enterococcus* bacterium that is not susceptible to the antibiotic vancomycin

virulence: degree of pathogenicity of an organism

An **infectious disease** is any disease caused by the growth of pathogenic microbes in the body. It may or may not be communicable (i.e., contagious). Although modern science had controlled, eradicated, or decreased the incidence of many infectious diseases, emerging novel pathogens continue to plague the globe, taxing economic and social resources, and proving hazardous to the health and well-being of patients, families, communities, and cultural systems. Examples of such threatening infectious diseases are presented in this chapter. Other infectious diseases are discussed in the appropriate chapters (e.g., see Chapter 19 for information on tuberculosis [TB]). It is important to understand infectious causes and the treatment of contagious, serious, common infections as well as emerging noncommon infections. Table 66-1 presents select infectious diseases, their causative organisms, mode of transmission, and usual **incubation period** (time between contact and development of the first signs and symptoms).

The nurse plays an important role in infection control and prevention. Educating patients may decrease their risk of becoming infected or may decrease the sequelae of infection. Using appropriate barrier precautions, observing prudent hand hygiene, and ensuring aseptic care of intravenous (IV) catheters and other invasive equipment also assists in reducing infections.

The Infectious Process

The Chain of Infection

A complete chain of events is necessary for infection to occur. Six elements are necessary, including a causative organism, a reservoir of available organisms, a portal of exit from the reservoir, a mode of transmission from the reservoir to the **host** (an organism that provides living conditions to support a microorganism) and a mode of entry into a susceptible host.

Nurses must clearly understand the elements of the chain of infection in order to identify points at which they can intervene to interrupt the chain, thus protecting patients, themselves, and others from infectious diseases. Figure 66-1 illustrates these concepts.

Causative Organism

The types of microorganisms that cause infections are bacteria, rickettsiae, viruses, protozoa, fungi, and helminths.

Reservoir

Reservoir is the term used for any person, plant, animal, substance, or location that provides nourishment for microorganisms and enables further dispersal of the organism. Infections may be prevented by eliminating the causative organisms from the reservoir.

Portal of Exit

The organism must have a portal of exit from a reservoir. An infected host must shed organisms to another or to the environment for transmission to occur. Organisms exit through the respiratory tract, the gastrointestinal tract, the genitourinary tract, or the blood.

Route of Transmission

A route of transmission is necessary to connect the infectious source with its new host. Organisms may be transmitted through food intake, sexual contact, skin-to-skin contact, percutaneous injection, or infectious particles carried in the air. A person who carries or transmits a pathogen but does not have apparent signs and symptoms of infection is called a **carrier**.

Specific organisms require specific routes of transmission for infection to occur. For example, *Mycobacterium tuberculosis* is almost always transmitted by the airborne route. Health care providers do not "carry" *M. tuberculosis* bacteria on their hands or clothing. In contrast, bacteria such as *Staphylococcus aureus* are easily transmitted from patient to patient on the hands of health care providers. Some organisms cause infection through several routes. For example, the virus **severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)**, the virus that causes the **coronavirus disease 2019 (COVID-19)**, is highly contagious (see discussion later in this chapter). When appropriate, the nurse explains routes of disease transmission to patients.

Susceptible Host

For infection to occur, the host must be **susceptible** (not possessing immunity to a pathogen). Previous infection or vaccine administration may render the host **immune** (not susceptible) to further infection with an agent. Although exposure to potentially infectious microorganisms occurs essentially on a constant basis, people have complex immune systems that generally prevent infection from occurring. A person who is immunosuppressed has much greater susceptibility to infection than a healthy person.

Portal of Entry

A portal of entry is needed for the organism to gain access to the host. Again, specific organisms may require specific portals of entry for infection to occur. For example, airborne *M. tuberculosis* does not cause disease when it settles on the skin of an exposed host; the only entry route for *M. tuberculosis* is through the respiratory tract. The portal of entry for the SARS-CoV-2 virus is respiratory; however, the virus can remain airborne indoors for hours, accumulate over time, and can travel in airflows over distances greater than 6 feet (Prather, Wang, & Schooley, 2020).

TABLE 66-1 Select Infectious Diseases, Causative Organisms, Modes of Transmission, and Usual Incubation Periods

Disease or Condition	Organism	Usual Mode of Transmission	Approximate Incubation Period (Infection to First Symptom)
Acquired immune deficiency syndrome (AIDS)	Human immune deficiency virus (HIV)	Sexual; percutaneous; perinatal	Variable. Median of 10 yrs without effective therapy
Anthrax	*Bacillus anthracis*	Airborne, contact, or ingestion	1–43 days (inhalation) 5–7 days (cutaneous) 1–6 days (gastrointestinal)
Chancroid	*Haemophilus ducreyi*	Sexual	3–5 days
Chickenpox	Varicella zoster	Airborne or contact	10–21 days
Coronavirus disease 2019 (COVID-19)	Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)	Droplet and contact are principal modes In some situations, may be aerosolized	2–14 days
Cytomegalovirus infection	Cytomegalovirus	Transfusion and transplantation; sexual; perinatal	Highly variable: 3–8 wks after transfusion, 3–12 wks after delivery of newborn
Diarrheal disease (common causes)	*Campylobacter* species	Ingestion of contaminated food	2–5 days
	Clostridioides difficile	Fecal–oral	Variable; over 2 days
	Salmonella species	Ingestion of contaminated food or drink	12–36 h
	Shigella species	Ingestion of contaminated food or drink; direct contact with carrier	1–3 days
	Yersinia species	Ingestion of contaminated food or drink; direct contact with carrier	3–7 days
Ebola	Ebola virus	Contact with blood or body fluids	2–21 days
Gonorrhea	*Neisseria gonorrhoeae*	Sexual; perinatal	1–14 days
Hand, foot, and mouth disease	Coxsackievirus	Direct contact with nose and throat secretions and with	3–5 days

		feces of people who are infected	
Hantavirus pulmonary syndrome	Sin Nombre virus	Contact (direct or indirect) with rodents	2 days to 6 wks
Hepatitis, foodborne	Hepatitis A virus	Ingestion of contaminated food or drink; direct contact with carrier	14–42 days
	Hepatitis E virus	Ingestion of contaminated food or drink; direct contact with carrier	15–65 days
Hepatitis, bloodborne	Hepatitis B virus	Sexual; perinatal; percutaneous	45–180 days
	Hepatitis C virus	Sexual; perinatal; percutaneous	15 days to 6 mo
Herpes simplex	Human herpes viruses 1 and 2	Contact with mucous membrane secretions	2–12 days
Histoplasmosis	*Histoplasma capsulatum*	Inhalation of airborne spores	3–17 days
Hookworm disease	*Necator americanus; Ancylostoma duodenale*	Contact with soil contaminated with human feces	A few weeks to many months
Impetigo	*Staphylococcus aureus, Streptococcus pyogenes*	Contact with carrier or with patient's soiled towels or combs	4–10 days
Influenza	Influenza virus A, B, or C	Droplet spread	24–72 h
Legionnaires disease	*Legionella pneumophila*	Airborne from water source	2–10 days
Lyme disease	*Borrelia burgdorferi*	Tick bite	3–32 days
Lymphogranuloma venereum	*Chlamydia trachomatis*	Sexual	Weeks to years
Malaria	*Plasmodium vivax; Plasmodium malariae; Plasmodium falciparum; Plasmodium ovale*	Bite from *Anopheles* species mosquito	9–40 days
Marburg hemorrhagic fever	Marburg virus	Unknown route of transmission from animals to humans; person-to-person by droplets and direct contact	5–15 days
Meningococcal meningitis or	*Neisseria meningitidis*	Contact with pharyngeal	2–10 days

bacteremia		secretions; perhaps airborne	
Mononucleosis	Epstein–Barr virus	Contact with pharyngeal secretions	4–6 wks
Mycobacterial diseases (nontuberculosis *Mycobacterium* species)	*Mycobacterium avium; Mycobacterium kansasii; Mycobacterium fortuitum; Mycobacterium gordonae;* other *Mycobacterium* species	Variable; probably contact with soil, water, or other environmental source; none is person-to-person transmissible	Variable
Norovirus	Norovirus	Fecal–oral by food or water or by person-to-person spread	10–48 h
Pediculosis	*Pediculus humanus capitis* (head louse); *Pthiriasis pubis* (crab louse)	Direct or indirect contact	1–2 wks
Pertussis (whooping cough)	*Bordetella pertussis*	Contact with respiratory droplets	7–10 days
Pinworm disease	*Enterobius vermicularis*	Direct contact with egg-contaminated articles	1–2-mo life cycle; often takes months of infection before recognition
Pneumocystis jirovecii pneumonia	*Pneumocystis jirovecii*	Unknown; not transmitted person to person	Infants: 1–2 mo; adults: unclear
Pneumococcal pneumonia	*Streptococcus pneumoniae*	Droplet spread	Probably 1–3 days
Rabies	Rabies virus	Bite from rabid animal	3–8 wks
Respiratory syncytial disease	Respiratory syncytial virus	Self-inoculation by mouth or nose after contact with infectious respiratory secretions	1–10 days
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Bite from infected tick	2–21 days
Roseola infantum	Human herpes virus 6	Saliva	10–15 days
Rotavirus gastroenteritis	Rotavirus	Fecal–oral route	24–72 h
Rubella	Rubella virus	Droplet spread; direct contact	14–21 days
Scabies	*Sarcoptes scabiei*	Direct skin contact	2–6 wks
Smallpox	Variola major and minor	Airborne droplets and	7–17 days

(Eradicated since 1980)		contact	
Syphilis	*Treponema pallidum*	Sexual; perinatal	10 days to 12 wks
Tetanus	*Clostridium tetani*	Puncture wound	3–21 days
Tinea (ringworm)	*Microsporum* species; *Trichophyton* species	Direct and indirect contact with lesions	4–10 days
Trichinosis	*Trichinella spiralis*	Ingestion of insufficiently cooked foods, especially pork and beef	8–15 days
Tuberculosis	*Mycobacterium tuberculosis*	Airborne	2–10 wks to the formation of primary lesion
West Nile virus	West Nile virus	Bite of infected mosquitoes; from transfusions and transplants; perinatal	2–14 days
Zika virus	Zika virus	Bite of infected *Aedes* mosquitoes	3–14 days

Washington, DC: Public Health Foundation; Krow-Lucal, E. R., Biggerstaff, B. J., & Staples, J. E. (2017). Estimated incubation period for Zika virus disease. *Emerging Infectious Diseases*, *23*(5), 841–845.

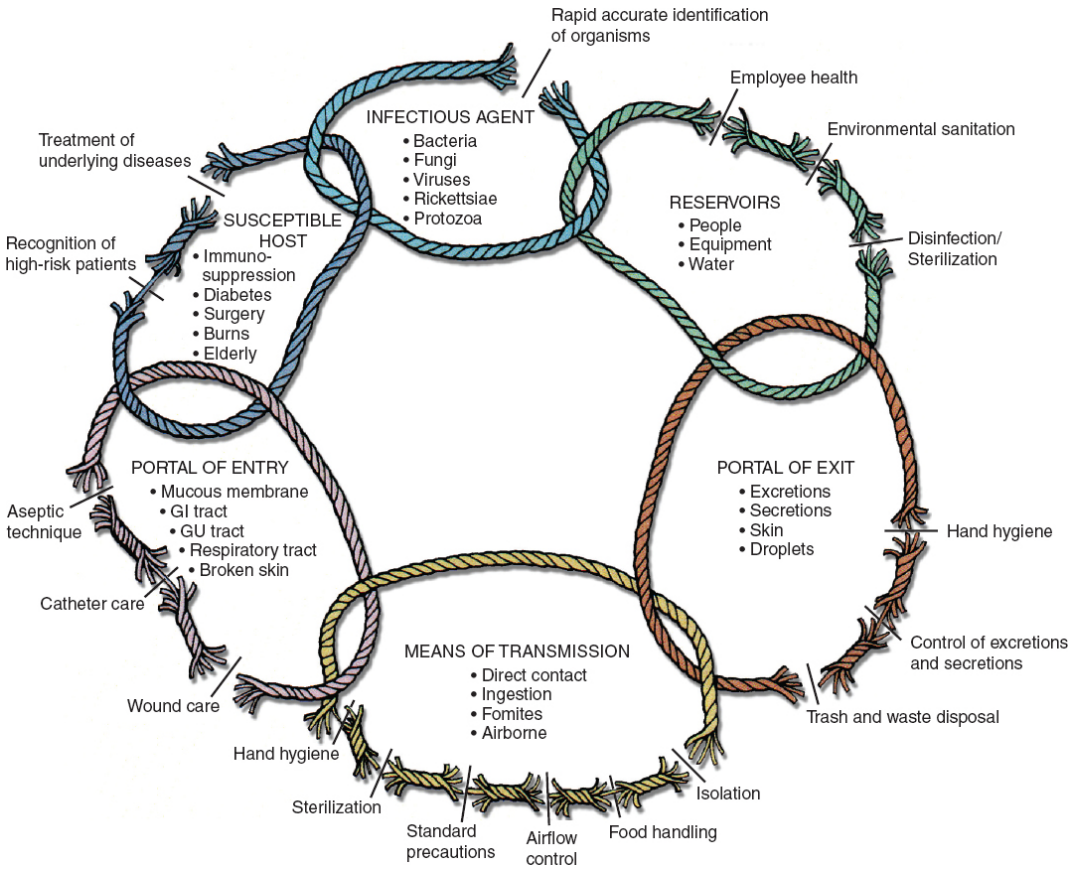

Figure 66-1 • Health care workers' interventions used to break the chain of infection transmission.

Colonization, Infection, and Infectious Disease

Relatively few anatomic sites (e.g., brain, blood, bone, heart, vascular system) are sterile. Bacteria found throughout the body usually provide beneficial **normal flora** (nonpathogenic organisms colonizing a host) to compete with potential pathogens, to facilitate digestion, or to work in other ways symbiotically with the host.

Colonization

The term **colonization** is used to describe the presence of microorganisms without host interference or interaction. Organisms reported in microbiology test results often reflect colonization rather than infection. The patient's health care team must interpret microbiology test results accurately to ensure appropriate treatment.

Infection

Infection indicates a host interaction with an organism. A patient colonized with *S. aureus* may have staphylococci on the skin without any skin interruption or irritation. However, if the patient has an incision, *S. aureus* entering the wound can induce an immune system reaction of local inflammation and migration of white cells to the site. Clinical evidence of redness, heat, and pain and laboratory

evidence of white blood cells in the wound specimen smear suggest infection. In this situation, the host identifies the staphylococci as *foreign.* Infection is recognized by the host reaction (manifested by signs and symptoms) and by laboratory-based evidence of white blood cell reaction and microbiologic organism identification.

Infectious Disease

Infectious disease is the state in which the infected host displays a decline in wellness due to the infection. When the host interacts immunologically with an organism but remains symptom free, the definition of infectious disease has not been met. For example, most people who are infected with *M. tuberculosis* have no symptoms. This is considered **latency,** or the time interval after primary infection when a microorganism lives within the host without producing clinical evidence of disease. The severity of an infectious disease ranges from mild to life-threatening (Norris, 2019). Figure 66-2 depicts the range of response to bacterial infection at the cellular and host level.

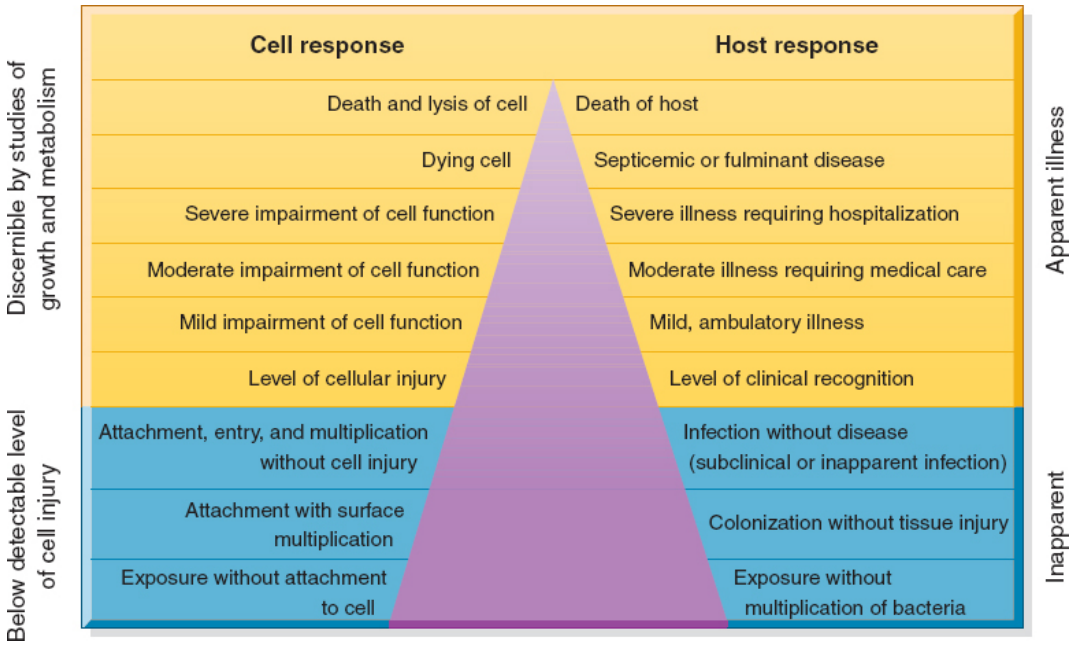

Figure 66-2 • Biologic spectrum of response to bacterial infection at the cellular level (*left*) and of the intact host (*right*). Redrawn from Evans, A. S., & Brachman, P. S. (1998). *Bacterial infections in humans: Epidemiology and control* (3rd ed., p. 40). New York: Plenum.

The primary source of information about most bacterial infections is the microbiology laboratory report, which should be viewed as a tool to be used along with clinical indicators to determine if a patient is colonized or infected. Microbiology reports from clinical specimens usually show three components: the smear and stain, the culture and organism identification, and the antimicrobial susceptibility (i.e., sensitivity). As a marker for the likelihood of infection, the smear and stain generally provide the most helpful information because they

describe the mix of cells present at the anatomic site at the time of specimen collection. Culture and sensitivity results specify which organisms are recognized and which antibiotic agents actively affect the bacteria.

Infection Control and Prevention

The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) are the principal agencies involved in setting guidelines about infection prevention. The impact of infectious diseases changes over time as microorganisms mutate, as human behavior patterns shift, or as therapeutic options change. The CDC provides timely recommendations about many of the situations that a nurse may face when caring for or educating a patient with an infectious disease and routinely publishes recommendations, guidelines, and summaries. Through its Internet site and its weekly journal, the *Morbidity and Mortality Weekly Report (MMWR),* the CDC reports significant cases, **outbreak**s (the occurrence of a disease within a population that exceeds normal expectations), environmental hazards, or other public health problems. Examples of important CDC guidelines and summaries include *Immunization Schedule*s (CDC, 2020b) and *Interim Infection Prevention and Control Recommendations for Healthcare Personnel During the COVID-19 Pandemic* (CDC, 2020c).

Nurses serve important roles in preventing the transfer of organisms given their frequent encounters with patients and families. It is essential for the nurse to model appropriate and effective hand hygiene practices in all aspects of patient care. Nurses can also help reduce hand-to-hand spread of organisms by serving as patient advocates. The nurse should observe the hand hygiene activities of other professionals and alert them to lapses in technique that are observed. Nurses need to educate patients and their families to feel comfortable in reminding health care workers to perform hand hygiene before patient contact.

This chapter summarizes several aspects of infectious diseases. However, the field of infection control and prevention changes rapidly. The COVID-19 **pandemic** provides a striking example of how a new infectious agent can place new expectations and responsibilities on health care workers, including nurses. A pandemic is an **epidemic** (an outbreak of infectious disease within a population that exceeds anticipated levels of impact) that spreads across multiple countries or continents. The COVID-19 crisis created unprecedented challenges with health care systems modifying everyday practices, and making administrative system wide changes. Nurses carried out complex care, simultaneously adapting to frequent changes in protocols, therapies, and other day-to-day routines, while also providing direction and support for stressed patients and family members. See Chapter 68 for discussion of moral distress during the COVID-19 pandemic.

Preventing Infection in Health Care Settings

The prevention of infection in the health care setting focuses upon following the appropriate standard and transmission-based precautions as well as reducing the risk of a **health care–associated infection (HAI)**. HAIs, formerly called *nosocomial infections,* are infections that were not present or incubating at the time of the patient's admission to the health care setting.

There are many types of HAIs. The most widely used system for tracking HAIs is the CDC National Healthcare Safety Network (NHSN) (CDC, 2020d). The system can be used by individual facilities to analyze risk-adjusted outcomes. Centers for Medicare and Medicaid Services (CMS) uses this standardized source to post outcomes on their Web site, Hospital Compare, so that the public can view the data (see Resources section). CMS also uses these data for imposing financial penalties for facilities who have less favorable HAI rates.

The NHSN has reporting systems for several health care facility types. These include acute care facilities, ambulatory care centers, long-term care facilities, outpatient dialysis centers, inpatient rehabilitation facilities, inpatient psychiatric facilities, and home dialysis facilities (CDC, 2020d).

Isolation Precautions

Isolation precautions are guidelines created to prevent transmission of microorganisms in health care facilities. The Healthcare Infection Control Practices Advisory Committee (HICPAC) of the CDC recommends two tiers of isolation precautions. The first tier, called **standard precautions**, is designed for the care of *all* patients and is the primary strategy for preventing HAIs. The second tier, called **transmission-based precautions**, is designed for care of patients with known or suspected infectious diseases spread by airborne, droplet, or contact routes. In addition, Occupational Safety and Health Administration (OSHA) regulations are followed to prevent exposure to bloodborne pathogens and hazardous substances (Occupational Safety and Health Administration [OSHA], 2012).

Standard Precautions

The basis of standard precautions is that all patients are colonized or infected with microorganisms, whether or not there are signs or symptoms, and that a uniform level of caution should be used in the care of all patients. The health care worker should use additional barriers in the form of personal protective equipment (PPE), including gloves, masks, eye protection, and cover gowns, depending on the expected degree of exposure to patient excretions or secretions. The elements of standard precautions include appropriate hand hygiene, the use of PPE, proper handling of patient care equipment and linen, environmental control, prevention of injury from sharps devices, and patient room assignments within health care facilities. Hand hygiene, glove use, needlestick prevention, and avoidance of splash or spray of body fluids are discussed in the following sections. See Chapter 32, Chart 32-5 for a description of standard precautions.

Hand Hygiene

The most frequent cause of bacterial transmission in health care institutions is spread of microorganisms by the hands of health care workers. Health care workers should perform hand hygiene frequently during patient care. Chart 66-1 describes the indications for different hand hygiene methods (CDC, 2002).

Chart 66-1

Hand Hygiene Methods

Hand Decontamination with Alcohol-Based Product

- After contact with body fluids, excretions, mucous membranes, nonintact skin, or wound dressings; as long as hands are not visibly soiled
- After contact with a patient's intact skin (e.g., after taking pulse or blood pressure or lifting a patient)
- In patient care, when moving from a contaminated body site to a clean body site
- After contact with inanimate objects in the patient's immediate vicinity
- Before caring for patients with severe neutropenia or other forms of severe immune suppression
- Before donning sterile gloves when inserting central catheters
- Before inserting urinary catheters or other devices that do not require a surgical procedure
- After removing gloves

Handwashing

- When hands are visibly dirty or contaminated with biologic material from patient care
- When health care workers do not tolerate waterless alcohol product

Adapted from Centers for Disease Control and Prevention (CDC). (2002). Guideline for hand hygiene in health care settings. *MMWR. Morbidity and Mortality Weekly Report, 51*(RR 16), 1–56.

When hands are visibly dirty or contaminated with biologic material from patient care, the worker should wash hands with soap and water. In intensive care units and other locations in which virulent or resistant organisms are likely to be present, antimicrobial agents (e.g., chlorhexidine gluconate, iodophor, chloroxylenol) may be used. Effective handwashing requires at least *20 seconds of vigorous scrubbing,* with special attention to the area around nail beds and between fingers, where there is a high bacterial load. Hands should be thoroughly rinsed after washing (CDC, 2002).

If hands are not visibly soiled, health care providers are encouraged to use alcohol-based, waterless antiseptic agents for routine hand decontamination. These solutions are superior to soap or antimicrobial handwashing agents in their speed of action and effectiveness against most microorganisms. Because they are formulated with emollients, they are usually better tolerated than other agents, and

because they can be used without sinks and towels, health care workers may be more adherent with their use. Nurses working in home health care or other settings where they are relatively mobile should carry pocket-sized containers of alcohol-based solutions. The spore form of the bacterium *Clostridioides difficile* is resistant to alcohol and other hand disinfectants; therefore, the use of gloves and handwashing (soap and water for physical removal) are required when *C. difficile* has been identified (CDC, 2019c).

Normal skin flora usually include relatively benign coagulase-negative staphylococci or diphtheroids. Health care workers may temporarily carry more potentially pathogenic bacteria such as *S. aureus* or *Pseudomonas aeruginosa*. This temporary carriage is considered **transient flora** which will likely be shed with hand hygiene and natural skin degeneration over time.

Hand hygiene decreases bacterial transmission to patients by reducing bacterial load on health care workers' hands. The Joint Commission includes hand hygiene as one of the National Patient Safety Goals and focuses on this behavior in surveys of health care facilities (The Joint Commission, 2021). All health care settings should have mechanisms to measure and improve adherence with hand hygiene by all personnel who care for patients (Schierhorn, 2019).

Artificial fingernails or nail extenders have been epidemiologically linked to several significant infection outbreaks and therefore should not be worn when providing patient care. Natural nails should be kept less than 0.6 cm (0.25 inch) long, and nail polish should be removed when chipped because it can support increased bacterial growth (CDC, 2002).

Glove Use

Gloves provide an effective barrier for hands from the microflora associated with patient care. Gloves should be worn when a health care worker has contact with any patient secretions or excretions and must be discarded after each patient care contact. Because microbial organisms colonizing health care workers' hands can proliferate in the warm, moist environment provided by gloves, hands must be washed or disinfected after gloves are removed. As patient advocates, nurses have an important role in promoting hand hygiene and glove use by other hospital workers, such as laboratory personnel, technicians, physicians, and others who have contact with patients.

Compared with vinyl gloves, latex or nitrile gloves are preferred because they resist puncture better and provide greater comfort and fit. Improvements in latex gloves have reduced the incidence of latex hypersensitivity, but some workers continue to experience local skin irritation or more severe reactions, including generalized dermatitis, conjunctivitis, asthma, angioedema, and anaphylaxis (see Chapter 33). The nurse who experiences irritation or an allergic reaction associated with exposure to latex should report symptoms to an occupational health specialist or a primary provider and avoid latex-based products.

Needlestick Prevention

The most important aspect of reducing the risk of bloodborne infection is avoidance of percutaneous injury. Extreme care is essential in all situations in

which needles, scalpels, and other sharp objects are handled. Used needles should not be recapped. Instead, they are placed directly into puncture-resistant containers close to where they are used. If a situation dictates that a needle must be recapped, the nurse must use a mechanical device to hold the cap or use a one-handed approach to decrease the likelihood of skin puncture. OSHA requires use of needleless devices and other instruments designed to prevent injury from sharps when appropriate (OSHA, 2012).

Avoidance of Splash and Spray

When the health care professional is involved in an activity in which body fluids may be sprayed or splashed, appropriate barriers must be used. If a splash to the face may occur, goggles and a facemask are warranted. If the health care worker is involved in a procedure in which clothing may be contaminated with biologic material, a cover gown should be worn (CDC, 2007).

Transmission-Based Precautions

Reducing the risk of HAIs requires specific preventive activities in addition to implementing standard precautions. Some microbes are so contagious or epidemiologically important that, in addition to standard precautions, a second tier of precautions—transmission-based precautions—should be used when such organisms have been identified. Transmission-based categories are airborne, droplet, and contact precautions (CDC, 2007). As the term implies, the precautions are based on the routes of transmission. Diseases spread by very small respiratory particles that are suspended as aerosol require airborne precautions, those spread by larger respiratory droplets require droplet precautions, and those spread by touch require contact precautions.

Airborne precautions are required for patients with presumed or proven pulmonary TB, varicella, or other airborne pathogens such as COVID-19. When hospitalized, patients should be in airborne infection isolation rooms, engineered to provide negative air pressure, rapid turnover of air, and air either highly filtered or exhausted directly to the outside. If a facility does not have negative pressure rooms available, portable high-efficiency particular air (HEPA) filters may be used. Health care providers should wear an N95 respirator (i.e., protective mask) (see Chapter 68, Fig. 68-1) at all times while in the patient's room. The nurse should be able to validate room negative pressure by reading a pressure manometer placed outside the room or by witnessing that a tissue held at the gap between the door and the floor will be pulled toward the room.

Droplet precautions are used for organisms such as influenza or meningococcus that can be transmitted by close contact with respiratory or pharyngeal secretions. When caring for a patient requiring droplet precautions, the nurse should wear a facemask within 3 to 6 feet of the patient; however, because the risk of transmission is limited to close contact, the door may remain open.

Contact precautions are used for organisms that are spread by skin-to-skin contact, such as antibiotic-resistant organisms or *C. difficile.* Contact precautions are designed to emphasize cautious technique and the use of barriers. When possible, the patient requiring contact isolation is placed in a private room to

facilitate hand hygiene and decreased environmental contamination. Masks are not needed, and doors do not need to be closed (see Chart 66-2).

COVID-19 Considerations

Guidelines for preventing transmission of COVID-19 in health care facilities include using a combination of all the transmission-based precautions and adding other prevention elements, such as increased use of PPE, enhanced cleaning, and adjusted visitor policies (CDC, 2020c). The SARS-CoV-2 virus is primarily transmitted by close contact to droplets and aerosol and by touching contaminated surfaces, with subsequent self-infection when touching the face. In most social interactions, the virus appears to be spread from droplets from the infected person to another. In the health care setting, airborne transmission can occur when aerosol-generating procedures are conducted. Procedures such as intubation, extubation, suctioning, and administering nebulized medication can mechanically aerosolize droplets so that infective particles can be inhaled. Similar transmission may be possible with other close contact, such as may be required in the care of a patient infected with COVID-19. Due to COVID-19's **virulence** (degree of pathogenicity of an organism), contagiousness, and lack of treatment, guidelines advise facilities to use a combination of droplet, airborne, and contact precautions (CDC, 2020c). See discussion later in this chapter.

Chart 66-2

Summary of Types of Precautions and Patients Requiring the Precautions

Standard Precautions

Use standard precautions for the care of all patients.

Airborne Precautions

In addition to standard precautions, use airborne precautions for patients known or suspected to have serious illnesses transmitted by airborne droplet nuclei. Examples of such illnesses include:

- Measles
- Varicella (including disseminated zoster)[a]
- Tuberculosis

Airborne precautions are also used when performing aerosol-generating procedures for patients with coronavirus disease 2019 (COVID-19) (along with a focus on droplet and contact precautions).

Droplet Precautions

In addition to standard precautions, use droplet precautions for patients known or suspected to have serious illnesses transmitted by large particle droplets. Examples of such illnesses include:

- Invasive *Haemophilus influenzae* type b disease, including meningitis, pneumonia, epiglottitis, and sepsis
- Invasive *Neisseria meningitidis* disease, including meningitis, pneumonia, and sepsis
- Other serious bacterial respiratory infections spread by droplet transmission, including:
  - Diphtheria (pharyngeal)
  - Primary atypical pneumonia (*Mycoplasma pneumoniae*)
  - Pertussis
  - Pneumonic plague
  - Streptococcal (group A) pharyngitis, pneumonia, or scarlet fever in infants and young children
- Serious viral infections spread by droplet transmission, including:
  - COVID-19 (along with contact precautions; and airborne precautions during aerosol-generating procedures)
  - Adenovirus[a]
  - Influenza
  - Mumps
  - Parvovirus B19
  - Rubella

Contact Precautions

In addition to standard precautions, use contact precautions for patients known or suspected to have serious illnesses easily transmitted by direct patient contact

or by contact with items in the patient's environment. Examples of such illnesses include:

- Gastrointestinal, respiratory, skin, or wound infections or colonization with multidrug-resistant bacteria judged by the infection control program, based on current state, regional, or national recommendations, to be of special clinical and epidemiologic significance
- Enteric infections with a low infectious dose or prolonged environmental survival, including:
  - *Clostridioides difficile*
  - For patients who are diapered or incontinent: enterohemorrhagic *Escherichia coli* O157:H7, *Shigella* species, hepatitis A, or rotavirus
- Respiratory syncytial virus, parainfluenza virus, or enteroviral infections in infants and young children
- Skin infections that are highly contagious or that may occur on dry skin, including:
  - Diphtheria (cutaneous)
  - Herpes simplex virus (neonatal or mucocutaneous)
  - Impetigo
  - Major (noncontained) abscesses, cellulitis, or pressure injuries
  - Pediculosis
  - Scabies
  - Staphylococcal furunculosis in infants and young children
- Zoster (disseminated or in the immunocompromised host)[a]
- Viral and hemorrhagic conjunctivitis
- Viral hemorrhagic infections (Ebola, Lassa, or Marburg)

[a]Certain infections require more than one type of precaution.

Adapted from Centers for Disease Control and Prevention (CDC). (2007). 2007 *Guideline for isolation precautions: Preventing transmission of infectious agents in healthcare settings*. Retrieved on 3/13/2020 at: www.cdc.gov/hicpac/2007ip/2007ip_part1.html; Centers for Disease Control and Prevention (CDC). (2020c). Interim infection prevention and control recommendations for healthcare personnel during the coronavirus disease 2019 (COVID-19) pandemic. Retrieved on 7/17/2020 at: www.cdc.gov/coronavirus/2019-ncov/hcp/infection-control-recommendations.html

To protect against potential airborne transmission, health care workers in close contact with patients infected with COVID-19 were advised to use N95 respirators or powered air-purified respirators (PAPRs) (CDC, 2020c). When there is not an adequate supply of such devices to use for all patients with confirmed or suspected COVID-19 infection, a system should be designed to prioritize their use for aerosol-generating procedures. Some health care facilities have been able to reprocess N95s to expand their availability (CDC, 2020e). See Chapter 56 for recommendations for preventing and treating occupationally induced dermatologic conditions during the COVID-19 pandemic (American Academy of Dermatology [AAD], 2020).

Gowns and gloves are worn to prevent transmission by contact. Health care workers must carefully put on, use, and safely take off PPE. Using the correct sequence for putting on and taking off PPE is especially important with SARS-CoV-2 as well as other highly contagious or virulent pathogens. The recommended sequence for putting on and safely removing PPE is outlined in Chart 66-3.

Specific Organisms with HAI Potential

Prior to the COVID-19 crisis, the WHO and CDC had focused increased attention on HAIs, which have also received increased focus from The Joint Commission, the Institute for Healthcare Improvement (IHI), and Medicare. HAI rates for each hospital are posted on the Hospital Compare Web site (see the Resources section). The Hospital Compare site also reports on some infections where the actual acquisition location is difficult to determine. For example, Hospital Compare shows rates for *C. difficile*, considering any case first diagnosed after the third day of hospitalization as a hospital onset case.

Chart 66-3

Use of Personal Protective Equipment (PPE) When Caring for the Patient with Suspected or Confirmed COVID-19

Donning (Putting on the Gear)

More than one donning method may be acceptable. Training and practice using your health care facility's procedure is critical. Below is one example of donning.

1. **Identify and gather the proper PPE to don.** Ensure choice of gown size is correct (based on training).
2. **Perform hand hygiene using hand sanitizer.**
3. **Put on isolation gown.** Tie all of the ties on the gown. Assistance may be needed by another HCP.
4. **Put on NIOSH-approved N95 filtering facepiece respirator or higher (use a facemask if a respirator is not available).** If the respirator has a nosepiece, it should be fitted to the nose with both hands, not bent or tented. Do not pinch the nosepiece with one hand. Respirator/facemask should be extended under chin. Both your mouth and nose should be protected. Do not wear respirator/facemask under your chin or store in scrubs pocket between patients.[a]
   a. **Respirator:** Respirator straps should be placed on crown of head (top strap) and base of neck (bottom strap). Perform a user seal check each time you put on the respirator.
   b. **Facemask:** Mask ties should be secured on crown of head (top tie) and base of neck (bottom tie). If mask has loops, hook them appropriately around your ears.
5. **Put on face shield or goggles.** When wearing an N95 respirator or half facepiece elastomeric respirator, select the proper eye protection to ensure that the respirator does not interfere with the correct positioning of the eye protection, and the eye protection does not affect the fit or seal of the respirator. Face shields provide full face coverage. Goggles also provide excellent protection for eyes, but fogging is common.
6. **Put on gloves.** Gloves should cover the cuff (wrist) of gown.
7. **HCP may now enter patient room.**

Doffing (Taking Off the Gear)

More than one doffing method may be acceptable. Training and practice using your health care facility's procedure is critical. Below is one example of doffing.

1. **Remove gloves.** Ensure glove removal does not cause additional contamination of hands. Gloves can be removed using more than one technique (e.g., glove-in-glove or bird beak).
2. **Remove gown.** Untie all ties (or unsnap all buttons). Some gown ties can be broken rather than untied. Do so in gentle manner, avoiding a forceful movement. Reach up to the shoulders and carefully pull gown down and away from the body. Rolling the gown down is an acceptable approach. Dispose in trash receptacle.[a]
3. **HCP may now exit patient room.**
4. **Perform hand hygiene.**

5. **Remove face shield or goggles.** Carefully remove face shield or goggles by grabbing the strap and pulling upwards and away from head. Do not touch the front of face shield or goggles.
6. **Remove and discard respirator (or facemask if used instead of respirator).**[a] Do not touch the front of the respirator or facemask.
    a. **Respirator:** Remove the bottom strap by touching only the strap and bring it carefully over the head. Grasp the top strap and bring it carefully over the head, and then pull the respirator away from the face without touching the front of the respirator.
    b. **Facemask:** Carefully untie (or unhook from the ears) and pull away from face without touching the front.
7. **Perform hand hygiene after removing the respirator/facemask** and before putting it on again if your workplace is practicing reuse.

Preferred PPE – Use
N95 or Higher Respirator
Face shield or goggles
N95 or higher respirator
When respirators are not available, use the best available alternative, like a facemask.
One pair of clean, nonsterile gloves
Isolation gown
Acceptable Alternative PPE – Use
Facemask
Face shield or goggles
Facemask
N95 or higher respirators are preferred but facemasks are an acceptable alternative.
One pair of clean, nonsterile gloves
Isolation gown
Face shield or goggles
N95 or higher respirator
When respirators are not available, use the best available alternative, like a facemask.
One pair of clean, nonsterile gloves
Isolation gown

[a]Facilities implementing reuse or extended use of PPE will need to adjust their donning and doffing procedures to accommodate those practices.

Reprinted from Centers for Disease Control and Prevention (CDC). COVID-19 Factsheets. Retrieved on 2/16/2021 at: www.cdc.gov/coronavirus/2019-ncov/downloads/A_FS_HCP_COVID19_PPE.pdf

Antibiotic-Resistant Organisms

Extensive use of antibiotic agents in agriculture and health care has led to a growing prevalence of organisms with fewer effective antibiotics. Approximately 3 million people develop antibiotic-resistant infections in the United States each year, and approximately 35,000 die from these infections (CDC, 2019a). Bacteria that most commonly develop resistance include *P. aeruginosa* (resistant to fluoroquinolone antibiotics, carbapenems), *Acinetobacter* species (resistant to many antibiotics, including carbapenems), and both *Klebsiella pneumoniae* and *Escherichia coli* (resistant to extended-spectrum beta-lactam antibiotics).

Concerns about antibiotic-resistant organisms and the loss of effective antibiotic therapy for serious infections have grown. The Joint Commission National Patient Safety Goals include requirements to have a program to analyze and reduce antibiotic resistant-infections (The Joint Commission, 2021). The CDC provides explanations about the causes of multiple drug resistant organisms, current efforts

to control them, estimates of incidence, and mortality rates for significant pathogens (CDC, 2019a).

Clostridioides difficile

C. difficile is a spore-forming bacterium that has significant HAI potential. An especially virulent strain has affected health care facilities throughout North America in the past several years. After marked increases in the first decade after 2000, a 29% decrease in the rate of hospital-onset *C. difficile* infection from 2015 to 2018 was recorded (CDC, 2019b). While the exact reason for the decrease is not clear, some believe it is due to increased focus on antimicrobial stewardship, a program to assure the right antibiotic for the right patient at the right time (CDC, 2019b). Despite this drop in rates of infection, *C. difficile* is considered the most common cause of HAI in U.S. hospitals (CDC, 2019b). Infection is usually preceded by antibiotic agents that disrupt normal intestinal flora and allow the antibiotic-resistant *C. difficile* spores to proliferate within the intestine. The organism causes pathology by releasing toxins into the lumen of the bowel. In pseudomembranous colitis (the most extreme form of *C. difficile* infection), debris from the injured lumen of the bowel and from white blood cells accumulates in the form of pseudomembranes or studded areas of the colon. The destruction of such a large anatomic area can cause sepsis.

Because antibiotics are used so extensively in health care settings, many patients are at risk for infection with *C. difficile.* The potential for health care–associated acquisition is increased because the spore is relatively resistant to disinfectants and can be spread on the hands of health care providers after contact with equipment previously contaminated with *C. difficile.* Control is best achieved by using contact precautions for patients who are infected, with use of gowns and gloves for all patient contact. Because the spores are resistant to alcohol, waterless hand products are not as effective as handwashing with soap and water for use in hand hygiene. Bleach-based cleaning products are optimal because bleach can kill spores, whereas other cleaning agents often do not. Frequently touched equipment, such as overbed tables and side rails, should be cleaned daily and whenever visibly soiled. IV poles and other peripheral items should be cleaned when the patient is discharged (CDC, 2019c).

Methicillin-Resistant *Staphylococcus aureus*

Methicillin-resistant *Staphylococcus aureus* (MRSA), a common human pathogen, refers to *S. aureus* that is resistant to methicillin or its comparable pharmaceutical agents, oxacillin and nafcillin. Soon after penicillin was discovered in the 1940s, *S. aureus* became all but universally penicillin resistant. Alternative therapies in the form of cephalosporins and synthetic penicillin solutions such as methicillin were introduced. During the late 1970s, MRSA became increasingly more prevalent, as transmission within hospitals and nursing homes was well documented.

Health Care–Associated MRSA. Health care providers transmit MRSA to patients easily because *S. aureus* has an affinity for skin colonization. The patient who is colonized with MRSA has an increased probability of developing an

infection with MRSA, especially when invasive procedures (e.g., IV therapy, respiratory therapy, surgery) are performed. Such infections are characterized as healthcare-associated methicillin-resistant *Staphylococcus aureus* (HA-MRSA). HA-MRSA may persist as normal flora in the patient for an extended time. The patient who is colonized also serves as a reservoir for MRSA transmission to others. In recent years, the incidence of invasive HA-MRSA has decreased (Kourtis, Hatfield, Baggs, et al., 2019). Although the exact reasons for the decline are unknown, it is likely that infection control efforts (especially those focused on reduction of bloodstream infections) and declining lengths of hospital stay (therefore decreasing exposure within health care agencies) are important factors.

Community-Associated MRSA. New strains of MRSA have caused infections and outbreaks in children, members of sports teams, and prison inmates, and in other people who had no apparent health care exposure. These community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) infections are typically caused by strains of *S. aureus* that are molecularly distinct from HA-MRSA. The CA-MRSA strains typically produce more toxins than HA-MRSA and localized skin and soft tissue infections, and can lead to necrotizing fasciitis or **bacteremia** (laboratory-confirmed presence of bacteria in the bloodstream). Often, skin symptoms are initially mistaken for insect or spider bites (Kourtis et al., 2019). CA-MRSA infections have resulted in serious skin and soft tissue infections; pneumonia; and, in rare cases, death.

Control of MRSA in Health Care Facilities. Nurses must be prepared to educate patients and their families about the definitions of colonization and infection. The CDC recommends contact precautions for patients with MRSA colonization or infection (CDC, 2007). That guidance has become increasingly controversial as some research has reported that contact precautions may not decrease the acquisition of new infections (Renaudin, Llorens, Goetz, et al., 2017). In facilities that use contact precautions for MRSA, nurses must explain the reason for isolation to patients and their families.

Vancomycin and linezolid are typically the preferred treatment options for serious MRSA infection. However, there is concern that MRSA will eventually become resistant to even these medications because they are used so frequently.

Multidrug Resistant Enterobacteriaceae

A group of gram-negative organisms called Enterobacteriaceae, organisms associated with gastrointestinal colonization, are becoming resistant to multiple classes of antibiotics. Clinically important Enterobacteriaceae include *E. coli* and *Klebsiella* species, among others. Some produce enzymes known as extended spectrum beta-lactamases that disrupt the efficacy of some common antibiotics including penicillins and cephalosporins (Comerford & Durkin, 2020). Extended spectrum beta-lactamases infections increased by approximately 50% between 2012 and 2017 and were identified in the community and all health care settings (CDC, 2019a).

Carbapenem antibiotics can be used for extended spectrum beta-lactamases infections. However, some of these bacteria have also developed resistance to carbapenem antibiotics. These carbapenem-resistant Enterobacteriaceae (CRE)

organisms are very difficult to treat. Among patients who are hospitalized and infected with CRE organisms, the mortality rate is approximately 50% (CDC, 2020f).

Patients with extended spectrum beta-lactam resistance or carbapenem resistance should be isolated, using contact precautions. If multiple patients with CRE on one unit within a facility are identified, or if there is other evidence of transmission, additional prevention steps should be implemented. These steps include dedicating personnel to solely care for these groups of patients, conducting cultures of other patients in the unit or service, and enhanced investigation of new cases (CDC, 2020f).

Candida Auris

Candida auris is a multi-drug resistant fungus, a yeast species that is difficult to identify in the laboratory, and difficult to remove with hospital disinfectants. It has caused outbreaks in acute care and long-term care settings. Between 2017 and 2018, reported cases increased by over 300% (CDC, 2019c). Although a patient can have an asymptomatic colonization, it can also cause bloodstream and other serious infections, with mortality rates approaching 30% (CDC, 2019c).

Patients with *C. auris* colonization or infection should be placed in contact precautions and should be reported to local health departments. When multiple patients are diagnosed with *C. auris*, an investigation should include culturing to detect other patients in the unit or area close to the patient with confirmed *C. auris* who also may be colonized (CDC, 2019c).

Vancomycin-Resistant *Enterococcus*

Vancomycin-resistant *Enterococcus* (VRE) refers to *Enterococcus* bacterium that is resistant to the antibiotic vancomycin; it is the second most frequently isolated source of HAIs in the United States. This gram-positive bacterium can produce significant disease when it infects blood, wounds, or the urinary tract (CDC, 2019a).

Enterococcus has several traits that make it an easily transmittable HAI organism. It is a part of the normal flora of the gastrointestinal tract; it is bile resistant and able to withstand harsh anatomic sites, such as the intestine; and it persists well on the hands of health care providers and on environmental objects.

Enterococcus is a relatively antimicrobial-resistant organism at baseline; thus, therapy is limited to penicillin formulations (e.g., ampicillin), vancomycin in combination with an aminoglycoside (e.g., gentamicin), or linezolid. VRE colonization and infection may serve as a reservoir of vancomycin-resistant coded genes that may be transferred to the more virulent *S. aureus.* The two most frequently cultured enterococcal species are *Enterococcus faecalis* (approximately 7% resistant) and *Enterococcus faecium* (CDC, 2019a).

Health Care–Associated Bloodstream Infections

Any vascular catheter can serve as the source for a bloodstream infection. Central lines (vascular catheters where the tip ends in or near the heart) are more likely to be associated with bloodstream infection. Central line–associated bloodstream

infections (CLABSIs) add an estimated average cost of $50,000 per hospital stay and increase the risk of mortality by an estimated threefold (Agency for Healthcare Research and Quality [AHRQ], 2017). Increasingly, long-term central catheters are used to provide IV therapy to patients who are hospitalized as well as to patients in long-term care facilities, patients in clinics, and patients receiving home health care. In all instances, the nurse must use appropriate care to reduce the risk of bacteremia and to be alert to signs of its presence.

The recommended bundle approach for preventing CLABSIs includes hand hygiene; maximal barrier precautions; chlorhexidine skin antisepsis; optimal catheter site selection, with avoidance of the femoral vein for central venous access in adult patients; and daily review of line necessity with prompt removal of unnecessary lines (see Chapter 11, Chart 11-2).

Preventing Infection in the Community

The CDC as well as state and local public health departments share responsibility for prevention and control of infection in the community. Methods of infection prevention include sanitation techniques (e.g., water purification, disposal of sewage and other potentially infectious materials), regulated health practices (e.g., the handling, storage, packaging, and preparation of food by institutions), and immunization programs.

Most infections occur in the community, out of health care settings. Nurses working in schools or public health facilities educate patients and the public to reduce the incidence of influenza, foodborne infections, and other infections. Local epidemics and pandemics are the most significant type of community-acquired infections.

Pandemics are usually caused by novel viruses which begin to circulate among a population that universally has no immunity. The epidemiologic definition of a pandemic, based on the degree of spread, has often been used socially to instead convey disaster. In recent centuries, significant pandemics have included the 1918 influenza pandemic, the pandemic in the 1980s and 1990s caused by the then-novel human immune deficiency virus (HIV), the 2009 H1N1 influenza pandemic, and most recently the 2019–2021 COVID-19 pandemic (see the discussion of COVID-19 later in this chapter).

Novel virus based pandemics can be catastrophic compared with other anticipated public health problems because they last longer than other emergency events, often occur in “waves,” have the potential to deplete the available health care workforce, and reduce the supply of medical equipment because of their widespread nature. The frequency and severity of pandemics cannot be accurately predicted, but models suggest that even a medium-intensity pandemic can quickly overwhelm the existing health care infrastructure (CDC, 2016).

The COVID-19 pandemic has changed many previous infection prevention practices as well as the way health care is delivered. Some clinicians have proposed that just as the crisis caused by the HIV pandemic led to sweeping changes in the delivery of health care that included the use of Standard

Precautions, the COVID-19 crisis may lead to the use of Universal Pandemic Precautions (Weber, Babcock, Hayden, et al., 2020). These new precautions would have individual implications, as all health care workers would universally use masks and eye protection during patient care (Weber et al., 2020). Health care facilities would increase the screening and isolation for patients with symptoms of possible viral disease (Weber et al., 2020). Such an approach would likely protect workers from exposure to SARS-CoV-2 in anticipated future waves and would protect from other pathogens spread through a contact and droplet route.

Nurses play a crucial role during a pandemic as they provide care while themselves becoming potentially exposed. During these times, nurses demonstrate the importance of following standard precautions and transmission-based precautions. With COVID-19 and other pandemics, critically important PPE supplies as well as lifesaving equipment and drugs can become scarce. As the extreme burden on nurses caring for patients with COVID-19 quickly became evident, formalized recommendations to improve nurse education, to add occupational prevention measures, and to include a nursing perspective in national planning were drafted (Veenema, Meyer, Bell, et al., 2020).

Vaccination Programs

The goal of vaccination programs is to use wide-scale efforts to prevent specific infectious diseases from occurring in a population. Public health decisions about vaccination efforts are complex. Risks and benefits for the person and the community must be evaluated in terms of morbidity, mortality, and financial cost and benefit. Successful vaccine programs have reduced the incidence of many infectious diseases in the United States. (See later section COVID-19 Vaccines for further details of that program.)

Vaccines are suspensions of antigen preparations that are intended to produce a human immune response to protect the host from future encounters with the organism. Because no vaccine is completely safe for all recipients, contraindications on package inserts of a vaccine and CDC “Vaccine Information Statements” must be heeded. These documents provide details about studied experiences with allergy and other complications and provide crucial information about refrigeration, storage, dosage, and administration.

The recommended immunization schedules are revised by the CDC as epidemiologic evidence warrants. The two principal schedules are for children and adults (CDC, 2020b). Variations to the recommended immunization schedule should be made on a case-by-case basis, depending on the patient’s risk factors as well as likely exposures. An annual influenza vaccine is recommended for all people 6 months or older, unless contraindicated. Health care workers should be immune to measles, mumps, rubella, pertussis, tetanus, hepatitis B, and varicella.

The CDC provides information about individual vaccines and vaccine-preventable diseases (see the Resources section). Advice about optimal vaccinations for travelers is available at the CDC and WHO Web sites as well.

The incidence of vaccine-preventable diseases, such as measles, mumps, rubella, and diphtheria, is affected by immigration from developing countries.

Vaccine campaigns in developing countries are often financially and logistically constrained, and immigrants from such areas may be more likely than U.S. residents to be unprotected. Individual and epidemic risks are reduced when vaccination campaigns reach all communities.

Reporting Problems with Vaccines

Nurses should ask adult vaccine recipients to provide information about any problems encountered after vaccination. If a patient reports problems after receiving a vaccination, a Vaccine Adverse Event Reporting System (VAERS) form must be completed with the following information: type of vaccine received, timing of vaccination, onset of the adverse event, current illnesses or medication, history of adverse events after vaccination, and demographic information about the recipient. Forms can be submitted online (see the Resources section).

Contraindications to Vaccines

As a general rule, multiple vaccines may be given at the same visit and separating the dosing by time is not indicated. If they must be given on separate visits, it is then wise to separate by at least 4 weeks so that there is no immune reaction interfering with the response to the second vaccine (CDC, 2020b). Patients who have developed anaphylaxis or other moderate or severe sequelae after a previous dose should not receive further doses. Some live vaccines (e.g., varicella, MMR [against measles, mumps, and rubella], yellow fever) are contraindicated for people who are severely immunosuppressed or pregnant. All decisions about vaccination should be made by the patient's primary provider after careful review of vaccine-specific contraindications.

Common Vaccines

Measles, Mumps, and Rubella Vaccine

Since the time of licensing of the MMR vaccines, endemic rubeola (measles) has been eliminated in the United States, and mumps and rubella have decreased substantially. To maintain this effective public health strategy, routine MMR vaccination should be given to children at 12 to 15 months of age, with repeat dosing at 4 to 6 years of age. Adults who have not received the MMR vaccine should receive one to two doses (CDC, 2020b).

Patients should be advised that fever, transient lymphadenopathy, or hypersensitivity reaction might occur following an MMR vaccination. The risk of side effects is greater in vaccine recipients who have not previously received the vaccine than in those who have received repeat doses. Antipyretic agents may be used to decrease the risk of fever.

Varicella (Chickenpox) Vaccine and Zoster (Shingles) Vaccine

Varicella zoster virus (VZV) causes chickenpox and herpes zoster. In its natural state, VZV often attacks children, causing disseminated disease in the form of chickenpox. The severity of chickenpox may be increased among adolescents, adults, pregnant women, and those who are immune compromised (CDC, 2020b).

Transmission occurs by the airborne and contact routes. With rare exception, varicella infects a person only once. The incubation period is about 2 weeks (range, 10 to 21 days). During a prodrome of general malaise (often noticed about 2 days before the rash develops), the newly infected host is capable of transmitting the virus to other susceptible contacts. Typically, the vesicular, pustular rash spreads rapidly from few to many lesions in a matter of hours. New lesions continue to form for 2 to 3 days and appear at different stages throughout this time. By the fourth symptomatic day, the lesions begin to dry, and new lesions usually do not develop. Fever is common during the 4 to 6 days of rash progression. When the lesions have crusted, the patient is no longer contagious.

The varicella vaccine is effective in preventing chickenpox in approximately 70% to 90% of people who receive two doses of vaccine. The vaccine is also available as part of MMRV, a formulation providing a combined vaccine for measles, mumps, rubella, and varicella. The vaccine should not be given to those who have severely depressed immune function, are pregnant, have moderate or severe concurrent illnesses, or have demonstrated allergy to varicella vaccine (CDC, 2019a).

Herpes zoster, also known as shingles, is a painful, localized rash caused by recurrent VZV. Vesicles occur along single associated nerve groups. VZV may be transmitted from the rash of those with shingles to people who are susceptible to varicella; the new varicella infections are manifested as chickenpox, not shingles. It is estimated that more than 30% of people over age 60 will develop shingles. A new vaccine was approved in 2017 and is recommended for people older than age 50 as it reduces the risk of shingles by approximately 90% (CDC, 2020b).

Influenza Vaccine

Influenza is an acute viral respiratory disease that predictably and periodically causes epidemics and pandemics. Epidemics occur every 2 to 3 years, with a highly variable degree of severity. An estimated 12,000 to 61,000 deaths per year since 2010 have been associated with influenza or its sequelae (i.e., pneumonia, cardiopulmonary collapse). Older adults are more susceptible to influenza, and the incidence of the disease in the United States is increasing as the number of older adults increases (CDC, 2020i).

Each year, different influenza vaccine formulations are released and are based on predictions of what strains will likely circulate. The CDC recommends that everyone over the age of 6 months get an annual influenza vaccine. There are now many flu vaccine options. Trivalent vaccines are composed of three strains (two type A influenza and one type B influenza) or quadrivalent, composed of four strains (two of type A and two of type B). The formulations can be given as an injection or as a nasal spray. There are different strengths for different age groups and different formulations available for those with egg allergy (CDC, 2020i).

Although the effectiveness of the vaccine varies from year to year, the vaccine reduces the risk of illness from flu by 50% to 60% overall when the circulating strains are included in the vaccine that year. The vaccine is less effective in preventing illness in older adults but reduces hospitalization and mortality in that age group (CDC, 2020i).

Human Papillomavirus Vaccine

Human Papillomavirus (HPV) is the most prevalent of all sexually transmitted viruses and is the principal cause of cervical cancer (see Chapter 51) (CDC, 2020q). It can also cause reproductive organ and oropharyngeal cancers. HPV vaccination at age 11 or 12 is recommended for both males and females. The vaccines are administered in a series according to CDC guidelines. The vaccine is not recommended for those with a history of hypersensitivity to any vaccine component, those with a history of anaphylactic latex allergy, or for women who are pregnant (Meites, Szilagyi, Chesson, et al., 2019).

Planning for a Pandemic

The U.S. Department of Health and Human Services has published pandemic plans that are updated and revised as new threats are recognized and new containment strategies are developed. The plans address federal, state, and local responsibilities, and the need for coordination with the WHO and other international partnerships and agencies (Homeland Security Council, 2006). These plans encourage all health care institutions to have their own pandemic plans and to test the components of the plans regularly.

Home-Based Care of the Patient with an Infectious Disease

The nurse who cares for the patient with an infectious disease in the home should provide information about infection risk prevention to the patient, the family, and the caregiver (see Chart 66-4). Recognizing that a health history may not identify all active or latent infections, the caregiver should carefully follow standard precautions in the home. The nurse should establish a work environment that facilitates hand hygiene and aseptic technique.

Family caregivers should receive an annual influenza vaccine. This is especially true if the caregiver or the patient is older than 50 years, has underlying cardiac or pulmonary disease, or has underlying immunosuppression.

Patients requiring home care are often people with immunosuppression from underlying conditions, such as HIV infection or cancer, or those who have treatment-induced immunosuppression, as occurs with many antineoplastic agents. Careful assessment for signs of infection is important.

Reducing Risk to the Patient

Equipment Care

All caregivers must pay careful attention to disinfection and aseptic technique while providing care and using medical equipment. Catheter-related sepsis should be suspected in a patient who has unexplained fever, redness, swelling, and drainage around a vascular catheter insertion site. Indwelling urinary catheters

should be discontinued whenever possible, because each day of use increases the risk of infection. The nurse should promptly report signs of urinary tract infection or generalized sepsis to the patient's primary provider.

Chart 66-4  HOME CARE CHECKLIST

Prevention of Infection in the Home Care Setting

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of infectious disease and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the need for infection risk prevention for the patient (preventing recurrence or new infections), caregivers, and family in the home.
  - Verbalize the route of transmission for agent of infection.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications.
  - Adhere to antibiotic regimen (patient) or completion of vaccination series (patient and caregiver).
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., diet, activity) or home environment necessary to decrease risk for infection.
  - Perform satisfactory hand hygiene technique, oral hygiene, total body hygiene, and maintain skin integrity (patient).
  - Ensure thorough hand hygiene (alcohol-based disinfectant or handwashing) after care (family/caregiver).
  - Avoid contact with someone who has a known infectious disease.
  - Cook all foods thoroughly and store meat, poultry, and fish products separately from other food groups.
  - Use separate eating utensils and towels.
  - Demonstrate aseptic technique in the care of technical equipment such as IV catheter and indwelling urinary catheter.
- Identify signs and symptoms of infection to report to the primary provider, such as fever; chills; wet or dry cough; breathing problems; white patches in the mouth; swollen glands; nausea; vomiting; persistent abdominal pain; persistent diarrhea; problems with urination or changes in the character of the urine; red, swollen, or draining wounds; sores or lesions on the body; persistent vaginal discharge with or without itching; and severe fatigue.
- Demonstrate how to monitor for signs of infection.
- Describe to whom, how, and when to report signs of infection.
- Describe appropriate actions to take should infection occur.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health-promotion, disease prevention, and screening activities.

Resources

See Chapter 29, Chart 29-7: Home Care Checklist: The Patient at Risk for Infection for additional information.

ADLs, activities of daily living; IADLs, instrumental activities of daily living; IV, intravenous.

Patient Education

When assessing the risk of infection in the home environment of the patient who is immunosuppressed, it is important to realize that intrinsic colonizing bacteria and latent viral infections present a greater risk than do extrinsic environmental contaminants. The nurse should reassure the patient and family that their home needs to be clean but not sterile. Family members seldom need to use masks, gowns, or other elements of PPE. Commonsense approaches to cleanliness and risk reduction are helpful.

For patients with neutropenia or T-cell dysfunction (e.g., patients with acquired immune deficiency syndrome [AIDS]), it is wise to restrict visits of people with potentially contagious illnesses. The patient who is immunosuppressed is vulnerable to acquiring bacterial infection with enteric pathogens from food; therefore, family members should be reminded about the need to follow recommendations for hygiene, storage, and safe cooking times and temperatures.

Reducing Risk to Household Members

Establishing reasonable barriers to infection transmission in the household is an important part of home care. The route of transmission of the organism in question must first be determined. The nurse can then educate household members about strategies to reduce their risk of becoming infected. If the patient has active pulmonary TB, the public health department should be contacted to provide screening and treatment for family members. If the patient has herpes zoster, family members who have had varicella vaccine or who have previously had chickenpox are considered immune and need no precautions. However, if a family member is immunosuppressed or otherwise susceptible to varicella, maintaining physical separation is an important strategy during the time when the patient has draining lesions. When the patient is infected with enteric organisms, the family should be reassured that common household disinfectants are effective in controlling environmental contamination.

Family members who assist in the care of a patient with a bloodborne infection such as HIV or hepatitis C can prevent transmission by carefully handling any sharp objects that are contaminated with blood. Family education may include discussion about the need for caution when shaving the patient, performing dressing changes, or administering any IV or injected medication. To collect and dispose of used needles, syringes, and vascular access equipment, the family should use containers designed for sharps disposal. With the exception of TB, the opportunistic infections associated with AIDS do not usually pose a risk to the

healthy family member. Family members should be reassured that dishes are safe to use after being washed with hot water and that linens and clothing are safe to use after being washed in a hot water cycle.

Chart 66-5  ASSESSMENT

Assessing for Infectious Disease

The nurse should ask the patient the following questions:

- Do you have a history of previous or recurrent infections?
- Have you had fever? How high has your temperature been? Is your temperature constant, or does it rise and fall? Has fever been associated with chills? Have you taken any medication to relieve fever?
- Do you have a cough? Is the cough chronic or acute? Is it associated with shortness of breath? Does the cough produce sputum? Is the sputum bloody? Have you had a tuberculin skin test recently or blood test to detect tuberculosis (TB)? If so, what were the results? Have you been given isoniazid prophylaxis for TB infection? Have you been treated for TB in the past?
- Do you have pain? Where is the pain? What is the nature of the pain? Do you have a sore throat, headache, myalgias, or arthralgias? Is there pain on urination or other activity?
- Do you have any swelling? Is there drainage associated with the swelling? Is the swollen area warm to the touch?
- Do you have a draining lesion? Is the drainage associated with trauma or a previous procedure? Is the drainage pus or clear? Does the drainage have an odor?
- Do you have diarrhea, vomiting, or abdominal pain?
- Do you have a rash? What is the nature of the rash—is it flat, raised, red, crusted, weeping, or lacelike? Have you taken medications that could have induced the rash? Have you been exposed to another person with an identified infectious disease or rash?
- What is your vaccination history? Are your immunizations up-to-date?
- Have you had an insect or animal bite? Have you had an animal scratch or other exposure to pets, farm animals, or experimental animals?
- What medications do you use? Have you taken antibiotic agents recently or long term? Are you being treated with corticosteroids, immunosuppressive agents, or chemotherapy?
- Have you been treated for other infectious diseases in the past? Have you been hospitalized for infectious diseases?
- If sexual history is pertinent: Have you had sexual exposure to another person with a known sexually transmitted infection (STI)? Have you been treated for STIs in the past? Are you pregnant, or have you recently been pregnant? Have you been tested for human immune deficiency virus (HIV)?
- Have you traveled abroad, including developing countries? What was the immunization or antimicrobial prophylaxis used for protection while you were traveling?
- What is your occupation? What are your recreational activities? Hobbies?

Nursing Management

Assessment

Symptoms of infectious diseases vary significantly for different diseases and different people. For some infections, visible symptoms such as rash, redness, or swelling provide early warnings of infection. In other infections, such as TB and HIV, asymptomatic latency is prolonged, and infection must be determined through diagnostic procedures.

A careful history along with a review of the patient's medical record will determine current symptoms and underlying conditions. Chart 66-5 outlines questions the nurse should ask when obtaining a health history.

Physical examination may reveal signs of infection. Generalized signs of chronic infection may include significant weight loss or pallor associated with anemia of chronic diseases. Acute infection may manifest with fever, chills, lymphadenopathy, or rash. Localized signs vary by source of infection. Purulent drainage, pain, edema, and redness are strongly associated with localized infection. Cough and shortness of breath may be caused by influenza, pneumonia, or TB, as well as many noninfectious causes.

Nursing Interventions

Preventing Infection Transmission

Preventing the spread of infection requires an understanding of the usual routes of transmission of the organism. The patient in a health care facility may pose a contagious risk to others if the disease is easily spread (such as *C. difficile*) or is spread through an airborne route (such as TB). In these situations, strict adherence to isolation measures is important to reduce the opportunity for spread. Preventing transmission of organisms from patient to patient requires participation of all members of the health care team. Recent research also highlights the importance of the inpatient environment for potential reservoirs for organisms that cause HAIs (Cohen, Spirito, Liu, et al., 2019). See the Nursing Research Profile in Chart 66-6.

Quality and Safety Nursing Alert

It is imperative that nurses disinfect their hands before and after contact with patients in any setting and after performing a potentially hand-contaminating activity. Hands must be disinfected each time gloves are removed.

Educating About the Infectious Process

The first step in preventing the spread of infections is diagnosis. The nurse can educate the patient to understand the diagnosis and to adhere to the treatment regimen. Infectious diseases often seem mysterious and are frequently socially stigmatizing. Patient education requires empathy and sensitivity. Some infections must be reported to public health officials for contact tracing and complete follow-

up. Nurses are key to educating patients about guidelines for preventing transmission of infectious diseases such as COVID-19 in the community (see later discussion in this chapter).

The nurse must stress the importance of immunization to parents of young children and to others for whom vaccines are recommended, such as older adults or those who are immunosuppressed or have chronic illness or disability. Nurses should recognize their personal responsibility to receive the hepatitis B vaccine and an annual influenza vaccine to reduce potential transmission to themselves and vulnerable patient groups. Most recently, the nurse has a professional responsibility to be vaccinated for COVID-19 and to advocate for all professional and personal contacts to receive the vaccine at the first available opportunity.

Chart 66-6 NURSING RESEARCH PROFILE

Environmental Concerns for Possible Inpatient Transmission of Bacterial Pathogens

Cohen, B., Spirito, C. M., Liu, J., et al. (2019). Concurrent detection of bacterial pathogens in hospital roommates. *Nursing Research, 68*(1), 80–83.

Purpose

The inpatient environment is a potential reservoir for organisms. The purpose of this study was to determine the incidence of concurrent detection of bacterial pathogens among hospital roommates.

Design

The study was a retrospective analysis using administrative and clinical data collected from four inpatient facilities in New York City between 2006 and 2012. A computerized algorithm identified the presence of concurrent organisms among roommates, defined as two patients sharing a room for at least 1 day and having a first positive culture for that organism within 3 days following cohabitation.

Findings

A total of 741,271 patient admissions were included in the analysis. The algorithm identified 373 valid concurrent detection events among roommates. Among these events, 158 (42%) were pairs in which the patients' first positive cultures were drawn after they were no longer sharing a room but within 3 days of cohabitation. In 144 pairs (39%), the first positive cultures were drawn while the patients were still sharing a room but on different days. In the remaining 71 pairs (19%), the patients' positive cultures were drawn while they were sharing a room on the same day.

Nursing Implications

This study illustrates the important role nurses play in planning and implementing interventions to reduce bioburden in the inpatient environment, particularly in patient rooms. Nurses need to pay attention to the methods used for environmental decontamination as part of a comprehensive approach to infection prevention in hospitals. In particular, nurses may be able to improve environmental decontamination by identifying frequently missed surfaces or equipment that require attention from environmental services teams.

Controlling Fever and Accompanying Discomforts

Fever must always be investigated to determine the source. Fever may potentiate beneficial functions in the syndrome of reactions known as *acute-phase reaction.* These reactions include changes in liver protein synthesis; alterations in serum metals, such as iron; and increased production of certain classes of white blood cells and other cells of the immune system (Norris, 2019). Most fevers are physiologically controlled so that the temperature remains below 41°C (105.8°F). However, severe fever may cause complications. Even mild fevers accompanied by fatigue, chills, and diaphoresis are often uncomfortable for the patient. Whether

fever is treated or untreated, adequate fluid intake is important during febrile episodes. See Chapter 19 for management of fever in the patient with COVID-19.

Quality and Safety Nursing Alert

Because fever is a key symptom, outpatients with fever should be instructed to obtain accurate temperature readings. Frequently, family caregivers know that a patient has warm skin but do not take a temperature reading. Body temperature information can be very helpful in adjusting therapy or in reevaluating a preliminary diagnosis.

Monitoring and Managing Potential Complications

The patient with a rapidly progressive infectious disease should have vital signs and level of consciousness closely monitored. Results from radiologic and laboratory diagnostics (microbiologic, parasitologic, immunologic, hematologic, cytologic, etc.) must be interpreted in the context of other clinical findings to assess the course of the infectious disease.

Antibiotic therapy is frequently complex, and modifications are necessary because of drug susceptibility test results and disease progression. To rapidly ensure therapeutic blood levels, antibiotic therapy should be initiated as soon as it is prescribed rather than waiting until routine medication scheduling times. Chart 66-7 describes nursing interventions for infection.

Diarrheal Diseases

Worldwide, diarrheal diseases are a significant cause of mortality, especially for children (CDC, 2020j). In the United States, the epidemiology of diarrheal diseases changes continually. Water disinfection, pasteurization, and appropriate food packaging have decreased the incidence of diseases such as typhoid and cholera. However, importation of foreign foods, environmental and ecologic changes, and changes in diagnostic test modalities have led to recognition of new trends and outbreaks.

Transmission

The portal of entry of diarrheal pathogens is oral ingestion. Although food is far from sterile, the high acidity of the stomach and the antibody-producing cells of the small bowel generally decrease the potential of pathogens. Infection can occur when the infectious dose is high enough or if the acidic digestive environment is neutralized. Decreased gastric acidity with disruption of normal bowel flora (as occurs after surgery), the use of antimicrobial agents, and other causes of immune suppression decrease intestinal defenses.

Causes

There are many viral, bacterial, and parasitic causes of diarrheal diseases. The most significant viral cause of diarrhea is the *Calicivirus* (often called *Norovirus*, a virus associated with outbreaks in long-term care facilities and cruise ships) (CDC, 2020k). Common causes of bacterial infection include *Campylobacter, Salmonella, Shigella,* and *E. coli*. A common parasitic infection of importance is *Giardia.* Diarrheal disease may also be caused by *Vibrio cholera*.

Chart 66-7 PLAN OF NURSING CARE

Care of the Patient with an Infectious Disease

Nursing Diagnosis: Risk for infection
Goal: Prevention of infection

Nursing Interventions	Rationale	Expected Outcomes
1. Prevent patient-to-patient infection spread.	1. Organisms that are spread through an airborne route or are very contagious through direct contact can be transmitted in a health care setting.	• No evidence of patient-to-patient transmission of infection • No evidence of transmission via health care workers • No occupationally acquired infections in nurses and other health care workers • No evidence of transmission due to contaminated equipment • Absence of bacteremia and sepsis • Absence of urinary tract infections • Absence of pneumonia
a. Provide isolation according to CDC guidelines and standard precautions.	a. CDC isolation strategies are developed to reduce the likelihood of transmission from patients who are infected to others.	
b. Ensure that patients with airborne infections remain in private rooms during hospital stay. If they must leave their rooms, arrangements should be made to decrease the likelihood of contact with others. Rooms should be ventilated according to CDC criteria. Personal protective equipment that includes N95 respirators should be worn as indicated.	b. Engineering controls are important in the prevention of airborne diseases. The N95 respirator is the minimal level of personal protection for tuberculosis (TB) control. The "N" indicates the filter resistance to oil aerosols; the "95" indicates that the respirator has 95% effectiveness in filtering test particles.	
c. Ensure that patients with highly transmissible, nonairborne	c. Increased prevention strategies are needed when the organism has high epidemic potential.	

organisms such as *C. difficile* and *Shigella* species are physically separated from other patients if hygiene or institutional policy dictates.	
d. Identify areas needing environmental decontamination.	d. Prevents patient-to-patient spread
2. Prevent health care workers' transfer of organisms from patient to patient.	2. Transfer of organisms on the hands of health care workers is a common route of transmission. Hospital organisms colonizing the hands of health care workers may be virulent.
a. Perform hand hygiene (by handwashing or by using alcohol-based solution) consistently and thoroughly, disinfecting hands before and after each patient contact, and after procedures that offer contamination risk while caring for an individual patient.	a. Hand hygiene is important in reducing transient flora on outer epidermal layers of skin. Alcohol-based hand disinfectants are effective methods to reduce transient flora.
b. Use gloves when handling any body fluid from any patient. Change gloves between patient care activities, and disinfect hands after gloves are removed.	b. Gloves provide effective barrier protection. Gloves quickly become contaminated and then become a potential vehicle for the transfer of organisms between patients. Microflora on hands are likely to

	proliferate while gloves are worn.
c. Avoid wearing artificial fingernails or extenders when providing patient care. Keep natural nails less than ¼ inch long and remove nail polish when chipped.	c. Artificial fingernails and extenders harbor microorganisms.
d. Monitor the hand hygiene and glove use behaviors of health care professionals caring for the patient.	d. Poor adherence to hand hygiene among health care workers has been well documented and should be anticipated. It is important for the nurse (as the patient's advocate) to communicate protective behavior.
3. Prevent transmission of infection from patient to health care worker.	3. Health care workers may acquire infections occupationally due to close contact with patients.
a. Avoid risk of infection with TB.	a. The most important element in the reduction of TB is early identification. Many of the symptoms of TB are subtle and may be first observed by the nurse who has prolonged contact with the patient.
1. Participate in the early identification of patients with active disease. Patients will be asked about risk	1. Identification of patients at risk can help to prevent exposure.

	factors, symptoms, previous exposure, and status of tuberculin skin test or other rapid tests.	
	2. Expedite diagnostic workup with chest x-ray, sputum analysis for organisms, and administration of TB testing as appropriate.	2. Confirmation of diagnosis facilitates development of an appropriate treatment plan, including prevention of spread of infection.
	3. Maintain engineering controls. Keep the patient in a private room with a closed door.	3. Confining airflow to the immediate vicinity of the patient and exhausting air to the outside reduces the likelihood of transmission to health care workers in areas outside of the patient room.
	4. Use protection in isolation room or when participating in procedures that are likely to generate cough, such as suctioning, intubation, or administering nebulized medications.	4. N95 respirators are designed to reduce health care workers' risk.
b. Avoid risk of		b. Health care workers

transmission of bloodborne diseases such as hepatitis B, hepatitis C, and the human immune deficiency virus.	can contract bloodborne diseases via percutaneous injury such as needlestick or by contact with blood or body fluids to mucous membranes, such as eyes and mouth.
1. Get hepatitis B vaccination.	1. Hepatitis B vaccine should be given to reduce risk from this contagious bloodborne virus.
2. Use standard precautions as defined by the CDC (see Chapter 32, Chart 32-5).	2. Standard precautions are based on the recognition that most patients are not identified as infected by physical assessment or history taking. Health care workers must assume that all patients may be infected with bloodborne or other infection and must use barrier precautions appropriately for *all* patients.
3. Use "needleless" syringes and other injury-preventing devices.	3. The use of injury-preventing devices decreases risk of transmission of bloodborne diseases.
c. Avoid risk of airborne diseases.	c. Influenza vaccine is recommended for health care workers

1. Receive influenza vaccination annually. 2. Get vaccinated or produce proof of immunity to measles, mumps, rubella, and varicella.	to reduce the likelihood of transmission in health care settings where patients who are immunocompromised can be exposed.
4. Prevent patient exposure to contaminated medical equipment.	4. Technologic advances offer increased opportunity for invasive procedures. Equipment may be complex and difficult to clean.
a. Ensure that equipment being inserted through intact skin is sterilized between patient uses.	a. Sterilization renders equipment free of all microorganisms.
b. Ensure that equipment that has contact with mucous membranes is sterilized or receives “high-level disinfection” between patient uses.	b. High-level disinfection renders an object free of all microorganisms with the possible exception of spore-producing organisms.
c. Ensure that equipment used against intact skin is thoroughly cleaned and receives “low-level disinfection” between patient uses.	c. The disinfection goal for low-level disinfection is to reduce the load of microorganisms to a level that is not threatening to the host with intact skin.
5. Follow established guidelines for the routine removal and replacement of IV devices.	5. Indwelling IV devices can serve as a conduit for organisms to migrate into the bloodstream.

6. Remove urinary catheters at the earliest time possible.	6. The risk of urinary tract infections is directly proportional to the length of time that a urinary catheter remains in place.	
7. Remove endotracheal and nasogastric tubes as soon as possible.	7. The risk for pneumonia is increased as the use of indwelling equipment increases.	

NURSING DIAGNOSIS: Lack of knowledge about disease, cause of infection, and preventive measures
GOAL: Acquisition of knowledge about the infectious process

Nursing Interventions	Rationale	Expected Outcomes
1. Listen carefully to what the patient says about illness and previous treatment.	1. Listening facilitates detection of misunderstanding and misinformation and provides opportunity for education.	• Patient actively participates in treatment • Patient adheres to infection control measures
2. Provide pertinent explanations about: a. Organism and route of transmission b. Treatment goals c. Follow-up schedule d. Prevention of transmission to others	2. Knowledge about specific diagnoses and treatments may promote adherence.	
3. Allow opportunities for questions and discussions.	3. The patient's questions indicate issues that need clarification.	
4. Educate the patient and family about: a. Prophylaxis or immunization, if recommended b. Community resources, if necessary	4. Understanding of the risks and precautions associated with an infectious disease may reduce the opportunity for further spread.	

c. Means of preventing transmission within the home

NURSING DIAGNOSIS: Fever
GOAL: Return to normal body temperature

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor temperature, pulse, and respirations at regular intervals.	1. Graph fever curve to help evaluate when fever occurs, how long it lasts, and whether it responds to therapy.	• Body temperature within normal limits • Maintenance of fluid and electrolyte balance
2. Administer antipyretic agents as prescribed.	2. Prompt treatment will improve outcomes.	

COLLABORATIVE PROBLEMS: Potential complications include bacteremia or sepsis, septic shock, dehydration, and abscess formation
GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Bacteremia, Sepsis		
1. Assess patient for evidence of infection at any location and monitor laboratory results for indicators of infection.	1. Vigilance for bacterial or fungal infection at any site promotes early recognition and treatment and reduces the likelihood of secondary infections.	• No episode of infection • Effective treatment for identified bacterial and fungal infections without progression to bloodstream infection • Early improvement in septic course
2. Assess treatment effectiveness of all identified infections.	2. The natural course of some infections may be rapid unless antibiotic agents are given promptly.	
3. Administer antibiotic agents as prescribed with first dose given at the earliest time possible.	3. Prompt treatment will improve outcomes.	
Septic Shock		
1. Routinely, and as warranted, monitor vital signs for patients with recognized	1. Early recognition of the signs and prompt treatment of impending shock may reduce the	• Absence of symptoms of septic shock

infections and for patients who are severely immunosuppressed at risk for shock. In particular, be alert to signs of: a. Fever b. Tachycardia (>90 bpm) c. Tachypnea (>20 breaths/min) d. Evidence of decreased perfusion or dysfunction of vital organs in the form of: 1. Change in mental status 2. Hypoxemia as measured by arterial blood gases 3. Elevated lactate levels 4. Urine output (<0.5 mL/kg/h within 6 hours)	associated severity or mortality.	• Hemodynamic and respiratory status within normal range
2. Administer antibiotic agents, fluid replacement, vasopressors, and oxygen as prescribed.	2. Therapeutic maintenance of hemodynamic and respiratory status is necessary until infection is effectively treated with an antimicrobial regimen.	
Dehydration		
1. Assess for dehydration (thirst, dryness of mucous membranes, loss of	1. Signs of dehydration provide a basis for fluid replacement and suggest possible further	• Attains fluid balance (output approximates

skin turgor, reduced peripheral pulses, urine output <400 mL in 24 hours or <0.5 mL/kg/h over 6 hours).	complications of circulatory collapse.	intake: body weight unchanged) • Mucous membranes appear moist; normal skin turgor • Serum electrolytes within normal limits
2. Monitor weight.	2. Rapid changes in weight indicate fluid volume changes.	
3. Monitor intake and output and serum electrolyte levels.	3. Dehydration produces a deficit in some electrolytes. Decreased urine production may indicate hypovolemia and decreased renal perfusion.	
4. Replace fluids as needed. If the patient can tolerate oral fluids, offer fluids every 2–4 hours. Administer IV fluids as prescribed.	4. When possible, oral hydration is preferable because the patient can select the beverage, control the rate and interval of replacement, and care for self at home. In addition, the risks associated with vascular devices are avoided. If IV fluid is required, IV solutions are selected to facilitate intestinal reabsorption of fluid and electrolytes.	
Abscess Formation		
1. Assess vascular access sites, wound sites, pressure injuries, and other appropriate sites for apparent collections of purulent material.	1. Collections of purulent material often require drainage before antimicrobial therapy is effective.	• Absence of abscess • Takes antibiotic agents as prescribed
2. Assess the patient who has had abdominal surgery or trauma to abdominal area for	2. Intra-abdominal abscess formation is most common following traumatic or surgical disruption of the GI tract.	

localized signs of intra-abdominal abscess. These signs include: a. Low-grade fever b. Elevated peripheral white blood cell count c. Localized pain d. Abdominal tenderness e. Visible or palpable mass f. Postoperative diarrhea g. GI bleeding	Signs are often initially subtle.	
3. Assess patient who has had percutaneous abscess drainage to determine whether drainage has been successful. Be alert to all of the previously mentioned signs and symptoms.	3. After percutaneous drainage, recurrent or persistent signs of abscess may indicate the need for surgical treatment.	
4. Administer antibiotic agents as prescribed.	4. Antibiotic agents, along with drainage, are the most important elements of intra-abdominal abscess management.	

CDC, Centers for Disease Control and Prevention; GI, gastrointestinal; IV, intravenous; TB, tuberculosis.

Calicivirus (Norovirus)

Calicivirus, which is often referred to as the *Norovirus,* is the most common cause of foodborne illness and gastroenteritis in the United States. Onset of illness is usually acute, with vomiting and watery diarrhea that generally last for approximately 2 days. Most outbreaks occur between November and April. Dehydration is the most common complication. *Calicivirus* has been associated with large diarrheal outbreaks in schools, day care centers, cruise ships, long-term care facilities, and hospitals (CDC, 2020k).

Calicivirus is transmitted easily from person to person by direct contact and by ingesting contaminated food. Waterborne outbreaks have been associated with

sewage-contaminated wells and contaminated swimming pools. Although people with *Calicivirus* infection typically recover within 2 to 3 days, they may continue to transmit the virus to others for approximately 2 more weeks (CDC, 2020k).

Caliciviruses can withstand environmental extremes of heat or cold and are resistant to chemical disinfection, which are significant reasons for their epidemic potential. Control of *Calicivirus* in health care facilities requires a coordinated program to make decisions about isolation, environmental disinfection diagnosis method, and coordination with public health officials. Contact precautions should be used when caring for patients with incontinence and during outbreaks of the virus. Workers should wear masks if they are cleaning heavily soiled areas or caring for a patient who is actively vomiting. The CDC recommends disinfecting surfaces with a freshly prepared bleach solution, with 5 to 25 tablespoons of bleach per gallon of water, or other product that is approved by the Environmental Protection Agency (EPA) for *Norovirus* disinfection (CDC, 2020k).

Campylobacter Infections

Campylobacter species are frequent causes of diarrheal disease in the United States (CDC, 2020l). The bacterium, which is abundant in animal foods, is especially common in poultry but can also be found in beef and pork. Direct person-to-person transmission appears to be less common than it is for other enteric pathogens, such as *Shigella.*

Cooking and storing food at appropriate temperatures protect against *Campylobacter* infection. Kitchen utensils used in meat preparation must be kept away from other food to prevent transmission from *Campylobacter* and other foodborne organisms (CDC, 2020l).

After a person is infected, the bacterium directly attacks the lumen of the intestine and may cause disease through enterotoxin release. Symptoms can range from mild abdominal cramping and minimal diarrhea to severe disease with profuse watery bloody diarrhea and debilitating abdominal cramping. Antimicrobial therapy is recommended only for patients who are seriously ill (CDC, 2020l).

Salmonella Infection

Salmonella is a gram-negative bacillus with many species, including the very pathogenic *Salmonella typhi* (cause of typhoid fever). Of the nontyphi species, most organisms are prevalent in animal food sources, especially eggs and chicken. However, the bacteria also can contaminate other meats, nuts, produce, and processed foods (CDC, 2020m).

Salmonella infections produce variable symptoms, including an asymptomatic carrier state, gastroenteritis, and systemic infection. Diarrhea with gastroenteritis is common. Disseminated disease and bacteremia, sometimes accompanied by diarrhea, occur less often.

The person with *Salmonella*-caused diarrhea will seldom transmit infections to others. Hand hygiene is imperative after any contact with a person with *Salmonella* diarrhea. Although patients with systemic salmonellosis require antimicrobial

therapy, those with gastroenteritis only are not usually treated, because antibiotic use may increase the period of time that the patient carries the bacteria while not improving the clinical outcome.

Shigella Infection

Shigella species are gram-negative organisms that invade the lumen of the intestine and can cause severe watery (sometimes bloody) diarrhea and disseminated disease. *Shigella* species are spread through the fecal–oral route, with easy transmission from one person to another. *Shigella* exhibits a high level of virulence, as infection with very few bacteria can cause disease. Because transmission occurs easily with improper hygiene, it is not surprising that *Shigella* organisms disproportionately affect pediatric populations. Disease in the very young may infrequently be complicated by pulmonary or neurologic symptoms.

Antimicrobial therapy should be instituted early. Frequently, initial therapy choices must be altered when final microbiologic testing reveals the organism's sensitivity (Williams & Berkley, 2018).

Escherichia coli

E. coli is the most common aerobic organism colonizing the large bowel. When *E. coli* bacteria are cultured from fecal specimens, the results usually reflect normal flora. However, certain strains of *E. coli* with increased virulence have been responsible for significant outbreaks of diarrheal disease in recent years. These more pathologic strains are subgrouped as Shiga toxin–producing *Escherichia coli* (STEC) because of their production of enterotoxins. STEC strains often cause choleralike disease, with rapid, severe dehydration and an increased risk of death.

Several outbreaks of STEC have been linked to the ingestion of undercooked beef and to vegetables that have been contaminated by animal wastewater (Shane, Mody, Crump, et al., 2017). This bacterium lives in the intestines of cattle and can be introduced into meat at the time of slaughter. Prevention of disease from STEC strains is aimed at educating the public to wash fruits and vegetables thoroughly, to separate foods during preparation, and to use a food thermometer to assure meat has been cooked thoroughly (CDC, 2020n).

Giardia lamblia

Transmission of the protozoan *Giardia lamblia* occurs when food or drink is contaminated with viable cysts of the organism. People often become infected while traveling to endemic areas or by drinking contaminated water from mountain streams within the United States. The organism can be transmitted by close contact, such as occurs in day care settings. Transmission by sexual contact has also been documented.

Frequently, the infection goes unnoticed. Infection is often recognized more easily in children than in adults. In extreme cases, the patient may experience abdominal pain and chronic diarrhea, usually described as containing mucus and

fat but not blood. Microscopic examination of stool specimens reveals the trophozoite or cyst stages of the parasitic life cycle.

The CDC recommends metronidazole to treat *Giardia* (CDC, 2020o). Patients with *Giardia* infections should be instructed that the organism can be easily transmitted in family or group settings. Personal hygiene measures should be reinforced, and those who travel or camp where water is not treated and filtered should be advised to avoid local water supplies unless water is purified before drinking or using it in cooking.

Vibrio Cholerae

Cholera is rare in the United States but remains a significant infectious cause of death worldwide. The causative organism is transmitted by contaminated food or water. Cases in the United States have been from contaminated shellfish found in the Gulf of Mexico or from contaminated shellfish brought into the United States by visitors. Cholera causes disease with a very rapid onset of copious diarrhea in which up to 1 L of fluid per hour can be lost. Dehydration, with subsequent cardiopulmonary collapse, may cause rapid progression from onset of signs and symptoms to death. Rehydration efforts should be vigorous and sustained. If oral rehydration cannot be accomplished, the patient may need IV fluid replacement (CDC, 2018).

Cholera should be suspected in patients who have watery diarrhea after eating shellfish harvested from the Gulf of Mexico. Confirmation of the causative organism can be made by stool culture. It is imperative that all cases are reported to local and state public health authorities.

NURSING PROCESS

The Patient with Infectious Diarrhea

Assessment

The most important element of assessment in the patient with diarrhea is to determine hydration status. The goal of rehydration is to correct the dehydration. Assessment includes evaluation for thirst, dryness of oral mucous membranes, sunken eyes, a weakened pulse, and loss of skin turgor. Careful observation for these signs is especially important in cases of rapidly dehydrating diseases (most notably cholera) and in younger children.

Intake and output measurements are crucial in determining fluid balance. Liquid stool should be measured and recorded, along with the frequency of stools. It is important to note the consistency and appearance of stool as key indicators of the type and severity of the diarrheal disease. The presence of mucus or blood should also be documented.

When conducting a health history, the nurse asks the patient what they have eaten recently and about recent travel, treatment with antibiotics, and potential exposure to others with diarrheal disease. Frequently, patients attribute symptoms to the most recent meal eaten. However, because the incubation period for most diarrheal conditions is longer than the time interval between meals, the nurse must obtain detailed information about the meal preceding the illness as well as all food intake in the previous 3 to 4 days. When eliciting this kind of history, it is helpful to ask the patient to list every food tasted. The nurse also asks if the patient is employed in a food preparation service, because the local public health departments should be notified about any person with infectious diarrhea who works in the food industry.

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Hypovolemia associated with fluid lost through diarrhea
- Lack of knowledge about the infection and the risk of transmission to others

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Bacteremia
- Hypovolemic shock

Planning and Goals

The most important goals are maintenance of fluid and electrolyte balance, increased knowledge about the disease and risk of transmission, and absence of complications.

Nursing Interventions

Correcting Dehydration Associated With Diarrhea

The patient is assessed to determine the degree of dehydration and the amount and route of rehydration needed. Oral rehydration therapy is a strategy used to reduce the severe complications of diarrheal disease regardless of causative agent. It is inexpensive and effective for most patients, but it is often underused due to some cultural beliefs worldwide discouraging oral intake during episodes of diarrhea. The WHO and the United Nations Children's Emergency Fund (UNICEF) recommend zinc replacement and oral rehydration salts (ORS) solution for the treatment of children and adults with dehydration and electrolyte imbalance associated with cholera and other forms of diarrheal disease. Commercial ORS preparations are available and should be mixed with clean, safe water. When the ORS preparations are not available, salted vegetable soup or chicken soup can be used for fluid replacement. The ORS formula contains (in grams per liter) (CDC, 2018):

- sodium chloride: 2.6
- glucose (anhydrous): 13.5
- potassium chloride: 1.5
- trisodium citrate (dihydrate): 2.9

The most important consideration is to provide more fluid than normal. Sports drinks do not replace fluid losses correctly and should not be used, unless they are the only fluid that is available or tolerated (CDC, 2018).

Mild Dehydration. The patient exhibits dry oral mucous membranes of the mouth and increased thirst. The rehydration goal at this level of dehydration is to deliver about 50 mL of ORS per 1 kg of weight over a 4-hour interval (CDC, 2018).

Moderate Dehydration. Common findings are sunken eyes, loss of skin turgor, increased thirst, and dry oral mucous membranes. The rehydration goal at this level of dehydration is to deliver about 100 mL/kg of ORS over 4 hours.

Severe Dehydration. The patient with severe dehydration shows signs of shock (i.e., rapid thready pulse, cyanosis, cold extremities, rapid breathing, lethargy, or coma; see Chapter 11) and should receive IV replacement until hemodynamic and mental status return to normal. When improvement is evident, the patient can be treated with ORS.

Administering Rehydration Therapy

Because diarrheal episodes are often accompanied by vomiting, rehydration and refeeding can be difficult. Oral rehydration therapy should be delivered frequently in small amounts. When patients are persistently vomiting, they often require frequent administration of fluids by spoonfuls. IV therapy is necessary for the patient who is severely dehydrated or in shock.

It is important for children and adults with acute diarrheal symptoms to maintain caloric intake. As soon as dehydration has been corrected, an age-appropriate, unrestricted diet is allowed. Recommended foods include starches, cereals, yogurt, fruits, and vegetables. Foods that are high in simple sugars, such as undiluted apple juice or gelatin, should be avoided (CDC, 2018).

Increasing Knowledge and Preventing Spread of Infection

Public health nurses, school nurses, and others who are involved in patient education should emphasize principles of safe food preparation, with special attention to meat, poultry, and fish preparation and cooking as follows (CDC, 2020p):

- Fish and whole cuts of meat must reach a temperature of 145°F (63°C).
- Ground meat must reach 160°F (71°C).
- Leftovers and poultry (both ground or whole cut) must reach 165°F (74°C).
- Before and after food preparation, all food should be maintained at temperatures below 40°F (5°C) or above 140°F (60°C).

In planning events that involve food preparation for groups of people, it is important to ensure adequate provision for proper storage and reheating to temperature thresholds. It is also important to use different surfaces, knives, and other equipment for raw meat, poultry, and fish and to keep these items separate from other foods.

Diarrheal diseases discussed in this section must be reported to local or state health departments. The goal of reporting is to provide information for determining incidence trends and promptly identifying any restaurants or other food preparation establishments that may have served contaminated food.

In both homes and health care delivery settings, good hygiene and principles of standard precautions should be emphasized.

Monitoring and Managing Potential Complications

Bacteremia. *E. coli, Salmonella,* and *Shigella* are organisms that can enter the bloodstream and disseminate to other organs. Blood cultures are necessary for the patient who is acutely febrile with diarrhea. If initial smear results reveal gram-negative organisms, antibiotic therapy is instituted.

Hypovolemic Shock. Shock associated with diarrheal diseases demands accurate intake and output assessment and vigorous fluid replacement. In rare instances, patients with severe fluid imbalance require intensive care nursing support with aggressive hemodynamic monitoring (see Chapter 11).

Evaluation

Expected patient outcomes may include:

1. Attains fluid balance
   a. Output approximates intake.
   b. Mucous membranes appear moist.
   c. Skin turgor is normal.
   d. Adequate amounts of fluids and calories are ingested.
   e. Absence of vomiting.
   f. Stools are of normal color and consistency.
2. Acquires knowledge and understanding about infectious diarrhea and transmission potential
   a. Takes proper precautions to prevent spread of infection to others.

b. Describes principles and techniques of safe food storage, preparation, and cooking.

3. Absence of complications
   a. Temperature is within normal range.
   b. Blood culture reports are negative.
   c. Fluid balance is achieved.

Sexually Transmitted Infections

Sexually transmitted infections (STIs) are diseases acquired through sexual contact with a person who is infected. Select STIs and their routes of transmission are included in Table 66-1. Infections caused by organisms not generally considered STIs can also be transmitted during sexual contact—for example, *G. lamblia,* usually associated with contaminated water, can be transmitted through sexual exposure. STIs are sometimes called sexually transmitted diseases (STDs) as well.

STIs are the most common infectious diseases in the United States and are epidemic in most parts of the world. Portals of entry of STI-causing microorganisms and sites of infection include the skin and mucosal linings of the urethra, cervix, vagina, rectum, and oropharynx.

More than 2 million STIs are reported among Americans annually. However, many infections go undiagnosed or unreported, so surveillance data underestimate true incidence. Surveillance reliability is diminished when public health departments are underfunded, and when some populations have decreased access to care (CDC, 2020q).

Education about prevention of STIs includes information about risk factors and behaviors that can lead to infection. Using straightforward language and personal testimonials for targeted audiences (e.g., people who want information about protecting themselves) and conducting presentations with trusted establishments (e.g., churches, health care facilities) are the recommended educational strategies. Included in this education is information about the relative value of condoms in reducing the risk of infection. The use of condoms to provide a protective barrier from transmission of STI-related organisms has been broadly promoted, especially since the recognition of HIV/AIDS. At first referred to as a method to ensure *safe sex,* the use of condoms has been shown to reduce but not eliminate the risk of transmission of HIV and other STIs. Thus, the term *safer sex* more appropriately connotes the public health message to be used when promoting the use of condoms. See Chapter 32 for most information about AIDS and HIV.

STIs provide a unique set of challenges for nurses, physicians, and public health officials. Because of perceived stigma and possible threat to emotional relationships, people with symptoms of STIs are often reluctant to seek health care in a timely fashion. STIs may progress without symptoms, and a delay in diagnosis and treatment is potentially harmful because the risk of complications for the person who is infected and the risk of transmission to others increase over time.

Infection with one STI suggests the possibility of infection with other diseases as well. After one STI is identified, diagnostic evaluation for others should be conducted. The possibility of HIV infection should be pursued when any STI is diagnosed.

Syphilis

Syphilis is an acute and chronic infectious disease caused by the spirochete *Treponema pallidum.* It is acquired through sexual contact or may be congenital in origin. The rates of primary and secondary syphilis have been on the rise, with a 15% increase between 2017 and 2018 (CDC, 2020q).

Stages of Syphilis

The course of untreated syphilis can be divided into three stages: primary, secondary, and tertiary. These stages reflect the time from infection and the clinical manifestations observed in that period and are the basis for treatment decisions.

Primary syphilis occurs 2 to 3 weeks after initial inoculation with the organism. Painless lesions at the site of infection, called chancres, usually resolve spontaneously within 3 to 12 weeks, with or without treatment (Norris, 2019).

Secondary syphilis occurs by hematogenous spread leading to generalized infection. The rash of secondary syphilis occurs from 1 week to 6 months after the chancre (Norris, 2019). Transmission can occur through contact with these lesions. Generalized signs of infection may include lymphadenopathy, arthritis, meningitis, hair loss, fever, malaise, and weight loss.

After the secondary stage, there is a period of latency, when the person who is infected has no signs or symptoms of syphilis. Latency can be interrupted by a recurrence of secondary syphilis symptoms (Norris, 2019).

Tertiary syphilis is the final stage in the natural history of the disease. It is estimated that between 20% and 40% of those infected do not exhibit signs and symptoms in this final stage. Tertiary syphilis may present as a slowly progressive inflammatory disease with the potential to affect multiple organs. The most common manifestations at this level are aortitis and neurosyphilis, as evidenced by dementia, psychosis, paresis, stroke, or meningitis (Norris, 2019).

Assessment and Diagnostic Findings

Because syphilis shares symptoms with many diseases, clinical history and laboratory evaluation are important. The conclusive diagnosis of syphilis can be made by direct identification of the spirochete obtained from the chancre lesions of primary syphilis. Serologic tests used in the diagnosis of secondary and tertiary syphilis require clinical correlation in interpretation. The serologic tests are summarized as follows (O'Bryne, 2019):

- *Nontreponemal* or *reagin tests,* such as the Venereal Disease Research Laboratory (VDRL) or the rapid plasma reagin circle test (RPR-CT), are

generally used for screening and diagnosis. After adequate therapy, the test result is expected to decrease quantitatively until it is read as negative, usually about 2 years after therapy is completed.

- *Treponemal tests,* such as the fluorescent treponemal antibody absorption (FTA-ABS) test and the microhemagglutination test for *Treponema pallidum* (MHA-TP), are used to verify that the screening test did not represent a false-positive result. Positive results usually are positive for life and therefore are not appropriate to determine therapeutic effectiveness

Medical Management

Treatment of all stages of syphilis is administration of antibiotic medications. Penicillin G benzathine is the medication of choice for early syphilis or early latent syphilis of less than 1 year's duration. It is given by intramuscular injection at a single session. Patients with late latent or latent syphilis of unknown duration should receive three injections at 1-week intervals. Patients who are allergic to penicillin are usually treated with doxycycline. The patient treated with penicillin is monitored for 30 minutes after the injection to observe for a possible allergic reaction (CDC, 2020s).

Treatment guidelines established by the CDC are updated on a regular basis. Recommendations provide special guidelines for treatment in the setting of pregnancy, allergy, HIV infection, pediatric infection, congenital infection, and neurosyphilis. The CDC Web site, "Sexually Transmitted Diseases," provides a link to the most recent guidelines as well as additional information about drug shortages and other concurrent treatment considerations. The Web site also regularly updates guidance about how to modify usual STI/STD screening and treatment care during the COVID-19 pandemic (CDC, 2020s).

Nursing Management

Syphilis is a reportable communicable disease. In any health care facility, a mechanism must be in place to ensure that all patients who are diagnosed are reported to the state or local public health department to ensure community follow-up. The public health department is responsible for identification of sexual contacts, contact notification, and contact screening.

Lesions of primary and secondary syphilis may be highly infective. Gloves are worn when direct contact with lesions is likely, and hand hygiene is performed after gloves are removed. Isolation in a private room is not required (see Chart 66-8).

Chlamydia trachomatis and *Neisseria gonorrhoeae* Infections

Chlamydia trachomatis and *Neisseria gonorrhoeae* are the most commonly reported infectious diseases in the United States. Coinfection with *C. trachomatis*

often occurs in patients infected with *N. gonorrhoeae.* The greatest risk of *C. trachomatis* infection occurs in young women between 15 and 24 years of age (CDC, 2020q, 2020r).

Chart 66-8 **PATIENT EDUCATION**

Preventing the Spread of Syphilis

The nurse instructs the patient to:

- Complete the full course of therapy if multiple penicillin injections are required.
- Refrain from sexual contact with previous or current partners until the partners have been treated.
- Be aware that if you have primary or secondary syphilis, skin lesions and other sequelae of infection will improve with proper treatment, and serology eventually will reflect cure.
- Recognize that condoms significantly reduce the risk of transmission of syphilis and other STIs.
- Be aware that having multiple sexual partners increases the risk of acquiring syphilis and other STIs.

STIs, sexually transmitted infections.

Clinical Manifestations

Both *C. trachomatis* and *N. gonorrhoeae* infections frequently do not cause symptoms in women. When symptoms are present, mucopurulent cervicitis with exudates in the endocervical canal is the most frequent finding. Women with gonorrhea can also present with symptoms of urinary tract infection or vaginitis. See Chapter 51 for more in-depth coverage of STIs in women.

Although men are more likely than women to have symptoms when infected, infection with *N. gonorrhoeae* or *C. trachomatis* can be asymptomatic. When symptoms are present, they may include burning during urination and penile discharge. Patients with *N. gonorrhoeae* infection may also report painful, swollen testicles (CDC, 2020q, 2020r).

Complications

In women, pelvic inflammatory disease (PID), ectopic pregnancy, endometritis, and infertility are possible complications of either *N. gonorrhoeae* or *C. trachomatis* infection. In men, epididymitis, a painful disease that may lead to infertility, may result from infection with either bacterium. In both men and women, arthritis or bloodstream infection may be caused by *N. gonorrhoeae* (CDC, 2020q, 2020r).

Assessment and Diagnostic Findings

The patient is assessed for fever, discharge (urethral, vaginal, or rectal), and signs of arthritis. Diagnostic methods used in *N. gonorrhoeae* infection include Gram stain (appropriate only for male urethral samples), culture, and nucleic acid amplification tests (NAATs). Gram stain and the direct fluorescent antibody test can be used in chlamydia. NAATs are also available for *C. trachomatis*. In the female patient, samples are obtained from the endocervix, anal canal, and pharynx. In the male patient, specimens are obtained from the urethra, anal canal, and pharynx. Because *N. gonorrhoeae* organisms are susceptible to environmental changes, specimens for culture must be delivered to the laboratory immediately after they are obtained.

Because as many as 70% of chlamydial infections are asymptomatic, the CDC recommends *Chlamydia* testing for all women who are pregnant. Annual testing is also recommended for women younger than 25 years who are sexually active, and for women over 25 years who have a new sexual partner or multiple partners (CDC, 2020q, 2020r).

Medical Management

Because patients are often coinfected with both gonorrhea and chlamydia, dual therapy is recommended, even if only gonorrhea has been laboratory proven (CDC, 2020r). The CDC guidelines should be used to determine alternative therapy for the patient who is pregnant or allergic or who has a complicated chlamydial infection. The CDC updates STI therapy recommendations regularly because of growing challenges with bacterial antibiotic resistance patterns and drug shortages (CDC, 2020r).

Although the number of resistant strains of gonorrhea has increased, that is not the reason for the use of combination antibiotic therapy. Such therapy is prescribed in order to treat both gonorrhea and chlamydia, because many patients with gonorrhea have a coexisting chlamydial infection.

Patients with uncomplicated gonorrhea who are treated with CDC-recommended therapy do not routinely need to return for a proof-of-cure visit. If the patient reports a new episode of symptoms or tests are positive for gonorrhea again, the most likely explanation is reinfection rather than treatment failure. Serologic testing for syphilis and HIV should be offered to patients with gonorrhea or chlamydia, because any STI increases the risk of other STIs (CDC, 2020r).

Nursing Management

Gonorrhea and chlamydia are reportable communicable diseases. In any health care facility, a mechanism should be in place to ensure that all patients who are diagnosed are reported to the local public health department to ensure follow-up of the patient. The public health department also is responsible for interviewing the patient to identify sexual contacts so that contact notification and screening can be initiated.

The target group for preventive patient education about gonorrhea and chlamydia is the adolescent and young adult population. Along with reinforcing the importance of abstinence, when appropriate, education should address postponing the age of initial sexual exposure, limiting the number of sexual partners, and using condoms for barrier protection. Young women and those who are pregnant should also be instructed about the importance of routine screening for chlamydia.

NURSING PROCESS

The Patient with a Sexually Transmitted Infection

Assessment

The patient should be asked to describe the onset and progression of symptoms and to characterize any lesions by location and by describing drainage, if present. Brief explanations of why the information is needed are often helpful. Clarification of terms may be necessary if either the patient or nurse uses words that are unfamiliar to the other.

Protecting confidentiality is important when discussing sexual issues. When a detailed sexual history is necessary, it is important to respect the patient's right to privacy. When obtaining a sexual history, the CDC recommends the following systematic interview of key areas, the "five Ps": *p*artners, *p*revention of pregnancy, *p*rotection from STIs, *p*ractices, and *p*ast history of STIs.

Asking specific information about sexual contacts usually should be done only when the nurse is part of a team that will conduct partner notification. The nurse should describe to the patient the public health notification process and resources that are available to assist sexual partners or infants and children.

During the physical examination, the examiner looks for rashes, lesions, drainage, discharge, or swelling. Inguinal nodes are palpated to elicit tenderness and to assess swelling. Women are examined for abdominal or uterine tenderness. The mouth and throat are examined for signs of inflammation or exudate. The nurse wears gloves while examining the mucous membranes, and gloves are changed and replaced after vaginal or rectal examination.

Diagnosis

Nursing Diagnoses

Based on assessment data, major nursing diagnoses may include the following:

- Lack of knowledge about the disease and risk for spread of infection and reinfection
- Anxiety associated with anticipated stigmatization and to prognosis and complications
- Impaired ability to manage regime associated with integrating a therapeutic regimen for treatment

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Ectopic pregnancy
- Infertility
- Transmission of infection to fetus, resulting in congenital abnormalities and other outcomes
- Neurosyphilis
- Gonococcal meningitis
- Gonococcal arthritis

- Syphilitic aortitis
- HIV-related complications

Planning and Goals

Major goals are increased patient understanding of the natural history and treatment of the infection, reduction in anxiety, increased adherence with therapeutic and preventive goals, and absence of complications.

Nursing Interventions

Increasing Knowledge and Preventing Spread of Disease

Education about STIs and prevention of the spread to others are often accomplished simultaneously. The patient who is infected should be told what the causative organism is and should receive an explanation of the usual course of the infection (including the interval of potential communicability to others) and possible complications. The nurse should stress the importance of following therapy as prescribed and the need to report any side effects or symptom progression. Discussion should emphasize that the same behaviors that led to infection with one STI increase the risk of infection with other STIs, including HIV. Methods used to contact sexual partners should be discussed. The patient should understand that until the partner has been treated, continued sexual exposure to the same person may lead to reinfection.

Target groups for preventive patient education about STIs include the adolescent and young adult populations. Along with reinforcing the importance of abstinence, when appropriate, education should address postponing the age of initial sexual exposure, limiting the number of sexual partners, and using condoms for barrier protection. The use of condoms reduces but does not eliminate the risk of transmission of HIV and other STIs.

Reducing Anxiety

When appropriate, the patient is encouraged to discuss anxieties and fear associated with the diagnosis, treatment, or prognosis. By individualizing education, factual information applied to specific needs may offer reassurance. Patients may need help in planning discussion with partners. If the patient is especially apprehensive about this aspect, referral to a social worker or other specialist may be appropriate. For example, such support is especially important when the patient has newly diagnosed HIV infection. Patients with HIV may benefit from programs that combine support, education, counseling, and therapeutic goals. Such programs are designed to offer coordinated care throughout the course of disease progression.

Increasing Adherence

In group settings (e.g., an outpatient obstetric setting) or in a one-to-one setting, open discussion about STI information facilitates patient education. Discomfort can be reduced by factual explanation of causes, consequences, treatments, prevention, and responsibilities. Because most communities have expanded STI prevention resources, referrals to appropriate agencies can complement

individual educational efforts and ensure that later questions or uncertainties can be addressed by experts.

Monitoring and Managing Potential Complications

Infertility and Increased Risk of Ectopic Pregnancy. STIs may lead to PID and increased risk of ectopic pregnancy and infertility. See Chapters 50 and 51 for additional information.

Congenital Infections. All STIs can be transmitted to infants in utero or at the time of birth. Complications of congenital infection can range from localized infection (e.g., throat infection with *N. gonorrhoeae*), to congenital abnormalities (e.g., stunting of growth or deafness from congenital syphilis), and to life-threatening disease (e.g., congenital herpes simplex virus).

Neurosyphilis, Gonococcal Meningitis, Gonococcal Arthritis, and Syphilitic Aortitis. STIs can cause disseminated infection. The central nervous system may be infected, as seen in cases of neurosyphilis or gonococcal meningitis. Gonorrhea that infects the skeletal system may result in gonococcal arthritis. Syphilis can infect the cardiovascular system by forming vegetative lesions on the mitral or aortic valves (CDC, 2020s).

Human Immune Deficiency Virus–Related Complications. HIV infection, if untreated, leads to the profound immunosuppression that is characteristic of AIDS. Complications of HIV infection include many opportunistic infections, including those due to *Pneumocystis jirovecii, Cryptococcus neoformans,* cytomegalovirus, and *Mycobacterium avium* (see Chapter 32).

Evaluation

Expected patient outcomes may include:

1. Exhibits knowledge about STIs and their transmission
2. Demonstrates a less anxious demeanor
   a. Discusses anxieties and goals for treatment
   b. Inspects self for lesions, rashes, and discharge
   c. Accepts support, education, and counseling when indicated
   d. Assists with sharing information about infection with sexual partners
   e. Discusses risk reduction behaviors and safer sex practices
3. Adheres to treatment
4. Achieves effective treatment
5. Reports for follow-up examinations if necessary
6. Absence of complications

Emerging Infectious Diseases

As defined by the CDC, **emerging infectious diseases** are human diseases of infectious origin that have increased within the past two decades or that are likely to increase in the near future. Examples of emerging infectious diseases presented

here include COVID-19, Zika virus, West Nile virus, Ebola virus disease, Legionnaires disease, and pertussis. Bioterrorism agents such as anthrax and plague are also considered emerging infectious diseases because a bioterrorist act would introduce a new mode of transmission for these agents. Other examples, covered earlier in this chapter, include novel influenza viruses, CRE, and *C. auris*.

Infectious diseases may begin anywhere in the world; therefore, epidemiologists worldwide collaborate to share information about the detection of new diseases, their clinical presentations, laboratory identification methods, and possible treatments. In the United States, the CDC is the central agency for this coordination. The CDC collaborates with numerous agencies, including other U.S. government agencies (such as the National Institutes of Health [NIH] and Food and Drug Administration [FDA]) as well as the WHO and other international agencies, faith-based agencies, nongovernmental organizations, and businesses throughout the world. Elaborate disease surveillance and reporting methods are established with the goal of early detection and control of actual and potential epidemics and pandemics (CDC, 2017).

Many factors contribute to newly emerging or re-emerging infectious diseases. These include travel, globalization of food supply and central processing of food, population growth, increased urban crowding, population movements (e.g., those that result from war, famine, or human-made or natural disasters), ecologic changes, human behavior (e.g., risky sexual behavior, IV/injection drug use), antimicrobial resistance, and breakdown in public health measures.

Emerging infectious diseases are important from an epidemiologic standpoint because their incidence is not stable. When the pattern of disease in a community is not well understood in the medical-scientific community, patients, families, and others in the community often become alarmed about these diseases. During times of increased concern about bioterrorism, whether triggered by actual events or by hoaxes, nurses have responsibility to rationally separate facts from fears. In discussions with patients and other caregivers, it is important to keep the focus on what is known and to clarify the plan for diagnosis, treatment, and containment.

COVID-19

The COVID-19 pandemic began in Wuhan, China, in late 2019. As research into the novel pathogen responsible for the 2019–2021 global pandemic progresses, new information about the pathogenesis, risks, clinical manifestations, and management of patients infected with SARS-CoV-2 continues to emerge. Of those individuals in the United States diagnosed with COVID-19, the case fatality rate is estimated to be 5.6% (Johns Hopkins University & Medicine Coronavirus Resource Center, 2020).

Pathophysiology

COVID-19 transmission occurs through virus-laden droplets and aerosols exhaled by an infected host while breathing, speaking, coughing, and sneezing (Prather,

Wang, & Schooley, 2020). SARS-CoV-2 gains entry into host cells through the angiotensin-converting enzyme 2 (ACE2) cellular surface receptors (see Chapter 27, Fig. 27-2) (Vaduganathan, Vardeny, Michel, et al., 2020). In addition, the aerosols of SARS-CoV-2 can accumulate, remain infectious in indoor air for hours, and can be inhaled deep into the lungs (Prather et al., 2020). The virus multiplies rapidly within an infected host and, unless checked by the immune system, symptoms begin with a week of transmission (Prather et al., 2020).

Risk Factors

Individuals of any age, gender, and ethnicity can be at risk for infection; however, adults 65 years of age and older, and those who reside in long-term care or skilled nursing facilities are at higher risk of death from COVID-19 (NIH COVID-19 Treatment Guidelines Panel, 2020). Some studies suggest that men with COVID-19 have a higher fatality rate compared to women (Chen, Zhou, Dong, et al., 2020; Deng, Yin, Chen, et al., 2020). While information on risk continues to evolve, Chart 66-9 lists the demonstrated and possible risk factors for COVID-19 in adults. Having a history of several chronic diseases, particularly if the diseases are not properly managed, appears to be associated with higher risk of severe disease and death (CDC, 2020g; CDC, 2020h). Patients who are immunosuppressed for a variety of reasons (e.g., active neoplasm, organ transplant recipient) are also thought to be at higher risk of dying from COVID-19 (CDC, 2020g; CDC, 2020h; NIH COVID-19 Treatment Guidelines Panel, 2020).

Clinical Manifestations

COVID-19 clinical manifestations occur on a wide spectrum, from mild symptoms that can be managed at home to severe illness with manifestations that can cause multisystem morbid complications requiring care in an ICU setting. While primarily respiratory in nature, mild COVID-19 manifestations may include fever, nonproductive cough, sore throat, fatigue, myalgias (muscle aches), nasal congestion, nausea, vomiting, diarrhea, anosmia (loss of smell), and ageusia (loss of taste) (Cascella, Rajnik, Cuomo, et al., 2020; Kim & Gandhi, 2020). See Chapter 19 for further discussion of the spectrum of clinical manifestations in the patient with COVID-19.

Chart 66-9  RISK FACTORS

Development of Severe Illness due to COVID-19 in Adults

Increased Risk Demonstrated

- Cancer
- Chronic kidney disease
- COPD
- Down Syndrome
- Heart failure, coronary artery disease, or cardiomyopathy
- Immunocompromised state from solid organ transplant
- Obesity (body mass index [BMI] of 30 kg/m^2 or higher but ≤40 kg/m^2)
- Severe obesity (BMI ≥40 kg/m^2)
- Pregnancy
- Sickle cell disease
- Smoking
- Type 2 diabetes

Possible Increased Risk

- Asthma (moderate-to-severe)
- Cerebrovascular disease
- Cystic fibrosis
- Dementia
- Hypertension
- Immunocompromised state from blood or bone marrow transplant, immune deficiencies, HIV, use of corticosteroids, or use of other immune weakening medicines
- Liver disease
- Overweight (BMI ≥25 kg/m^2, but ≤30 kg/m^2)
- Pulmonary fibrosis
- Thalassemia
- Type 1 diabetes

COPD, chronic obstructive pulmonary disease.

Retrieved on 7/24/2020 at: www.cdc.gov/coronavirus/2019-ncov/hcp/clinical-guidance-management-patients.html; Centers for Disease Control and Prevention (CDC). (2020h). COVID-19: People with certain medical conditions. Retrieved on 7/24/2020 at: www.cdc.gov/coronavirus/2019-ncov/need-extra-precautions/people-with-medical-conditions.html

Medical Management

Patients with mild symptoms, about 80% of patients, can be managed at home (Cascella et al., 2020; Kim & Gandhi, 2020). Those with severe illness are hospitalized (Kim & Gandhi, 2020). See Chapter 19 for further discussion of medical management of the patient with mild, moderate, and severe COVID-19 infection.

Nasopharyngeal samples are the recommended method of diagnosing SARS-CoV-2 (NIH COVID-19 Treatment Guidelines Panel, 2020). Those testing people for possible infection with SARS-CoV-2 either work with their state, tribal, local, and territorial health departments to coordinate testing through public health laboratories, or with commercial or clinical laboratories using molecular and antigen tests. The type of specimen collected is based on the test being used and the specific manufacturer instructions (CDC, 2020a).

Ideally, the diagnosis of COVID-19 is confirmed by patient self-administration of bilateral nasal swabbing for viral antigen or nucleic acid. Self-swabbing minimizes the risk of person-to-person transmission of respiratory droplets. The act of patient self-swabbing should be observed by a health care provider whenever possible to assure it is performed properly (CDC, 2020a).

COVID-19 Vaccines

Operation Warp Speed was an unprecedented response to the study of safety and efficacy of new vaccine platforms never before used in humans (Castells & Phillips, 2020). Two SARS-CoV-2 mRNA vaccines were authorized for emergency use in the United States in December of 2020, less than a year after the SARS-CoV-2 sequence was discovered (Castells & Phillips, 2020). Both vaccines require 2 doses for efficacy, the second dose of the Pfizer-BioNTech 21 days after the first dose, and the Moderna mRNA 28 days later. Early reports indicated the Pfizer-BioNTech vaccine had an anaphylaxis rate of 1 in 100,000 compared with a rate of 1 in 1,000,000 for other vaccines (Castells & Phillips, 2020). Ongoing efforts are needed by nurses and all health care workers to maintain a proactive response to support public confidence and reduce vaccine hesitancy. Anaphylaxis is a treatable reaction that requires early recognition and an appropriate and timely response (see Chapter 33). A VAERS form must be completed for any adverse reaction and can be submitted online (see the Resources section). Nurses should be vaccinated for COVID-19 and should advocate for all of their professional and personal contacts receiving the vaccine at the first available opportunity.

Nursing Management

Nursing management of the patient with COVID-19 mirrors that of medical management. The majority of patients with known or suspected mild COVID-19 may be managed on an outpatient basis within their homes, which conserves hospital resources and diminishes the likelihood of exposure to others, including health care workers (Kim & Gandhi, 2020). Few medications are used to either

treat COVID-19 or to mitigate its effects in patients with mild disease who are managed at home; thus, care is largely supportive. The nursing management of patients with mild COVID-19 mirrors that of other viral respiratory illnesses.

Patients with moderate or severe COVID-19 are most often managed in the hospital setting. Health care workers are at increased risk for acquiring COVID-19 and should wear complete PPE as discussed earlier in this chapter (CDC, 2020c). See Chapter 19 for further discussion of nursing management of the patient with mild, moderate, and severe COVID-19 infection. Supportive care for a patient, whether at home or in the hospital setting, requires very careful use of infection control measures and psychological support for the patient and family.

Early in the COVID-19 pandemic, important measures were recommended by the CDC to help mitigate the spread of SARS-CoV-2. Nurses should provide education to help patients and their families implement these measures to help slow viral transmission. One measure is to wear a mask with 2 or more layers of breathable fabric that snugly covers the nose and mouth; this type of mask should be worn in public places to help patients and families protect themselves and others (Prather et al., 2020). One study of mask usage reported that among 139 clients exposed to two symptomatic hair stylists with confirmed COVID-19, while both the stylists and the clients wore face masks, no symptomatic secondary cases were identified (Hendrix, Walde, Findley, et al., 2020). Another important practice is to 'socially distance' by remaining at least 6 feet apart from others and avoiding crowds. The nurse should also encourage frequent handwashing with at least 20 seconds of scrubbing, rinsing, and drying after washing (CDC, 2002). If handwashing is not possible, then hand sanitizer with at least 60% alcohol should be used.

Zika Virus

The Zika virus was first discovered as a pathogen in monkeys in the Zika Forest of Uganda in the 1940s; it was found to cause human disease in the 1950s. The epidemiologic pattern changed as the first large outbreak in humans did not occur until 2007 in Micronesia. The disease was not seen in the Western Hemisphere until July 2015, when a large outbreak began in Brazil. Within the next year, infections were noted in countries throughout the Americas and Pacific Islands (WHO, 2016).

The incubation period for Zika virus disease is estimated to be between 3 and 14 days (Krow-Lucal, Biggerstaff, & Staples, 2017). Among patients who are symptomatic, most have self-limiting illness of 2 to 7 days duration with mild fever, rash, headache, conjunctivitis, or joint and muscle pain. Zika has been associated with microcephaly and other congenital abnormalities in infants of some women infected with Zika during pregnancy. The virus can also cause Guillain–Barré syndrome, a condition with nerve and muscle weakness that often quickly progresses to a paralysis (WHO, 2016).

Zika is primarily transmitted through bites of infected mosquitos from the *Aedes* genus. Sustained outbreaks have been more common in tropical areas where these mosquitos thrive. The *Aedes* mosquito is also the carrier of other mosquito-

borne viruses such as dengue, chikungunya, and yellow fever. Unlike these other mosquito-borne diseases, Zika can also be transmitted through sexual transmission. This combination of transmission routes makes prevention efforts especially challenging. People can travel to epidemic areas, and later, as asymptomatic infected carriers, transmit the virus to their sexual partners. Because of the concern about congenital infection, women who are pregnant are advised to avoid travel to endemic areas and to use abstinence or safer sex methods if their sexual partners have traveled to such regions. Similarly, couples with exposure to areas where there is ongoing transmission are counseled in contraceptive options (CDC, 2020s).

West Nile Virus

The West Nile virus was first recognized in the 1930s in Africa and was first seen in humans in the United States in 1999. Those infected have a range of presentations. Approximately 20% of people who are infected have a mild disease called *West Nile fever*. These patients usually experience headache, fever, and a persistent fatigue that may continue for several months. In these patients, fewer than 1% of infections develop into more serious disease, which is characterized by severe neuroinvasive illness, meningitis, encephalitis, and paralysis or poliomyelitis. The mortality rate for people with neuroinvasive diseases is approximately 10% (CDC, 2020t).

The incubation period (i.e., from mosquito bite to onset of symptoms) is between 2 and 14 days. Currently, there is no treatment for West Nile virus infection. Medical and nursing management consists of fluid replacement, airway management, and supportive nursing care when meningitis or symptoms are present.

Birds are the natural reservoir for the virus, and since 1999, the population of infected birds in the United States has increased steadily. Mosquitoes become infected when feeding on birds and can transmit the virus to animals and humans. Human-to-human transmission of West Nile virus is very rare; however, transplacental mother-to-infant transmission and blood transfusion or organ transplant transmission have rarely occurred (CDC, 2020t).

Ebola Virus Disease

The first human outbreak of Ebola virus disease occurred in 1976. For decades, the virus maintained a pattern of sporadic outbreaks in remote African villages, followed by intervening periods without any recognized cases worldwide. In 2014, the virus broke this pattern and rampaged through the West African countries Liberia, Guinea, and Sierra Leone, with secondary cases in other countries in Africa, Europe, and the United States with approximately 28,600 cases (CDC, 2020u). Between 2017 and 2020, several significant outbreaks occurred in the Republic of the Congo, with an estimated 3400 cases (CDC, 2020u).

Pathophysiology

Ebola is spread through direct contact with blood or body fluids (urine, vomit, feces, saliva, sweat, semen, and breast milk) from the person who is ill from the virus and possibly from contact with semen of a man who has recovered from Ebola. It is not spread through air, water, or insect bite. In Africa, it may occasionally be spread by handling infected bats or infected wild animals that are sometimes hunted for food. Ebola virus is only detected in blood after the patient becomes symptomatic and viral levels rise significantly as the disease progresses (CDC, 2020u).

The incubation period from exposure to first symptoms ranges from 2 to 21 days. If there are no symptoms by 21 days after exposure, there is essentially no risk of developing Ebola. Patients are not contagious to others before symptoms occur. Thorough identification of Ebola contacts and careful symptom monitoring can prevent subsequent waves of transmission (CDC, 2020u).

Clinical Manifestations

The initial clinical manifestations include high fever, muscle aches, and fatigue. Between the third and fifth symptomatic day, the patient often develops severe diarrhea, abdominal pain, and vomiting. Patients are at great risk for severe dehydration at this point as many produce over 5 L of liquid stool per day. This stage can persist for a week or more, and many patients develop hemodynamic shock (see Chapter 11). Patients may also show increasing neurologic symptoms during that period, such as confusion, agitation, delirium, or encephalitis. Approximately 5% will develop bleeding or hemorrhage, a very poor prognostic indicator. Patients who do not die during the first 2 weeks of the disease are likely to survive (CDC, 2020u).

Medical Management

No therapies have been approved for Ebola, but two antiviral treatments are under investigation (CDC, 2020u). Treatment is largely supportive maintenance of the circulatory and respiratory systems. It is likely that the patient who is infected will need ventilator and dialysis support during the acute phase of illness (CDC, 2020u).

Ebola Vaccines

In late 2019, the FDA approved the first Ebola vaccine effective at reducing the incidence of the Zaire strain of Ebola. The vaccine is approved for adults 18 years and older. Patient education is important as potential recipients should be informed that the vaccine has not shown protection for strains other than the Zaire strain, and adverse reactions (including anaphylaxis) have been reported (U.S. FDA, 2019).

Nursing Management

Nursing management mirrors that of medical management and is largely supportive. Supportive care for a patient with such a devastating disease requires very careful use of infection control measures and psychological support for the patient and family.

Health care workers are at increased risk for acquiring Ebola because they may have contact with body fluids or equipment contaminated from exposure to body fluids. Because patients with Ebola emit abundant viral particles in body fluids, especially in vomit and diarrhea, the patient should be promptly isolated in a private room, away from other patients. Health care workers should wear complete PPE. Systems must be set up so that an observer guides each worker to meticulously don PPE before direct contact with a patient who is infected to ensure that all equipment is worn correctly. After a worker has direct contact with a patient who is infected, an observer should direct careful doffing (removal) of PPE to ensure that no exposure occurs in the process. (See Chart 66-3 and Resources section for more information on donning and doffing PPE.) Equipment used for the patient with Ebola virus should be used solely for that patient and should be disposed of after use. If equipment must be reused, it should be sterilized or scrupulously cleaned with a bleach-based solution before reuse. Care for the patient with Ebola requires hospitals and transport systems to develop plans to coordinate staffing, supply maintenance, handling of waste, and communication with the public (WHO, 2020). Because care for Ebola patients is so complex, during a time of increased risks, communities are encouraged to assign some facilities as the designated facilities for Ebola care. Other facilities will have the responsibility to carefully screen patients with suspected Ebola and to cautiously transport them to a designated Ebola care facility.

Legionnaires Disease

Legionnaires disease is a multisystem illness that usually includes pneumonia and is caused by the gram-negative bacterium *Legionella pneumophila.* Named after an outbreak among people attending a convention of the American Legion in 1976, its potential to cause outbreaks has been demonstrated repeatedly in hospitals and other settings. It continues to be considered an emerging infectious disease because there are new patterns in recent years. There are approximately 5000 new cases each year (CDC, 2020v).

Legionella organisms are found in many man-made and naturally occurring water sources. Although the organisms may initially be introduced to the plumbing system in low numbers, growth is enhanced by water storage, sediment, temperatures ranging from 25°C to 42°C (77°F to 108°F), and certain amoebae frequently present in water that can support intracellular growth of legionellae. Because incidence appears to increase in the summer and autumn months, vacation-related exposure to hotel or cruise ship plumbing and air-conditioning systems, whirlpool spas, and decorative fountains may be the causative risk (Soda, Barskey, Shah, et al., 2017).

Pathophysiology

Legionella pneumophila is transmitted by the aerosolized route from an environmental source to a person's respiratory tract. In hospitals, patients may be exposed to aerosols created by cooling towers, water exposure from in-room plumbing, and respiratory therapy equipment. Person-to-person transmission does not occur. Because underlying medical conditions can increase host susceptibility and subsequent severity of disease, and because hospital plumbing systems are often very complex, outbreaks occur in hospitals more frequently than at other centers within the community. The mortality rate for Legionnaires disease may be as high as 10%; for those who acquire the disease while in a health care facility, the rate is approximately 25% (Soda et al., 2017).

Risk Factors

Risk factors for *Legionella* infection include diseases that lead to severe immunosuppression, such as AIDS, hematologic malignancy, end-stage kidney disease, or the use of immunosuppressive agents. Other factors associated with increased risk include diabetes, smoking, exposure to whirlpool spas, and recent travel (CDC, 2020v; Soda et al., 2017).

Clinical Manifestations

The lungs are the principal organs of infection; however, other organs may also be involved. The incubation period ranges from 2 to 10 days. Early symptoms may include malaise, myalgias, headache, and dry cough. The patient develops increasing pulmonary symptoms, including productive cough, dyspnea, and chest pain. Patients are usually febrile, and body temperatures may reach or exceed 39.4°C (103°F). Diarrhea and other gastrointestinal symptoms are common. In severe cases, multiorgan involvement and failure may follow (CDC, 2020v).

Assessment and Diagnostic Findings

The diagnostic approach generally involves using information obtained from the history, physical examination, x-rays, laboratory findings, and assessment of therapeutic effectiveness. Chest x-ray abnormalities may vary in severity and in location within the lungs. Laboratory tests available for the diagnosis of *Legionella* include culture or tests that detect either antigen or antibody. The most frequently used test is the urinary antigen. The greatest limitation of the test is that it detects only one subgroup of one of the several species of *Legionella.* The CDC recommends using multiple tests when Legionnaires disease is suspected because none of the tests is completely accurate (CDC, 2020v).

Medical Management

The antibiotic agents of choice are azithromycin or a fluoroquinolone such as moxifloxacin. The antibiotic doxycycline may also be used (CDC, 2020v).

Nursing Management

The nursing management described for the patient with any pneumonia (see Chapter 19) should form the basis of care for the patient with *Legionella* pneumonia. Isolation is not required because *Legionella* is not transmitted between humans. Legionellosis should be reported to public health authorities. When the patient has acquired the infection in a health care facility, water sampling should be performed to determine if the water supply is contaminated and to verify eradication after water treatment.

Pertussis

Pertussis, also known as whooping cough, a common childhood disease in the pre-vaccine era, is an example of a disease that has re-emerged. Incidence rates declined until the 1980s, when rates for all age groups began to increase steadily for the next three decades, peaking in 2012 and plateauing in the following years (CDC, 2020w).

Pertussis is caused by the bacterium *Bordetella pertussis*. It is highly contagious, and patients usually present to health care professionals with a paroxysmal (sudden) cough that is accompanied by a characteristic whoop—a high-pitched noise heard when inhaling.

Pathophysiology

B. pertussis is transmitted by droplets. The bacteria easily attach to pharyngeal epithelial cells, where they release a number of antigens, toxins, and other substances that trigger the immune system. Because most of the disease manifestations are caused by this immune reaction, patients are usually contagious only early in the disease (when the bacteria are still present) and not during the protracted period of cough (when the immune reaction is causing the pathology).

Clinical Manifestations

Pertussis causes a range of respiratory symptoms, with cough being the most frequent. It is generally most severe for infants who have not yet been vaccinated. Pneumonia is the most common consequence of infection, but the disease can also lead to seizures, encephalopathy, and, rarely, death. People who have been vaccinated seldom have severe disease (CDC, 2020w).

Assessment and Diagnostic Findings

Most diagnoses of pertussis are made, at least initially, without laboratory confirmation. The clinical case definition, unless there is a preexisting condition to

explain the symptoms, is a new cough lasting at least 2 weeks with inspiratory whoop or vomiting after cough. Laboratory confirmation can be made by clinical culture or by polymerase chain reaction assay for *B. pertussis*. Serologic testing, although less reliable, can also strengthen the diagnostic suspicion. The best source for a culture is a nasopharyngeal specimen obtained by swab or aspirate (CDC, 2020w).

Medical Management

Early treatment for pertussis is important to prevent complications. The antibiotic agents of choice are azithromycin, erythromycin, or clarithromycin (Comerford & Durkin, 2020). The antibiotic trimethoprim sulfamethoxazole may also be used (CDC, 2020w). Close contacts of a patient with proven or suspected pertussis should receive prophylaxis with one of these agents to reduce the risk of disease.

Nursing Management

Patients who are hospitalized with pertussis should be isolated in droplet precautions until they have received 5 days of appropriate therapy. Household members should receive antimicrobial prophylaxis and should be advised to report any symptoms of an upper respiratory infection.

Immunization is an important element of pertussis prevention. There are two acellular formulations of pertussis vaccine; both are combinations of diphtheria and pertussis. The pediatric formula, called DTaP, is designed for children between 2 months and 6 years. The teen and adult formulation, called Tdap, contains a decreased amount of the diphtheria element. Tdap should be given to children over 11 years, all adults every 10 years, and pregnant women early in pregnancy (CDC, 2020w). All adults who are around infants under 12 months on a regular basis should be vaccinated to reduce the risk of transmitting pertussis.

Travel and Immigration

Travel, trade, migration, and wars have led to many epidemics throughout history. The potential for epidemics is greatest when travelers and immigrants introduce microorganisms to which the host population has little or no immunity. Examples of important epidemics in the Western Hemisphere have included yellow fever, malaria, hookworm, leprosy, smallpox, measles, mumps, and syphilis. The COVID-19 pandemic demonstrates how global travel contributes to a rapidly occurring epidemic.

In the United States, an infrastructure with enforced vaccination, clean water, and insect and rodent control decreases the risk that epidemics will progress even when travel may introduce exotic microorganisms. The CDC maintains an active surveillance system to monitor and halt the incidence of many diseases prospectively. However, the 2016 experience with Zika virus reinforced knowledge

that insect transmission can lead to significant outbreaks. Insects can infest cargo; in addition, travelers who may have been exposed abroad to insect-borne infections may then serve as reservoirs for further disease spread. For example, concern grows that vector-borne diseases such as dengue and malaria may increase in the United States as mosquitoes can transmit disease locally when a reservoir of infected humans is established.

Immigration and Acquired Immune Deficiency Syndrome

The fact that AIDS reached pandemic proportions less than a decade after its recognition attests to the efficiency of world travel in spreading disease. Such rapid transmission rates are especially dramatic because HIV essentially requires intimate contact between two people through sexual activity or sharing blood through needles (see Chapter 32).

Immigration and Tuberculosis

Immigration has long been an important influence in the epidemiology of TB in the United States. In 2017, the year with the lowest total of new TB cases in the United States since the 1950s, 70% of those reported were individuals who were foreign-born. The incidence among those who are foreign-born has been increasing steadily (CDC, 2020x). Multi-drug resistance is also more prevalent in cases among those who are foreign-born because the bacille Calmette–Guérin (BCG) vaccine is used in many countries. After receiving BCG, people often have some degree of tuberculin skin test reactivity for a prolonged time, thus making the diagnosis of TB infection challenging.

The QuantiFERON-TB Gold (QFT-G) test is an enzyme-linked immunosorbent assay (ELISA) that detects the release of interferon-gamma by white blood cells when the blood of a patient with TB is incubated with peptides similar to those in *M. tuberculosis.* The results of the QFT-G test are available in less than 24 hours and are not affected by prior vaccination with BCG. See Chapter 19 for more detailed discussion.

Immigration and Vector-Borne Diseases

Malaria and dengue are diseases that cause significant morbidity and mortality throughout the developing world. These diseases may be introduced to the United States via travel, immigration, or commerce with approximately 2000 cases each year (CDC, 2020y). Malaria and dengue are caused by microorganisms that can be spread to humans by mosquitoes in the United States that thrive in tropical zones and breed in stagnant water sources. Although malaria was eradicated in the United States in the 1950s, limited local outbreaks have occurred regularly when mosquitoes acquire the bacteria from a person recently traveling from an area in which malaria is endemic and transmit it to a small number of people. Similarly, an

increase of dengue virus in the Caribbean has caused concern that outbreaks may occur in the United States (CDC, 2020y).

CRITICAL THINKING EXERCISES

1 ebp The community clinic where you work has had an increase in STIs in the last 6 months. Identify how STIs occur. What evidence-based strategies could be used in the community to decrease the incidence of STIs? Identify the criteria used to evaluate the strength of the evidence for the practices you identify.

2 pq You are a home health nurse making a home visit for a 75-year-old patient with multiple medical conditions who has recently been discharged from the hospital following an ICU stay of 10 days for COVID-19. What are your priorities for providing information about infection prevention to the patient, the family, and the caregiver?

3 ipc You are serving on a committee to address pandemic preparation. What members of the interprofessional care team should be included in this committee? What methods should the team offer to address possible shortages of PPE? What methods could be used to provide prophylaxis or vaccines, if they are available?

67 Emergency Nursing

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe emergency care as a collaborative, holistic approach that ideally includes the patient, the family, and significant others.
2. Identify the priorities of care for the patient with an emergency disorder, particularly the patient with multiple system injuries.
3. Compare and contrast the emergency management of patients with heat stroke, frostbite, and hypothermia.
4. Specify the similarities and differences of the emergency management of patients with swallowed or inhaled poisons, skin contamination, and food poisoning.
5. Explain the emergency management of patients with drug overdose, those with acute alcohol intoxication, those who have been sexually assaulted, and those who have been victims of human trafficking.
6. Differentiate between the emergency care of patients who are overactive, those who are violent, those who are depressed, and those who are suicidal.

NURSING CONCEPTS

Addiction
Assessment
Behaviors
Medical Emergencies
Oxygenation
Thermoregulation
Violence

GLOSSARY

antivenin: antitoxin manufactured from venom of poisonous snakes to assist the patient's immune system response to envenomation

carboxyhemoglobin: hemoglobin that is bound to carbon monoxide and therefore is unable to bind with oxygen, resulting in hypoxemia

corrosive poison: alkaline or acidic agent; causes tissue destruction after contact

cricothyroidotomy: surgical opening of the cricothyroid membrane to obtain an airway that is maintained with a tracheostomy or endotracheal tube

envenomation: injection of a poisonous material by sting, spine, bite, or other means

fasciotomy: surgical incision of the extremity to the level of the fascia to relieve pressure and restore neurovascular function to the extremity

multiple trauma: trauma caused by a single catastrophic event that causes life-threatening injuries to at least two distinct organs or organ systems

primary survey: an assessment of the patient triaged to the emergent or resuscitation category that focuses on stabilizing life-threatening conditions; uses the mnemonic ABCDE, which stands for *A*irway, *B*reathing, *C*irculation, *D*isability, and *E*xposure

rhabdomyolysis: a toxic syndrome caused by widespread injury to skeletal muscle, resulting in myoglobinuria and acute kidney injury

secondary survey: an assessment of the patient triaged to the emergent or resuscitation category that commences after the primary survey is completed and life-threatening insults addressed; includes obtaining vital signs, completing a head-to-toe examination, and obtaining the patient's pertinent medical-surgical history, including the history of the current event

sentinel event: an unanticipated event that results in patient harm

triage: process of assessing patients to determine management priorities

The term *emergency management* traditionally refers to care given to patients with urgent and critical needs. However, because many people lack access to health care, the emergency department (ED) is used frequently for nonurgent problems. Therefore, the philosophy of emergency management has broadened to include the concept that an emergency is whatever the patient or the family considers it to be.

The emergency nurse has had specialized education, training, and expertise in assessing and identifying patients' health problems in crisis situations. In addition, the emergency nurse establishes priorities, monitors, and continuously assesses patients who are acutely ill and injured, supports and attends to families, supervises allied health personnel, and educates patients and families within a time-limited, high-pressured care environment. Nursing interventions are accomplished interdependently, in consultation with or under the direction of a physician or advanced practitioner such as a nurse practitioner or physician assistant. The roles of nursing and medicine are complementary in an emergency situation. Appropriate nursing and medical interventions are anticipated based on assessment data. Members of the ED staff work as a team in performing the highly technical, hands-on skills required to care for patients in emergency situations (Emergency Nurses Association [ENA], 2020a).

People seek emergency care for serious life-threatening conditions, such as cardiac arrhythmias, acute coronary syndrome, acute heart failure, pulmonary edema, and stroke. Priorities for managing these cardiac and other conditions are discussed in Chapters 22, 23, 25, and 62. Emergency management of trauma and conditions not found elsewhere in this book are discussed in this chapter. Facts about ED visits in the United States are presented in Chart 67-1.

Chart 67-1

Facts About Emergency Department Visits—2017

In 2017, there were 139 million visits to emergency departments (EDs); 40 million were as a result of an injury. Additional relevant statistics included the following:

- The most common reasons for ED visits were abdominal pain, chest pain, cough, and fever.
- Most patients had health insurance, with only 16% of patients without insurance.
- Approximately 14.5% of patients arrived at the ED by ambulance.
- 14.5 million visits resulted in admission; of these, 2 million required admission to an intensive care unit (ICU).
- Injuries and poisonings accounted for 18.9% of all ED visits.
- The leading causes of injuries were unintentional, totaling 68.2% of injury admissions, with falls and motor vehicle collisions making up 32% of these.
- Nearly 40% of patients were seen by a provider in less than 15 minutes after arrival to the ED.

Adapted from Rui, P., & Kang, K. (2017). National Hospital Ambulatory Medical Care Survey: 2017 emergency department summary tables. National Center for Health Statistics. Retrieved on 4/20/2020 at: www.cdc.gov/nchs/data/nhamcs/web_tables/2017_ed_web_tables-508.pdf

ISSUES IN EMERGENCY NURSING CARE

Emergency nursing is demanding because of the diversity of conditions and situations that present unique challenges. These challenges include legal issues, occupational health and safety risks for ED staff, and the challenge of providing holistic care in the context of a fast-paced, technology-driven environment in which serious illness and death are encountered on a daily basis. Another dimension of emergency nursing is providing nursing care in disasters. Disasters result in mass casualty incidents that ensue after natural disasters (e.g., earthquakes, tsunamis); from exposure to pathogens during outbreaks, epidemics, and pandemics; from human-made unintentional disasters (e.g., bridge collapse, train crash); or from weapons of terror (e.g., blast, biologic, chemical, radiologic terroristic events) (see Chapter 68).

Documentation of Consent and Privacy

Consent to examine and treat the patient is part of the ED record. The patient needs to give consent for invasive procedures (e.g., angiography, lumbar puncture) unless they

are unconscious or in a critical condition and unable to make decisions. If the patient is unconscious and brought to the ED without family or friends, this fact must be documented. Monitoring of the patient's condition, as well as all instituted treatments and the times at which they were performed, must be documented. After treatment, a notation is made on the record about the patient's condition, response to the treatment, and condition at discharge or transfer and about instructions given to the patient and family for follow-up care.

The patient is also provided with a statement of the privacy policy of the health care agency, according to federal law. Patients involved in violent events can be provided with an alias, and access to the electronic health record (EHR) is limited to protect the privacy of the patient. A patient may also request extra privacy by limiting access to their room and by choosing not to receive phone calls, mail, flowers, other gifts, or certain visitors. These practices relate to the federally mandated privacy policy stipulated in the Health Insurance Portability and Accountability Act (HIPAA).

According to the Emergency Medical Treatment and Active Labor Act (EMTALA), every ED with a Medicare provider agreement must perform a medical screening examination on all patients arriving with an emergency medical complaint if their acute signs and symptoms could result in serious injury or death if left untreated. EDs are also required to provide treatment aimed at stabilizing each patient's condition. If the patient must be transferred to another facility, the patient's consent for transfer should be obtained, if possible. In addition, acceptance by the receiving facility and primary provider must be obtained, and an appropriate method of transfer for the patient should be secured. Documentation of assessment and treatment must be sent with the patient upon transfer (ENA, 2020a).

Limiting Exposure to Health Risks

ED staff are at an increased risk for exposure to communicable diseases through blood, respiratory droplets, or other body fluids. This risk for exposure to any communicable disease is further compounded because of the common use of a multitude of invasive treatments for patients in the ED (e.g., suturing, wound débridement, aerosol generating procedures). This increased risk had been apparent for many years because of increasing numbers of people infected with hepatitis, human immune deficiency virus (HIV), and tuberculosis; however, these risks became magnified because of concerns of infecting ED staff with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus responsible for the pandemic of coronavirus disease 2019 (COVID-19); see following discussion.

The potential for exposure to highly contagious organisms, hazardous chemicals or gases, and radiation related to acts of terrorism or natural or human-engineered disasters presents additional risks to ED staff. See Chapter 68 for information about decontamination procedures.

Quality and Safety Nursing Alert

To limit the risk of exposure to airborne diseases, early identification and strict adherence to transmission-based precautions for patients who are potentially infected and contagious is crucial.

COVID-19 Considerations

In response to the COVID-19 pandemic, all emergency health care providers must adhere strictly to standard precautions for minimizing exposure, because not all patients who are infected with SARS-CoV-2 are symptomatic. Universal screening measures should be implemented upon arrival to the ED for all ED staff, patients, and visitors/family members (assuming that their presence in the ED is not prohibited). Patients and visitors/family members should wear their own mask or face coverings as tolerated, and if they do not have them, they should be provided upon their arrival to the ED. ED staff should wear facemasks at all times while in the hospital. In general, cloth masks, bandanas, and scarves are not considered suitable masks for use by health care workers (ENA, 2020b). Health care workers, patients, and visitors all need to be educated on the importance of hand hygiene and social distancing (Centers for Disease Control and Prevention [CDC], 2020a).

The ENA (2020b) issued a statement that all emergency nurses providing direct care for patients with suspected or confirmed COVID-19 must be provided the appropriate level of personal protective equipment (PPE) to safely care for these patients. The PPE provided to emergency nurses in this situation should meet standards set by the National Institute for Occupational Safety and Health (NIOSH) (see Chapter 66 for further discussion of PPE); N95 respirators, which include a facemask that seals firmly to the face and that filters at least 95% of airborne particles, are recommended over other less effective masks or face coverings (CDC, 2020b).

Violence in the Emergency Department

Not only do ED staff members encounter patients who may be violent because of the effects of substance use disorder (SUD), injury, or other emergencies, they may also encounter other violent situations. Patients and families waiting for assistance may be emotionally volatile. Often, ED waiting rooms are the sites where feelings of dissatisfaction, fear, and anger are channeled violently. EDs assign security officers to the area and have installed silent alarm systems or metal detectors to identify weapons in order to protect patients, families, and staff. Safety is the first priority.

Patients and family members under the influence of illicit drugs or alcohol, or who may have psychiatric disorders, including delirium or dementia, or who may be influenced by social situations such as gang membership, are at risk for committing a violent act, whether intentional or not (CDC, 2019a). The environment of the ED, including being subjected to long wait times and at times crowded conditions, may also increase their risk of committing violent events. Physical threats are most often accompanied by verbal abuse, which is the most common type of violence (Copeland & Henry, 2017). Although not a typical occurrence, a patient or family member may come to the ED armed. To avoid angry confrontations, members of gangs and families who are feuding need to be separated in the ED, in the waiting room, and later in the inpatient nursing unit. Nurses and other personnel must be prepared to deal with these circumstances. The ED should be locked against entry if security is questionable.

Patients who are violent or potentially violent must be vigilantly monitored by the ED staff. Care must be taken to avoid injury. Patients from prison and those who are under guard need to be handcuffed to the bed and appropriately assessed to ensure the

safety of hospital staff and other patients. The emergency nurse must understand how to employ safe use of restraints. The Joint Commission has strict standards regarding documentation of the reason, monitoring for safety, and ensuring the dignity of the patient who is restrained. Precautions to be taken to avoid injury include the following situations (ENA 2020a; Ziaei, Massoudifar, Rajabpour-Sanati, et al., 2018):

- For prisoners, the hand or ankle restraint (handcuff) is never released, and a guard is always present in the room.
- A mask can be placed on the patient to prevent spitting or biting, if a mask is not already being used.
- Nonrestraint techniques should be tried when possible—for example, talking with the patient, minimizing environmental stimulation.
- Physical restraints are used on any patient who is violent only as needed and, if used, should be humanely and professionally given; nonetheless, the staff should be cognizant that the patient could head-butt, even if restrained.
- Distance should be maintained from the patient to avoid grabbing; staff should not wear items that can be grabbed by the patient, such as dangling jewelry and stethoscopes. Furthermore, distance should be maintained between the patient and the door so that an escape route for the staff member is preserved.
- Objects should not be left within patient reach; even an intravenous (IV) line spike can become a tool of violence if the patient is determined.
- Courses on safety (de-escalation and physical restraint techniques) assist the staff with preparing for various violent situations.

In the case of gunfire in the ED, self-protection is a priority. There is no advantage to protecting others if health care providers are injured. Security officers and police must gain control of the situation first, and then care is provided to the injured.

Providing Holistic Care

Patients and families experiencing sudden injury or illness are often overwhelmed by anxiety because they have not had time to adapt to the crisis. They experience real and terrifying fear of death, mutilation, immobilization, and other assaults on their personal identity and bodily integrity. When confronted with trauma, severe disfigurement, severe illness, or sudden death, the family experiences several stages of crisis. The stages begin with anxiety and progress through denial, remorse and guilt, anger, grief, and reconciliation. The initial goal for the patient and family is anxiety reduction, a prerequisite to effective and appropriate coping. During this stressful time, safety is of primary importance. Close observation and preplanning are essential and security personnel are stationed nearby in the event that a patient or family member responds to stress with physical violence.

Assessment of the patient and family's psychological function includes evaluating emotional expression, degree of anxiety, and cognitive functioning. Possible nursing diagnoses include:

- Anxiety or death anxiety associated with uncertain potential outcomes of the illness or trauma
- Difficulty coping associated with acute situational crisis

Possible nursing diagnoses for the family include:

- Family grief
- Interrupted family process
- Impaired or risk for impaired family coping associated with acute situational crises

Patient-Focused Interventions

Clinicians caring for the patient should act confidently and competently to relieve anxiety and promote a sense of security. Explanations should be given that the patient can understand. Human contact and reassuring words reduce the panic of the person who is severely injured or ill and aid in dispelling fear of the unknown.

The patient who is unconscious should be treated as if conscious—that is, the patient should be touched, called by name, and provided an explanation of every procedure that is performed. As the patient regains consciousness, the nurse should orient the patient by stating their name, the date, and the location. This basic information should be provided repeatedly, as needed, in a reassuring way.

Ensuring patient safety is a major focus in clinical practice settings. Some of the most common **sentinel events** (unanticipated events that result in patient harm) in the ED include delays to care and medication errors. Common root causes for these sentinel events revolve around nurse staffing patterns, patient volume, and specialty availability. Solutions to patient safety issues in the ED include ensuring optimal nurse staffing, pharmacy presence, and rapid diagnostics turnaround times to minimize wait time to diagnosis and fostering teamwork and support by leadership. All errors should be reported and investigated even if a patient was not harmed. In this way, future injury or death may be avoided (The Joint Commission, 2020).

Family-Focused Interventions

The family is kept informed about where the patient is, how they are doing, and the care that is being given. Encouraging family members to stay with the patient, when possible, also helps alleviate their anxieties. In many facilities, family presence during resuscitation is permitted to assist the family to cope through this difficult time. Many family members respond very well to this approach. Research has indicated that families view emergency professionals favorably when a family member was resuscitated. They view their role as supportive and protective of the patient. Allowing family presence in the critical care areas of the hospital, whenever possible, enhances the family role and builds trust in the caregivers (Toronto & LaRocco, 2019). The presence of a family facilitator, who is trained to provide support to family members, is vital to the success of a family presence program (ENA, 2017). Additional interventions are based on the assessment of the stage of crisis that the family is experiencing. Measures to help family members cope with sudden death are presented in Chart 67-2.

Chart 67-2

Helping Family Members Cope with Sudden Death

When able to do so, the nurse takes the following actions:

- Take the family to a private place.
- Talk to the family together so that they can grieve together and hear the information given together.
- Reassure the family that everything possible was done; inform them of the treatment rendered.
- Avoid using euphemisms such as "passed on." Show the family that you care by touching, offering coffee, water, and the services of a chaplain.
- Encourage family members to support each other and to express emotions freely (grief, loss, anger, helplessness, tears, disbelief).
- Avoid giving sedation to family members; this may mask or delay the grieving process, which is necessary to achieve emotional equilibrium and to prevent prolonged depression.
- Encourage the family to view the body if they wish; this action helps to integrate the loss. Cover disfigured and injured areas before the family sees the body. Go with the family and do not leave them alone. Show acceptance by touching the body to give the family "permission" to touch.
- Spend time with the family, listening to them and identifying any needs that they may have for which the nursing staff can be helpful.
- Allow family members to talk about the deceased and what the person meant to them; this permits ventilation of feelings of loss. Encourage the family to talk about events preceding admission to the emergency department. Do not challenge initial feelings of anger or denial.
- Avoid volunteering unnecessary information (e.g., the patient was drinking).

Note: These interventions might not be advisable or permitted if "social distancing" prohibitions are in place, such as those prohibitions implemented to thwart transmission of severe acute respiratory coronavirus 2 (SARS-CoV-2) infection during the coronavirus disease (COVID-19) pandemic.

Anxiety and Denial

During these crises, family members are encouraged to recognize and talk about their feelings of anxiety. Asking questions is encouraged. Honest answers given at the level of the family's understanding must be provided. Although denial is an ego-defense mechanism that protects individuals from recognizing painful and disturbing aspects of reality, prolonged denial is not encouraged or supported. The family must be prepared for the reality of what has happened and what may come (Ocak & Avsarogullari, 2019).

Remorse and Guilt

Expressions of remorse and guilt are common, with family members accusing themselves (or each other) of negligence or minor omissions. Family members are urged to verbalize their feelings to help them cope appropriately.

Anger

Expressions of anger, common in crisis situations, are a way of handling anxiety and fear. Anger is frequently directed by the family at the patient, but it is also often expressed toward the physician, the nurse, or admitting personnel. The therapeutic

approach is to allow the anger to be expressed and to assist the family members to identify their feelings of frustration.

Grief

Grief is a complex emotional response to anticipated or actual loss. The key nursing intervention is to help family members work through their grief and to support their coping mechanisms, letting them know that it is normal and acceptable for them to cry, feel pain, and express loss. The hospital chaplain and social services staff serve as invaluable members of the team when assisting families to work through their grief (see Chapter 13).

Caring for Emergency Personnel

Concerted efforts have been made to focus on the needs of the ED staff, especially after serious and stressful events (ENA, 2020a). Events can range from a local trauma case involving children; to treating someone known to the emergency worker, such as a colleague or family member; to a more complex natural disaster or mass casualty incident. It is important to remember that all staff members may not necessarily respond in the same way; an event that is stressful to one person may not be as stressful to another. Compassion fatigue may result from continuous exposure to suffering and injury, and energy is expended on a daily basis. Fatigue occurs when the affected staff members cannot replenish energy stores (Schmidt & Haglund, 2017). In addition, because stress is a daily occurrence in the ED, staff may not recognize the personal effect of any one event or the cumulative effect of day-to-day crisis interventions. ED leadership should be aware of staff coping patterns and support systems, patterns of interactions between staff members, staff members' health problems, including addiction, and appropriately assist with identifying behaviors caused by workplace stress. The availability of nonjudgmental counseling is essential to promoting a healthy staff.

After serious events, critical incident stress management (CISM) is useful to critique individual and group performance and to facilitate healthy coping. Optimally, this consists of three steps: defusing, debriefing, and follow-up. Defusing occurs immediately after the critical incident. During this session, affected staff are encouraged to discuss their feelings about the incident, are reassured that negative reactions and feelings are normal but that these diminish over time, and are given contact information so that they may talk to someone if they have disturbing symptoms (e.g., sleeplessness, excessive worry). Debriefing typically occurs 1 to 10 days after the critical incident. Debriefing sessions follow a format similar to the initial defusing session; however, during these sessions, participating staff are encouraged to discuss their feelings about the incident and are again reassured that their negative reactions and feelings are normal and that their negative feelings will diminish over time. At the end of these sessions, participants should have a feeling of closure and be able to resume their professional roles at an emotional level commensurate to that prior to the critical incident. Some staff may require further professional follow-up, however. Follow-up may occur after the debriefing session is completed for those participants who have persistent negative symptoms and may consist of continued individual or group counseling and therapy (Schmidt & Haglund, 2017).

COVID-19 Considerations

Holistic, patient-centered care remains a top priority in EDs, even during disaster situations such as the COVID-19 pandemic. It is also a top priority that emergency nurses have the mechanisms and support to properly manage their heightened stress during such situations. Assuring holistic care of patients and families and supporting the emotional well-being of emergency staff pose unique challenges during such disasters as the COVID-19 pandemic.

In particular, regulations and mitigation strategies enforced in response to the COVID-19 pandemic prohibit family and visitor presence during hospitalizations in geographic regions experiencing an upswing in confirmed cases in order to keep patients, family members, and health care workers safe (Hart, Turnbull, Oppenheim, et al., 2020). Family presence and visitation policies are adapted in efforts to maintain open communication and family involvement in patient care. These adaptive strategies rely heavily on technology, which include the use of smartphones and computers, and require stable Internet connection and technologic literacy. Barriers exist for patients and families who either lack technologic literacy or who come from socioeconomically disadvantaged backgrounds, which preclude their ability to be able to tap into engaging in virtual conversations (Hart et al., 2020).

During these difficult times, ED staff are encouraged to develop a communication plan with family members, designating one person as the point of contact, ensuring that contact person has adequate access to technology, and identifying and eliminating any barriers to effective communication. Videoconferencing can be used when possible, particularly during end-of-life situations (Hart et al., 2020). The use of support teams that includes pastoral care, palliative care, and behavioral health should be mobilized to assist in the grieving process (Hart et al., 2020).

The emotional burden experienced by emergency nurses on the frontlines of the COVID-19 pandemic has been reported to be greatly magnified. Emergency nurses reportedly experienced fear as they faced a shortage of PPE, emotional and physical exhaustion, and ongoing stress. In some cases, nurses were the only persons physically present with patients who were severely ill and provided the only source of distant communication between patients and their family members. Confronted with not being able to provide the care for patients as they would have done under nonpandemic conditions, many emergency nurses experienced moral distress. Moral distress can be disruptive to emotional health; symptoms may include “self-criticism, intense feelings of shame, guilt, or disgust and may contribute to depression or post-traumatic stress disorder” (American Psychiatric Nurses Association, 2020, p. 1). Although the ultimate long-term impact of COVID-19 on the health of emergency nurses is not known at this time, supportive strategies must be implemented in order to preserve the health care workforce that has experienced severe stress as a consequence of COVID-19 (The Joint Commission, 2020).

EMERGENCY NURSING AND THE CONTINUUM OF CARE

A key principle underlying emergency care is that the patient is rapidly assessed, treated, and referred to the appropriate setting for ongoing care. This makes the ED a temporary

point on the continuum of care. In 2017, only 10.4% of patients who received care in an ED in the United States were admitted to the hospital, which means emergency nurses must plan and facilitate the patient's safe discharge and follow-up care in the home, community, and the transitional care environment (CDC, 2017a).

Discharge Planning

Before discharge, instructions for continuing care are given to the patient and to the family or significant others, if possible. A variety of formats are used including verbal, written, or video instructions; research findings suggest that video instructions are well received by patients and family members (Wilkin, 2020). Many EDs have preprinted standard instruction sheets for the more common conditions (e.g., concussion), which can then be individualized. Discharge instructions should be available in commonly used languages. A language interpreter should be used as necessary to provide instructions in any format.

Instructions should include information about prescribed medications, treatments, diet, activity, and when to contact a health care provider or schedule follow-up appointments. Discharge planning is the "teachable moment" for the patient, providing the opportunity to present injury prevention or smoking cessation strategies, alcohol counseling opportunities, and more. It is imperative that instructions are written legibly, use simple language, and are clear in their important points. When providing discharge instructions, the nurse also considers any special needs the patient may have related to hearing or visual impairments. Alternative formats of instruction (e.g., large print, Braille, audiotape, online videoclips) should be available to meet the needs of patients with hearing or visual impairments.

Community and Transitional Services

Before discharge, some patients require the services of a social worker to help them meet continuing health care needs. Home health care resources may be contacted before discharge to arrange services. This is particularly important for patients who may need assistance, such as those who are older adults or those with disability. Identifying continuing health care needs and making arrangements for meeting these needs can prevent return visits to the ED or readmission to the hospital.

For patients who are returning to long-term care facilities and for those who already rely on community agencies for continuing health care, communication about the patient's condition and any changes in health care needs that have occurred must be provided to the appropriate facilities or agencies. This communication is essential to promote continuity of care and to ensure ongoing care that meets the patient's changing health care needs.

Many patients who utilize EDs have health problems that are nonurgent. Moreover, some patients return repeatedly to the ED with nonurgent problems (ENA, 2019). It is posited that patients who present to the ED with nonurgent problems do so because there is a dearth of outpatient health care resources to fill their needs. In order to fill these gaps, some areas of the United States, particularly rural areas, are offering mobile integrated health-community paramedicine programs. Emergency medical system (EMS) personnel provide in-home visits, without emergency calls, to identify needs and

provide education and in-home care. If necessary, they can also transport patients to the ED. These programs have decreased unnecessary EMS calls (ENA, 2019).

Gerontologic Considerations

The ED is a common point of entry into the health care system for patients 65 years and older. The CDC (2017b) reports that 32% of ED visits by patients older than 65 years resulted in hospital admission. As age increases, the percentage of admissions increases. Of these admissions, 17% were related to trauma, primarily falls (CDC, 2017b). Older adult patients typically arrive with one or more presenting conditions. Nonspecific symptoms, such as weakness and fatigue, episodes of falling, incontinence, and change in mental status, may be manifestations of acute, potentially life-threatening illness in the older person. Emergencies in this age group may be more difficult to manage because older adult patients may have an atypical presentation, an altered response to treatment, a greater risk of developing complications, or a combination of these factors.

The older adult patient may perceive the emergency as a crisis signaling the end of an independent lifestyle or even death. The nurse should give attention to the patient's feelings of anxiety and fear (Cortez, 2018).

The older adult patient may have limited sources of social and financial support during times of crises. The nurse should assess the psychosocial resources of the patient (and of the caregiver, if necessary) and anticipate discharge needs. Referrals for support services (e.g., to the social service department or a gerontologic nurse specialist) may be necessary.

Obesity Considerations

The growing rate of obesity in the United States has implications for treating patients with obesity within the ED, in terms of stocking appropriately sized equipment, gowns, and stretchers; ensuring that equipment (e.g., computed tomography [CT] scanners) is able to handle a greater weight capacity; and recognizing specific disorders and complications that may occur in these patients. For instance, research suggests that increased mortality is associated with the degree of obesity (ENA, 2020a). Other considerations in ED management of patients with obesity include an understanding that it is generally more challenging to insert IV lines and airways. Ventilation also can be a challenge from the increased weight of the chest wall and the increased incidence of hypoventilation and sleep apnea among patients with obesity. Special consideration must be taken with lipophilic medications, as they take longer to clear from the larger volume of adipose tissue. Weight-based medications must be calculated carefully using ideal body mass. X-rays may be difficult to visualize because of poor penetration (Richardson & Harris, 2018).

Complications that patients with obesity are more prone to experience during hospitalization include respiratory failure, acute kidney injury (AKI), pneumonia, deep vein thrombosis, and pressure injuries. Patients with severe obesity who have femur fractures have a significantly higher risk of death, as well as a higher risk of acute respiratory distress syndrome (ARDS) and sepsis than patients of normal weight

(Richardson & Harris, 2018). Although many of these complications do not occur until later in the hospital stay, some preventive measures (e.g., encouraging turning, coughing, and deep-breathing exercises to prevent atelectasis) may be initiated in the ED. Functional recovery time is extended in patients with obesity, resulting in longer lengths of stay and increased hospital costs. Initiating prevention measures in the ED, such as early backboard removal and providing early preventive respiratory care, are targeted to improve recovery time (Richardson & Harris, 2018). Arranging transfers of patients with obesity must also take into consideration the availability of appropriately sized equipment.

PRINCIPLES OF EMERGENCY CARE

By definition, emergency care is care that must be rendered without delay. In an ED, several patients with diverse health problems—some life-threatening, some not—may present to the ED simultaneously. One of the first principles of emergency care is triage.

Triage

The word **triage** comes from the French word *trier,* meaning "to sort." In the daily routine of the ED, triage is used to sort patients into groups based on the severity of their health problems and the immediacy with which these problems must be treated.

A basic and widely used triage system that had been in use for many years utilized three categories: emergent, urgent, and nonurgent. In this system, emergent patients had the highest priority, urgent patients had serious health problems but not immediately life-threatening ones, and nonurgent patients had episodic illnesses.

A comprehensive, valid, and reliable five-level triage severity rating system that recognizes that EDs are used for both emergency and routine health care is also used. The increased number of triage levels assists the triage nurse to more precisely determine the needs of the patient and the urgency for treatment. Systems that meet these criteria for validity and reliability that are commonly used in the United States are the Emergency Severity Index (ESI) and the Canadian Triage and Acuity Scale (CTAS). The ESI assigns patients into five levels, from level 1 (most urgent) to level 5 (least urgent). With the ESI, patients are assigned to triage levels based on both their acuity and their anticipated resource needs (Soontorn, Sitthimongkol, Thosingha, et al., 2018). The CTAS system's five levels include time parameters that guide how frequently patients must be reassessed by either a nurse or provider. Patients assigned to the *resuscitation* category must receive continuous nursing surveillance, those in the *emergent* category must be reassessed at least every 15 minutes, patients in the *urgent* category must be reassessed at least every 30 minutes, patients in the *less urgent* category must be reassessed at least every 60 minutes, and those in the *nonurgent* category must be reassessed at least every 120 minutes. The goal of all triage is rapid assessment and decision making, preferably under 5 minutes (ENA, 2020a).

Although the ESI and the CTAS are valid and reliable triage severity rating systems, many EDs in the United States have high patient volumes and slow flow. Patients arriving at the ED may experience bottlenecks at triage. To further refine the system, triage bypass moves an incoming patient directly to a bed if open beds are available in

the ED. This reduces patient waiting time; the receiving nurse performs the initial assessment and vital signs. In team triage (or provider in triage [PIT]), the triage nurse works with the physician or nurse practitioner or physician assistant within the triage area itself. Team triage can move patients to diagnostics and possibly discharge without full admission to the ED. Both of these additional triage concepts decrease wait time for treatment and improve flow in the ED (ENA, 2020a). The flow of patients within the ED needs to be as efficient as possible so that wait times are diminished, and so that flow is conducive for EMS agencies and for true emergencies.

Triage is an advanced skill. Emergency nurses spend many hours learning to classify different illnesses and injuries to ensure that patients most in need of care do not needlessly wait. Protocols may be followed to initiate laboratory or x-ray studies while the patient is in the triage area. Collaborative protocols are developed and used by the triage nurse based on their level of experience (ENA, 2018a). Nurses in the triage area collect additional crucial baseline data: full vital signs including pain assessment, history of the current event and past medical history, neurologic assessment findings, weight, allergies (especially to latex and medications), intimate partner violence screening, and necessary diagnostic data. Asking questions is key to appropriate triage decisions. The following questions reflect the minimum information that should be obtained from the patient or from the person who accompanied the patient to the ED (so long as that person is not suspected of abuse or neglect; see later discussion) and then are documented (ENA, 2020a):

- What were the circumstances, precipitating events, location, and time of the injury or illness?
- When did the symptoms appear?
- Was the patient unconscious after the injury or onset of illness?
- How did the patient get to the ED?
- What was the health status of the patient before the injury or illness?
- Is there a history of medical illness or previous surgeries? A history of admissions to the hospital?
- Is the patient currently taking any medications, especially hormones, insulin, digitalis, or anticoagulants? Is the patient using any complementary or alternative therapies such as herbology, naturopathy, Reiki, massage, or acupuncture?
- Does the patient have any allergies, especially to latex, medications, eggs, or nuts?
- Does the patient use tobacco products or recreational drugs? How frequently? What type? When was the last time they were used?
- Does the patient have any fears? Does the patient feel in danger or in an unsafe situation?
- When was the last meal eaten? (This is important if general anesthesia is to be given or if the patient is unconscious.)
- When was the last menstrual period?
- Is the patient under a provider's care? What is the name and contact information for the provider?
- What was the date of the patient's most recent tetanus immunization?

In addition to the collection of initial vital signs and medical history, triage consists of providing basic first aid, which may include application of ice, bleeding control, and

basic wound care, as well as initiating protocol-based prescriptions (e.g., x-rays, administering antipyretic or mild analgesic agents, obtaining an electrocardiogram [ECG] or urinalysis, removing sutures). The triage nurse also is responsible for and monitors the waiting area, maintains a safe environment, reassesses patients who are waiting, and is the initial liaison to the families of patients.

Routine ED triage protocols differ significantly from the triage protocols used in disasters and mass casualty incidents (field triage). Routine triage directs all available resources to the patients who are most critically ill, regardless of potential outcome. In field triage (or hospital triage during a disaster), scarce resources must be used to benefit the most people possible (ENA, 2020a). This distinction affects triage decisions (see Chapter 68).

COVID-19 Considerations

In response to the COVID-19 pandemic, it is important to decrease the spread of infection and properly screen and triage all patients presenting to the ED for infection with or exposure to SARS-CoV-2. All patients should enter the ED with a face covering, which may be cloth, and maintain social distance restrictions away from other patients of 6 feet, if possible. If possible, patients should monitor their own temperature prior to arrival to the ED and notify the ED staff if they are experiencing any of the signs and symptoms of COVID-19. These include (CDC, 2020c):

- Fever or chills
- Cough
- Shortness of breath or difficulty breathing
- Fatigue
- Muscle or body aches
- Headache
- New loss of taste or smell
- Sore throat
- Congestion or runny nose
- Nausea or vomiting
- Diarrhea

It is also important that all patients who present to the ED are screened to find if they have traveled to areas with a high prevalence of COVID-19, or been exposed to others suspected or known to be infected with SARS-CoV-2 within the last 2 weeks. Patients who are asymptomatic and without any possible exposure within the past 2 weeks should be triaged to a designated area away from those patients who are symptomatic or were likely exposed (CDC, 2020c).

Assess and Intervene

For the patient assigned to an urgent or higher triage category, stabilization, provision of critical treatments, and prompt transfer to the appropriate setting (intensive care unit, operating room, general care unit) are the priorities of emergency care. Although treatment is initiated in the ED, ongoing definitive treatment of the underlying problem

is provided in other settings, and the sooner the patient is stabilized and moved to that area, the better the outcome.

A systematic approach to effectively establishing and treating health priorities is the primary survey/secondary survey approach. The **primary survey** focuses on stabilizing life-threatening conditions. The ED staff work collaboratively and follow the ABCDE (*A*irway, *B*reathing, *C*irculation, *D*isability, *E*xposure) method:

- Establish a patent airway.
- Provide adequate ventilation, employing resuscitation measures when necessary. Patients who have experienced trauma must have the cervical spine protected and chest injuries assessed first, immediately after the airway is established.
- Evaluate and restore cardiac output by controlling hemorrhage, preventing and treating shock, and maintaining or restoring effective circulation. This includes the prevention and management of hypothermia. In addition, peripheral pulses are examined, and any immediate closed reductions of fractures or dislocations are performed if an extremity is pulseless.
- Determine neurologic disability by assessing neurologic function using the Glasgow Coma Scale (GCS) (see Chapter 63, Chart 63-4) and a motor and sensory evaluation of the spine (see Chapter 60, Fig. 60-9). A quick neurologic assessment may be performed using the AVPU mnemonic:
  - *A*—alert. Is the patient alert and responsive?
  - *V*—verbal. Does the patient respond to verbal stimuli?
  - *P*—pain. Does the patient respond only to painful stimuli?
  - *U*—unresponsive. Is the patient unresponsive to all stimuli, including pain?
- Undress the patient quickly but gently so that any wounds or areas of injury are identified; this may entail cutting away articles of clothing (ENA, 2020a).

After these priorities have been addressed, the ED team proceeds with the **secondary survey**. This includes the following:

- Complete health history, including the history of the current event
- Head-to-toe assessment (includes a reassessment of airway and breathing parameters and vital signs)
- Diagnostic and laboratory testing
- Insertion or application of monitoring devices such as ECG electrodes, arterial lines, or urinary catheters
- Splinting of suspected fractures
- Cleansing, closure, and dressing of wounds
- Performance of other necessary interventions based on the patient's condition

Once the patient has been assessed, stabilized, and tested, appropriate medical and nursing diagnoses are formulated, initial important treatment is started, and plans for the proper disposition of the patient are made (ENA, 2020a). Many emergent and urgent conditions and priority emergency interventions are discussed in detail in the remaining sections of this chapter.

In addition to the management of the illness or injury, the ED nurse must also focus on providing comfort and emotional support to the patient and family. Included in this is pain management. Effective pain management must be instituted early and should include rapid-acting agents that result in minimal sedation so that the patient can

continue to interact with the staff for ongoing assessment. Moderate sedation can help facilitate short procedures in the ED; the patient will not remember the procedure later. The patient is closely monitored during the procedure and then rapidly awakens when it is complete (see Chapter 15).

It is essential that family crisis intervention services are available for families of patients in the ED. Even if a patient's condition is not emergent, the situation may be perceived as such by the family. Every family needs attention and support. The chaplain and social worker may be available to assist with interventions.

AIRWAY OBSTRUCTION

Acute upper airway obstruction is a life-threatening medical emergency.

Pathophysiology

The airway may be partially or completely occluded. Partial obstruction of the airway can lead to progressive hypoxia, hypercarbia, and respiratory and cardiac arrest. If the airway is completely obstructed, permanent brain injury or death will occur within 3 to 5 minutes secondary to hypoxia. Air movement is absent in the presence of complete airway obstruction. Oxygen saturation of the blood decreases rapidly because obstruction of the airway prevents entry of air into the lungs. Oxygen deficit occurs in the brain, resulting in unconsciousness, with death following rapidly.

Upper airway obstruction has a number of causes, including aspiration of foreign bodies, anaphylaxis, viral or bacterial infection, trauma, and inhalation or chemical burns. For older adult patients, especially those in extended care facilities, sedative and hypnotic medications, diseases affecting motor coordination (e.g., Parkinson's disease), and mental dysfunction (e.g., dementia, intellectual disability) are risk factors for asphyxiation by food. As patients age, atrophy of the posterior pharynx occurs, resulting in aspiration or difficulty swallowing. In adults, aspiration of a bolus of meat is the most common cause of airway obstruction. Peritonsillar abscesses, epiglottitis, and other acute infectious processes of the posterior pharynx can also result in airway obstruction. The most common causes of airway obstruction are from an allergic reaction (i.e., causing laryngospasm), infection, or angioedema (ENA, 2020a).

Clinical Manifestations

Typically, a person with a foreign-body airway obstruction cannot speak, breathe, or cough. The patient may clutch the neck between the thumb and fingers (i.e., universal distress signal). Other common signs and symptoms include choking, apprehensive appearance, refusing to lie flat, inspiratory and expiratory stridor, labored breathing, the use of accessory muscles (suprasternal and intercostal retraction), flaring nostrils, increasing anxiety, restlessness, and confusion. Cyanosis and loss of consciousness, which develop as hypoxia worsens, are late signs. Action must be taken before these manifestations develop, if possible, or immediately if the patient has already exhibited these signs.

Assessment and Diagnostic Findings

Assessment of the patient who has a foreign object occluding the airway may involve simply asking the person whether they are choking and require help. If the person is unconscious, inspection of the oropharynx may reveal the offending object. X-rays, laryngoscopy, or bronchoscopy also may be performed. Oxygen supplementation should be considered immediately.

Management

If the patient can breathe and cough spontaneously, a partial obstruction should be suspected. The patient is encouraged to cough forcefully and to persist with spontaneous coughing and breathing efforts as long as good air exchange exists. There may be some wheezing between coughs. If the patient demonstrates a weak, ineffective cough, high-pitched noise while inhaling, increased respiratory difficulty, or cyanosis, the patient should be managed as if there were complete airway obstruction.

After the obstruction is removed, rescue breathing is initiated. If the patient has no pulse, cardiac compressions are instituted. These measures provide oxygen to the brain, heart, and other vital organs until definitive medical treatment can restore and support normal heart and ventilatory activity (ENA, 2020a). See Chapter 25 for review of current CPR guidelines.

Establishing an Airway

Establishing an airway may be as simple as repositioning the patient's head to prevent the tongue from obstructing the pharynx. Alternatively, other maneuvers, such as the head-tilt/chin-lift maneuver, the jaw-thrust maneuver, or insertion of specialized equipment, may be needed to open the airway, remove a foreign body, or maintain the airway. In all maneuvers, the cervical spine must be protected from injury. After these maneuvers are performed, the patient is assessed for breathing by watching for chest movement and listening and feeling for air movement. In such a case, nursing diagnoses would include impaired airway clearance associated with obstruction of the airway by the tongue, an object, or fluids (blood, saliva) and impaired breathing associated with airway obstruction or injury.

An oropharyngeal airway is a semicircular tube or tubelike plastic device that is inserted over the back of the tongue into the lower posterior pharynx in a patient who is breathing spontaneously but who is unconscious. This type of airway prevents the tongue from falling back against the posterior pharynx and obstructing the airway. It also allows health care providers to suction secretions. The nasopharyngeal airway provides the same airway access but is inserted through the nares. With an airway in place the patient may breathe spontaneously. If breathing is ineffective or absent, bag-valve-mask ventilation is necessary (Atanelov & Rebstock, 2020).

Quality and Safety Nursing Alert

In the case of potential facial trauma or basal skull fracture, the nasopharyngeal airway should not be used because it could enter the brain cavity instead of the pharynx.

Endotracheal Intubation

The purpose of endotracheal intubation is to establish and maintain the airway in patients with respiratory insufficiency or hypoxia. Endotracheal intubation is indicated to establish an airway for a patient who cannot be adequately ventilated with an oropharyngeal or nasopharyngeal airway, bypass an upper airway obstruction, prevent aspiration, permit connection of the patient to a resuscitation bag or mechanical ventilator, or facilitate the removal of tracheobronchial secretions (see Fig. 67-1). Because of the level of skill required, endotracheal intubation is performed only by those who have had extensive training. These may include physicians, nurse anesthetists, respiratory therapists, flight nurses, and nurse practitioners. However, the emergency nurse commonly assists with intubation.

Rapid sequence intubation may be indicated, which provides management of the patient in a situation similar to that in the operating room. Medications used to facilitate rapid sequence intubation include a sedative, an analgesic, and a neuromuscular blockade agent; these are usually given by the provider performing the intubation.

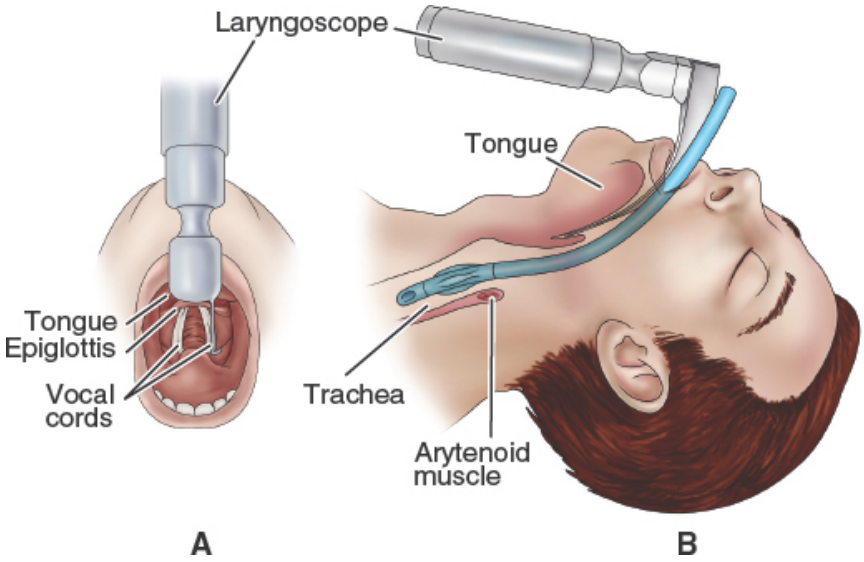

Figure 67-1 • Endotracheal intubation in a patient without a cervical spine injury. **A.** The primary glottic landmarks for tracheal intubation as visualized with proper placement of the laryngoscope. **B.** Positioning the endotracheal tube.

Intubation with a King Tube or Laryngeal Mask Airway

If the patient is not hospitalized and cannot be intubated in the field, emergency medical personnel may insert a King Tube, which rapidly provides pharyngeal ventilation. When the tube is inserted into the trachea, it functions like an endotracheal tube (see Fig. 67-2).

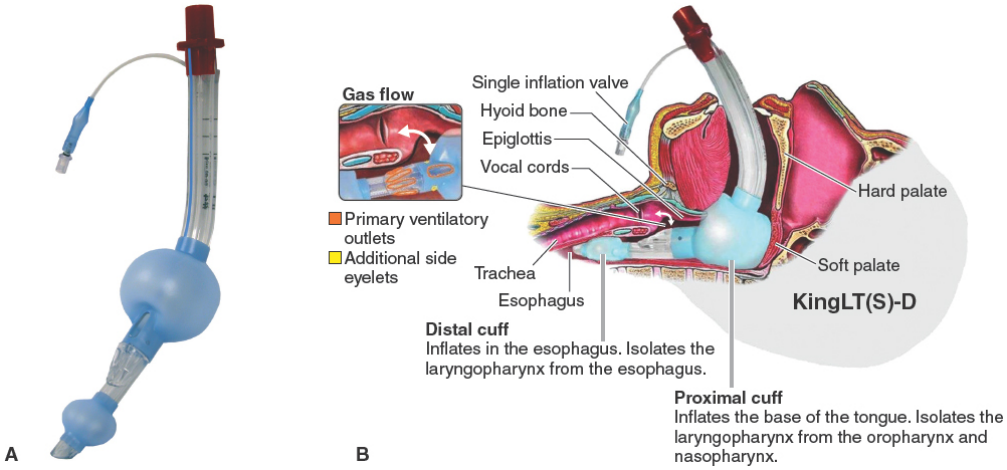

Figure 67-2 • King Tube (**A**) correctly placed in esophageal position (**B**). Reprinted with permission from King Systems Corporation, Noblesville, Indiana.

The two balloons that surround the tube are inflated after the tube is inserted. One balloon is large and occludes the oropharynx. This permits ventilation by forcing air through the larynx. The smaller balloon is inflated with air and occludes the esophagus at a site distal to the glottis. Breath sounds are auscultated after balloon inflation to make sure that the oropharyngeal balloon (or cuff) does not obstruct the glottis. One variant type of King Tube is designed so that a gastric tube may also be passed for suction. If it is difficult to establish an airway, a laryngeal mask airway (LMA) may be inserted as an interim airway device. The design of the LMA provides a "mask" in the subglottic airway with a cuff inflated within the esophagus. It allows easy insertion for rapid airway control until a more definitive airway can be placed. Some LMAs also permit removal of secretions from the esophagus (Bosson & Gordon, 2018) (see Chapter 15, Fig. 15-4A).

Cricothyroidotomy

Cricothyroidotomy is the opening of the cricothyroid membrane to establish an airway. This procedure is used in emergency situations in which endotracheal intubation is either not possible or contraindicated, as in airway obstruction from extensive maxillofacial trauma, cervical spine injuries, laryngospasm, laryngeal edema (after an allergic reaction or extubation), hemorrhage into neck tissue, or obstruction of the larynx. A cricothyroidotomy is replaced with a formal tracheostomy when the patient is able to tolerate this procedure.

Maintaining Ventilation

After the airway is determined to be unobstructed, the nurse must ensure that ventilation is adequate by checking for equal bilateral breath sounds. Satisfactory management of ventilations may prevent hypoxia and hypercapnia. The nurse must quickly assess for absent or diminished breath sounds, open chest wounds, and difficulty delivering artificial breaths for the patient. The nurse should monitor pulse oximetry, capnography, and arterial blood gases if the patient requires airway or ventilatory assistance. A tension pneumothorax can mimic hypovolemia, so ventilatory assessment precedes assessment for hemorrhage. A pneumothorax (both simple and tension) or sucking (open) chest

wound is managed with a chest tube and occlusion of the sucking wound; immediate relief of increasing positive intrathoracic pressure and maintenance of adequate ventilation should occur (see Chapter 19).

HEMORRHAGE

Stopping bleeding is essential to the care and survival of patients in an emergency or disaster situation. Hemorrhage that results in the reduction of circulating blood volume is a main cause of shock. Minor bleeding, which is usually venous, generally stops spontaneously unless the patient has a bleeding disorder or has been taking anticoagulant agents. Internal hemorrhage can hide in many anatomic spaces and compartments, resulting in shock without external evidence of hemorrhage. The internal spaces and compartments that are capable of housing large amounts of blood include the retroperitoneum, pelvis, chest, and thighs (ENA, 2020a).

The patient is assessed for signs and symptoms of shock: cool, moist skin (resulting from poor peripheral perfusion), decreasing blood pressure, increasing heart rate, delayed capillary refill, and decreasing urine volume (see Chapter 11). The goals of emergency management are to control the bleeding, maintain adequate circulating blood volume for tissue oxygenation, and prevent shock. Patients who hemorrhage are at risk for cardiac arrest caused by hypovolemia with secondary anoxia. Nursing interventions are carried out collaboratively with other members of the emergency health care team (ENA, 2020a).

Management

Fluid Replacement

Whenever a patient is hemorrhaging—whether externally or internally—a loss of circulating blood results in a fluid volume deficit and decreased cardiac output. Therefore, fluid replacement is imperative to maintain circulation. Typically, two large-gauge IV catheters are inserted, preferably in an uninjured extremity, to provide a means for fluid and blood replacement. Blood samples are obtained for analysis, typing, and cross-matching. Replacement fluids are given as prescribed, depending on clinical estimates of the type and volume of fluid lost. Replacement fluids may include isotonic electrolyte solutions (e.g., lactated Ringer's, normal saline), colloids, and blood component therapy.

Packed red blood cells are infused when there is massive blood loss, which may also necessitate transfusion of other blood components, including platelets and clotting factors (ENA, 2020a). See Chapter 28 for full discussion of blood component therapy indications and treatment.

Quality and Safety Nursing Alert

The infusion rate is determined by the severity of the blood loss and the clinical evidence of hypovolemia. Blood replacement therapy that involves transfusing several units of blood products should be given via warmer when possible, because administration of large amounts of blood that has been refrigerated has a core cooling effect that may lead to cardiac arrest and coagulopathy.

Control of External Hemorrhage

If a patient is hemorrhaging externally (e.g., from a wound), a rapid physical assessment is performed as the patient's clothing is cut away in an attempt to identify the area of hemorrhage. Direct, firm pressure is applied over the bleeding area or the involved artery at a site that is proximal to the wound (see Fig. 67-3). Most bleeding can be stopped or at least controlled by application of direct pressure. Otherwise, unchecked arterial bleeding can result in death. A firm pressure dressing is applied, and the injured part is elevated to stop venous and capillary bleeding, if possible. If the injured area is an extremity, the extremity is immobilized to control blood loss.

A tourniquet is applied to an extremity when the external hemorrhage cannot be controlled in any other way and until surgery can be performed. The tourniquet is applied just proximal to the wound and tied tightly enough to control arterial blood flow. The tourniquet is labeled with the date and time it was applied. If the patient has suffered a traumatic amputation with uncontrollable hemorrhage, the tourniquet remains in place until the patient is in the operating room. Time of tourniquet application and removal should be documented. Tourniquet placement among military personnel with battle-associated trauma has demonstrated clear mortality reduction, although it occasionally has led to amputation or fasciotomy (Cornelius, Campbell, & McGauly, 2017).

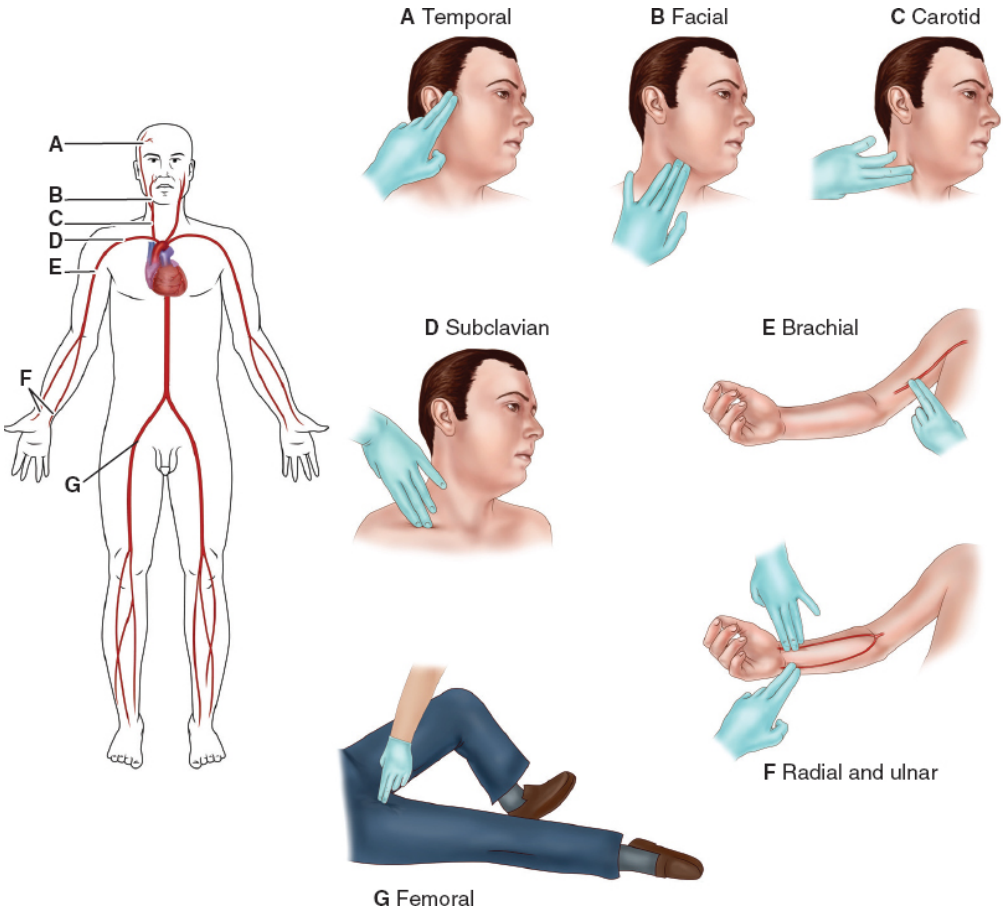

Figure 67-3 • Pressure points for control of hemorrhage.

Control of Internal Hemorrhage

If the patient shows no external signs of bleeding but exhibits tachycardia, falling blood pressure, thirst, apprehension, cool and moist skin, or delayed capillary refill, internal hemorrhage is suspected. Typically, packed red blood cells, plasma, and platelets are given at a rapid rate, and the patient is prepared for more definitive treatment (e.g., surgery, pharmacologic therapy). In addition, arterial blood gas specimens are obtained to evaluate pulmonary function and tissue perfusion and to establish baseline hemodynamic parameters, which are then used as an index for determining the amount of fluid replacement the patient can tolerate and the response to therapy. The patient is maintained in the supine position and monitored closely until hemodynamic or circulatory parameters improve, or until they are transported to the operating room or intensive care unit.

HYPOVOLEMIC SHOCK

Shock is a condition in which there is loss of effective circulating blood volume. Inadequate organ and tissue perfusion follows, ultimately resulting in cellular metabolic derangements. In any emergency situation, the onset of shock should be anticipated by immediately assessing all people who are injured. The underlying cause of shock (hypovolemic, cardiogenic, neurogenic, anaphylactic, or septic) must be determined. Of

these, hypovolemia is the most common cause. See Chapter 11 for further discussion of management of hypovolemic shock.

WOUNDS

Wounds involving injury to soft tissues can vary from minor tears to severe crushing injuries. The types of wounds that may occur are defined in Chart 67-3. The main goal of treatment is to restore the physical integrity and function of the injured tissue while minimizing scarring and preventing infection. Proper documentation of the characteristics of the wound, using precise descriptions and correct terminology, is essential. Such information may be needed in the future for forensic evidence. Photographs are helpful because they provide an accurate, visible depiction of the wound. Photographs also become important for exigent wounds (i.e., wounds that will eventually heal). Patients experiencing intimate partner violence (IPV) or trauma may need the photographs later to visually describe the extent of injury.

Chart 67-3

Definition of Terms: Wounds

Abrasion: denuded skin
Avulsion: tearing away of tissue from supporting structures
Cut: incision of the skin with well-defined edges, usually longer than deep
Ecchymosis/contusion: blood trapped under the surface of the skin
Hematoma: tumorlike mass of blood trapped under the skin
Laceration: skin tear with irregular edges and vein bridging
Patterned: wound representing the outline of the object (e.g., steering wheel) causing the wound
Stab: incision of the skin with well-defined edges, usually caused by a sharp instrument; a stab wound is typically deeper than long

Determining *when* and *how* the wound occurred is important because a treatment delay increases infection risk. Using aseptic technique, the clinician inspects the wound to determine the extent of damage to underlying structures or the presence of a foreign body. Sensory, motor, and vascular function is evaluated for changes that might indicate complications.

Management

Wound Cleansing

Hair around the wound may be clipped (only as directed) if it is anticipated that the hair will interfere with wound closure. Typically, the area around the wound is cleansed with normal saline solution or a polymer agent (e.g., Shur-Clens). The antibacterial agent povidone-iodine should not be allowed to get deep into the wound without thorough rinsing. Povidone-iodine is used only for the initial cleansing because it injures exposed and healthy tissue, resulting in further tissue damage (ENA, 2020a).

If indicated, the area is infiltrated with a local intradermal anesthetic through the wound margins or by regional block. Patients with soft tissue injuries usually have localized pain at the site of injury. The nurse then assists with cleaning and débriding the wound. The wound is irrigated gently and copiously with sterile isotonic saline solution to remove surface dirt. Devitalized tissue and foreign matter are removed because they impede healing and may promote infection. Any small bleeding vessels are clamped, tied, or cauterized. After wound treatment, a nonadherent dressing is applied to protect the wound and to serve as a splint and as a reminder to the patient that the area is injured.

Primary Closure

The decision to suture a wound depends on the nature of the wound, the time since the injury was sustained, the degree of contamination, and the vascularity of tissues. If primary closure is indicated, the wound is sutured or stapled, usually by the emergency provider, with the patient receiving either local anesthesia or moderate sedation (see Chapter 15). Wound closure begins when subcutaneous fat is brought together loosely with a few sutures to close off the dead space. The subcuticular layer is then closed, and finally the epidermis is closed. Sutures are placed near the wound edge, with the skin edges leveled carefully to promote optimal healing. Instead of sutures, sterile strips of reinforced microporous tape or a bonding agent (skin glue) may be used to close clean, superficial wounds (ENA, 2020a).

Delayed Primary Closure

Delayed primary closure may be indicated if tissue has been lost or there is a high potential for infection. A thin layer of gauze (to ensure drainage and prevent pooling of exudate), covered by an occlusive dressing, may be used. The wound is splinted in a functional position to prevent motion and decrease the possibility of contracture.

If there are no signs of suppuration (formation of purulent drainage), the wound may be sutured (with the patient receiving a local anesthetic). The use of antibiotic agents to prevent infection depends on factors such as how the injury occurred, the age of the wound, and the risk of contamination. The site is immobilized and elevated to limit accumulation of fluid in the interstitial spaces of the wound.

Tetanus prophylaxis is given as prescribed, based on the condition of the wound and the patient's immunization status. If the patient's last tetanus booster was given more than 5 years ago, or if the patient's immunization status is unknown, a tetanus booster must be given (ENA, 2020a). The patient is educated about signs and symptoms of infection and is instructed to contact the primary provider or clinic if there is sudden or persistent pain, fever or chills, bleeding, rapid swelling, foul odor, drainage, or redness surrounding the wound.

TRAUMA

Trauma (an unintentional or intentional wound or injury inflicted on the body from a mechanism against which the body cannot protect itself) is the fourth leading cause of death in the United States. Trauma is the leading cause of death in children and in adults

younger than 44 years. The incidence is increasing in adults older than 44 years. SUD is often implicated as a factor in both blunt and penetrating trauma (ENA, 2020a).

Collection of Forensic Evidence

In assessing and managing any patient with an emergency condition, but especially the patient experiencing trauma, meticulous documentation is essential. Included in documentation are descriptions of all wounds, mechanism of injury, time of events, and collection of evidence. In trauma care, the nurse must be exceedingly careful with all potential evidence, handling and documenting it properly.

The basics of care management for patients with traumatic injury include an understanding that trauma in any patient (living or dead) has potential legal or forensic science implications if criminal activity is suspected. Hence, proper management from both a medical and forensic evidence perspective is essential.

When clothing is removed from the patient who has experienced trauma, the nurse must be careful not to cut through or disrupt any tears, holes, blood stains, or dirt present on the clothing if criminal activity is suspected. Each piece of clothing should be placed in an individual paper bag. Plastic bags are not used because they retain moisture; moisture may promote mold and mildew formation, which can destroy evidence. If the clothing is wet, it should be hung to dry. Clothing should not be given to families. Valuables should be inventoried and either placed in the hospital safe or clearly documented to which family member they were given. If a police officer is present to collect clothing or any other items from the patient, each item is labeled and the transfer of custody to the officer, the officer's name, the date, and the time are documented. Evidence cannot be left unattended in the room; a formal chain of custody must be maintained for the evidence to be valid and useful for legal purposes (ENA, 2020a).

All deaths of patients who experienced trauma are reported to the medical examiner. If suicide or homicide is suspected in a patient who experienced trauma, the medical examiner examines the body on site or has the body moved to the coroner's office for autopsy. All tubes and lines must remain in place. The patient's hands must be covered with paper bags to protect evidence on the hands or under the fingernails. In the patient who has survived trauma, tissue specimens may be swabbed from the hands and nails as potential evidence. Photographs of wounds or clothing are essential and should include a reference ruler in one photo and another without the ruler.

Documentation should also include any statements made by the patient in the patient's own words and surrounded by quotation marks. A chain of evidence is essential. If the patient's case is reviewed in a court of law in the future, clear documentation assists the judicial process and helps to identify the activities that occurred in the ED.

Injury Prevention

Any discussion of trauma management must address injury prevention. A component of the emergency nurse's daily role is to provide injury prevention information to every patient with whom there is contact, including patients admitted for reasons other than injury (ENA, 2020a). The only way to reduce the incidence of trauma is through prevention.

There are three components of injury prevention. The first is education. Providing information and materials to help prevent violence and to maintain safety at home and in vehicles is important. Involvement in local injury prevention organizations, nursing organizations, and health fairs promotes wellness and safety. In practice, nursing and other health care professionals should avoid using the word *accident,* because trauma events are *preventable* and should be viewed as such rather than as "fate" or "happenstance." Responsibility and accountability must be assigned to traumatic incidents, particularly because of the high rate of trauma recidivism (repeated trauma). People who are at risk for trauma and trauma recidivism should be identified and provided with education and counseling directed toward altering risky behaviors and preventing further trauma (ENA, 2020a).

The second component of injury prevention is legislation. Nurses should be actively involved in safety legislation at the local, state, and federal levels. Such legislation is meant to provide universal safety measures, not to infringe on rights.

The third component is automatic protection. Airbags and automotive design are included in this category. These mechanisms provide for safety without requiring personal intervention.

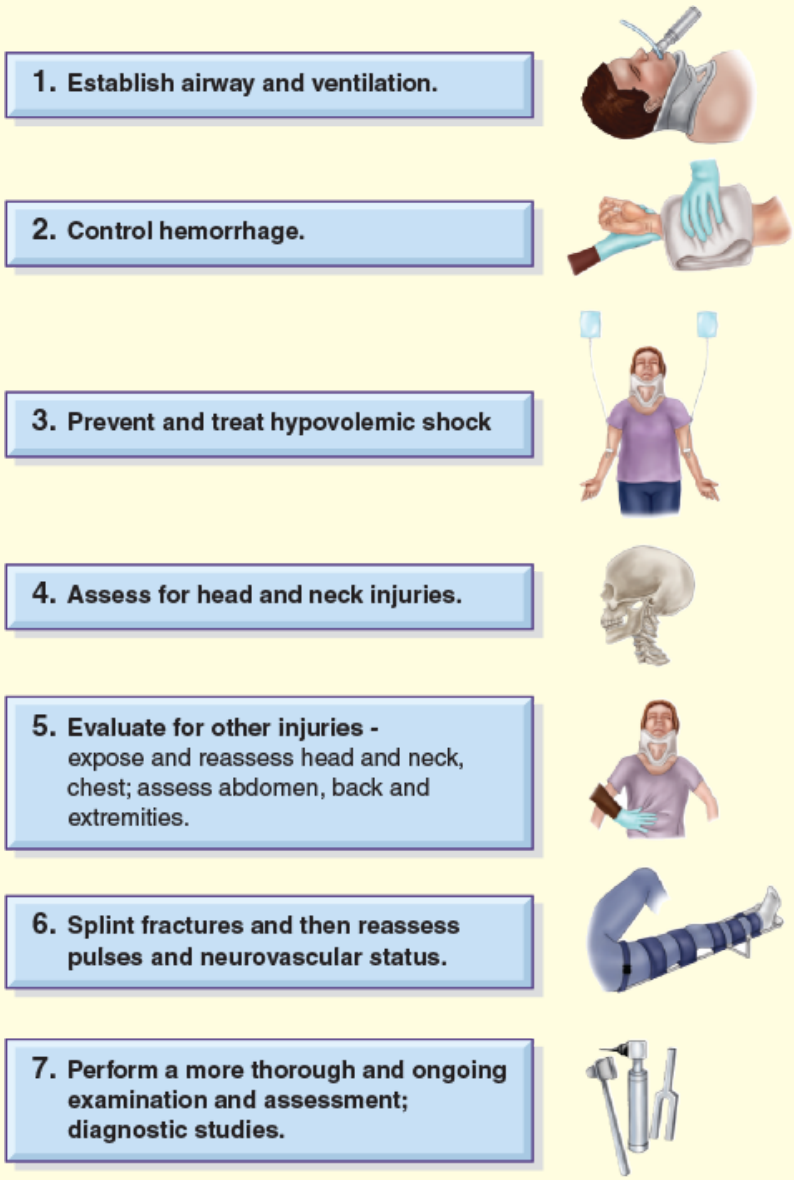
Emergency nurses may develop injury prevention programs using a focus similar to the ABCDE approach used in the primary survey in trauma care. In this case, however (ENA, 2020a):

- *A*—describes *a*ssessment of the community for common injury mechanisms
- *B*—is used to describe *b*uilding a coalition of key community members
- *C*—refers to *c*ommunicating awareness of the trauma mechanisms and risks prevalent in the local community
- *D*—stands for *d*eveloping and implementing interventions, which may be educational or legislative
- *E*—refers to *e*valuating the injury prevention program soon after it is launched, which may result in either continuation or revision of the program

Multiple Trauma

Multiple trauma is caused by a single catastrophic event that causes life-threatening injuries to at least two distinct organs or organ systems. Mortality in patients with multiple trauma is related to the severity of the injuries, the number of systems and organs involved, and the severity of each injury alone and in combination. Patients with single-system trauma can also have life-threatening or very severe traumatic injuries. Immediately after injury from major trauma, including multiple trauma or severe single-system trauma, the body is hypermetabolic and severely stressed. In addition, major trauma can cause hypothermia, acidosis, and coagulopathy, sometimes called the *triad of death* because each of these factors is associated with increased mortality (Saqe-Rockoff, Schubert, Ciardiello, et al., 2018).

Assessment and Diagnostic Findings



External evidence of trauma may be sparse or absent. Patients with multiple trauma should be assumed to have a spinal cord injury until it is proven otherwise. The injury regarded as the least significant in appearance may be the most lethal. For example, the pelvic fracture not identified until an x-ray is obtained may cause rapid and massive hemorrhage into the pelvic cavity, but an obvious amputation of the arm may have already stopped bleeding from the body's normal response of vasoconstriction.

Management

The goals of treatment are to determine the extent of injuries and to establish priorities of treatment. Any injury interfering with a vital physiologic function (e.g., airway, breathing, circulation) is an immediate threat to life and has the highest priority for immediate treatment. Essential lifesaving procedures are performed simultaneously by the emergency team. As soon as the patient is resuscitated, clothes are removed or cut off and a rapid physical assessment is performed. Transfer from field management to the ED must be orderly and controlled, with attention and silence given to listen to the verbal report from EMS personnel. Treatment in a trauma center is appropriate for patients experiencing major trauma. Treatment priorities are presented in Chart 67-4.

Chart 67-4

Priority Management in Patients with Multiple Injuries

Adapted from American College of Surgeons. (2018). *Advanced trauma life support* (10th ed.). Chicago, IL: Author.

A trauma alert is typically activated for patients with major trauma who present to trauma centers. Trauma alert activations are based upon specific criteria that are established by the individual institution. The trauma alert mobilizes the designated members of the trauma team, whose composition varies depending upon the size of the hospital and availability of its resources and staff (Dehli, Uleberg, & Wisborg, 2018). Common members of the trauma team include a trauma surgeon, trauma emergency nurse, x-ray technician, and nursing assistant. An advanced practice nurse and a chaplain may also be included as members of the trauma team (Crawford, 2019). The trauma emergency nurse typically is responsible for assessing and monitoring the patient, ensuring/maintaining airway and IV access, administering prescribed medications, collecting laboratory specimens, and documenting activities and the patient's subsequent responses.

In addition to managing the treatment priorities described in Chart 67-4, the trauma emergency nurse must implement interventions that can mitigate the effects of hypothermia. In some trauma centers, the ambient temperature in the trauma bay where the patient with major trauma is treated is kept higher than normal (e.g., 26°C [78.8°F]). Any wet clothing is removed and warm blankets may be applied. IV fluids may be warmed while they are infusing. See the Nursing Research Profile in Chart 67-5.

Large volumes of IV crystalloids might need to be infused to manage the effects of hypovolemia (see Chapter 11); however, normal saline can exacerbate the metabolic acidosis that ensues. Therefore, the preferred IV crystalloid solution is typically lactated Ringer's. However, large volumes of any crystalloid solution may also dilute the presence of clotting factors, causing coagulopathy. Therefore, the patient with major trauma is judiciously managed with crystalloid IV fluids as needed. Blood component therapy may be required (see Chapter 28). The trauma team is responsible for continuously monitoring the patient's hemodynamic status as well as the temperature of the patient and the ambient environment in order to reduce the risks of the deadly trio of hypothermia, acidosis, and coagulopathy (Saqe-Rockoff et al., 2018).

Intra-Abdominal Injuries

Intra-abdominal injuries are categorized as penetrating or blunt trauma. *Penetrating* abdominal injuries (i.e., gunshot wounds, stab wounds) are serious and usually require surgery. Penetrating abdominal trauma results in a high incidence of injury to hollow organs, particularly the small bowel. The liver is the most frequently injured solid organ due to its size and anterior placement in the right upper quadrant of the abdomen. In gunshot wounds, the most important prognostic factor is the velocity at which the missile enters the body. High-velocity missiles (bullets) produce extensive tissue damage. All abdominal gunshot wounds that cross the peritoneum require surgical exploration. On the other hand, some stab wounds may be managed nonoperatively due to low velocity and less penetration of the implement (i.e., weapon) (ENA, 2020a).

Blunt trauma to the abdomen may result from motor vehicle crashes, falls, blows, or explosions. Blunt trauma is commonly associated with extra-abdominal injuries to the chest, head, or extremities. Patients with blunt trauma pose a challenge because injuries may be difficult to detect. The incidence of delayed and trauma-related complications is greater than for penetrating injuries. This is especially true of blunt injuries involving the liver, kidneys, spleen, or blood vessels, which can lead to massive blood loss into the peritoneal cavity (ENA, 2020a).

Assessment and Diagnostic Findings

As the history of the traumatic event is obtained, the abdomen is inspected as a part of the secondary survey for obvious signs of injury, including penetrating injuries, bruises, and abrasions. Abdominal assessment continues with auscultation of bowel sounds to provide baseline data from which changes can be noted. Absence of bowel sounds may be an early sign of intraperitoneal involvement, although stress can also decrease or halt peristalsis and thus bowel sounds. Further abdominal assessment may reveal progressive abdominal distention, involuntary guarding, tenderness, pain, muscular rigidity, or rebound tenderness along with changes in bowel sounds, all of which are signs of

peritoneal irritation. Hypotension and signs and symptoms of shock may also be noted. In addition, the chest and other body systems are assessed for injuries that frequently accompany intra-abdominal injuries (ENA, 2020a).

Chart 67-5  **NURSING RESEARCH PROFILE**

Improving Thermoregulation for Patients with Trauma

Saqe-Rockoff, A., Schubert, F. D., Ciardiello, A., et al. (2018). Improving thermoregulation for trauma patients in the emergency department: An evidence-based practice project. *Journal of Trauma Nursing*, *25*(1), 14–20.

Purpose

Research indicates there is a strong association between increased mortality in patients with trauma and hypothermia. Therefore, hypothermia is an important modifiable risk factor for patients with trauma. A variety of rewarming methods currently exist and are utilized with varying degrees of success. Gaps in emergency nursing practice include the assessment of temperature as well as limited personnel knowledge regarding the management of patients with hypothermia and the utilization of rewarming techniques.

Design

The setting was a 450 bed Level I trauma center with more than 75,000 annual ED visits. The project goals were to decrease time to temperature assessment upon patient arrival to the trauma bay and to improve use of best practice rewarming methods among patients with trauma. The research team utilized the Iowa Model of Evidence-Based Practice to provide a framework for the evaluation of current practice and implementation of best practices. Practice changes that were instituted on patients with trauma during the study period included providing warmed blankets, ensuring regulated standardized trauma bay temperature, assessing patient temperature on arrival with appropriate escalation of rewarming as needed, and using a rapid infuser with warmed fluid as needed. In order to implement these changes, a standardized protocol checklist was developed. The impact of the interventions was assessed by *post hoc* chart reviews. Data analysis included descriptive statistics for assessment of differences pre and post project implementation.

Findings

There were 193 patients with trauma during the study period. There was no appreciable difference in time to temperature assessment upon patient arrival to the trauma bay pre and post project implementation. However, there was an increase in patients identified with hypothermia post implementation and a significant increase in core temperature assessment from 4% to 23% ($p < 0.001$). Use of blankets in normothermic patients increased ($p = 0.002$). There was a significant increase in the average temperature of the trauma bay post implementation.

Nursing Implications

Nurses often identify lack of education, access to information, and lack of time as barriers for implementing evidence-based practice changes. Staff education and implementation of relatively simple tools such as the hypothermia checklist used in this study can encourage implementation of best practices and consistency of care of patients with trauma who are at risk for hypothermia. Incorporating best practices for thermoregulation of the patient with trauma may lead to improved patient outcomes and decreased mortality rates.

Laboratory studies that aid in assessment include the following:

- Serial hemoglobin and hematocrit levels to evaluate trends reflecting the presence or absence of bleeding

- Lactate to determine acidosis and need for continued resuscitation
- Arterial blood gas (ABG) for pH (acidosis), base deficit for resuscitation evaluation, and ventilation parameters ($PaCO_2$, PaO_2)
- International normalized ratio (INR) to identify coagulopathy or presence of pharmacologically induced anticoagulation
- White blood cell (WBC) count to detect elevation (generally associated with trauma)

Internal Hemorrhage

Hemorrhage frequently accompanies abdominal injury, especially if the liver or spleen has been traumatized. Therefore, the patient is assessed continuously for signs and symptoms of external and internal bleeding. The front of the body, flanks, and back are inspected for bluish discoloration, asymmetry, abrasion, and contusion. Abdominal CT scans permit detailed evaluation of abdominal contents and retroperitoneal examination. Abdominal ultrasounds can be used to rapidly assess patients who are hemodynamically unstable to detect intraperitoneal bleeding. This is referred to as the focused assessment with sonography for trauma (FAST) examination. During the resuscitation period, pain is managed using administration of small dosages of opioids (ENA, 2020a).

Quality and Safety Nursing Alert

The location of pain can indicate certain types of intra-abdominal injuries. Pain in the left shoulder is common in a patient with bleeding from a ruptured spleen, whereas pain in the right shoulder can result from laceration of the liver.

Intraperitoneal Injury

The abdomen is assessed for tenderness, rebound tenderness, guarding, rigidity, spasm, increasing distention, and pain. Referred pain is a significant finding because it suggests intraperitoneal injury. To determine if there is intraperitoneal injury and bleeding, the patient is usually prepared for diagnostic procedures, such as diagnostic peritoneal lavage (DPL), abdominal ultrasonography, or abdominal CT scanning. DPL, although no longer the standard diagnostic study used to evaluate a traumatized abdomen, remains a viable backup procedure that is easily performed and is very useful during mass casualty incidents when CT scanners may not be readily available. DPL involves the instillation of 1 L of warmed lactated Ringer's or normal saline solution into the abdominal cavity. After a minimum of 400 mL has been returned, a fluid specimen is sent to the laboratory for analysis. Positive laboratory findings include a red blood cell count greater than 100,000/mm^3; a WBC count greater than 500/mm^3; or the presence of bile, feces, or food (ENA, 2020a).

Genitourinary Injury

A focused genitourinary examination, which typically includes a rectal and vaginal examination, is performed to determine any injury to the pelvis, bladder, urethra, vagina, or intestinal wall. In the male patient, a high-riding prostate gland (abnormal position) discovered during a rectal examination indicates a potential urethral injury. A digital

vaginal examination is performed on female patients to determine if there is an open pelvic fracture that has torn the vagina (ENA, 2020a).

Quality and Safety Nursing Alert

To decompress the bladder and monitor urine output in a patient with a genitourinary injury, an indwelling catheter is inserted after a rectal examination has been completed, not before the examination. In addition, urethral catheter insertion when a possible urethral injury is present is contraindicated; a urology consultation and further evaluation of the urethra are required.

Management

As indicated by the patient's condition, resuscitation procedures (restoration of airway, breathing, and circulation) are initiated as described previously.

With blunt trauma, the patient is kept on a stretcher to immobilize the spine. If the patient has been placed on a backboard, it should be removed as early as possible to prevent skin breakdown. Cervical spine immobilization is maintained until cervical x-rays have been obtained and cervical spine injury has been ruled out. Likewise, once the backboard is removed, logrolling can be used to protect the spine until x-rays are obtained and confirm that there is no evidence of injuries.

Knowing the mechanism of injury (e.g., penetrating force from a gunshot or knife, blunt force from a blow) is essential to determining the type of management needed. All wounds are located, counted, and documented. If abdominal viscera protrude, the area is covered with sterile, moist saline dressings to keep the viscera from drying.

Typically, oral fluids are withheld in anticipation of surgery, and the stomach contents are aspirated with an orogastric tube to reduce the risk of aspiration and to decompress the stomach in preparation for diagnostic procedures.

Trauma predisposes the patient to infection by disruption of mechanical barriers, exposure to exogenous bacteria from the environment at the time of injury, aspiration of vomitus, and diagnostic and therapeutic procedures (hospital-acquired infection). Tetanus prophylaxis and broad-spectrum antibiotics are given as prescribed.

Throughout the stay in the ED, the patient's condition is continuously monitored for changes. If there is continuing evidence of shock, blood loss, free air under the diaphragm, evisceration, hematuria, severe head injury, musculoskeletal injury, or suspected or known abdominal injury, the patient is rapidly transported to surgery. In most cases, blunt liver and spleen injuries are managed nonsurgically. The goal for the management of all patients who have experienced trauma is to minimize the length of stay in the ED. The patient should be moved to the definitive destination quickly so that care and rehabilitation can continue (ENA, 2020a).

Crush Injuries

Crush injuries occur when a person is caught between opposing forces (e.g., run over by a moving vehicle, crushed between two cars, crushed under a collapsed building).

Assessment and Diagnostic Findings

The patient is observed for the following:

- Hypovolemic shock resulting from extravasation of blood and plasma into injured tissues after compression has been released (see Chapter 11)
- Spinal cord injury (see Chapter 63)
- Erythema and blistering of skin (see Chapter 56)
- Fractures (usually an extremity) (see Chapter 37)
- AKI (e.g., acute tubular necrosis [ATN]) (see Chapter 48)

Management

In conjunction with maintaining the airway, breathing, and circulation, the patient is observed for AKI. Injury to the back can cause renal trauma. Severe muscular damage may cause **rhabdomyolysis**, a toxic syndrome caused by a release of myoglobin from ischemic skeletal muscle, resulting in ATN. See Chapter 48 for the treatment of AKI, renal trauma, and ATN. Rhabdomyolysis may also result from major burns (see Chapter 57), heat stroke, and abuse of illicit drugs, in addition to crush injuries (see later discussions). The classic triad of clinical manifestations suggestive of rhabdomyolysis includes myalgias (muscle cramps), generalized muscle weakness, and darkened urine. The serum creatine kinase (CK) is monitored as the most sensitive indicator of rhabdomyolysis; levels in excess of 6000 IU/L are considered diagnostic (Atias-Varon, Sherman, Yanovich, et al., 2017). In addition to treatment aimed at preventing or treating ATN, major soft tissue injuries are splinted promptly to control bleeding and pain. The serum lactic acid level is monitored; a decrease to less than 2.0 mmol/L is an indication of successful resuscitation (Nicks, McGinnism, Borron, et al., 2018).

If an extremity is injured, it is elevated to relieve swelling and pressure. If compartment syndrome develops, the physician may perform a **fasciotomy** (i.e., surgical incision to the level of the fascia) to restore neurovascular function (see Chapter 37). Medications for pain and anxiety are then given as prescribed, and the patient is quickly transported to the operating suite for wound débridement and fracture repair. A hyperbaric oxygen chamber (if available) may be used to hyperoxygenate crushed tissue, if indicated.

Fractures

Immediate appropriate management of a fracture may determine the patient's eventual outcome and may mean the difference between recovery and disability. When the patient is being examined for fracture, the body part is handled gently and as little as possible. Clothing is cut off to visualize the affected body part. Assessment is conducted for pain over or near a bone, swelling (from blood, lymph, and exudate infiltrating the tissue), and circulatory disturbance. The patient is assessed for ecchymosis, tenderness, and crepitation (see Chapter 37). The nurse must remember that the patient may have multiple fractures accompanied by head, chest, spine, or abdominal injuries.

Management

Immediate attention is given to the patient's general condition. Assessment of airway, breathing, and circulation (which includes pulses in the extremities) is conducted. The patient is also evaluated for neurologic or abdominal injuries before the extremity is treated, unless a pulseless extremity is detected.

If a pulseless extremity is identified, repositioning of the extremity to proper alignment is required. If the pulseless extremity involves a fractured femur, Hare traction (a portable in-line traction device) may be applied to assist with alignment. If repositioning is ineffective in restoring the pulse, a rapid total-body assessment must be completed, followed by transfer of the patient to the operating room for arteriography and possible arterial repair versus amputation.

After the initial evaluation has been completed, all injuries identified are evaluated and treated. The fractured body part is inspected. Using a systematic head-to-toe approach, the nurse inspects the entire body, observing for lacerations, swelling, and deformities, including angulation (bending), shortening, rotation, and asymmetry. All peripheral pulses, especially those distal to the fractured extremity, are palpated. The extremity is also assessed for coolness, blanching, and decreased sensation and motor function, which are indicative of injury to the extremity's neurovascular supply.

A splint is applied before the patient is moved. Splinting immobilizes the joint at a site distal and proximal to the fracture, relieves pain, restores or improves circulation, prevents further tissue injury, and prevents a closed fracture from becoming an open one. To splint an extremity, one hand is placed distal to the fracture and some traction is applied while the other hand is placed beneath the fracture for support. The splints should extend beyond the joints adjacent to the fracture. Upper extremities must be splinted in a functional position. If the fracture is open, a moist, sterile dressing is applied.

After splinting, the vascular status of the extremity is checked by assessing color, temperature, pulse, and blanching of the nail bed. In addition, the patient is assessed for neurovascular compromise if pain or pressure is reported. See Chapter 37 for a complete description of fracture management (ENA, 2020a).

ENVIRONMENTAL EMERGENCIES

Emergencies that can occur due to environmental factors include heat related illnesses, including the extremes of heat stroke, frostbite, and hypothermia; nonfatal drowning; decompression sickness; animal, human, and insect bites.

Heat-Induced Illnesses

Heat-induced illnesses may range in severity from mild and self-limiting to life-threatening emergencies. The most serious of these—heat stroke—is an acute medical emergency caused by failure of the heat-regulating mechanisms of the body. It is the inability to maintain cardiac output in the face of moderately high body temperatures and is associated with dehydration. The most common cause of heat stroke is nonexertional, prolonged exposure to an environmental temperature of greater than 39.2°C (102.5°F), although a heat index of greater than 35°C (95°F) is associated with increased mortality (ENA, 2020a). It usually occurs during extended heat waves,

especially when they are accompanied by high humidity. Exertional heat stroke is caused by strenuous physical activity that occurs in a hot environment (ENA, 2020a).

Chart 67-6 HEALTH PROMOTION

Preventing Heat-Induced Illnesses

The nurse provides the following advice for the patient treated for heat-induced illness:

- Avoid immediate re-exposure to high temperatures; hypersensitivity to high temperatures may remain for a considerable time.
- Maintain adequate fluid intake, wear loose clothing, and reduce activity in hot weather.
- Monitor fluid losses and weight loss during workout activities or exercise and replace fluids and electrolytes.
- Use a gradual approach to physical conditioning, allowing sufficient time for return to baseline temperature.
- Plan outdoor activities to avoid the hottest part of the day (between 10 AM and 2 PM).

For older patients living in urban settings with high environmental temperatures:

- The nurse directs these patients to places where air conditioning is available (e.g., shopping mall, library, church) and advises them that fans alone are not adequate to prevent heat-induced illness.

People at risk for nonexertional heat stroke are those not acclimatized to heat, those who are older or very young, those unable to care for themselves, those with chronic and debilitating diseases, and those taking certain medications (e.g., major tranquilizers, anticholinergics, diuretics, beta-blockers) (ENA, 2020a; Tintinalli, Stapczyski, Ma, et al., 2020). Older adults, the very young, people with mental illness, and people with chronic diseases have the highest rates of mortality (CDC, 2017a). Exertional heat stroke occurs in healthy individuals during sports or work activities (e.g., exercising in extreme heat and humidity). Hyperthermia results because of inadequate heat loss. Strategies used to prevent heat-induced illnesses are reviewed in Chart 67-6.

Less severe forms of heat-induced illnesses include heat exhaustion and heat illness or heat cramps. The causes of heat exhaustion are the same as for heat stroke. Heat illness is caused by a loss of electrolytes, typically during strenuous physical activity in a hot environment (ENA, 2020a).

Gerontologic Considerations

Most heat-related deaths occur in older adults because their circulatory systems are unable to compensate for stress imposed by heat. Older adults have a decreased ability

to perspire as well as a decreased ability to vasodilate and vasoconstrict. They have less subcutaneous tissue, a decreased thirst mechanism, and a diminished ability to concentrate urine to compensate for heat. Many older adults do not drink adequate amounts of fluid, partly because of fear of incontinence, and thus have a greater risk of heat stroke. In addition, many older adults fear being victims of crime, so even if their residence lacks air conditioning, they tend to keep windows closed despite high temperatures and humidity levels (ENA, 2020a).

Assessment and Diagnostic Findings

Heat stroke, whether the cause is exertional or nonexertional, causes thermal injury at the cellular level, resulting in coagulopathies and widespread damage to the heart, liver, and kidneys. Recent patient history reveals exposure to elevated ambient temperature or excessive exercise during extreme heat. When assessing the patient, the nurse notes the following symptoms: profound central nervous system (CNS) dysfunction (manifested by confusion, delirium, bizarre behavior, coma, seizures); elevated body temperature (40.6°C [105°F] or higher); hot, dry skin; and usually anhidrosis (absence of sweating), tachypnea, hypotension, and tachycardia. The patient with heat exhaustion, on the other hand, may exhibit similarly high body temperatures accompanied by headaches, anxiety, syncope, profuse diaphoresis, gooseflesh, and orthostasis. The cardinal manifestations of heat illness include muscle cramps, particularly in the shoulders, abdomen, and lower extremities; profound diaphoresis; and profound thirst (ENA, 2020a).

Management

The main goal is to reduce the high body temperature as quickly as possible, because mortality in heat stroke or morbid progression to heat stroke with less serious forms of heat-induced illnesses is directly related to the duration of hyperthermia. For the patient with heat stroke, simultaneous treatment focuses on stabilizing oxygenation using the CABs (*C*irculation, *A*irway, and *B*reathing) of basic life support. This includes establishing IV access for fluid administration.

After the patient's clothing is removed, the core (internal) temperature is reduced to 39°C (102°F) as rapidly as possible, preferably within 1 hour. One or more of the following methods may be used as prescribed (ENA, 2020a):

- Cool sheets and towels or continuous sponging with cool water
- Ice applied to the neck, groin, chest, and axillae while spraying with tepid water
- Cooling blankets
- Immersion of the patient in a cold water bath is the optimal method for cooling (if available)

During cooling procedures, an electric fan is positioned so that it blows on the patient to augment heat dissipation by convection and evaporation. The patient's temperature is constantly monitored with a thermistor placed in the rectum, bladder, or esophagus to evaluate core temperature. Caution is used to avoid hypothermia and to prevent hyperthermia, which may recur spontaneously within 3 to 4 hours. The cooling process should stop at 38°C (100.4°F) in order to avoid iatrogenic hypothermia (ENA, 2020a).

Throughout treatment, the patient's status is monitored carefully, including vital signs, ECG findings (for possible myocardial ischemia, myocardial infarction, and

arrhythmias), central venous pressure (CVP), and level of responsiveness, all of which may change with rapid alterations in body temperature. A seizure may be followed by recurrence of hyperthermia. To meet tissue needs exaggerated by the hypermetabolic condition, 100% oxygen is given. Endotracheal intubation and mechanical ventilation to support failing cardiopulmonary systems may be required.

IV infusion therapy of normal saline or lactated Ringer's solution is initiated as directed to replace fluid losses and maintain adequate circulation. Fluids are given carefully because of the dangers of myocardial injury from high body temperature and poor kidney function. Cooling redistributes fluid volume from the periphery to the core.

Urine output is also measured frequently, because ATN may occur as a complication of heat stroke from rhabdomyolysis (see previous discussion). Blood specimens are obtained for serial testing to detect bleeding disorders, such as disseminated intravascular coagulation (DIC), and for serial enzyme studies to estimate thermal hypoxic injury to the liver, heart, and muscle tissue. Permanent liver, cardiac, and CNS damage may occur.

Additional supportive care may include dialysis for AKI, anticonvulsant medications to control seizures, potassium for hypokalemia, and sodium bicarbonate to correct metabolic acidosis. Benzodiazepines such as diazepam may be prescribed to suppress seizure activity, while a phenothiazine such as chlorpromazine may be prescribed to suppress shivering (Tintinalli et al., 2020).

Patients with heat exhaustion or heat illness may be managed less aggressively. These patients should lie supine in a cool environment. Patients with heat exhaustion may require IV fluids but may also take oral fluids, if they are tolerated. Patients with heat illness are given oral sodium supplements and oral electrolyte solutions (ENA, 2020a). Patients who have experienced a heat-induced illness should receive education to prevent another heat-related illness (see Chart 67-6).

Frostbite

Frostbite is trauma from exposure to freezing temperatures and freezing of the intracellular fluid and fluids in the intercellular spaces. It results in cellular and vascular damage. Frostbite can result in venous stasis and thrombosis. Body parts most frequently affected by frostbite include the feet, hands, nose, and ears. Frostbite ranges from first degree (redness and erythema) to fourth degree (full-depth tissue destruction) (ENA, 2020a).

Assessment and Diagnostic Findings

A frozen extremity may be hard, cold, and insensitive to touch and may appear white or mottled blue-white. The extent of injury from exposure to cold is not always initially known. The patient history should include environmental temperature, duration of exposure, clothing worn, humidity, and the presence of wet conditions (ENA, 2020a).

Management

The goal of management is to restore normal body temperature. Constrictive clothing and jewelry that could impair circulation are removed. Wet clothing is removed as

rapidly as possible. If the lower extremities are involved, the patient should not be allowed to ambulate as this may exacerbate tissue damage (CDC, 2019b).

Controlled yet rapid rewarming is instituted. Frozen extremities are usually placed in a 37°C to 40°C (98.6°F to 104°F) circulating bath for 30- to 40-minute spans. This treatment is repeated until circulation is effectively restored. Early rewarming appears to decrease the amount of ultimate tissue loss. During rewarming, an analgesic for pain is given as prescribed, because the rewarming process may be very painful. To avoid further mechanical injury, the body part is not handled. Massage is contraindicated.

Once rewarmed, the part is protected from further injury and is elevated to help control swelling. Sterile gauze or cotton is placed between affected fingers or toes to prevent maceration, and a bulky dressing is placed on the extremity. A foot cradle may be used to prevent contact with bedclothes if the feet are involved. Hemorrhagic blebs, which may develop 1 hour to a few days after rewarming, are left intact and not ruptured. Nonhemorrhagic blisters are débrided to decrease the inflammatory mediators found in the blister fluid.

A physical assessment is conducted with rewarming to observe for concomitant injury, such as soft tissue injury, dehydration, alcohol intoxication, or fat embolism. Problems such as hyperkalemia (e.g., from release of potassium in the damaged cells) and hypovolemia, which occur frequently in people with frostbite, are corrected. Risk of infection is also great; therefore, aseptic technique is used during dressing changes, and tetanus prophylaxis is given as indicated. Nonsteroidal anti-inflammatory drugs (NSAIDs) are prescribed for their anti-inflammatory effects and to control pain (ENA, 2020a).

Additional measures that may be carried out when appropriate after emergency stabilization measures have been instituted include the following:

- Whirlpool bath for the affected body parts to aid circulation and débridement of necrotic tissue to help prevent infection
- Escharotomy (incision through the eschar) to prevent further tissue damage, to allow for normal circulation, and to permit joint motion
- Fasciotomy to treat compartment syndrome

After rewarming, hourly active motion of any affected digits is encouraged to promote maximal restoration of function and to prevent contractures (Mayo Clinic, 2019). Discharge instructions also include encouraging the patient to avoid tobacco, alcohol, and caffeine because of their vasoconstrictive effects, which further reduce the already deficient blood supply to injured tissues.

Hypothermia

Hypothermia is a condition in which the core (internal) temperature is 35°C (95°F) or less as a result of exposure to cold or an inability to maintain body temperature in the absence of low ambient temperatures. Urban hypothermia (extreme exposure to cold in an urban setting) is associated with a high mortality rate; older adults, infants, people with concurrent illnesses, and those who are homeless are particularly susceptible. Alcohol ingestion increases susceptibility because it causes systemic vasodilation. Some medications (e.g., phenothiazines) or medical conditions (e.g., hypothyroidism, spinal cord injury) decrease the ability to shiver, hampering the body's innate ability to generate body heat. Fatigue and sleep deprivation are also associated with the

development of hypothermia. Heat loss of 2% is normal but increases with exposure. Wet clothing accelerates heat loss, and immersion in cold water increases heat loss by 25% (ENA, 2020a). Victims of trauma are also at risk for hypothermia resulting from treatment with cold fluids, unwarmed oxygen, and exposure during examination. The patient may also have frostbite, but hypothermia takes precedence in treatment.

Assessment and Diagnostic Findings

Hypothermia leads to physiologic changes in all organ systems. There is progressive deterioration, with apathy, poor judgment, ataxia, dysarthria, drowsiness, pulmonary edema, acid–base abnormalities, coagulopathy, and eventual coma. Shivering may be suppressed at a temperature of less than 32.2°C (90°F), because the body's self-warming mechanisms become ineffective. Cardiac output and blood pressure may be so weak that peripheral pulses become undetectable. Cardiac arrhythmias may also occur. Other physiologic abnormalities include hypoxemia and acidosis (ENA, 2020a).

Management

Management consists of removal of wet clothing, continuous monitoring, rewarming, and supportive care.

Monitoring

The CABs of basic life support are a priority. The patient's vital signs, CVP, urine output, arterial blood gas levels, blood chemistry determinations (blood urea nitrogen [BUN], creatinine, glucose, electrolytes), and chest x-rays are evaluated frequently. Core body temperature is monitored with an esophageal, bladder, or rectal thermistor. Continuous ECG monitoring is performed, because cold-induced myocardial irritability leads to conduction disturbances, especially ventricular fibrillation. An arterial line is inserted and maintained to record blood pressure and to facilitate blood sampling.

Rewarming

Rewarming methods include active internal (core) rewarming and passive (spontaneous) or active external rewarming (Higginson, 2018).

Active internal rewarming methods are used for moderate to severe hypothermia (less than 28°C to 32.2°C [82.5°F to 90°F]) and include cardiopulmonary bypass, warm fluid administration, warmed humidified oxygen by ventilator, and warmed peritoneal lavage. Monitoring for ventricular fibrillation as the patient's temperature increases from 31°C to 32°C (88°F to 90°F) is essential.

Passive or active external rewarming is used for mild hypothermia (32.2°C to 35°C [90°F to 95°F]). Passive external rewarming uses over-the-bed heaters to the extremities and increases blood flow to the acidotic, anaerobic extremities. The cold blood from peripheral tissues has high lactic acid levels. As this blood returns to the core, it causes a significant drop in the core temperature (i.e., core temperature afterdrop) and can potentially cause cardiac arrhythmias and electrolyte disturbances. Active external rewarming uses forced-air warming blankets. Care must be taken to prevent extremity burn from these devices, because the patient may not have effective sensation to feel the burn.

Supportive Care

Supportive care during rewarming includes the following as directed (ENA, 2020a):

- External cardiac compression (typically performed only as directed in patients with temperatures higher than 31°C [88°F])
- Defibrillation of ventricular fibrillation. A patient whose temperature is less than 32°C (90°F) experiences spontaneous ventricular fibrillation if moved or touched. Defibrillation is ineffective in patients with temperatures lower than 31°C (88°F); therefore, the patient must be rewarmed first.
- Mechanical ventilation with positive end-expiratory pressure (PEEP) and heated humidified oxygen to maintain tissue oxygenation
- Administration of warmed IV fluids to correct hypotension and to maintain urine output and core rewarming, as described previously
- Administration of sodium bicarbonate to correct metabolic acidosis if necessary
- Administration of antiarrhythmic medications
- Insertion of an indwelling urinary catheter to monitor urinary output and kidney function

Nonfatal Drowning

Nonfatal drowning is defined as survival for at least 24 hours after submersion that caused a respiratory arrest. The most common consequence is hypoxemia. Children under 5 years of age and those over the age of 85 have the highest risk of drowning. An estimated 320,000 drownings occur throughout the world annually, accounting for 7% of global mortality from unintentional injury (World Health Organization [WHO], 2020). Drowning and nonfatal drowning can be prevented by avoiding rip currents offshore; approximately 85% of shore drownings involve a rip current. Pool drownings can be prevented by surrounding the pool with fencing, a self-latching/closing gate, and providing swimming lessons. Supervision near water is still the best prevention measure. When boating, a personal flotation device (PFD), even for swimmers, prevents drowning events. Approximately 50% of nonfatal drownings require hospital admission for management (WHO, 2020).

Factors associated with drowning and nonfatal drowning include alcohol ingestion, inability to swim, diving injuries, hypothermia, and exhaustion. The majority of drowning events occur in pools, lakes, and bathtubs. Suicide by drowning rarely occurs in pools and rarely involves alcohol (WHO, 2020).

Efforts to save the patient should not be abandoned prematurely. Successful resuscitation with full neurologic recovery has occurred in patients who have experienced nonfatal drowning after prolonged submersion in cold water (Parenteau, Stockinger, Hughes, et al., 2018). This is possible because of a decrease in metabolic demands and the diving reflex. The nonfatal drowning process involves the onset of hypoxia, hypercapnia, bradycardia, and arrhythmias. If there is a violent struggle associated with the nonfatal drowning episode, exercise-induced acidosis and tachypnea can result in aspiration. Hypoxia and acidosis cause eventual apnea and loss of consciousness. When the victim loses consciousness and makes a final effort to breathe, the terminal gasp occurs. Water then moves passively into the airways prior to death.

After resuscitation, hypoxia and acidosis are the major complications experienced by a person who has experienced nonfatal drowning; immediate intervention in the ED is essential. Resultant pathophysiologic changes and pulmonary injury depend on the type of fluid (fresh or salt water) and the volume aspirated. Freshwater aspiration results in a loss of surfactant and, therefore, an inability to expand the lungs. Salt-water aspiration leads to pulmonary edema from the osmotic effects of the salt within the lungs. If a person survives submersion, ARDS, resulting in hypoxia, hypercarbia, and respiratory or metabolic acidosis, can occur (ENA, 2020a).

Management

Therapeutic goals include maintaining cerebral perfusion and adequate oxygenation to prevent further damage to vital organs. Cardiopulmonary resuscitation is the factor with the greatest influence on survival. The most important priority in resuscitation is to manage the hypoxia, acidosis, and hypothermia. Prevention and management of hypoxia are accomplished by ensuring an adequate airway and respiration, thus improving ventilation (which helps correct respiratory acidosis) and oxygenation. Arterial blood gases are monitored to evaluate oxygen, carbon dioxide, bicarbonate levels, and pH. These parameters determine the type of ventilatory support needed. The use of endotracheal intubation with PEEP improves oxygenation, prevents aspiration, and corrects intrapulmonary shunting and ventilation–perfusion abnormalities (caused by aspiration of water). If the patient is breathing spontaneously, supplemental oxygen may be given by mask. However, an endotracheal tube is necessary if the patient does not breathe spontaneously.

Because of submersion, the patient is usually hypothermic. A rectal probe or other core measurement device is used to determine the degree of hypothermia. Prescribed rewarming procedures (e.g., extracorporeal warming, warmed peritoneal dialysis, inhalation of warm aerosolized oxygen, torso warming) are started during resuscitation. The choice of warming method is determined by the severity and duration of hypothermia and available resources. Intravascular volume expansion and inotropic agents are used to treat hypotension and impaired tissue perfusion. ECG monitoring is initiated, because arrhythmias frequently occur. An indwelling urinary catheter is inserted to measure urine output. Hypothermia and accompanying metabolic acidosis may compromise kidney function. Nasogastric intubation is used to decompress the stomach and to prevent the patient from aspirating gastric contents.

Even if the patient appears healthy, close monitoring continues with serial vital signs, serial arterial blood gas values, ECG monitoring, intracranial pressure assessments, serum electrolyte levels, intake and output, and serial chest x-rays. After a nonfatal drowning, the patient is at risk for complications such as hypoxic or ischemic cerebral injury, ARDS, and life-threatening cardiac arrest. The patient is also at heightened risk for aspiration; vomiting frequently occurs in patients requiring rescue breathing and in up to 86% of patients requiring CPR (ENA, 2020a).

Decompression Sickness

Decompression sickness, also known as “the bends,” occurs in patients who have engaged in diving (lake/ocean diving), high-altitude flying, or flying in commercial

aircraft within 24 hours after diving. It occurs relatively infrequently in the United States, but its effects can be hazardous. Being aware of decompression sickness and assessing the patient properly ensures appropriate management and results in decreased morbidity.

Decompression sickness results from formation of nitrogen bubbles that occur with rapid changes in atmospheric pressure. They may occur in joint or muscle spaces, resulting in musculoskeletal pain, numbness, or hypesthesia. More significantly, nitrogen bubbles can become air emboli in the bloodstream and thereby produce stroke, paralysis, or death. Taking a rapid history about the events preceding the onset of symptoms is essential (Tintinalli et al., 2020).

Assessment and Diagnostic Findings

To identify decompression sickness, a detailed history is obtained from the patient or diving partner. Evidence of rapid ascent, loss of air in the tank, buddy breathing, recent alcohol intake or lack of sleep, or a flight within 24 hours after diving suggests possible decompression sickness. Some patients describe a perfect dive yet still have the signs and symptoms of decompression sickness, in which case they must receive treatment for the condition.

Signs and symptoms include joint or extremity pain, numbness, hypesthesia, and loss of range of motion. Neurologic symptoms mimicking those of a stroke or spinal cord injury can indicate an air embolus. Cardiopulmonary arrest can also occur in severe cases and is usually fatal. Any neurologic symptoms should be rapidly assessed. All patients with decompression sickness need rapid transfer to a hyperbaric chamber (ENA, 2020a).

Management

A patent airway and adequate ventilation are established, as described previously, and 100% oxygen is given throughout treatment and transport. A chest x-ray is obtained to identify aspiration, and at least one IV line is started with lactated Ringer's or normal saline solution. Research findings suggest that among patients requiring air transport (e.g., helicopter), oxygen saturations and symptoms improve when both oxygen and IV fluids are given. If air transport is required, the aircraft should remain at low altitude (i.e., below 300 m [approximately 1000 feet]) (Holleran, Wolfe, & Frakes, 2018).

The cardiopulmonary and neurologic systems are supported as needed. If an air embolus is suspected, the head of the bed should be lowered. If the patient's wet clothing is still present, it is removed. The patient is kept warm. Transfer to the closest hyperbaric chamber for treatment is initiated. However, the patient who is awake and alert without central neurologic deficits may be able to travel by ground ambulance or by automobile, depending on the severity of symptoms. Throughout treatment, the patient is continually assessed, and changes are documented. If aspiration is suspected, antibiotic agents and other treatment may be prescribed (ENA, 2020a).

Animal and Human Bites

Bites are a common reason for visits to the ED. Dog bites constitute 80% to 90% of these bites and are responsible for the majority of deaths from bites by a nonvenomous animal (Tintinalli et al., 2020). Cat bites have a high risk of infection because of the presence of *Pasteurella* in their saliva. All animal bites must be reported to public health authorities, which must provide follow-up screening of the offending animal for rabies. If the animal cannot be located and rabies vaccination verified, rabies prophylaxis for the person who has been bitten must be instituted (ENA, 2020a).

Human bites are frequently associated with rapes, sexual assaults, or other forms of battery. The human mouth contains more bacteria than that of most other animals, so a high risk of bite-related infection exists. Depending on the circumstances surrounding the event, the victim may delay seeking treatment. The ED nurse should inspect any bitten tissue for pus, erythema, or necrosis. A health care provider should take photographs, which can be used as evidence in criminal and legal proceedings. Guidelines for collecting forensic evidence for photographing with and without a measuring device should be followed. Cleansing with soap and water is then necessary, followed by the administration of antibiotics and tetanus toxoid as prescribed (Tintinalli et al., 2020).

Snakebites

Venomous (poisonous) snakes caused more than 2000 of the 6000 snakebites in the United States annually (Tintinalli et al., 2020). Across the globe, between 4.5 and 5.4 million people get bitten by snakes each year, with 81,000 to 138,000 dying from complications (WHO, 2019). Children between 1 and 9 years of age are the most likely victims. The greatest number of bites occurs during the daylight hours and early evening of the summer months. The most frequent poisonous snakebite in the United States occurs from Crotalidae, otherwise called pit vipers, such as water moccasins, copperheads, and rattlesnakes. The most common site is the upper extremity (ENA, 2020a). Of pit viper bites, 75% to 80% result in **envenomation** (injection of a poisonous material by sting, spine, bite, or other means); the rest result in what are called *dry bites* (Tintinalli et al., 2020). Venomous snakebites are medical emergencies.

Nineteen different species of venomous snakes are found in various regions within the United States. Nurses should be familiar with the types of snakes common to the geographic region in which they practice. However, the exotic pet industry sells atypical snakes as “pets.” Because of this, venomous snakes such as cobras and asps may be found outside of their native region.

Clinical Manifestations

Snake venom consists primarily of proteins and has a broad range of physiologic effects. It may affect multiple organ systems, especially the neurologic, cardiovascular, and respiratory systems.

Classic clinical signs of envenomation are edema, ecchymosis, and hemorrhagic bullae, leading to necrosis at the site of envenomation. Symptoms include lymph node tenderness, nausea, vomiting, numbness, and a metallic taste in the mouth. Without decisive treatment, these clinical manifestations may progress to include fasciculations, hypotension, paresthesias, seizures, and coma (ENA, 2020a).

Management

Initial first aid at the site of the snakebite includes having the person lie down, removing constrictive items such as rings, providing warmth, cleansing the wound, covering the wound with a light sterile dressing, and immobilizing the injured body part below the level of the heart. CABs are the priorities of care. Ice, incision and suction, or a tourniquet is *not* applied. Tetanus and analgesia should be given as necessary. Initial evaluation in the ED is performed quickly and includes information about the following (Tintinalli et al., 2020):

- Whether the snake was venomous or nonvenomous; discourage bringing the snake for identification—even a dead snake's venom is poisonous. Do *not* handle any snake brought to the ED. If the snake is transported to the ED, caution should be taken because the snake is frequently in a stunned, not dead, state. The bite reflex can remain intact for up to 90 minutes after the death of the snake.
- Where and when the bite occurred and the circumstances of the bite.
- Sequence of events, signs, and symptoms (fang punctures, pain, edema, and erythema of the bite and nearby tissues).
- Severity of poisonous effects. Call the local poison control phone number to gain access to information about an exotic snakebite presentation and management, as necessary. The poison control center may also be able to assist with retrieving antivenin for these particular species.
- Vital signs.
- Circumference of the bitten extremity or area at several points. The circumference of the extremity that was bitten is compared with the circumference of the opposite extremity.
- Laboratory data (complete blood count, urinalysis, and coagulation studies).

The course and prognosis of snakebite injuries depend on the kind and amount of venom injected; where on the body the bite occurred; and the general health, age, and size of the patient. There is no one specific protocol for treatment of snakebites. In general, ice, tourniquets, heparin, and corticosteroids are not used during the acute stage. Corticosteroids are contraindicated in the first 6 to 8 hours after the bite because they may depress antibody production and hinder the action of **antivenin** (antitoxin manufactured from the snake venom and used to treat snakebites).

Parenteral fluids may be used to treat hypotension. If vasopressors are used to treat hypotension, their use should be short term. Surgical exploration of the bite is rarely indicated. Typically, the patient is observed closely for at least 6 hours. The patient is *never* left unattended.

Administration of Antivenin

Although envenomation does not always occur, it should always be suspected with snakebites. An assessment of progressive signs and symptoms is essential before considering administration of antivenin, which is most effective if given within 4 hours and no greater than 12 hours after the snakebite. The decision to administer antivenin depends on worsening tissue injury and evidence of systemic and coagulopathic symptoms. Rattlesnakes are more likely to cause coagulation abnormalities as well as

more systemic effects. Coagulation abnormalities are not restricted to severe envenomation (Tintinalli et al., 2020).

The most readily available antivenin in the United States is Crotalidae polyvalent immune Fab antivenom (FabAV or CroFab). The dose depends on the type of snake and the estimated severity of the bite. Indications for antivenin depend on the progression of symptoms, including coagulopathy and systemic reaction (ENA, 2020a).

Crotalidae polyvalent immune Fab antivenom does not require pretesting (i.e., skin sensitivity screening for an allergic reaction; see Chapter 33), albeit monitoring for a hypersensitivity reaction is still necessary. Outside of the United States, however, other antivenin formulas that may be commercially available may still result in severe serum sickness. If the dose exceeds 10 vials, serum sickness will most likely occur. Serum sickness is a type of hypersensitivity response that results in fever, arthralgias, pruritus, lymphadenopathy, and proteinuria and can progress to neuropathies (ENA, 2020a). However, FabAV must be given cautiously to patients receiving anticoagulation therapy. Administration of FabAV may result in a recurring coagulopathy. The dosage and administration of FabAV are different from previously manufactured types of antivenin and should be reviewed carefully before the medication is given.

Before administering antivenin and every 15 minutes thereafter, the circumference of the affected part is measured. Premedication with diphenhydramine or cimetidine may be indicated, because these antihistamines may decrease the allergic response to antivenin. Antivenin is given as an IV infusion whenever possible, although intramuscular administration can be used.

Depending on the severity of the snakebite, the antivenin is diluted in 500 to 1000 mL of normal saline solution. The infusion is started slowly, and the rate is increased after 10 minutes if there is no reaction. The total dose should be infused during the first 4 to 6 hours after the bite. The initial dose is repeated until symptoms decrease, after which time the circumference of the affected part should be measured every 30 to 60 minutes for the next 48 hours to detect symptoms of compartment syndrome (swelling, loss of pulse, increased pain, and paresthesias) (ENA, 2020a).

There is no limit to the number of antivenin vials that can be given. The decision to continue to administer vials is based upon patient symptoms. Consultation with a snakebite expert is essential at this point; this consultant may be identified and found through contacting the Poison Control Center (see the Resources section) or a local zoo reptile center. The most common cause of allergic reaction to the antivenin is too-rapid infusion. Reactions may consist of a feeling of fullness in the face, urticaria, pruritus, malaise, and apprehension. These symptoms may be followed by tachycardia, shortness of breath, hypotension, and shock. In this situation, the infusion should be stopped immediately and IV diphenhydramine given. Vasopressors are used for patients in shock, and resuscitation equipment must be on standby while antivenin is infusing. It is important to note that serum sickness (hypersensitivity) can occur within the first few weeks after discharge. The patient and the patient's family members should be educated about the clinical manifestations of serum sickness (i.e., fever; rash starting on the chest and spreading to the back; arthralgia; gastrointestinal [GI] disturbances [e.g., nausea, vomiting, diarrhea, abdominal pain], and headache) and return to the ED if they occur (Tintinalli et al., 2020).

Spider Bites

There are two venomous spiders found in the United States that may interact with humans: the brown recluse and the black widow. Both are usually found in dark places such as closets, woodpiles, and attics, as well as in shoes (ENA, 2020a).

Brown recluse spider bites are painless. Systemic effects such as fever and chills, nausea and vomiting, malaise, and joint pain develop within 24 to 72 hours. The site of the bite may appear reddish to purple in color within 2 to 8 hours after the bite. Necrosis occurs in the next 2 to 4 days in approximately 10% of cases. The center of the bite may become necrotic, and surgical débridement may be necessary. Wound care consists of cleansing with soap and water, and hyperbaric oxygen treatments may be helpful. Most wounds heal within 2 to 3 months (ENA, 2020a; Tintinalli et al., 2020).

Black widow spider bites feel like pinpricks. Systemic effects usually occur within 30 minutes—much more rapidly than with brown recluse spider bites. Signs and symptoms include abdominal rigidity, nausea and vomiting, hypertension, tachycardia, and paresthesias. Severe pain also develops within 60 minutes and increases over 1 to 2 days. Treatment involves application of ice to the site to decrease swelling and discomfort, along with elevation and assessment of tetanus immunization status. Analgesic agents and benzodiazepines may relieve muscle spasms. Cardiopulmonary monitoring is essential. Antivenin is effective for severe black widow spider bites. This antivenin is horse serum based; therefore, testing for sensitivity must be performed prior to administration (ENA, 2020a).

Tick Bites

Tick bites are common in many areas of the United States, and they usually occur in grassy or wooded areas. It is important to learn the place where the bite occurred as well as the location of the bite on the body. The tick bite itself is not usually the problem; rather, it is the pathogen transmitted by the tick that can cause serious disease. Ticks can carry diseases such as Rocky Mountain spotted fever, tularemia, west Nile virus, and Lyme disease.

Ticks transmit pathogens through their saliva; therefore, the earlier the tick is removed, the better the prognosis. The tick should be removed with tweezers using a straight upward pull (see Fig. 67-4), and the patient should be informed of the signs and symptoms of diseases carried by ticks, especially if the patient lives in or has visited an area endemic for tick-related diseases (e.g., Lyme disease) (ENA, 2020a).

Lyme disease has three stages. Stage I may present with erythema migrans (a classic "bull's-eye" rash) that typically can be found in the axilla, groin, or thigh area and that appears within 4 weeks after the tick bite, with a peak manifestation time of 7 days after the bite. Classically, this rash is at least 5 cm in diameter with bright red borders. It is accompanied by flulike signs and symptoms that may include chills, fever, myalgia, fatigue, and headache. Without treatment, the rash subsides within 3 to 4 weeks. However, the rash and flulike manifestations can be significantly reduced within days if prompt treatment with antibiotic agents (e.g., doxycycline) is initiated. If antibiotics are not given, stage II Lyme disease may present within 4 to 10 weeks following the tick bite and may manifest with joint pain, memory loss, poor motor coordination, adenopathy, and cardiac abnormalities. Facial nerve palsy is the most common manifestation of stage II Lyme disease (Tintinalli et al., 2020). Stage III can begin anywhere from weeks to more than a year after the bite and has serious long-term

chronic sequelae, including arthritis, neuropathy, myalgia, and myocarditis. Even after appropriate treatment with antibiotics, 10% to 20% of patients may experience long-term effects including fatigue and arthralgias; some experience neurologic symptoms that may persist for over 10 years (Tintinalli et al., 2020).

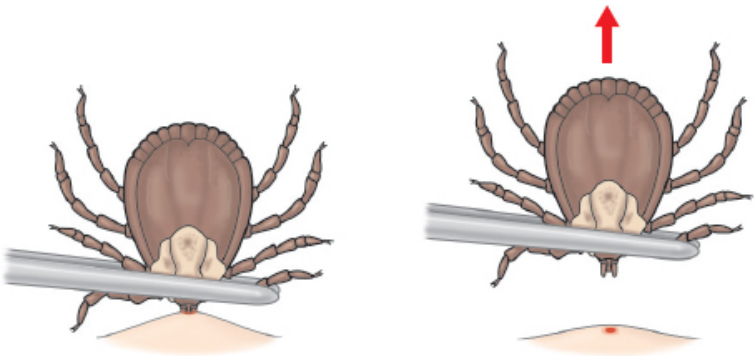


Figure 67-4 • Removal of tick with tweezers using a straight upward pull.

POISONING

A poison is any substance that, when ingested, inhaled, absorbed, applied to the skin, or produced within the body in relatively small amounts, injures the body by its chemical action. Poisoning from inhalation and ingestion of toxic materials, both intentional and unintentional, constitutes a major health hazard and an emergency situation. Emergency treatment is initiated with the following goals:

- Removal or inactivation of the poison before it is absorbed
- Provision of supportive care in maintaining vital organ function
- Administration of a specific antidote to neutralize a specific poison
- Implementation of treatment that hastens the elimination of the absorbed poison

Ingested (Swallowed) Poisons

Swallowed poisons may be corrosive. **Corrosive poisons** include alkaline and acid agents that can cause tissue destruction after coming in contact with mucous membranes. Alkaline products include lye, drain cleaners, toilet bowl cleaners, bleach, nonphosphate detergents, oven cleaners, and button batteries (batteries used to power watches, calculators, hearing aids, or cameras). Acid products include toilet bowl cleaners, pool cleaners, metal cleaners, rust removers, and battery acid.

Control of the airway, ventilation, and oxygenation are essential. In the absence of cerebral or renal damage, the patient's prognosis depends largely on successful management of respiration and circulation. Measures are instituted to stabilize cardiovascular and other body functions. ECG, vital signs, and neurologic status are monitored closely for changes. Shock may result from the cardiodepressant action of the substance ingested, from venous pooling in the lower extremities, or from reduced circulating blood volume resulting from increased capillary permeability (see Chapter

11). An indwelling urinary catheter is inserted to monitor kidney function. Blood specimens are obtained to determine the concentration of drug or poison (ENA, 2020a).

Efforts are made to determine what substance was ingested; the amount; the time since ingestion; signs and symptoms, such as pain or burning sensations, any evidence of redness or burn in the mouth or throat, pain on swallowing or an inability to swallow, vomiting, or drooling; age and weight of the patient; and pertinent health history.

Quality and Safety Nursing Alert

The local poison control center should be called if an unknown toxic agent has been taken or if it is necessary to identify an antidote for a known toxic agent.

Measures are instituted to remove the toxin or decrease its absorption. If there is a specific chemical or physiologic antagonist (antidote), it is given as early as possible to reverse or diminish the effects of the toxin. If this measure is ineffective, procedures may be initiated to remove or dilute the ingested substance. These procedures include administration of multiple doses of activated charcoal, dialysis, or hemoperfusion. Hemoperfusion involves detoxification of the blood by processing it through an extracorporeal circuit and an adsorbent cartridge containing charcoal or resin, after which the cleansed blood is returned to the patient (ENA, 2020a).

The patient who has ingested a corrosive poison, which can be a strong acid or alkaline substance, is given water or milk to drink for dilution. However, dilution is not attempted if the patient has acute airway edema or obstruction; potential for vomiting; or if there is clinical evidence of esophageal, gastric, or intestinal burn or perforation. The following gastric emptying procedures may be used as prescribed:

- Gastric lavage for the patient who is obtunded is only useful within 1 hour of ingestion, for sustained-release substances, or massive life-threatening amounts of a substance; however, complications of aspiration and stomach or esophageal perforation outweigh its usefulness. If performed, gastric aspirate is saved and sent to the laboratory for testing (toxicology screens).
- Activated charcoal administration if the poison is one that is absorbed by charcoal; given orally or by nasogastric tube, it is effective in small intermittent doses to decrease vomiting. It should be diluted as a slurry so that it is easier to drink or pass through the nasogastric tube. Activated charcoal absorbs most commonly ingested poisons except corrosives, heavy metals and hydrocarbons, iron, and lithium.

Cathartics, which had traditionally accompanied the use of activated charcoal, are rarely indicated because they can result in severe electrolyte imbalances, diarrhea, and hypovolemia (ENA, 2020a). Furthermore, syrup of ipecac to induce vomiting in the patient who is alert is not recommended due to the risk of aspiration and should *never* be used with corrosive poisons or with petroleum distillates (e.g., lubricating oil, fuel oil) or further corrosive damage to the upper airway and pharyngeal structures may occur.

Quality and Safety Nursing Alert

Vomiting is never induced after ingestion of caustic substances (acid or alkaline) or petroleum distillates.

Throughout detoxification, the patient's vital signs, CVP, and fluid and electrolyte balance are monitored closely. Hypotension and cardiac arrhythmias are possible. Seizures are also possible because of CNS stimulation from the poison or from oxygen deprivation. If the patient complains of pain, analgesic agents are given cautiously. Severe pain causes vasomotor collapse and reflex inhibition of normal physiologic functions.

After the patient's condition has stabilized and discharge is imminent, written material should be given to the patient indicating the signs and symptoms of potential problems related to the poison ingested and signs or symptoms requiring evaluation by a health care provider. If poisoning was determined to be a suicide or self-harm attempt, a psychiatric consultation should be requested before the patient is discharged. In cases of inadvertent poison ingestion, poison prevention and home poison-proofing instructions should be provided to the patient and family.

Carbon Monoxide Poisoning

Carbon monoxide poisoning may occur as a result of industrial or household incidents or attempted suicide. It is the most common cause of fatality from poisoning and is frequently under-reported to poison control centers or misdiagnosed (Tintinalli et al., 2020). Carbon monoxide exerts its toxic effect by binding to circulating hemoglobin and thereby reducing the oxygen-carrying capacity of the blood. Hemoglobin absorbs carbon monoxide 200 times more readily than it absorbs oxygen. Carbon monoxide–bound hemoglobin, called **carboxyhemoglobin**, does not transport oxygen.

Clinical Manifestations

Because the CNS has a critical need for oxygen, CNS symptoms predominate with carbon monoxide toxicity. A person with carbon monoxide poisoning may appear intoxicated (from cerebral hypoxia). Other signs and symptoms include headache, muscular weakness, palpitation, dizziness, and confusion, which can progress rapidly to coma. Skin color, which can range from pink or cherry-red to cyanotic and pale, is not a reliable sign. Pulse oximetry may reveal a high hemoglobin saturation, which may be deceiving, since the hemoglobin molecule is saturated with carbon monoxide rather than oxygen (ENA, 2020a).

Management

Exposure to carbon monoxide requires immediate treatment. Goals of management are to reverse cerebral and myocardial hypoxia and to hasten elimination of carbon monoxide. Whenever a patient inhales a poison, the following general measures apply:

- Move the patient to fresh air immediately, if possible.
- Open all doors and windows.
- Loosen all tight clothing.

- Initiate traditional cardiopulmonary resuscitation.
- Prevent chilling; wrap the patient in blankets.
- Keep the patient as quiet as possible.
- Do not give alcohol in any form or permit the patient to smoke.

In addition, for the patient with carbon monoxide poisoning, carboxyhemoglobin levels are analyzed on arrival at the ED and before treatment with oxygen if possible. To reverse hypoxia and accelerate the elimination of carbon monoxide, 100% oxygen is given at atmospheric or preferably hyperbaric pressures. Oxygen is given until the carboxyhemoglobin level is less than 5%. The patient is monitored continuously. Psychoses, spastic paralysis, ataxia, visual disturbances, and deterioration of mental status and behavior may persist after resuscitation and may be symptoms of permanent brain damage (Tintinalli et al., 2020).

When unintentional carbon monoxide poisoning occurs, the health department should be contacted so that the dwelling or building in question can be inspected. A psychiatric consultation is warranted if it has been determined that the poisoning was a suicide attempt.

Skin Contamination Poisoning (Chemical Burns)

Skin contamination injuries from exposure to chemicals are challenging because of the large number of possible offending agents with diverse actions and metabolic effects. The severity of a chemical burn is determined by the mechanism of action, the penetrating strength and concentration, and the amount and duration of exposure of the skin to the chemical. A wet chemical should be removed as soon as possible with copious amounts of water. Dry substances should be gently brushed off the skin before the area is flushed (ENA, 2020a). The skin should be flushed with a constant stream of cool water as the patient's clothing is removed. The skin of health care personnel assisting the patient should be appropriately protected if the burn is extensive or if the agent is significantly toxic or still present. Prolonged lavage with generous amounts of tepid water is important. The decontamination shower (deluge) in the ED is the optimal place for total body flushing. The staff attending the patient should wear proper PPE to prevent cross-contamination (Veenema, 2019).

Attempts to determine the identity and characteristics of the chemical agent are necessary in order to specify future treatment. The standard burn treatment appropriate for the size and location of the wound (antimicrobial treatment, débridement, tetanus prophylaxis, antidote administration as prescribed) is instituted (ENA, 2020a) (see Chapter 57). The patient may require plastic surgery for further wound management. The patient is instructed to have the affected area reexamined at 24 and 72 hours and in 7 days because of the risk of underestimating the extent and depth of these types of injuries.

Food Poisoning

Food poisoning is a sudden illness that occurs after ingestion of contaminated food or drink. Botulism is a serious form of food poisoning that requires continual surveillance

(see Chapter 68, Table 68-6). Assessment questions for patients with suspected food poisoning are discussed in Chart 67-7.

The key to treatment is determining the source and type of food poisoning. If possible, the suspected food should be brought to the medical facility and a history obtained from the patient or family.

Food, gastric contents, vomitus, serum, and feces are collected for examination. The patient's respirations, level of consciousness (LOC), blood pressure and hemodynamic status, and muscular activity are monitored closely. Measures are instituted to support the respiratory system. Death from respiratory paralysis can occur with botulism, fish poisoning, and some other food poisonings.

Because large volumes of electrolytes and water are lost by vomiting and diarrhea, fluid and electrolyte status should be assessed. Severe vomiting produces alkalosis, and severe diarrhea produces acidosis. Hypovolemic shock may also occur from severe fluid and electrolyte losses. The patient is assessed for signs and symptoms of fluid and electrolyte imbalances, including lethargy, rapid pulse rate, fever, oliguria, anuria, hypotension, and delirium. Baseline weight and serum electrolyte levels are obtained for future comparisons.

Measures to control nausea are also important to prevent vomiting, which could exacerbate fluid and electrolyte imbalances. An antiemetic medication is given parenterally as prescribed if the patient cannot tolerate fluids or medications by mouth (Tintinalli et al., 2020). For mild nausea, the patient is encouraged to take sips of weak tea, carbonated drinks, or tap water. After nausea and vomiting subside, clear liquids are usually prescribed for 12 to 24 hours, and the diet is gradually progressed to a low-residue, bland diet.

Chart 67-7  ASSESSMENT

Food Poisoning

Use the following questions to elicit information about the circumstances surrounding the possibility of food poisoning:

- How soon after eating did the symptoms occur? (Immediate onset suggests chemical, plant, or animal poisoning.)
- What was eaten in the previous meal? Did the food have an unusual odor or taste? (Most foods causing bacterial poisoning *do not* have unusual odor or taste.)
- Did anyone else become ill from eating the same food?
- Did vomiting occur? What was the appearance of the vomitus?
- Did diarrhea occur? (Diarrhea is usually absent with botulism and with shellfish or other fish poisoning.)
- Are any neurologic symptoms present? (These occur in botulism and in chemical, plant, and animal poisoning.)
- Does the patient have a fever? (Fever is characteristic in salmonella, ingestion of fava beans, and some fish poisoning.)

SUBSTANCE USE DISORDER (SUD)

SUD is the misuse of specific substances, such as drugs or alcohol, to alter mood or behavior. Drug abuse is the use of drugs for other than legitimate medical purposes. People who abuse drugs often take a variety of drugs simultaneously (such as alcohol, barbiturates, opioids, and tranquilizers), and the combination may have additive and addictive effects.

"Rave parties" are large-scale parties attended by hundreds of people involved in illicit drug use. At these events, one of the most commonly used drugs is 3,4-methylenedioxymethamphetamine (MDMA), or Ecstasy, a methamphetamine-based drug that users believe produces a "harmless high." ED nurses should be aware of rave parties in their geographic area so that they can prepare for a potential influx of patients who abuse this drug (ENA, 2020a). Others may combine Ecstasy with sildenafil; this drug combination is nicknamed "sextasy."

Spice is a synthetic cannabinoid sold commercially as a smoking mixture under the names "spice," "incense," or "K2." Its chemical structure and effects are similar to marijuana, targeting the same receptor sites in the brain. Spice is sold with variable concentrations and unregulated potency (National Institute on Drug Abuse, 2018).

Bath salts are synthetic stimulants similar to Ecstasy known as "mephedrone," "drone," or "MCAT." Their effects are similar to amphetamines, MDMA, and cocaine. Although bath salts are most commonly swallowed or snorted, they may also be smoked or injected; the method of intake affects the severity and duration of effects (Table 67-1). The structural formula 3,4-methylenedioxypyrovalerone (MDPV) is the most common type of bath salt abused (ENA, 2020a).

Abuse of various inhalants (see Table 67-1) has also increased in popularity; these products generally result more often in cravings than withdrawal when their use is stopped. The method of inhalation varies with the product chosen and requires several deep inhalations to reach euphoria. Methods include sniffing or snorting by directly inhaling the fumes. "Bagging" (sniffing from a bag) or "huffing" (sniffing from a rag or cloth) provide the greatest concentration; "dusting" is another method that delivers the inhalant by directly spraying it into the nostrils. Long-term use results in cortical atrophy and brain stem dysfunction, in addition to cardiomyopathy and emphysema like abnormalities of the lung. Significant others or parents may report that the patient has had poor school or work performance or attendance, weight loss, poor hygiene, fatigue, nosebleeds, and decreased appetite (National Institute on Drug Abuse, 2020).

Clinical manifestations vary with the substance used, but the underlying principles of management are essentially the same. Table 67-1 identifies commonly abused drugs, listing their clinical manifestations and therapeutic management. Treatment goals for a patient with a drug overdose are to support the respiratory and cardiovascular functions, to enhance clearance of the agent, and to provide for safety of the patient and staff. People who abuse IV/injection drugs are at increased risk for HIV infection, acquired immune deficiency syndrome, hepatitis B and C, and tetanus.

Cannabis remains popular, available, and in some states, is now legal. A newer method of cannabis abuse is butane honey oil (BHO) or "dabs." BHO is created at home by heating cannabis with butane to strip the chemical from the plant, which is then heated further to remove the butane. It may be further distilled to "shatter" by being placed in a vacuum to remove any residual butane. The product results in a "dab" which can then be inhaled. Butane in the presence of an ignition source can result in explosion

and fire resulting in chemical and thermal burns (National Institute on Drug Abuse, 2019).

Acute Alcohol Intoxication

Alcohol is a psychotropic drug that affects mood, judgment, behavior, concentration, and consciousness. Many people who drink heavily are young adults or those older than 60 years. There is a high prevalence of alcoholism among patients presenting to the ED for management; up to 31% have histories of SUD with alcohol. Among patients who present to the ED with various injuries, up to 50% may have histories of SUD with alcohol (ENA, 2020a). Because patients with SUD from alcohol return frequently to the ED, they present a challenge to the health professionals who care for them. The CDC advocates routine screening for SUD with alcohol in all outpatient settings, including EDs. Therefore, screenings, brief interventions, and referral to treatment (SBIRT) for patients presenting with suspected SUD with alcohol are recommended. All level I and II verified trauma centers are required to provide this service. SBIRT is considered cost-effective in saving quality of life-years lost and preventing the morbid consequences of continued SUD with alcohol (American College of Emergency Physicians [ACEP], 2017).

Alcohol, or ethanol, is a multisystem toxin and CNS depressant that causes drowsiness, impaired coordination, slurring of speech, sudden mood changes, aggression, belligerence, grandiosity, and uninhibited behavior. In excess, it can also cause stupor and eventually coma and death (i.e., alcohol poisoning). Frequently, underage minors and college students arrive at the ED with alcohol poisoning from binge drinking.

In the ED, the patient who is intoxicated with alcohol or who presents with alcohol poisoning is assessed for head injury, hypoglycemia (which mimics intoxication), and other health problems. Possible nursing diagnoses include impaired breathing associated with CNS depression and impaired impulse control associated with severe intoxication from alcohol.

Treatment involves detoxification of the acute poisoning, recovery, and rehabilitation. Commonly, the patient uses mechanisms of denial and defensiveness. The nurse should approach the patient in a nonjudgmental manner, using a firm, consistent, and accepting attitude. Speaking in a calm and slow manner is helpful because alcohol interferes with thought processes. If the patient appears intoxicated, hypoxia, hypovolemia, and neurologic impairment must be ruled out before it is assumed that the patient is intoxicated. Typically, a blood specimen is obtained for analysis of the blood alcohol level.

TABLE 67-1 Emergency Management of Patients with Drug Overdose

Drug	Clinical Manifestations	Therapeutic Management
Cocaine *Routes may include:* • Intranasally ("snorting")—inhaled into nostrils through straws • By smoking ("freebasing")—cocaine hydrochloride dissolved in ether to yield a pure cocaine alkaloid base ("crack," "rocks"); smoking in a small pipe delivers large quantities of cocaine to lungs. • IV • Polysubstance (cocaine and heroin)	Cocaine is a CNS stimulant that can cause: • Increased heart rate and blood pressure • Hyperpyrexia • Seizures • Sluggish, dilated pupillary response • Muscle rigidity • Increased energy, agitation, aggression • Ventricular arrhythmias • Intense euphoria, then anxiety, sadness, insomnia, and sexual indifference • Cocaine hallucinations with delusions • Psychosis with extreme paranoia and ideas of persecution • Hypervigilance Chronic psychotic symptoms may persist. Overall psychotic symptoms are short-lived compared to methamphetamines	1. Maintain airway and provide respiratory support. 2. Control seizures. 3. Monitor cardiovascular effects; have antiarrhythmic drugs and defibrillator available. 4. Treat for hyperthermia. 5. If cocaine was ingested, evacuate stomach contents and use activated charcoal to treat. Whole bowel irrigation may be necessary to treat body packers ("mules"). 6. Refer for psychiatric evaluation and treatment in an inpatient unit that eliminates access to the drug. Include drug rehabilitation counseling.
Opioids Heroin Opium or paregoric Morphine, codeine, semisynthetic derivatives: oxycodone, methadone, meperidine, tramadol, fentanyl	Acute intoxication (overdose) can result in: • Pinpoint pupils (may be dilated with severe hypoxia) • Decreased blood pressure • Marked respiratory depression/arrest • Pulmonary edema • Stupor → coma • Seizures Fresh needle marks along course of any superficial vein Skin abscesses (from "popping")	1. Support respiratory and cardiovascular functions. 2. Establish IV lines; obtain blood for chemical and toxicologic analysis. Patient may be given bolus of glucose to eliminate possibility of hypoglycemia. 3. Administer narcotic antagonist (naloxone hydrochloride IV, IM) as prescribed to reverse severe respiratory depression and coma.

		4. Continue to monitor level of responsiveness and respirations, pulse, and blood pressure. Duration of action of naloxone hydrochloride is shorter than that of heroin; repeated dosages may be necessary. 5. Send urine for analysis; opioids can be detected in urine. 6. Obtain an ECG. 7. Do not leave patient unattended; they may lapse back into coma rapidly. Clinical status may change from minute to minute. Hemodialysis may be indicated for severe drug intoxication. Activated charcoal may be considered if opioids were taken orally and if the patient is alert. 8. Monitor for pulmonary edema, which is frequently seen in patients who abuse/overdose on narcotics. 9. Refer patient for psychiatric and drug rehabilitation evaluation before discharge.
Barbiturates		
Pentobarbital, secobarbital, amobarbital, gamma-hydroxybutyrate (GHB, "liquid Ecstasy")	*Acute intoxication (may mimic alcohol intoxication):* • Respiratory depression • Flushed face • Decreased pulse rate; decreased blood pressure • Increasing nystagmus (to vertical and horizontal gaze) • Sluggish pupils	1. Maintain airway and provide respiratory support. 2. Endotracheal intubation or tracheostomy is considered if there is any doubt about the adequacy of airway exchange. a. Check airway frequently.

	• Lack of convergence of eyes • Depressed deep tendon reflexes • Decreasing mental alertness • Difficulty in speaking • Poor motor coordination and flaccid muscles • Coma, death *GHB:* • Sexual disinhibition • Amnesia, myoclonus, agitation • Overdoses when mixed with alcohol	b. Perform suctioning as necessary. 3. Support cardiovascular and respiratory functions; most deaths result from respiratory depression or shock. 4. Start infusion through large-gauge needle or IV catheter to support blood pressure; coma and dehydration result in hypotension and respond to infusion of IV fluids with elevation of blood pressure. 5. Evacuate stomach contents or lavage if within 1 h of ingestion to prevent absorption; repeated doses of activated charcoal may be given. 6. Assist with hemodialysis for patient with severe overdose. 7. Maintain neurologic and vital sign flow sheet. 8. Patient awakening from overdose may demonstrate combative behavior. 9. Refer for psychiatric and drug rehabilitation consultation to evaluate suicide potential and drug abuse.
Inhalants Amyl nitrate Freon Propane Trichloroethylene Gasoline Perchloroethylene Toluene (metallic paint spray) Helium Canned air Hand sanitizer *Routes may include:*	Effects mimic those of alcohol, with dizziness and imbalance: • Euphoria, headache, disinhibition, altered level of consciousness to coma • Renal, hepatic, and cardiac toxicity • Aplastic anemia	1. Provide airway support, ventilation, and oxygen. 2. Treat cardiac arrhythmias and hypotension. 3. Provide advanced cardiac life support as needed.

• Sniffing/snorting—direct inhalation of fumes • "Bagging"—sniff from a bag • "Huffing"—sniff from a rag/cloth • "Dusting"—direct spray into the nostrils	• Fetal growth retardation • Respiratory depression, arrest from CNS depression • Vasodilation • Nosebleeding • Vertical and horizontal nystagmus • Lack of convergence of eyes • Sluggish pupils • Temperature fluctuations • Circumoral red spots/rash • Air embolus	4. Monitor for profound hypotension when amyl nitrate is combined with MDMA and sildenafil or with anesthetic agents. 5. Monitor for hypertension when volatile solvents are used.
Amphetamine-Type Drugs (pep pills, "uppers," "speed," "crystal meth")		
amphetamine dextroamphetamine methamphetamine ("speed") 3,4-methylenedioxymethamphetamine (MDMA) ("Ecstasy," "Adam")[a] 3,4-methylenedioxy-*N*-ethylamphetamine (MDEA) ("Eve") 3,4-methylenedioxyamphetamine (MDA); methylphenidate "ice," "rocks," "crystal meth" 3,4-methylenedioxypyrovalerone (MDPV) or 4-methylmethcathinone; "Bath salts" (synthetic stimulant)	• Nausea, vomiting, anorexia • Palpitations, tachycardia • Increased blood pressure • Tachypnea, anxiety • Nervousness • Diaphoresis, mydriasis • Repetitive or stereotyped behavior • Irritability, insomnia, agitation • Visual misperceptions, auditory hallucinations • Fearfulness, anxiety, depression, hostility, paranoia • Hyperactivity, rapid speech, euphoria, hyperalertness • Decreased inhibition • Seizures, coma, hyperthermia • Cardiovascular collapse • Rhabdomyolysis • MDMA is both a hallucinogenic and a stimulant.	1. Provide airway support, ventilation, cardiac monitoring; insert IV line. 2. Use GI evacuation in cases of oral overdose; activated charcoal, gastric lavage if within 1 h of ingestion. 3. Keep in calm, cool, quiet environment; elevated temperature potentiates amphetamine toxicity. Maintain normothermia, cooling the patient as necessary. 4. Administer small doses of diazepam (IV) or haloperidol as prescribed for CNS and muscular hyperactivity. 5. Administer appropriate pharmacologic therapy as prescribed for severe hypertension and ventricular arrhythmias. 6. Treat seizures with benzodiazepines (e.g., diazepam) as prescribed.

	• MDPV and 4-methylmethcathinone effects last >24 h.	7. Treat sympathetic stimulation with beta-blocker agents as prescribed. 8. Try to communicate with patient if delusions or hallucinations are present. 9. Place in a protective environment (preferably psychiatric security room with video monitoring) to observe for suicide attempt. 10. Refer for psychiatric and drug rehabilitation evaluation.
Hallucinogens or Psychedelic-Type Drugs		
Lysergic acid diethylamide (LSD) Phencyclidine HCl (PCP, "angel dust") Mescaline, psilocybin Ketamine ("special K") Synthetic cannabinoids ("spice," "incense," "K2") Butane honey oil (BHo)—"dabs," "shatter"	• Nystagmus • Pupil dilation • Mild hypertension • Marked confusion bordering on panic • Incoherence, hyperactivity • Withdrawn • Combative behavior; delirium, mania, self-injury (lasts 6–12 h) • Hallucinations, body image distortion • Hypertension, hyperthermia, acute kidney injury • Flashback—recurrence of LSD-like state without having taken the drug; may occur weeks or months after drug was taken • Ketamine—"out-of-body" experience; increased aggressiveness • Manufacturing can result in burns	1. Evaluate and maintain patient's circulation, airway, and breathing. 2. Determine by urine or serum drug screen whether the patient has ingested hallucinogenic drug or has a toxic psychosis. 3. Try to communicate with and reassure the patient. a. "Talking down" involves understanding the process through which the patient is proceeding and helping the patient overcome fears while establishing contact with reality. b. Remind the patient that fear is common with this problem. c. Reassure the patient that they are not losing their mind but are experiencing the effect of drugs and

that this will wear off.

d. Instruct the patient to keep the eyes open; this reduces the intensity of reaction.

e. Reduce sensory stimuli by minimizing noise, lights, movement, tactile stimulation.

4. Sedate the patient as prescribed if hyperactivity cannot be controlled; diazepam or a barbiturate may be prescribed.

5. Search for evidence of trauma; patients who use hallucinogens have a tendency to "act out" their hallucinations.

6. Manage seizures with benzodiazepines (e.g., diazepam) as necessary.

7. Observe patient closely; patient's behavior may become hazardous. Have safety officers stationed near the patient's room.

8. Monitor for hypertensive crisis if patient has prolonged psychosis due to drug ingestion.

9. Place patient in a protected environment under proper medical supervision to prevent self-inflicted bodily harm.

Management for Phencyclidine Abuse

1. Place patient in a calm, supportive environment to minimize stimuli; protect from self-injury.

2. Avoid talking down.

		3. Do not leave patient unobserved. Treat symptoms as they occur. a. Drug effects are unpredictable and prolonged. b. Symptoms are likely to exacerbate; patient becomes out of control. 4. Refer all patients in this category for psychiatric and drug evaluation/rehabilitation.
Drugs Producing Sedation, Intoxication, or Psychological and Physical Dependence (nonbarbiturate sedatives)		
diazepam chlordiazepoxide oxazepam lorazepam midazolam flunitrazepam ("roofies," "date rape drug")[a]	Seizures, coma, circulatory collapse, death *Acute intoxication:* • Respiratory depression • Decreasing mental alertness • Confusion • Slurred speech, decreased blood pressure • Ataxia • Pulmonary edema • Coma, death **Flunitrazepam:** • Disinhibition with antegrade amnesia • Weakness and unsteadiness with impaired judgment • Powerlessness	1. Endotracheal tube is inserted as a precaution; use assisted ventilation to stabilize and correct respiratory depression. Observe for sudden apnea and laryngeal spasm. 2. Assess for hypotension. a. Insert indwelling urinary catheter for patient who is comatose; decreased urinary volume is an index of reduced renal flow associated with reduced intravascular volume or vascular collapse. b. Start volume expansion with saline or dextrose as prescribed. 3. Evacuate stomach contents; lavage (if within 1 h of ingestion); activated charcoal. 4. Start ECG monitoring. Observe for arrhythmias. 5. Administer flumazenil, a benzodiazepine

		antagonist (reversal agent). 6. Refer patient for psychiatric evaluation (potential suicide intent).
Salicylate Poisoning		
Aspirin (present in compound analgesic tablets) • Toxic levels (150–200 mg/kg body weight) • Chronic toxicity (occurs in older adults due to decreased kidney function) • Long-term intoxication (>100 mg/kg/day for more than 2 days)	• Restlessness • Tinnitus, deafness • Blurring of vision • Hyperpnea • Hyperpyrexia • Sweating • Epigastric pain, vomiting • Dehydration • Respiratory alkalosis and metabolic acidosis • Disorientation, coma • Cardiovascular collapse • Coagulopathy	1. Treat respiratory depression. 2. Induce gastric emptying by lavage (if within 1 h after ingestion). 3. Give activated charcoal to adsorb aspirin. 4. Support patient with IV infusions as prescribed to establish hydration and correct electrolyte imbalances, including administration of sodium bicarbonate. 5. Enhance elimination of salicylates as directed by forced diuresis, alkalinization of urine, peritoneal dialysis, or hemodialysis, according to severity of intoxication. 6. Monitor serum salicylate level for efficacy of treatment. 7. Administer specific prescribed pharmacologic agent for bleeding and other problems. 8. Recognize that concretions formed in the gut may result in prolonged exposure as they are digested. 9. Refer patient for psychiatric evaluation (potential suicide intent). 10. Monitor thromboelastography for platelet function.

Acetaminophen (present in prescription and nonprescription analgesics, antipyretics, and cold remedies) • Toxic levels (≥140 mg/kg body weight)	Lethargy to encephalopathy and death GI upset, diaphoresis Right upper quadrant pain Abnormal liver function tests, prolonged prothrombin time, increased bilirubin, disseminated intravascular coagulation Hepatomegaly leading to liver failure Metabolic acidosis Hypoglycemia Stage I—within 24 h; GI irritation, possible metabolic acidosis and coma if severe ingestion Stage II—24–48 h; monitor liver and coagulation studies. Stage III—after 48 h; hepatic encephalopathy/jaundice, vomiting, right upper quadrant pain, coagulopathy, hypoglycemia, acute kidney injury	1. Maintain airway. 2. Obtain acetaminophen level. 3. Laboratory studies—liver function tests, prothrombin time/partial thromboplastin time, complete blood count, blood urea nitrogen, creatinine. 4. Lavage (if within 1 h after ingestion); activated charcoal. 5. Prepare for possible hemodialysis, which clears acetaminophen but does not halt liver damage. 6. Administer NAC as soon as possible. NAC replenishes essential liver enzymes and requires a total of 18 doses every 4 h. Charcoal absorbs NAC; do not administer together. Repeat NAC dose if patient vomits. 7. Refer patient for psychiatric evaluation (potential suicide intent).
Tricyclic Antidepressants		
amitriptyline doxepin nortriptyline imipramine	Arrhythmia: ventricular fibrillation/tachycardia, sinus tachycardia Hypotension Pulmonary edema, hypoxemia, acidosis Confusion, agitation, coma Visual hallucinations Clonus, tremors, hyperactive reflexes, nystagmus, myoclonic jerking Seizures Blurred vision, flushing, hyperthermia	1. Provide airway support, ventilation, cardiac monitoring; insert IV line with normal saline solution. 2. If within 1–2 h after overdose, insert a nasogastric tube and instill activated charcoal every 4 h × 3. 3. Administer a sodium bicarbonate drip to decrease arrhythmias; the alkaline environment increases the protein binding of the

		metabolite. Synchronized cardioversion may be indicated with some arrhythmias refractory to sodium bicarbonate. Torsades de pointes should be treated with IV magnesium sulfate. 4. Administer vasopressors. 5. Manage seizure activity with benzodiazepines (e.g., diazepam) as necessary. 6. Refer patient for psychiatric evaluation for potential suicide intent and evaluation of medication regimen for effectiveness.
Selective Serotonin Reuptake Inhibitors and Other Antidepressants		
trazodone fluoxetine paroxetine sertraline venlafaxine escitalopram bupropion	Decreased level of consciousness, confusion Respiratory depression Increased heart rate Serotonin syndrome may occur if the SSRI was taken in conjunction with dextromethorphan or meperidine Agitation, seizures Hyperthermia, diaphoresis Hypertension, headache, shivering, "goose flesh," cardiac arrhythmias, loss of consciousness	1. Administer activated charcoal with possibly whole bowel irrigation if a sustained-release medication was taken. 2. Use seizure precautions and administer benzodiazepines (e.g., diazepam) as prescribed.
Anabolic Steroids		
"roids," "juice," methandrostenolone, stanozolol, nandrolone Synthetic testosterone	Increase in LDL, decrease in HDL Alter carbohydrate metabolism Hyponatremia, hypokalemia Hypocalcemia/osteoporosis Mood swings/violent behaviors Invincibility, depression, potential for suicide attempts Memory loss, cognitive disability	1. Provide supportive therapy appropriate to patient's emotional manifestations. 2. Protect the patient from self-harm/harming others. 3. Encourage the patient to stop use; refer patient for psychiatric evaluation.

	Immunosuppression Used to bulk up muscles, so skeletal muscle hypertrophy is a common manifestation.

→, precedes; CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal; HDL, high-density lipoprotein; IM, intramuscular; IV, intravenous; LDL, low-density lipoprotein; NAC, N-acetylcysteine; SSRI, selective serotonin reuptake inhibitor.

[a]Polydrug use at "rave clubs" frequently involves MDMA, alcohol, amphetamines, LSD, and sometimes dextromethorphan. Terms such as "Ecstasy" may refer to flunitrazepam, GHB, ephedrine, and/or caffeine, in addition to MDMA.

Adapted from Emergency Nurses Association (ENA). (2020a). *Sheehy's manual of emergency care* (8th ed.). St. Louis, MO: Mosby; Tintinalli, J. E., Stapczyski, J. S., Ma, O. J., et al. (2020). *Tintinalli's emergency medicine manual* (9th ed.). New York: McGraw-Hill Medical.

If drowsy, the patient should be allowed to sleep off the state of alcoholic intoxication. During this time, maintenance of a patent airway and observation for symptoms of CNS depression are essential. The patient should be kept warm with blankets. On the other hand, if the patient is noisy or belligerent, sedation may be necessary. If sedation is used, the patient should be monitored carefully for hypotension and decreased LOC.

In addition, the patient is examined for alcohol withdrawal delirium and for injuries and organic disease (such as head injury, seizures, pulmonary infections, hypoglycemia, and nutritional deficiencies) that may be masked by alcoholic intoxication. People with alcoholism suffer more injuries than the general population. Acute alcohol intoxication is the cause of trauma for many patients without alcoholism as well. Pulmonary infections are also more common in patients with alcoholism, resulting from respiratory depression, an impaired defense system, and a tendency toward aspiration of gastric contents. The patient may show little increase in temperature or WBC count. The patient may be hospitalized or admitted to a detoxification center in an effort to examine problems underlying SUD (ENA, 2020a).

Alcohol Withdrawal Syndrome

Alcohol withdrawal syndrome is an acute toxic state that occurs as a result of sudden cessation of alcohol intake after a bout of heavy drinking or, more typically, after prolonged intake of alcohol. Severity of symptoms depends on how much alcohol was ingested and for how long. Delirium tremens, the most severe form of alcohol withdrawal syndrome, may be precipitated by acute injury or infection (e.g., pneumonia, pancreatitis, hepatitis). Delirium tremens is a life-threatening condition and carries a high mortality rate if untreated (Moore, Fuehrlein, & Rosenheck, 2017).

Patients with alcohol withdrawal syndrome show signs of anxiety, uncontrollable fear, tremor, irritability, agitation, insomnia, and incontinence. Usually, all vital signs are elevated in the alcoholic toxic state. Approximately 5% of patients with alcohol withdrawal syndrome experience delirium tremens, which manifest with visual, tactile, olfactory, and auditory hallucinations that often are terrifying; the patient exhibits agitation. Autonomic overactivity occurs and is evidenced by tachycardia, hypertension, dilated pupils, hyperthermia, and profuse perspiration. Classically, delirium tremens

commence within approximately 48 to 96 hours after the last drink of alcohol (Hoffman & Weinhouse, 2020).

The goals of management for alcohol withdrawal syndrome are to give adequate sedation and support to allow the patient to rest and recover without danger of injury or peripheral vascular collapse. A physical examination is performed to identify preexisting or contributing illnesses or injuries (e.g., head injury, pneumonia). A drug history is obtained to elicit information that may facilitate adjustment of any sedative requirements. Baseline blood pressure is determined, because the patient's subsequent treatment may depend on blood pressure changes.

Usually, the patient is sedated as directed with a sufficient dosage of benzodiazepines to establish and maintain sedation, which reduces agitation, prevents exhaustion, prevents seizures, and promotes sleep. The patient should be calm, able to respond, and able to maintain an airway safely on their own. A variety of medications and combinations of medications are used (e.g., chlordiazepoxide, lorazepam, and clonidine). Haloperidol, esmolol, or midazolam may be given for delirium tremens. Dosages are adjusted according to the patient's symptoms (agitation, anxiety) and blood pressure response (ENA, 2020a).

The patient is placed in a calm, nonstressful environment (usually a private room) and observed closely. The room remains lighted to minimize the potential for illusions (visual misrepresentations) and hallucinations. Homicidal or suicidal responses may result from hallucinations. Closet and bathroom doors are closed to eliminate shadows. A staff member is designated to stay with the patient as much as possible. The presence of another person has a reassuring and calming effect, which helps the patient maintain contact with reality. To orient the patient to reality, any illusions are explained.

Quality and Safety Nursing Alert

Restraints are used as prescribed, if necessary, if the patient is aggressive or violent, but only when other alternatives have been unsuccessful. The patient who is restrained must be watched continuously on a one-on-one basis by an ED staff member. The least restrictive device that will prevent injury to the patient or others is used. Caution is taken to ensure that restraints are applied properly and that they are not impairing circulation to any part of the patient's body or interfering with respirations. Restraints should be used in tandem with verbal intervention to calm the patient and promote adherence. Restraints must be released according to protocol. Physical observation (e.g., skin integrity, circulatory status, respiratory status) is ongoing, and the patient's response is documented.

Fluid losses may result from GI losses (vomiting), profuse perspiration, and hyperventilation. In addition, the patient may be dehydrated as a result of alcohol's effect of decreasing antidiuretic hormone. The oral or IV route is used to restore fluid and electrolyte balance.

Temperature, pulse, respiration, and blood pressure are recorded frequently (every 30 minutes with delirium tremens) to monitor for peripheral circulatory collapse or hyperthermia (the two most serious complications).

Frequently seen complications include infections (e.g., pneumonia), trauma, hepatic failure, hypoglycemia, and cardiovascular problems. Hypoglycemia may accompany alcohol withdrawal syndrome because alcohol depletes liver glycogen stores and impairs gluconeogenesis; many patients with alcoholism also are malnourished. Parenteral dextrose may be prescribed if the liver glycogen level is depleted. Orange juice, sports drinks, or other sources of carbohydrates are given to stabilize the blood glucose level and counteract tremulousness. Supplemental vitamin therapy and a high-protein diet are provided as prescribed to counteract nutritional deficits. The patient should be referred to an alcoholic treatment center for follow-up care and rehabilitation.

VIOLENCE, ABUSE, AND NEGLECT

EDs are often the first place where victims of family violence, abuse, or neglect go to seek help.

Family Violence, Abuse, and Neglect

In the United States, about 1 in 4 women and nearly 1 in 10 men have experienced sexual violence, physical violence, and/or stalking by an intimate partner during their lifetime. Over 43 million women and 38 million men have experienced psychological aggression by an intimate partner (CDC, 2019c). IPV may include physical violence, sexual violence, stalking, psychological aggression, neglect, financial abuse, or intimidation by a former or intimate partner (ENA, 2018b). It is important to recognize that IPV does occur in all cultures and populations; these may include teenagers, older adults, and heterosexual, transgender, and same sex couples (ENA, 2018b).

Those who have been subjected to IPV have significantly higher rates of visits to the ED than the general population. Because patients subjected to IPV often have contact first with nurses in the health care system, ED nurses must be vigilant in their assessments of both women and men who present with injuries that may be consistent with IPV (Herzog, Maina, & Maposa, 2019). In addition, ED nurses must be aware that men and women with disability are at higher risk of domestic violence and abuse than people without disability and should include questions that screen for IPV in their evaluations (see Chapter 50, Chart 50-3).

Gerontologic Considerations

It is estimated that more than 1 in 10 adults 70 years or older (14%) have been abused or neglected, a type of IPV called *elder abuse* (Rosay & Mulford, 2017). The majority of elder abuse is perpetrated by family members (National Center on Elder Abuse, 2017). Elder abuse takes many forms, including physical, sexual, emotional, and verbal abuse; neglect; violation of personal rights; abandonment; and financial abuse (ENA, 2020a).

Clinical Manifestations

When people who have been abused seek treatment, they may present with physical injuries or health problems such as anxiety, insomnia, or GI symptoms related to stress. The possibility of IPV should be investigated whenever a person presents with multiple injuries that are in various stages of healing, when injuries are unexplained, and when the explanation does not fit the physical picture (see Chart 67-8). The possibility of neglect should be investigated whenever a person who is dependent shows evidence of inattention to hygiene, to nutrition, or to know medical needs (e.g., unfilled medication prescriptions, missed appointments with health care providers). In the ED, the most common physical injuries seen are unexplained bruises, lacerations, abrasions, head injuries, or fractures. The most common clinical manifestations of neglect are malnutrition and dehydration (ENA, 2020a).

Assessment and Diagnostic Findings

Nurses in EDs are in an ideal position to provide early detection and interventions for victims of IPV. This requires an acute awareness of the signs of possible IPV, including abuse, maltreatment, and neglect. Nurses must be skilled in interviewing techniques that are likely to elicit accurate information. A careful history is crucial in the screening process. Asking questions in private—away from others—may be helpful in eliciting information about abuse, maltreatment, and neglect. Nurses need to be aware that women may withhold directly answering questions regarding IPV in fear of retaliation, loss of children, and retribution against the children (Herzog et al., 2019).

Chart 67-8  **ASSESSMENT**

Assessing for Abuse, Maltreatment, and Neglect

The following questions may be helpful when assessing a patient for abuse, maltreatment, and neglect:

- I noticed that you have a number of bruises. Can you tell me how they happened? Has anyone hurt you?
- You seem frightened. Has anyone ever hurt you?
- Patients sometimes tell me that they have been hurt by someone at home or at work. Could this be happening to you?
- Are you afraid of anyone at home or work, or of anyone with whom you come in contact?
- Has anyone failed to help you to take care of yourself when you needed help?
- Has anyone prevented you from seeing friends or other people whom you wish to see?
- Have you signed any papers that you did not understand or did not wish to sign?
- Has anyone forced you to sign papers against your will?
- Has anyone forced you to engage in sexual activities within the past year?
- Has anyone prevented you from using an assistive device (e.g., wheelchair, walker) within the past year?
- Has anyone you depend on refused to help you take your medicine, bathe, groom, or eat within the past year?

Whenever evidence leads the nurse to suspect abuse or neglect, an evaluation with careful documentation of descriptions of events and drawings or photographs of injuries is important, because the medical record may be used as part of a legal proceeding. Assessment of the patient's general appearance and interactions with significant others, an examination of the entire surface area of the body, and a mental status examination are crucial.

Management

The aims of IPV screening include earlier identification of patients who have been abused and prevention of continued abusive events, including homicide (ENA, 2018b). Whenever abuse, maltreatment, or neglect is suspected, the health care provider's main concern should be the safety and welfare of the patient. Treatment focuses on the consequences of the abuse, violence, or neglect and on prevention of further injury. Protocols of most EDs require that a multidisciplinary approach be used. Nurses, physicians, social workers, and community agencies work collaboratively to develop and implement a plan for meeting the patient's needs.

If the patient is in immediate danger, they should be separated from the person who is abusive or neglectful whenever possible. Referral to a shelter may be the most appropriate action, but many shelters are inaccessible to people with mobility limitations.

When abuse or neglect is the result of stress experienced by a caregiver who is no longer able to cope with the burden of caring for an older adult or a person with chronic disease or a disability, respite services may be necessary. Support groups may be helpful

to these caregivers. When mental illness of the person who is abusive or neglectful is responsible for the situation, alternative living arrangements may be required.

Nurses must be mindful that competent adults are free to accept or refuse the help that is offered to them. Some patients insist on remaining in the home environment where the abuse or neglect is occurring. The wishes of patients who are competent and not cognitively impaired should be respected. However, all possible alternatives, available resources, and safety plans should be explored with the patient.

Mandatory reporting laws in most states require health care workers to report suspected abuse of children or older adults to an official agency, usually Child or Adult Protective Services. All that is required for reporting is the suspicion of abuse; the health care worker is not required to prove abuse or neglect. Likewise, health care workers who report suspected abuse are immune from civil or criminal liability if the report is made in good faith. Subsequent home visits resulting from the report of suspected abuse are a part of gathering information about the patient in the home environment. In addition, many states have resource hotlines for use by health care workers and by patients who seek answers to questions about abuse and neglect (ENA, 2020a).

Sexual Assault

The definition of *rape* is forced sexual acts, especially if these acts involve vaginal or anal penetration. Attempted rape may include verbal threats of rape (ENA, 2020a). Perpetrators and victims may be either male or female. Rape crisis centers offer support and education and help people who have been sexually assaulted through the subsequent police investigation and courtroom experience.

The manner in which the patient is received and treated in the ED is important to their future psychological well-being. Crisis intervention should begin when the patient enters the health care facility. The patient should be seen immediately. Most hospitals have a written protocol that addresses the patient's physical and emotional needs as well as collection of forensic evidence.

In many states, the emergency nurse has the opportunity to become trained as a sexual assault nurse examiner (SANE). Preparing for this role requires specific training in forensic evidence collection, history taking, documentation, and ways to approach the patient and family. Specialized training also includes learning proper photographic methods and the use of colposcopy. Colposcopy facilitates assessment by magnifying tissues and looking for evidence of microtrauma. Evidence is collected through photography, videography, and analysis of specimens. Another tool useful to the SANE is the light-staining microscope, which enables the examiner to identify motile and nonmotile sperm and infectious organisms. This tool saves time and also enhances assessment. The SANE complements the ED staff and can spend more time with both the patient and police officers investigating the incident (ENA, 2020a).

Assessment and Diagnostic Findings

The patient's reaction to rape has been termed *rape trauma syndrome* and is seen as an acute stress reaction to a life-threatening situation. The nurse performing the assessment is aware that the patient may go through several phases of psychological reactions, which have been described as follows (ENA, 2020a):

- An acute disorganization phase, which may manifest as an expressed state in which shock, disbelief, fear, guilt, humiliation, anger, and other such emotions are encountered or as a controlled state in which feelings are masked or hidden and the victim appears composed.
- A phase of denial and unwillingness to talk about the incident, followed by a phase of heightened anxiety, fear, flashbacks, sleep disturbances, hyperalertness, and psychosomatic reactions that is consistent with PTSD (see later discussion).
- A phase of reorganization, in which the incident is put into perspective. Some victims never fully recover and go on to develop chronic stress disorders and phobias.

Management

The goals of management are to provide support, to reduce the patient's emotional trauma, and to gather available evidence for possible legal proceedings. All of the interventions are aimed at encouraging the patient to gain a sense of control over their life.

Throughout the patient's stay in the ED, the patient's privacy and sensitivity must be respected. The patient may exhibit a wide range of emotional reactions, such as hysteria, stoicism, or feelings of being overwhelmed. Support and caring are crucial. The patient should be reassured that anxiety is natural and asked whether a person who can provide support may be called. Appropriate support is available from professional and community resources. The National Sexual Assault Hotline (see the Resources section, under the Rape, Abuse, and Incest National Network) will automatically route the patient to the nearest assault or crisis intervention center for services, as needed. The patient should never be left alone.

Physical Examination

A written, witnessed informed consent must be obtained from the patient (or parent or guardian if the patient is a minor) for examination, for taking of photographs, and for release of findings to police. A history is obtained only if the patient has not already talked to a police officer, social worker, or crisis intervention worker. The patient should not be asked to repeat the history. Any history of the event that is obtained should be recorded in the patient's own words. The patient is asked whether they have bathed, douched, brushed their teeth, changed clothes, urinated, or defecated since the attack, because these actions may alter interpretation of subsequent findings. The time of admission, time of examination, date and time of the alleged rape, and the patient's emotional state and general appearance (including any evidence of trauma, such as discoloration, bruises, lacerations, secretions, or torn and bloody clothing) are documented. If the patient has no recollection of the event, drugs that induce retrograde amnesia may have been involved, such as alcohol, ketamine, gamma-hydroxybutyrate, benzodiazepines, or flunitrazepam. Urine drug test must be completed within 96 hours of the event to capture the presence of these drugs. Emesis can also be collected for testing (ENA, 2020a).

For the physical examination, the patient is helped to undress and is draped properly. Each item of clothing is placed in a separate paper bag. As noted previously, plastic bags

are not used in order to avoid possible destruction of evidence from mold or mildew formation. The bags are labeled and given to appropriate law enforcement authorities.

The patient is examined (from head to toe) for injuries, especially injuries to the head, neck, breasts, thighs, back, and buttocks. Body diagrams and photographs aid in documenting the evidence of trauma. The physical examination focuses on the following:

- External evidence of trauma (bruises, contusions, lacerations, stab wounds)
- Dried semen stains (appearing as crusted, flaking areas) on the patient's body or clothes
- Broken fingernails and body tissue and foreign materials under nails (if found, samples are taken)
- Oral examination, including a specimen of saliva and cultures of gum and tooth areas

Pelvic and rectal examinations are also performed. The perineum and other areas are examined with a Wood lamp or other filtered ultraviolet light. Areas that appear fluorescent may indicate semen stains. The color and consistency of any discharge present is noted. A water-moistened, rather than lubricated, vaginal speculum is used for the examination. Lubricant contains chemicals that may interfere with later forensic testing of specimens and acid phosphatase determinations. The rectum is examined for signs of trauma, blood, and semen. During the examination, the patient should be advised of the nature and necessity of each procedure and given the rationale for each (ENA, 2020a).

Specimen Collection

During the physical examination, numerous laboratory specimens may be collected, including the following:

- Vaginal aspirate, examined for presence or absence of motile and nonmotile sperm.
- Secretions (obtained with a sterile swab) from the vaginal pool for acid phosphatase, blood group antigen of semen, and precipitin test against human sperm and blood.
- Separate smears from the oral, vaginal, and anal areas.
- Culture of body orifices for gonorrhea.
- Blood serum for syphilis and HIV testing and deoxyribonucleic acid (DNA) analysis. A sample of serum for syphilis may be frozen and saved for future testing.
- Pregnancy test if there is a possibility that the female patient may be pregnant.
- Any foreign material (leaves, grass, dirt), which is placed in a clean envelope.
- Pubic hair samples obtained by combing or trimming. Several pubic hairs with follicles are placed in separate containers and identified as the patient's hair.

To preserve the chain of evidence, each specimen is labeled with the name of the patient, the date and time of collection, the body area from which the specimen was obtained, and the names of personnel collecting specimens. The specimens are then given to a designated person (e.g., crime laboratory technician), and an itemized receipt is obtained (ENA, 2020a).

Treating Potential Consequences of Rape

After the initial physical examination is completed and specimens have been obtained, any associated injuries are treated as indicated. The patient is given the option of prophylaxis against sexually transmitted infections (STIs) (also referred to as sexually transmitted disease [STDs]). Ceftriaxone given intramuscularly with 1% lidocaine may be prescribed as prophylaxis for gonorrhea. In addition, a single oral dose of metronidazole and either a single oral dose of azithromycin or a 7-day oral regimen of doxycycline may be prescribed as prophylaxis for syphilis and chlamydia (ENA, 2020a).

Antipregnancy measures may be considered if the patient is a female of childbearing age. A postcoital contraceptive medication, such as an oral contraceptive medication that contains levonorgestrel and ethinyl estradiol, may be prescribed after a pregnancy test. To promote effectiveness, the contraceptive medication should be given within 12 to 24 hours and no later than 72 hours after penile-vaginal intercourse. The 21-day package is prescribed so that the patient does not mistakenly take the inert tablets included in the 28-day package. An antiemetic agent may be given as prescribed to decrease discomfort from side effects. A cleansing douche, mouthwash, and fresh clothing are usually offered.

Follow-Up Care

The patient is informed of counseling services to prevent long-term psychological effects. Counseling services should be made available to both the patient and the family. A referral is made to the National Sexual Assault Hotline (see the Resources section) or directly to a local crisis intervention center. Appointments for follow-up surveillance for pregnancy and for STI and HIV testing also are made (ENA, 2020a).

The patient is encouraged to return to their previous level of functioning as soon as possible. When leaving the ED, the patient should be accompanied by a family member or friend.

Human Trafficking

Human trafficking is a type of modern-day slavery and one of the fastest growing global health issues. Human trafficking is defined as the exploitation of individuals with the use of force, fraud, coercion, or deception (ENA, 2018c; Roney & Villano, 2020). In 2016, an estimated 40.3 million people were trafficked; 1 in 4 of these were children, with nearly 25 million people involved in forced labor (ENA, 2018c). In the United States in 2018, over 23,078 contacts used the National Human Trafficking Hotline, which was a 25% increase compared to 2017 (Polaris Project, National Human Trafficking Hotline, 2018). People subjected to human trafficking have limited access to health care, and the ED may be the only access point to identify their situation (ENA, 2018c).

A victim of trafficking may present to the ED with injury, accompanied by a significantly older boyfriend or travel partner. The victim may have a history of being a chronic runaway, or of homelessness, and of self-mutilation. Common behaviors exhibited by these patients may include cowering or deferring to the person accompanying them, who may appear controlling, and appearing frightened or agitated. The patient may have a special mark/tattoo present, poor dentition, and multiple injuries in various stages of healing. Common physical complaints include injuries, poor healing or poorly healed old injuries, abdominal pain, dizziness, headaches, rashes, or sores.

Patients may demonstrate addiction, panic attacks, impulse control, hostility, and suicidal ideation (Roney & Villano, 2020).

The ED nurse may be well positioned to offer an opportunity for the patient to speak, alone without an accompanying companion, who could be a perpetrator of abuse. Targeted, appropriate questions may include asking patients if they are in control of their own money; whether or not they are able to come and go as they please; and who is the person or persons accompanying them (ENA, 2020a). Patients may decline assistance. The National Human Trafficking Hotline may be tapped into as a resource (see the Resources section).

PSYCHIATRIC EMERGENCIES

A psychiatric emergency is an urgent, serious disturbance of behavior, affect, or thought that makes the patient unable to cope with life situations and interpersonal relationships. A patient presenting with a psychiatric emergency may display overactive or violent, underactive or depressed, or suicidal behaviors.

The most important concern of the ED personnel is determining whether the patient is at risk for injuring self or others. The aim is to try to maintain the patient's self-esteem (and life, if necessary) while providing care. Determining whether the patient is under psychiatric care is important so that contact can be made with the therapist or provider who works with the patient.

Patients Who Are Overactive

Patients who display disturbed, uncooperative, and paranoid behavior and those who feel anxious and panicky may be prone to assaultive and destructive impulses and abnormal social behavior. Intense nervousness, depression, and crying are evident in some patients. Disturbed and noisy behavior may be exacerbated or compounded by alcohol or drug intoxication.

A reliable source for obtaining an accurate history is needed to identify events leading to the crisis. Past mental illness, hospitalizations, injuries, serious illnesses, the use of alcohol or drugs, crises in interpersonal relationships, or intrapsychic conflicts are explored. Because abnormal thoughts and behavior may be manifestations of an underlying physical disorder, such as hypoglycemia, drug or alcohol toxicity, a stroke, a seizure disorder, or head injury, a physical assessment is also performed.

The immediate goal is to gain control of the situation. If the patient is potentially violent, security or police should be nearby. Restraints are used as a last resort and only as prescribed. Approaching the patient with a composed, confident, and firm manner is therapeutic and has a calming effect. Helpful interventions include the following:

- Introduce yourself by name.
- Tell the patient, "I am here to help you."
- Repeat the patient's name from time to time.
- Speak in one-thought sentences, and be consistent.
- Give the patient space and time to slow down.
- Show interest in, listen to, and encourage the patient to talk about personal thoughts and feelings.

- Offer appropriate and honest explanations.

A psychotropic agent (e.g., one that exerts an effect on the mind) may be prescribed for emergency management of functional psychosis. However, a patient with a personality disorder should not be treated with psychotropic medications, and psychotropic medications should not be used if the patient's behavior results from the use of hallucinogens (e.g., lysergic acid diethylamide [LSD]).

Agents such as chlorpromazine and haloperidol act specifically against psychotic symptoms of thought fragmentation and perceptual and behavioral aberrations. The initial dose depends on the patient's body weight and the severity of the symptoms. After administration of the initial dose, the patient is observed closely to determine the degree of change in psychotic behavior. Subsequent doses depend on the patient's response. Typically, after stabilization, the patient is transferred to an inpatient psychiatric unit, or psychiatric outpatient treatment is arranged (ENA, 2020a).

Patients with Posttraumatic Stress Disorder (PTSD)

PTSD is the development of characteristic symptoms after a psychologically stressful event that is considered outside the range of normal human experience (e.g., rape, combat, motor vehicle crash, natural catastrophe, terrorist attack). Symptoms of this disorder include intrusive thoughts and dreams, phobic avoidance reaction (avoidance of activities that arouse recollection of the traumatic event), heightened vigilance, exaggerated startle reaction, generalized anxiety, and societal withdrawal. PTSD may be acute, chronic, or delayed. PTSD often presents as multiple readmissions to the ED for minor or recurring complaints without evidence of injury.

Veterans Considerations

Veterans are known to be at heightened risk of PTSD, particularly if they served in combat situations. It is estimated that between 11% and 20% of veterans who served during Operation Iraqi Freedom (2003–2011) and Operation Enduring Freedom (2001–2014) have had PTSD symptoms in a given year. Furthermore, 12% of veterans who served during the Persian Gulf War (1991) have had PTSD symptoms in a given year, while approximately 30% of veterans who served during the Vietnam War (1962–1973) have had PTSD symptoms at some point in their lifetime. In addition, veterans of any era may have been subjected to sexual assault or sexual harassment during their time in service, which may have resulted in military sexual trauma (MST), a specific type of PTSD. Approximately 23% of female veterans have been sexually assaulted while serving, while 55% of female veterans and 38% of male veterans have been subjected to sexual harassment while serving. In response to these statistics, the U.S. Department of Veterans Affairs (DVA) has sponsored a National Center for PTSD, which provides resources and hotlines to help veterans effectively deal with the effects of PTSD (see the Resources section) (DVA, 2020).

Patients Who Are Underactive or Depressed

In the ED, depression may be seen as the main condition bringing the patient to the health care facility, or it may be masked by anxiety and somatic complaints. The person who is depressed has a mood disturbance. Any patient who is depressed may be at risk for suicide. Most suicide attempts are expressions of extreme distress, not bids for attention (ENA, 2020a).

The patient must be screened regarding any attempts or thoughts of suicide. Questions such as "Have you ever thought about taking your own life?" may be helpful. In general, the patient is relieved to have an opportunity to discuss personal feelings. The emergency nurse's responsibility when caring for a patient with depression is to maintain a high suspicion for the diagnosis, especially for those populations at risk (see following discussion) (ENA, 2020a).

Patients Who Are Suicidal

Attempted suicide is an act that stems from depression (e.g., loss of a loved one, loss of body integrity or status, poor self-image) and can be viewed as a cry for help and intervention. Males are at greater risk of successfully committing suicide than females, who attempt suicide more often (ENA, 2020a). Others at risk are older adults; young adults; people who are enduring unusual loss or stress; those who are unemployed, divorced, widowed, or living alone; those showing signs of significant depression (e.g., weight loss, sleep disturbances, somatic complaints, suicidal preoccupation); and those with a history of a previous suicide attempt, suicide in the family, or psychiatric illness.

Being aware of people at risk and assessing for specific factors that predispose a person to suicide are key management strategies. Specific signs and symptoms of potential suicide include the following:

- Communication of suicidal intent, such as preoccupation with death or speaking of someone else's suicide (e.g., "I'm tired of living." "I've put my affairs in order." "I'm better off dead." "I'm a burden to my family.")
- History of a previous suicide attempt, with risk being much greater in these cases
- Family history of suicide
- Loss of a parent at an early age
- Specific plan for suicide
- A means to carry out the plan

Emergency management focuses on treating the consequences of the suicide attempt (e.g., gunshot wound, drug overdose) and preventing further self-injury. A patient who has made a suicidal attempt may do so again. Crisis intervention is used to determine suicidal potential, to discover areas of depression and conflict, to find out about the patient's support system, and to determine whether hospitalization or psychiatric referral is necessary. Depending on the patient's potential for suicide, the patient may be admitted to the intensive care unit, referred for follow-up care, or admitted to the psychiatric unit.

Unfolding Patient Stories: Carl Shapiro • Part 2

Recall from Chapter 23 Carl Shapiro, who was diagnosed with hypertension and hyperlipidemia during a routine visit to his primary provider. He arrives in the ED with a blood pressure of 210/110. The nurse discovers that he stopped his antihypertensive medication due to erectile dysfunction. How does the nurse maintain patient privacy in the ED during discussion of personal issues? What topics should be included in an individualized discharge plan to address his concerns, educational needs, and continuity of care when the nurse receives orders for an ACE inhibitor, captopril, and discharge home?

Care for Carl and other patients in a realistic virtual environment: vSim (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

CRITICAL THINKING EXERCISES

1 ebp A 48-year-old male arrived in the ED via ambulance. EMS personnel report that the patient was fishing when his boat overturned in a lake. He was in the water for at least 15 minutes before someone was able to get to him. The patient was initially unresponsive but was resuscitated by EMS en route to the hospital. His current body temperature is 34°C (93°F). What evidence-based interventions, including methods of rewarming, are indicated? What additional supportive care will be required? Explain the rationale and levels of support for these methods of treatment.

2 ipc A 19-year-old female college student arrives in the ED accompanied by her friend. She had just been at a party and states an acquaintance she knew forced her to have intercourse against her will. She is tearful and shaking and she appears to have some visible bruising. What priority nursing actions should be taken? What resources will need to be utilized in her care? Who should be consulted for the patient and what type of consent must she provide? Detail the steps that will be taken as you begin to care for this patient. What follow-up care will this patient need?

3 pq A 32-year-old female was brought to the ED by her fiancé. He states he had been working on a faulty hot water heater in the basement most of the day; when he came upstairs, the patient voiced complaints of a headache that had begun about 2 hours ago. He brought her to the ED when she began to complain of dizziness, palpitations, and she seemed to become increasingly confused. What questions would you include in your assessment? Explain the management of this patient and additional care that would be required. What concerns would you have for her fiancé?

68 Disaster Nursing

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the types of disasters that the nurse may encounter as a member of the health care team.
2. Identify essential components of an emergency operations plan and disaster preparedness including personal protection and decontamination procedures.
3. Discuss how triage in a disaster differs from triage in an emergency department.
4. Explain clinical manifestations and treatment of injuries and illnesses resulting from natural disasters, from outbreaks, epidemics, and pandemics, and from various weapons of terror (blast, biologic, chemical, and radiologic events).

NURSING CONCEPTS

Health Care Systems
Managing Care
Safety

GLOSSARY

biologic weapon: a biologic agent that is used to spread disease among the general population or the military

chemical weapon: a chemical agent that is used to cause disability and mortality in the general population or the military

decontamination: process of removing, or rendering harmless, contaminants that have accumulated on personnel, patients, and equipment

disaster: a sudden disruption or event that interrupts the functioning of a community

disaster nursing: adaptation of nursing knowledge and skills to recognize and meet the health needs of individuals during times of crises

epidemic: a widespread outbreak of a specific infectious disease from a single source within a community or population that exceeds anticipated levels of impact

mass casualty incident (MCI): situation in which the number of casualties exceeds the number of available resources

material safety data sheet (MSDS): provides information to employees and health care providers regarding specific chemical agents; includes chemical name, physical data, chemical ingredients, fire and explosive hazard data, health and reactive data, spill or leak procedures, special protection information, and special precautions (*synonym*: the Workers' Right to Know)

natural disaster: a natural event such as a tornado, hurricane, flood, or earthquake that results in significant damage and loss of life

outbreak: the occurrence of a disease within a population that exceeds normal expectations

pandemic: an epidemic that spreads across multiple countries or continents

personal protective equipment (PPE): equipment beyond standard precautions; may include different levels of equipment to provide complete protection, depending on the nature of the suspected biologic, chemical, or radiologic agent

radiologic weapon: byproducts of radiation contamination that are used to cause morbidity and mortality in the general population or the military

terrorism: unlawful, systematic use of violence or threats of violence against people in order to coerce or intimidate

weapons of mass destruction (WMD): weapons used to cause widespread death and destruction

Health care facilities must be prepared for any type of disaster. A **disaster** is a sudden disruption or event that interrupts the functioning of a community (Veenema, 2019). This chapter focuses on disaster preparedness and the role of the nurse in preparing for and responding to disasters. **Disaster nursing** requires the adaptation of nursing knowledge and skills to recognize and meet the health and emotional needs of individuals during such times of crises known as disasters. Nurses serve on the frontline in providing care during a disaster or health crisis; they are called upon to work through difficult situations, sometimes with limited resources. They must utilize innovative thinking, lead effective coordination efforts, and clearly communicate the needs of their patients as well as their own personal needs (Veenema, 2019). Nursing responsibilities include preparing for and managing patients harmed by the effects of all disasters, including natural disasters, outbreaks, epidemics, and pandemics, as well as injuries and illnesses that can occur after biologic, chemical, and nuclear or radiation incidents, which may result from attacks of terrorism. Information about the process that nurses should follow in order to respond to these emergencies is applicable to other types of disasters as well.

Disaster Planning

The possibility and reality of mass casualties associated with disasters is not new to human history. Historically, communities that anticipated and devised plans to deal with the effects of disasters had better morbidity and mortality rates than those that did not. Within the United States, a plan that adheres to guidelines devised by the National Incident Management System (NIMS), which is directed by the U.S. Department of Homeland Security Federal Emergency Management Agency (FEMA), is essential for every community and facility. The preparation based on the NIMS guidelines is effective for terrorist events; **terrorism** is the unlawful, systematic use of violence or threats of violence against people in order to coerce or intimidate. NIMS guidelines are also followed for any other disaster situation, including natural disasters, outbreaks, epidemics, and pandemics. **Natural disasters** are caused by environmental forces including storms, floods, fires, earthquakes, and similar forces of nature

that result in significant damage or loss of life (Veenema, 2019). Airplane crashes, train crashes, and toxic substance spills are other disasters that can result in mass casualties and tax the resources of health care facilities and their communities.

Federal, State, and Local Responses to Disasters

Many resources are available at the federal, state, and local levels to assist in the management of disasters, mass casualty incidents, public health crises, and emergencies. A **mass casualty incident (MCI)** is defined as any incident that causes a large number of casualties to the extent that necessary resources become too scarce (Veenema, 2019). When resources to care for casualties become scarce, the greatest good for the greatest number of patients becomes the mode of operation. Local communities must be prepared to act in isolation (i.e., called *sustainability planning*) and provide competent care for up to 5 days before federal or other state resources may become available (FEMA, 2019).

Disasters are categorized by type based upon anticipated use of resources and incident duration. A list of local resources with specific instructions about how and when to contact these agencies or organizations should be readily available to local disaster planning committees and frequently reviewed by those committees for necessary updates.

A disaster response strategy cannot succeed without appropriate physical assets and staff trained and prepared to carry out the plan. Assets such as increased security; stockpiles of equipment and medications; and planning, drills, and training are essential (Veenema, 2019). Hazard vulnerability assessments should be performed to identify potential and actual threats that involve a particular facility or community. Mutual aid agreements among various communities must take these vulnerabilities into account. Successful execution of a response plan is based on knowledge, confidence, and readiness.

Federal Agencies

The National Health Security Strategy was designed to protect the health of all citizens of the United States in the event of any large-scale MCI or disaster (Veenema, 2019). This national strategy aims to prioritize the use of limited resources and to ensure a rapid coordinated response by the entire affected community so that the maximum number of lives are

saved, property is preserved and protected, and basic health care needs are met in the aftermath of any incident that results in mass casualties (FEMA, 2019). State authorities must request federal assistance with resources through appropriate government channels. A request for federal resources generally is made when local resources have become or are expected to become depleted.

Federal agencies that may provide resources in response to an MCI or a disaster include the Department of Health and Human Service (HHS), the Department of Defense, and the Department of Homeland Security (see Table 68-1). Each of these federal departments oversees hundreds of agencies that may respond to MCIs.

Nurses may be called upon to volunteer to provide support to select agencies or programs set up to respond to an MCI or a disaster. For example, Disaster Medical Assistance Teams (DMATs) organize voluntary medical personnel who can set up and staff a field hospital; DMATs are located across the country. Teams deploy with enough personnel, supplies, and equipment to be self-sufficient for 72 hours at a fixed or temporary medical site. During MCIs, team responsibilities may include triage, providing medical care despite adverse conditions, and preparing patients for evacuation (Veenema, 2019).

The Department of Homeland Security, through the National Terrorism Advisory System (NTAS), designates a level of security threat that is intended to alert the country to credible threats of terrorism. The NTAS notes two levels of terrorism threats, which include *bulletins* and *alerts*. An NTAS bulletin describes trends and developments in threats of terrorism; whereas, an NTAS alert more fully warns of a credible threat of terrorism within the United States. The NTAS alerts may be more specifically designated as an *elevated alert*, meaning that there is indeed a credible alert posted, or an *imminent alert,* meaning that there is a specific pending threat of terrorism within the United States (Department of Homeland Security [NTAS], 2019).

Additional support during disasters is available from the American Red Cross, which provides support systems and shelters as needed. A nongovernment, nonprofit agency, the American Red Cross mobilizes support for those in need because of the effects of disasters through training and mobilizing volunteers.

TABLE 68-1 Select U.S. Federal Agencies Involved in Disaster Response

Agency and Website	Responsibilities
Centers for Disease Control and Prevention (CDC) www.cdc.gov	Primary agency for disease prevention; controls activities and provides backup support to state and local health departments.
Department of Health and Human Service (HHS) www.hhs.gov	Primary agency for coordinating health, medical, and health-related social services under the federal emergency response plan.
Department of Defense (DoD) www.defense.gov	The armed service branches of DoD including the Army, Air Force, Coast Guard, Marine Corps, Navy, and National Guard, are the frontline military defense against acts of war and terrorist threats.
Department of Homeland Security www.dhs.gov	Develops and coordinates a comprehensive national strategy to strengthen federal, state, and local counterterrorism efforts.
Food and Drug Administration (FDA) www.fda.gov/home	Responsible for protecting the

	public health by ensuring the safety, efficacy, and security of human and veterinary drugs, biologic products, and medical devices; and by ensuring the safety of the food supply, cosmetics, and products that emit radiation
National Disaster Medical System (NDMS) www/phe.gov/Preparedness/responders/ndms/Pages/default.aspx	A multiagency system that supports and manages the coordination of medical responses to major emergencies and federally declared disasters that works in collaboration with public and private entities. NDMS is designed to care for victims of any incident that exceeds the capability of the state, regional, or federal health care system. Includes teams such as: • Disaster Medical Assistance

	Teams (DMATs) • Disaster Mortuary Operational Response Team (DMORTs) • Veterinary Medical Assistance Teams (VMATs) • National Medical Response Teams for Weapons of Mass Destruction (NMRTs)
U.S. Public Health Service (USPHS) www.usphs.gov/	A division of HHS that works to preserve and protect the public health of the nation. The USPHS consists of physicians, nurses, dentists, veterinarians, scientists, engineers, and other professionals who work in a variety of governmental agencies that promote the safety of the nation.

COVID-19 Considerations

In response to the coronavirus disease 2019 (COVID-19) pandemic, the Centers for Disease Control and Prevention (CDC) has provided an abundance of education addressing safety measures to combat the virus and precautions for populations at risk and offered regulatory guidance. These important regulations have informed government decisions enacted to ensure the safety of individuals during the pandemic (CDC, 2020a).

In addition to these measures, the Food and Drug Administration (FDA) accelerated the review of diagnostic tests to mitigate the spread of the virus. The FDA was responsible for ensuring that testing methods would provide both accurate and reliable results (FDA, 2020). Congress enacted an Emergency Use Authorization (EUA) that relaxed regulations and ultimately increased the availability of tests. The FDA then revised their standard procedures to allow for laboratory testing prior to FDA validation assessment, an unprecedented policy change that also allowed for increased testing capabilities (FDA, 2020).

State and Local Agencies

State and local resources that might be mobilized in response to a disaster may include branches of the CDC or American Red Cross, poison control centers, and other local volunteer organizations. The Metropolitan Medical Response Team Systems are local teams of health care providers located in cities considered possible terrorist targets who are funded for specialty responses. Many state and federal task forces have been developed to assist in the development and improvement of civilian medical response to chemical and biologic terrorism.

Most cities and all states have an Office of Emergency Management (OEM) or Office of Emergency Services (OES). The OEM/OES coordinates the disaster relief efforts at the state and local levels. The OEM/OES is responsible for providing interagency coordination during an emergency. It maintains a corps of emergency management personnel, including a leader, responders, planners, and administrative and support staff (Toner, 2017).

State and local governments play the primary role in the management of public health emergencies, such as the COVID-19 pandemic, until a request is made by a state that federal assistance is needed (Veenema, 2019). The Public Health Service (PHS) and FEMA are the two federal agencies that coordinate these efforts. In response to the COVID-19 pandemic, FEMA partnered with HHS to ensure adequacy of medical supplies and testing sites (FEMA, 2020a).

The Incident Command System

The Incident Command System (ICS) is a federally mandated command structure that coordinates personnel, facilities, equipment, and communication in any emergency situation. The ICS is the center of operations for organization, planning, and transport of patients in the event of a specific local MCI. Successful incident management requires equipment compatibility, effective communication, adequate distribution of resources, and clear differentiation of members' roles. The ICS ensures that any hazardous substances used during an MCI are identified promptly and that appropriate **personal protective equipment (PPE)** is distributed. PPE describes the use of equipment beyond standard precautions and may include different levels of protection, depending on the nature of the suspected biologic, chemical, or radiologic event (see later discussion). In addition to these responsibilities, the ICS is also responsible for determining when an MCI has ended (Veenema, 2019).

The Hospital Incident Command System (HICS) is a modification of the ICS that is used by both hospitals and law enforcement agencies. The HICS incident commander is the hospital emergency preparedness coordinator who oversees and coordinates all efforts surrounding the event. The HICS team includes a safety officer, public information officer, liaison officer, operations chief, logistics chief, planning chief, and finance chief. Each team member has a specific responsibility and communicates directly back to the incident commander (Veenema, 2019).

Hospital Emergency Preparedness Plans

Health care facilities are required by the Joint Commission to create a plan for emergency preparedness and to practice this plan with all employees at least twice a year. In general, these plans are developed by the facility's safety/disaster management committee and are overseen by an administrative liaison (California Hospital Association, 2017).

Before the basic emergency operations plan (EOP) can be developed, the planning committee of the health care facility evaluates characteristics of the community to identify the likely types of natural and man-made disasters that might occur. This hazard vulnerability analysis process is the responsibility of the local health care facility and its safety committee, safety officer, or emergency department (ED) manager. This information can be gathered by questioning local law enforcement, fire departments, and emergency medical systems and assessing the patterns of local train

traffic, automobile traffic, and flood, earthquake, tornado, or hurricane activity. Consideration is also given to possible MCIs that could arise because of the community's proximity to chemical plants, nuclear facilities, or military bases. Federal, judicial, or financial buildings, schools, and any places where large groups of people gather can be considered high-risk areas (Veenema, 2019).

The emergency preparedness planning committee must have a realistic understanding of its resources. The goal of each health care institution is to remain self-sufficient to provide and sustain core services without the support of external assistance for at least 96 hours from the inception of the incident; ideally, this self-sufficiency should last for 7 days (Veenema, 2019). The committee might also outline how staff would triage and assign priority to patients when resources are limited (e.g., when ventilators are in short supply). Multiple factors influence a facility's ability to respond effectively to a sudden influx of patients who are injured or sick, and the committee must anticipate various scenarios to improve its preparedness.

COVID-19 Considerations

As the incidence of COVID-19 cases in the United States continued to rise at a rapid pace during the early phases of this pandemic, political leaders began to encourage physical distancing among individuals to slow the rate of transmission; this practice became known as social distancing. The goal of social distancing was to attempt to flatten the curve of new infections, thereby avoiding a surge of demand on the health care system. However, the effects of social distancing were not enough to decrease the burden experienced by many U.S. hospitals in key geographic areas, such as New York City and New Orleans. Hospitals in these areas reported shortages of key equipment needed to care for patients who were critically ill, including ventilators and PPE for medical staff (Ranney, Griffeth, & Jha, 2020).

Insufficient PPE (e.g., respirators, face shields, gowns, hand and equipment sanitizer) for frontline health care workers resulted not only in exposures to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), but also in the deaths of health care workers from COVID-19. In response to these shortages, health care providers made pleas to government officials to try to secure adequate PPE for their frontline workers (Ranney et al., 2020). On February 4, 2020, the HHS Secretary declared the EUA of respiratory protective devices, which authorized the

use of additional respiratory protective devices. During this time, the FDA provided frequent updates to manufacturers, facilities, and local and state jurisdictions to increase the production of respirators and additional PPE (CDC, 2020a).

On April 8, 2020, the FEMA COVID-19 Supply Chain Task Force developed a four-step plan to preserve critical resources for medical use. The four steps included preservation, acceleration, expansion, and allocation (FEMA, 2020b). The shortage of critical medical supplies became a global crisis. In the United States, the Defense Production Act (DPA) allowed the president to direct private companies to produce equipment needed for a national emergency. A crucial role for the government is to coordinate efforts to ensure that areas that have been impacted the most are receiving needed equipment and supplies. As U.S. health care facilities continued to care for the growing number of patients hospitalized and critically ill with COVID-19, government officials worked to secure essential equipment needed to care for patients and ensure the safety of their workforce (Ranney et al., 2020).

Components of the Emergency Operations Plan

The principles of emergency management must be a part of the EOP design and include a comprehensive plan for tackling all potential and actual hazards. The main goal is the protection of the community. The EOP should be integrated with local, state, and federal government plans and coordinated with the private sector and volunteers. It must be coordinated in advance to achieve a single common purpose; yet the plan must be flexible enough to adapt to any potential disaster. Essential components of the EOP include the following (California Hospital Association, 2017):

- *Activation response:* The EOP activation response of a health care facility defines where, how, and when the response is initiated.
- *Internal/external communication plan:* Communication is critical for all parties involved, including communication to and from the prehospital arena.
- *Plan for coordinated patient care:* A response is planned for organized patient care into and out of the facility, including transfers from within the hospital to other facilities. The site of the disaster can determine where the greater number of patients may self-refer.

- *Security plans:* A coordinated security plan involving facility and community agencies is key to the control of an otherwise chaotic situation.
- *Identification of external resources:* Resources outside the facility are identified, including local, state, and federal resources and information about how to activate these resources.
- *Plan for people management and traffic flow:* "People management" includes strategies to manage the patients, the public, the media, and the personnel. Specific areas are assigned, and a designated person is delegated to manage each of these groups.
- *Data management strategy:* A data management plan for every aspect of the disaster will save time at every step. A backup system for documenting, tracking, and staffing is developed if the facility utilizes an electronic health record.
- *Demobilization response:* Deactivation of the response is as important as activation; resources should not be unnecessarily exhausted. The person who decides when the facility resumes daily activities is clearly identified. Any possible residual effects of a disaster must be considered before this decision is made.
- *After action report or corrective plan:* Facilities often see increased volumes of patients 3 months or more after an incident. Postincident response must include a critique and a debriefing for all parties involved, immediately and again at a later date.
- *Plan for practice drills:* Practice drills that include community participation allow for troubleshooting any issues before a real-life incident occurs.
- *Anticipated resources:* Food and water must be available for staff, families, and others who may be at the facility for an extended period.
- *MCI planning:* MCI planning includes such issues as planning for mass fatalities and morgue readiness.
- *Education plan for all of the above:* A strong education plan for all personnel regarding each step of the plan allows for improved readiness and additional input for fine-tuning the EOP.

As noted previously, hospitals are required to periodically hold disaster drills. Results from these drills can identify flaws within the EOP as well as unanticipated needs prior to any real disaster situation. Evidence

indicates that full-scale regional exercises that coordinate responses from both hospitals and emergency medical services (EMS) are the most effective drills because they clearly identify breakdowns in communication (FEMA, 2019).

Initiating the Emergency Operations Plan

Notification of a disaster situation to a health care facility varies with each situation. In general, the notification to the facility comes from outside sources unless the initial incident occurred at the facility. The disaster activation plan should clearly state how the EOP is to be initiated. If communication is functioning, field incident command will give notice of the approximate number of patients who are arriving, although the number of patients who are self-referring will not be known (Tintinalli, Ma, Yealy, et al., 2020).

COVID-19 Considerations

In response to the COVID-19 pandemic, the CDC provided evidence-based guidance for maintaining the EOP for all health care facilities, which provided guidance for staff, patients, and visitors. The guidelines were developed to minimize the spread of the virus within the community and to ensure all hospital staff were trained, equipped, and capable of executing these mitigation practices (CDC, 2020b).

Identifying Patients and Documenting Patient Information

Patient tracking is a critical component of casualty management. Disaster tags, which are numbered and include triage priority, name, address, age, location and description of injuries, and treatments or medications given, are used to communicate patient information. The tag should be securely placed on the patient and remain with the patient at all times. The tag number and the patient's name, if known, are recorded in a disaster log. The log is used by the command center to track patients, assign beds, and provide families with information.

Triage

Triage is the sorting of patients to determine the priority of their health care needs and the proper site for treatment. In nondisaster situations, health care workers assign a high priority and allocate the most resources

to those who are the most critically ill (see Chapter 67). For example, under ordinary circumstances, a young adult who has a chest injury and is in cardiac arrest would receive advanced cardiopulmonary resuscitation, including medications, chest tubes, intravenous (IV) fluids, blood, and possibly emergency surgery in an effort to restore life. However, in a disaster, when health care providers are faced with a large number of casualties, the fundamental principle guiding resource allocation is to do the greatest good for the greatest number of people. Decisions are based on the likelihood of survival and consumption of available resources. Therefore, this same patient, and others with conditions associated with a high mortality rate, will be assigned as a low triage priority in a disaster situation, even if the person is conscious. Although this may sound uncaring, from an ethical standpoint the expenditure of limited resources on people with a low chance of survival, and denial of those resources to others with serious but treatable conditions, cannot be justified.

The triage officer rapidly assesses those injured at the disaster scene. Patients are immediately tagged and transported or given lifesaving interventions. One person performs the initial triage while other EMS personnel perform immediate lifesaving measures (e.g., intubation) and transport patients. Although EMS personnel carry out initial field triage, secondary and continuous triage at all subsequent levels of care is essential (Tintinalli et al., 2020).

TABLE 68-2 Triage Categories During a Mass Casualty Incident

Triage Category	Priority	Color	Typical Conditions
Immediate: Injuries are life-threatening but survivable with minimal intervention. Individuals in this group can progress rapidly to expectant if treatment is delayed.	1	Red	Sucking chest wound, airway obstruction secondary to mechanical cause, shock, hemothorax, tension pneumothorax, asphyxia, unstable chest and abdominal wounds, incomplete amputations, open fractures of long bones, and second/third-degree burns of 15–40% total body surface area
Delayed: Injuries are significant and require medical care but can wait hours without threat to life or limb. Individuals in this group receive treatment only after immediate casualties are treated.	2	Yellow	Stable abdominal wounds without evidence of significant hemorrhage; soft tissue injuries; maxillofacial wounds without airway compromise; vascular injuries with adequate collateral circulation; genitourinary tract disruption; fractures requiring open reduction, débridement, and external fixation; most eye and central nervous system injuries
Minimal: Injuries are minor, and treatment can be delayed hours to days. Individuals in this group should be moved away from the main triage area.	3	Green	Upper extremity fractures, minor burns, sprains, small lacerations without significant bleeding, behavioral disorders or psychological disturbances
Expectant: Injuries are extensive, and chances of survival are unlikely even with definitive care. Persons in this group should be separated from other casualties, but not abandoned. Comfort measures should be provided when possible.	4	Black	Patients who are unresponsive with penetrating head wounds, high spinal cord injuries, wounds involving multiple anatomic sites and organs, second/third-degree burns in excess of 60% of body surface area, seizures or vomiting within 24 h after radiation exposure, profound shock with multiple injuries, agonal respirations, no pulse, no blood pressure, pupils fixed and dilated

Adapted from Tintinalli, J. E., Ma, O. J., Yealy, D., et al. (2020). *Tintinalli's emergency medicine manual: A comprehensive study guide* (9th ed.). New York: McGraw-Hill Medical.

It is important that an experienced ED provider is positioned at the entrance to provide primary triage at the acute care facility. Traffic control within the facility is one of the most important components of managing the disaster and resources (Veenema, 2019). The triage area may be outside the entry or just at the door of the ED. This facilitates the triage of all patients—those arriving by medical transport and those who walk into the ED. Some patients who have already been seen in the field may be reclassified in the triage area based on their current presentation.

Triage categories separate patients according to the severity of injury. A common triage method is the use of a special color-coded tagging system so that the triage category is immediately obvious. This system consists of four colors: red, yellow, green, and black. Each color signifies a different level of priority. Table 68-2 describes each category and gives examples of how different injuries would be classified (see Chapter 67). Alternative triage systems exclusively for MCI have also been designed. One triage system that has gained support in the United States and is used for mass casualty transport is the SALT (*S*ort, *A*ssess, *L*ifesaving interventions, *T*reatment/*T*ransport) system. It instructs the providers to quickly "*S*ort" casualties by assessing a patient's ability to follow commands, then to individually "*A*ssess" casualties to rapidly apply "*L*ifesaving interventions," and assign a priority for "*T*reatment and/or *T*ransport." SALT triage was developed to allow for rapid evaluation and sorting of patients of any age, injured in any type of event (Veenema, 2019).

Managing Internal Problems

The American Red Cross has developed a basic survival/shelter resource kit; however, each facility must determine its supply lists based on its own needs assessment. The EOP committee should determine the top 10 critical medications used during normal day-to-day operations and then anticipate which other medications may be required in a disaster or in an MCI. For example, the health care facility might plan to have available a stockpile of antidotes (e.g., cyanide kits) or antibiotics used in treating biologic agents. Information should be available about stocking or restocking any of the basic and special supplies, how those supplies are requested, and the time required to receive those supplies.

Communicating with the Media and Family

Communication is a key component of disaster management. Communication within the vast team of disaster responders is paramount; however, effective, informative communication with the media and worried family members is also crucial.

Managing Media Requests for Information

Although the media have an obligation to report the news and can play a positive role in communication, reporters and newscasters and their support teams can compromise operations and patient confidentiality. The disaster plan should include a clearly defined process for managing all media requests, including social media, and include a designated spokesperson, the public information officer, a site for the dissemination of information (away from patient care areas), and a regular schedule for providing updates.

The EOP helps prevent the release of contradictory or inaccurate information. Initial statements should focus on current efforts and what is being done to better understand the scope and impact of the situation. Information about casualties should not be released. Security staff should not allow media personnel access to patient care areas. However, media resources may be mobilized to notify the general population when disease containment is needed in case of an epidemic or the potential for one, including the location of shelters, necessity of quarantines, and point of dispensing units in the case of bioterrorism (Veenema, 2019).

Caring for Families

Friends and family members converging on the scene must be cared for by the facility. The public information officer's role is to provide direction for the families and provide them with information as it becomes available. They may be feeling intense anxiety, shock, or grief and should be provided with information and updates about their loved ones as soon as possible and regularly thereafter. They should not be in the triage or treatment areas but in a designated area staffed by available social workers, counselors, therapists, or clergy. Access to this area should be controlled to prevent families from being disturbed. Information regarding loved ones can also be obtained at this time, which assists in identification of both the injured and the deceased.

There may be times during a disaster situation such as an outbreak, epidemic, or pandemic that health care facilities must restrict visitation or access to the hospital. Health care organizations and nurses who typically

pride themselves on providing patient- and family-centered care may be forced to prohibit visitors from accompanying loved ones to the hospital in order to reduce the spread of a virus or other infectious diseases which could be potentially fatal to visitors who are living with chronic health conditions. The health care team, which may be organized by the nurse, is responsible for developing a clear communication plan that designates a primary point of contact and eliminates barriers to communication (Hart, Turnbull, Oppenheim, et al., 2020). To keep families informed and encourage interactions among patients and their support network, hospitals have relied heavily on using technology during these disaster situations (e.g., FaceTime™, Google Hangouts™, Skype™, Zoom™). Some patients and their families may come from socioeconomically disadvantaged backgrounds and not have access to computer systems and associated software that can facilitate remote conversations. An adequate plan addresses the needs of families who may be socioeconomically disadvantaged and puts into effect plans that can meet their needs (Hart et al., 2020).

COVID-19 Considerations

In response to the COVID-19 pandemic, many U.S. hospitals restricted visitors and family members from entering the hospitals for the health and safety of visitors, patients, and employees. The CDC provided strict visitation guidelines for health care facilities in order to reduce the risk of transmission and combat the lack of PPE. Many hospitals restricted visitors in all inpatient locations, behavioral health units, EDs, and ambulatory procedure units. Many elective procedures were cancelled (see Chapter 52, Chart 52-4). One support person was permitted to be with the obstetric patient during labor, delivery, and postpartum care. When possible, the identified support person was to remain with the patient for the duration of the admission. Temporary visitation may have been granted for patients in extenuating circumstances (e.g., imminent death), or for specific populations who required extra support, including patients with developmental disability or cognitive impairment. Facilities were encouraged to identify alternative methods for patients and families to communicate and interact, including the use of technology as described previously (CDC, 2020c).

Chart 68-1 discusses cultural variables to consider when coping with disaster-related injuries and death.

The Nurse's Role in Disaster Response Plans

Nurses make up the largest component of the health care workforce across the globe (Veenema, 2019). The role of the nurse during a disaster varies. Nurses may be asked to perform duties outside their areas of expertise and may take on responsibilities normally held by physicians or advanced practice nurses. For example, a critical care nurse may intubate a patient or even insert a chest tube. A nurse may perform wound débridement or suturing. A nurse may serve as the triage officer. In these situations, it is imperative that nurses strive to maximize patient safety and be aware of state regulations related to nursing practice (American Nurses Association [ANA], 2017; Casey, 2017).

Chart 68-1

Cultural Considerations

Any disaster or mass casualty incident can be expected to involve members of diverse religious, ethnic, and cultural groups or may be targeted at and predominately affect a specific religious or ethnic group. Health care providers likewise include members of all religious, ethnic, and cultural backgrounds and should bear in mind that victims may have needs relating to the following:

- Family roles and extended family importance
- Language difficulties that increase fears and frustrations
- Privacy
- Rituals about handling the dead
- Specific religious practices related to medical treatment, hygiene, or diet
- Specific places/times for prayer
- Timing of funeral services
- Travel and visa restrictions limiting access to one's country of origin, family, work, or educational opportunities.

Some religious communities have plans for emergencies and disasters, and local hospitals should integrate these plans to the extent possible into their emergency operations plans.

Although the exact role of a nurse in disaster management depends on the specific needs of the facility at the time, it should be clear which nurse or physician is in charge of a given patient care area and which procedures each individual nurse may or may not perform. Assistance can

be obtained through the HICS, and nonmedical personnel can provide services where possible. Nurses may be asked to delegate care to others, including students, staff assisting from other institutions, or volunteers. This process requires the nurse to rapidly assess the skills of those who are available to assist in patient care. Nurses must continue to emphasize patient safety and delegate appropriately. As the availability of coworkers, clinical experts, or support services may be limited, nurses may need to rely more upon their own competence or the collective competence of a new team (ANA, 2020).

During a disaster, nurses may feel a tension between maintaining traditional patient-centered approaches to care, which aim to achieve the maximum good for individual patients, and the need for public-focused approaches, which prioritize fair resource allocation during crisis conditions. A public health approach to ethics can provide nurses guidance in balancing this tension. "Public health emergencies require clinicians to change their practice, including in some situations, acting to prioritize the community above the individual in fairly allocating scarce resources" (Berlinger, Wynia, Powell, et al., 2020, p. 1). Nurses should remember that nursing care in a disaster focuses on essential care from a perspective of what is best for all patients (see Chart 68-2). In addition, acquiring knowledge of the hospital disaster plan, participating in drills, and honing competencies related to disaster management are essential (Casey, 2017). Nurse leaders and administrators should be cognizant of potential security issues and assess and plan for surge capacity capability and inhouse resources such as water, supplies, pharmaceuticals, and generator power. They also should predetermine means to evacuate the hospital if necessary, including identifying an ultimate destination or destinations. The hospital must plan for shortages of all kinds—staff, medications, water/food, and equipment (Veenema, 2019).

New settings and atypical roles for nurses arise during a disaster—for example, the nurse may provide shelter care in a temporary housing area or bereavement support and assistance with identification of deceased loved ones. People may require crisis intervention, or the nurse may participate in counseling other staff members and in critical incident stress management (CISM). Special care may be warranted for at-risk populations during a disaster (see Chart 68-3).

Chart 68-2  **ETHICAL DILEMMA**

Who Receives a Mechanical Ventilator When They Are Scarce Commodities During a Pandemic?

Case Scenario

You are a staff nurse who works in an emergency department (ED) in a university-affiliated hospital. Your community is in the midst of a surge of positive cases of coronavirus disease 2019 (COVID-19), and all ICU beds are filled with patients with COVID-19. For the past 12 hours, there have been no mechanical ventilators available for patients who are admitted and who are in severe respiratory distress until a patient who is intubated dies in the ICU, freeing up a ventilator. Currently, there are two patients waiting in the ED who would be intubated and mechanically ventilated if ventilators were available. Both patients have no significant medical or surgical history, are of normal weight, are nonsmokers, and take no prescription medications. One of these patients is T.C., a 55-year-old woman who is a cashier at a supermarket. The other patient is E.W., a 22-year-old female nursing student. Since both T.C. and E.W. are considered to be equivalent in terms of purported benefits of mechanical ventilation, the hospital's predetermined randomization protocol is implemented to determine who receives the ventilator. T.C. is selected to receive ventilatory support. As E.W.'s primary nurse, you question why T.C. is selected over E.W. and wonder if E.W.'s younger age and presumably longer lifespan and her chosen field of work as a future nurse should have given her preferential advantages over T.C. in receiving ventilatory support.

Discussion

During times of crises with scarcity of critical resources, protocols must be devised to assure that scarce resources are allocated in a fair and just manner. Most hospitals in the United States devised such contingency protocols in response to the COVID-19 pandemic. These protocols were devised to maximize potential benefits to society and ensure fair and equitable access to needed resources. In order to ensure fairness, patients eligible to receive resources may not face discrimination because of ethnic origin or race, socioeconomic status, sexual orientation, gender, or age.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Patient autonomy is typically the preeminent ethical principle in all but crises situations. How can you ensure that E.W.'s dignity may be preserved despite these

trying circumstances? Presumably, E.W.'s age can mean that she has more years of life ahead of her than T.C. Should this give her an advantage over T.C.? Should purported benefits to therapy be quantified by projecting years of productive life?

- Frontline health care workers are triaged to receive some benefits before others during pandemics (e.g., priority for vaccinations). E.W. is not a frontline worker. However, she is a nursing student and could be a future frontline worker. There are some who may argue that while E.W. could be a future frontline worker, that T.C., as a supermarket cashier, is already functioning as an essential worker. Should either one of them be given preferential consideration for receiving ventilatory support due to their current or potential designation as frontline workers? Why or why not?
- What resources may be available to assist you in reconciling this distressing rationing situation in your ED? How can you ensure that just and fair decisions are being made for your patients and for the people you serve within your community?

Chart 68-3

Caring for People with Disability During a Disaster

When a disaster occurs, the multiple agencies involved attempt to provide food, water, and shelter to all those affected. People with disability have specific needs that require attention. It is recommended that people with disability have a personal support network to check on them after a disaster and to provide needed assistance. They should also have a backup system and an evacuation plan. Agencies need to be aware that service animals are also affected during a disaster and may be brought to shelters with their companions.

Evacuation assistance is imperative for people with disability. Directions to personal equipment (e.g., communication aids, medications, oxygen) should be available to rescue personnel. In a rapid evacuation, mobility devices, oxygen, suction, and medications will be needed at the shelters. Special efforts to keep those with vision or hearing impairment informed should be implemented. People skilled in sign language are also valuable resources during a disaster. The American Red Cross and the National Organization on Disability provide information on their websites for disaster preparedness for people with disability (see the Resources section).

Considering Ethical Conflicts

Disasters can present a disparity between the resources of the health care agency and the needs of those affected by the disaster (Leider, DeBruin, Reynolds, et al., 2017). This generates ethical dilemmas for nurses and other health care providers. Issues include conflicts related to the following:

- Assisted suicide
- Confidentiality
- Consent
- Duty
- Futile therapy
- Rationing care
- Resuscitation

Nurses may find it difficult to not provide care to the dying or to withhold information to avoid spreading fear and panic. Clinical scenarios that are unimaginable in normal circumstances confront the nurse in extreme instances. Other ethical dilemmas may arise out of health care providers' instincts for self-protection and protection of their families.

Nurses can plan for the ethical dilemmas they will face during disasters by establishing a framework for evaluating ethical questions before they arise and by identifying and exploring possible responses to difficult clinical situations. They can consider how the fundamental ethical principles of autonomy, nonmaleficence, beneficence, and distributive justice will influence their decisions and care in disaster response (Ram-Tiktin, 2017) (see Chapter 1).

COVID-19 Considerations

The COVID-19 crisis has created unprecedented challenges and ethical issues for frontline health care professionals, including insufficient supplies of PPE, shortages of lifesaving equipment, compromised standards of care, and conflicts between professional duties and personal health and safety concerns. As a result, many nurses and other health care providers have been at risk for or experienced moral distress (Altman, 2020). Examples of ethical issues related to COVID-19 included:

- Strictly limited hospital visitation policies that hampered nurses from involving families in care decisions
- Isolation measures that resulted in patients dying without family physically present
- Dire situations in which patients could have been denied potentially lifesaving therapies due to shortages and triaged care

The Code of Ethics for Nurses highlights the importance of providing safe, quality patient care. However, nurses also have an obligation to self-care and to providing support to their own families. Nurses may worry that they will cause harm to a loved one and struggle with how to balance their professional responsibilities with their personal commitments (Johns Hopkins University [JHU], 2020). These equally important obligations contribute to conflicts during pandemics when nurses must care for critically ill infectious patients, often under extreme circumstances that may include an insufficiency and inadequacy of resources and uncontained contagion. During pandemics, nurses must decide how much care they can provide to others while also taking care of themselves. They must be supported in these crucial decisions by the systems in which they

provide care and by society (ANA, 2020). Nurses may struggle with the call to volunteer and respond in a pandemic. According to a policy statement drafted by the ANA (2020) in response to the COVID-19 pandemic, nurses may choose not to respond for the following reasons:

- Being a member of a vulnerable group
- Safety concerns related to a lack of PPE or inadequate testing
- Inadequate support to meet personal or family needs
- Concerns regarding professional and legal protection for providing nursing care

Organizational support for the nurse must be assured. Nurses must continue to advocate for systems and protocols that protect their ethical obligations as nurses, as well as ensure equity and fairness to all concerned in times of pandemics (ANA, 2020) (see Ethical Dilemmas in Chart 68-2, and in Chapter 19, Chart 19-7, and Chapter 48, Chart 48-9).

Managing Behavioral Issues

Disasters by nature are stressful and life-changing experiences which may cause adverse psychological effects, social disruption, and increased risks for vulnerable populations, including violence and abuse (Sloand, Killion, Yarandi, et al., 2017). Although most individuals function well during a disaster, both people and communities suffer immediate and sometimes long-term psychological trauma that most often relates to fear and anxiety (Veenema, 2019). Common responses to disaster include:

- Anxiety
- Compassion fatigue
- Depression
- Impaired performance
- Interpersonal conflicts
- Posttraumatic stress disorder
- Somatization (fatigue, general malaise, headaches, gastrointestinal disturbances, skin rashes)
- Substance use disorder (SUD)

Factors that influence a person's response to disaster include the degree and nature of the exposure to the disaster; loss of friends, family members, and pets; existing coping strategies; available resources and support; and the personal meaning attached to the event. Other factors, such as loss of home and valued possessions, extended exposure to danger, and exposure to toxic contamination, also influence response and increase the risk of adjustment problems. Those exposed to the dead and

injured, those endangered by the event, older adults, children, emergency first responders, and health care personnel caring for victims are considered to be at higher risk for emotional sequelae. A person's normal response to stress and bereavement will also affect their response after a disaster (Emergency Nurses Association [ENA], 2020).

Nurses can assist victims of disaster through active listening and providing emotional support, giving information, and referring patients to therapists or social workers. Experience has shown that few victims of disaster seek these services, and early intervention minimizes psychological consequences. Nurses can also discourage victims from subjecting themselves to repeated exposure to the event through media replays and news articles, as well as encourage them to return to normal activities and social roles when appropriate (ENA, 2020).

Critical Incident Stress Management

CISM is an approach to preventing and treating the emotional trauma that can affect emergency responders as a consequence of their jobs and that can also occur to anyone involved in a disaster or MCI. CISM is handled by teams, which are available to the OEM. There are 350 such teams in the United States. All branches of emergency services have CISM teams, as do the military and civilian industries (e.g., airline industry).

Components of a management plan include education (preparedness) before an incident occurs about critical incident stress and coping strategies; field support (ensuring that staff get adequate rest, food, and fluids, and rotating workloads) during an incident; and defusings, debriefings, demobilization, supportive services to the family and follow-up care after the incident (Kalanlar, 2019; Veenema, 2019) (see Chapter 67 for further discussion on CISM).

Preparedness and Response

Preparedness and response planning are essential to identify risks of disasters and minimize the negative impact of potential disasters on individuals and communities.

Recognition and Awareness

Preparedness for disasters includes devising specific community contingency plans that prepare residents, particularly those who are

vulnerable (e.g., older adults, people with disability) for access to necessary life-sustaining resources and for evacuation, as necessary. Preparedness also includes an awareness of the potential for covert use of **weapons of mass destruction (WMD)** (i.e., weapons used to cause widespread death and destruction), self-protection, and early detection, containment, or decontamination of substances and agents that may affect others by secondary exposure. The strength of many toxins, mobility of many members of society, and long incubation periods for some organisms and diseases can result in an epidemic that can quickly and silently spread across the entire country. For example, a formerly healthy person with a rapid onset of pneumonia and respiratory failure can have an ominous illness, such as COVID-19.

Nurses should have a heightened awareness of trends that may suggest deliberate dispersal of toxic or infectious agents or the onset of an outbreak, epidemic, or pandemic that may include the following:

- An unusual increase in the number of people seeking care for fever, respiratory, or gastrointestinal symptoms
- Clusters of patients who present with the same unusual illness from a single location. For example, clusters can be from a specific geographic location, such as a city, or from a single sporting or entertainment event or social gathering (e.g., wedding, funeral)
- A large number of fatalities, especially when death occurs within 72 hours after hospital admission
- Any increase in disease incidence in a normally healthy population. These cases should be reported to the state health department and to the CDC

If any of these trends are noted, a targeted patient history is taken in an attempt to identify the possible agent involved. This history includes an occupational, work, and environmental assessment, in addition to the regular admission history. An exposure history contains, at a minimum, information about current and past exposures to possible hazards and an assessment of the patient's typical day and any deviations in routines. The work history includes, at a minimum, a description of all previous jobs, including short-term, seasonal, and part-time employment and any military service. The environmental history includes an assessment of present and previous home locations, water supply, and any hobbies, to name a few factors. The admission history should include such information as recent travel, especially international travel, and contact with others who have been ill or have recently died of a fatal illness. This

is just a brief review of the history that may need to be obtained to identify an exposure agent (Veenema, 2019).

In all cases, unusual trends, suspicions, or findings are reported to the appropriate resources in the facility and to proper authorities in the community. Resources can include the infection control department, the state health department, the CDC, the local poison control center, various internet sites, and **material safety data sheets (MSDS)** (see the Resources section). The MSDS provides information to employees and health care providers regarding specific chemical agents; it includes the chemical name, physical data, chemical ingredients, fire and explosive hazard data, health and reactive data, spill or leak procedures, special protection information, and special precautions. Reporting furnishes data elements to those agencies responsible for epidemiology and response. Reporting also allows for sharing of information among facilities and jurisdictions and can help determine the source of infections or exposure and prevent further exposures and even deaths (Occupational Safety and Health Administration [OSHA], 2012).

COVID-19 Considerations

Patterns of illness can continue to evolve during outbreaks, epidemics, and pandemics that involve novel pathogens. For instance, at the beginning of the COVID-19 pandemic, it was thought that children could not become infected with SARS-CoV-2; however, as the virus continued to spread, it became clear that the number of children infected was, in fact, equivalent to the rate of infection in adults. The majority of children who were infected, however, experienced much milder symptoms. It was only after cases in New York City peaked and began to decline that pediatricians began to see a new pattern in which dozens of children exposed to COVID-19 were becoming extremely ill, yet presented with different symptoms than adults. The CDC (2020d) began to warn of multisystem inflammatory syndrome in children (MIS-C), a condition which causes inflammatory changes to a variety of organs, including the heart, lungs, kidneys, brain, skin, eyes, or gastrointestinal organs. The cause remains unknown, but many of the children with MIS-C had been infected with SARS-CoV-2 or had been exposed to someone who had the virus. MIS-C can be serious and even deadly without prompt medical care (CDC, 2020d).

Personal Protective Equipment (PPE)

Another component of preparedness and response involves the protection of the health care provider by additional PPE. Chemical or biologic agents and radiation are silent killers and are generally colorless and odorless. The purpose of PPE is to shield health care workers from the chemical, physical, biologic, and radiologic hazards that may exist when caring for patients who have been contaminated or who can spread contagion. The U.S. Environmental Protection Agency (EPA) has divided protective clothing and respiratory protection into the following four categories, levels A through D:

- *Level A* protection is worn when the highest level of respiratory, skin, eye, and mucous membrane protection is required. This includes a self-contained breathing apparatus (SCBA) and a fully encapsulating, vapor-tight, chemical-resistant suit with chemical-resistant gloves and boots.
- *Level B* protection requires the highest level of respiratory protection but a lesser level of skin and eye protection than with level A situations. This level of protection includes the SCBA and a chemical-resistant suit, but the suit is not vapor tight.
- *Level C* protection requires an air-purified respirator, which uses filters or sorbent materials to remove harmful substances from the air. A chemical-resistant coverall with splash hood, chemical-resistant gloves, and boots are included in level C protection.
- *Level D* protection is the typical work uniform and is used for nuisance contamination only; it does not provide adequate protection in cases in which respiratory or skin threats are present. Other PPE such as gloves or mask may be required based on the situation.

Levels C and D PPE are the levels most often used in hospital facilities. Protective equipment must be donned before contact with a patient who has been contaminated. The acute care facility's standard precaution PPE (level D) generally is not adequate for protection from a patient who has been chemically, biologically, or radiologically contaminated. Level C PPE is adequate for the average patient exposure. The health care provider must use equipment that is capable of providing protection against the agent involved. This may mean using a splash suit along with a full-face positive- or negative-pressure respirator (a filter-type gas mask) or even an SCBA for medical personnel in the field.

Chart 68-4  NURSING RESEARCH PROFILE

Whole-Process Training to Improve Use of Personal Protective Equipment

Tan, W., Ye, Y., Yang, Y., et al. (2020). Whole-process emergency training of personal protective equipment helps healthcare workers against COVID-19. *Journal of Occupational and Environmental Medicine, 62*(6). 420–423.

Purpose

Health care workers are at increased risk of exposure to the pathogen that causes coronavirus disease 2019 (COVID-19). Without proper knowledge of the donning and doffing of personal protective equipment (PPE), health care professionals are more susceptible to infection, illness, and possibly death. The purpose of this study was to evaluate the effectiveness of a three-phase training program on the proper use of PPE for health care workers in China.

Design

This study was developed in a hospital system in Beijing, China, where health care workers were caring for patients who had a known or suspected diagnosis of COVID-19. Qualified instructors and training assistants developed an educational program on appropriate use of PPE (e.g., hats, N95 respirators, goggles, face shields, shoe covers, and protective coveralls) across various areas of workflow (e.g., clean, possibly contaminated, contaminated). Teaching strategies included lecture and demonstration by faculty, followed by simulation, which allowed participants to practice what they had learned prior to being evaluated in phase three. Program developers established scoring criteria to evaluate the effectiveness of participants' performance. Two researchers independently scored participants on a variety of predetermined outcomes (e.g., proficiency levels) before and after the training sessions. Paired *t* tests were used to analyze differences in scores before and after the educational session. Prior to conducting large-scale training and evaluation, researchers conducted an experimental or pilot study using a smaller number of participants.

Findings

Thirty-eight health care workers participated in the initial experimental training, including 31 nurses. Significant differences were found between pre- and posttest scores. Almost three quarters of the participants (73.68%) did not pass the pretest. However, 100% were successful following the educational program. Subsequently, 263 health care workers participated in the large-scale training, including 225 nurses; posttest scores were also significantly improved in this sample.

Participants struggled the most with the use of N95 respirators and protective coveralls.

Nursing Implications

Multimodal educational programs, which include simulation have the potential to provide critical educational experiences for nurses that assist in keeping them safe and reducing the transmission of life-threatening viruses. Simulation enables experts to guide health care workers during an extremely stressful time and allows learners to practice the skills they need to protect themselves, their coworkers, and their patients. Such programs are essential in preparing an educated workforce to be ready to face the next pandemic or crisis.

No single PPE is capable of protecting against all hazards. Under no circumstances should responders wear any PPE without proper training, practice, and fit testing of respirator masks as necessary (OSHA, 2017). See the Nursing Research Profile in Chart 68-4.

N95 respirator masks are used to reduce the nurse's exposure to particles, which include small-particle aerosols and large droplets (see Fig. 68-1). The mask filters out at least 95% of airborne particles and, in ideal situations, should be discarded after each patient encounter or aerosol-generating procedure. The mask should be discarded when it becomes damaged or deformed, no longer forms an effective seal to the face, becomes wet or visibly dirty, breathing becomes difficult, or it becomes contaminated with blood, respiratory or nasal secretions, or other bodily fluid (CDC, 2020e). Alternatively, a regular surgical mask provides the nurse protection against large droplets, splashes or sprays, bodily or other hazardous fluids, and protects the patient from the nurse's respiratory emissions. This mask does not require a tight seal, does not provide the wearer with a reliable level of protection from inhaling smaller airborne particles, and is not considered respiratory protection. Ideally, surgical masks should also be discarded after each patient encounter (CDC, 2020e). The CDC provides guidance to health care facilities regarding when it is appropriate to wear an N95 respirator mask versus a regular surgical mask during patient encounters. The N95 respirator mask must be evaluated, tested, and approved for the individual prior to wearing per facility policy and procedures.

Figure 68-1 • N95 respirator. Courtesy of 3M Health Care.

Decontamination

Decontamination, the process of removing accumulated contaminants or rendering them harmless, is critical to the health and safety of health care providers by preventing secondary contamination. The decontamination plan should establish procedures and educate employees about decontamination procedures, identify the equipment needed and methods to be used, and establish methods for disposal of contaminated materials (Veenema, 2019).

Although many principles and theories surround decontamination of a patient, authorities agree that to be effective, decontamination must include a minimum of two steps. First step is the removal of the patient's clothing and jewelry and then rinsing the patient with water. Depending on the type of exposure, this step alone can remove a large amount of the contamination and decrease secondary contamination. The second step consists of a thorough soap-and-water wash and rinse. The hospital must be prepared to perform additional decontamination prior to entry into the facility. The hospital personnel may also treat "walking wounded" who did not receive any decontamination at the scene (Tintinalli et al., 2020).

Quality and Safety Nursing Alert

When patients arrive at the facility after being assessed and treated by a prehospital provider, it should not be assumed that they have been thoroughly decontaminated.

Natural Disasters

Natural disasters may result in mass casualties. Natural disasters can occur anywhere at any time and include events such as tornadoes, hurricanes, floods, avalanches, tidal waves (e.g., tsunamis), earthquakes, and volcanic eruptions (see Table 68-3). In the event of a natural disaster, loss of communications, potable water, and electricity is usually the greatest obstacle to a well-coordinated emergency response, and preparatory planning is essential. Wireless technology (e.g., cellular phones, computers, other communication devices) may not be functional (Tintinalli et al., 2020).

The majority of the immediate casualties are trauma related. These mass casualties require the trauma system to provide triage, transport of patients (in poor weather and road conditions), and management within the trauma centers. Most patients usually begin arriving within an hour of the event. However, the "walking wounded" may not seek care for 5 days to 2 weeks after the event or may seek care for injuries received during cleanup activities. Casualties arrive at hospitals in three waves. The first wave consists of people who are minimally (generally) injured who arrive of their own accord. The second wave consists of patients who are severely injured. The third wave consists of patients who are injured and who arrive after they are discovered by rescuers. For example, in the event of earthquakes, rescuers may find injured patients in collapsed buildings; the majority of fatalities from injuries in this case primarily involve the head and chest (Veenema, 2019).

TABLE 68-3 Select Natural Disasters

Event	Issues and Injuries
Earthquakes	Associated with multiple aftershocks, tsunamis Buildings require tethering in earthquake-prone areas *Injuries:* Physical injury; dehydration; pulmonary problems
Flooding	Can accompany other natural disasters Results in home and community destruction *Injuries:* Nonfatal drowning/drowning (e.g., people swept away in currents); waterborne and vector-borne diseases (e.g., shigellosis, *Escherichia coli* infection, hepatitis A, giardiasis, leptospirosis, malaria, plague, dengue fever); physical injury from debris
Hurricanes	Cause flooding (see previous discussion) and tornadoes (see later discussion) Failure to evacuate Food and water safety *Injuries:* From recovery activities (e.g., chainsaws), stress-related disorders, and GI and other vector-borne diseases; physical injury; bites from traumatized pets
Tornadoes	Minimal warning, fast moving (approximately 30 mph and travel approximately 20 km) Massive destruction, shelter loss *Injuries:* Physical injury; blastlike effects from pressure (see discussion of blast injuries in text)
Tsunamis	As with flooding (see above) but with much more rapid onset resulting in immediate large volume of water on land *Injuries:* Physical injury from debris; vector-borne diseases (see the Flooding section); cholera
Volcanic eruptions	Hazards from lava, openings in ground, gases, ash up to a 20-mile radius *Injuries:* Acid rain; toxic gases result in inhalation injury; physical injury

GI, gastrointestinal.

Adapted from Veenema, T. G. (2019). *Disaster nursing and emergency preparedness* (4th ed.). New York: Springer.

Excessive exposure to the natural elements and the need for food and water (by both patients and emergency responders) are critical issues. Without cover (e.g., buildings may be unsafe or destroyed) or potable water (e.g., water may be either contaminated or unavailable), injuries from exposure to heat, cold, or contaminated food or water can occur. Safety equipment that protects rescue workers from injury, exposure, and potentially dangerous animals (e.g., snakes, alligators, spiders) must be

readily available. Rescue workers may also injure themselves in the process of extrication or cleanup (e.g., chain saws, building collapse). Hypothermia can occur rapidly in workers who are exposed to water at temperatures of 23.9°C (75°F) or less. As is true during all disasters, mental health workers and shelters are needed throughout the community. Veterinary assistance is also essential because pets are frequently abandoned and injured. In addition, emergency response workers must be prepared to treat the most common ailments experienced after exposure to a specific natural disaster. For instance, pulmonary problems peak with earthquakes and volcanic eruptions because of the increased particulate matter in the air (Veenema, 2019).

In some instances, early warning systems have assisted in decreasing the number of deaths from tornadoes and hurricanes. Even with the advent of early warning systems, some people are unable or unwilling to leave prior to the occurrence of the natural disaster.

When buildings collapse, rapid response to identify and remove trapped victims is the only means of improving survivability. Water-damaged buildings are not safe and require extensive examination before experts can ensure safe occupancy. Larger-scale issues that can cause significant later morbidity and mortality include the absence of water purification, waste removal, removal of human and animal remains, and vector control. Removal or disposal of biologic, chemical, and nuclear agents must also be considered (Tintinalli et al., 2020).

Outbreaks, Epidemics, and Pandemics

An **outbreak** is the occurrence of a disease within a population that exceeds normal expectations. Outbreaks can be classified as communicable disease outbreaks, outbreaks caused by exposure to chemicals or toxins, and outbreaks from unknown sources. An outbreak may be transmitted via persons, animals, or from the environment (WHO, 2020b).

An **epidemic** is a widespread outbreak of a specific infectious disease from a single source within a community or population that exceeds anticipated levels of impact. An epidemic exists when new cases exceed the expected incidence of that disease. The rate and transmission of the infectious disease is dependent on multiple factors which include preexisting levels of the disease in the community, environmental changes that occurred as a result of the disease, population density and displacement, disruption of utilities, interruption of health services, and

public sanitation. In order for a true epidemic to occur, there must be a vulnerable population, the presence of a disease agent, and a mechanism that supports large-scale transmission (Veenema, 2019). During an epidemic, there is a need to respond quickly and intentionally as catastrophic loss of human life and economic devastation may occur. Epidemics may be deemed an emergency if any of the following characteristics are present (Veenema, 2019):

- Large number of cases projected to occur
- Disease leads to serious disability or death
- Disease threatens to cause social or economic disruption
- Officials are unable to manage resources adequately due to the surge in cases. This includes sufficient number of trained personnel, necessary supplies and equipment (e.g., vaccines, medications, testing equipment, etc.)
- Risk to transmit the disease internationally

A **pandemic** is an epidemic that spreads across multiple countries or continents. There are many more individuals affected and greater number of deaths associated with pandemics than epidemics. In March 2020, the World Health Organization (WHO) characterized COVID-19 as a pandemic (WHO, 2020a).

Communicable disease outbreaks, which may eventually lead to epidemics or pandemics, are investigated through public health surveillance and the monitoring of clusters of illnesses. Interviews, questionnaires, and home visits may be beneficial when people are experiencing the same symptoms of illness (CDC, 2018b). It is imperative to identify the source of the illness and institute measures for the containment of the outbreak. An outbreak is over when the numbers of new cases fall below the number of normally expected cases (CDC, 2018b).

Weapons of Terror

Geopolitical forces and interests and the availability of destructive technology have brought the possibility of more terrorist events to our doorstep. Terrorism involves the systematic use of violence to create feelings of fear. Examples include the destruction of the World Trade Center towers and the damage to the Pentagon on September 11, 2001; the Boston Marathon bombing on April 15, 2013; and the coordinated series of terrorist attacks in Paris on November 13, 2015; in Brussels on

March 22, 2016; and the London attacks on Westminster Bridge and Parliament on June 3, 2017. Over 26,445 deaths had occurred in 2017 from terrorism-related violence; over the last decade, deaths across the world from terrorism ranged from a low of 7827 in 2010 to a high of 44,490, in 2014 (Ritchie, Hasell, Appel, et al., 2020). Terrorists have become increasingly sophisticated, organized, and therefore effective. It is no longer a question of *whether* a terrorist event will again lead to mass casualties, but *when* such an event will occur. The U.S. Department of Homeland Security was created after the attacks of September 11, 2001, to coordinate federal and state efforts to combat terrorist activity.

Terrorists preferentially use WMD which may leverage the use of blasts or biologic, chemical, or radiologic agents. Although terrorist events are not everyday events, they can occur at any facility, and every nurse needs to know the basics of caring for patients who have been affected.

Blast Injury

A blast may result from terrorism but can also occur anywhere at any time if the right (or wrong) circumstances come together (e.g., welding inside of a tank that formerly contained tar but was not properly cleaned can result in an explosion as well as severe tar burns to the worker).

Types of Explosive Devices

The bomb most commonly utilized by terrorists is the pipe bomb, which contains low-velocity explosives and may also contain nails or other implements that cause more damage when the explosive ignites. Another type of commonly used explosive device is the Molotov cocktail, which uses a common flammable liquid such as gasoline in a glass bottle and a source of ignition, such as a rag. This forms a simple yet effective incendiary device. Other types of explosive devices include fertilizer bombs and dirty bombs, which include a radioactive source that spreads radiation after the initial blast (Durakovic, 2017).

Hazards following a bombing include secondary devices (set to explode at a predetermined time, typically after the arrival of rescue personnel); building collapse; contamination from biologic, chemical, or radiologic weapons; and the presence of terrorists among the patients and bystanders. The entire scene of the bombing is a crime scene and is treated as such. Triage of patients involved in a bombing is the same as

for all other disasters, with a heightened awareness that serious internal injuries from the blast wave may not be immediately evident.

Physical Injuries

Distance from the blast, whether the blast space was enclosed, composition of the explosive, whether a building collapsed, and the efficiency of medical resources available after the blast all affect patient outcomes after a blast injury. The actual blast that occurs during the initial seconds of the bombing or explosion causes a pressure wave or primary blast wave. Injuries can result from the impact of the explosion, the primary blast wave, or shrapnel (i.e., debris from the bomb). The majority of injuries are caused by the primary blast wave (Tintinalli et al., 2020). A blast wave has four effects. These include spalling, which refers to the pressure wave itself; implosion, which refers to rupture of organs from entrapped gases; shearing, which refers to the blast response of different body tissues, dependent on their density; and irreversible work, which refers to the presence of forces that exceed the tensile strength of an organ or tissue. If the blast occurs in an enclosed space, the wave has the opportunity to be reflected and thus amplified (Veenema, 2019). The various phases of blasts and related injuries are detailed in Table 68-4.

Blast Lung

Blast lung results from the blast wave as it passes through air-filled lungs. The result is hemorrhage and tearing of the lung, ventilation–perfusion mismatch, and possible air emboli. Typical signs and symptoms include dyspnea, hypoxia, tachypnea or apnea (depending on severity), cough, chest pain, and hemodynamic instability. Management involves providing respiratory support that includes administration of supplemental oxygen with nonrebreathing mask but may also require endotracheal intubation and mechanical ventilation. If a hemothorax or pneumothorax is present, a chest tube must be inserted to re-expand the lung. In the event of an air embolus, the patient should be immediately placed in the prone, left lateral position to prevent migration of the embolus and will require emergent treatment in a hyperbaric chamber (Tintinalli et al., 2020). Complications following blast lung can include respiratory failure as well as acute respiratory distress syndrome (ARDS) (see Chapter 19).

Tympanic Membrane Rupture

Tympanic membrane (TM) rupture is the most frequent injury after subjection to a pressure wave because TM is the body's most sensitive

organ to pressure. There is an increased incidence of TM rupture when a blast occurs in close proximity to the patient and when it occurs in an enclosed space. Signs and symptoms include hearing loss, tinnitus, pain, dizziness, and otorrhea (Jorolemon, Lopez, & Krywko, 2019). The majority of TM ruptures heal spontaneously. Approximately 5% of patients with TM rupture from a blast will require hearing aids, whereas the majority will suffer only mild high-frequency hearing loss (ENA, 2019). Other ear injuries may include ossicular disruption and impaction of foreign bodies.

TABLE 68-4 Phases of Blasts and Associated Common Injuries

Phase of Blast Injury	Common Injuries
Primary: Results from initial blast or air wave.	Affects primarily air-filled organs: Tympanic membrane rupture, middle ear injury—permanent deafness may occur Pulmonary—pneumothorax, pulmonary contusions, air embolus Head injuries, including concussion, other severe brain injuries Abdominal hollow organ perforation, hemorrhage
Secondary: Results from debris from the scene or shrapnel from the bomb that act as projectiles	Penetrating trunk, skin, and soft tissue injuries Fractures, traumatic amputations
Tertiary: Results from pressure wave that causes the victim to be thrown	Head injuries Fractures, including skull
Quaternary: Results from preexisting conditions exacerbated by the force of the blast or by postblast injury complications	Severe injuries with complex injury patterns—burns, crush injuries, head injuries Common preexisting conditions that become exacerbated—COPD, asthma, cardiac conditions, diabetes, and hypertension

COPD, chronic obstructive pulmonary disease.

Adapted from Jorolemon, M. R., Lopez, R. A., & Krywko, D. M. (2019). Blast injuries. In *StatPearls [Internet]*. Treasure Island, FL: StatPearls Publishing. Retrieved on 3/27/2020 at: www.ncbi.nlm.nih.gov/books/NBK430914/

Abdominal and Head Injuries

Blast abdomen may be evidenced by abdominal hemorrhage and internal organ injury. The typical signs and symptoms of internal abdominal injury

can include pain, guarding, rebound tenderness, rectal bleeding, nausea, and vomiting (Jorolemon et al., 2019) (see Chapter 67).

Head injuries are typically minor, but those that are severe result in the majority of postblast deaths. These injuries can occur without a direct blow to the head and may result from the blast itself, building collapse, or flying debris. Concussions commonly occur post blast, and the usual follow-up evaluation and treatment for postconcussive syndrome is indicated (see Chapter 63). Approximately 30% of head injuries involve vascular structures (e.g., arteriovenous fistula, pseudoaneurysm, or dissection) (Veenema, 2019).

Special Populations

Special populations may have different blast-associated risks. For instance, older adults are particularly susceptible to bone fractures because they tend to have decreased bone density. They also tend to have more preexisting morbid conditions that may be exacerbated by the explosion. Patients who are pregnant are particularly susceptible to placental shear forces that may result in abruptio placentae. People with mobility disability may have difficulty extricating themselves from the site of the blast (CDC, 2018a).

Biologic Weapons

Biologic weapons are weapons that spread disease among the general population or the military. They can be used for sabotage, such as food or water contamination with a small target area or may be used by global terrorists with intentions to spread fear and disruption of daily life (Tintinalli et al., 2020).

Effects of Biologic Weapons

Biologic weapons are easily obtained and easily disseminated and can result in significant mortality and morbidity (see Table 68-5). The potential use of biologic weapons calls for continuous increased surveillance by health departments and an increased index of suspicion by clinicians. Many biologic weapons result in signs and symptoms similar to those of common disease processes. Appropriate management of a biologic threat includes rapid recognition of the potential weapon; the use of proper PPE; decontamination, isolation, or quarantine of patients who are infected when appropriate; and the administration of appropriate vaccinations, antidotes, or medications to people at risk.

Biologic weapons are delivered in either a liquid or a dry state, applied to foods or water, or vaporized for inhalation or direct contact. Vaporization may be accomplished through spray or explosives loaded with the weapon. Because of increase in travel by people in industrialized nations, a biologic weapon could be released in one city and affect people in other cities thousands of miles away. The vector can be an insect, animal, or person, or there may be direct contact with the weapon itself.

Two of the biologic agents most likely to be used or weaponized are discussed in the next section. Table 68-6 describes other easily weaponized biologic agents.

TABLE 68-5 Categories of Biologic Weapons

Category	Mortality and Morbidity	Examples of Biologic Agents That May Be Weaponized
Category A	High mortality	*Bacillus anthracis* (anthrax) *Clostridium botulinum* (botulism) *Francisella tularensis* (tularemia) Viral hemorrhagic fevers (e.g., dengue, Ebola) Variola (i.e., smallpox) *Yersinia pestis* (plague)
Category B	Low mortality, moderate morbidity	*Brucella* species (brucellosis) *Coxiella burnetii* (Q fever) *Staphylococcus aureus, Vibrio* species (food poisoning) *Rickettsia typhi* (typhus) Arboviruses (viral encephalitis) *Cryptosporidium parvum* (cryptosporidiosis)
Category C	Low mortality, low morbidity	Hantavirus

Adapted from Veenema, T. G. (2019). *Disaster nursing and emergency preparedness* (4th ed.). New York: Springer.

Types of Biologic Weapons

Anthrax

Anthrax is recognized as the most likely weaponized biologic agent available and has been recognized as a highly debilitating agent for centuries. *Bacillus anthracis* is a naturally occurring gram-positive, encapsulated rod-shaped bacterium that lives in the soil in the spore state throughout the world. The bacterium sporulates (i.e., is liberated) when exposed to air and is infective only in the spore form. Contact with

infected animal products (raw meat) or inhalation of the spores results in infection. Cattle and other herbivores are vaccinated against anthrax to prevent transmission through contaminated meat. As an aerosol, anthrax is odorless and invisible and can travel a great distance before disseminating; hence, the site of release and the site of infection can be miles apart (ENA, 2020).

Clinical Manifestations

Anthrax is caused by replicating bacteria that release toxin, resulting in hemorrhage, edema, and necrosis. There are three main methods of infection: skin contact, gastrointestinal ingestion, and inhalation. Approximate incubation periods are 5 to 7 days (cutaneous), 1 to 6 days (gastrointestinal), and 1 to 43 days (inhalation). Skin lesions (the most common infection) cause edema with pruritus and macule or papule formation, resulting in ulceration with 1- to 3-mm vesicles. A painless eschar develops, which falls off in 1 to 2 weeks (ENA, 2020).

TABLE 68-6 Select Examples of Biologic Agents That Can Be Used as Weapons

Agent/Organism	Contagion	Decontamination and Protective Equipment	Signs and Symptoms	Treatment (Mortality Rate)
Botulism—*Clostridium botulinum:* Botulinum blocks acetylcholine-containing vesicles from fusing with the terminal membranes of the motor neuron end plate, resulting in a flaccid paralysis.	Direct contact Not contagious through human-to-human contact	Any skin exposure to the botulinum toxin can be treated with soap and water or a 0.1% hypochlorite solution. Standard precautions are used when treating patients with botulism.	*Gastrointestinal botulism:* Abdominal cramps, nausea, vomiting, and diarrhea *Inhalation botulism:* Fever; symmetric descending flaccid paralysis with multiple cranial nerve palsies. *Classic signs and symptoms include* diplopia, dysphagia, dry mouth, lack of fever, and alert mental status. *Other possible symptoms include* ptosis of the eyelids, blurred vision, enlarged sluggish pupils, dysarthria, and dysphonia. *Mortality secondary to:* Airway obstruction and inadequate tidal volume.	Supportive ventilatory therapy is necessary if respiratory infection occurs. Aminoglycosides and clindamycin are contraindicated because they exacerbate neuromuscular blockage. Equine antitoxin is used to minimize subsequent nerve damage. There is a 2% rate of anaphylaxis to the antitoxin; therefore, diphenhydramine and epinephrine must be immediately available for use. Supportive care—mechanical ventilation, nutrition, fluids, prevention of complications. (Mortality rate = 5%)
Plague—*Yersinia pestis:* nonsporulating, gram-negative coccobacillus. The bacterium causes destruction and necrosis of the lymph nodes.	Contagious *Bubonic plague:* Transmitted through flea bites with no person-to-person transmission *Pneumonic plague:* Transmitted through respiratory droplet contact	Isolation barrier precautions with full-face respirators; the patient should wear a mask. Rooms should receive a terminal cleaning. Clothing and linens with body fluids on them should be cleaned with the usual disinfectant. Routine precautions should be used in the case of death.	*Bubonic plague:* Sudden fever and chills, weakness, a swollen and tender lymph node (bubo) in the groin, axilla, or cervical area. The resultant bacteremia progresses to septicemia from the endotoxin and, finally, shock and death. *Primary septicemic plague:* Disseminated intravascular coagulation, necrosis of small vessels, purpura, and gangrene of the digits and nose (black death). *Pneumonic plague:* Severe bronchospasm, chest pain, dyspnea, cough, and hemoptysis. There is a 100% mortality associated with pneumonic plague if not treated within the first 24 h.	Streptomycin or gentamicin for 10–14 days. Start within 12–24 h. Tetracycline or doxycycline is an acceptable alternative if an aminoglycoside cannot be given. People with close contact exposure (<2 m) require prophylaxis with doxycycline for 7 days. (Mortality rate = 50%)
Tularemia—*Francisella tularensis:* Gram-negative, coccobacillus, one of the most infectious bacteria known.	Direct contact with infected animals or aerosolized as a bioterror weapon; bites Not contagious through human-to-human contact Found in Oklahoma, Missouri, Arkansas	Standard barrier precautions. Clothing and linens should be laundered under the usual hospital protocol.	*Initial:* Abrupt onset of fever, fatigue, chills, headache, lower backache, malaise, rigor, coryza, dry cough, and sore throat without adenopathy. Nausea and vomiting or diarrhea possible. *As disease progresses:* Sweating, fever, progressive weakness, anorexia, and weight loss demonstrate continued illness. *Mortality secondary to:* Pneumonitis (if inhalation is the source) with copious watery or purulent sputum, hemoptysis, respiratory insufficiency, sepsis, and shock.	Streptomycin or gentamicin/aminoglycoside for 10–14 days. Inhalation tularemia must be treated within 48 h of onset. In mass casualty situations, doxycycline or ciprofloxacin is recommended. For persons exposed to tularemia, tetracycline or doxycycline is recommended for 14 days. (Mortality rate = 2%)

Adapted from Emergency Nurses Association. (2020). *Sheehy's emergency nursing: Principles and practice* (7th ed.). St. Louis, MO: Elsevier Mosby; Emergency Nurses Association. (2019). *Trauma nursing core course* (8th ed.). Chicago: Author; and Veenema, T. G. (2019). *Disaster nursing and emergency preparedness* (4th ed.). New York: Springer.

Ingestion of anthrax results in fever, nausea and vomiting, abdominal pain, bloody diarrhea, and occasionally ascites. If severe diarrhea develops, decreased intravascular volume becomes the major treatment concern. The bacterium targets the terminal ileum and cecum. Sepsis can occur (ENA, 2020).

Inhaling anthrax results in severe clinical manifestations. Its symptoms mimic those of the flu, and usually treatment is sought only when the

second stage of severe respiratory distress occurs. Antibiotic therapy does not halt the progress of the disease. Inhaled anthrax can incubate for up to 60 days, making it difficult to identify its source. Initial signs and symptoms include cough, headache, fever, vomiting, chills, weakness, mild chest discomfort, dyspnea, and syncope without rhinorrhea or nasal congestion. Most patients have a brief recovery period followed by the second stage within 1 to 3 days, characterized by fever, severe respiratory distress, stridor, hypoxia, cyanosis, diaphoresis, hypotension, and shock. These patients require optimization of oxygenation, correction of electrolyte imbalances, and ventilatory and hemodynamic support. More than 50% of these patients have hemorrhagic mediastinitis on a chest x-ray (a hallmark sign). Inhalation anthrax may progress to include meningitis with subarachnoid hemorrhage. Death results approximately 24 to 36 hours after the onset of severe respiratory distress. The mortality rate approaches 100% (ENA, 2020).

Management

At present, anthrax is penicillin sensitive; however, strains of penicillin-resistant anthrax are thought to exist. Recommended treatment includes penicillin, ciprofloxacin, levofloxacin, and doxycycline (ENA, 2020). If antibiotic treatment begins within 24 hours after exposure, death can be prevented. In a mass casualty situation, treatment with ciprofloxacin or doxycycline is recommended, because these easily given oral antibiotic agents are stockpiled and there should be sufficient dosages to fully treat many patients who have been anthrax-exposed. Treatment is continued for 60 days. For patients who have been directly exposed to anthrax but have no signs and symptoms of disease, ciprofloxacin or doxycycline is used for prophylaxis for 60 days (U.S. Department of Health and Human Services, 2018).

Standard precautions are needed when caring for a patient infected with anthrax. The patient is not contagious, and the disease cannot spread from person to person. Equipment should be cleaned using standard hospital disinfectant. After death, cremation is recommended because the spores can survive for decades and represent a threat to morticians and forensic medicine personnel. A vaccination, which includes six doses is available for the Department of Defense, and the CDC is in the process of developing a civilian vaccination protocol (ENA, 2020).

Smallpox

Smallpox (variola) is classified as a deoxyribonucleic acid (DNA) virus. It has an incubation period that ranges from 7 to 17 days. It is extremely

contagious and spread by direct contact, by contact with clothing or linens, or by droplets from person to person only after the fever has decreased and the rash phase has begun (ENA, 2020). Aerosolization of the virus would result in widespread dissemination.

The WHO declared eradication of smallpox in 1977 and stopped worldwide vaccination in 1980. In the United States, the last child was vaccinated in 1972. Therefore, a large portion of the current population has no immunity to the virus. A smallpox vaccination plan, introduced in 2003, proposed that a designated number of ED staff receive the first vaccinations to ensure that ED staff would be immunized in the event of a smallpox outbreak. The government estimated that 0.1% of those people receiving the vaccine would have serious side effects. Of these, approximately 4% would have life-threatening complications, and 0.1% would die. Currently, only people with a high likelihood of exposure to smallpox are encouraged to receive the vaccination (CDC, 2017).

Clinical Manifestations

Signs and symptoms of smallpox infection include high fever, malaise, headache, backache, and prostration. After 1 to 2 days, a maculopapular rash appears, evolving at the same rate, beginning on the face, mouth, pharynx, and forearms. Only then does the rash progress to the trunk and become vesicular to pustular (Veenema, 2019). There is a large amount of virus in the saliva and pustules. The person remains contagious until the rash crusts over and falls off (ENA, 2020). There are two forms of smallpox: variola major and variola minor. Variola major is more common, results in a higher fever and more extensive rash, and has a 30% case fatality rate (i.e., the likelihood of fatality per case diagnosed). Hemorrhagic smallpox, a subtype of variola major, includes all of the above signs and symptoms plus a dusky erythema and petechiae leading to frank hemorrhage of the skin and mucous membranes, and it results in death by day 5 or 6 (Veenema, 2019).

Management

Treatment includes supportive care with antibiotic agents for any additional infection. Antivirals and immune globulin may aid in treatment; however, vaccination remains the most effective method of prevention (ENA, 2020). The patient should be isolated in a negative-pressure environment, using strict airborne and contact precautions. Laundry and biologic wastes should be autoclaved before being washed with hot water and bleach. Standard decontamination of the room is effective. All people who have household or face-to-face contact with the

patient after the fever begins should be vaccinated within 4 days to prevent infection and death. A patient with a temperature of 38°C (101°F) or higher within 17 days after exposure must be placed in isolation. Cremation is preferred for all deaths, because the virus can survive in scabs for up to 13 years (Veenema, 2019).

Chemical Weapons

Chemical weapons may be used as agents in warfare or for terrorist purposes. These are overt agents whose effects are more apparent and occur more quickly than those caused by biologic weapons (see Table 68-7). Poisonous exposure to everyday chemicals also may occur; the same management principles discussed later apply when patients are exposed to these chemical agents when not used as weapons. Typical exposures in these instances include industrial chemicals, gasoline, turpentine, kerosene, and insecticides (ENA, 2019).

Characteristics of Chemicals

Volatility

Volatility is the tendency for a chemical to become vapor. The most common volatile agents are phosgene and cyanide. Most chemicals are heavier than air, except for hydrogen cyanide. Therefore, in the presence of most chemicals, people should stand up to avoid heavy exposure (because the chemical will sink toward the floor or ground).

TABLE 68-7 Common Chemical Agents

Agent	Action	Signs and Symptoms	Decontamination and Treatment
Nerve Agents			
Sarin Soman	Inhibition of cholinesterase	Increased secretions (salivation, lacrimation, emesis, urination), gastrointestinal motility, diarrhea, bronchospasm	Soap and water Supportive care Benzodiazepines Pralidoxime Atropine
Blood Agent			
Cyanide	Inhibition of aerobic metabolism	Inhalation—tachypnea, tachycardia, coma, seizures; bright red skin; can progress to respiratory arrest, respiratory failure, cardiac arrest, death	Soap and water Sodium nitrite Sodium thiocyanate Amyl nitrate Hydroxocobalamin
Vesicant Agents			
Lewisite Sulfur mustard Nitrogen mustard Phosgene	Blistering agents	Superficial to partial-thickness burn with vesicles that coalesce; conjunctivitis, nasal irritation	Soap and water Blot; do not rub dry
Pulmonary Agents			
Phosgene Chlorine	Separation of alveoli from capillary bed	Pulmonary edema, bronchospasm, chest tightness, burning sensation, blurry vision; phosgene can result in pain then blisters followed by partial to full-thickness burn	Copious flushing Move to fresh air—away from gases Airway management Ventilatory support Bronchoscopy

Adapted from Emergency Nurses Association. (2020). *Sheehy's manual of emergency care: Principles and practice* (7th ed.). St. Louis, MO: Elsevier Mosby; Emergency Nurses Association. (2019). *Trauma nursing core course* (8th ed.). Chicago: Author; and Veenema, T. G. (2019). *Disaster nursing and emergency preparedness* (4th ed.). New York: Springer.

Persistence

Persistence means that the chemical is less likely to vaporize and disperse. More volatile chemicals do not evaporate very quickly. Most industrial chemicals (e.g., cyanide) are not very persistent. Weaponized agents (chemicals developed as weapons by the military or terrorists [e.g.,

mustard gas]) are more likely than industrial chemicals to penetrate the skin and mucous membranes and cause secondary exposure.

Toxicity

Toxicity is the potential of an agent to cause injury to the body. The median lethal dose (LD_{50}) is the amount of the chemical that will cause death in 50% of those who are exposed. For example, cyanogen chloride has the highest LD_{50}, twice that of hydrogen cyanide and eight times higher than sulfur mustard (OSHA, 2012). The median effective dose (ED_{50}) is the amount of the chemical that will cause signs and symptoms in 50% of those who are exposed. The concentration time (CT) is the concentration released multiplied by the time exposed (in milligrams per minute). For example, if 1000 mg of a chemical is released and the time a person is exposed to this amount of chemical is 10 minutes, then the CT would be 10,000 mg/min.

Latency

Latency is the time from absorption to the appearance of signs and symptoms. Sulfur mustards and pulmonary agents have the longest latency, whereas other vesicants, nerve agents, and cyanide produce signs and symptoms within seconds.

Limiting Exposure

Evacuation is essential, as is removal of the person's clothing and decontamination as close to the scene as possible and before transport of the person who has been exposed. Soap and water are effective means of decontamination in most cases. Staff involved in decontamination efforts must wear PPE and contain and dispose of the runoff after decontamination procedures (ENA, 2020).

Types of Chemicals

Vesicants

Vesicants are chemicals that cause blistering and result in burning, conjunctivitis, bronchitis, pneumonia, hematopoietic suppression, and death. Examples of vesicants include lewisite, phosgene, nitrogen mustard, and sulfur mustard. In World War I and in the Iran–Iraq conflict of 1980 to 1988, vesicants were used to disable opponents. Vesicants were the main incapacitating agents, resulting in minimal (less than 5%)

death but large numbers of injuries (Veenema, 2019). Liquid sulfur mustard was the most frequently used vesicant in these conflicts.

Clinical Manifestations

The initial presentation after exposure to a vesicant is similar to that of a large superficial to partial-thickness burn in the warm and moist areas of the body (i.e., perineum, axillae, antecubital spaces). There is stinging and erythema for approximately 24 hours, followed by pruritus, painful burning, and small vesicle formation after 2 to 18 hours. These vesicles can coalesce into large, fluid-filled bullae. Lewisite and phosgene result in immediate pain after exposure. Tissue damage occurs within minutes (Veenema, 2019).

If the eyes are exposed, there will be pain, photophobia, lacrimation, and decreased vision. This progresses to conjunctivitis, blepharospasm, corneal ulcer, and corneal edema.

Respiratory effects are more serious and often are the cause of mortality with vesicant exposure. Manifestations may include dyspnea, necrosis of large airway mucosa with sloughing, chemical pneumonitis, pulmonary edema, and ARDS which may lead to respiratory failure and death (Veenema, 2019). Gastrointestinal exposure may cause nausea and vomiting, leukopenia, and upper gastrointestinal bleeding.

Management

Appropriate decontamination includes soap and water. Scrubbing and the use of hypochlorite solutions should be avoided because they increase penetration. Once the substance has penetrated, it cannot be removed. Eye exposure requires copious irrigation. For respiratory exposure, intubation and bronchoscopy to remove necrotic tissue are essential. With lewisite exposure, dimercaprol is administered IV for systemic toxicity and topically for skin lesions. All persons with sulfur mustard exposures should be monitored for 24 hours for latent (delayed) effects (ENA, 2020).

Nerve Agents

The most toxic agents in existence are the nerve agents such as sarin, soman, tabun, and VX. They are inexpensive, effective in small quantities, and easily dispersed. In the liquid form, nerve agents evaporate into a colorless, odorless vapor. Organophosphates (pesticides) are similar in nature to the nerve agents used in warfare and are readily available in the farming industry (ENA, 2020).

Nerve agents can be inhaled or absorbed percutaneously or subcutaneously. These agents bond with acetylcholinesterase so that acetylcholine is not inactivated; the adverse result is hyperstimulation (continuous stimulation) of the nerve endings. Carbamates, which are insecticides originally extracted from the Calabar bean, are derivatives of carbamic acid; they are nerve agents that specifically inhibit acetylcholinesterase for several hours and then spontaneously become unbound from the acetylcholinesterase. However, organophosphates require the formation of new enzyme (acetylcholinesterase) before nervous system function can be restored.

A very small drop of a nerve agent is enough to result in sweating and twitching at the site of exposure. A larger amount results in more systemic symptoms. Effects can begin anywhere from 30 minutes up to 18 hours after exposure. The more common organophosphates and carbamates (e.g., sevin, malathion) that are used in agriculture result in less severe symptoms than do those used in warfare or in terrorist attacks. In an ordinary situation (e.g., nonwarfare, nonterrorist attack situation), a patient could arrive at the ED having been unintentionally exposed to organophosphates or intentionally exposed to these agents in a suicidal attempt (ENA, 2020).

Clinical Manifestations

Signs and symptoms of nerve gas exposure are those of cholinergic crisis and include bilateral miosis, visual disturbances, increased gastrointestinal motility, nausea and vomiting, diarrhea, substernal spasm, indigestion, bradycardia and atrioventricular block, bronchoconstriction, laryngeal spasm, weakness, fasciculations, and incontinence. The patient must be examined in a dark area to truly identify miosis. Neurologic responses include insomnia, forgetfulness, impaired judgment, depression, and irritability. A lethal dose results in loss of consciousness, seizures, copious secretions, fasciculations, flaccid muscles, and apnea (ENA, 2019).

Management

Decontamination with copious amounts of soap and water or saline solution for 8 to 20 minutes is essential. The water is blotted off, not wiped off, the skin. Wiping may have the unintended effect of rubbing more of the agent into the skin. Fresh 0.5% hypochlorite solution (bleach) can also be used. The airway is maintained, and suctioning is frequently required. Plastic airway equipment should not be used, because plastic will absorb sarin gas and may result in continued exposure to the agent.

Atropine 2 to 4 mg is administered by IV, followed by 2 mg every 3 to 8 minutes for up to 24 hours of treatment. Alternatively, IV atropine 1 to 2 mg per hour may be given until clear signs of anticholinergic activity have returned (decreased secretions, tachycardia, and decreased gastrointestinal motility). Another medication that may serve as an antidote is pralidoxime, which allows cholinesterase to become active against acetylcholine. Pralidoxime 1 to 2 g in 100 to 150 mL of normal saline solution is given over 15 to 30 minutes. Pralidoxime has no effect on secretions and may have any of the following side effects: hypertension, tachycardia, weakness, dizziness, blurred vision, and diplopia. Diazepam or other benzodiazepines are used to control seizures, to decrease fasciculations, and to alleviate apprehension and agitation (ENA, 2020).

Blood Agents

Blood agents such as hydrogen cyanide and cyanogen chloride have a direct effect on cellular metabolism, resulting in asphyxiation through alterations in hemoglobin. Cyanide is an agent that has profound systemic effects. It is commonly used in the mining of gold and silver and in the plastics and dye industries.

A cyanide release is often associated with the odor of bitter almonds. In house fires, cyanide is released during the combustion of plastics, rugs, silk, furniture, and other construction materials. There is a significant correlation between blood cyanide and carbon monoxide levels in patients who survive fires, and in some cases, the cause of death is cyanide poisoning (Veenema, 2019).

Clinical Manifestations

Cyanide can be ingested, inhaled, or absorbed through the skin and mucous membranes. Cyanide is protein bound and inhibits aerobic metabolism, leading to respiratory muscle failure, respiratory arrest, cardiac arrest, and death. Its inhalation results in flushing, tachypnea, tachycardia, nonspecific neurologic symptoms, stupor, coma, and seizure preceding respiratory arrest (ENA, 2019).

Management

Rapid administration of amyl nitrate, sodium nitrite, and sodium thiosulfate is essential to the successful management of cyanide exposure. First, the patient is intubated and placed on a ventilator. Next, amyl nitrate pearls are crushed and placed in the ventilator reservoir to induce methemoglobinemia. Cyanide has a 20% to 25% higher affinity for

methemoglobin than it does for hemoglobin; it binds methemoglobin to form either cyanomethemoglobin or sulfmethemoglobin. The cyanomethemoglobin is then detoxified in the liver by the enzyme rhodanese. Next, IV sodium nitrite is given to induce the rapid formation of methemoglobin. IV sodium thiosulfate is then given; it has a higher affinity for cyanide than methemoglobin and stimulates the conversion of cyanide to sodium thiocyanate, which can be excreted by the kidneys (ENA, 2019). Although they may be lifesaving, these emergency medications do have side effects—sodium nitrite can result in severe hypotension, and thiocyanate can cause vomiting, psychosis, arthralgia, and myalgia.

The production of methemoglobin is contraindicated in patients with smoke inhalation, because they already have decreased oxygen-carrying capacity secondary to the carboxyhemoglobin produced by smoke inhalation. In facilities where a hyperbaric chamber is available, it may be used to provide oxygenation while the previously discussed therapies are initiated. An alternative suggested treatment for cyanide poisoning is hydroxocobalamin (vitamin B_{12a}). Hydroxocobalamin binds with cyanide to form cyanocobalamin (vitamin B_{12}). It must be administered IV in large doses (Tintinalli et al., 2020). Administration of hydroxocobalamin can result in a transient pink discoloration of mucous membranes, skin, and urine. In high doses, tachycardia and hypertension can occur, but they usually resolve within 48 hours.

Pulmonary Agents

Pulmonary agents such as phosgene and chlorine destroy the pulmonary membrane that separates the alveolus from the capillary bed, disrupting alveolar–capillary oxygen transport mechanisms. Capillary leakage results in fluid-filled alveoli. Phosgene and chlorine both vaporize rapidly causing this pulmonary injury. Phosgene has the odor of freshly mown hay.

Signs and symptoms include pulmonary edema with shortness of breath, especially during exertion. An initial hacking cough is followed by frothy sputum production. A particulate air filter mask is the only protection required to protect health care personnel. Phosgene does not injure the eyes. In a review of a chlorine spill in South Carolina that exposed 155 patients, the most useful tool for identifying worsening symptoms was the pulse oximeter. Ordinary triage systems did not predict the severity of exposure (Veenema, 2019).

Nuclear Radiation Exposure

The threat of nuclear warfare or exposure to a radiologic weapon is very real with the availability of nuclear material and easily concealed simple devices, such as the so-called dirty bomb, for dispersal. A dirty bomb is a conventional explosive (e.g., dynamite) that is packaged with radioactive material that scatters when the bomb is detonated. It disperses radioactive material and may be called a **radiologic weapon**, but it is not a *nuclear* weapon, which uses a complex nuclear fission reaction that is thousands of times more devastating than the dirty bomb (Durakovic, 2017).

Sources of radioactive material include not only nuclear weapons but also reactors and simple radioactive samples, such as weapons-grade plutonium or uranium, freshly spent nuclear fuel, or medical supplies (e.g., radium, certain cesium isotopes) used in cancer treatments and radiology. Exposure to a large number of people can be accomplished by placing a radioactive sample in a public place. Thousands may be exposed this way; some may be immediately affected, and others may require health monitoring for many years to assess long-term effects (Durakovic, 2017).

Any terrorist act or unintentional radiation release can be sizable and may require the entire hospital and prehospital staff to be prepared, recognize signs and symptoms of exposure, and rapidly treat victims without contamination of personnel, visitors, patients, or the facility itself.

Types of Radiation

Atoms consist of protons, neutrons, and electrons. The protons and neutrons are in balance in the nucleus. The protons repel each other because they are all positively charged. The number of protons is specific for each element in the periodic table. There is a specific ratio of protons and neutrons for each different atom, and the result is element stability. When an element is radioactive, there is an imbalance in the nucleus, resulting from an excess of neutrons.

To achieve stability, a radioactive nuclide can eject particles until the most stable number (an even number) of protons and neutrons exists. A proton can become a neutron by ejecting a positron; conversely, a neutron can become a proton by ejecting a negative electron. An alpha particle is released when two protons and two electrons are ejected (beta particles are electrons).

Alpha particles cannot penetrate the skin. A thin layer of paper or clothing is all that is necessary to protect the skin from alpha radiation.

However, this low-level radiation can enter the body through inhalation, ingestion, or injection (open wound). Only localized damage occurs.

Beta particles have the ability to moderately penetrate the skin to the layer in which skin cells are being produced. This high-energy radiation can cause skin damage if the skin is exposed for a prolonged period and can cause injury if beta particles penetrate the skin.

Gamma radiation is a short-wavelength electromagnetic energy that is emitted when there is excess core nucleus energy. Gamma particles are penetrating. Therefore, it is difficult to shield against gamma radiation. X-rays are an example of gamma radiation. Gamma radiation often accompanies both alpha particle and beta particle emission (Tintinalli et al., 2020).

Measurement and Detection

Radiation is measured in several different units. The *rad* is the basic unit of measurement. A rad is equivalent to 0.01 J of energy per kilogram of tissue. To determine the damaging effect of the rad, a conversion to the *rem* (roentgen equivalents man) is necessary. The rem reflects the type of radiation absorbed and the potential for damage. For example, 200,000 mrem results in mild radiation sickness (1 rem = 1000 mrem) (Tintinalli et al., 2020). Typical natural yearly exposure for a person is 360 mrem. Another important concept is *half-life*. The half-life of a radioactive product is the time it takes to lose half of its radioactivity.

The only way to detect radiation is through a device that determines the exposure per minute. There are various devices for this purpose. The Geiger counter (or Geiger–Müller survey meter) can measure background radiation quickly through detection of gamma radiation and some beta radiation. With high-level radiation, the Geiger counter may underestimate exposure. Other devices include the ionization chamber survey meter, alpha monitors, and dose rate meters (ENA, 2020). Personal dosimeters are simple tools that identify radiation exposure and are worn by radiology personnel every day.

Exposure

Exposure is affected by time, distance, and shielding. The longer a person is within the radiation area, the higher the exposure. In addition, the larger the amount of radioactive material in the area, the greater the exposure. The farther away the person is from the radiation source, the lower the exposure. Shielding from the radiation source also decreases exposure.

Three types of radiation-induced injury can occur: external irradiation, contamination with radioactive materials, and incorporation of radioactive material into body cells, tissues, or organs (ENA, 2020):

- *External irradiation* exposure occurs when all or part of the body is exposed to radiation that penetrates or passes completely through the body. In this type of exposure, the person is not radioactive and does not require special isolation or decontamination measures. Irradiation does not necessarily constitute a medical emergency.
- *Contamination* occurs when the body is exposed to radioactive gases, liquids, or solids either externally or internally. If internal, the contaminant can be deposited within the body. Contamination requires immediate medical management to prevent incorporation.
- *Incorporation* is the actual uptake of radioactive material into the cells, tissues, and susceptible organs. The organs involved are usually the kidneys, bones, liver, and thyroid.

Sequelae of contamination and incorporation can occur days to years later. The thyroid gland can be largely protected from radiation exposure by administration of stable iodine (potassium iodide) before or promptly after the intake of radioactive iodine. Priorities in the treatment of any type of radiation exposure are always treatment for life-threatening injuries and illnesses first, followed by measures to limit exposure, contamination control, and finally decontamination (Tintinalli et al., 2020).

Decontamination

Hospital and community disaster plans should be in effect when managing a radiation disaster. Access restriction is essential to prevent contamination of other areas of the hospital. Triage outside the hospital is the most effective means of preventing contamination of the facility itself. Floors are covered to prevent tracking of contaminants throughout the treatment areas. Strict isolation precautions should be in effect. All air ducts and vents must be sealed to prevent spread. Waste is controlled through double-bagging and the use of plastic-lined containers outside of the facility. All radiation-contaminated waste must be disposed of in appropriate color-coded yellow and magenta canisters.

Staff are required to wear protective clothing, such as water-resistant gowns, two pairs of gloves, masks, caps, goggles, and booties. Dosimetry

devices should be worn by all staff members participating in patient care. The radiation safety officer in the hospital should be notified immediately to assist with surveys (using a radiation survey meter) of the incoming patients and to provide dosimeters to all staff personnel involved in direct care of patients who have been exposed. There is minimal risk to staff if the patients are properly surveyed and decontaminated.

Each patient arriving at the hospital should first be surveyed with the radiation survey meter for external contamination and then directed toward the decontamination area as needed. The majority of patients can be safely decontaminated with soap and water. Decontamination occurs outside of the ED with a shower, collection pool, tarp, and collection containers for patient belongings, as well as soap, towels, and disposable paper gowns for patients. Water runoff needs to be contained. Patients who are uninjured can perform self-decontamination with handheld showers. After the patient has showered, a resurvey is conducted to determine whether the radioactive contaminants have been removed. Additional washings should occur until the patient is free of contamination. It is important to ensure that during showers, previously clean areas are not contaminated with runoff from the washed contaminated areas (e.g., hair should be washed in a position that protects the body from contamination). Wounds are irrigated and then covered with a water-resistant dressing prior to total body decontamination.

Internal contamination or incorporation requires decontamination through catharsis, gastric lavage with chelating agents (agents that bind with radioactive substances and are then excreted), or both. Samples of urine, feces, and vomitus are surveyed to determine internal contamination levels. Biologic samples are taken through nasal and throat swabs, and a complete blood count with differential is obtained (Tintinalli et al., 2020).

Acute Radiation Syndrome

Acute radiation syndrome (ARS) can occur after exposure to radiation. It is the dose, rather than the source, that determines whether ARS develops. Factors that determine whether the patient's response to exposure will result in ARS include a high dose (minimum 100 rad) and rate of radiation with total body exposure and penetrating-type radiation. Age, medical history, and genetics also affect the outcome after exposure. The course is predictable. Table 68-8 identifies the phases of ARS.

Each body system is affected differently in ARS. Systems with cells that rapidly reproduce are most commonly affected. The hematopoietic

system is the first system affected and serves as an indicator of the severity of radiation exposure (Veenema, 2019). A predictor of outcome is the absolute lymphocyte count at 48 hours after exposure. A significant exposure would be indicated by blood lymphocyte counts of 300 to 1200/mm^3. Barrier precautions should be implemented to protect the patient from infection. Neutrophils decrease within 1 week, platelets decrease within 2 weeks, and red blood cells decrease within 3 weeks. Hemorrhagic complications including fever and sepsis are common.

TABLE 68-8 Phases of Effects of Acute Radiation Syndrome

Phase	Time of Occurrence	Signs and Symptoms
Prodromal phase (presenting symptoms)	48–72 h after exposure	Nausea, vomiting, loss of appetite, diarrhea, fatigue High-dose radiation—fever, respiratory distress, and increased excitability
Latent phase (a symptom-free period)	After resolution of prodromal phase; can last up to 3 wks With high-dose radiation, latent period is shorter	Decreasing lymphocytes, leukocytes, thrombocytes, red blood cells
Manifest illness phase	After latent period phase	Infection, fluid and electrolyte imbalance, bleeding, diarrhea, shock, and altered level of consciousness
Recovery phase OR	After manifest illness phase	Can take weeks to months for full recovery
Death	After manifest illness phase	Increased intracranial pressure is a sign of impending death

Adapted from Centers for Disease Control and Prevention (CDC). (2018c). *Acute radiation syndrome: A fact sheet for clinicians*. Retrieved on 3/1/2020 at: www.emergency.cdc.gov/radiation/arsphysicianfactsheet.asp

The gastrointestinal system, with its rapidly reproducing cells, is also readily affected by radiation. Doses of radiation required to produce symptoms are approximately 600 rad or higher. The gastrointestinal symptoms usually occur at the same time as the changes in the hematopoietic system. Nausea and vomiting occur within 2 hours after exposure. Sepsis, fluid and electrolyte imbalance, and opportunistic infections can occur as complications. An ominous sign is the presence of high fever and bloody diarrhea; these typically appear on day 10 after exposure (ENA, 2019).

The central nervous system is affected when the dose exceeds 1000 rad (ENA, 2019). The symptoms occur when damage to the blood vessels of the brain results in fluid leakage. Signs and symptoms include cerebral edema; nausea; vomiting; headache; and increased intracranial pressure, which heralds a poor outcome and imminent death. Central nervous system injury with this amount of exposure is irreversible and occurs before hematopoietic or gastrointestinal system symptoms appear. Cardiovascular collapse is usually seen in conjunction with these injuries.

Skin effects can also indicate the dose of radiation exposure. With an exposure of 600 to 1000 rad, erythema occurs; it can disappear within hours and then reappear. The patient who has been exposed must be evaluated hourly for the presence of erythema. With exposures greater than 1000 rad, desquamation (radiation dermatitis) of the skin occurs. Necrosis becomes evident within a few days to months at doses greater than 5000 rad (CDC, 2018c).

Secondary injury can occur when the radiation exposure occurs during a traumatic event such as a blast or burn. Trauma in addition to radiation exposure increases patient mortality. Attention must first be directed toward the primary assessment for trauma. Airway, breathing, circulation, and fracture reduction require immediate attention. All definitive treatments must occur within the first 48 hours. Thereafter, all surgical procedures should be delayed for 2 to 3 months because of the potential for delayed wound healing and the possible development of opportunistic infections several weeks after exposure (Veenema, 2019).

Survival

There are three categories of predicted survival after radiation exposure: probable, possible, and improbable. Triage of victims at the scene, after decontamination, is conducted using the routine system for disaster triage. Presenting signs and symptoms determine the potential for survival and therefore the category of predicted survival during triage.

Probable survivors have either no initial symptoms or only minimal symptoms (e.g., nausea and vomiting), or these symptoms resolve within a few hours. These patients should have a complete blood count drawn and may be discharged with instructions to return if any symptoms recur.

Possible survivors present with nausea and vomiting that persist for 24 to 48 hours. They experience a latent period, during which leukopenia, thrombocytopenia, and lymphocytopenia occur. Barrier precautions and protective isolation are implemented if the patient's lymphocyte count is less than 1200/mm^3. Supportive treatment includes administration of

blood products, prevention of infection, and provision of enhanced nutrition.

Improbable survivors have received more than 800 rad of total-body penetrating irradiation. People in this group demonstrate an acute onset of vomiting, bloody diarrhea, and shock. Any neurologic symptoms suggest a lethal dose of radiation (ENA, 2019). These patients still require decontamination to prevent further contamination of the area and of others. Personal protection is essential, because it is virtually impossible to fully decontaminate these patients; all of their internal organs have been irradiated. The survival time is variable; however, death usually occurs swiftly due to shock. If there are no neurologic symptoms, patients may be alert and oriented, similar to a patient with extensive burns. In a mass casualty situation, these patients would be triaged into the black category, where they will receive comfort measures and emotional support. If it is not a mass casualty situation, aggressive fluid and electrolyte therapies are essential.

CRITICAL THINKING EXERCISES

1 pq You are one of the several nurses volunteering at a music festival. You suddenly hear a loud explosion and hundreds of attendees are screaming and scattering in all directions. You see people are bleeding and notice that some individuals are on the ground not moving. You know you need to organize efforts and provide care. What are the priority actions you should take in order to ensure the safety of yourself and others on the scene? How will information be communicated to the community? What strategies will you utilize in this situation to triage those who have been impacted? As EMS arrive, who will have priority to be transported to the hospital?

2 ebp You are working in the emergency department and caring for a patient who complains of a fever for the past 2 days, cough, shortness of breath, severe fatigue, and loss of appetite. You are concerned that this patient may have COVID-19. Identify the immediate precautions that you will need to implement when providing care for this patient. When conducting an assessment, what questions will you ask this patient? Discuss the education you will provide the patient and family to reduce the potential transmission of SARS-CoV-2 and the evidence-based resources you will use to support this education.

Appendix A

Diagnostic Studies and Interpretation

Test Value Studied

Reference Ranges—Hematology
Reference Ranges—Serum, Plasma, and Whole Blood Chemistries
Reference Ranges—Immunodiagnostic Tests
Reference Ranges—Urine Chemistry
Reference Ranges—Cerebrospinal Fluid (CSF)

Selected Abbreviations Used in Reference Ranges

Conventional Units

kg = kilogram
gm = gram
mg = milligram
µg = microgram
µµg = micromicrogram
ng = nanogram
pg = picogram
dL = 100 milliliters
mL = milliliter
mm^3 = cubic millimeter

fL = femtoliter
mM = millimole
nM = nanomole
mOsm = milliosmole
mm = millimeter
µm = micron or micrometer
mm Hg = millimeters of mercury
U = unit
mU = milliunit
µU = microunit
mEq = milliequivalent
IU = international unit
mIU = milli-international unit

SI Units

g = gram
L = liter
d = day
h = hour
mol = mole
mmol = millimole
µmol = micromole
nmol = nanomole
pmol = picomole

TABLE A-1 Reference Ranges—Hematology[a]

Test	Reference Range		Clinical Significance
	Conventional Units	SI Units	
Bleeding time	3–10 min Ivy method	3–10 min	Prolonged in thrombocytopenia, defective platelet function, and aspirin therapy
Factor V assay (labile factor)	50–150%		Decreased in liver disease, factor V inhibitors, myeloproliferative disorders, DIC, and fibrinolysis
Factor VIII assay (-antihemophilic factor)	55–145%	55–145 AU	Increased in late normal pregnancy, thromboembolic -conditions, liver disease, postoperative period, and rebound period after sudden cessation of a Coumadin-type drug Decreased in hemophilia A, immunologic reactions, -postpartum, von Willebrand disease, DIC, fibrinolysis, and myeloproliferative disorders
Factor IX assay (Christmas factor)	60–140%	60–140 AU	Decreased in uncompensated cirrhosis, liver disease, nephrotic syndrome, various anticoagulant drugs, DIC, and vitamin K deficiency
Factor X	45–155%		Decreased in liver disease, oral anticoagulant drugs, -amyloidosis, DIC, and vitamin deficiency
Fibrinogen	200–400 mg/dL	2–4 g/dL	Increased in pregnancy, infections, inflammation, acute MI, nephritic syndrome, cancers, and stroke Decreased in liver disease, DIC, cancer, primary fibrinolysis, and hereditary and congenital hypofibrinogenemia
Fibrin degradation products	<10 µg/mL	<10 mg/mL	Used to establish diagnosis of DIC and other thromboembolic disorders
Fibrinolysis	No lysis in 24 h		Increased activity associated with

(whole blood clot lysis time)			hemorrhage and circulatory collapse, surgery, long-term DIC, liver disease, pregnancy complications, and other conditions
Activated partial thromboplastin time (aPTT)	Lower limit of normal: 21–35 s		Prolonged in deficiency of fibrinogen; factors II, V, VIII, IX, X, XI, and XII; in heparin therapy; DIC; liver disease; and other conditions
Prothrombin (PT)	Lower limit of normal: 11 s Lower limit of normal: 13 s		Impaired in deficiency of factors II, V, VIII, IX, and X; DIC; liver disease; and other conditions
INR	0.8–1.2		Prolonged by deficiency of factors I, II, V, VII, and X; fat malabsorption; severe liver disease; warfarin (Coumadin) anticoagulant therapy; and other conditions
Erythrocyte count	Males: 4,200,000–5,400,000/mm^3	4.2–5.4 × 10^{12}/L	Increased in severe diarrhea and dehydration, polycythemia, acute poisoning, and pulmonary fibrosis
	Females: 3,600,000–5,000,000/mm^3	3.6–5.0 × 10^{12}/L	Decreased in all anemias, in leukemia, and after hemorrhage when blood volume has been restored
Erythrocyte Indices			
Mean corpuscular volume (MCV)	82–98 mcm^3	82–98 fL	Increased in macrocytic anemia; decreased in microcytic anemia
Mean corpuscular - hemoglobin (MCH)	26–34 pg/cell	0.40 to 0.53 fmol/cell	Increased in macrocytic anemia; decreased in microcytic anemia
Mean corpuscular hemoglobin concentration (MCHC)	32–36 g/dL	4.9 to 5.5 mmol/L	Decreased in severe hypochromic anemia
Reticulocytes	0.5–1.5% of	Number	Increased with any condition

	RBCs	fraction: 0.005–0.015	stimulating increase in bone marrow activity (e.g., infection, blood loss [acute and chronically following iron therapy in iron deficiency - anemia], polycythemia vera)
			Decreased with any condition depressing bone marrow - activity, acute leukemia, late stage of severe anemias
ESR	Males under 50 yrs: 0–15 mm/h Males over 50 yrs: 0–20 mm/h Females under 50 yrs: 0–20 mm/h Females over 50 yrs: 0–30 mm/h	<15 mm/h <20 mm/h <25 mm/h <30 mm/h	Increased in tissue destruction, whether inflammatory or degenerative; during menstruation and pregnancy; in acute febrile diseases; and other conditions
Hematocrit	Males: 42–52% Females: 36–48%	Volume fraction: 0.42–0.52 Volume fraction: 0.36–0.48	Decreased in anemias, including anemia of pregnancy, acute blood loss, and other conditions
			Increased in erythrocytosis of any cause, and in dehydration or hemoconcentration associated with shock
Hemoglobin	Males: 14.0–17.4 g/dL Females: 12.0–16 g/dL	140–174 g/L mmol/L 120–160 g/L	Decreased in anemias, pregnancy, hemorrhage, with excessive fluid intake, and other conditions
			Increased in polycythemia, chronic obstructive pulmonary disease, failure of oxygenation because of congestive heart failure, and normally in people living at high altitudes

Leukocyte alkaline phosphatase	40–100 units		Increased in polycythemia vera, myelofibrosis, various cancers, and other conditions Decreased in chronic myeloid leukemia, paroxysmal - nocturnal hemoglobinuria, idiopathic thrombocytopenic purpura, hereditary hypophosphatasia, progressive muscular dystrophy, marked eosinophilia, nephritic syndrome, and siderocytic anemia
Leukocyte count Neutrophils	Total: 4500–11,000/mm^3 45–73%	4.5×10^9/L Number fraction: 0.45–0.73	Neutrophils increase with acute infections, trauma or surgery, leukemia, malignant disease, necrosis; decreased with viral infections, bone marrow suppression, primary bone marrow disease
Eosinophils	0–4%	Number fraction: 0.00–0.04	Eosinophils increased in allergy, parasitic disease, collagen disease, subacute infections; decreased with stress, use of some medications (ACTH, epinephrine, thyroxine)
Basophils	0–1%	Number fraction: 0.00–0.01	Basophils increased with acute leukemia and following - surgery or trauma; decreased with allergic reactions, stress, allergy, parasitic disease, use of corticosteroids
Lymphocytes	20–40%	Number fraction: 0.2–0.4	Lymphocytes increased with infectious mononucleosis, viral and some bacterial infections, hepatitis; decreased with aplastic anemia, SLE, immune deficiency including AIDS
Monocytes	2–8%	Number fraction: 0.02–0.08	Monocytes increased with viral infections, parasitic disease, collagen and hemolytic disorders; decreased with use of corticosteroids, RA, HIV infection

Platelet count	140,000–400,000/mm^3	0.14–0.4 × 10^{12}/L	Increased in cancer, myeloproliferative disease, RA, and postoperatively Decreased in thrombocytopenic purpura, acute leukemia, aplastic anemia, and during cancer chemotherapy

[a]Laboratory values and reference ranges may vary in different laboratories.

ACTH, adrenocorticotropic hormone; AIDS, acquired immune deficiency syndrome; DIC, disseminated intravascular coagulation; ESR, erythrocyte sedimentation rate; HIV, human immune deficiency virus; INR, international normalized ratio; MI, myocardial infarction; RA, rheumatoid arthritis; RBC, red blood cell; SLE, systemic lupus erythematosus.

TABLE A-2 Reference Ranges—Serum, Plasma, and Whole Blood Chemistries

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Acetoacetate	0.2–1.0 mg/dL	19.6–98 mcmol/L	Diabetic ketoacidosis and fasting	
Acetone	0.3–2.0 mg/dL	51.6–3440/mcmol/L	Diabetic ketoacidosis, toxemia of pregnancy, and carbohydrate-free diet, high-fat diet	
Acid, total phosphatase	Males: 2–12 U/L Females: 0.3–9.2 U/L	Males: 2–12 U/L Females: 0.3–9.2 U/L	Carcinoma of prostate, advanced Paget disease, hyperparathyroidism, and Gaucher disease	
Acid, phosphatase, prostatic—RIA	<2.5 ng/mL	<2.5 µg/L	Carcinoma of prostate	
Alkaline phosphatase	Adults: 52–142 U/L	0.43–1.70 mkat/L	Conditions reflecting increased osteoblastic activity of bone, including many liver diseases, bone diseases, and other conditions	
Adrenocorticotropic hormone (ACTH) (plasma)—RIA[a]	<120 pg/mL	<120 ng/L	Pituitary-dependent Cushing syndrome, ectopic ACTH syndrome, and primary adrenal atrophy	Adrenocortical tumor, adrenal insufficiency secondary to hypopituitarism
Aldolase	3–8 Sibley–Lehninger U/dL at 37°C	22–59 mU/L at 37°C	Hepatic necrosis, granulocytic leukemia, myocardial infarction, and skeletal muscle disease	
Aldosterone (plasma)—RIA	Supine: 3–16 ng/dL Upright: 7–30 ng/dL Adrenal vein: 200–800 ng/dL	0.08–0.30 nmol/L 0.14–0.90 nmol/L 5.54–22.16 nmol/L	Primary and secondary aldosteronism	Addison disease
$Alpha_1$-antitrypsin	110–140 mg/dL	1.1–1.4 g/L		Certain forms of chronic lung and liver disease in young adults
Alpha-hydroxybutyric dehydrogenase	<140 U/L	<140 U/L	Myocardial infarction, granulocytic leukemia, hemolytic anemias, and muscular dystrophy	
Ammonia (plasma)	15–45 mcg/dL (varies with method)	11–32 mcmol/L	Severe liver disease, and hepatic decompensation	

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Amylase	25–125 U/L Older adults: 24–151 U/L	0.4–2.1 µkat/L 0.4–2.5 µkat/L	Acute pancreatitis, mumps, duodenal ulcer, carcinoma of head of pancreas, prolonged elevation with pseudocyst of pancreas, and medications that constrict pancreatic duct sphincters: morphine, codeine, cholinergics	Chronic pancreatitis, pancreatic fibrosis and atrophy, cirrhosis of liver, and pregnancy (2nd and 3rd trimesters)
Arsenic	<70 mcg/dL; poisoning: 100–150 mcg/dL	<0.93–2.6 mcmol/L; poisoning: 133–6.65 mcmol/L	Intentional or unintentional poisoning, and excessive occupational exposure	
Ascorbic acid (vitamin C)	0.4–1.5 mg/dL	23–85 mcmol/L	Large doses of ascorbic acid as a prophylactic against the common cold	
ALT (alanine aminotransferase), formerly SGPT	Males: 10–40 U/mL Females: 8–35 U/mL	Males: 0.17–0.68 mckat/L Females: 0.14–0.60 mckat/L	Same conditions as AST (SGOT), but increase is more marked in liver disease than AST (SGOT)	
AST (aspartate aminotransferase), formerly SGOT	Males: 10–40 U/L Females: 15–30 U/L	Males: 0.34–0.68 mckat/L Females: 0.25–0.51 mckat/L	Myocardial infarction, skeletal muscle disease, and liver disease	
Bilirubin	Total: 0.3–1.0 mg/dL Direct: <0.5 mg/dL Indirect: 0.1–1 mg/dL	5–17 mcmol/L <6.8 µmol/L 1.7–17.1 µmol/L	Hemolytic anemia (indirect), biliary obstruction and disease, hepatocellular damage (hepatitis), and pernicious anemia	
Brain (B-type) natriuretic peptide (BNP)	<100 pg/mL	100 ng/L	Heart failure, cardiac volume overload	
Calcitonin	Basal: <8.4 pg/mL Stimulation test Males: <190 pg/mL Females: <35 pg/mL	8.4 ng/L <190 ng/L <35 ng/L	Medullary carcinoma of the thyroid, some nonthyroid tumors, Zollinger-Ellison syndrome	
Calcium	8.8–10.4 mg/dL	2.20–2.6 mmol/L	Tumor or hyperplasia of parathyroid, hypervitaminosis D, multiple myeloma, nephritis with uremia, malignant tumors, sarcoidosis, hypoparathyroidism, skeletal immobilization, excess calcium intake: milk-alkali syndrome	Hyperthyroidism, diarrhea, celiac disease, vitamin D deficiency, acute pancreatitis, nephrosis, and parathyroidectomy
CO_2, venous	Adults: 24–32 mEq/L Infants: 22–24 mEq/L	24–32 mmol/L 22–24 mmol/L	Tetany, respiratory disease, intestinal obstruction, vomiting, and pheochromocytoma	Acidosis, nephritis, eclampsia, diarrhea, and anesthesia
Catecholamines (plasma)—RIA	Epinephrine: <100 pg/mL Norepinephrine: <400 pg/mL Dopamine: <143 pg/mL	<540 pmol/L <2360 pmol/L <935 pmol/L		
Ceruloplasmin	25–63 mg/dL	250–630 mg/L		Wilson disease (hepatolenticular degeneration)
Chloride	96–106 mEq/L	96–106 mmol/L	Nephrosis, nephritis, urinary obstruction, cardiac decompensation, and anemia	Diabetes, diarrhea, vomiting, pneumonia, heavy metal poisoning, Cushing syndrome, intestinal obstruction, and other febrile conditions

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Cholesterol	Males: <205 mg/dL Females: <190 mg/dL	<5.3 mmol/L <4.9 mmol/L	Lipemia, obstructive jaundice, diabetes, and hyperthyroidism	Pernicious anemia, hemolytic anemia, hypothyroidism, severe infection, and terminal states of debilitating disease
Cholinesterase	Serum: 0.6–1.6 delta pH Red cells: 0.6–1 delta pH	0.6–1.6 U 0.6–1 U	Nephrosis and exercise	Nerve gas exposure (greater effect on red cell activity) and insecticide poisoning
Complement, C_3	75–175 mg/dL	0.75–1.75 g/L	Some inflammatory diseases, acute myocardial infarction, cancer	Acute glomerulonephritis and disseminated lupus erythematosus with renal involvement
Complement, C_4	14–40 mg/dL	0.15–0.45 g/L	Some inflammatory diseases, acute myocardial infarction, and cancer	Often decreased in immunologic disease, especially with active systemic lupus erythematosus, and hereditary angioneurotic edema
Complement, total (hemolytic)	90–94% complement	30–60 U/mL	Some inflammatory diseases	Acute glomerulonephritis, meningitis, and subacute bacterial endocarditis
Copper	70–150 mcg/dL	11–24 mcmol/L	Cirrhosis of liver and pregnancy	Wilson disease
Cortisol-RIA	8 AM: 5–23/mcg/dL 4 PM: 3–16 mcg/dL	138–635 nmol/L 80–330 nmol/L	Stress: infectious disease, surgery, burns, etc.; pregnancy; Cushing syndrome; pancreatitis; and eclampsia	Addison disease and anterior pituitary hypofunction
C-peptide reactivity Creatine	0.78–1.89 ng/mL	0.26–0.63 mmol/L 15.3–61 mcmol/L	Insulinoma Pregnancy, skeletal muscle necrosis or atrophy, starvation, and hyperthyroidism	Diabetes
Creatine phosphokinase (CPK)	Males: 50–325 mU/mL Females: 50–250 mU/mL	50–325 U/L 50–250 U/L	Myocardial infarction, skeletal muscle diseases, intramuscular injections, Crush syndrome, hypothyroidism, alcohol withdrawal delirium, alcoholic myopathy, and cerebrovascular disease	
Creatine kinase (CK) isoenzymes	MM band present (skeletal muscle)–MB band absent (heart muscle)		MB band increased in myocardial infarction, ischemia	
Creatinine	Males: 0.6–1.2 mg/dL Females: 0.4–1.0 mg/dL	71–106 mmol/L 36–90 mmol/L	Nephritis, chronic renal disease	
Cryoglobulins, qualitative	Negative		Multiple myeloma, chronic lymphocytic leukemia, lymphosarcoma, systemic lupus erythematosus, rheumatoid arthritis, infective subacute endocarditis, some malignancies, and scleroderma	
11-Deoxycortisol	1 mcg/dL	<0.029 mcmol/L	Hypertensive form of virilizing adrenal hyperplasia due to an 11-β-hydroxylase defect	

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Dibucaine inhibition	Normal: 79–84%	0.79–0.84%		Important in detecting carriers of abnormal cholinesterase activity who are at risk for a number of conditions
Dihydrotestosterone	Males: 50–210 ng/dL Females: none detectable	1.72–7.22 nmol/L		Testicular feminization syndrome
Estradiol—RIA	Females: Follicular: 10–90 pg/mL Midcycle: 100–500 pg/mL Luteal: 50–240 pg/mL Follicular phase: 2–20 ng/dL Midcycle: 12–40 ng/dL Luteal phase: 10–30 ng/dL Postmenopausal: 1–5 ng/dL Males: 0.5–5 ng/dL	 37–370 pmol/L 367–1835 pmol/L 184–881 pmol/L	Pregnancy or ovarian tumor	Ovarian failure
Estriol—RIA	Nonpregnant females: <0.5 ng/mL Pregnant females: 1st trimester: up to 1 ng/mL 2nd trimester: 0.8–7 ng/mL 3rd trimester: 5–25 ng/mL	<1.75 nmol/L Up to 3.5 nmol/L 2.8–24.3 nmol/L 17.4–86.8 nmol/L	Pregnancy	Ovarian failure
Estrogens, total—RIA	Females: cycle days: Day 1–10: 61–394 pg/mL Day 11–20: 122–437 pg/mL Day 21–30: 156–350 pg/mL Males: 20–80 pg/mL	 61–394 ng/L 122–437 ng/L 156–350 ng/L 20–80 ng/L	Pregnancy, measured on a daily basis, can be used to evaluate response of hypogonadotropic, hypoestrogenic women to human menopausal or pituitary gonadotropin	Fetal distress, ovarian failure
Estrone—RIA	Females: Day 1–10: 4.3–18 ng/dL Day 11–20: 7.5–19.6 ng/dL Day 21–30: 13–20 ng/dL Males: 2.5–7.5 ng/dL	 15.9–66.6 pmol/L 27.8–72.5 pmol/L 48.1–74 pmol/L 9.3–27.8 pmol/L	Pregnancy	Ovarian failure
Ferritin—RIA	Males: 18–270 ng/mL Females: 18–160 ng/mL	18–270 µg/L 18–160 µg/L	Nephritis and hemochromatosis Certain neoplastic diseases, acute myeloid leukemia, and multiple myeloma	Iron deficiency
Folic acid—RIA	3–13 ng/mL	6.8–29.5 nmol/L		Megaloblastic anemias of infancy and pregnancy, inadequate diet, liver disease, malabsorption syndrome, and severe hemolytic anemia
Follicle-stimulating hormone (FSH)—RIA	Males: 1.24–7.8 mIU/mL Females: Follicular phase: 1.68–15 mIU/mL Peak of middle cycle: 21.9–56.6 mIU/mL Luteinic phase: 0.61–16.3 mIU/mL Menopausal females: 14.2–52.3 mIU/mL	1.24–7.8 IU/L 1.68–15 IU/L 21.9–56.6 IU/L 0.61–16.3 IU/L 14.2–52.3 IU/L	Menopause and primary ovarian failure	Pituitary failure

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Galactose	<5 mg/dL	<0.28 mmol/L		Galactosemia
Gamma glutamyl transpeptidase	Males: 20–30 U/L Females: 1–24 U/L	0.03–0.5 mckat/L 0.02–0.4 mckat/L	Hepatobiliary disease, drug toxicity, myocardial infarction, renal infarction, and Zollinger-Ellison syndrome	
Gastrin—RIA	Fasting: 50–155 pg/mL Postprandial: 80–170 pg/mL	50–155 ng/L 80–170 ng/L	Duodenal ulcer and pernicious anemia	
Glucose	Fasting: 60–100 mg/dL	≤5.6 mmol/L	Diabetes, nephritis, hypothyroidism, early hyperpituitarism, cerebral lesions, infections, pregnancy, and uremia	Hyperinsulinism, hyperthyroidism, late hyperpituitarism, Addison disease, and extensive hepatic damage
Glucose tolerance (oral)	Features of a normal response 1. Normal fasting between 60–110 mg/dL 2. No sugar in urine 3. Upper limits of normal Fasting = 125 mg/dL 1 h = 190 mg/dL 2 h = 140 mg/dL 3 h = 125 mg/dL	3.3–6.05 mmol/L 6.88 mmol/L 10.45 mmol/L 7.70 mmol/L 6.88 mmol/L	2-h value >200 mg/dL (11.1 mmol/L) is diagnostic for diabetes	Decreased 2- and 3-h values may occur with hypoglycemia in diabetes
Glucose-6-phosphate dehydrogenase (red cells)	Screening: Decolorization in 20–100 min Quantitative: 1.86–2.5 IU/mL RBC	 1860–2500 U/L		Drug-induced hemolytic anemia
Glycoprotein (alpha-1-acid)	50–120 mg/dL	0.5–1.2 g/L	Neoplasm, tuberculosis, diabetes complicated by degenerative vascular disease, pregnancy, rheumatoid arthritis, rheumatic fever, infectious liver disease, and systemic lupus erythematosus	
Growth hormone—RIA	Males: 0–4 ng/mL Females: 0–10 ng/mL	0.4 mcg/L 0–18 mcg/L	Acromegaly, pregnancy, and estrogen therapy	Hypopituitarism
Haptoglobin	30–200 mg/dL	0.3–2.0 g/L	Chronic infections and various inflammatory conditions	Hemolytic anemia and hemolytic blood transfusion reaction
Hemoglobin (plasma)	Males: 12.4–17.4 g/dL Females: 11.7–16 g/dL	112–174 g/L 117–160 g/L	Transfusion reactions, paroxysmal nocturnal hemoglobinuria, and intravascular hemolysis	Anemia, pregnancy, and chronic renal disease
Glycohemoglobin ([GHB], hemoglobin A_{1c}, hemoglobin A1)	Patients without diabetes and patients with diabetes with good glycemic control: 4.4–6.4%		Suboptimal glucose control	
Hexosaminidase, total	Controls: 333–375 nM/mL/h	333–375 mcmol/L/h	Sandhoff disease	Tay–Sachs disease and heterozygotes
Hexosaminidase A	Controls: 55–76% of total Heterozygotes: 26–45% of total Tay–Sachs disease: 0–4% of total Diabetes: 39–59% of total	Fraction of total: 0.49–0.68 0.26–0.45 0–0.04 0.39–0.59		

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
High-density lipoprotein cholesterol (HDL cholesterol)	Males: 35–65 mg/dL Females: 35–80 mg/dL	0.91–1.68 mmol/L 0.91–2.07 mmol/L		HDL cholesterol is lower in patients with increased risk for coronary artery disease
17-Hydroxyprogesterone—RIA	Males: 0.5–2.0 ng/mL Females: 0.2–3.0 ng/mL Children: <1.0 ng/mL	1.5–6.0 nmol/L 0.6–9.0 nmol/L <3.0 nmol/L	Congenital adrenal hyperplasia, pregnancy, some cases of adrenal or ovarian adenomas	
Immunoglobulin A	Adults: 60–400 mg/dL	600–4000 mg/L	Gamma A myeloma, Wiskott–Aldrich syndrome, autoimmune disease, and hepatic cirrhosis	Ataxia telangiectasis, agammaglobulinemia, hypogammaglobulinemia, transient dysgammaglobulinemia, and protein-losing enteropathies
Immunoglobulin D	0–14.0 mg/dL	0–140 mg/L	IgD multiple myeloma, some patients with chronic infectious diseases	
Immunoglobulin E	3–434 IU/mL	3–432 kUI/L	Allergic reactions, parasitic infections	
Immunoglobulin G	Adults: 700–1500 mg/dL	7–15 g/L	IgG multiple myeloma following hyperimmunization, autoimmune disease states, and chronic infections	Congenital and acquired hypogammaglobulinemia, IgA multiple myelomas, Waldenström (IgM) macroglobulinemia, some malabsorption syndromes, and extensive protein loss
Immunoglobulin M	Adults: 60–300 mg/dL	600–3000 mg/L	Waldenström macroglobulinemia, parasitic infections, and hepatitis	Agammaglobulinemias, multiple myeloma, and chronic lymphocytic leukemia
Insulin—RIA	0–35 mcU/mL	144–243 pmol/L	Insulinoma and acromegaly	Diabetes
Iron	50–150/mcg/dL	9–29 mcmol/L	Pernicious anemia, aplastic anemia, hemolytic anemia, hepatitis, and hemochromatosis	Iron deficiency anemia
Iron-binding capacity	IBC: 250–350 mcg/dL TIBC: 250–450 mcg/dL % Saturation: 10–50	45–63 mcmol/L 54–65 mcmol/L Fraction of total iron-binding capacity: 0.2–0.5	Iron deficiency anemia, acute and chronic blood loss, and hepatitis	Chronic infectious diseases and cirrhosis
Isocitric dehydrogenase	50–180 U	0.83–3 U/L	Hepatitis, cirrhosis, obstructive jaundice, metastatic carcinoma of the liver, and megaloblastic anemia	
Lactic acid (whole blood)	Venous: 5–15 mg/dL Arterial: 3–11 mg/dL	0.5–1.7 mmol/L 0.36–1.25 mmol/L	Increased muscular activity, heart failure, hemorrhage, shock, lactic acidosis, some febrile infections, and severe liver disease	
Lactic dehydrogenase (LDH)	<61 mU/mL	90–176 U/L	Untreated pernicious anemia, myocardial infarction, pulmonary infarction, and liver disease	

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
[a]LDH isoenzymes Total lactic dehydrogenase	140–280 mU/mL	140–280 U/L Fraction of total LDH:	LDH-1 and LDH-2 are increased in myocardial infarction, megaloblastic anemia, and hemolytic anemia LDH-4 and LDH-5 are increased in pulmonary infarction, congestive heart failure, and liver disease Lead poisoning	
LDH-1	17–27%	0.17–0.27		
LDH-2	29–39%	0.29–0.39		
LDH-3	19–27%	0.19–0.27		
LDH-4	8–16%	0.08–0.16		
LDH-5	6–16%	0.06–0.16		
Lead (whole blood)	Up to 40 mcg/dL	Up to 2 mcmol/L		
Leucine aminopeptidase	75–200 U/mL	75–200 kilounits/L	Liver or biliary tract disease, pancreatic disease, metastatic carcinoma of liver and pancreas, and biliary obstruction	
[b]Lipase	<140 U/mL	<140 U/L	Acute and chronic pancreatitis, biliary obstruction, cirrhosis, hepatitis, and peptic ulcer	
Lipids, total	400–800 mg/dL	4–8 g/L	Hypothyroidism, diabetes, nephrosis, glomerulonephritis, and hyperlipoproteinemias.	Hyperthyroidism
Low-density lipoprotein cholesterol (LDL cholesterol)	mg/dL desirable levels: <160 if no coronary artery disease (CAD) and <2 risk factors <130 if no CAD and two or more risk factors <100 if CAD present		LDL cholesterol is higher in patients with increased risk for coronary artery disease	
Luteinizing hormone—RIA	Males: 1.5–9.3 mU/mL Females: Follicular phase: 1.9–12.5 mU/mL Midcycle: 8.7–76.3 mU/mL	1.5–9.3 U/L 1.9–12.5 U/L 8.7–76.3 U/L	Pituitary tumor or ovarian failure	Pituitary failure
Lysozyme (muramidase)	4.0–15.6 mcg/mL	0.28–1.10 mcmol/L	Certain types of leukemia (acute myeloid leukemia), inflammatory states, and infections	Acute lymphocytic leukemia
Magnesium	1.8–2.6 mg/dL	0.74–1.07 mmol/L	Excess ingestion of magnesium-containing antacids	Chronic alcoholism, severe renal disease, and diarrhea
Mercury	<10 mcg/L	<50 mcmol/L	Mercury poisoning	
Myoglobin	No myoglobin	0 mcg/mL	Myocardial infarction, myocardial ischemia, rhabdomyolysis, and malignant hyperthermia	Rheumatoid arthritis and myasthenia gravis
5′ nucleotidase	3.2–11.6 IU/L	3.2–11.6 U/L	Hepatobiliary disease	
Osmolality	50–1200 mOsm/kg 300–900 mOsm/kg in 24 h	275–300 mmol/L	Diabetes insipidus, osmotic diuresis	Inappropriate secretion of ADH, Addison disease
Parathyroid hormone	10–50 pg/mL	10–50 ng/L	Hyperparathyroidism, chronic renal disease	Hypoparathyroidism
Phenylalanine	1.2–3.5 mg/dL 1st wk 0.7–3.5 mg/dL thereafter	0.07–0.21 mmol/L 0.04–0.21 mmol/L	Phenylketonuria	
Phosphohexose isomerase	20–90 IU/L	20–90 U/L	Malignancy, disease of heart, liver, and skeletal muscles	
Phospholipids	125–300 mg/dL	1.25–3 g/L	Diabetes or nephritis	

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Phosphorus, inorganic	2.7–4.5 mg/dL	0.87–1.45 mmol/L	Chronic nephritis and hypoparathyroidism	
Potassium	3.5–5 mEq/L	3.5–5 mmol/L	Renal disease, acidosis, cell lysis, tissue breakdown, or hemolysis	Hyperparathyroidism, vitamin D deficiency, GI losses, diuretic administration
Prealbumin	16–35 mg/dL	160–350 mg/L	Malnutrition, severe or chronic illness, and liver disease	
Progesterone—RIA	Follicular phase: up to 0.8 ng/mL Luteal phase: 10–20 ng/mL End of cycle: <1 ng/mL Pregnant: up to 50 ng/mL in 20th wk	2.5 nmol/L 31.8–63.6 nmol/L <3 nmol/L Up to 160 nmol/L	Useful in evaluation of menstrual disorders and infertility and in the evaluation of placental function during pregnancies complicated by toxemia, diabetes, or threatened miscarriage	
Prolactin—RIA	4–30 ng/mL	4–30 mcg/L	Pregnancy, functional or structural disorders of the hypothalamus, pituitary stalk section, and pituitary tumors	
Prostate-specific antigen (PSA)	Age under 60 <4 ng/mL Age over 60 <6.6 ng/mL		Prostatic cancer, benign prostatic hyperplasia, and prostatitis	
Protein, total Albumin Globulin	6–8 g/dL 3.5–5.2 g/dL 1.7–3.3 g/dL	60–80 g/L 35–52 g/L 17–33 g/L	Hemoconcentration, shock, globulin fraction increased in multiple myeloma, chronic infection, and liver disease	Malnutrition, hemorrhage, loss of plasma from burns, and proteinuria
Protein Electrophoresis Albumin Alpha-1 globulin Alpha-2 globulin Beta globulin Gamma globulin	 3.5–5.2 g/dL 0.1–0.3 g/dL 0.6–1 g/dL 0.5–1.0 g/dL 0.6–1.3 g/dL	35–55 g/L 35–52 g/L 1–3 g/L 6–10 g/L 5–10 g/L 6–13 g/L		
Protoporphyrin erythrocyte (whole blood)	Males: 11–45 mcg/dL Females: 19–52 mcg/dL	0.20–0.80 mcmol/L 0.34–0.92 mcmol/L	Lead toxicity, erythropoietic porphyria	
Pyridoxine	5–30 ng/mL	20–1.21 nmol/L		A wide spectrum of clinical conditions, such as depression, peripheral neuropathy, anemia, and reactions to certain drug therapies
Pyruvic acid (whole blood)	0.3–0.9 mg/dL	34–102 mcmol/L	Diabetes, severe thiamine deficiency, acute phase of some infections, possibly secondary to increased glycogenolysis and glycolysis	
Renin (plasma)—RLA	Normal diet: Supine: 0.3–1.9 ng/mL/h Upright: 0.6–3.6 ng/mL/h Low-salt diet Supine: 0.9–4.5 ng/mL/h Upright: 4.1–9.1 ng/mL/h	 0.08–0.52 ng/L/S 0.16–1.00 mcg/L/S 0.25–1.25 mcg/L/S 1.13–2.53 mcg/L/S	Renovascular hypertension, malignant hypertension, untreated Addison disease, primary salt-losing nephropathy, low-salt diet, diuretic therapy, and hemorrhage	Frank primary aldosteronism, increased salt intake, salt-retaining steroid therapy, antidiuretic hormone therapy, and blood transfusion
Sodium	135–145 mEq/L	135–145 mmol/L	Hemoconcentration, nephritis, and pyloric obstruction	Alkali deficit, Addison disease, myxedema
Sulfate (inorganic)	0.5–1.5 mg/dL	0.05–0.15 mmol/L	Nephritis and nitrogen retention	

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Testosterone—RIA	Females: 20–80 ng/dL Males: 240–1200 ng/dL	0.7–2.8 nmol/L 18.3–41.8 nmol/L	Females: Polycystic ovary and virilizing tumors	Males: Orchidectomy for neoplastic disease of the prostate or breast, estrogen therapy, Klinefelter syndrome, hypopituitarism, hypogonadism, and hepatic cirrhosis
T_3 (triiodothyronine) uptake	25–35%	Relative uptake fraction: 0.25–0.35	Hyperthyroidism, thyroxine-binding globulin (TBG) deficiency, and androgens and anabolic steroids	Hypothyroidism Pregnancy, TBG excess, estrogens and antiovulatory drugs
T_3 total circulating—RIA	260–480 pg/dL	4.0–7.4 pmol/L	Pregnancy and hyperthyroidism	Hypothyroidism
T_4 (thyroxine)—RIA	5.4–11.5 mcg/dL	57–148 nmol/L	Hyperthyroidism, thyroiditis, elevated thyroxine-binding proteins caused by oral contraceptives, and pregnancy	Primary and pituitary hypothyroidism, idiopathic involvement, cases of diminished thyroxine-binding proteins caused by androgenic and anabolic steroids, hypoproteinemia, and nephrotic syndrome
T_4, free	0.7–2 ng/dL	10–26 pmol/L	Euthyroid patients with normal free thyroxine levels may have abnormal T_3 and T_4 levels caused by drug preparations	
Thyroid-stimulating hormone (TSH)—RIA	0–15 mIU/L	0–15 mIU/L	Hypothyroidism	Hyperthyroidism
Thyroid-binding globulin	16–32 mcg/dL	120–180/mcg/L	Hypothyroidism, pregnancy, estrogen therapy, oral contraceptive use, and genetic and idiopathic liver disease	Use of androgens and anabolic steroids, nephrotic syndrome, and marked hypoproteinemia
Transferrin	200–380 mg/dL	2.3–3.2 g/L	Pregnancy, iron deficiency anemia due to hemorrhaging, acute hepatitis, polycythemia, and oral contraceptive use	Pernicious anemia in relapse, thalassemic and sickle cell disease, chromatosis, neoplastic and hepatic diseases, and malnutrition
Triglycerides	Males: 44–180 mg/dL Females: 10–190 mg/dL	0.44–2.01 mmol/L 0.11–2.21 mmol/L	Increased risk for atherosclerosis	
Troponin Troponin I Troponin T	 <0.35 ng/mL <0.1 ng/mL	 <0.35 mcg/L <0.1 mcg/L	 Myocardial infarction Rhabdomyolysis and severe crushing injuries	
Tryptophan	1.4–3 mg/dL	68.6–147 nmol/L	Tyrosinosis	Tryptophan-specific malabsorption syndrome
Tyrosine	0.5–4 mg/dL	27.6–220.8 mmol/L	Acute glomerulonephritis	Severe hepatic failure
Urea nitrogen (BUN)	8–20 mg/dL	2.9–7.5 mmol/L	Obstructive uropathy, mercury poisoning, and nephrotic syndrome	Pregnancy
Uric acid	Males: 3.4–7.0 mg/dL Females: 2.4–6.0 mg/dL	202–416 mcmol/L 143–357 mmol/L	Gouty arthritis, acute leukemia, lymphomas treated by chemotherapy, and toxemia of pregnancy	Defective tubular reabsorption

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Viscosity	1.4–1.8 relative to water at 37°C (98.6°F)		Patients with marked increase of the gamma globulins and hypervitaminosis A	
Vitamin A	30–120 mcg/dL	1.05–4.20 mcmol/L		Vitamin A deficiency, celiac disease, sprue, obstructive jaundice, giardiasis, and parenchymal hepatic disease
Vitamin B_1 (thiamine)	1.6–4 mcg/dL	47.4–135.7 nmol/L		Anorexia, beriberi, polyneuropathy, and cardiomyopathies
Vitamin B_6 (pyridoxal phosphate)	5–30 ng/mL	20–121 nmol/L		Chronic alcoholism, malnutrition, uremia, and malabsorption, such as celiac disease
Vitamin B_{12}—RIA	200–900 pg/mL	148–666 pmol/L	Hepatic cell damage and in association with the myeloproliferative disorders (the highest levels are encountered in myeloid leukemia)	Strict vegetarianism, alcoholism, pernicious anemia, total or partial gastrectomy, ileal resection, sprue and celiac disease, and fish tapeworm infestation
Vitamin E	0.5–1.8 mg/dL	12–42 mcmol/L		Vitamin E deficiency
Xylose absorption test	2 h, 30–50 mg/dL	2–3.35 mmol/L		Malabsorption syndrome
Zinc	55–150 mcg/dL	7.65–22.95 mcmol/L	Coronary artery disease, arteriosclerosis, and industrial exposure	Metastatic liver disease, tuberculosis, and sprue

[a]By radioimmunoassay.
[b]Varies among methods.
ADH, antidiuretic hormone; BUN, blood urea nitrogen; RIA, radioimmunoassay; RLA, renin-like activity; SGOT, serum glutamic oxaloacetic transaminase.

TABLE A-3 Reference Ranges—Immunodiagnostic Test

Test	Normal Value	Clinical Significance
Acetylcholine receptor binding antibody	Negative or <0.03 nmol/L	Considered to be diagnostic for myasthenia gravis in patients with symptoms
Anti–ds-DNA antibody	<70 U by enzyme-linked immunosorbent assay (ELISA) <1:20 by indirect fluorescence	Valuable in supporting diagnosis or monitoring disease activity and prognosis of systemic lupus erythematosus (SLE)
Antiglomerular basement membrane antibody	Negative or <5 UL	Primarily used in the differential diagnosis of glomerular nephritis induced by antiglomerular basement membrane antibodies from other types of glomerular nephritis
Anti-insulin antibody	<3% binding of labeled beef and pork insulin by patient's serum; or <9 mIU/L	Helpful in determining the best therapeutic agent in patients with diabetes and the cause of allergic manifestations. Also used to identify insulin resistance
Antinuclear antibody (ANA)	Negative, <1:40	Increased in SLE, chronic hepatitis, scleroderma, leukemia, and mononucleosis
Antiparietal cell antibody	Negative	Helpful in diagnosing chronic gastric disease and differentiating autoimmune pernicious anemia from other megaloblastic anemias
Antiribonucleoprotein antibody	Negative	Helpful in differential diagnosis of systemic rheumatic disease
Antiscleroderma antibody	Negative	Highly diagnostic for scleroderma
Anti-Smith antibody	Negative	Highly diagnostic of SLE
Anti–SS-A/anti–SS-B antibody	Negative	SS-A antibodies are found in Sjögren syndrome alone or associated with lupus SS-B antibodies are associated with primary Sjögren syndrome
Antithyroglobulin and antimicrosomal antibodies	<1:100 titer by gelatin or hemagglutination	Presence and concentration is important in evaluation and treatment of various thyroid disorders, such as Hashimoto

		thyroiditis and Graves disease. May indicate previous autoimmune disorders
CA 15–3 tumor marker	<30 IU/mL	Increased in metastatic breast cancer
CA 19–9 tumor marker	<37 IU/mL	Increased in pancreatic, hepatobiliary, gastric, and colorectal cancer; gallstones
CA 125	0–35 IU/mL	Increased in colon, upper gastrointestinal (GI), ovarian, and other gynecologic cancers: pregnancy, peritonitis
Carcinoembryonic antigen (CEA)—RLK	0–2.5 mcg/L (nonsmoker) 0–5 mcg/L (smoker)	The repeatedly high incidence of this antigen in cancers of the colon, rectum, pancreas, and stomach suggests that CEA levels may be useful in the therapeutic monitoring of these conditions, but it is not a screening test
Cold agglutinins	Negative or <1:64	Increased in mycoplasma pneumonia, viral illness, mononucleosis, multiple myeloma, and scleroderma
C-reactive protein	<1 mg/dL (<10 mg/L)	Increase indicates active inflammation
High sensitivity assay for C-reactive protein (hs-CRP)	0.2–8.0 mg/L	Cardiovascular disease risk
Cytomegalovirus antibodies (CMV IgG)	Negative: <0.9 units/mL	Positive >1:0 unit/mL if exposed to CMV at any time. Acute and convalescent specimens can help identify acute infection
Cytomegalovirus antibodies (CMV IgM)	Negative: <0:79	Positive >1:20 usually indicates acute infection
	Equivocal: 0:80–1.20	Repeat specimen in 1–2 wks for equivocal result
Epstein–Barr virus (EBV) serology (viral capsid antigen IgG and IgM, early antigen IgG, and nuclear antigen IgG)	Negative	Differentiation of acute from chronic or old infection

Hepatitis A virus antibodies, IgM (HAV-Ab/IgM)	Negative	Positive in acute-stage hepatitis A; develops early in disease
Hepatitis A virus antibodies, IgG (HAV-Ab/IgG)	Negative	Positive if previous exposure and immunity to hepatitis A
Hepatitis B surface antigen (HBsAg)	Negative	Positive in acute-stage hepatitis B
Hepatitis B surface antibody (HBsAb)	Negative	Positive if previous exposure and immunity to hepatitis B
Hepatitis C virus antibodies	Negative	Positive in exposure to hepatitis C virus; may indicate acute, chronic, or cleared infection
Hepatitis C virus RNA	Negative	Positive in hepatitis C infection, can be quantitative
Homocysteine	0.54–2.30 mg/L (4–17 mcmol/L)	Cardiovascular disease risk Folic acid deficiency Vitamin B_{12} deficiency
Infectious mononucleosis tests (monospot, monotest, heterophile antigen test, EBV, antiviral capsid antigen IgM and IgG)	Negative	Positive monospot and monotest are presumptive, positive EBV IgM and IgG indicate acute and recent or past infection, respectively
Lyme disease titer	Negative, <1:256 by indirect fluorescent antibody method; nonreactive by ELISA	Positive results help diagnose Lyme disease. False positive may occur with high rheumatoid factor titers or syphilis Positive ELISA confirmed by Western blot test
Pyroglobulin test	Negative	These abnormal proteins may be associated with myeloma, lymphoma, polycythemia vera, and SLE
Rheumatoid factor	Negative	Elevated in rheumatoid arthritis, lupus endocarditis, tuberculosis, syphilis, sarcoidosis, and cancer
T- and B-cell lymphocyte surface markers	T- and B-cell lymphocyte surface markers:	Used to evaluate immune system by identifying the specific cells involved in the immune response. Valuable in diagnosis of

T-helper/T-suppressor ratio	Percent T cells (CD2) 60–88% Percent helper cells (CD4) 34–67% Percent suppressor cells (CD8) 10–42% Percent B cells (CD19) 3–21% Absolute counts: Lymphocytes 0.66–4.60 thou/mL T cells 644–2201 cells/mL Helper cells 493–1191 cells/mL Suppressor T cells 182–785 cells/mL B cells 92–392 cells/mL Lymphocyte ratio: T_H/T_S ratio >1	lymphocytic leukemia, lymphoma, and immunodeficiency diseases including AIDS; and in the assessment of patient response to chemotherapy and radiation

TABLE A-4 Reference Ranges—Urine Chemistry

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Acetone (Ketones)	<2.0 mg/dl	<0.05 mmol/L	Diabetic ketoacidosis, starvation	
Aldosterone	With normal salt diet: Normal: 3–19 mcg/24 h Reno vascular: 10–40 mcg/24 h Tumor: 20–100 mcg/24 h	 11.1–55.5 nmol/24 h 8–51 nmol/24 h 55.4–277 nmol/24 h	Primary aldosteronism (adrenocortical tumor), secondary aldosteronism, salt depletion, potassium loading ACTH in large doses, heart failure, cirrhosis with ascites formation, nephrosis, pregnancy	
Alpha amino nitrogen	50–200 mg/24 h	3.6–14.3 nmol/24 h	Leukemia, phenylketonuria, other metabolic diseases	
Amylase	1–17 units excreted per h	0.017–0.29 U/h	Acute pancreatitis	
Arylsulfatase A	1 h test 2–19 U/mL 24-h test 170–2000/24 h	2–19 units/h 2.89–34 mckat/L		
Calcium	100–250 mg/24 h	2.5–6.2 mmol/24 h	Hyperparathyroidism, Vitamin D intoxication, Fanconi syndrome	Hypoparathyroidism
Catecholamines	Total: 0–275 mcg/24 h Epinephrine: 0–20% Norepinephrine: 60–90%	0–275 mcg/24 h Fraction total: 0–20 mcg/24 h Fraction total: 0.60–0.90	Pheochromocytoma Neuroblastoma	Vitamin D deficiency

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Chorionic gonadotrophin, qualitative (pregnancy test)	Negative		Pregnancy, chorionepithelioma, hydatidiform mole	
Copper	15–60 mcg/24 h	0.22–0.9 mcmol/24 h	Wilson disease, cirrhosis, nephrosis	
Coproporphyrin	50–300 mcg/24 h	0.075–0.45 mcmol/24 h	Poliomyelitis, lead poisoning, porphyria	
Cortisol, free	<50 mcg/24 h	<138 nmol/24 h	Cushing syndrome	
Creatinine	Males: 14–16 mg/kg body weight/24 h Females: 11–20 mg/kg body weight/24 h	124–230 mmol/kg body weight/24 h 97–177 mmol/kg body weight/24 h	Muscular dystrophy Fever, carcinoma of liver, pregnancy, hyperthyroidism, myositis	
Creatine	0–270 mg/24 h	0–2.05 mmol/24 h	Typhoid fever, salmonella infections, tetanus	Muscular atrophy, anemia, advanced degeneration of kidneys, leukemia
Cystine and cysteine	10–100 mg/24 h	0.08–0.83 mmol/24 h	Cystinuria	
Delta aminolevulinic acid	1.5–7.5 mg/dL	11–57/mcmol/day	Lead poisoning, porphyria hepatica, hepatitis hepatic carcinoma	
11-Desoxycortisol	20–100 mcg/24 h	0.6–2.9 unit/24 h	Hypertensive form of virilizing adrenal hyperplasia due to an 11-beta hydroxylase defect	
Estriol (placental)	Weeks of pregnancy 12 16 20 24 28 32 36 40	mcm/24 h <1 2–7 4–9 6–13 8–22 12–43 14–45 19–46	mmol/24 h <3.5 7–24.5 14–32 21–45.5 28–77 42–150 49–158 66.5–160	Decreased values occur with fetal distress of many conditions, including preeclampsia, placental insufficiency, and poorly controlled diabetes
Estrogens, total (fluorometric)	Females: Onset of menstruation: 4–25 mcg/24 h Ovulation peak: 28–100 mcg/24 h Luteal peak: 22–105 mcg/24 h Menopausal: 1.4–19.6 mcg/24 h Males: 5–18 mcg/24 h	 4–25 mcg/24 h 28–100 mcg/24 h 22–105 mcg/24 h 1.4–19.6 mcg/24 h 5–18 mcg/24 h	Hyperestrogenism due to gonadal or adrenal neoplasm	Primary or secondary amenorrhea
Etiocholanolone	Males: 1.9–6 mg/24 h Females: 0.5–4 mg/24 h	6.5–20.6 mcmol/24 h 1.7–13.8 mcmol/24 h	Adrenogenital syndrome Idiopathic hirsutism	
Follicle-stimulating hormone—RIA	Females: Follicular: 5–20 IU/24 h Luteal: 5–15 IU/24 h Midcycle: 15–60 IU/24 h Menopausal: 50–100 IU/24 h Males: 5–25 IU/24 h	 5–20 IU/d 5–15 IU/d 15–60 IU/d 50–100 IU/d 5–25 IU/d	Menopause and primary ovarian failure	Pituitary failure
Glucose	Negative		Diabetes, pituitary disorders, increased ICP, lesion in floor of 4th ventricle	

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Hemoglobin and myoglobin	Negative		Extensive burns, transfusion of incompatible blood, myoglobin increased in severe crushing injuries to muscles	
Homovanillic acid		5.5–27.5 mcmol/d	Neuroblastoma	Addison disease
17-hydroxycortic-osteroids	8 mg/24 h 2–10 mg/24 h	5.5–27.5 mcmol/d	Cushing syndrome	Anterior pituitary hypofunction
5-hydroxyindoleacetic acid, qualitative	Negative		Malignant carcinoid tumors	
17-ketosteroids, total	Males: 4–14 mg/24 h Females: 2–12 mg/24 h	35–76 mcmol/24 h 21–55 mcmol/24 h	Interstitial cell tumor of testes, simple hirsutism, occasionally adrenal hyperplasia, Cushing syndrome, adrenal cancer, virilism, adrenoblastoma	Thyrotoxicosis, female hypogonadism, diabetes, hypertension, debilitating disease of mild to moderate severity, eunuchoidism, Addison disease, panhypopituitarism, myxedema, nephrosis
Lead	<125 mcg/24 h	<60 mcmol/24 h	Lead poisoning	
Luteinizing hormone	Males: 5–18 IU/24 h Females: Follicular phase: 2–25 IU/24 h Ovulatory peak: 30–95 IU/24 h Luteal phase: 2–20 IU/24 h Postmenopausal: 40–110 IU/24 h	 2–25 IU/d 30–95 IU/d 2–20 IU/d 40–110 IU/d	Pituitary tumor, ovarian failure	Failure of pituitary or hypothalamus, anorexia nervosa
Metanephrines, total	<1.4 mg/24 h	<7 mcmol/24 h	Pheochromocytoma; a few patients with pheochromocytoma may have elevated urinary metanephrines but normal catecholamines and vanillylmandelic acid (VMA)	
Osmolality	50–1200 mOsm/kg	50–1200 mmol/kg	Useful in the study of electrolyte and water balance	
Oxalate	Up to 45 mg/24 h	Up to 500/mcmol/24 h	Primary hyperoxaluria	
Phenylpyruvic acid qualitative	Negative		Phenylketonuria	
Phosphorus, inorganic	0.9–1.3 g/24 h	29–42 mmol/24 h	Hypoparathyroidism, vitamin D intoxication, Paget disease, metastatic neoplasm to bone	Hypoparathyroidism, vitamin D deficiency
Porphobilinogen, qualitative	Negative		Chronic lead poisoning, acute porphyria, liver disease	
Porphobilinogen quantitative	0–1 mg/24 h	0–4.4 mcmol/24 h	Acute porphyria, liver disease	

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Porphyrins, qualitative	Negative		See porphyrins, quantitative	
Porphyrins, quantitative (coproporphyrin and uroporphyrin)	Coproporphyrin: 50–160 mcg/24 h Uroporphyrin: up to 50 mcg/24 h	0.075–0.24 mcmol/24 h Up to 0.06 mcmol/24 h	Porphyria, lead poisoning (only coproporphyrin increased)	
Potassium	26–123 mEq/24 h	26–123 mmol/24 h	Hemolysis, chronic renal disease, acidosis, Cushing syndrome, corpus luteum cysts	Diarrhea, adrenocortical insufficiency
Pregnanediol	Females: Proliferative phase: 0.5–1.5 mg/24 h Luteal phase: 2–7 mg/24 h Menopause: 0.2–1 mg/24 h	 1.6–4.8 mcmol/24 h 6–22 mcmol/24 h 0.6–3.1 mcmol/24 h	When placental tissue remains in the uterus following parturition, some cases of adrenocortical tumors	Placental dysfunction, threatened abortion, intrauterine death
Pregnancy: Weeks of gestation 10–12 12–18 18–24 24–28 28–32	mg/24 h 5–15 5–25 15–33 20–42 27–47	mcmol/24 h 15.6–47 15.6–78.0 47.0–103.0 62.4–131.0 84.2–146.6		
Pregnanetriol	Females: 0.1–2.2 mg/24 h Males: 0.4–2.5 mg/24 h	0.3–6.5 mcmol/24 h 1.2–7.5 mcmol/24 h	Congenital adrenal androgenic hyperplasia	
Protein	<150 mg/24 h	<150 mg/24 h	Nephritis, heart failure, mercury poisoning, Bence Jones protein in multiple myeloma, febrile states, hematuria	
Sodium	75–200 mEq/24 h	75–200 mmol/24 h	Useful in detecting gross changes in water and salt balance	
Titratable acidity	20–40 mEq/24 h	20–40 mmol/24 h	Metabolic acidosis	Metabolic alkalosis
Urea nitrogen	9–16 g/24 h	0.32–0.57 mol/L	Excessive protein catabolism	Impaired kidney function
Uric acid	250–750 mg/24 h	1.48–4.43 mmol/24 h	Gout	Nephritis
Urobilinogen	Random urine: <0.25 mg/dL 24-h urine: up to 4 mg/24 h	<0.42 mol/24 h Up to 6.76 mcmol/24 h	Liver and biliary tract disease, hemolytic anemias	Complete or nearly complete biliary obstruction, diarrhea
VMA	0.7–6.8 mg/24 h	3.5–34.3 mcmol/24 h	Pheochromocytoma, neuroblastoma, ingestion of coffee, tea, aspirin, bananas, and several different drugs	Renal insufficiency
Xylose absorption test (5-h)	16–33% of ingested xylose	Fraction absorbed: 0.16–0.33		
Zinc	0.15–1.2 mg/24 h	2.3–18.4 mcmol/24 h		Malabsorption syndromes

TABLE A-5 Selected Reference Ranges—Cerebrospinal Fluid

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
RBCs	None	None	Any RBCs are due to traumatic tap or subarachnoid hemorrhage	
WBCs	0–5 cells/mm^3	0–5 × 10^6/L	Tumor, meningitis, subarachnoid hemorrhage, infarct, and abscesses	
Chloride	120–130 mEq/L	120–130 mmol/L	Not neurologically significant	Acute generalized meningitis and tuberculous meningitis
Glucose	50–75 mg/100 mL	3.00–4.00 mmol/L	Not neurologically significant	Associated with bacteria in CSF
Protein	14–45 mg/100 mL	150–450 mg/L	Tubercular meningitis, neurosyphilis, poliomyelitis, Guillain–Barré syndrome, subdural hematoma, tumors, and multiple sclerosis	Can occur in hyperthyroidism and benign intracranial hypertension after removal of large amounts of CSF

CSF, cerebrospinal fluid; RBCs, red blood cells; WBCs, white blood cells.

  - skeletal, 1174, 1176–1177
  - skin, 1174, 1175
  - straight/running, 1174
  - types of, 1174–1175
- Tramadol, 214
- Trandolapril, for hypertension, 872t
- Tranquilizers, 406t, 1954
- Transarterial chemoembolization (TACE), 1405
- Transbronchial brushing, 492
- Transbronchial needle aspiration, 492
- Transcatheter Arterial Embolization (TAE), 1276, 1406
- Transcranial Doppler, 1988
- Transcultural nursing, 72
- Transcutaneous electrical nerve stimulation (TENS), 924, 1123, 1155
- Transdermal contraceptives, 1661
- Transducer-tipped catheter, 2002
- Transection, 1380, 2055
- Transesophageal echocardiography (TEE), 680–681
- Transfusion, 899–907
  - complications, 901

    - acute hemolytic reaction, 902–903
    - allergic reaction, 903
    - bacterial contamination, 904
    - delayed hemolytic reactions, 904
    - disease acquisition, 904, 905c
    - febrile nonhemolytic reaction, 901–902
    - transfusion-associated circulatory overload, 903–904
    - transfusion-related acute lung injury, 904
  - informed consent for, 900, 900c
  - long-term, 905, 905t
  - nursing management for transfusion reactions, 905–906
  - of packed red blood cells, 901c
  - and patient education, 901
  - pharmacologic alternatives to, 906–907, 906c
  - of platelets or fresh-frozen plasma, 902c
  - pretransfusion assessment
    - patient history, 900
    - physical assessment, 900
  - procedures, 901, 901c
  - setting for, 899
  - sickle cell disease and, 919
- Transfusion-associated circulatory overload (TACO), 903–904
- Transfusion dependence, 963
- Transfusion-related acute lung injury (TRALI), 903, 904
- Transient flora, 2145
- Transient ischemic attack (TIA), 1000, 2035
- Transitional care
  - components of, 35c
  - definition of, 34
  - nurse as coordinator of, 35–36
- Transitional care nurse (TCN), 48, 163
- Transitional services, 2184
- Transjugular intrahepatic portosystemic shunt (TIPS)
  - for ascites, 1374, 1374f
  - for variceal bleeding, 1378f, 1379
- Translation services, 27
- Transmissible spongiform encephalopathies (TSE), 2093
- Transmission-based precautions, 2145, 2151
- Transrectal ultrasound (TRUS), 1747
- Transsacral (caudal) block, 429

- Transsphenoidal approach, 2010t, 2016
- Transtheoretical Model of Change, 64, 64t
- Transthyretin, 1453
- Transtracheal oxygen catheter, 611f, 614
- Transurethral incision of prostate (TUIP), 1755, 1762, 1763t, 1764f
- Transurethral microwave thermotherapy (TUMT), 1755
- Transurethral needle ablation (TUNA), 1755
- Transurethral resection of the prostate (TURP), 1743, 1755, 1762, 1763t, 1764f
- Transurethral resection syndrome, 1762, 1765c
- Transvaginal surgical mesh, 1688
- Transvaginal/transrectal electrical stimulation, 1614c
- Transvaginal ultrasound, for ectopic pregnancy, 1669–1670
- Transverse rectus abdominal myocutaneous (TRAM) flap, 1709, 1736, 1736f
- Trapeze, 1152, 1176
- Trastuzumab, 330, 1279, 1734
- Trauma, 2191–2196
  - chest, 589–598
    - blunt trauma, 589–592
    - penetrating trauma, 592–593
    - traumatic pneumothorax, 593
  - forensic evidence, 2191–2192
  - genitourinary, 1625–1626
    - bladder trauma, 1625–1626
    - ureteral trauma, 1625
    - urethral trauma, 1626
  - injury prevention, 2192
  - mechanical, 107–108
    - ocular trauma, 1924–1926
    - orbital, 1923–1924
  - multiple, 2179, 2192–2196
  - neurologic, 2055–2086
  - renal, 1600–1602
  - of upper respiratory airway, 510–524
- Traumatic brain injuries (TBI), 2056, 2066
  - body temperature maintaining, 2064
  - closed (blunt), 2058
  - home care checklist, 2069, 2069c
  - management of, 2057–2058

  - mild, 2060
  - multisystem assessment, 2063t
  - nursing process, 2061–2069
  - pathophysiology of, 2056–2057, 2057f
  - penetrating, 2058, 2193
  - prevention of, 2065–2066
  - skin integrity, maintaining, 2066
  - veterans considerations, 2057
- Traumatic pneumothorax, 593
- Travel, infectious diseases and, 2176
- Tremors, Parkinson's disease, 2123, 2123f
- Trench mouth. *See* Necrotizing gingivitis
- Trendelenburg position, 434, 434f, 1315
- Treponemal tests, 2169
- *Treponema pallidum,* 2169
- TRH. *See* Thyroid-releasing hormone
- Triage, 2179, 2185–2187, 2222–2223
  - assess and intervene, 2186–2187
  - categories during mass casualty incident, 2223t
  - emergent, 2185
  - nonurgent, 2185
  - protocols, 2185–2186
  - urgent, 2185
- Triamcinolone, 500t, 1050, 1483t
- Triamcinolone acetonide, 1820t
- Triamterene, 1395
  - for hypertension, 873t
- Triceps reflex, 1982–1983
- Trichiasis, 1897, 1901, 1927
- Trichloroacetic acid, 1681
- Trichomoniasis, 1679, 1752
- Tricuspid area, 668
- Tricuspid valve, 765
  - anatomy of, 766f
- Tricyclic antidepressants (TCAs), 217, 1115
  - body weight and, 1346c
  - for depression, 181
  - in fibromyalgia, 1091
  - overdose of, 2209t
- Trigeminal nerve (CN V), 2107t

  - branches, distribution of, 2108f
  - microvascular decompression of, 2108–2109
- Trigeminal neuralgia, 2107t, 2108–2109
- Triglycerides, 672, 674, 727, 1211t
- Triiodothyronine (T_3), 1446, 1452. *See also* Thyroid gland
- Trimethoprim–sulfamethoxazole, 1025
  - in impetigo, 1835
  - for urinary tract infections, 1608t
- Triptans, 2028–2029
- Tropical sprue, 1296t
- Troponin, 725, 739
- Trousseau sign, 248, 249f, 252, 1446, 1473
- Truth-telling, 28
- Trypsin, 1208, 1210, 1211t, 1416, 1417
- TSE. *See* Testicular self-examination
- TSH. *See* Thyroid-stimulating hormone
- Tubal embryo transfer (TET), 1668
- Tubal ligation (female sterilization), 1659c, 1659f, 1660,
- Tuberculin (TB) skin test, 548, 1079
- Tuberculosis (TB), 2147t. *See also Mycobacterium* sp.; *See also* pulmonary tuberculosis
  - HIV infection and, 1022
  - immigration and, 2176
- Tuberculous peritonitis, 1298
- Tubo-ovarian abscess, 1685
- TUIP. *See* Transurethral incision of prostate
- Tularemia, 2233t
- Tumor
  - antigen–antibody complexes, 308
  - benign *vs.* malignant, 303t
  - brain, 2113–2118
  - brain, primary
    - home care checklist, 2120c
    - nursing process, 2118–2121
    - types of, 2113–2114
  - grading, 301, 309–312
  - orbital and ocular, 1929–1931
  - radiosensitive, 316
  - removal, 2121
  - spinal cord, 2121–2122

  - staging, 302, 309–312, 1855
  - surgical techniques for, 314t
- Tumor-associated antigens (TAAs), 308, 1405, 1700
- Tumor lysis syndrome, 329, 974
  - management of, 362t
  - manifestation of, 362t
- Tumor necrosis factor-alpha (TNF-α)
  - for psoriasis, 1844
- Tumors of head of pancreas, 1440–1442
  - assessment and diagnostic findings, 1441
  - clinical manifestations, 1441
  - continuing and transitional care, 1442
  - medical management, 1441
  - nursing management, 1441–1442
  - self-care, 1442
- TURP. *See* Transurethral resection of the prostate
- T wave, 691, 694
- Tympanic membrane, 1936, 1936f, 1937, 1937f, 1938, 1939, 1939f
- Tympanic membrane (TM) rupture, 2231–2232
- Tympanogram, 1942
- Tympanoplasty, 1935, 1950
- Type 1 diabetes, 1488, 1490
- Type 2 diabetes, 1488, 1490–1491
- Tyrosine kinase inhibitors, 332–333, 955, 1735
- Tzanck smear, 1813

U

- U-500 insulin, 1502
- Ulcerative colitis, 1220
  - assessment and diagnostic findings, 1233
  - clinical manifestations, 1306
  - Crohn's disease and, 1303
- Ulcerogenic tumors, 1442–1444
- Ulnar shaft fracture, 1181
- Ultrasound-guided core biopsy, of breast, 1715
- Ultraviolet-A (UVA), 1844
- Ultraviolet-B (UVB), 1844

W

- Wiskott–Aldrich syndrome (WAS), 1006t

- Wolff–Parkinson–White (WPW) syndrome, 703
- World Health Organization (WHO), 970
- World Trade Center towers, destruction of, 2230
- Wound-ostomy-continence (WOC) nurse, 1354

X

- Xanthine oxidase inhibitors, 1090
- Xenografts, 1883
- Xerosis, 1816
- Xerostomia, 517
- X-linked inheritance, 123
  - definition of, 123

Y

- Yankauer suction, 1240

Z

- Zafirlukast (Accolate), 502, 637t
- Zenker diverticulum, 1255
- Zidovudine, 1933
- Zika virus, 2103
- Zileuton, 497, 637
- Zoledronic acid, 977
- Zollinger–Ellison syndrome (ZES), 1271

Contents 56
Case Studies in This Book 143
Special Charts in This Book 146
UNIT 1: Principles of Nursing Practice 158
Chapter 1: Professional Nursing Practice 161
Nursing 165
The Patient: Consumer of Nursing and Health Care 165
The Patient's Basic Needs: Maslow Hierarchy of Needs 165
Health 166
Wellness 167
Health Promotion 167
Health Care 168
Influences on Health Care Delivery 168
Population Demographics 169
Changing Patterns of Disease and Wellness 170
Advances in Technology and Genetics 171
Quality, Safety, and Evidence-Based Practice 173
Interprofessional Collaborative Practice 174
The Practice of Nursing 178
Critical Thinking 178
The Nursing Process 182

Ethical Nursing Care 210
Chapter 2: Medical-Surgical Nursing 232
The Practice of Nursing in Today's Health Care Delivery System 234
Medical-Surgical Nursing 235
The Nurse as Coordinator of Care Transitions 236
Critical-Care Nursing 238
Rehabilitation Nursing 239
• Nursing Process: The Patient with Self-Care Deficits in Activities of Daily Living 242
• Nursing Process: The Patient with Impaired Physical Mobility 249
Home Health Nursing 271
Discharge Planning for Transition to the Community or Home Care Setting 282
Continuing the Transition through Community Resources and Referrals 282
Chapter 3: Health Education and Health Promotion 287
Purpose of Health Education 289
Meeting Nursing Standards 290
Supporting Informed Decision Making and Self-Care 290
Promoting Adherence to the Therapeutic Regimen 291
The Nature of Teaching and Learning 295
Learning Readiness 296
The Learning Environment 299
Teaching Techniques and Resources 299
The Nursing Process in Patient Education 301
Assessment 304
Nursing Diagnosis 304
Planning 304
Implementation 308
Evaluation 309
Health Promotion 310
Definition 310
Health Promotion Models 312

Components of Health Promotion 314
Health Promotion Strategies Throughout the Lifespan 319
Adolescents 320
Young and Middle-Aged Adults 320
Gerontologic Considerations 324
Nursing Implications of Health Promotion 326
Chapter 4: Adult Health and Physical, Nutritional, and Cultural Assessment 333
The Role of the Nurse Conducting a Health Assessment 335
Effective Communication 335
Cultural Concepts 336
Cultural Competence 337
Ethical Use of Health Assessment Data 338
The Role of Technology 338
Assessment in the Home or Community 339
Health History 339
The Informant 340
Components of the Health History 341
Physical Assessment 363
Examination Considerations 363
Components of the Physical Examination 364
Nutritional Assessment 370
Lifespan Considerations 371
Components of Nutritional Assessment 372
Factors Influencing Nutritional Status in Various Situations 385
Analysis of Nutritional Status 385
Cultural Assessment 385
Culturally Mediated Considerations 386
Chapter 5: Stress and Inflammatory Responses 399
Fundamental Concepts 402
Constancy and Homeostasis 403
Stress and Adaptation 404
Overview of Stress 404

Types of Stressors 404
Stress as a Stimulus for Disease 405
Psychological Responses to Stress 406
Physiologic Response to Stress 408
Maladaptive Responses to Stress 414
Indicators of Stress 415
Stress at the Cellular Level 417
Control of the Steady State 418
Cellular Adaptation 419
Cellular Injury 422
Cellular Response to Injury: Inflammation 427
Cellular Healing 429
Nursing Management 430
Promoting a Healthy Lifestyle 434
Enhancing Coping Strategies 435
Educating About Relaxation Techniques 437
Educating About Stress Management 439
Promoting Family Health 439
Enhancing Social Support 441
Recommending Support and Therapy Groups 442
The Role of Stress in Health Patterns 442
Chapter 6: Genetics and Genomics in Nursing 449
Genomic Framework for Nursing Practice 454
Integrating Genetic and Genomic Knowledge 456
Genes and Their Role in Human Variation 456
Inheritance Patterns 464
Chromosomal Differences and Genetic Conditions 476
Genetic and Genomic Technologies in Practice 477
Genetic Testing 478
Genetic Screening 482
Population Screening 486
Testing and Screening for Adult-Onset Conditions 487
Single Gene Conditions 488
Genomic Conditions 488

The Nursing Role in Testing and Screening for Adult-Onset Conditions 492
Personalized Genomic Treatments 493
Pharmacogenomics 493
Ethical, Legal, and Social Issues Surrounding Genetics 497
Ethical Concerns 497
Legal Aspects of Personalized Health Care 499
Ancestry, Cultural, Social, and Spiritual Concerns Related to Genetic and Genomic Practice 500
Applications of Genetics and Genomics in Nursing Practice 503
Genetics and Genomics in Health Assessment 504
Genetic Counseling and Evaluation Services 511
Genetics and Genomics Tomorrow 518
Chapter 7: Disability and Chronic Illness 528
Disability 529
Definitions of Disability 530
Prevalence of Disability 530
Characteristics of Disability 531
Federal Legislation 542
Right of Access to Health Care 543
Barriers to Health Care 550
Federal Assistance Programs 553
Nursing Care of Patients with Disability 555
Nursing Considerations during Hospitalization 556
Health Promotion and Prevention 556
Significance of “People-First” Language 559
Gerontologic Considerations 559
Disability in Medical-Surgical Nursing Practice 560
Home, Community-Based, and Transitional Care 562
Chronic Disease and Chronic Illness 565
Multiple Chronic Conditions 565
Health Disparities and Chronic Disease 568
Definitions of Chronic Diseases or Conditions 570
Prevalence and Causes of Chronic Conditions 571

Prevention of Chronic Disease 576
Characteristics of Chronic Conditions 577
Implications of Managing Chronic Conditions 581
Veterans Considerations 583
Gerontologic Considerations 583
Nursing Care of Patients with Chronic Conditions 584
Home, Community-Based, and Transitional Care 585
Nursing Care for Special Populations with Chronic Illness 587
Chapter 8: Management of the Older Adult Patient 596
Overview of Aging 598
Demographics of Aging 598
Health Status of the Older Adult 598
Nursing Care of the Older Adult 600
Theories of Aging 601
Age-Related Changes 602
Physical Aspects of Aging 602
Psychosocial Aspects of Aging 620
Cognitive Aspects of Aging 626
Pharmacologic Aspects of Aging 628
Mental Health Problems in the Older Adult 633
Depression 634
Substance Use Disorder 636
Delirium 638
Alzheimer's Disease 638
Pathophysiology 641
Clinical Manifestations 642
Assessment and Diagnostic Findings 642
Medical Management 643
Nursing Management 644
Vascular Dementia 649
Additional Aspects of Health Care of the Older Adult 650
Geriatric Syndromes 650
Elder Neglect and Abuse 655

Social Services 656
Health Care Costs of Aging 657
Home Health Care 657
Hospice Services 657
Aging with a Disability 658
Ethical and Legal Issues Affecting the Older Adult 658
UNIT 2: Concepts and Principles of Patient Management 667
Chapter 9: Pain Management 670
Fundamental Concepts 674
Definition of Pain 674
Effects of Pain 674
Types and Categories of Pain 675
Pain Assessment 686
Performing the Comprehensive Pain Assessment: Patient Interview 687
Reassessing Pain 696
Pain Management 697
Pharmacologic Management of Pain: Multimodal Analgesia 697
Nonpharmacologic Methods of Pain Management 728
Nursing Implications of Pain Management 729
Chapter 10: Fluid and Electrolytes 743
Fundamental Concepts 746
Amount and Composition of Body Fluids 746
Regulation of Fluid within the Body Compartments 750
Systemic Routes of Gains and Losses 754
Laboratory Tests for Evaluating Fluid Status 756
Homeostatic Mechanisms 758
Gerontologic Considerations 762
Fluid Volume Disturbances 765
Hypovolemia 765
Pathophysiology 765
Clinical Manifestations 765

Assessment and Diagnostic Findings 765
Gerontologic Considerations 768
Medical Management 769
Nursing Management 773
Hypervolemia 775
Pathophysiology 775
Clinical Manifestations 776
Assessment and Diagnostic Findings 776
Medical Management 776
Nursing Management 778
Electrolyte Imbalances 780
Sodium Imbalances 780
Sodium Deficit (Hyponatremia) 783
Pathophysiology 783
Clinical Manifestations 784
Assessment and Diagnostic Findings 784
Medical Management 785
Nursing Management 786
Sodium Excess (Hypernatremia) 788
Pathophysiology 789
Clinical Manifestations 790
Assessment and Diagnostic Findings 790
Medical Management 790
Nursing Management 791
Potassium Imbalances 792
Potassium Deficit (Hypokalemia) 793
Pathophysiology 794
Clinical Manifestations 795
Assessment and Diagnostic Findings 795
Medical Management 797
Nursing Management 797
Potassium Excess (Hyperkalemia) 799
Pathophysiology 799
Clinical Manifestations 801

Assessment and Diagnostic Findings 801
Medical Management 801
Nursing Management 803
Calcium Imbalances 804
Calcium Deficit (Hypocalcemia) 805
Pathophysiology 806
Clinical Manifestations 806
Assessment and Diagnostic Findings 808
Medical Management 809
Nursing Management 810
Calcium Excess (Hypercalcemia) 811
Pathophysiology 811
Clinical Manifestations 812
Assessment and Diagnostic Findings 812
Medical Management 812
Nursing Management 814
Magnesium Imbalances 814
Magnesium Deficit (Hypomagnesemia) 815
Pathophysiology 816
Clinical Manifestations 817
Assessment and Diagnostic Findings 817
Medical Management 817
Nursing Management 818
Magnesium Excess (Hypermagnesemia) 818
Pathophysiology 818
Clinical Manifestations 819
Assessment and Diagnostic Findings 819
Medical Management 819
Nursing Management 820
Phosphorus Imbalances 820
Phosphorus Deficit (Hypophosphatemia) 821
Pathophysiology 822
Clinical Manifestations 823
Assessment and Diagnostic Findings 823

Medical Management 823
Nursing Management 824
Phosphorus Excess (Hyperphosphatemia) 825
Pathophysiology 825
Clinical Manifestations 826
Assessment and Diagnostic Findings 826
Medical Management 826
Nursing Management 827
Chloride Imbalances 827
Chloride Deficit (Hypochloremia) 828
Pathophysiology 828
Clinical Manifestations 828
Assessment and Diagnostic Findings 830
Medical Management 830
Nursing Management 830
Chloride Excess (Hyperchloremia) 830
Pathophysiology 830
Clinical Manifestations 831
Assessment and Diagnostic Findings 831
Medical Management 831
Nursing Management 831
Acid–Base Disturbances 832
Acute and Chronic Metabolic Acidosis (Base Bicarbonate Deficit) 834
Pathophysiology 835
Clinical Manifestations 836
Assessment and Diagnostic Findings 836
Medical Management 837
Acute and Chronic Metabolic Alkalosis (Base Bicarbonate Excess) 839
Pathophysiology 839
Clinical Manifestations 839
Assessment and Diagnostic Findings 840
Medical Management 841

Acute and Chronic Respiratory Acidosis (Carbonic Acid Excess) 841
Pathophysiology 841
Clinical Manifestations 842
Assessment and Diagnostic Findings 843
Medical Management 843
Acute and Chronic Respiratory Alkalosis (Carbonic Acid Deficit) 844
Pathophysiology 844
Clinical Manifestations 845
Assessment and Diagnostic Findings 845
Medical Management 845
Mixed Acid–Base Disorders 846
Compensation 846
Blood Gas Analysis 846
Parenteral Fluid Therapy 847
Purpose 847
Types of Intravenous Solutions 848
Isotonic Fluids 848
Hypotonic Fluids 852
Hypertonic Fluids 853
Other Intravenous Therapies 853
Nursing Management of the Patient Receiving Intravenous Therapy 854
Managing Systemic Complications 854
Managing Local Complications 856
Promoting Home, Community-Based, and Transitional Care 863
Chapter 11: Shock, Sepsis, and Multiple Organ Dysfunction Syndrome 874
Overview of Shock 877
Normal Cellular Function 878
Pathophysiology 878
Stages of Shock 881
Compensatory Stage 882

Clinical Manifestations 883
Medical Management 884
Nursing Management 885
Progressive Stage 890
Pathophysiology 891
Clinical Manifestations 891
Medical Management 893
Nursing Management 894
Irreversible Stage 896
Medical Management 897
Nursing Management 897
General Management Strategies in Shock 898
Fluid Replacement 898
Vasoactive Medication Therapy 901
Nutritional Support 902
Hypovolemic Shock 907
Pathophysiology 907
Medical Management 908
Nursing Management 912
Cardiogenic Shock 913
Pathophysiology 914
Clinical Manifestations 914
Assessment and Diagnostic Findings 915
Medical Management 915
Nursing Management 920
Distributive Shock 922
Sepsis and Septic Shock 925
Pathophysiology 927
Medical Management 929
Nursing Management 933
Neurogenic Shock 936
Medical Management 936
Nursing Management 937
Anaphylactic Shock 937

Medical Management 938
Nursing Management 938
Multiple Organ Dysfunction Syndrome 939
Pathophysiology 940
Clinical Manifestations 940
Medical Management 941
Nursing Management 941
Promoting Home, Community-Based, and Transitional Care 942
Educating Patients About Self-Care 942
Continuing and Transitional Care 942
Chapter 12: Management of Patients with Oncologic Disorders 951
Epidemiology 954
Pathophysiology of the Malignant Process 955
Carcinogenesis 957
Proliferative Patterns 958
Role of the Immune System 965
Detection and Prevention of Cancer 967
Primary Prevention 967
Secondary Prevention 967
Tertiary Prevention 970
Diagnosis of Cancer 970
Tumor Staging and Grading 971
Anatomic Stage Group 980
Management of Cancer 980
Surgery 980
Diagnostic Surgery 981
Surgery as Primary Treatment 982
Prophylactic Surgery 985
Palliative Surgery 986
Reconstructive Surgery 986
Nursing Management 986
Radiation Therapy 987
Radiation Dosage 988

Administration of Radiation 989
Toxicity 992
Nursing Management 994
Protecting Caregivers 994
Chemotherapy 995
Cell Kill and the Cell Cycle 995
Classification of Chemotherapeutic Agents 996
Adjunct Chemotherapeutic Agents 996
Administration of Chemotherapeutic Agents 997
Nursing Management 1009
Protecting Caregivers 1013
Hematopoietic Stem Cell Transplantation 1014
Types of Hematopoietic Stem Cell Transplantation 1014
Nursing Management 1019
Immunotherapy and Targeted Therapy 1021
Immunotherapy 1021
Targeted Therapies 1028
Nursing Management 1030
Complementary, Alternative, and Integrative Health Therapies 1036
COVID-19 Considerations 1037
Nursing Care of the Patient with Cancer 1037
Maintaining Tissue Integrity 1037
Promoting Nutrition 1072
Relieving Pain 1075
Decreasing Fatigue 1077
Improving Body Image and Self-Esteem 1080
Addressing Sexuality 1081
Assisting in the Grieving Process 1081
Management of Psychosocial Distress 1082
Monitoring and Managing Potential Complications 1082
Promoting Home, Community-Based, and Transitional Care 1089
Gerontologic Considerations 1092

Cancer Survivorship 1093
Providing Care to the Patient with Advanced Cancer 1095
Chapter 13: Palliative and End-of-Life Care 1115
Palliative Care and End-of-Life Care 1117
The Evolution of End-of-Life Care 1119
Settings for Palliative Care and End-of-Life Care 1121
Institution-Based Palliative Care 1123
Outpatient-Based Palliative Care 1126
Community-Based Palliative Care 1127
Hospice Care 1127
Communication in Palliative Care 1132
Advanced Care Planning 1136
Symptom Assessment and Management 1138
Expected Physiologic Changes 1138
Time of Death 1152
Providing Psychosocial and Spiritual Support 1153
Hope and Meaning in Illness 1154
Providing Culturally Sensitive Care at the End-of-Life 1155
Spiritual Care 1156
Grief, Mourning, and Bereavement 1159
Special Issues for the Nurse in End-of-Life Care 1164
Medically Administered Nutrition and Hydration 1164
Palliative Sedation at the End-of-Life 1165
Clinicians' Attitudes toward Death 1171
Patient and Family Concerns 1171
Professional Caregiver Issues 1173
Supporting Ourselves 1174
UNIT 3: Perioperative Concepts and Nursing Management 1185
Chapter 14: Preoperative Nursing Management 1188
Perioperative Nursing 1190
Advances in Surgical and Anesthesia Approaches 1191
Surgical Classifications 1191
Preadmission Testing 1192

Special Considerations during the Perioperative Period 1195
Gerontologic Considerations 1197
Bariatric Patients 1197
Patients with Disability 1198
Patients Undergoing Ambulatory Surgery 1199
Patients Undergoing Emergency Surgery 1199
Required Preoperative Documents 1200
Preoperative Assessment 1203
Nutritional and Fluid Status 1205
Dentition 1208
Drug or Alcohol Use 1208
Respiratory Status 1212
Cardiovascular Status 1213
Hepatic and Renal Function 1213
Endocrine Function 1213
Immune Function 1214
