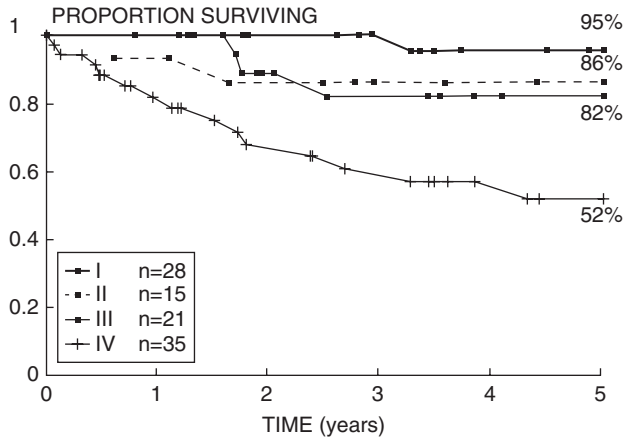
cannulation of the submandibular duct after excision of floor of mouth cancer. The study identified an incidence of postoperative neck swelling in only 15% of patients within the first 25 postoperative months, concluding that sialodochoplasty is a sound procedure that does not compromise the cancer resection.[88] In T1N0M0 lesions, the reported incidence of occult metastasis has been 21% while it is 62% in T2N0M0 SCCa of the FOM.[9] Regardless of the T stage, Spiro and colleagues[89] suggested that tumor thickness (more than 2-mm depth of invasion having more incidence of cervical metastasis), rather than tumor staging, may be a better way to select oral cancer patients who are likely to benefit from elective neck dissections.

Disease-specific cumulative 5-year survival for patients with FOM cancer has been reported to be 76%, with 95% survival rate for stage I, 86% for stage II, 82% for stage III, and 52% for stage IV (Figure 28-4).[9]



• **Figure 28-4** Disease-specific survival by pathologic group stage. (From Hicks WL, Loree TR, Carcia RI et al: Squamous cell carcinoma of the floor of mouth: a 20 year review. *Head and Neck* 19:400-405, 1997.)

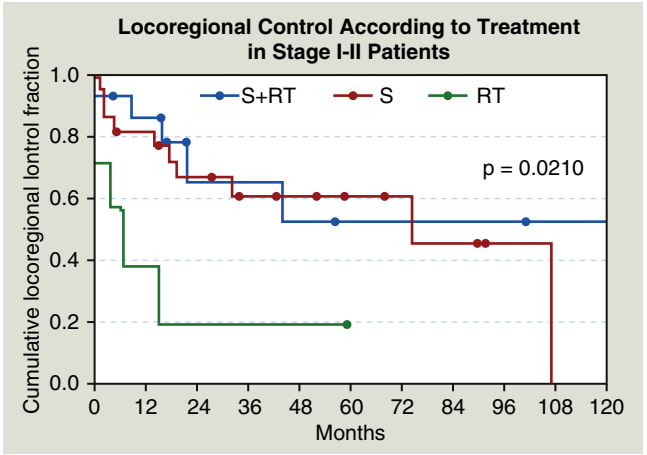
• **Figure 28-5** Verrucous carcinoma of the buccal mucosa.

Cancer of the Buccal Mucosa

The incidence of squamous cell carcinomas of the buccal mucosa (Figures 28-5 and 28-6) in western countries is mostly related to the use of tobacco, with an overall low incidence of 10% of all oral cancers. In Southeast Asia (especially in India) the incidence of SCCa has been correlated with the chewing of a combination of tobacco, betel nut, and lime with an estimated prevalence of more than 40% of oral cancers in this geographical region.

In a retrospective review of 121 previously untreated patients with SCCa of the buccal mucosa, the locoregional recurrence was 57% for all patients, with 80% occurring in the primary site alone.[90] Even patients with T1 and T2 lesions who received surgery only had a recurrence rate of 41%. Patients with T3-T4 lesions had better long-term locoregional

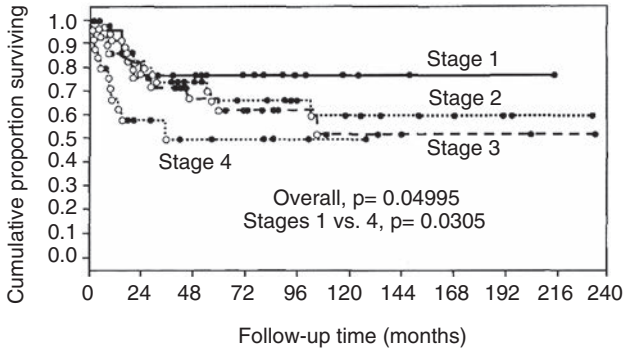
• **Figure 28-6** Invasive squamous cell carcinoma of the buccal mucosa and lower vestibule with gingival extension.



• **Figure 28-7** Locoregional control curve for patients with buccal mucosa cancer stage I-II disease. The 5-year locoregional control rates for S, RT, and S+RT groups are 60.7%, 19.1%, and 52.2%, respectively (p = 0.0210). *S*, Surgery alone; *RT*, radiotherapy; *S+RT*, surgery followed by postoperative radiotherapy. (From Lin CS, Jen YM, Cheng MF et al: Squamous cell carcinoma of the buccal mucosa: an aggressive cancer requiring multimodality treatment, *Head Neck* 28[2]:150-157, 2006.)

control and survival rates when treated by a combination of surgery and radiotherapy than when treated by either modality alone (Figure 28-7). Patients with buccal mucosa SCCa have a worse stage-for-stage survival rate than do patients with any other cancerous sites in the oral cavity. The presence of regional metastasis has a significant effect on survival rates. In a study conducted at the M.D. Anderson Cancer Center, the 5-year survival rate for patients with positive neck nodes was 43% versus 70% when the neck was negative[91] (Figure 28-8).

As a result of the reported high recurrence rate and potential poor prognosis of carcinomas of the buccal mucosa,[92] multimodality combinations of surgery and radiation with or without chemosensitizers are recommended for patients with this type of lesion. Nair and co-workers reported an 85% 3-year disease-free survival rate for stage I and 63% for stage II when the primary modality of treatment was radiotherapy with either interstitial radium needles or external beam.[93] Most publications provide better outcomes with a combination of surgery and postoperative radiation in more advanced stages.



• **Figure 28-8** Effect of disease stage on survival in buccal mucosa cancer. The impact of disease stage is shown here on a Kaplan-Meier plot. For patients with stage I, II, III, and IV disease, 5-year survival rates were 78%, 66%, 62%, and 50%, respectively. (From Diaz EM Jr, Holsinger FC, Zuniga ER et al: Squamous cell carcinoma of the buccal mucosa: one institution's experience with 119 previously untreated patients, *Head Neck* 25[4]:267-273, 2003.)

Cancer of the Tongue

Likely to be the most common oral cancer, SCCa of the tongue (Figure 28-9) accounts for about 20% of all oral and pharyngeal cancers, including lip cancer.[94]

Epidemiologic data show an increased incidence in younger adults ages 20 to 44[95] with some suggestive evidence of higher locoregional failure in the younger patients.[96] In a recent article, the overall survival rate has been correlated with tumor grade and tumor size, with no difference in survival rates between patients with tongue cancer and patients with cancer in other sites of the oral cavity[97] (Figure 28-10). Neck metastasis of early (T1-T2) squamous cell carcinoma of the tongue was correlated with tumor thickness, muscle invasion, poorly differentiated tumors, infiltrating-type invasion front, presence of perineural invasion, and presence of angiolymphatic invasion.[98]

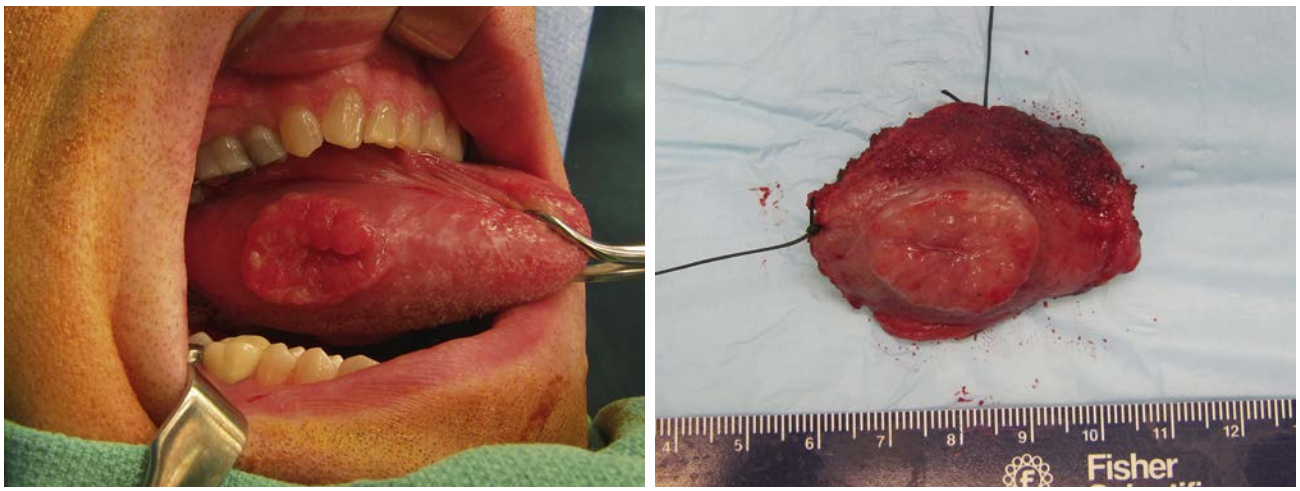
While positive cervical lymphatic metastasis has always been documented as having a very negative effect on survival, a retrospective analysis of 266 patients comparing clinical versus pathologic lymph node staging demonstrated statistically significant survival differences in pathologic lymph node stages as well.[99]

In the past decade, significant data has been added to the literature in the management of base-of-tongue cancer by Transoral Robotic Surgery (TORS).

A recent review of articles on the subject from 2000 to 2014 by Helman and associates concluded that TORS has a positive role in oropharyngeal cancer by decreased morbidity, length of stay and total intubation time.[99a] Prospective studies are being conducted comparing TORS to non-robotic approaches in oropharyngeal carcinomas.

Squamous Cell Carcinoma of the Retromolar Trigone, Alveolar Ridge, and Palate

The gingival tissues on the alveolar ridge or the retromolar trigone are in very close proximity to the underlying periosteum, and significant difficulties have been encountered

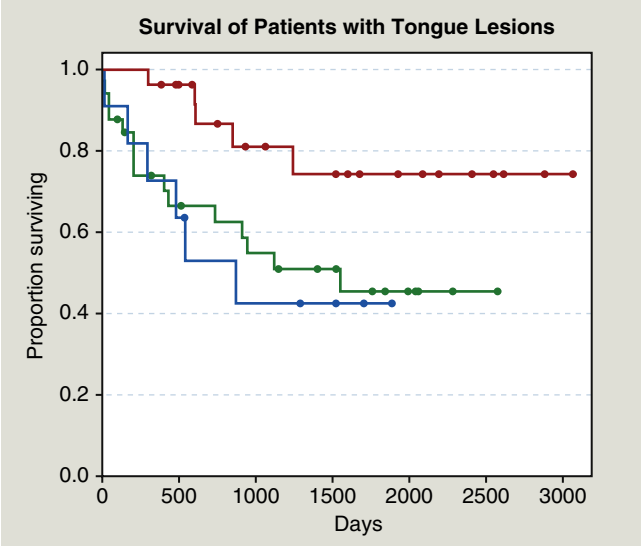


• **Figure 28-9** Squamous cell carcinoma of the tongue.

trying to identify bony invasion. Computed tomography has been useful in the diagnosis of bone involvement, but inaccurate. A study by Lane and colleagues[100] found an incidence of 50% mandibular invasion in retromolar SCCa that was not identified radiographically by CT in 27% of the patients. The effectiveness of skeletal scintigraphy is of relative value as well. Tsuchimochi and co-workers[101] described accumulation of technetium-99m methylene diphosphonate in areas of the mandible invaded by cancer. Bone scans have increased uptake in areas of osteoblastic activity; therefore the radioisotope concentrates in the immature bone surrounding the tumor as well as in the reactive periosteum in adjacent contact with the tumor, making this test highly sensitive but nonspecific with a potential false-positive result. Magnetic resonance imaging has a reported accuracy of 87% in establishing the involvement of the mandibular bone marrow, even in the absence of discontinuity of the cortical bone.[102]

A comparison between different imaging modalities and direct inspection after periosteal stripping was conducted by Brown and associates.[103] The results showed that orthopantomograms, CT, and periosteal stripping with direct inspection underpredicted the width and depth of bony invasion, whereas bone scans and MRI overestimated it.

Diagnosis of tumor extension into bone is critical to render proper treatment. Genden et al[104] recommended a panoramic radiograph and CT scan for all tumors of the retromolar trigone. In patients with trismus, extensive soft tissue involvement, or sensory disturbance, an additional MRI would be indicated.



• **Figure 28-10** Disease-free survival of tongue cancer with respect to tumor grade. Kaplan-Meier curve illustrating the disease-free probabilities with respect to tumor grade. Grade 1 is shown at the top as a *red* line, grade 2 at the bottom as a *green* line, and in the middle is grade 3 as a *blue* line. (From Friedlander PL, Schantz SP, Shaha AR et al: Squamous cell carcinoma of the tongue in young patients: a matched-pair analysis, *Head Neck* 20[5]:363-368, 1998.)

The treatment plan would include a bone resection in most cases. If the tumor approaches the periosteum, a marginal resection would be indicated to achieve tumor clearance and appropriate clean margins. When the cancer has early cortical mandibular invasion, conservation surgery preserving some mandibular continuity has been shown to be a valid option without evidence of disease 2 years after treatment in 78% of patients with T1, 73.1% of T2, 63.5% of T3, and 33.3% of T4.[105]

When the preoperative assessment is positive for involvement into the marrow space, a segmental resection is indicated. I. A. McGregor and colleagues[106] reported a readily available route of cancer spread through the porous alveolar ridge in edentulous patients. Of 46 nonirradiated mandibles (10 partially dentated and 36 edentulous), 41 were invaded through the alveolar ridge. They also found that perineural spread through the inferior alveolar nerve was a regular occurrence after bony invasion reached the mandibular canal.

A. D. McGregor and associates suggested that a more aggressive pattern of invasion through cortical bone was present in previously irradiated mandibles.[107] The pattern of invasion in 16 irradiated mandibles was more variable with multiple foci of tumor present in areas where the tumor was adjacent to the bone, implying the need for more radical resections in post-irradiated mandibles with tumor.

Boyle and Strong[108] recommended the following contraindications to marginal resections of the mandible:

1. Gross involvement of the cortical or cancellous bone of the mandible
2. Inability to preserve the inferior alveolar artery
3. Significant resorption of the mandible, suggesting very thin and weak residual bone
4. A previously irradiated mandible
5. Cancer abutting the mandible on more than two surfaces

Regarding contraindication 2, if the consideration to perform a radical resection because of the inability to preserve the inferior alveolar artery is based on evidence for direct invasion into the canal, then there is no doubt of the need to perform a segmental mandibulectomy and even evaluate the nerve margins for perineural spread.

On the other hand, the rationale is clouded if the justification for a segmental resection is based on the concern for vascular supply to the mandible as a result of the inability to preserve the inferior alveolar artery. If the canal was not infiltrated and there is no evidence of deep invasion, the mandible may remain viable through periosteal blood supply, even after sacrificing the inferior alveolar vessels.

Carcinomas of the hard palate and upper alveolus are uncommon. Alveolectomy, palatectomy, and infrastructure maxillectomy are the procedures of choice for this specific location.[109] Whereas squamous cell carcinomas still represent more than 50% of the malignant lesions of the hard palate, minor salivary gland tumors represent from one third to almost one half of the pathology in this location.[110,111]

The management of the neck in gingival and alveolar cancer has become a controversial issue that may require prospective data in order to establish a treatment strategy.

Soo and co-workers[112] reported an incidence of 14% neck metastasis at the time of diagnosis of maxillary gingival carcinoma. Overholt and colleagues[113] reported 13% neck metastasis at the time of diagnosis of palatal carcinoma.

More recent data from Simental and associates[114] have shown a much higher incidence of occult neck metastasis when patients with negative nodes at the time of presentation eventually developed neck metastasis despite control of their primary cancer. Only 7.6% of the patients in their group had clinically positive neck disease at the time of the initial evaluation, but an additional 27% of patients had cervical failures at the site of first failure for a total of 34.6%. Similar data were published by Zwetyenga et al,[115] with a 28% incidence of positive lymph node(s) in advanced upper gingival and hard palate cancer. Additional data from Toronto, showed similar results with occult nodal metastases of 26% of patients clinically staged as N0.[115a] Montes and Schmidt demonstrated that the aggregate of all patients with different stages of oral maxillary squamous cell carcinoma, 42.9% of the patients manifested disease to the cervical lymph nodes.[115b]

The accumulated experience in the management of the negative neck in cancer of this location supports surgical intervention through a selective neck dissection.

Types of Neck Dissection

Several clinical and pathologic characteristics have been described as predictive factors for oral cancer metastasis to regional cervical nodes. The radical neck dissection, initially described by Jawdynski in 1888[116] and later published and systematized by Crile in 1906[117] and advocated by Martin in 1951,[118] is the main treatment modality in the management of tumor metastasis to the lymph nodes of the neck.

In 1963 Suarez[119] and later in 1967, Bocca[120] published a technique preserving the spinal accessory nerve, sternocleidomastoid muscle, and internal jugular vein, achieving a similar degree of regional control while avoiding the morbidity associated with the removal of these three structures.

In 1972 Lindberg[121] described the distribution of cervical metastasis in relation to the primary tumor after reviewing 2004 patients with SCCa of the head and neck. This finding, later validated in additional studies by Shah[122] and Byers and colleagues,[123] led to the implementation of selective neck dissections for patients with clinically negative necks or for very selected patients with positive necks. Outstanding and detailed reviews of the historic evolution of neck dissections have been published by Ferlito and colleagues[124] and Subramanian and associates.[125]

In 2001 the American Head and Neck Society proposed an update for the classification of neck dissections.[126] The different levels of the cervical lymph nodes and the new classification of neck dissections are represented in detail within Tables 28-1 and 28-2. The classification of 1991 differs only in the description of selective neck dissections (SNDs) (Figure 28-11), which are now described as SND with the use of parentheses to denote the levels or sublevels removed.

Despite performance of a neck dissection, the presence of extracapsular spread and soft tissue deposits of cancer diminishes the survival rates significantly. The presence of cervical lymph node metastasis reduced the 5-year survival rate by 50%, while extracapsular spread or soft tissue deposits of cancer roughly decreased the survival rate by an additional 50% (Figures 28-12 and 28-13).[127]

Since the early 1990s, sentinel lymph node biopsy has been used mostly for breast cancer and melanoma.[128,129] The technique involves the histologic sampling of the lymph node that drains a radioisotope after it is injected at the site of the primary tumor. A review by Devaney and colleagues concludes that a negative sentinel node biopsy does not necessarily exclude the presence of other positive cervical lymph nodes.[130] Therefore this technique should still be considered an investigational procedure until further data are available.

TABLE 28-2 Types of Neck Dissections

Surgery	Structures Removed
Radical neck dissection	Lymph node levels I-V, sternocleidomastoid muscle, internal jugular vein, and accessory nerve
Extended neck dissection	Lymph node levels I-V, sternocleidomastoid muscle, internal jugular vein, and accessory nerve plus at least one lymphatic or nonlymphatic structure not sacrificed during radical neck dissection (parapharyngeal nodes, superior mediastinal nodes, perifacial nodes, carotid artery, hypoglossal nerve, vagus nerve, paraspinal muscles, etc.)
Modified radical neck dissection	Radical neck dissection minus at least one of the three major structures (namely, sternocleidomastoid muscle, internal jugular vein, or accessory nerve); the structure preserved should be specifically named
Selective neck dissection	At least one of the six lymph node levels/sublevels preserved; none of the structures (namely, sternocleidomastoid muscle, internal jugular vein, and accessory nerve) are sacrificed (the removed levels or sublevels should be mentioned within parentheses: I-III, II-VI, VI, etc.)

Follow-up

Long-term follow-up of patients after treatment for SCCa of the oral cavity is critical. Appointments should be scheduled based on individual risk of recurrence and the development of second primary tumors. Furthermore, follow-up is dictated by the need for additional treatments associated with morbidity from the surgery and the necessity of providing social and psychological support. These visits should include an annual chest radiograph and measurement of liver enzymes as well as thyroid function tests in patients who have received radiation to the lower neck.

The American Head and Neck Society recommends the following follow-up regimen:

- First year post-treatment: 1 to 3 months
- Second year: 2 to 4 months
- Third year: 3 to 6 months
- Fourth and fifth years: 4 to 6 months
- Beyond 5 years: 12 months

A recent British study on practices of 50 units revealed that all patients were followed monthly for the first year, with 90% having visits every 2 months during the second year. Although variations occurred during the third and fourth years, by the fifth year 6-month visits

were universal. Not surprising given the uniformity of results, risk-assessed variations in follow-up were not present.[131]

Ultrasonographic examinations have been added to the armamentarium of imaging devices used for identification of cervical node metastasis for follow-up of patients with head and neck cancer who did not receive neck dissection. In a study published by Hiroshi Yusa and colleagues,[132] 52 patients were examined by ultrasound after the initial primary resection. They accurately diagnosed 24 nodes in 10 patients, while 21 of the nodes were not palpable. Ultrasound examination appears to be useful for follow-up of cervical node metastasis in patients with oral and maxillofacial cancer.

Summary

Squamous cell carcinoma of the oral and maxillofacial region continues to present a challenge in regard to diagnosis, treatment, and patient survival. A number of risk factors have been identified, with others under debate. As our understanding of the genetic changes involved evolves, so may our treatment options. At present, once a patient is diagnosed, a thorough workup must ensue and treatment must be rendered in an expeditious fashion. In the oral cavity, surgery remains the primary modality, with adjuvant therapy (radiation or chemoradiation) as indicated. Close follow-up of patients is required long term in order to identify recurrence or second primary disease and should be tailored based on patient risk factors from the initial cancer as well as the presence of persistent high-risk behaviors.

29 Melanoma

RABIE M. SHANTI, DONGSOO DAVID KIM, GHALI E. GHALI

Epidemiology

Skin cancer is the most common malignant neoplastic entity affecting humans. These neoplasms can be divided into non-melanoma skin cancers (NMSCs) and malignant melanoma, a malignancy of melanocytes. NMSCs account for 95% of all skin neoplasms and melanomas for the remaining 5%. The American Cancer Society (ACS) estimated that 76,100 cases of melanoma would be diagnosed in the United States in 2014.[1] Approximately 55,000 cases of malignant melanoma were diagnosed in 2004, and 62,190 cases were diagnosed in 2006, indicating a steady increase in incidence. Furthermore from 2006 to 2010, the incidence of melanoma among whites increased by 2.7% per year.[1]

Even though melanoma makes up a small fraction of all skin cancers, it is responsible for the majority (75%) of all skin cancer–related deaths. Malignant melanoma was responsible for approximately 5020 deaths in the United States in 2006, and the ACS estimated 9710 deaths in 2014.[1] Malignant melanoma accounts for approximately 4% of all cancer-related deaths in the United States (Box 29-1). Such staggering statistics make melanoma a significant public health problem in the United States and globally.

The mortality rate and incidence of melanoma have been on the rise since the 1960s; however, in patients whose disease is detected early, 5-year survival appears to be improved.[1] Since the primary mode of therapy (i.e., surgery) has not changed, one can attribute an improvement in disease prognosis to increased public awareness and early detection of these lesions. Unfortunately, this improvement is limited to disease detected at an early stage, for the overall mortality rate secondary to melanoma is still on the rise. This chapter discusses the etiology, risk factors, clinical and histologic characteristics, diagnosis, staging, and management of this potentially fatal skin neoplasm.

Incidence and Etiology

Melanoma is one of a few malignancies in the United States with an increasing incidence. In 1935, the incidence of melanoma was 1:1500; however, by 2008-2010 the incidence had increased to 1:34 in men and 1:53 in women.[1] In considering the epidemiology of melanoma, one must recognize that age is an important risk factor for its development. While the incidence and mortality of melanoma have been increasing steadily, those older than 65 have experienced a significantly higher rise in incidence and mortality rates in comparison to younger age groups.[2] The previously mentioned 1:34 men and 1:53 women incidence of melanoma is from birth to death; however, the incidence from birth until the age of 49 is 1:284 men and 1:206 women.[1] The incidence will increase with age reaching an incidence of 1:48 men and 1:113 women for those 70 years of age and older.[1] At present, 25% of individuals affected by this disease are under the age of 40. It is the most common malignancy in women ages 25 to 29 and is second only to breast cancer in women ages 30 to 34.[3] Children make up 1% to 4% of the melanoma patient population, and as has been observed in all patient populations, the incidence of melanoma in children has also increased significantly.[4] Strouse and colleagues reported a 46% increase in the incidence of melanoma in pediatric patients from 1973 to 2001.[5]

Approximately 20% of all melanomas are found in the head and neck region. Fewer than 1% of lesions are found in the oral cavity.[6] These oral lesions, although rare, are associated with a high mortality rate. In general, the torso, back, and head and neck are the most common anatomic sites in men, whereas the extremities are the most common anatomic sites in women.[3] This topographic difference between the two genders has been used to explained the higher incidence of mortality among men in comparison to women; the sites involved in men are considered to have a worse prognosis.[7]

Excessive ultraviolet (UV) light exposure was thought to be the primary etiologic factor in the development of malignant melanomas. The link between Caucasian race and living nearer the equator, such as in Australia or the southeastern United States, is undeniable. However, this link does not provide a biologic explanation for many cases, such as subungual or mucosal melanomas. There is now compelling evidence that, as in all malignant neoplasms,

genetic aberrations play a crucial role in the development of all melanomas. Evidence also links periods of high-intensity UV light exposure, rather than chronic exposure, with the development of melanomas.[8] An exception is the lentigo maligna melanoma. This form of melanoma, as with the NMSCs (i.e., basal cell and squamous cell carcinomas), tends to be associated with more prolonged UV light exposures.

Caucasians are the typical patients who develop malignant melanomas. African-American, Hispanic, and Asian individuals rarely develop the disease. Darker-skinned races tend to have higher mortality rates with melanoma because of the predilection toward developing the acral lentiginous subtype and typically presenting with advanced-stage disease at diagnosis. Women tend to be slightly more affected than men worldwide and have slightly better overall survival than males. The countries with the highest rates of melanoma are Australia and New Zealand, with 37.7 cases per 100,000 men and 29.4 cases per 100,000 women. In comparison, the United States has approximately 6.4 cases per 100,000 men and 11.7 cases per 100,000 women. California, Florida, Texas, New York, and Pennsylvania have the highest estimated rates of new melanoma cases.[1]

Many risk factors for the development of melanoma have been identified (Box 29-2). Generally accepted risk factors are Fitzpatrick skin type 1 or 2 (Table 29-1), red or blonde hair, family history, actinic keratosis, pronounced freckling of the upper back, three or more blistered sunburns before adulthood, and an outdoor job (e.g., lifeguard) for more than 3 years before the age of 20. Individuals with two of these risk factors have an estimated threefold to fourfold increase in incidence of developing a melanoma; those with three or more have an increase incidence of approximately 20-fold.

• Box 29-1 Melanoma Statistics

4% of all cancer deaths
5% of all skin cancers
75% of all skin cancer–related deaths
20% occur in head and neck region
1:34 men, 1:53 women incidence rate in 2008-2010

• Box 29-2 Melanoma Risk Factors

Family history
Fitzpatrick skin type 1 or 2
Three or more blistering sunburns before age 20
Three or more years before age 20 with an outdoor job (e.g., lifeguard)
Actinic keratosis lesions
Pronounced freckling of upper back
Red or blonde hair
Immunosuppression
Older age
Dysplastic nevus syndrome
Congenital nevi >20 mm

These risk factors do not adequately address melanomas in areas not exposed to UV light. These lesions are thought to arise de novo and not as a result of environmental exposure. A family history of melanoma increases the risk by two to eight times. Immunosuppression has also been associated with an increased risk of melanoma development. Older age is also a well-recognized risk factor.[4]

An association between benign melanocytic proliferations (e.g., nevus) and malignant melanoma has clearly been established by Skender-Kalnenas and co-workers.[9] They evaluated 289 cases of thin, malignant melanomas and the association with benign melanocytic proliferations. A nevus was found to be associated with more 50% of lesions, and of these nevi, 56% were dysplastic, 41% were common acquired, and 3% were congenital. The association with melanocytic proliferation was greater with increasing age of the patient.

The majority of melanomas arising in the head and neck region, approximately 70%, have been found to arise in pigmented lesions. This includes pigmented lesions of the oral cavity (Figures 29-1 and 29-2). A change in the character of pigmented lesions, particularly in patients with

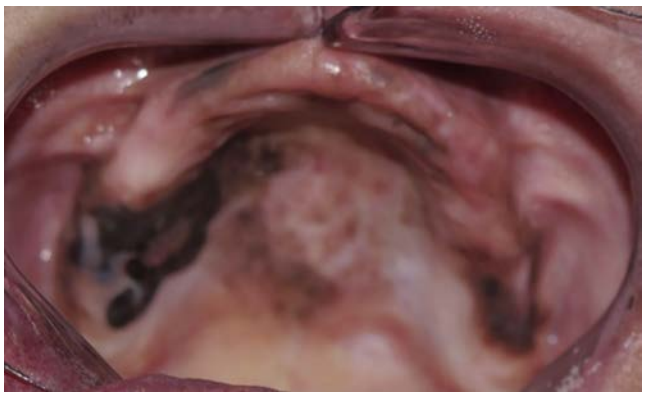
TABLE 29-1 Fitzpatrick Skin Type Classification

Type	Characteristics
1	Always burns easily, no immediate pigment darkening, never tans
2	Always burns easily, trace immediate pigment darkening, tans with difficulty and minimally
3	Burns minimally, immediate pigment darkening, tans gradually and uniformly (light brown)
4	Burns minimally, immediate pigment darkening, tans well (moderate brown)
5	Rarely burns, immediate pigment darkening, tans very well (dark brown)
6	Rarely burns, immediate pigment darkening, tans profusely (black)

• Figure 29-1 Oral melanoma.

any other risk factors, should raise the level of suspicion for a malignant transformation. All pigmented lesions (Figure 29-3) without an obvious etiology (e.g., amalgam tattoo) in the oral cavity should be biopsied and followed periodically, because the mortality of intraoral melanomas approaches 100%. Congenital nevi larger than 20 mm have a malignant transformation rate of approximately 20%, and lesions associated with dysplastic nevus syndromes have a 100% rate of malignant transformation over an individual's lifetime; removal of these lesions is recommended.[9]

• **Figure 29-2** Oral melanoma.



• **Figure 29-3** Mucosal melanoma involving the hard palate, and bilateral maxillary gingiva.

As a result of the high mortality associated with late melanomas, the index of suspicion with pigmented lesions of the head, neck, and oral cavity should be high. The authors recommend using, and instructing patients to use, the ABCDE and P method of evaluation:

Asymmetry: Irregular "lopsided" lesions
Border: Notched, angled, nonlinear borders
Color: Multiple colors within a lesion or loss of color (amelanotic)
Diameter: Greater than 6 mm lesion or changes in size of existing lesion
Elevation: Changes in height or new-onset nodularity of lesion
Persistence: Lesion that demonstrates persistent erythema, scaling, itching, or ABCDE changes.

Melanomas have been clinically and histologically subdivided into five types (Table 29-2): superficial spreading (Figure 29-4), nodular (Figure 29-5), lentigo maligna (Figure 29-6), acral lentiginous (Figure 29-7), and desmoplastic. Of all of these melanoma histologic variants, the superficial spreading form is the most common, and lentigo maligna is the least common. Nodular melanoma is considered the most aggressive type of malignant melanoma.

Diagnosis

Accurate diagnostic and prognostic information yielded by the pathologic specimen is critical in deciding the patient's treatment options. The "gold standard" for the diagnosis of melanoma remains conventional hematoxylin and eosin (H&E) stained tissue sections (Figure 29-8). The first step in diagnosis of melanoma begins with a biopsy. The ideal biopsy, if the size of lesion permits, is an incisional biopsy with 1- to 3-mm margins and with enough depth to ensure that the lesion is not transected.[10]

TABLE 29-2 Subtypes of Malignant Melanoma

	Prevalence	Age	Clinical Features	Common Sites
Superficial spreading	70% of all; common in light-skinned people	4th-5th decade	Classic ABCDE features; pigmented macule	Head, neck, trunk, back, extremities
Nodular	15% of all	4th-5th decade	Rapid growth; usually from normal skin; poorer prognosis; 5% amelanotic	Head, neck, trunk
Acral lentiginous	10% of all	6th-7th decade	Tan, flat irregular macule; not associated with sun-exposed areas	Plantar, hands, subungal surfaces common
Desmoplastic	Rare; commonly associated with lentigo maligna lesions	6th-7th decade	Sun-exposed areas; pigmented or flesh colored	Head and neck
Lentigo maligna	5%-10% of all; associated with chronic sun exposure	7th-8th decade	Irregular, tan-brown macule	Head and neck; neck and cheeks commonly

Typically, the biopsy is performed either by a punch biopsy or scalpel elliptical excision. Performing an excisional rather than incisional biopsy allows for more accurate microscopic staging of the lesion. However, in critical areas of the face or in the presence of large lesions, an incisional biopsy is acceptable.

Variation in histologic morphology and similarity to benign melanocytic lesions make the histopathologic diagnosis quite difficult. Shoo and colleagues reported a 14.3% discordance rate in the histopathologic diagnosis of thin melanoma and benign nevi between referring centers and their institution.[11] In comparison to other cutaneous and mucosal neoplasms, numerous histologic criteria are used to establish a diagnosis of melanoma, but none alone are adequate enough to establish this diagnosis.[9] The pathologist must include in the pathology report the following information: the melanoma subtype, thickness, anatomic level, presence or absence of microscopic ulceration, positive or negative margins, perineural involvement, perivascular involvement, presence of mitoses, and presence of vertical growth phase (Figure 29-9). Although the staging of cutaneous and mucosal melanoma is discussed later in this chapter, it is worth noting that the previous American Joint Committee on Cancer (AJCC) melanoma TNM staging included only tumor thickness and presence of tumor ulceration in the T category strata, except for T1 lesions, which included Clark's level. However, the revised melanoma staging system released by the AJCC in 2009 included primary tumor mitotic rate, which has replaced Clark's level in the T category strata because of its significance as an adverse predictor of survival (see Table 29-6).[12] The mitotic rate of melanoma has been traditionally evaluated by counting mitotic figures on H&E-stained tissue sections, and averaging the number of mitotic figures per square millimeter (mitoses/mm^2).[13] Today, an area of ongoing scientific research is the incorporation of computer-assisted analysis for calculation of immunolabeled mitoses in order to simplify and standardize this process.[13]

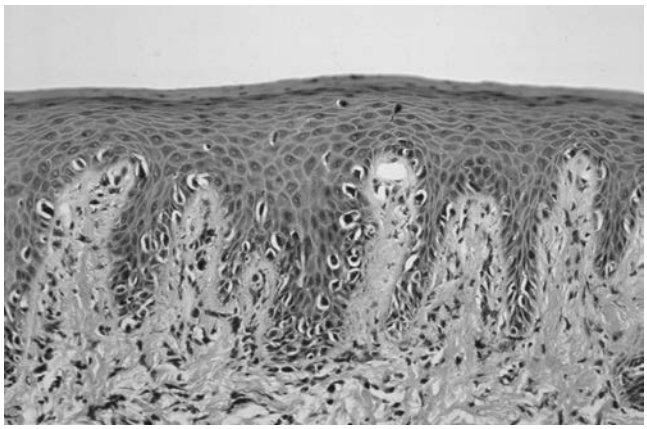
Histologically, the features of melanomas are somewhat dependent on the subtype and phase of growth. All melanomas show melanocyte cellular atypia and an altered cellular maturation. Fine intracellular granules, abnormal mitoses, hyperchromatic nuclei, prominent nucleoli, multinucleated giant melanocytes, and abnormal collections of cells ("nests") may all be seen. Various immunohistochemical markers have become useful in the pathologic diagnosis of melanoma (Table 29-3). Of these, S-100 and HMB-45 are the most frequently used melanocytic markers.[14] Anti-HMB-45 is a monoclonal antibody that recognizes the melanosomal glycoprotein gp100; thus positive staining is related to active early melanosome formation.[15] A more sensitive test for the diagnosis of melanoma is the monoclonal antibody to S-100 protein. The sensitivity of

TABLE 29-3 Common Immunohistochemical Markers for Melanoma

	S-100	HMB-45	MART-1/Melan-A and Tyrosinase
Antigen	Calcium channel binding protein	Cytoplasmic glycoprotein (part of gp 100 premelanosome complex)	Transmembrane protein (melanocyte differentiation antigen)
Cell type	Melanoma cells, nevus components, histiocytes, schwannomas, neurofibromas, nerve sheath tumor cells	Melanoma cells, fetal and neonatal melanocytes, nevus components	Melanocytic cells, perivascular smooth muscle cells, adrenocortical tumors, ovarian tumors
Drawbacks	Not specific for melanoma; cannot differentiate benign and malignant cells	Not specific for melanoma; spindle cell variants do not stain with HMB-45; cannot differentiate benign and malignant cells	Not specific for melanoma; cannot differentiate benign and malignant cells



• **Figure 29-10** Medium-power hematoxylin and eosin photomicrograph of a melanoma with radial growth phase.

S-100 antibody as a melanocytic marker is near 100%. However, the S-100 protein antibody does retain immunoreactivity to tumors that originate from adipocytes, chondrocytes, Schwann cells, and myoepithelial cells.[14] Therefore, the monoclonal antibody against the HMB-45 antigen is more specific for melanocytic neoplasms, with the exception of the spindle cell and desmoplastic melanoma variants.[14]

Microinvasive melanoma and melanoma in situ represent the radial growth phase of these lesions (Figure 29-10). Melanoma in situ is a proliferation of malignant melanocytes restricted to the epidermis. Pagetoid spread (single, atypical cells spread through the epidermis) and atypical, dendritic melanocytes arrayed along the dermoepithelial junction are classic histologic findings seen with melanoma in situ. Melanoma in situ is seen in all major subtypes except the nodular form. Microinvasive melanoma is characterized by epidermal involvement with *microscopic* extension into the papillary dermis. Microinvasiveness can be defined as follows: the largest dermal nest of cells is smaller than the largest epidermal nest of cells; and no dermal mitoses are present. Frequently a lymphocytic infiltrate is also present as well.[16]

When a melanoma breaches the basement membrane and involves the underlying dermis, it is said to be in a vertical growth phase (see Figure 29-9). In this phase the lesion has metastatic potential and thus a poorer prognosis. The vertical phase is characterized by at least one dermal mitosis or one or more dermal cell nests larger than the largest epidermal cell nest. Table 29-4 describes the basic histologic features of the various subtypes of malignant melanoma.

The growth characteristics of melanomas typically manifest with a long horizontal radial growth phase. These early lesions tend to spread within the epithelium without violating the basement membrane and penetrating into the underlying tissues. Late lesions tend to penetrate the basement membranes, grow vertically, and invade deeper tissues. This vertical growth phase was noted by early investigators to have profound significance in predicting overall survival and in directing treatment of the disease. In 1969 and 1970, Clark and Breslow, respectively, developed histologic classifications based on the depth of the lesion alone[17,18] (Table 29-5). Clark's anatomically based system has been replaced in the current staging protocols in favor of Breslow's millimetric depth system. Breslow's classification, which measures from the granular cell layer to the depth of the tumor, has been shown to have better predictive value and less variability between observers. Melanoma depth has also been shown to have a strong relationship with regional lymph node metastasis and distant metastatic disease. These prognostic implications of lesion depth make it one of the major prognostic indicators of melanoma, and thus it is currently a major part of the AJCC staging system for melanoma.[12]

Several lesions can be mistaken for melanoma. These include pigmented basal cell carcinomas, seborrheic keratosis, nevi, lentigines, and dermatofibromas. Clinicians should have a high index of suspicion for melanoma, and excisional biopsies should be performed. Improved rates of survival were demonstrated in patients who had excisional (8.9%) versus incisional (25%) biopsies.[19] Delay in definitive treatment, altered local host factors, and an increased time for lesion dissemination have been postulated as reasons for the

TABLE 29-5 Depth Classifications and Associated Survival Rates

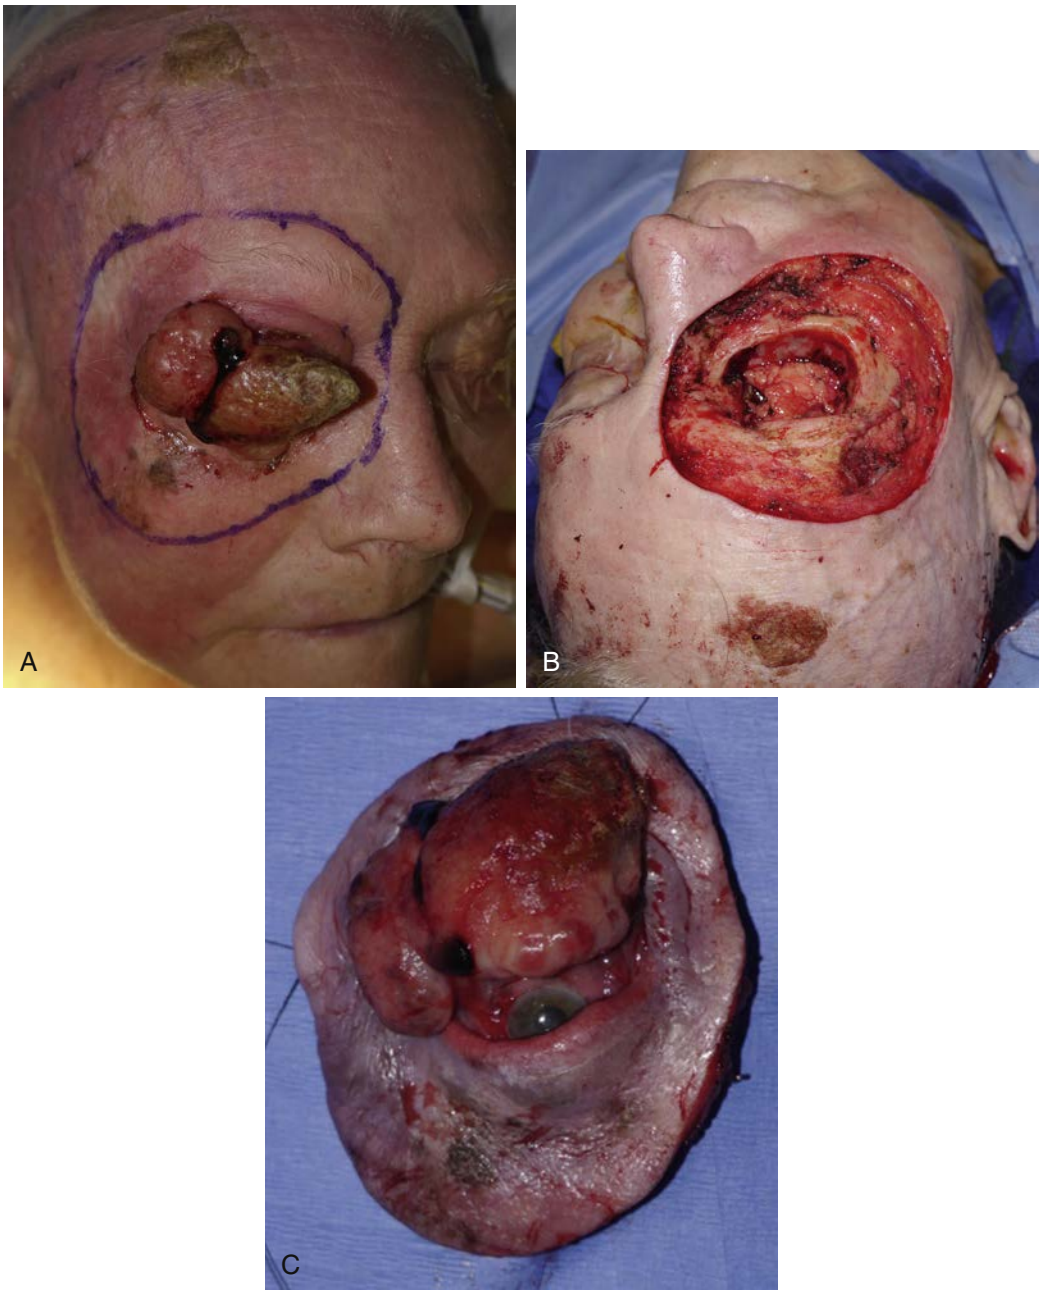
Clark's Level	Clark's Classification	Breslow's Depth (mm)	Clark's 10-yr Survival	Breslow's 10-yr Survival
Within epithelium	Level I	N/A	96%	N/A
Penetrates papillary dermis	Level II	0.0-0.75 mm	96%	98%
Fills papillary dermis	Level III	0.76-1.69 mm	90%	89%
Penetrates reticular dermis	Level IV	1.70-3.59 mm	67%	67%
Invades subcutaneous tissue	Level V	>3.6 mm	26%	43%

decreased survival rate. Shave biopsies should not be performed, because they do not indicate the depth of lesion involvement. As previously stated, biopsies with 2- to 3-mm margins of surrounding tissue extending down to the underlying fascia are preferred. Incisional or punch biopsies should only be considered with very large lesions.

Definitive excision of the lesion and the extent is a source of debate. There have been five multicenter prospective randomized clinical trials which have evaluated the relationship between excision margin status and risk of local recurrence, as well as the impact of margin status on survival in patients with cutaneous melanoma.[20] These trials include the World Health Organization (WHO) Melanoma Program Trial No. 10,[21] United Kingdom Melanoma Study Group,[22] French Cooperative Group Trial,[23] Swedish Melanoma Trial Group,[24] and Intergroup Melanoma Surgical Trial.[25] The WHO Melanoma Program Trial No. 10 investigated a randomized cohort of 612 melanoma patients. In this trial, patients were stratified into either a Breslow depth < 1 mm or a Breslow depth 1 to 2 mm. The investigators compared 1-cm versus 3 to 5 cm excision margins. With a greater than 15-year follow-up, the investigators did not identify a statistically significant difference in distant recurrence rates and survival rates based on these margins of excision. Of note, patients managed with a 1-cm margin of excision had a greater local recurrence rate, but this was not of statistical significance. The United Kingdom Melanoma Study Group investigated the margin of excision necessary for cutaneous melanoma that are 2 mm or greater in thickness. The investigators in this study identified that for tumors that were 2 mm or greater in thickness a 1-cm margin was associated with a statistically significant increase in locoregional recurrence in comparison to 3 cm margins.

The French Cooperative Group Trial consisted of 337 patients with melanoma of the trunk, limbs, and head and neck with tumors ≤2 mm Breslow thickness; 2-cm versus 5-cm excision margins were compared. This multicenter trial could not identify a statistically significant advantage for 5-cm margins in the management of tumors ≤2 mm Breslow thickness. Likewise, the Swedish Melanoma Group Trial also could not identify a statistical difference in recurrence rates when comparing 2-cm versus 5-cm margins of excision. Furthermore, the Intergroup Melanoma Surgical Trial stratified patients into two groups: Group A were proximal extremity and trunk melanoma patients, and Group B were head and neck melanoma and distal extremity patients. Group A patients were randomly subdivided into either 2-cm or 4-cm margin of excision subgroups, whereas all Group B patients had a 2-cm margin of excision. Of note, all patients in this study were additionally stratified by tumor thickness and presence/absence of ulceration. The investigators reported that the 10-year survival was not statistically different when comparing 2-cm versus 4-cm margin of excision in Group A patients. Furthermore, locoregional control was the same when comparing 2-cm versus 4-cm margin of excision in Group A patients.

In summary, as Cruse and colleagues[26] have proposed, local recurrence is not affected by excision margins, but is by lesion thickness. The WHO proposes that 1-cm margins should be used for lesions less than 1 mm in thickness, and



• **Figure 29-11** **A,** Patient with upper eyelid cutaneous melanoma with a tumor thickness of 8 mm underwent resection with a 3-cm margin of excision including exenteration. **B,** Final defect. **C,** Clinical photo of specimen. (Photos courtesy Dr. Melvyn Yeoh, Shreveport, LA.)

3-cm margins should be used for lesions greater than 1 mm (Figure 29-11).[21] The authors feel that 1- to 2-cm margins, with appreciation of facial aesthetic subunits and adjacent vital structures, are adequate in all except scalp lesions. Scalp lesions have been shown to have higher rates of in-transit metastasis, and it is recommended to take wider margins (3-4 cm) with these resections.

Management of Regional Disease

The treatment of choice for melanoma is surgical excision. In most cases wide local excision adequately controls local disease. Melanoma is believed to initially metastasize via spread to regional lymphatics. At the time of initial diagnosis, 82% of patients have localized disease and 11% of patients are found to have spread to regional sites.[27,28] Accurate assessment of the regional node status is a major prognostic factor for overall survival and locoregional control; it also plays an important role in directing therapy. The management of regional lymphatics is a topic of considerable debate in the literature—in particular, management of patients with a clinically negative neck.

In patients with clinically positive lymph nodes, or a positive sentinel lymph node biopsy (SLNB), the suggested

therapy is a therapeutic lymphadenectomy (removal of *all* nodes in the involved drainage basin). This approach may be curative or at least decrease the morbidity associated with a regional recurrence. The morbidity of the dissection and the ability of the patient to tolerate the procedure must be taken into account before a therapeutic neck dissection. In the case of head and neck cutaneous melanoma, a positive SLNB will allow for appropriate escalation of treatment, such as regional lymph node dissection, addition of adjuvant therapies, and/or enrollment in a clinical trial. Performing an SLNB is not indicated for patients presenting with a lymph node with clinical features highly suggestive for regional disease. In these cases, a fine-needle aspirate is typically performed, and also for patients with disseminated disease.[29]

Elective lymph node dissection (ELND) is based on the same physiologic and anatomic rationale as the therapeutic neck dissection. However, prospective randomized trials have shown no improvement in overall survival associated with ELNDs,[30-33] one of these being the Intergroup Melanoma Surgical Trial. The low risk for thin melanomas to involve regional lymphatics, the potential morbidity of neck dissections, and the success of sentinel lymph node biopsies have effectively limited the usefulness of elective neck dissections.

SLNB has been used successfully in the treatment of melanoma and is currently the standard of care for evaluating the regional lymphatics in thin lesions and with clinically negative necks.[34,35] Most centers use the following indications for SLNB: Breslow thickness 1.0 mm, Clark level IV, ulceration or regression, subungual location, and no clinical or radiographic evidence of lymph node metastasis. The concept of SLNB is based on studies showing that lymphatic drainage is predictable and the initial nodes involved fall within a specific nodal basin. In theory, if the sentinel node(s) have not been involved with metastatic disease, the other remaining "downstream" nodes in that basin will not harbor disease. A therapeutic lymphadenectomy is completed if a patient is found to have a positive sentinel node.

Sentinel node mapping requires a coordinated effort by the surgeon, pathologist, and nuclear medicine physician. Currently, the most predictable way to identify sentinel nodes is by using a combined vital blue dye (sulfan blue) and technetium-99m sulfur colloid mapping technique. The periphery of the lesion is injected with the vital dye, lymphoscintigraphy is performed, and the markers are given time to distribute into the regional nodes. A conservative incision is made to access the nodal basin identified by the prior lymphoscintigraphy. The incision is placed so the surgeon is able to access the neck or parotid region for a therapeutic lymphadenectomy, if the sentinel node biopsy is positive. Intraoperatively, dye staining of the lymphatics and verification with a gamma probe are used to identify the sentinel node(s). The pathologist then performs serial sections on the collected lymph nodes. The protocol used to evaluate sentinel nodes varies according to the institution. However, some combination of serial sectioning, hematoxylin and eosin staining, and immunohistochemical stains is generally used. Serial sectioning is work-intensive for the pathologist and, although better than standard node evaluation techniques, still examines only less than 1% of the submitted node. Recently, molecular analysis techniques have been investigated and have been found to increase the accuracy of SLNB techniques while decreasing the workload involved with serial sectioning. These techniques will likely play a more important role in the future of SLNB analysis, but they should not be used currently in management decisions and escalation of treatment.

Positivity with SLNB has been reported to occur in 17% to 19% of cases of trunk or extremity melanoma, and 10% of head and neck cases. It is important to mention that in cases of head and neck melanoma, SLNB allows for identification of microscopic nodal disease and subsequent escalation of treatment.[36] The identification of microscopic nodal disease via SLNB has been shown to improve regional disease control. However, a Surveillance Epidemiology and End Results (SEER) database cohort analysis of 7266 patients published in 2014 was unable to demonstrate a significant association between SLNB and improved disease-specific survival for patients with head and neck melanoma.[28]

Staging of Melanoma

It is important that all providers use the same criteria and definitions in the literature and in a patient's management. The nomenclature and criteria for discussing melanomas have been provided by the AJCC.[12] Staging is important in the stratification of disease, in the prognostication of mortality, and in directing therapy. It was recognized that improvements in the staging of melanoma could be made by applying evidence-based methods to create and then validate a staging system for melanoma. Buzaid and associates[37] published a paper pointing out the inadequacies of the preexisting AJCC staging system for melanoma. The Melanoma Staging Committee of the AJCC was formed in 1998.[37] It was made up of experts from all relevant medical specialties and included leaders from most of the major melanoma treatment centers. An additional modification of the existing staging system was included in the 7th edition of the AJCC Cancer Staging Manual in their paper published in 2009.[12] The previous staging system in the 6th edition of the AJCC Cancer Staging Manual emphasized that thickness and ulceration are the predominant predictors of survival and that depth of invasion matters only in thin (≤1 mm) lesions. In the 7th edition of the AJCC Cancer Staging Manual, primary tumor mitotic rate has replaced Clark's level of invasion as the main criterion differentiation subcategory T1a from T1b. Thickness proved meaningful in whole numbers groups (≤1 mm, 1.01-2 mm, 2.01-4 mm, >4 mm). Ulceration was a negative predictor of survival throughout all groups. The number of metastatic lymph nodes was also found to be a prognostic factor. Site of distant metastasis and the presence of elevated lactate dehydrogenase (LDH) levels were also found to be prognostic and

were included in the staging system.[10,38,39] Patients with an elevated LDH are all categorized as M1c irrespective of all other M-category strata. Tables 29-6 through 29-10 describe the current AJCC (TNM) staging system for cutaneous malignant melanoma.

Today, the role of positron emission tomography (PET), and other advanced imaging modalities such as computed tomography (CT) or magnetic resonance imaging (MRI), for staging of malignant melanoma has yet to be defined. Wasif and colleagues evaluated use of staging studies in 25,643 patients with cutaneous melanoma using the SEER database.[36] Based on their analysis, in the year 2000, 4.2% of patients with early-stage cutaneous melanoma had a cross-sectional imaging study performed, and in 2007 this had increased to 12.2%. The 2012 National Comprehensive Cancer Network (NCCN) guidelines for staging of cutaneous melanoma do not recommend any cross-sectional imaging studies for stage I through IIC disease. They do, however, state that a chest x-ray is optional for patients with stage IIB or IIC disease.[37] Based on their recommendation, cross-sectional imaging studies (e.g., PET, MRI, CT) are optional for patients with stage III or stage IV disease. Similarly, the American Academy of Dermatology does not recommend any imaging study for patients with a primary melanoma with a thickness less than 4 mm.[10,36] PET has been found to have a lower sensitivity for the detection of occult nodal disease when compared to SLNB.[10,36] In summary, cross-sectional imaging studies should be reserved for patients with advanced-stage disease (stage III/IV).

Includes microstaging of primary melanoma and nodes after lymphadenectomy; Stage 0 and IA do not require pathologic evaluation of nodes.

In summary, appropriate therapy is based on accurate staging and, in the case of malignant melanoma, consists of assessment of histologic features of the primary tumor and measurement of serum LDH level. As with any neoplastic disease process, assessment of the patient's performance status will aid in risk stratification of patients for surgery and other adjuvant therapies.

Treatment

As mentioned previously, surgery is the mainstay of current melanoma treatment. Wide local excision of small, thin lesions is curative in many cases. SLNB with therapeutic lymphadenectomy, when indicated, is the current standard of care for the surgical management of melanoma in the head and neck. There is some question as to the efficacy of this approach in extremity melanomas, related to the morbidity of groin or axillary lymphadenectomy, without a benefit in overall survival. The current literature also debates the therapeutic value of many current treatments, including sentinel node biopsy (as a staging intervention), radiation therapy, chemotherapy, molecular targeted therapy, and interferon alfa therapy.

SLNB is not used as a therapeutic modality in itself. It is currently used to direct therapy (surgical vs. adjuvant). Gutzmer and colleagues[40] described three theories as to how SLNB itself may affect prognosis. The first, which improves prognosis, is that micrometastatic disease is removed from the regional nodal basin. This implies that early metastatic disease is primarily within the lymphatics, and the disease then spreads to distant sites after some time. The second, which does not change overall prognosis, is that lymphatic and hematogenous metastasis occur simultaneously and that lymphatic micrometastasis found in SLNB indicates aggressiveness of the tumor (aka the marker hypothesis). The last theory, which worsens prognosis, is that malignant cells are removed from an immunologically active environment, therefore impairing the body's response to the malignant cells. The results of their paper showed an improvement in locoregional control, but no advantage in death from distant metastasis. Their conclusions favored the marker hypothesis.

The Multicenter Selective Lymphadenectomy Trial (MSLT-I) raised the question of whether SLNB was beneficial.[41] In the MSLT-I study, patients were randomized into two groups; 60% of patients underwent SLNB, and those with positive sentinel nodes underwent a therapeutic lymphadenectomy. The remaining patients had a wide local excision and observation. Regional recurrences were then treated with therapeutic lymphadenectomy. The findings of the MSLT-I study showed no significant differences in overall survival between the two groups. However, there was a significantly higher 5-year survival rate in the SLNB-positive group (who underwent therapeutic lymphadenectomy) and higher 5-year distant disease-free survival in the SLNB group. The MSLT-I study suggested that SLNB was more a tool of prognosis and for identifying patients who may benefit from adjuvant therapy.[41] Regardless of any positive or negative therapeutic effects, SLNB has been shown to be invaluable in prognosis and is the standard of care in the evaluation of nodal disease in melanoma.

Melanomas have been traditionally thought to be a radioresistant tumor. The facts dispute this assumption. Although not recommended as a primary treatment modality, the use of adjuvant radiation therapy for regional disease is well supported in the literature. The use of radiation does improve local control of disease. However, there have been no compelling data showing an increase in overall survival.[42,43] The ideal radiation dose schedule has yet to be defined. Ballo and co-workers[43] have used a hypofractionated schedule in their practice consisting of 30 Gy in five 6-Gy fractions twice per week for 2.5 weeks. The authors explain that patients who present with extracapsular extension, disease in more than 3 nodes, nodes ≥3 cm, recurrent disease, and cervical location are more appropriate candidates for adjuvant radiotherapy.

Systemic therapy in the management of malignant melanoma is essentially in an adjuvant or palliative role. The role of conventional chemotherapy has yet to be defined, and also has yet to show any significant survival benefits. Dacarbazine and temozolomide are the chemotherapeutic agents of choice. Dacarbazine (DTIC, Bayer Pharmaceuticals, West Haven, CT) is an intravenous DNA alkylating agent, whereas temozolomide (Temodar, Merck & Co., White House Station, NJ) is an oral DNA alkylating agent. Both of these agents have shown poor response rates when used for single-agent therapy. A phase III clinical trial reported by Middleton and colleagues demonstrated equal efficacy of dacarbazine and temozolomide from a survival perspective; however, because temozolomide is an oral alternative that has been shown to have a better overall response, one can argue for selective temozolomide over dacarbazine.[44] Nevertheless, one must not forget that for cases of advanced-stage disease or metastatic melanoma, immunotherapy (see later discussion) offers better outcomes than do conventional chemotherapeutic agents.

Today, immunotherapy and cytotoxic chemotherapy are the pharmacologic agents of choice for patients with advanced disease (stage III/IV) or those with disseminated disease.[45] Interferon alfa-2b is the primary systemic agent in use today for adjuvant therapy in patients with advanced disease. There is debate as to the effectiveness of this agent; however, the results of the Eastern Cooperative Oncology Group trials, documented by Kirkwood and co-workers, showed a significant 5-year disease-free survival and an improvement in overall survival in the high-dose interferon (HDI) groups.[46,47] Furthermore, Wheatley and associates[48] performed a meta-analysis of 12 interferon alfa-2b trials and concluded there was a benefit in disease-free survival, but that there was no change in overall survival. Because of data such as these and the toxicities (e.g., fatigue, cognitive dysfunction, depression, suicide risk) associated with HDI, some practitioners may not recommend interferon therapy. In the United States, although debated, interferon alfa-2b is currently recommended for use in high-risk melanoma as an adjuvant therapy. The rationale for the use of HDI following disease resection is based on histologic and animal model evidence that interferon alfa-2b induces tumor regression via an indirect immunomodulatory mechanism.[49,50] These studies and others have shown that the effect of alfa-2b interferon is based on modulation of the host immune system, rather than via a direct antitumor mechanism.[51] IL-2, a cytokine-based agent, is used to stimulate the proliferation and activity of T cells in hopes of inducing tumor regression.[52,53] Today, recombinant IL-2 is recommended as a first-line agent for unresectable stage IV melanoma with a good performance status and no evidence of or treated central nervous system (CNS) disease, irrespective of BRAF mutation status.[52] This intravenous agent is marketed under the trade name Proleukin (aldesleukin, Prometheus Laboratories, San Diego).

Because of the rise in the incidence of melanoma, current statistics such as a 20% 5-year survival for patients with advanced melanoma and unresectable tumors, and the resistance of melanoma to radiation therapy and conventional chemotherapy, there has been significant scientific effort to identify pharmacologic agents that can directly induce or substitute the host's antitumor immune mechanism.[51] In the previous edition of this chapter, the treatment of melanoma with systemic therapy was limited to interferon alfa-2b for adjuvant therapy, and interleukin-2 (IL-2) and the aforementioned DNA alkylating agents (i.e., dacarbazine and temozolomide) for metastatic disease.[43]

However, today there are three new systemic agents that are approved for the treatment of melanoma: ipilimumab, an anti-CTLA4 monoclonal antibody, pegylated-interferon-alpha 2b for adjuvant therapy; BRAF inhibitor for patients with metastatic melanoma harboring $BRAF^{V600}$ mutation; and trametinib, a specific inhibitor of mitogen-activated protein kinase (MEK).

In the previous edition of this text, we described an ongoing phase III clinical trial involving the aforementioned anti-CTLA4 monoclonal antibody, ipilimumab, which was administered with or without a glycoprotein 100 (gp100) peptide vaccine for patients with unresectable stage II or IV melanoma. In 2010, Hodi and colleagues reported in the *New England Journal of Medicine* the results of this phase III trial.[54] Of the 676 patients enlisted in the trial, the median overall survival was 10 months among patients receiving ipilimumab plus gp100, as compared to 6.4 months for patients receiving gp100 alone. In 2011 the FDA approved ipilimumab (Yervoy, Bristol-Myers Squibb, New York) for treatment of metastatic melanoma.[55] Today, ipilimumab is recommended as a first-line agent in the treatment of unresectable BRAF mutation–negative tumors in patients with a poor performance status and untreated CNS disease.[51] For the case of BRAF mutation–negative tumors in a patient with a good performance status with absent/treated CNS disease, ipilimumab is considered a second-line agent, second to IL-2.[51]

Pegylated interferon alpha-2b (pIFN alfa-2b) is interferon alfa-2b that is conjugated to polyethylene glycol in order to reduce its rate of absorption and rate of clearance, while also increasing its immunogenicity.[52] In 2011 the FDA approved subcutaneous pegylated interferon alfa-2b (Sylatron, Merck & Co., Whitehouse Station, NJ) as a treatment for melanoma with microscopic nodal involvement after surgical resection. The Society for Immunotherapy of Cancer consensus statement on tumor immunotherapy, released in 2013, recommends standard interferon alpha-2b for patients with macroscopic nodal disease.[52] In summary, pegylated interferon alfa-2b could be considered in patients with microscopic nodal disease after surgical resection, whereas standard interferon alfa-2b should be used in patients with macroscopic nodal disease (N1b and N2-N3 disease).[45,51]

About half of melanomas harbor a mutation in BRAF; the most common genotypes are $BRAF^{V600E}$ and $BRAF^{V600K}$.[56,57] Detection of $BRAF^{V600}$ mutations has become routine in the evaluation of patients with advanced

disease or metastatic melanoma. Historically the presence of metastatic CNS disease is associated with lack of benefit from systemic therapies; however, today mainly BRAF inhibitors have shown evidence of benefit from systemic therapy if the tumor is BRAF mutation positive.[51] Today, two compounds are available within the selective BRAF inhibitor class: vemurafenib (Zelboraf, Genentech, South San Francisco, CA) and dabrafenib (Tafinlar, GlaxoSmithKline, London). The aforementioned mutations are point mutations causing $BRAF^{V600E}$ and $BRAF^{V600K}$ kinases to be constitutively active, resulting in sustained MAPK signaling and perpetual cell growth.[57] The BREAK-1 (phase I),[58] BREAK-2 (phase II),[59] BREAK-3 (phase III),[60] and BREAK-MB (phase II)[61] clinical trials have proven the safety of dabrafenib in patients with metastatic melanoma. Furthermore, a benefit of dabrafenib was identified for patients with unresectable stage III/IV BRAF mutation positive tumors in improving progression-free and overall patient survival. For instance, in the BREAK-3 trial an objective response rate with dabrafenib was determined to occur in 53% of patients, whereas with dacarbazine only 19% of patients had an objective response to treatment. Furthermore, these trials identified a higher response rate in the $BRAF^{V600E}$ positive tumors. Similarly, trametinib (GSK1120212, GlaxoSmithKline Pharmaceuticals, Philadelphia, PA), an oral MEK inhibitor, has also been found to improve overall survival in patients with metastatic melanoma with a BRAF mutation as a single agent when compared with conventional chemotherapy, dacarbazine.[62] In summary, today oncologists have at their disposal several pharmaceutical agents to combat disseminated melanoma. One must also not overlook the necessity and value of recommending a clinical trial for patients with unresectable disease.

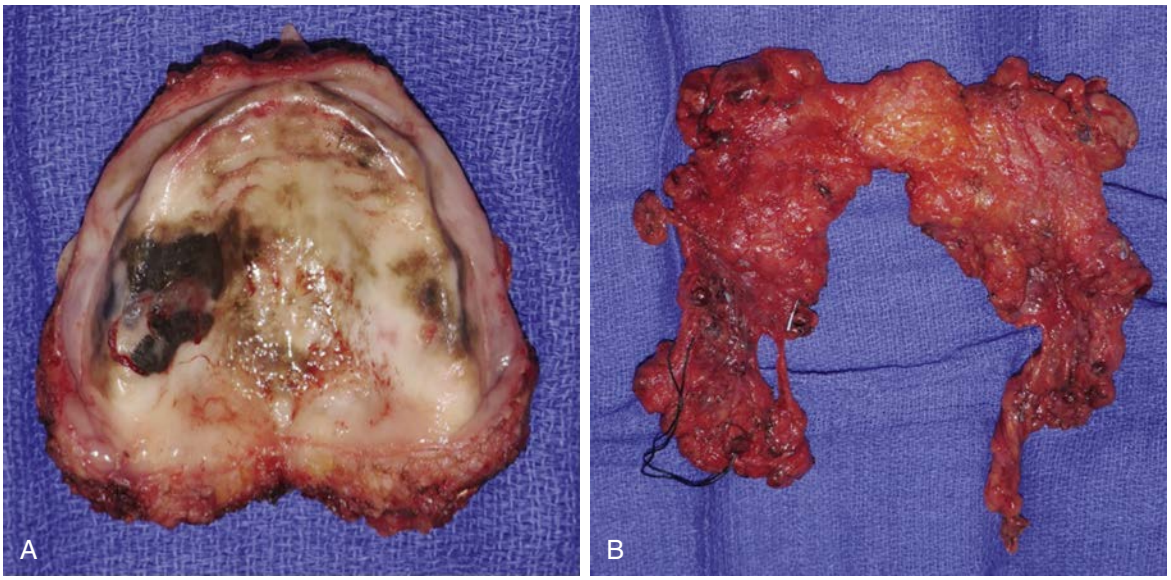
Oral Mucosal Malignant Melanoma

As previously discussed, melanoma is a cancer of melanocytes. Within the skin, melanocytes are located within the stratum basale of the epidermis, and their function is to produce melanin, a vital pigment that serves to protect the skin from damage from ultraviolet rays. However, melanocytes have been identified in extracutaneous tissues, including the nasal cavity, paranasal sinuses, oral cavity, larynx, tracheobronchial tree, uvea, esophagus, gallbladder, rectum, anal canal, vagina, and cervix.[63] Given that these anatomic sites are sun-shielded, the true function of melanocytes within these tissues is not well understood. Some studies have described non-pigment functions of melanocytes that include phagocytosis, antigen presentation, and cytokine production.[63-65] Therefore, the current thought is that melanocytes could play a role in the innate immune system within mucosal surfaces, as well as the skin. Similar to skin melanocytes, these extracutaneous melanocytes have the potential to become cancerous. However, mucosal malignant melanomas are still considered rare neoplasms, representing 1.4% of all melanomas.[63] The head and neck is the most common location of mucosal melanomas, accounting for 25% to 50% of cases, with the nasal cavity being the most common head and neck subsite.[66] Although these lesions are rare, they are unfortunately associated with a high mortality rate (5-year survival is around 25% irrespective of tumor stage), which is indicative of their highly aggressive biologic behavior.

TABLE 29-11 AJCC-TNM Classification and Clinical Staging of Mucosal Melanoma

Primary Tumor			
T3	Mucosal disease		
T4a	Moderately advanced disease. Tumor involving bone, deep soft tissue, cartilage, or overlying skin		
T4b	Very advanced disease. Tumor involving brain, dura, skull base, lower cranial nerves (IX, X, XI, XII), masticator space, carotid artery, prevertebral space, or mediastinal structures		
Regional Lymph Nodes			
Nx	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastases		
N1	Regional lymph node metastases present		
Distant Metastasis			
M0	No distant metastasis		
M1	Distant metastasis present		
Clinical Stage			
Stage III	T3	N0	M0
Stage IVA	T4a	N0	M0
	T3-T4a	N1	M0
Stage IVB	T4b	Any N	M0
Stage IVC	Any T	Any N	M1

Oral mucosal malignant melanoma is typically detected on routine oral evaluation. It is worth noting that whereas fewer than 2% of cutaneous melanomas are amelanotic, within the oral cavity 25% to 75% of cases are amelanotic.[66,67] With regard to the distribution of oral and sinonasal mucosal melanoma, 48% of lesions will occur in the oral cavity and 52% in the sinonasal region.[68,69] With sinonasal mucosal melanoma, 84% of cases will involve the nasal cavity. Within the oral cavity, Hicks and colleagues reviewed 703 cases of oral mucosal melanoma and reported that 32% of cases involved the palate, making the palate the most commonly involved subsite followed by maxillary gingiva.[69] The diagnosis of mucosal melanoma of the head and neck, unlike its cutaneous counterpart, should include an incisional biopsy. The reason we recommend an incisional biopsy is that the depth of invasion and microscopic features of a mucosal melanoma are not part of the staging process (Table 29-11). Therefore, preserving the periphery of the lesion could aid in determining surgical margins at the time of tumor extirpation. Furthermore, histologic diagnosis is



• **Figure 29-12** **A,** Specimen following bilateral subtotal maxillectomy for T3 mucosal melanoma (no bony invasion) with 3-cm surgical margin. **B,** Specimen following bilateral selective neck dissection (level I-IV).

complicated by the fact that only 50% to 70% of oral cavity melanomas stain positive for melanin.[70] Therefore, immunohistochemistry staining for S-100, MART-1, and HBM-45 is frequently performed to aid in histologic diagnosis.

Unfortunately, because of the rarity of this malignancy, there are no set guidelines or randomized clinical trials to aid in the management of these patients. Furthermore, from a public health perspective, unlike cutaneous melanoma, there is no known risk factor for mucosal melanomas to aid in disease prevention.

Because of the aggressive biologic behavior of this neoplasm and its poor overall survival, treatment consists of surgery, adjuvant radiation, and adjuvant chemotherapy/immunotherapy. Patients should be treated with multimodality therapy unless the extent of disease renders tumor unresectable, or the patient's performance status contraindicates surgery or adjuvant therapies. Nonetheless, as with all other forms of malignant melanoma, surgery typically offers the best outcome for the patient. However, because of the complexity of the local anatomy of the maxillo-mandibular complex, especially the maxilla, tumors that are diagnosed at a later stage could be deemed unresectable. Unlike cutaneous melanoma, surgeons treating oral mucosal melanoma do not have any randomized clinical trials to guide their decision making in choosing the size of surgical margin, and indication for SLNB versus ELND. The authors feel that a wide surgical margin (≥3 cm) should be safe enough (Figure 29-12). A liberal margin is imperative because frozen-section analysis is unreliable when dealing with mucosal melanoma, a result of the necessity for immunohistochemistry in histologic analysis. Furthermore, there is evidence to suggest that a negative margin offers survival benefit to these patients. Similarly, the role of lymph node dissection is not known. The incidence of nodal disease at first presentation for oral mucosal melanoma ranges from 25% to 48%.[71] Therefore, in the authors' practice, patients with oral mucosal melanoma will undergo an ELND, with the goal of appropriate staging and directing adjuvant radiation therapy. If the patient is able to tolerate adjuvant radiation therapy to the cervical lymph nodes, one could consider this option in patients with extracapsular extension and/or presence of two or more involved lymph nodes. Six percent to 14% of patients will present with distant metastasis.[71] Furthermore, there have been documented cases of distant metastasis of mucosal melanoma without lymph node involvement in other anatomic sites (i.e., anorectal); therefore, consideration should be given to obtaining an initial PET scan to assess for regional and distant disease.

Wushou and colleagues performed one of the more comprehensive and up-to-date reviews on oral mucosal malignant melanoma and identified a 4.69-fold increase in mortality in patients 60 years of age or younger.[68] These investigators also reported a 1.52-fold increase in mortality in patients managed with surgery alone, and a 12.84-fold increase in mortality in patients treated with nonsurgical modalities. These data highlight the importance of surgery in the management of oral mucosal malignant melanoma, and the need for adjuvant therapy. Even though both cutaneous and mucosal melanomas are considered radioresistant, it is common practice to recommend adjuvant radiation to the primary tumor site because of subclinical disease.[72]

As previously mentioned, 50% of malignant melanomas will be positive for BRAF mutation; however, in the case of all mucosal melanomas, only 9% will harbor this mutation.[73] Yet roughly 25% of all mucosal melanomas will harbor mutations in c-Kit.[73] In patients with c-Kit gene mutation, imatinib (Gleevec, Novartis Pharmaceuticals, Basel) could be beneficial. As in the case of cutaneous melanoma, vemurafenib and dabrafenib could be considered in patients with BRAF gene mutation. Del Vecchio

and colleagues evaluated the role of ipilimumab in 855 patients with unresectable cutaneous, ocular, and mucosal melanoma who had failed all other therapeutic options.[74] Within their cohort, 71 patients had metastatic mucosal melanoma, and with a medial follow-up of 21.8 months, they reported a response rate of 12% with immune-related disease control rate of 36%, and an overall survival of 6.4 months. The role of systemic therapies is less defined with mucosal melanomas. Adjuvant chemotherapeutics such as dacarbazine, platinum analogues, nitrosoureas, and IL-2 have shown a poor response rate.[72] Therefore, the role of chemotherapeutics in mucosal melanoma is primarily adjuvant or palliative. In conclusion, oral mucosal melanoma is a disease with a very poor prognosis; therefore, these patients should be managed with tumor extirpation with wide surgical margins with consideration for ELND, adjuvant radiation therapy, and conventional or novel systemic melanoma therapies.

Summary

Malignant melanoma is an increasingly common, potentially deadly entity that the oral and maxillofacial surgeon must be able to recognize. This disease is on the rise in pediatric and adult patient populations and has become a global health burden. Just within the United States, new cases of invasive melanoma will cost close to $2 billion annually.[53] It is imperative to fully understand the treatment and prognostic factors associated with this disease. Proper management requires a high index of suspicion and use of proper biopsy and excision techniques, as well as understanding the role of surgery in identifying and controlling locoregional and distant disease. Current issues in the management of malignant melanomas include an emphasis on sentinel node biopsy, as well as a treatment stratification based on the new AJCC staging system. Ongoing clinical trials will hopefully allow for better diagnostic and prognostic information, which will improve the management of this formidable disease.

30 Lymphoma

KETAN PATEL, AVANTI MEHROTRA, DEEPAK KADEMANI

Introduction

Lymphoma is a general term for a complex group of heterogeneous lymphoreticular malignancies. Lymphoma is the sixth most common malignancy and the second most common neoplasm of the head and neck after squamous cell carcinoma and accounts for 50% to 59% of head and neck neoplasms in children.[1,2] They constitute approximately 3% to 5% of all known malignancies and are generally divided into two morphologically distinct types: Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).[3-6] These malignancies typically arise within the lymphatic tissues and can progress to extranodal disease as in NHL. Cervical lymph node involvement can be present in any type of lymphoma. HL extends by means of contiguous nodal spread, whereas NHL tends to disseminate hematogenously and is typically a systemic diagnosis. Within the head and neck, Waldeyer ring is the most common site of involvement,[7-9] accounting for more than half of all extranodal head and neck lymphomas. Oral involvement by lymphoma may represent a localized disease process but is more often part of a systemic process that secondarily involves the cervical lymph nodes.

Lymphoma arising within the oral cavity accounts for less than 5% of all oral malignancies, and approximately 85% of these lesions involve the pharyngeal tonsil and the palate (Figure 30-1). Extralymphatic sites include the salivary glands, paranasal sinuses, oral cavity, and larynx.

Lymphomas are currently classified based on morphologic, immunophenotypic, genetic, and clinical features. Several classification systems have been used to classify lymphomas, including the World Health Organization (WHO) classification, which is based on the principles defined in the Revised European-American Classification of Lymphoid Neoplasm (REAL). Both the WHO and REAL classifications divide lymphomas based on cell of origin into two large categories: Hodgkin Lymphoma and Non Hodgkin Lymphoma (NHL).

HL is subdivided into Classical Hodgkin and Nodular Lymphocyte Predominant HL (NLPHL).

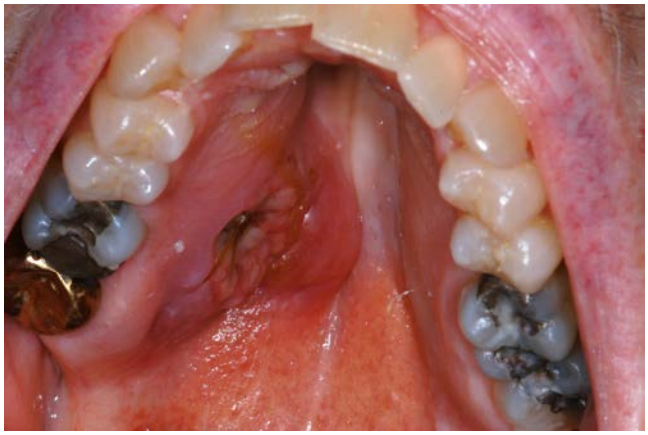
NHL is a group of heterogenous diseases that vary widely in pathology, behavior, and therapy. This is broadly divided into B-cell NHL and T-NK (natural killer)-cell lymphoma, which are then further subdivided[3,4,10-12] (Box 30-1).

Diagnosis

Patients often present with a neck mass to oral and maxillofacial surgeons (Figure 30-2). Therefore, it is critical when assessing neck masses to have a well-developed algorithm for their evaluation (Figure 30-3). This will enable earlier-stage diagnosis and expeditious treatment.

Nodal presentation of a lymphoma typically presents with a neck mass of small to medium-sized lymph nodes with a rubbery consistency that progressively become larger. Lymph nodes larger than 1 cm that persist for more than 4 to 6 weeks in the absence of infection should be evaluated histologically.[13] There are several specific criteria for biopsy of suspected lymphoma. It is preferable that the largest accessible lymph node be removed for histologic diagnosis. Excisional biopsy provides the highest yield diagnostically. The excised lymph node should preferably be intact and undistorted. Fine-needle aspiration (FNA) may on occasion be diagnostic when augmented with immunophenotyping studies and is a useful diagnostic modality for intra-abdominal, thoracic, or retroperitoneal lymph nodes. FNA is often used to obtain tissue for surveillance in the post-treatment setting.[9,13]

The diagnosis of lymphoma is based on the histopathologic examination of enlarged cervical lymph nodes or from extralymphatic tissue. Immunophenotyping of lymphomas, by either immunohistochemistry or flow cytometry, is critical for accurate classification of a lymphoma. The majority of B-cell lymphomas express the pan-B cell antigen CD20, whereas T-cell lymphomas express the T-cell antigen CD3. Both sets are positive for the leukocyte common antigen CD45. Hodgkin lymphoma lacks the B-cell and T-cell antigens. The classical Hodgkin pathognomic cell is the Reed-Sternberg cell that typically expresses CD15 and CD30.



• **Figure 30-1** Non-Hodgkin lymphoma (follicular type) presenting as an intraoral palatal mass with mucosal ulceration.

• BOX 30-1 Classifications of Lymphomas

Hodgkin Lymphoma

- Classical Hodgkin lymphoma
- Nodular sclerosis
- Mixed cellularity
- Lymphocyte-rich
- Lymphocyte-depleted
- Nodular lymphocyte predominant Hodgkin lymphoma

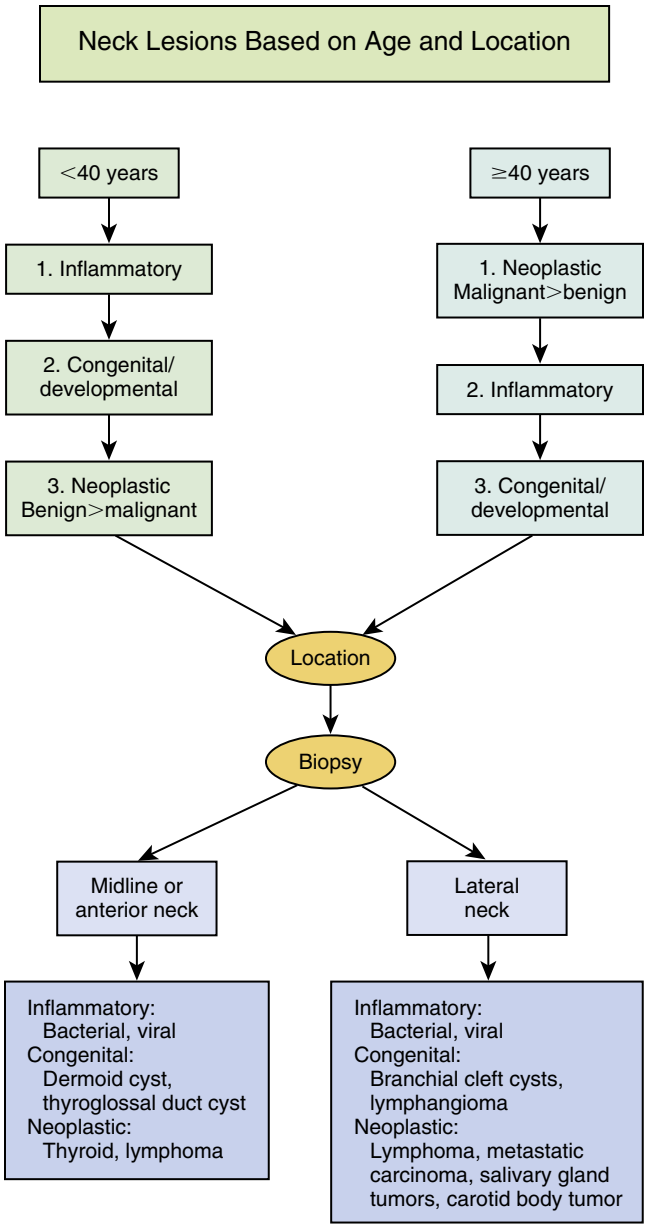
Non-Hodgkin Lymphoma

- Precursor B-cell neoplasms
- Mature B-cell neoplasms
- Small cell lymphoma/chronic lymphocytic leukemia
- Extranodal marginal zone B-cell lymphoma of mucosa associated lymphoid tissue (MALT-lymphoma)
- Follicular
- Mantle cell
- Diffuse large cell
- Burkitt (African and endemic)
- Others
- Precursor T-cell
- Mature NK/T-cell
- Extranodal NK/T-cell lymphoma, nasal type
- Anaplastic large cell
- Mycosis fungoides
- Others

The clinical staging of NHL and HL is based on a combination of clinical, radiologic, and surgical findings. In order to appropriately stage lymphoma, a complete medical history, physical examination, urinalysis, blood chemistries, complete blood count with differential, and bone marrow biopsy are required. Imaging modalities are also required, and this centers on obtaining a computed tomography (CT) scan with intravenous contrast, which should include the head and neck, mediastinum, abdomen, and pelvis. Positron emission tomography (PET)-CT scan is now used whenever possible for initial staging. A bone marrow biopsy is typically performed from the iliac crest, because approximately 18% of non-HLs involve the bone marrow.[13-16] If central nervous system (CNS) involvement is suspected, a lumbar puncture is indicated. Lumbar puncture with cerebrospinal fluid flow cytometry is performed in high-risk cases of DLBCL involving the head and neck area, paranasal sinuses, or bone marrow and in testicular and extranodal disease. For patients with head and neck lesions, a nasopharyngoscopy should also be performed. The immunohistochemical analysis of the tumor is essential for diagnosis and for targeting novel therapies.

• **Figure 30-2** Elderly female patient with palpable cervical and parotid tail enlargement. Diagnosed as diffuse large cell non-Hodgkin lymphoma.

The Ann Arbor staging system (see Figure 30-3) is applicable to both HL and NHL and provides the basis for staging.[9,12,13,15,17] The Ann Arbor system depends on the number of lymph node regions involved, the presence of extranodal disease, the presence of disease above and below the diaphragm, and the existence of concomitant constitutional symptoms (*category A* for those patients without systemic symptoms; *category B* for patients with defined systemic symptoms including fever, chills, night sweats, and greater than 10% weight loss). These symptoms are more commonly associated with HL and are prognostically significant if present for both NHL and HL. In addition to routine histologic examination, the presence of genetic and chromosomal abnormalities is common in lymphoma. Aneuploidy occurs in HL; translocations such as *c-myc* gene may be seen in Burkitt lymphoma, and *bcl-2* may often be found in follicular lymphomas. Infection such as Epstein-Barr virus, HIV-1, *Helicobacter pylori,* hepatitis B and C, and human herpesvirus 8 may all be implicated in the pathogenesis of lymphoma.[3,12,15,18-21] The presence of chronic inflammation also increases the risk of developing

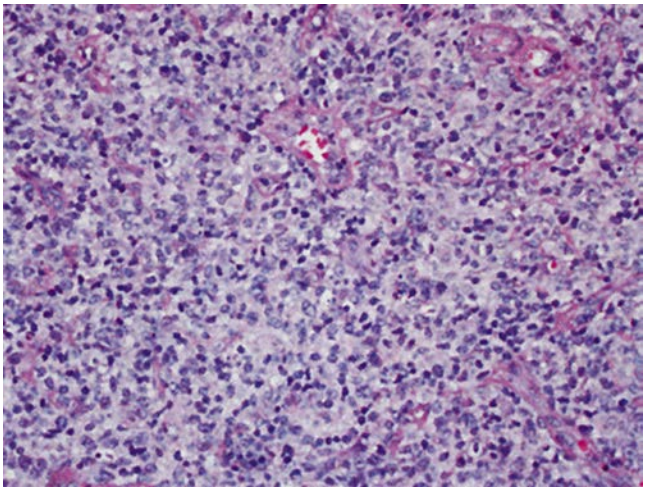


• **Figure 30-3** Evaluation of a neck mass. (Adapted from Bagheri S: *Clinical review of oral and maxillofacial surgery*, St Louis, 2008, Mosby.)

lymphoma as is seen with mucosa-associated lymphoid tissue (MALT) lymphoma in patients with Sjögren syndrome and rheumatoid arthritis.[16,21-27]

Hodgkin Lymphoma

HL is a disorder that is localized to the lymph nodes in more than 90% of cases. HL can be divided into two forms: classical HL (CHL) and nodular lymphocyte predominant HL (NLPHL). CHL is further subtyped into nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted forms. Distinguishing CHL from NLPHL is the most important breakpoint because of their differing clinical presentation, behavior, and immunohistologic features. The majority of cases (95%) are of the classical form, with



• **Figure 30-4** Large collection of Hodgkin cells. Multinucleated Reed-Sternberg cells are also present.

the nodular sclerosis subtype accounting for 70% of these cases.[13,28] This type of classic lymphoma has a bimodal age distribution, with a peak incidence between 20 and 25 years and a second peak in the eighth decade. In the majority of cases (98%), the malignant cells of CHL arise from a mature B-cell.[28] The uninucleated forms are referred to as Hodgkin cells or Reed-Sternberg cell variants, whereas the multinucleated, diagnostic cells are referred to Reed-Sternberg cells (Figure 30-4). All Hodgkin cells in CHL have a similar immunophenotype: *CD15 +ve, CD30 +ve, and CD20 –ve.* Approximately 5% of HL cases are of the NLPHL type, which may occur at any age with a peak between 30 and 50 years old.[28] Like CHL, NLPHL also arises from a mature B cell. However, the neoplastic cells in this type are characterized as large cells with convoluted nuclei. Hence, they are referred to as popcorn or L&H cells (lymphocytic and/or histiocytic Reed-Sternberg cell variants). In contrast to classic RS cells, L&H cells are typically *CD30 –ve, CD45 +ve, and CD20 +ve.*[12] HL is very uncommon in children less than 5 years of age.[12]

HL accounts for approximately 14% of all lymphomas, making it significantly less common than NHL.[3,6,10,15] HL presents rarely as extranodal disease (1% to 4%), whereas NHL occurs in extranodal sites in up to a third of cases.[13,29] Classically, HL occurs in a single lymph node that then progressively involves contiguous lymph node structures. This pattern is in contrast to NHL, where noncontiguous spread to lymphatic structures or extranodal sites is more commonly seen. Clinically, HL causes generalized symptoms or laboratory abnormalities in 41% of patients, as compared with 27% of patients with NHL.[9] The distinction between HL and NHL can only be made histopathologically, because clinical and radiographic presentation often fail to distinguish between these two groups of lymphomas. The distribution of lymph node involvement between HL and NHL varies, with 24% of patients with HL versus 33% of patients with NHL presenting with cervical lymphadenopathy.

Non-Hodgkin Lymphoma (NHL)

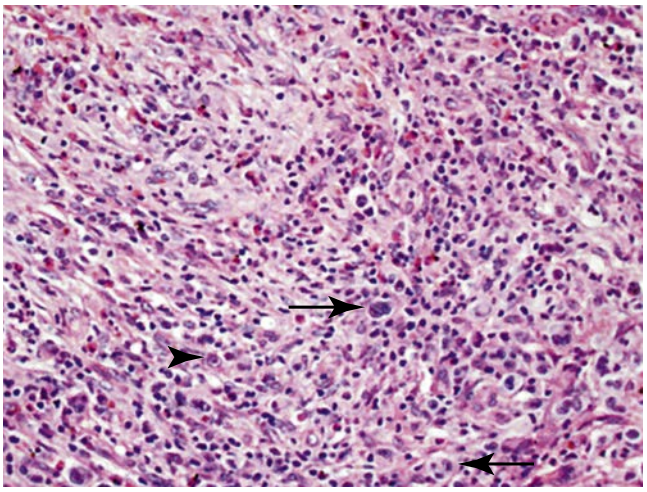
NHL represents a diverse group of lymphoreticular neoplasms, which may be divided broadly into B-cell and T-cell forms. Mature B-cell lymphomas constitute more than 85% of NHL worldwide.[28] Some forms include follicular lymphoma, B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma, diffuse large B-cell lymphoma, lymphoplasmacytic lymphoma, splenic marginal zone lymphoma, extranodal marginal zone B-cell lymphoma of MALT lymphoma, mantle-cell lymphoma, and Burkitt lymphoma. All of these lymphomas share expression of the pan-B-cell marker CD20. In addition, many of them also have other specific immunophenotypic profiles that allow for definitive classification. Plasma cell proliferations, such as myeloma or plasmacytoma, also fall under the category of mature B-cell neoplasms, but these are typically CD20(–).

The gastrointestinal system is the most frequently involved extranodal site, which occurs in over 50% of patients.[16,20,30-33] This is followed by the head and neck, which is affected in 11% to 33% of patients.[33] NHL of the head and neck arises in lymph nodes in 65% of cases and in extranodal sites in 25% to 30%.[16] NHL of the head and neck occurs predominantly in patients between the ages of 50 and 60. NHL may spread to regional and distant lymphatic sites as well as parenchymal organs including liver, spleen, lung and bone marrow.

Follicular lymphoma (FL) occurs in an older population, has a relatively indolent course, and constitutes approximately 40% of NHL in adults. It typically manifests as painless lymphadenopathy, splenomegaly, and bone marrow involvement. This lymphoma has a follicular center cell origin and histologically has nodular effacement of the lymph node. The lymphoma cells are CD20, CD10, BCL6, and BCL2(+). BCL2 is an anti-apoptosis gene, which is expressed in FL and allows for distinction from reactive follicular hyperplasia, which is BCL2(–).[28]

Extranodal marginal zone B-cell lymphoma of MALT lymphoma also displays an indolent clinical evolution. This type of lymphoma is commonly seen within the head and neck and in particular extralymphatic sites such as the thyroid and salivary glands and is commonly associated with other autoimmune diseases such as Hashimoto thyroiditis and Sjögren syndrome.[24,25,30,34-38] This lymphoma forms characteristic lymphoepithelial lesions in which the neoplastic lymphocytes infiltrate and injure ducts and glands of the involved organ (Figure 30-5).

Diffuse large B-cell lymphoma (DLBCL) is the most common type of NHL in the head and neck, constituting over 50% of cases. This form of lymphoma has a median age of occurrence of 60 and most often presents as a rapidly enlarging single or extranodal mass.[2,39] Waldeyer ring is the most commonly involved site in the head and neck for DLBCL, which can also affect the paranasal sinuses and oral cavity but is relatively rare in the orbital adnexa. Histologically, the lymphoma cells are CD20(+) B-cells whose nuclei are larger than the nuclei of a macrophage or endothelial cells. This lymphoma typically causes a diffuse effacement of the lymph node architecture (Figure 30-6). Some cases of DLBCL represent transformation of a more indolent lymphoma, such as FL or B-cell CLL/SLL. Gene expression profiling and identifying genetic subtype of DLBCL by molecular tying is rather important. DLBCL that have c-myc translocation portend poorer prognosis and have lesser response to therapy.[40] An even more aggressive form of DLBCL is when there is coexpression of c-myc and bcl-2 protein by IHC.[41] The term "double-hit" lymphoma is now used for DLBCL that have translocations of both c-myc gene at (8q24) and bcl 2 gene at (18q21).[39,42]

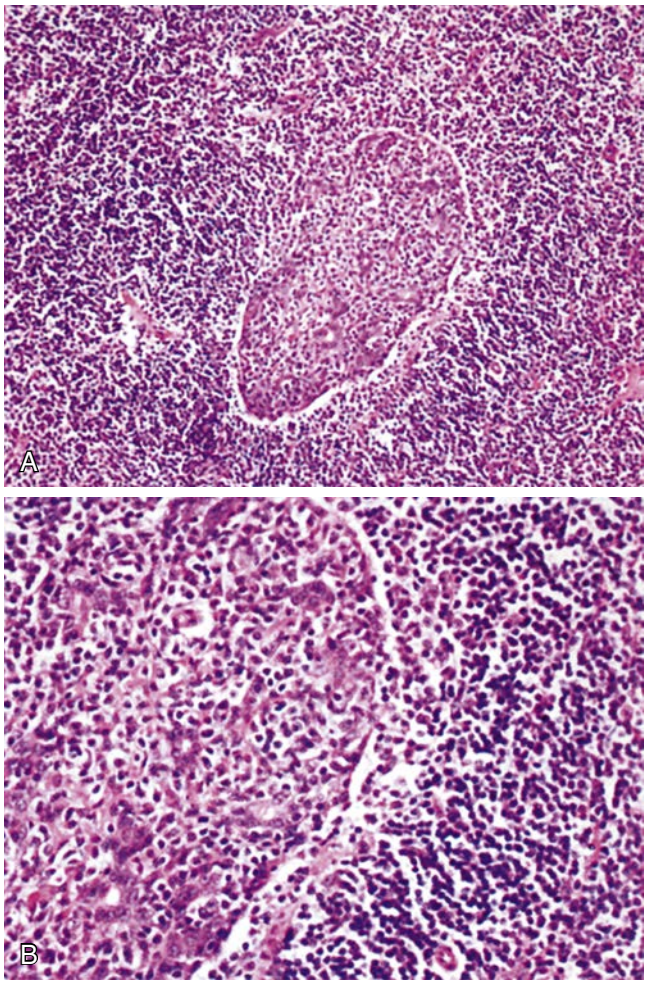


• **Figure 30-5** Diffuse large B-cell lymphoma. Medium-high power view showing sheet of large, atypical cells with moderate amounts of amphophilic cytoplasm. Small, reactive lymphocytes are interspersed. Scattered Reed-Sternberg cells *(arrows)* and uninucleated Hodgkin cells *(arrowhead)* present in the typical inflammatory background of classical Hodgkin lymphoma. Numerous eosinophils and plasma cells are a common finding.

Burkitt lymphoma, an aggressive form of B-cell lymphoma, has three notable forms: endemic (African), sporadic, and immunodeficiency associated.[32] Endemic BL involves the maxillofacial region in 50% of cases. Sporadic BL more often tends to involve the intra-abdominal contents. Immunodeficiency-associated BL often involves lymph nodes and bone marrow.

Angiocentric Lymphoma

Some lymphomas that involve the sinonasal tract show a peculiar angiocentric/angiodestructive growth pattern. These processes have historically gone by various confusing terms, including polymorphic reticulosis, lethal midline granuloma, lymphomatoid granulomatosis, and malignant midline reticulosis.[28] Histologically there is ulceration and a mixed inflammatory infiltrate, not the typical monotonous proliferation seen in other lymphomas. In addition to T-cell lymphoma, which would be CD3(+), and EBV-associated B-cell lymphoma (CD20+), extranodal NK/T-cell lymphoma, nasal type, can cause this pattern.

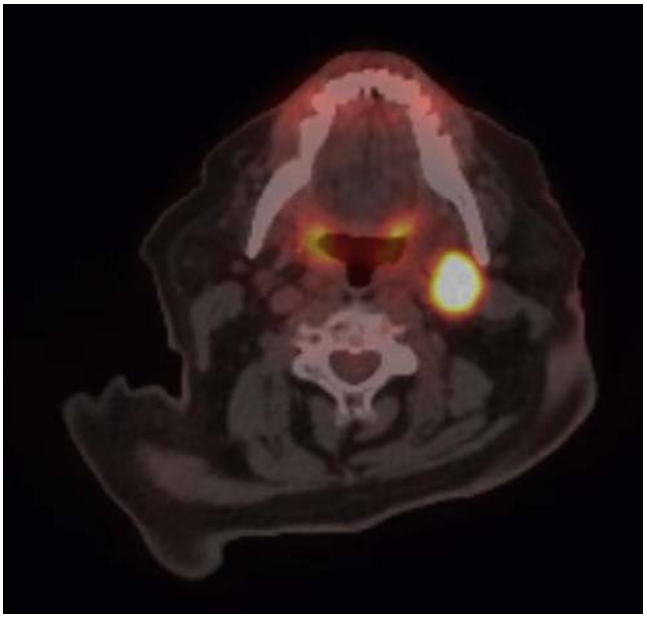


• **Figure 30-6** Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma). **A,** Aggregates of small to medium-sized lymphocytes with moderate amounts of cytoplasm. The lymphoma cells characteristically infiltrate the epithelial glands and ducts, forming lymphoepithelial lesions. **B,** Higher-power view of a lymphoepithelial lesion *(left half of field)*.

Nasal-type NK/T-cell lymphoma is almost always associated with EBV and typically is surface CD3(–) (as opposed to most T-cell lymphomas) and CD56(+). This lymphoma is thought to arise from activated NK cells or cytotoxic T-cells. Nasal-type NK/T-cell lymphoma has a variable prognosis, but often behaves in an aggressive manner.[28]

Post-transplant Lymphoproliferative Disorder

Patients who have undergone a solid organ transplant or allogeneic stem-cell transplant for hematologic malignancies are placed on immunosuppressive medications such as cyclosporine and mycophenolate to prevent transplant rejection or to reduce graft-versus-host disease. These patients are at an increased risk of development of lymphomas. This can frequently occur in the buccal mucosa or any lymphoid aggregate in the head and neck region. The disorder can range from a mild lymphoproliferative disorder, to low-grade lymphoma, to aggressive high-grade lymphoma. These are mostly EBV associated as well. Treatment involves reduction of immunosuppression, which places them at risk of transplant rejection. However, this is quite effective in the treatment of the lymphoma.



• **Figure 30-7** Positron emission tomography/computed tomography (PET/CT) scan of a diffuse large cell lymphoma with fluorodeoxyglucose-avid node in left neck.

Radiographic Evaluation

CT scan with intravenous contrast is the primary modality for radiologic assessment of enlarged lymph nodes associated with head and neck lymphoma. Enlarged cervical lymph nodes are typically isodense with muscle and usually appear as a homogeneous conglomerate mass. More recently, PET/CT has become the modality for the initial staging for lymphomas (Figure 30-7). Necrosis is not a prominent primary feature of lymphoma. Aggressive lymphoid lesions may have extracapsular lymph node extension with invasion of adjacent soft tissue structures. It is not uncommon for cervical lymph nodes to form a large matted mass, mimicking an extranodal primary malignancy.[43-45]

An extranodal lymphoma typically manifests as a firm submucosal mass, often lobulated; however, it classically presents with an intact overlying mucosa, unlike squamous cell carcinomas of the head and neck. Osteolytic bone lesions can be displayed by aggressive high-grade lesions similar to other malignant processes. Low-grade lymphomas such as MALT lymphoma are rarely associated with bone destruction. Magnetic resonance imaging (MRI) typically manifests low signal intensity on T1-weighted images, with intermediate signal intensity on T2-weighted images. However, the mainstay of diagnosis continues to be CT scan

with intravenous contrast with formal immunophenotypic analysis of lymphoid tissue and bone marrow biopsy.[45-47]

There are several specific sites within the head and neck that may develop lymphomatous disease and deserve special discussion. Waldeyer ring comprises a network of lymphoid tissue within the nasopharynx, which includes the nasopharynx, base of tongue, and pharyngeal tonsils. It is the most common site of extranodal lymphoma within the head and neck and accounts for more than 60% of extranodal lymphoma. The majority of Waldeyer ring–associated lymphoma is seen in patients in the sixth to seventh decade of life and has a 10% association with concomitant gastrointestinal tract lymphoma.[8,24,37] DLBCL is the most frequently seen morphologic variety of lymphoma in 50% to 60% of cases, and most patients present with early stage I or stage II disease.[13] HL has rarely been reported in the Waldeyer ring or nasopharynx. Radiographic examination typically demonstrates a large bulky mass involving one or all three lymphoid sites within Waldeyer ring. The most commonly affected site within Waldeyer ring is the pharyngeal tonsil, seen in 37% to 52% of cases, followed by the nasopharynx and least commonly the base of the tongue.[48,49] On radiographic examination, these lesions typically present as an isolated isodense mass to muscle with submucosal extension with relatively normal overlying mucosal tissue. Mucosal ulceration as seen in squamous cell carcinoma is not a typical feature.

Lymphomas of the oral cavity constitute 2% of extranodal lymphomas.[26] The majority of site involvement includes the palate, maxilla, and gingival tissues. Oral cavity lymphoma is more frequently seen in patients with immunosuppressive diseases and in particular those who have HIV infection.[50,51] More than 50% of lymphomas within the oral cavity are of the DLBCL variety, with follicular lymphoma and MALT lymphoma being the next most common, respectively.[52] The tumor may originate within the soft tissue structures as a localized exophytic bulky mass or may have osteolytic lesions as is typically seen with Burkitt lymphoma.[26,53]

Lymphoma is the second most common malignancy of the paranasal sinuses after squamous cell carcinoma.[35,54] In extranodal NHL of the head and neck, approximately 6% to 13% occur in the paranasal sinuses.[35,54] The most common variant is DLBCL. T-cell lymphoma invariably involves the nasal cavity, which is the primary site for this form of malignancy. Paranasal sinus lymphomas are considered moderately aggressive and commonly will extend into the orbital vaults. They are clinically and radiographically indistinguishable from the more commonly seen epidermoid tumors of the head and neck. Direct involvement of the nasal vault from paranasal sinus tumors is not unusual. However, a small percentage of lymphomas arise primarily in the nasal cavity. These are typically extranodal NK/T-cell lymphomas. The median age of presentation is 50, with a typical male predominance.[55] Lymphoma localized to the nasal vault will typically cause osteolytic bone destruction with concomitant extension into the paranasal sinuses, alveolar bone, or hard palate with soft tissue extension into the masticator, buccinator, pharyngotemporal, and infratemporal fossa, nasopharynx orbit, or intracranial vault. NK/T-cell lymphoma typically exhibits an aggressive clinical course with early multi-organ involvement and poor patient survival. Extranodal nasal NK/T-cell lymphoma is much more prevalent in Asia than in Latin America or Europe and has a high association with Epstein-Barr virus.[55-57]

Salivary gland lymphomas comprise 2% to 5% of all salivary gland neoplasms, with the parotid gland involved in more than 70% of cases.[58-60] Histopathologically, these are typically B-cell lymphomas, with the MALT-type occurring in one third of cases, follicular lymphoma in one third, and DLBCL in the remaining one third. MALT-type lymphomas are typically seen in the parotid parenchyma, whereas follicular lymphomas are more commonly seen within intraparotid lymph nodes.[58-60] Twenty percent of patients have an association with other immunotypical diseases such as Sjögren syndrome, as is seen with MALT lymphoma.[29] An important diagnostic and prognostic finding is the presence of extra salivary gland involvement to adjacent cervical lymph nodes, which is seen in 20% to 45% of cases.[29]

NHL may involve the mandible or maxilla. The peak incidence is between 25 and 40 years of age, with clinical manifestation representing persistent facial swelling, loose teeth, and gingival bleeding. The majority of maxillofacial lymphomas are DLBCL.[43,46] HL as a primary lesion is infrequently seen in the maxillofacial structures. However, 20% of cases with systemic involvement are associated with bony involvement, which may include the maxillofacial structures secondarily. Bone lesions are typically osteolytic in 70% of cases, sclerotic in 4.3%, and mixed in 16%.[26,61] Periosteal reaction can be seen with a variable soft tissue mass. Burkitt lymphoma will often present with primary disease being localized to the maxillofacial structures. Jaw lesions are seen in up to 50% of patients, most often occurring at the angle of the mandible. Typical radiographic features include loss of lamina dura with an associated osteolytic lesion with concomitant periosteal reaction.[62]

PET scan is now an important part of initial staging of lymphomas. Lymphoma masses are usually associated with increased hypermetabolic uptake. PET scan is used to monitor response as well. Resolution of hypermetabolic uptake on PET scan (negative PET scan even though mass may still be present) midway through chemotherapy is an extremely important prognostic factor and portends good prognosis. In Hodgkin lymphoma, PET scans are obtained after the initial two cycles of chemotherapy for prognostic information.

After the treatment is completed, disease may be followed by surveillance. Maximum recurrences occur within the first year, and most of the remaining recurrences happen within the second year after completion of treatment. Thus, having normal scan results at 1 year and 2 years after treatment is considered an important landmark in the course of treatment of lymphomas.

Treatment

Lymphomas are typically treated with medical management with chemotherapy or radiotherapy or else a combination of these, rather than primary surgical management. In most instances, for early stage I/II disease, treatment involves a reduced schedule of chemotherapy followed by radiation. However, for advanced-stage disease, treatment is chemotherapy. In advanced-stage disease, radiation therapy is added only for bulky disease. Radioimmunotherapy is yet another modality used for relapsed disease. It is a combination of monoclonal antibody labeled with a radioisotope such as yttrium-90 or iodine-131.

Several chemotherapeutic options are available for systemic management of lymphoreticular diseases. This is mostly a combination of targeted therapy (usually a monoclonal antibody) along with conventional cytotoxic chemotherapy. Some important regimens for NHL are:

- R-CHOP: rituximab-cyclophosphamide, hydroxyadriamycin, vincristine, and prednisone
- BR: bendamustine-rituximab
- RICE: rituximab-ifosfamide, carboplatin, etoposide
- R-DHAP: rituximab-dexamethasone, cytarabine, cisplatin
- R-CVP: rituximab-cyclophosphamide, vincristine, prednisone
- R-Hyper-CVAD: rituximab-cyclophosphamide, vincristine, doxorubicin, dexamethasone, methotrexate, cytarabine
- R-CODOX-M/ IVAC: rituximab-cyclophosphamide, doxorubicin, vincristine, methotrexate/ifosfamide, etoposide, cytarabine
- R-EPOCH: rituximab-etoposide, vincristine, infusional doxorubicin, cyclophosphamide, prednisone

Chemotherapy for NHL is very successful and produces excellent local, regional, and systemic control of the disease. The International Prognostic Index (IPI) helps predict prognosis and outcomes. The IPI scoring system incorporates age, clinical factors (ECOG performance status and serum lactate dehydrogenase concentration), and stage of the disease. This is therefore, used as a guide to establish a treatment plan as well. Depending on the IPI score, relapse and cure rates for different disease states are determined.

When patients relapse after first-line treatment, they are treated with salvage high-dose chemotherapy followed by autologous stem-cell transplantation. Certain types of NHL deserve some additional discussion. Indolent B-cell NHL (for example, follicular lymphoma, marginal zone lymphoma, low-grade mantle-cell lymphoma, or splenic marginal zone lymphomas) may be managed with observation for a certain period of time. They are followed along and treatment is undertaken only when progressive disease is identified or if the patient develops considerable constitutional symptoms. Sometimes, this happens years after initial diagnosis. For these asymptomatic, low-grade, indolent NHLs, cure is not possible. Thus, delaying therapy until symptom development or disease progression is no significant detriment to overall survival outcome.[63]

Mantle cell lymphoma can have different courses. Some are very aggressive and need aggressive chemotherapy. Intensive chemotherapy regimens such as hyper-CVAD regimen (fractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone) seem to improve initial response rate and remission.[64] However, this regimen is highly toxic, which can be associated with significant morbidity and mortality. Patients with mantle-cell lymphoma will often undergo autologous stem-cell transplantation during the first remission because of poor outcomes with less intensive treatment regimens. However, there is another subset of patients with mantle-cell lymphoma who have a more indolent course and have outcomes similar to those of patients with follicular lymphomas.

Burkitt lymphoma is a highly aggressive B-cell lymphoma associated with EBV and is traditionally associated with a dismal prognosis, with the majority of patients dying within 1 year of diagnosis. However, the use of intensive chemotherapy regimens has significantly improved patient survival. The use of the R-CODOX-M regimen (cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate), as described by Magrath and colleagues,[65] has shown the potential to cure the majority of adults with Burkitt lymphoma. The use of stem-cell transplantation in the initial management of patients with Burkitt lymphoma has not been shown to increase patient survival. Patients with relapse are rarely salvaged with any treatment approach.

MALT lymphomas are low-grade lymphomas. The majority of MALT lymphomas occur within the gastrointestinal tract and are associated with *H. pylori* infection. Frequently in patients with early-stage disease, eradication of *H. pylori* leads to tumor regression. Patients who do not respond to initial eradication of *H. pylori* or do not have documented *H. pylori* infection with gastric MALT lymphoma may be treated with combined chemo-radiotherapy. Patients with localized MALT lymphoma to the head and neck again are managed primarily with chemo-radiotherapy with localized field radiotherapy, with surgical dissection limited to local regional recurrence.[66,67]

T-cell non-Hodgkin lymphomas are also treated with the same regimens. However, these do not express the target CD20 on the surface. Thus, targeted therapy with rituximab is not used for T-cell NHL. Response to chemotherapy in T-cell NHL is not as robust. Regimens used include:

- CHOP: cyclophosphamide, hydroxyadriamycin, vincristine (Oncovin), prednisone
- Pralatrexate
- Anti-CD30 antibody: brentuximab vedotin

Hodgkin lymphoma is treated with different chemotherapy regimens. The early stage is treated with fewer cycles of chemotherapy in combination with radiation to follow. Advanced-stage disease is treated with chemotherapy alone.

Radiation therapy is employed for early-stage disease and for bulky disease. Commonly used chemotherapy regimens are:

- ABVD: adriamycin, bleomycin, vinblastine, dacarbazine
- BEACOPP: bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone
- Stanford V: mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, prednisone

Cure rates are high even in advanced-stage disease in younger patients, being more than 85%.[68]

For relapse disease, high-dose chemotherapy followed by autologous stem-cell transplant is a very effective salvage therapy. Anti-CD30 targeted therapy with brentuximab has shown excellent control for relapsing disease. Thus, long-term consequences of therapy need to be kept in mind when choosing treatment for these patients. Radiation therapy typically involves field radiation and is effective for local control. It does increase the risk of second malignancies in these patients. The risk for solid tumors increases from 2% at 10 years to 13% at 19 years. Potential long-term side effects of chemotherapy include myelodysplasia, cardiomyopathy, and pulmonary toxicity.

Post-transplant lymphoproliferative disease is a varied group of diseases. It can respond to reduction of immunosuppression. However, sometimes therapy with targeted agents such as rituximab is added. For aggressive, advanced disease or disease not responding to reduction of immunosuppression, chemotherapy with CHOP or R-CHOP can be used with an excellent success rate.

• BOX 30-2 Ann Arbor Staging System for Lymphoma

Stage I

Involvement of a single lymph node or localized involvement of a single extralymphatic organ or site.

Stage II

Involvement of two or more lymph node regions on the ipsilateral side of the diaphragm.

Localized involvement of the extralymphatic organ or site and one or more lymph node regions on the same side of the diaphragm (IIE).

Stage III

Involvement of lymph node regions on bilateral sides of the diaphragm, which may be accompanied by localized involvement of an associated extralymphatic organ or site.

Stage IV

Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node involvement.

Letter Designations

A—Asymptomatic
B—Constitutional symptoms: Fever >38° C, drenching night sweats, >10% weight loss within 6 months
E—Extranodal
X—Bulky disease; tumor diameter is greater than >10 cm

Discussion

Lymphomas are a heterogeneous group of lymphoreticular neoplasms. Patients with lymphomas generally have a better prognosis than patients with squamous cell carcinoma of the head and neck. The 5-year survival rate for HL is 73% and 65% for extranodal NHL head and neck lymphoma. HL accounts for approximately 30% of all malignant lymphomas. The typical presenting feature of lymphoma for both HL and NHL is the development of a mass within the head and neck or pain. There are several classification systems for lymphomatous disease, including the WHO and REAL classification systems. The Ann Arbor staging classification system is widely used in North America and is based on the anatomic extent of tumor involvement (Box 30-2). Patients presenting with stage I or stage II disease have a more favorable prognosis compared with patients presenting with advanced stage III or stage IV disease. The natural history and prognosis of HL are based on the histologic type, stage, and the presence or absence of systemic symptoms. The 5-year survival for all tumor types managed with chemo-radiotherapy is greater than 80%.

NHL is a neoplastic proliferation of lymphoid cells that is often disseminated and can be prognostically differentiated into several immunophenotypes as well as into low-, intermediate-, and high-grade lesions. Disease that is low- or intermediate-grade has a more favorable prognosis and, when localized, may well respond to localized field radiotherapy alone. Localized stage I and stage II low-grade NHLs are primarily treated with radiotherapy. Surgery is primarily used as a diagnostic modality. In deeply invasive disease or with documented evidence of systemic involvement, the addition of chemotherapy has improved patient survival.

The overall prognosis of patients with lymphoma is associated with histologic type and stage of disease at presentation. The IPI scoring system is rather helpful in predicting prognosis. Low-grade lesions have a 5-year survival of over 80% compared with 52% for those with high-grade histologic types. Stage is also an important prognostic feature, with 83% of patients with stage I disease surviving more than 5 years compared with only 49% of patients with stage II and higher.[15,65] Although post-treatment remission often occurs in treatment of low-grade lymphomas, the disease can often have an indolent course with a significant risk of transformation to a more aggressive lesion.

Oropharyngeal and oral cavity lymphomas are the second most common malignant disease in the oral cavity. It is critical for health care providers, and in particular maxillofacial surgeons, to be able to identify a well-defined algorithm for the management of neck masses and to recognize and initiate appropriate early management of lymphoreticular disease in order to improve overall survival.

Non-melanoma Skin Cancer of the Head and Neck

FAYETTE C. WILLIAMS, JON D. HOLMES

Introduction

Non-melanoma skin cancer (NMSC) is the most common malignancy in the United States, with more than 2 million patients treated each year.[1] More than $426 million is spent yearly on skin cancer treatment, with the majority of care provided in an office setting.[2] When defined as impaired ability to work and lost future earning potential due to premature death, an estimated $10.2 billion in yearly lost productivity has been calculated to result from skin cancers, excluding melanoma.[3] Available research on cost reveals a broad range of expenditures depending on the care setting and the treatment modality. Office settings offer the lowest average cost per episode of care ($492),[4] whereas inpatient treatment can result in more than a 10-fold increase in cost.[5] Although the true economic impact of NMSC treatment is likely underestimated, Medicare data show NMSC to be one of the five most costly cancers to treat. Further analysis suggests this high cost is due to the high frequency of diagnosis rather than the actual cost of each cancer treatment.[6] Given its increasing incidence, NMSC expenditures will only increase, and along with prevention, effective and efficient management is paramount. Although this chapter focuses on the diagnosis and treatment of the most common non-melanoma cutaneous malignancies—basal cell carcinoma (BCC) and squamous cell carcinoma (SCC)—other select skin cancers are included for completeness. In general, oncologic principles for the management of these cancers can be applied to other malignancies affecting the skin.

Epidemiology and Etiology

The increasing incidence of NMSC is multifactorial and may be attributed to increased photodamage from sun exposure, ozone depletion, increased longevity, and improved detection.[7] White populations show increased risk, especially with lighter skin type, blue eyes, freckles, and red/blonde hair. NMSC is uncommon in Black, Asian, and Hispanic populations. Blacks do not appear to be as affected by increased sun exposure, as their skin cancers tend to be in areas not exposed to sunlight. Indoor tanning among adolescents is common in the Unites States (21% of high school females engaged in indoor tanning in 2011) and increases the risk of basal cell carcinoma by 40% and squamous cell carcinoma by 102%.[8]

The role of ionizing radiation is further highlighted by the significant geographic variability in the incidence of NMSC. Certain areas of Australia show NMSC development in over 2% of the population, which is a 10-fold increase over European and United States cohorts of similar ancestry. Younger people are affected more frequently in Australia and the southwestern United States. Proximity to the equator influences rates of NMSC for White populations, with the incidence of squamous cell carcinoma doubling for every 10 degrees in latitude closer to the equator.[9]

In addition to ionizing radiation, several other risk factors deserve mention. Secondary NMSC can result from previous radiation treatment. The Childhood Cancer Survivor Study found a 6.3-fold increase in risk of developing NMSC within the radiation field, with 42% of these cases occurring in the head and neck. The median age at diagnosis of their first NMSC was 31, and almost half of patients had multiple recurrences.[10] Long-term immunosuppression increases the risk of skin cancer. A 2015 review noted kidney transplant recipients have a 65- to 250-fold greater risk than the general population of developing NMSC.[11,12] Similar increases in risk have been noted for heart, lung, liver, and pancreas transplant patients.[12-15] Skin cancer risk associated with transplantation is increased for sun-exposed skin even for patients living in regions of relatively low sun exposure, with lip cancer among the most common.[12] Interestingly, immunosuppression caused by HIV carries a 2-fold higher risk for skin SCC, but not BCCn.[16]

One of the most important risk factors for the development of a skin cancer is a history of prior skin cancer. The

5-year cumulative risk for development of a NMSC in a patient with a prior NMSC is 40%. Risk further increases over time as additional skin cancers are diagnosed in the same person. For a patient with a prior NMSC who develops a second skin cancer, there is an 82% risk that yet another NMSC will develop over the next 5 years.[17] In patients with a history of BCC, the risk for developing an SCC is 6%. Regardless of primary treatment modality, patients with skin cancer require structured follow-up, given their high risk for development of second primaries.

Pathology and Epidemiology

Epithelial Cancers

Basal Cell Carcinoma

The most common NMSC is basal cell carcinoma (BCC), which makes up approximately 80% of NMSCs.[18] Basal cell carcinomas arise from the basal cells of the epidermis and skin appendages. Although rarely associated with metastasis, they are capable of extensive local tissue destruction and, uncommonly, may invade deeper structures, including cartilage, bone, and muscle. Basal cell cancers are most commonly located in the head and neck, with the skin of the periorbital, perioral, and auricular areas being especially at risk (Figure 31-1). Rarely, large, neglected lesions can be fatal through local invasion of vital structures or distant metastasis.

Basal cell carcinomas are the most common skin cancer found in Whites, Asians, and Hispanics. In Black populations, BCC is the second most common skin cancer after SCC.[19] Although exposure to ultraviolet radiation is the major cause of BCC, other risk factors for BCC include age, skin type, radiation exposure, immunosuppression, and exposure to certain chemicals. Men have a 2-fold higher incidence than females, which may be related to their increased involvement in outdoor occupations and leisure activities and consequent increased exposure to solar radiation.[18] In addition to the association of basal cell carcinoma with basal cell nevus syndrome (Gorlin syndrome), other syndromes, including albinism and xeroderma pigmentosum, are also associated with BCC.[20,21] Although once considered infrequent before the age of 40, basal cell cancers are appearing in younger patients, likely secondary to increased sun exposure and tanning.[8]

Presentation

Basal cell carcinomas can be subdivided into four types, listed here in decreasing order of incidence: nodular (or nodulo-ulcerative), sclerosing (or morphea), basosquamous, and multicentric (superficial) type. Friedrich and colleagues reviewed 216 patients with BCCs that primarily affected the middle third of the face. Of the 216 patients, 124 were treated with surgery. Friedrich found that 83% of the BCCs were solid (or nodular), 10% were sclerosing, 4% were metatypical (basosquamous), and 3% were multicentric.[22] The nodular type usually appears as a firm, translucent (pearly) papule with telangiectatic blood vessels. Pigmentation can be present and can lead to a concern for melanoma, which should be taken into consideration when planning a biopsy (see biopsy techniques in Figure 31-5). Late stages are accompanied by crusting and a central ulcerated depression as the central portion becomes necrotic from lack of blood supply. This results in the classic "rodent ulcer" recognized by most clinicians as a BCC. Histologically, the lesions contain nests and strands extending perpendicular to the basement membrane. Squamous differentiation can occur within the lesion, leading to the basosquamous variety (Figure 31-2), which behaves in a more aggressive fashion that is more analogous to a squamous cell cancer with an increased incidence of recurrence and metastases.[23] The sclerosing variant may appear as a scar or fibrotic skin and lack elevation. It is made up of nests and cords of tumor cells within a dense fibrosis. Its borders are often indistinct, and microscopic extension into the surrounding dermis can lead to positive margins and an increased chance of recurrence following excision. As these lesions enlarge, the sclerosing type can develop central depressions, giving them the appearance of a scar. Finally, the superficial or multicentric form typically presents as a red, scaling

• **Figure 31-1** Basal cell carcinoma of the upper lip.

• **Figure 31-2** Basosquamous cell carcinoma of the ear.

lesion, and although it occurs on the skin of the head and neck, it is more common on the trunk and extremities. As these lesions enlarge, they can assume the appearance of a nonspecific dermatitis.[18]

Metastatic basal cell carcinoma is extremely uncommon, with fewer than 400 cases reported, and an estimated incidence of 0.0028% to 0.55% of cases. Metastasis can occur by both lymphatic and hematogenous spread. Metastasis to lymphatic basins seems to be associated with longer survival than hematologic spread to distant organs, which include bone, liver, and lung.[24] Given its rarity, management of metastatic BCC is not standardized. The most promising research currently focuses on inhibition of the Hedgehog signaling pathway. Vismodegib was approved in 2012 by the FDA as the first Hedgehog signaling pathway inhibitor to treat metastatic or recurrent locally advanced basal cell carcinoma in adults who cannot be treated with surgery or radiation.[25]

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is the second most common cutaneous malignancy and accounts for approximately 20% of skin cancers. Approximately 200,000 to 300,000 cases are diagnosed yearly, and 2000 people die each year from this disease.[26] SCC arises from the common precursor cell, the keratinocyte. Compared to most BCCs, SCCs are typically more aggressive and are more commonly associated with metastases and locoregional recurrence following treatment. Like BCC, cutaneous squamous cell cancer is strongly associated with exposure to UV radiation, and there is a direct correlation between cumulative solar exposure and risk for development of cutaneous SCC. A history of childhood sunburn and long-term exposure to solar radiation is common.[9]

Similarly, chronic immunosuppression in solid organ transplant patients is also associated with an increased incidence of squamous cell cancers. These cancers typically arise in sun-exposed areas, suggesting that UV radiation and immunosuppression combine to increase overall risk.[12] Additional etiologic factors include human papillomavirus (HPV-5, -16, and -18), exposure to certain chemicals (organic hydrocarbons and arsenic-containing compounds), and long-standing inflammatory conditions, such as fistulas and ulcers (e.g., Marjolin ulcer).[26]

Presentation

Squamous cell cancers are the most common skin cancer in Blacks and Asian Indians and the second most common cutaneous malignancy in Caucasians.[27] SCC is predominantly a cancer of the older patient (average age at diagnosis 70), and males predominate, again likely related to increased outdoor activities. The vast majority occur in the head and neck, with the skin of the upper face being especially susceptible. Squamous cell cancers typically arise in an area of actinic keratosis (AK) that appears as hyperkeratotic plaques. Approximately 10% of actinic keratoses will ultimately transform to squamous cell cancer.[28] Ulceration, possibly accompanied by bleeding, may develop with thickening of the plaque.

There are several varieties of squamous cell cancer worth noting. The vast majority are typical SCCs, which can be subdivided into well, moderate, and poorly differentiated based on the amount of keratin production (keratin pearls), and on how closely the tumor mimics normal skin histologically. A well-differentiated SCC typically contains an abundance of keratin pearl formation surrounded by well-formed keratinocytes lacking nuclei. Conversely, poorly differentiated tumors lack keratin formation, and the nucleated keratinocytes are haphazardly arranged and have a high mitotic index. Histologic evaluation may also take note of a dense inflammatory infiltrate, which is often associated with improved local control rates.

Keratoacanthoma (KA) is a controversial lesion that some consider a very well-differentiated squamous cell cancer. Keratoacanthomas are common lesions that, like BCC and SCC, usually occur on sun-exposed areas. They typically present as red, raised lesions with hyperkeratotic centers and are often difficult to distinguish from an SCC clinically. Characteristic rapid growth is usually followed by spontaneous involution in the majority of cases. Pronounced scarring can occur in some cases. Although a clinical history of rapid growth coupled with the clinical appearance can provide clues to the diagnosis, these lesions should be excised and examined histologically for confirmation of diagnosis and margin assessment. Rarely, keratoacanthomas can be associated with more aggressive behavior, including recurrence and metastasis, although the latter is controversial. Most clinicians recommend that KAs be treated as well-differentiated SCCs with surgical excision and margin analysis.[29-31]

Carcinomas of Skin Appendages

Microcystic Adnexal Carcinoma

Microcystic adnexal carcinoma arises from the sweat ducts and most commonly affects the skin of the head and neck, with more than half of cases occurring on the upper or lower lip. It usually presents in middle-aged and elderly Caucasians, and there does not seem to be a male or female predilection. Lack of symptoms and slow growth often result in late diagnosis. Perineural invasion, however, is common (as high as 80%), and patients who are symptomatic often present with complaints of numbness or pain.[32] As many as 60% of patients will experience metastatic spread. Deep infiltration with extension well beyond the clinical margin can be present and lead to a high recurrence rate (up to 70%) following traditional surgical excision.[33] For this reason, consideration should be given to Mohs micrographic excision (see discussion later) if available. Frozen section analysis during traditional surgical excision can also be of assistance. Radiation therapy plays little role in primary management, as these tumors are considered somewhat radiation resistant. It is usually reserved for palliation.[32] Benign tumors from adnexal structures can occur but can be clinically indistinguishable from malignant tumors (Figure 31-3).

• **Figure 31-3** Syringocystadenoma of the scalp.

Sebaceous Gland Carcinoma

Sebaceous gland carcinoma (SGC) is the most common eyelid malignancy in Asians and is most commonly associated with the meibomian glands of the upper eyelid.[34] Lower lid involvement and origin from the glands of Zeis is less common. Although extraocular SGC can occur in the head and neck, cases are rare. Its clinical presentation can lead it to be mistaken for a chalazion or other benign inflammatory condition affecting the eyelid.

Surgical excision is the treatment of choice, but recurrences are common. Deep orbital involvement makes complete excision difficult, and orbital exenteration should be considered. Mohs micrographic excision has been used with some success. Regional and distant metastases are not unusual and are usually associated with large size and recurrent tumors.[35] Although radiation treatment is typically reserved for a palliative role in most cases, some authors have suggested its use as an adjunct to surgical excision in an attempt to decrease local recurrence.[36]

Nonepithelial Cancers

Merkel Cell Carcinoma

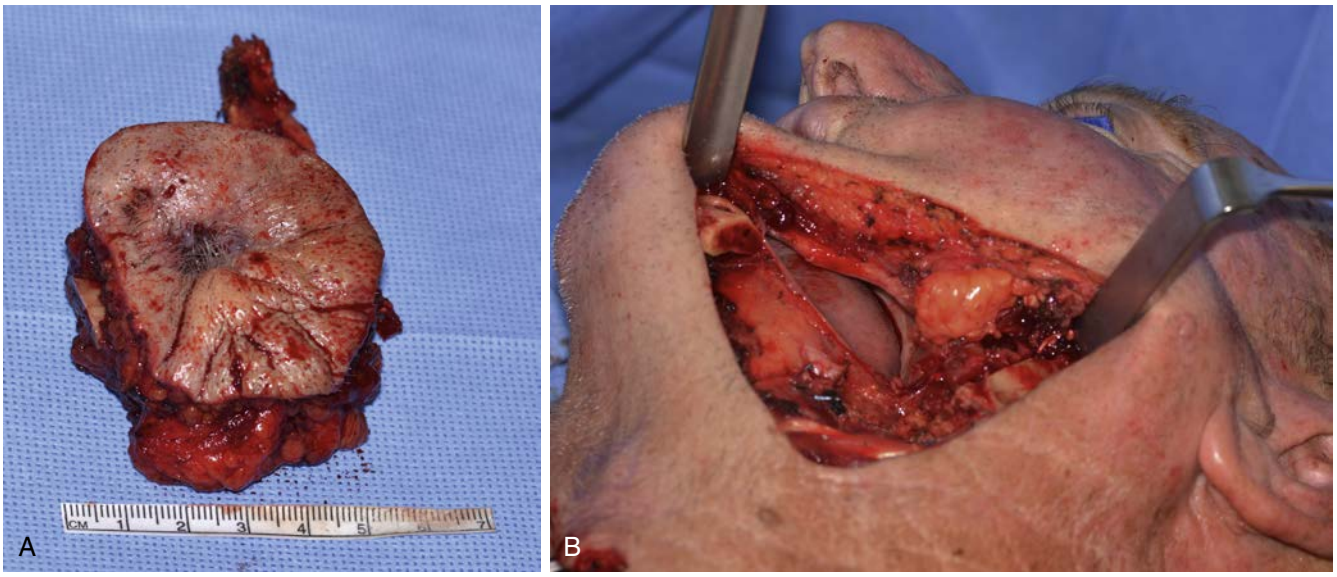
First described by Toker in 1972, Merkel cell carcinoma (cutaneous neuroendocrine carcinoma) is a rare neuroendocrine malignancy known for its rapid growth, high recurrence rate, and propensity to metastasize to regional lymph nodes.[37,38] Merkel cell carcinomas are usually associated with male and female Caucasians of advanced age, and 50% are located in the head and neck.[39] Although suspected, sun exposure has not been established as a definite etiologic factor in their development. Clinically, Merkel cell carcinoma typically presents as an indiscreet red or violaceous papule or plaque that grows rapidly. Originally thought to be of indolent behavior, it is now recognized that Merkel cell cancers are aggressive tumors with a high incidence of local recurrence, as well as metastases. Regional and distant metastasis rates as high as 75% have been reported.[29]

The rarity of Merkel cell cancer (MCC) precludes large trials to develop and compare treatment regimens, and therefore, treatment recommendations based on clinical experience are the norm. Most authors recommend aggressive treatment, including elective management of the at-risk lymph node basins. More recently, interest in sentinel lymph node biopsy has developed, and authors have reported on its utility in the management of MCC.[30,31,39] The behavior of MCC is often compared to that of melanoma, and some authors advocate wide excision margins (2 to 3 cm) to include the subcutaneous tissue and underlying fascia.[31] Others have suggested Mohs micrographic excision (see discussion later) as an acceptable alternative to wide excisions with arbitrary margins. Despite the aforementioned recommendations of most clinicians, there remains considerable controversy regarding the need for elective dissection of the nodal basins at risk. Recommendations vary, but some authors have suggested node dissection in cases of size greater than 1.5 cm or clinically apparent nodes. Multimodality therapy combining surgery and irradiation is indicated in most cases of this potentially lethal cutaneous cancer. MCC is radiosensitive, and in most cases, adjunctive radiation therapy should be considered to the primary site, as well as to the at-risk nodal basins to improve local and regional control.[40,41] Interestingly, Merkel cell carcinoma is one of the few cutaneous malignancies in which chemotherapy can play a significant role. MCC is chemosensitive, and chemotherapy has been used with some success in palliating patients deemed non-operative. Although chemotherapy has been shown to lead to significant remission rates (up to 70%), an improved overall survival rate has not been demonstrated.[31]

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFP) is a malignant tumor known for its indolent growth but propensity to recur following excision. It is rare, accounting for less than 0.1% of all malignancies. It primarily affects middle-aged patients (age 20 to 50 years), but it may present at any age and has a slight male predominance. Some authors report an increased incidence in African Americans.[42]

The majority of DFP occurs on the trunk, with only 10% to 15% occurring on the head and neck.[43] They usually present as a skin-toned or brown plaque that produces multiple protuberant nodules, although a solitary nodule can occur. DFP has an indolent growth phase initially, which is then followed by a more rapid growth in which the multiple nodules are usually noticed by the patient and medical care is sought. Invasion into the subcutaneous tissue is common, and long-standing lesions can invade fascia, muscle, and even bone.[42] Diagnosis is made following a biopsy, which is best obtained from a nodular area and extending into the subcutaneous tissue. Treatment of DFP is adequate surgical excision and annual follow-up. The hallmark of DFP is its propensity to recur following surgical excision. The tumor produces multiple, irregular extensions into the surrounding tissue, leading to extension well beyond the clinical margin. Early recommendations for conservative margins led to a disappointingly high recurrence rate. Currently, recommendations include peripheral margins of 3 to 4 cm that include the deep fascia,



• **Figure 31-4** **A,** Specimen of basal cell carcinoma of the cheek invading into the mandible resulting in a pathologic fracture. **B,** A segmental mandibulectomy was performed, which created a defect communicating with the oral cavity.

which results in recurrence rates from 20% to 60%.[35,43] Unfortunately, these margins are often difficult in the head and neck. Alternatively, Mohs micrographic excision (see discussion later) has been suggested to offer a more complete evaluation of the surgical margin and preserve uninvolved tissue. Mohs' technique has been recommended for primary excision in critical areas and in cases of recurrent tumor.[35,42] Recurrences, which usually occur in the first 3 years, are more common in lesions excised from the head and neck compared to other sites.[42] Death can occur and is usually the result of uncontrolled growth following multiple attempts at excision followed by direct extension into critical anatomic structures. Radiation therapy has been used in some cases as an adjunct to surgical excision and also in cases that are not amenable to surgical excision. The role of chemotherapy is only in cases of distant metastatic disease.[44]

Aggressive Skin Cancer of the Head and Neck

The vast majority of skin cancers affecting the skin of the head and neck are basal and squamous cell cancers, and most patients present with localized disease in which appropriate surgical excision will effect a cure. There is a significant subset of patients, however, who will present with a skin cancer that displays aggressive behavior and fails to respond to standard therapy, with multiple recurrences leading to substantial morbidity and, rarely, death. The challenge to the surgeon is to predict which tumors warrant more workup, such as imaging with computed tomography (CT) or magnetic resonance imaging (MRI) (see discussion later), or more aggressive therapy, such as lymph node sampling or consideration of adjunctive radiation therapy. Ideally, the ability to predict which cancers will behave more aggressively would spare the vast majority of patients additional unwarranted costs and the morbidity associated with a more aggressive approach. Although far from exact, there are several predictors of biologic aggressiveness that can be used to judge behavior in some cases of basal and squamous cell cancers, including location, diameter, depth, differentiation, perineural invasion, and patient characteristics.

Topographically, certain locations are associated with a more aggressive clinical course. This is described as the so-called "H-zone," which includes the eyelids, canthi, nose, nasolabial folds, upper lip, periauricular skin (including the preauricular skin of the cheek), and frontozygomatic region of the forehead.[45] For reasons incompletely understood, tumors arising in these locations tend to have a more vertical, as opposed to horizontal, growth pattern and therefore tend to invade more deeply. Additional factors suggested as contributing to the more aggressive behavior seen with tumors arising in these areas include embryonic fusion planes, density of nerve endings, and proximity to muscles of facial expression, cartilage, and bone. Cancers arising near the medial canthus can invade the orbit with involvement of the lacrimal apparatus and periorbital fat, making eradication without orbital exenteration difficult. Periauricular cancers can spread deeply along the cartilage of the helix, making a clear, deep margin difficult without temporal bone excision.[46]

The surface dimension of skin cancers has a well-accepted influence on prognosis, and for that reason it is included in the staging of these cancers. Both BCCs and SCCs larger than 2 cm have a much higher potential for recurrence following excision.[47,48] Depth of invasion may be equally or even more important than surface dimension in predicting behavior, with deeper invasion (greater than 4 mm) associated with an increased risk of local recurrence, as well as regional and distant metastases.[47-49] Neglected skin cancers can eventually invade facial bones (Figure 31-4).

Tumor histology has a direct bearing on behavior. Poorly differentiated SCCs and sclerosing BCCs have a distinctly more aggressive behavior. Other histologic variables appear to correlate with more aggressive behavior, with the most important being perineural invasion (PNI) or neurotropism, which is defined as invasion in, around, and through peripheral nerves. The loose connective tissue of the perineural space offers a well-known conduit for the conduction of cancerous cells. Although early investigators believed tumor cells traveled within lymphatics surrounding the nerve, currently it is known that tumor cells simply follow a path of least resistance in the natural cleavage plane that exists beneath the perineurium and endoneurium. Perineural invasion can either be noted clinically with a nerve deficit or be noted on biopsy or specimen examination.[50] SCCs more commonly demonstrate perineural invasion compared to BCCs, but involvement by either is an ominous finding. Sensory nerves are more commonly affected compared to motor, and most often the second and third divisions of the trigeminal nerve are affected in cutaneous malignancies affecting the face. Most patients with perineural invasion are asymptomatic, but patients may present with pain, burning sensation, anesthesia, or facial paralysis.[51] Clinically evident perineural invasion is associated with decreased 5-year local control rates compared to microscopic perineural invasion.[52] Cranial nerve deficits rarely improve following therapy. Histologic perineural invasion is associated with a 45% incidence of local recurrence, a 10% to 35% incidence of regional metastasis, and a 65% 5-year survival.[50,53] At 2 years, 46% of patients with PNI were dead of disease or alive with recurrence, in contrast to 9.1% of patients without PNI who were dead of disease or alive with recurrence.[54]

Perineural invasion is also associated with an increased risk of nodal metastases. The concept of "skip lesions" along the nerve is controversial and may be due to difficulty with histologic interpretation or a processing error. In examining nerve margins for tumor clearance, however, it is suggested that clearance of signs of perineural inflammation be used as an end-point rather than clearance of tumor cells. Patients with perineural invasion, especially those with clinically evident deficits, should be considered for more aggressive therapy, including sampling of at-risk nodal basins and consideration of adjunct radiation therapy if a major (named) nerve is involved.[49,50]

Certain patient characteristics may also serve as a guide to the potential for more aggressive tumor behavior. The effect of immunocompromise on the incidence and outcomes of cutaneous malignancy is well recognized. Transplant recipients are regarded as high risk for the development of NMSC, and their outcome following standard treatment is worse. Southwell and colleagues, along with others, have demonstrated a significantly higher incidence of recurrence and decreased survival in patients with immunocompromise.[55]

Most importantly, a recurrence following standard therapy is an indication of biologic aggressiveness and portends a worse outcome. Recurrent tumors are indicated for more aggressive therapy, and recurrence is often an indication for Mohs micrographic excision (see discussion later), which results in a significantly lower recurrence in these patients compared to traditional surgical excision or radiation.[56,57] It is hoped that the future will bring improved genetic markers for biologic aggressiveness to aid in therapy selection and prognosis.

Screening and Clinical Exam

Most skin cancers are not symptomatic. Given the relative low mortality associated with NMSC involving the head and neck, the primary benefit from early detection is the potential for less morbidity and disfigurement with excision. Although screening for malignancies has come under increasing scrutiny,[58] the American Cancer Society still recommends a cancer-related checkup every 3 years for asymptomatic men and women 20 to 39 years of age, and yearly for men and women age 40 and older. This includes examination of the skin. Clinical history, including environmental exposures that place patients at increased risk, may warrant more frequent checkups.[59] Although screening for skin cancers would seem relatively easy, considering the ability to visualize the area of concern, studies have failed to demonstrate the effectiveness of routine screening. In a review of the literature, Helfand and associates[60] found that although skin examination was accurate (sensitivity of 94% and specificity of 98% in one of the largest prospective studies evaluated), there was little support for formal, routine screening. They did find some support for screening of high-risk populations and suggested that strategies be developed to identify and screen those at highest risk. Because their review was not limited to NMSC of the head and neck, it would be difficult to know if screening and early detection do help minimize disfigurement in treatment of this subset.[60] Surgeons often deal with neglected cancers that reach large sizes, and it is difficult to know if these patients would avail themselves of screening opportunities even if they were available.

Physical Exam

Anatomy

The skin is made up of three layers: an outer epidermis, middle dermis, and subcutaneous layer. The outer layer consists of an outer keratinized layer with an underlying stratified squamous epithelium and innermost layer of germinative cells and melanocytes. The dermis is made up of connective tissue fibers embedded in an amorphous matrix of mucoproteins and mucopolysaccharides. The subcutis consists of adipose tissue with an underlying fascial layer. Supporting adnexal structures, including hair follicles, sebaceous glands, and sweat glands, reside in the deep dermis and subcutis. The many cell types that collectively make up the components of the skin give rise to the variety of malignant tumors classified as "skin cancer."

Skin Types

Exposure to ultraviolet radiation plays an important role in the development of most skin cancers. Likewise, a

TABLE 31-1 Fitzpatrick's Sun Reactive Skin Types

Skin Type	Skin Color	Tanning Response
I	Caucasian	Always burns, never tans
II	Caucasian	Usually burns, tans with difficulty
III	Caucasian	Sometimes mild burn, average tan
IV	Brown	Rarely burns, tans easily
V	Dark brown	Very rarely burns, tans very easily
VI	Black	No burn, tans very easily

patient's skin type predisposes to damage from exposure to solar radiation. Fitzpatrick[61] described a scale (Table 31-1) based on skin reactivity to 30 minutes of sun exposure in the Northern Hemisphere. Although the Fitzpatrick scale is commonly used in the assessment of a patient's suitability for certain aesthetic skin resurfacing procedures, it is also useful for evaluating a patient's risk for the development of cutaneous malignancies that arise secondary to UV exposure.[61] Glogau's photoaging scale (Box 31-1) is also useful to quantify an individual's cumulative damage from solar exposure.[62]

• BOX 31-1 Glogau's Photoaging Groups

Group I: Mild (typically ages 28-35)
- Little wrinkling or scarring
- No keratoses
- Requires little or no makeup

Group II: Moderate (typically ages 35-50)
- Early wrinkling, mild scarring
- Sallow color with early actinic keratoses
- Little makeup

Group III: Advanced (typically ages 50-65)
- Persistent wrinkling or moderate acne scarring
- Discoloration with telangiectasias and actinic keratoses
- Always wears makeup

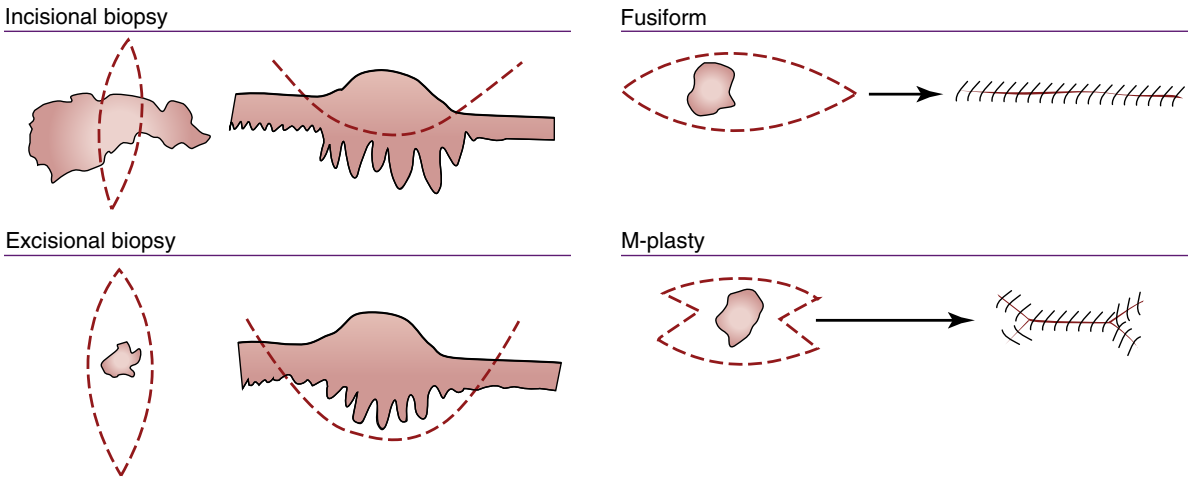
Group IV: Severe (typically ages 60-75)
- Wrinkling: photoaging, gravitational and dynamic
- Actinic keratoses with or without skin cancers or severe acne scarring
- Makeup with poor coverage

Nodes

Skin cancers typically spread by local extension; as noted previously, metastasis to regional lymph nodes is rare and represents an ominous finding. Lymph node involvement is usually associated with large, deeply invasive, or recurrent tumors. Distant metastasis is more rare, with the most common visceral site involved being the lung, especially for squamous cell cancers. The exact rate of lymph node metastasis from NMSC of the head and neck is unknown. O'Brien and his colleagues[63] reported on patterns of lymph node spread from cutaneous squamous cell cancer of the head and neck among 209 patients with known regional metastases. Among 209 patients, 171 (82%) had clinical parotid involvement, and of these, 28 had clinical neck disease. Whereas 143 patients had parotid disease alone, 38 (18%) had neck disease only. Level II was most commonly involved in the neck. Common sites of origin for metastases were usually lateral and included the cheek, pinna, and temple. Lesions from the anterior inferior face tend to metastasize to levels I, II, and III, whereas metastases from the nose tend to involve level I.[64] Involvement of parotid nodes can lead to facial nerve paralysis. At-risk patients presenting with a parotid mass, with or without facial nerve paralysis, should be carefully screened for potential skin cancer primary sites.

Biopsy

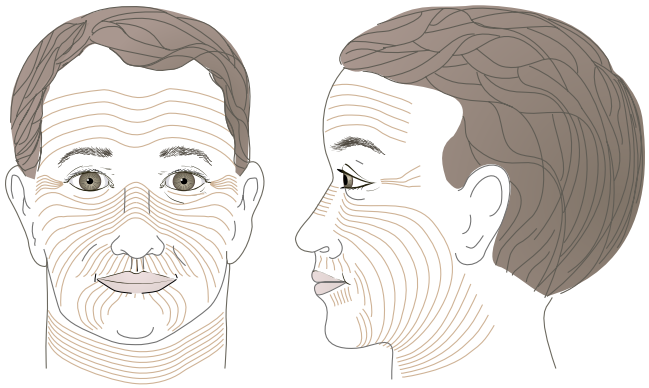
The goal of a biopsy is to remove a representative piece of tissue to allow histologic diagnosis. There are a variety of techniques available for obtaining tissue for histologic diagnosis, but all generally fall into two categories: incisional biopsy, including shave and punch biopsy techniques; and excisional biopsy (Figure 31-5).[65] The decision to perform an incisional or excisional biopsy should take into account the size and location of the lesion, as well as the surgeon's clinical impression of the lesion's behavior (benign or malignant). Incisional biopsies remove a portion of the lesion for histopathologic analysis before definitive treatment. A portion of adjacent tissue can be removed to allow the pathologist an opportunity to examine the transition between normal and abnormal tissue. Removal of tissue from this transition zone is more important in some vesiculobullous and pustular entities. It should be avoided in cases of suspected malignancy where there is a concern for seeding adjacent tissue, requiring a larger excision in the future. Obviously necrotic areas should be avoided for biopsy. Incisional biopsies are typically indicated in larger lesions, where complete removal is not appropriate without knowledge of the histologic diagnosis. Incisional biopsies are also indicated in areas where maximal preservation of tissue is important (e.g., eyelids) and histologic confirmation of diagnosis is necessary before planning definitive treatment. Incisional biopsies can take the form of shave or punch biopsy. Shave biopsy is best suited for raised lesions of suspected epidermal origin, such as basal cell carcinoma, early squamous cell carcinomas, and actinic keratosis. Although it can be used to remove benign nevi, it should not be used in cases of suspected melanoma in which the depth of the lesion guides therapeutic choices. It can also be a good technique for sampling bullous lesions because it allows the blister roof to remain attached. The technique is best performed with a straight razor blade slightly bowed between the thumb and index finger. The tissue to be sampled can be elevated by pinching the surrounding tissue, or placing the surrounding tissue under slight tension. The tissue can also be elevated with infiltration of local anesthetic directly deep, but not directly into, to the lesion. Excessive traction on



• **Figure 31-5** Biopsy techniques.

the surrounding tissue should be avoided because this can lead to a depressed scar. Bleeding is controlled with pressure, electrocautery, or application of a hemostatic agent, such as silver nitrate. Advantages of shave biopsy include less trauma and scarring at the biopsy site. The most important disadvantage is the potential that there will be inadequate tissue for diagnosis. Attempts to perform shave biopsies in larger squamous cell or verrucoid cancers, for example, can lead to sampling only superficial keratinaceous or necrotic debris. Sellheyer and colleagues[66] sought to compare the practice of shave versus excisional biopsy among plastic surgeons and dermatologists and found that dermatologists were more likely to perform shave biopsies of actinic keratosis (AK) and plastic surgeons were more likely to perform excisional biopsies. They suggested that shave biopsies were more appropriate in cases of diagnostically uncertain cutaneous lesions. They argued that this was especially true in cases of actinic keratosis, where shave biopsies provided a more cosmetic outcome and allowed treatment of confirmed AKs with cryosurgery or other topical therapy, sparing the morbidity of excision. Many surgeons would argue, however, that biopsy techniques that provide deeper tissue samples are preferred in cases of suspected malignancy. In addition to melanoma, the thickness of certain other cutaneous malignancies, including squamous cell and basal cell cancers, carries prognostic information (as discussed earlier) that is not available from shave biopsies. For this reason, in the authors' opinion, shave biopsy should be reserved for suspected benign or smaller malignant lesions. Full-thickness biopsies that extend into the subcutis are preferred for all other lesions.

An alternative biopsy technique is the punch biopsy, which can be either incisional or excisional, depending on the size of the lesion. Its utility lies in its ability to provide a full-thickness sample of the lesion for histologic examination. Available punch sizes range from 2 to 8 mm, with 3 to 4 mm being the most commonly employed. The technique is accomplished with the patient receiving a local anesthetic, and multiple samples can be obtained quickly. The punch



• **Figure 31-6** Relaxed skin tension lines (RSTLs) of the head and neck region.

should be held perpendicular to the skin surface, and tension can be placed on the surrounding tissue perpendicular to the resting skin tension lines (RSTLs) (Figure 31-6), which allows the final wound to take an oval shape parallel to the RSTLs, and more aesthetic healing. Once adequate depth is reached, the resulting core of tissue is amputated with a scalpel blade or scissors, taking care not to crush the specimen. The biopsy wound can be closed or left to heal by secondary intention.[65] Incisional biopsies can also be performed with a scalpel blade. Typically, fusiform incisions are designed to allow closure parallel to RSTLs. Incisional scalpel biopsies may be indicated when a larger piece of tissue is needed, or if the lesion in question lies deeper in the subcutaneous tissue. They are also helpful when tissue adjacent to the lesion is needed, as noted previously. If melanoma is suspected, the biopsy should be taken from the thickest portion, because depth and thickness serve as important prognostic indicators and guide selection of further therapy.

Excisional biopsies are typically reserved for smaller lesions, typically less than 2 cm. Fusiform type excisions with a length to width ratio of 3:1 are outlined parallel to the RSTLs. A margin of healthy-appearing tissue 2 to 3 mm wide at its closest point should be taken. A scalpel blade is

then used to excise the tissue, taking care not to crush or distort the specimen. Undermining of the adjacent tissue may be required for tension-free closure, but should be avoided if there is a question of incomplete removal so as to avoid seeding and distortion of adjacent tissue. If questionable, wounds may be dressed, and definitive closure delayed until final margins are available. The specimen should be oriented with a suture or ink. Advantages of excisional biopsy include providing the pathologist with the complete specimen for review and the possible convenience of a single surgery. The main disadvantage is that the pathology and margin status are unknown at the time of excision, and patients should be advised that final pathology may dictate further therapy.

In addition to choosing the appropriate technique for sampling the lesion, the surgeon must also decide on the most appropriate media in which to send the material to the pathologist. Although the vast majority of specimens are submitted for routine pathology in formalin, special circumstances may dictate that all or a portion of the specimen be submitted fresh or in alternative media. This decision is often made in concert with the histologist and is based on the need for special stains or studies, such as flow cytometry.

Imaging

Although advances in imaging have arguably had the greatest impact on the surgical care of head and neck cancer patients in general, imaging is rarely part of the workup of the routine patient with cutaneous malignancy of the face and neck. Clinical exam alone provides enough information in the majority of cases. Surgeons may consider imaging, however, in cases of deeply infiltrating, recurrent, or multiple lesions. Involvement of critical areas (eyelid or conchal bowl, for example) or higher potential for lymph node involvement (see discussions under management of lymph nodes and predictors of biologic aggressiveness) can also be indicators for cross-sectional imaging. In the past, surgeons dealing with larger skin malignancies were confronted with operating on tumors with only a clinical examination of the surface characteristics. Currently, excellent three-dimensional representations are available with which to plan surgery and allow more conformal radiation treatment.

In the 1980s computed tomography (CT) scan became a part of the evaluation of this subset of patients with more advanced cutaneous malignancies in an attempt to examine the extent of the primary involvement of adjacent anatomic structures and to search for evidence of regional nodal metastases. CT scans with 3-mm cuts and soft tissue windows are effective for evaluating depth of invasion and potential lymph node metastasis. Specific criteria, such as size, loss of fatty hilum, central necrosis and spherical shape, are available for defining nodes as suspicious for metastatic involvement.[67] Additional indications for CT imaging include long-standing scalp lesions or other lesions suspicious for bone involvement, which should be imaged with finer (1 mm) cuts with bone windows through the area of concern.

In the 1990s, magnetic resonance imaging (MRI) began to challenge the CT scan. Its exquisite anatomic detail and lack of radiation, however, are associated with higher cost and a lengthy, uncomfortable exam. At this point, MRI is reserved for evaluation of tumors with extensive soft tissue involvement and is especially helpful in evaluating potential perineural extension.[67] Also, newer techniques that modulate the magnetic field in an attempt to examine changes in the bone marrow hold promise for evaluating bone involvement that may offer better sensitivity than CT with fine cuts. Tumor invasion into the marrow space is accompanied by a lower intermediate signal and is best seen on T1-weighted sequences.[68]

The role of positron emission tomography/computed tomography (PET/CT) has yet to be fully defined in NMSC. Although this whole-body imaging modality has become a standard procedure in detecting malignancy in many areas of clinical oncology, data to support PET in routine staging of NMSC are still emerging. Isolated case reports document the use of PET in basal cell carcinoma[69,70] and squamous cell carcinoma[71,72] but few large studies exist to make useful conclusions. Cho et al[73] retrospectively reviewed 12 cases of cutaneous squamous cell carcinoma and noted that PET/CT detected the primary lesion in nine cases, lymph node involvement in three cases, and distant organ involvement in one case. All these areas were confirmed positive by histology, although PET-negative areas were not confirmed to be negative by histology. The authors noted that all patients with regional or distant metastatic disease had high-risk primaries as determined by size, location, poorly differentiated histology, and immune status of the patient. Fosko et al[74] published a series of six patients with head and neck basal cell carcinomas larger than 1 cm and noted that three of the primary lesions were not detected by PET/CT, including an aggressive 3.1-cm recurrent BCC with extensive perineural spread. Although the majority of cutaneous malignancies are SCC and BCC, PET imaging has been advocated in uncommon forms of skin cancer such as Merkel cell carcinoma,[75] apocrine sweat gland carcinoma,[76] primary cutaneous lymphoma,[77] and melanoma.[78-80]

Staging of Skin Cancer

Accuracy in staging of cancer is critical for comparison of treatment modalities and for following outcomes. The staging of non-melanoma skin cancers follows the tumor, node, and metastases (TNM) system proposed by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (IUAC).[81] The staging system undergoes constant review and updating, and the rules for staging of skin cancer are specific. Most cutaneous basal cell carcinomas are not staged, leading to the primary application of the non-melanoma staging to squamous cell carcinomas. Clinicians should be familiar with changes in the staging system and strive for consistency in staging. Technological advances lead to stage migration; for example, improved ability to detect earlier metastatic disease with CT scans leads to more patients being diagnosed with late-stage disease. Clinical staging of skin cancer is based on all clinical data available

before initiation of treatment, which at a minimum includes data from the physical exam. If available, imaging data are included. It does not include information gained during the surgical procedure. If surgery is performed, a pathologic staging is possible based on examination of the surgical specimen. This is designated by inserting the letter *p* in front of the TNM stage. Standard staging of non-melanoma skin cancer of the face excludes the eyelid, which has its own staging criteria based on different prognostic variables.

A summary of the current staging follows:

Primary Tumor

- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma in situ
- T1: Tumor less than 2 cm in greatest dimension with less than 2 high-risk features
- T2: Tumor more than 2 cm or Tumor any size with 2 or more high-risk features
- T3: Tumor with invasion of maxilla, mandible, orbit, or temporal bone
- T4: Tumor with invasion of skeleton (axial or appendicular) or perineural invasion of skull base

If there are multiple synchronous tumors, the lesion with the highest T stage is used and the number of separate tumors is indicated in parentheses. For example, if the largest lesion is 3 cm and there are 3 other lesions, all of which are smaller, the clinical T stage would be T2(3).

Regional Lymph Nodes

- NX: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastasis
- N1: Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
- N2a: Metastasis in a single ipsilateral lymph node, >3 cm but ≤6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension
- N2b: Metastases in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension
- N2c: Metastases in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension
- N3: Metastasis in a lymph node, >6 cm in greatest dimension

Distant Metastases

- MX: Distant metastasis cannot be assessed
- M0: No distant metastasis
- M1: Distant metastasis

Stage Grouping

- Stage 0: TisN0M0
- Stage I: T1N0M0
- Stage II: T2N0M0
  - T3N0M0
- Stage III: T4N0M0
  - Any TN1M0
- Stage IV: Any TN2M0
  - Any T
  - Any NM1

Also, additional descriptors are available to better define the system: an *m* suffix (T(m)NM) designates multiple primary sites, a *y* prefix (yTNM) indicates that staging was performed during or following multimodality treatment, an *r* prefix (rTNM) indicates a recurrent tumor staged after a disease-free interval, and an *a* prefix (aTNM) designates a stage determined at autopsy.

The current staging system offers clinicians a consistent system to classify tumors for comparison of treatment strategies and evaluating prognosis. Certain factors known to affect prognosis are taken into account. There are, however, shortcomings. The current system does not take into account several known factors that influence skin cancer behavior and survival. The most important factor neglected in the current system is the tumor-host relationship and factors that influence it, such as nutrition, immunologic factors, and performance status. Head and neck skin cancer patients typically are older and suffer from multiple other medical conditions. Certainly the TNM staging system will continue to undergo revisions to enhance its utility. Unfortunately, with these revisions, the simplicity of the system will be difficult to maintain. O'Brien[63,82] has suggested that the staging system should be altered to include the location of nodal disease (e.g., neck vs. parotid). The authors found that involvement of neck nodes was worse than involvement of parotid nodes. They also noted that involvement of neck nodes was a predictor of survival and that involvement of multiple nodes was associated with a worse outcome.

The seventh edition of the *AJCC Staging Manual*[81] introduces new parameters previously not incorporated into staging criteria for cutaneous squamous cell carcinoma. The T stage now accounts for high-risk features that are outlined in Table 31-2. The presence of two or more of these high-risk features elevates a T1 tumor to a T2. This highlights potentially more aggressive tumors regardless of size. Although this is a helpful addition, some clinicians have been critical of the omission of additional high-risk features such as basosquamous morphology, lymphovascular invasion, or inflammatory response.[83] Nodal involvement has been expanded to note size of nodes, number of nodes, and laterality. These updates should improve data

TABLE 31-2 High-Risk Features for Primary Tumor (T) Staging for Cutaneous Squamous Cell Carcinoma

Depth/invasion	>2 mm thickness (Breslow thickness)
	Clark level ≥IV
	Perineural invasion
Anatomic location	Primary site ear
	Primary site hair-bearing lip
Differentiation	Poorly differentiated or undifferentiated

collection and guide prognosis, but some authors believe additional characteristics should be included in the staging criteria. Organ transplant patients are well recognized as higher-risk groups because of their immune suppression, and many believe their tumors behave more aggressively.[84,85] Extracapsular extension in nodal basins is not included in the N-staging, although this is a known poor prognostic factor.[83]

Treatment

Surgery

Once the diagnosis is made and the indicated workup completed, the clinician must decide on treatment. Surgery is the mainstay of therapy for the vast majority of cutaneous head and neck malignancies. Because basal cell and squamous cell cancers make up the vast majority of skin cancers, our discussion focuses on the surgical principles involved in their treatment.

Cryotherapy

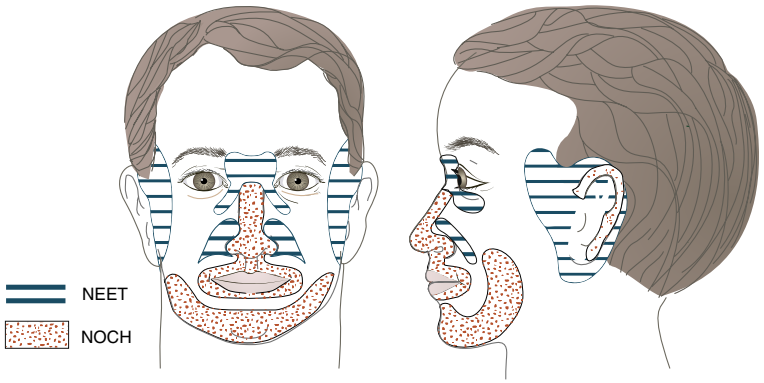
Although not specifically a surgical therapy, cryotherapy creates a wound more akin to traditional surgery than other medical therapies and is therefore considered here. Indeed cryotherapy (or cryosurgery) can be used in lieu of surgical excision in cases of actinic keratosis and some early BCC and SCC. The most common technique includes the application of liquid nitrogen with a spray device that cools the skin to −50° C and to a depth of 1 to 3.5 mm.[86] Multiple applications may be used, but most commonly two applications are performed. An area of surrounding skin should be frozen as well to ensure clearance of cancerous cells. The diameter of the surrounding "halo" that is visualized around the application area correlates roughly with the depth of the freeze. Use of local anesthetic is optional in most cases, as the cooling has an anesthetic effect. A local anesthetic can be infiltrated, however, if the thaw phase causes undue discomfort. Cryotherapy does not provide a specimen for histologic examination and is generally reserved for actinic keratosis and very early BCC and SCC with well-defined borders. An additional disadvantage is the potential for unfavorable scarring, including hypopigmentation. Cure rates in actinic keratosis are around 99%, and in smaller BCC and SCC (<2 cm) cure rates are also satisfactory (94% to 99%).[86-88]

Curettage/Electrodesiccation

Curettage of skin lesions followed by electrocautery or chemical cautery is used with success on many smaller skin lesions of the trunk and extremities, but it is rarely indicated on the skin of the face, where the potential for unfavorable scarring precludes its use in most cases. The technique involves removal of the lesion using sequentially smaller curettes and relies on the tactile sensation of the surgeon to identify when normal tissue has been reached and the tumor has been removed. It is used by many dermatologists as a first-line treatment of smaller BCCs.[89] Some authors have recommended curettage alone without the electrodesiccation in an attempt to avoid some of the hypertrophic scarring associated with the use of electrodesiccation. Alterations in pigmentation can still result in an unacceptable scar. If it is performed on the face, its use should be restricted to those areas known to heal well by secondary intention—the so-called NEET areas: concave surfaces of the nose, ear, eye, and temple. In contrast, it should be avoided on the NOCH surfaces: convex surfaces of the nose, lips, cheeks, and chin (Figure 31-7).[90] Curettage is best suited for the treatment of thick actinic keratosis and smaller, exophytic squamous and basal cell cancers (typically less than 1 to 2 cm). Cure rates are high (>90%) with selection of appropriate lesions. As with cryotherapy, no specimen is generated for histopathologic exam.[86,91]

Laser Excision, Ablation, and Resurfacing

A variety of lasers are available for use by surgeons to ablate and excise lesions; lasers also can act as an energy source for activating photosensitizers, which are administered to patients and selectively taken up by tumor cells. The biologic effect of a laser is dependent on its absorption by the target tissue, and the wavelength determines the ultimate effect. A variety of laser media are available, including CO_2, argon, ruby, and Nd:YAG, to alter the absorption characteristics of the beam. In addition, altering the size of the beam as well as the delivery mode—continuous, pulsed, or



• **Figure 31-7** Areas of the face that can heal by secondary intention.

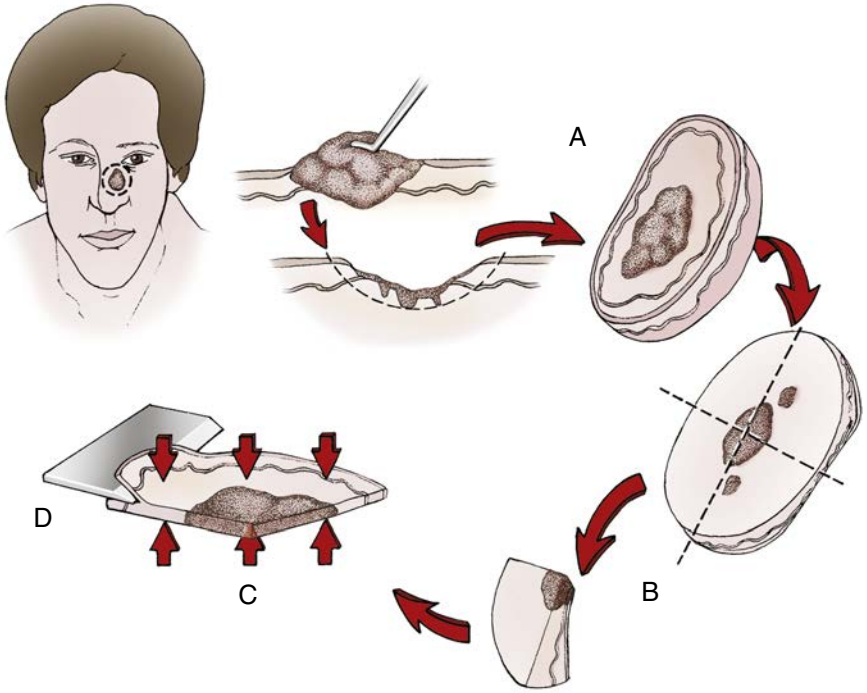
Q switched—changes the effect on the tissue as well. Lasers can be used in a continuous, focused mode for excisions with minimal thermal injury to surrounding tissue and excellent hemostasis. Larger beam sizes in a variety of energy modes can be used to ablate larger areas with minimal thermal injury to the underlying tissue, allowing for more rapid and complete healing by secondary epithelialization. Laser ablation is often indicated for resurfacing large areas of skin with actinic photodamage as an alternative to chemical peeling or other medical therapies. Hantash and colleagues[92] compared carbon dioxide laser resurfacing, topical 5% fluorouracil, and 30% trichloroacetic acid (TCA) peel for the prevention of squamous and basal cell carcinomas in patients with actinic keratosis and a history of non-melanoma skin cancer associated with severe photoaging. All demonstrated a statistically similar reduction in the number of actinic keratoses (range 83% to 92%), a lower incidence of NMSC, and decrease in the development of second primary skin cancers compared to the control group.

Mohs Micrographic Surgery

The current technique of Mohs micrographic surgery evolved from Dr. Frederic E. Mohs' chemosurgery technique, which he developed while working with Professor M. F. Guyer in the Department of Zoology at the University of Wisconsin.[93] Dr. Mohs was evaluating the effects of zinc chloride on cancerous tissue when he discovered that in addition to tissue necrosis, zinc chloride resulted in fixation of the tissue, which provided an excellent specimen for histologic examination. A paste was ultimately developed, which contained a binder *(Sanguinaria canadensis)*, a matrix (Stibnite; Hummel Chemical Co., South Plainfield, NJ), and zinc chloride 45% by weight. In 1941, Mohs presented his technique of chemosurgery. This technique involved application of the fixative for a prescribed time (maximum tissue penetration occurs at 18 hours following application), followed by removal and microscopic examination of the fixed tissue. Depth of penetration was controlled by altering the thickness and surface area on which the paste was applied. Successive layers were removed until tumor clearance was accomplished.[93,94] An important part of the procedure was the specific way in which Dr. Mohs oriented his specimen, which in theory allowed examination of 100% of the margin. Others argue that the most important component of the technique is that the surgeon performing the excision is also evaluating the margins. This decreases the potential for communication error, especially regarding specimen orientation, that may occur between surgeon and pathologist, because in this case they are one and the same.[95] At the time of his original work, frozen section analysis of margins was not available, and although labor intensive, the fixed tissue technique allowed for significantly improved cure rates compared to traditional surgical excision. Several modifications of the technique occurred, including elimination of the fixative in most cases, and in 1953 Dr. Mohs presented his technique modified for use with fresh tissue and frozen analysis of margins. Careful orientation of the specimen was the same, and the entire margin was still evaluated, which offered advantages over traditional surgical excision and margin analysis.

Although it is beyond the scope of this chapter to discuss the nuances of processing tissue for histologic examination, some discussion of margins is necessary to understand the advantage of Mohs surgery. A clinical margin refers to the edge of the lesion as appreciated clinically. A surgical margin is defined as the tissue edge of the specimen. Margins can be assessed as clear, close, or involved. Close margins are often defined differently by various pathologists, and surgeons should discuss the meaning of a "close" margin with the pathologist in order to decide whether or not further treatment, most commonly re-excision, is warranted. Tumor shrinkage of up to 40% can occur when a specimen is removed and processed, leading to a close margin when the excision seemed adequate clinically.[96] When a specimen is removed and oriented for the pathologist, there are several techniques for processing it for analysis. Traditionally, specimens are bisected or cross-sectioned in a vertical plane for examination. Alternatively, the specimen may be "bread-loafed" and cross-sectioned for greater visualization of the tumor and margins. The most comprehensive processing technique involves peripheral sectioning of all four sides of the tumor with or without a deep layer. Despite these variations, often less than 0.1% to 1% of the tumor margin is analyzed in the vertical sectioning techniques of traditional pathologic processing. It is impossible to examine the entire margin in a vertical technique because complete serial sectioning of a 1-cm tumor would require 2000 5-µm sections. By necessity, skip sectioning is performed. Asymmetric tumor growth can lead to tumor extensions between areas examined in a vertical technique.[95] By contrast, Mohs' micrographic excision technique is a horizontal and oblique sectioning technique, which theoretically allows examination of 100% of the deep and lateral tumor margins.

Mohs micrographic surgery is typically accomplished with the patient receiving a local anesthetic. The tumor is initially debulked using scalpel excision or curettes. This is followed by a lateral, beveled excision (45 degrees) joining a more horizontal excision of the deeper portion of the tumor bed. The specimen is carefully oriented with an accurate specimen map (Figure 31-8). Larger specimens may be divided by cross-sectioning, which is reflected on the specimen map. Inking edges with different colored inks can also aid in orientation. The specimen is inverted and mounted on the cryostat. Frozen margins are processed and examined from the undersurface of the specimen. These frozen sections are then evaluated and residual tumor is documented on the specimen map. Further layers are taken from the areas that were positive for tumor. The process is continued until a clear layer is reached. Typically this takes two or three layers.[97] Mohs' micrographic technique is best suited for tumors that grow in a contiguous fashion. Discontinuous tumor extension (emboli, for example) limits its utility because a clear margin may not ensure complete tumor removal—"skip" tumors may remain.



• **Figure 31-8** Mohs micrographic surgery. **A,** Tumor may be debulked with a curette and the remaining defect is excised. **B,** The specimen is oriented and frozen sections are obtained. **C,D,** The specimen is inverted on a cryostat to obtain full view of the deep margins by slicing with a microtome.

Reported indications for Mohs' micrographic technique include aggressive tumors (poor histologic characteristics), recurrent tumors, high-risk anatomic locations (H-zone of the face; see discussion earlier), and areas in which preservation of uninvolved tissue is of paramount importance for aesthetics or function (eyelids, for example) (Box 31-2).[98]

• BOX 31-2 Selected Indications for Mohs' Micrographic Surgery

Recurrent tumor
Tumor larger than 2 cm in diameter
Aggressive pathology or histologic features (perineural invasion, poorly differentiated squamous cell carcinoma, morphea-form basal cell carcinoma)
Tumors in certain anatomic locations where maximal preservation of tissue is desired (eyelid, canthus, ear, lip, nose)
Ill-defined borders
Tumors located in areas associated with aggressive behavior (H-zone)

Traditional Surgical Excision

Traditional surgical excision (TSE) involves removal of an arbitrary margin of healthy tissue in an attempt to encompass the tumor. This is followed by analysis of the margins with either intraoperative frozen sections or postsurgical permanent sections. The initial margin outlined around the lesion should take into account the size and histology of the lesion. Although there is no "gold standard" for initial margins, the literature does offer recommendations based on recurrence rates and positive margins following excision using various margins. For example, an initial peripheral margin of 4 mm will clear 98% of nodular basal cell cancers, whereas a 2-mm margin will clear only 75%. More generous margins, 8 to 10 mm, have been suggested for more aggressive BCC, such as the morphea-form subtype. For smaller BCCs (5 mm or less), initial margins of 3 mm may be acceptable.[99-102] Initial margins of 4 to 6 mm, which will clear the tumor in 95% of cases, are suggested for small to medium SCCs. More advanced lesions require margins of 10 to 20 mm. The depth of excision should include the subcutaneous tissue immediately subjacent to the tumor in most cases of squamous and basal cell cancers. Underlying fascia or periosteum is included in tumors with deep extension or fixation, and routinely in other histologies, such as DFP and Merkel cell carcinoma.[103]

Surgeons can use intraoperative examination of margins similar to Mohs' technique. Strong and his colleagues[104] describe their use of intraoperative peripheral in-continuity tissue examination in which 4-mm margins are taken for basal cell cancers and 6-mm margins are taken for squamous cell cancers. This is followed by orientation of the specimen and processing that allows frozen section examination of the margins similar to Mohs micrographic surgery. It requires excellent communication with the interpreting pathologist. The accuracy of intraoperative frozen section analysis for cutaneous malignancies of the head and neck is high (85% to 98.3%), but must be weighed against the resources necessary to carry out these procedures, and the low incidence of positive frozen margins requiring further excision.[105,106]

Treatment following positive margins on the final pathology report must be tailored to the individual patient. Most surgeons would recommend re-excision of squamous cell cancers with positive margins.[107] Treatment of positive margins in basal cell cancer excision is more controversial. Although some authors have suggested a watch and wait approach, most surgeons would opt for further excision if possible, with strong consideration given to Mohs' technique.[57,107,108] In some cases, however, re-excision may not be possible. Patients may refuse further surgery, or extensive flap coverage accomplished before final margin status may make accurate re-excision impossible. For this latter reason, surgeons may opt for delayed repair of the defect with careful analysis of permanent sections before committing to complex repair techniques. Positive margins can be an indication of biologic aggressiveness. In cases of initial positive margins, consideration should be given to postoperative radiation therapy even if re-excision has been performed. In addition, the need for a structured follow-up regimen should be stressed to the patient.

Traditional Surgical Excision versus Mohs Micrographic Surgery

There is ongoing debate regarding the choice of surgical technique for cutaneous malignancies of the head and neck. Kropp and colleagues noted that the 5-year overall survival in patients with head and neck skin cancer treated with Mohs excision was 86%, as compared to traditional surgical excision resulting in a 76% 5-year survival.[109] Despite the advantages of Mohs surgery discussed previously, there are well-known disadvantages, including the labor and time intensiveness of the technique, which can drive up costs of excision. Cost comparisons between Mohs micrographic surgery and traditional surgical excision (TSE) have been difficult, and results contradictory.[110,111] Bialy and colleagues[112] performed an interesting study comparing TSE and Mohs excision, and found that the costs were comparable when the Mohs technique was compared to TSE with frozen section control of margins or when compared to cases that included further treatment for inadequate margins. They cautioned, however, that choice of repair technique often influenced costs more than the method of excision. Dermatologic surgeons experienced in the Mohs technique often allow certain wounds to heal by secondary intention instead of performing coverage by local flap or grafting. Also, their excisions take place in an outpatient clinic. Patients undergoing surgery using local anesthesia may not tolerate excision of larger tumors, which often require multiple layers and lengthy procedures. This can build in a case selection bias when investigators attempt to compare the two techniques as larger, more complex tumors are more likely to undergo traditional surgical excision. Mohs surgery can be performed using a general anesthetic, but costs are increased significantly.[112] Given the sheer number of cutaneous malignancies, some have argued that Mohs surgery should be reserved for specific indications (see Box 31-2), and that traditional surgical excision is faster and allows for an acceptable cure rate. Finally, the decision to perform Mohs' excision technique versus traditional surgical excision may be determined by availability. Patients in many areas simply do not have access to a surgeon or dermatologist with training and competence in Mohs' surgical technique. Properly performed traditional surgical excision, with or without frozen section control, remains an option for most lesions in the head and neck.

Lymph Node Involvement in Cutaneous Malignancy

Regional lymph node metastases from cutaneous malignancies of the head and neck, although rare, must be considered. Lymph node metastases are an ominous finding and are usually associated with a poor outcome. Although clinically apparent nodal involvement is a clear indication for therapy, surgeons continue to search for predictors that would indicate the need for elective evaluation, including sampling of nodal basins at risk, in cutaneous malignancy, and without known regional metastasis. There are currently no accepted guidelines, and surgeons must rely on data gathered mostly from retrospective analysis and their own experience. Factors associated with regional metastases include recurrent lesions, thickness greater than 4 mm, and size greater than 2 cm. In addition, clinical perineural invasion is associated with a higher risk of nodal disease, and according to some authors, therapy should include treatment of first-echelon nodes (see earlier discussion on indicators of aggressive behavior in skin cancer).[54,113]

The lymph nodes in the parotid area deserve special attention because they serve as first-echelon nodes for many facial cutaneous malignancies.[114] As many as 20% of malignant parotid masses represent spread from cutaneous malignancy.[115] In Australia, metastatic cutaneous cancer is the most common parotid malignancy, with SCC occurring most frequently.[64] Metastatic parotid involvement by cutaneous SCC indicates the need to address the ipsilateral neck. In 73 patients with metastatic SCC involving the parotid, O'Brien found a high incidence of clinical and occult neck disease, 26% and 35%, respectively.[82] Based on a follow-up study, reported by Vauterin,[63] they recommended elective treatment of the neck with a supraomohyoid neck dissection, including the external jugular nodes, in patients with parotid involvement and a clinically negative neck. In cases of posterior lesions, level V should be included as well. In patients with clinical neck involvement, they recommended a comprehensive neck dissection.[103] One of the challenges facing surgeons is predicting which nodal basin would harbor occult disease if it is present. Lymphatic drainage of the face is not always predictable, and lymphoscintigraphy and sentinel node biopsy (SNB) techniques used in melanoma have demonstrated that drainage patterns can vary from predicted routes, and extended dissections may be needed to address occult disease.[116]

The sentinel node technique, previously validated in melanoma and breast cancer, has been investigated for use

in head and neck cancer, including non-melanoma skin cancer.[117-119] Theoretically, it allows the identification and removal of the lymph node that would first receive metastases from a given site. The technique involves injecting the area surrounding the primary site with a radioactive labeled tracer, usually ^{99m}Tc-sulfur colloid. Various molecular weights can be chosen depending on the transit time desired. At this point a radiograph can be taken to localize the sentinel node, which is the first node that receives lymph flow from the area of the tumor. The patient is then taken to the operating room, where the surgeon may inject a blue dye around the tumor. Again, this will drain to the first-echelon node, staining it blue, and assist the surgeon in identification during surgery. Also, the surgeon can use a gamma detection counter probe to identify the node with the highest concentration of radioactive colloid. This node is then removed. If it is positive, further treatment, such as radiation or more extended nodal dissection, may be indicated. Although its utility in cutaneous melanoma has been demonstrated, with accuracy of 82% to 100% and very few false negatives, the technique has shown only modest utility in non-melanoma skin cancers.[117,118] Basal cell cancers have a very low propensity for metastases, and therefore sentinel node biopsy does not seem to be warranted. Cutaneous squamous cell cancer, however, carries a higher risk for regional metastasis. Some studies have reported rates as high as 16% in cutaneous head and neck sites.[119] Sentinel node sampling may play a role in evaluation of patients whose cutaneous squamous cell cancer demonstrates poor histologic variables or those who present with large, deep lesions.[117,120] The sentinel-node technique can help overcome some of the inherent difficulties in nodal dissection for cutaneous malignancies, such as identifying which nodal basin is most likely draining the involved site, and therefore allow a more focused removal of the at-risk nodes. It may be especially indicated in Merkel cell cancers, which are known for their propensity to metastasize to regional nodes.[117,121] Devaney offered an excellent review of the current role of sentinel node biopsy for head and neck tumors, including cutaneous malignancies, and concludes that we will likely see further refinements and applications of the technique to a variety of head and neck cancers.[122] At this time, elective treatment of the neck with traditional or sentinel-node technique is not warranted without clinical evidence of involvement of regional lymph nodes, parotid, or neck.

Repair

The ability to repair or refer for repair a variety of wounds is an integral part of the management of skin cancers. The majority of wounds can be managed using healing by secondary intention, primary repair, or local flaps. Regional and even distant flaps may be necessary in a minority of cases. With experience, most surgeons develop their own preferences and "go-to" repair techniques. Here we review some of the general principles involved in repair of facial defects following excision of skin lesions. Before surgery, surgeons should have a reconstructive plan, which will be altered as necessary following excision, at which time the most appropriate method of repair is selected based on patient and defect characteristics. Consideration of the repair options preoperatively will help orient the excision in the appropriate manner, whether for primary closure or flap repair. An attempt should be made to orient the excision in such a way as to allow its closure along resting skin tension lines (see Figure 31-6). Likewise, if a local flap is required, proper planning can allow closure of the defect created by flap development along RSTLs as well. Although primary repair is convenient and possible in many cases, patients with large tumors or those with indications of biologic aggressive behavior (see earlier) may be best served with delayed repair. Delayed repair offers several advantages, including time for assessment of margins with permanent technique and an opportunity to assess the defect and choose the best technique for repair. Friedrich[22] examined 124 patients who underwent surgical treatment for 216 basal cell carcinomas, the majority of which were located in the middle third of the face. Further resections were indicated in 71% after histologic examination of the margins. Because of the complexity of techniques involved, surgeons should consider delayed reconstruction in cases of questionable margin status, aggressive histologic variables (such as perineural invasion or bone involvement), or if postoperative radiation is planned. Importantly, delayed repair can allow the patient an opportunity to see the defect and participate in the decision-making process. Wound contracture during the delay can result in a more favorable defect. In addition, granulation tissue that develops in the bed during the delay often results in better acceptance of skin grafts. Properly maintained, cutaneous wounds can be maintained with a moist dressing for weeks without an increased risk of infection. Escobar and Zide[123] reviewed 280 patients managed with delayed repair techniques following excision of skin lesions. Some patient repairs were delayed up to 35 days with minimal complications. Delayed repair may also be indicated to take advantage of the ability of skin to expand when placed under tension (skin creep). Skin creep occurs by two mechanisms: mechanical, which is a more acute phenomenon, and biologic, which is a more long-term response of skin to load. For example, skin expanders can be used intraoperatively to expand flaps, taking advantage of mechanical creep. They can also be buried and activated over weeks to allow expansion through growth of new tissue (biologic creep).[124] Some patients, however, will not accept delayed repair, and others may not be candidates for delayed repair for a variety of reasons; in these cases, repair at the time of excision may be warranted.

Surgical repair of all wounds is not always necessary, and healing by secondary intention is a viable alternative in some cases. Certain areas of the face are more amenable to healing by secondary intention and may not require repair (see Figure 31-7). Concave surfaces of the nose, ears, eyes, and temple are associated with more acceptable scarring following healing by secondary intention, whereas convex

surfaces of these same areas typically heal poorly by secondary intention (see previous discussion under biopsy). Wounds located at the junction of facial aesthetic subunits typically are well hidden.[125] Patient characteristics, such as age, should be taken into account. Although aged skin tends to heal with less scarring, these individuals may be unable to care for the wound without assistance.

In recent years, negative pressure applied to wounds by use of a vacuum-assisted closure (VAC) device has gained popularity. This device accelerates and improves wound contracture. Vacuum-assisted closure increases blood flow and granulation tissue formation and aids in the removal of fluid and surface contaminants.[126] Aside from aiding in the management of open wounds, it serves as an excellent bolster for skin grafting, leading to increased survival.[127] It may also be used in preparation for delayed skin grafting, as it typically results in an excellent granulation bed. It is not recommended in cases in which there is concern for residual tumor in the wound bed.

Full- or split-thickness skin grafting allows repair of large wounds that are not amenable to healing by secondary intention and in which flap repair is not indicated or necessary. Unlike flaps, grafts are dependent on nutrition from the recipient bed (plasmatic circulation or imbibition) for 48 to 72 hours until capillary ingrowth and inosculation occurs. During the early wound healing phase, absolute stability of the graft provides the best opportunity to prevent shearing and graft loss. Full-thickness grafts include the epidermis and dermis and usually provide a more aesthetic result with less late wound contracture if there is satisfactory acceptance of the graft. The supraclavicular and postauricular areas provide good-quality skin for full-thickness grafting with good color match for most facial sites. Skin harvested from the upper eyelids provides an excellent thin full-thickness graft. Disadvantages of full-thickness grafting include need for closure of the donor site and increased risk for either partial or complete graft failure. Split-thickness grafts include epidermis and a portion of the dermis. Healing of the donor site depends on epithelial migration from skin appendages and lateral edges. Split-thickness grafts are less aesthetic in most cases and are susceptible to more contracture. Advantages include the ability to cover larger areas and greater success with graft take.

Composite grafts contain skin and additional tissue, such as cartilage. Although sometimes used for reconstruction of small alar defects, healing of composite skin/cartilage grafts from the helix is unpredictable.

Flaps

Wounds that are not amenable to grafting require flap coverage. Flaps import their own blood supply, which may be random or axial. Most facial skin defects resulting from cancer extirpation can be managed with random, local flaps, including advancement, rotation, and transposition flaps. Use of flaps creates a second wound, which must be repaired, and the design of the flap should keep this in mind. Advancement and rotation flaps usually create excess tissue at one or both ends of the incision. Although they can occasionally be removed with Burow excision or some modification, this "dog ear" or "standing cone" frequently should be left in place, as it will resolve with time and allow maximal preservation of tissue. Axial pattern flaps are based on larger caliber vessels and can be designed with a narrow base carrying a large territory of tissue. They may be regional or distant in the form of free tissue transfer. Regional flaps commonly employed for larger facial wounds include cervicofacial and cervicopectoral flaps.[128] Free tissue transfer is indicated when local and regional tissues are not adequate and are usually required when composite defects have been created.

Regardless of technique, secondary procedures, such as dermabrasion or scar revision, are frequently necessary for an acceptable result. Patient education plays a critical role in managing expectations, because some patients have unrealistic goals, and surgeons can be drawn into an endless series of efforts to create an "invisible" wound with diminishing returns.

Medical Management

Systemic and Topical Medications

Basic sun protection is the starting point for all skin cancer prevention protocols. Targeted approaches to higher-risk patients are used on an as-needed basis. Chemoprevention involves administering a drug in the hopes of reversing or preventing malignant transformation. It has been applied successfully, using tamoxifen, to patients at increased risk for breast cancer. Chemoprevention is an appealing approach to patients who are at high risk for development of cancers. Field cancerization, as presented by Slaughter in 1953,[129] is a concept that is well known to oral cancer surgeons who have dealt with multiple recurrences following seemingly margin-free resections. Slaughter described histologic abnormalities in tissue not contiguous with the primary tumor, and proposed that this may result in multiple recurrences following treatment. Later work demonstrated that seemingly clear histologic margins harbored precancerous genetic abnormalities.[130] Similarly, some patients with NMSC suffer from multiple recurrences, leading to multiple surgical interventions, and certain populations are known to be at higher risk. These include patients with xeroderma pigmentosum, a rare, autosomal recessive disorder characterized by an impaired ability to repair UV radiation induced damage to DNA, with a resultant increase in skin cancer. These patients develop skin cancers early in life (as early as 2 years old) and with a frequency 1000 times that of the general population.[131] Also, patients with basal cell nevus syndrome—a rare autosomal dominant disorder characterized by multiple odontogenic keratocysts, multiple basal cell carcinomas, hypertelorism, frontal bossing, palmar or plantar pitting, calcified falx cerebri, bifid ribs, and medulloblastomas—are at risk and have been shown to benefit from chemoprevention with retinoids in some cases.[132] As discussed previously, non-melanoma skin cancers have been a vexing problem for transplant surgeons ever since chronic

immunosuppression, which leads to a marked increase in susceptibility to NMSC, made solid organ transplants feasible. For this reason, these high-risk patients have served as a popular test group for chemopreventive agents. Systemic retinoids were investigated early in an attempt to decrease this risk.

Retinoids are vitamin A derivatives and have been widely studied as chemopreventive agents in skin, oral, breast, and cervical cancers. The relationship between hypovitaminosis A and development of certain cancers led to the study of retinoids for chemoprevention when they were synthesized in the 1970s. By binding to two families, retinoid acid receptors and retinoid X receptors, retinoids affect keratinocytes by modifying their maturation, growth, cell surface, and immune modulation. Retinoids, both systemic and topical, have been the most widely studied medication for chemoprevention. Currently, two retinoids are available: isotretinoin and acitretin, which has a longer half-life. De Graaf and colleagues reviewed topical and systemic retinoids in transplant patients and found that acitretin was particularly effective for prevention of NMSC development in these patients, but the effect was present only while the patient was receiving therapy. Topical retinoids had some effect on actinic keratosis only. Unfortunately, side effects, such as elevation of triglyceride and cholesterol levels and negative liver function tests, limit their long-term use in many patients.[133] Campbell[134] also reviewed the use of the systemic retinoids isotretinoin, etretinate, and acitretin for skin cancer chemoprevention in high-risk patients, such as patients with basal cell nevus syndrome, transplant patients receiving immunosuppression therapy, and patients with multiple recurrent skin cancers. He also recommended starting with low doses and employing appropriate laboratory and radiographic screening to determine toxicity and side effects. Although systemic retinoids do not inhibit healing of surgical wounds, they can predispose to excessive granulation tissue. In addition, the dryness associated with retinoids can increase bacterial colonization, leading to increased risk of infection following surgery. Additionally, side effects of systemic retinoids, including dryness of nasal mucosa, cheilitis, xerosis, blepharitis, and conjunctivitis, often decrease patient compliance. Early treatment of these mucocutaneous effects with appropriate emollients and wetting agents can improve patient acceptance. Laboratory monitoring is required for hyperlipidemia and increased liver enzymes. Despite known risks of birth defects, there are still pregnancies in patients undergoing therapy with systemic retinoids. This has prompted a program, iPledge, which requires physicians, pharmacists, and patients to register through a central office and verify pregnancy-free status before filling prescriptions.[134] In an attempt to overcome the side effects of systemic medication, there has been a continuous search for effective topical medication for chemoprevention of cutaneous malignancies.

Topical Medications

Because patients at risk for development of skin cancers typically have large areas of photodamaged skin, investigators have sought methods to deal with this field effect in an attempt to prevent the development of skin cancers (chemoprevention) and improve the health and appearance of damaged skin while avoiding the side effects of systemic therapy. Common topical treatments for the prevention of NMSC include topical retinoids, topical 5-fluorouracil, diclofenac sodium, and topical imiquimod cream. Although some clinicians use some of these agents for the treatment of superficial cancers, the high relapse rate once therapy is stopped limits their utility in this regard, and most do not recommend their use for invasive cancer. Patients receiving topical therapy must be followed closely for side effects and compliance, and a structured follow-up regimen is recommended to monitor for the development of invasive lesions requiring surgical intervention. Here an overview of topical treatments is presented; more detailed reviews are available.[135,136]

Topical retinoids attempt to avoid the systemic side effects that limit the use of systemic formulations (see earlier discussion). Similar to the systemic formulations, topical retinoids, such as tretinoin, function to inhibit the growth of abnormal cell lines and induce normal maturation into dysregulated growth. Topical therapy with retinoids consists of application of topical tretinoin cream to affected areas. Although it has been used in the treatment of BCC, high relapse rates limit its use to noninvasive skin conditions. Side effects, including irritation and burning sensation, can limit patient compliance, and a variety of formulations and application schedules have been developed in an attempt to counter these side effects.[135]

Antimetabolites, such as 5-fluorouracil (5-FU), block development of certain metabolites critical for cell metabolism. 5-Fluorouracil is a fluoridated pyrimidine analogue that inhibits thymidylate synthetase, blocking the generation of thymidine, which is necessary for DNA synthesis. 5-Fluorouracil is available as a topical formulation, Efudex 5% (Valient Pharmaceuticals, Costa Mesa, CA). It is approved for the treatment of actinic keratosis, and clearance rates of 83% have been published. It has also been used for superficial BCC and SCC in situ. It is not indicated for invasive SCC. Application is associated with a brisk inflammatory response, which can limit patient compliance. Unfortunately, patients with the most intense inflammatory response often have the best result once healing has occurred. A more recent formulation of 0.5% fluorouracil has shown decreased side effects, and may be more tolerable, but is only indicated for the treatment of AK. Treatment with 5-FU is contraindicated in patients with dehydropyrimidine dehydrogenase deficiency (DPD).[135]

The use of nonsteroidal anti-inflammatory drugs has been investigated as a potential chemopreventive agent in a variety of neoplastic conditions, including squamous cell cancers and colon polyps. Cyclooxygenase (COX), specifically COX-2, has been demonstrated to be upregulated in areas of tumor growth. COX-2 inhibitors have been shown to alter the development of neoplasms, although the exact mechanism by which they produce antineoplastic effects is

unknown. Topical diclofenac sodium gel (Solaraze gel 3%, Bioglan Pharmaceuticals, Malvern, PA) is FDA approved for the treatment of actinic keratosis and is better tolerated than topical 5-fluorouracil treatment. Minor skin irritation can still be a concern, and contact allergic dermatitis develops in some patients. Treatment times are longer (up to 3 months), limiting patient compliance, and response rates of 47% on facial lesions are lower than that of topical 5-FU. It is an alternative, however, in patients who will not tolerate the side effects of Efudex.[135]

Imiquimod (Aldara, 3M Pharmaceuticals, St. Paul, MN), is an immunomodulator applied topically. The exact mechanism by which it exerts its effects on actinic keratosis is unknown, but it stimulates T-cell response, leading to upregulation of antitumor effects, such as production of tumor necrosis factor, and this effect can be long-term through the establishment of immunologic memory. Although initially approved for the treatment of genital warts, dermatologists began to use it "off label" in their clinical practices for a variety of neoplastic and non-neoplastic skin conditions, and it was recently approved by the Food and Drug Administration for the treatment of actinic keratosis.[137]

Imiquimod has been shown to be a well-tolerated and effective treatment for actinic keratosis.[83,138] When administered over a 12-week course, 92% of patients demonstrated some response, with 84% showing complete resolution and only 10% showing recurrence 1 year after treatment. Early work has demonstrated some effect on superficial BCC and SCC in situ, but at this time it is approved for treatment of AK only. As with Efudex, a brisk inflammatory response can limit its use in some patients.

Photodynamic Therapy

Given the high rates of multiple lesions in patients with NMSC and their propensity to recur, photodynamic therapy (PDT) is gaining popularity as a potential method for dealing with multiple, diffuse lesions. Photodynamic therapy relies on a complex interaction of a photosensitizing agent that is preferentially concentrated in abnormal tissue with light of various wavelengths, depending on the photosensitizer, to create necrosis through a non-thermal reaction. Tissue necrosis is mediated through the creation of singlet oxygen, a highly reactive species that induces cellular damage through several mechanisms. Advantages of PDT include minimal damage to surrounding tissues and no cumulative damage, which theoretically allows unlimited treatments. Given the propensity for many cutaneous malignancy patients to develop multiple lesions, this is an important advantage over excision or ablation using traditional methods. Minor discomfort, erythema, and itching are common side effects of treatment. Areas treated undergo healing through secondary intention with minimal or no scarring. Disadvantages include marked photosensitivity with systemic PDT, especially with regard to sun exposure, for variable lengths of time after the administration of the agent. Although a complete review of PDT is beyond the scope of this chapter, excellent reviews are available.[135,139]

Photodynamic therapy has been used with success in the treatment of actinic keratosis using systemic 5-aminolevulinic acid PDT, but photosensitivity not relieved with sunscreen can last up to 3 months. In response, investigators began using topical PDT with 5-aminolevulinic acid (ALA), a protoporphyrin precursor. It is absorbed by keratinocytes and converted into an endogenous photosensitizing agent. Effective management of actinic keratosis is possible while minimizing systemic side effects. Clearance rates for actinic keratosis are excellent and range from 70% to 90% at 3 years. Early response of superficial SCC and BCC led some investigators to recommend PDT, but disappointing results at longer term follow-up led most to not recommend PDT for invasive lesions.[140,141]

Radiation

Because of its efficiency and effectiveness, surgery is the treatment of choice for the vast majority of skin cancers. Radiation therapy, however, is indicated for some patients who are not surgical candidates (e.g., large lesions in anatomic locations not amenable to surgical excision without undue morbidity) and in a salvage role for multiply recurrent or multicentric lesions. It can also serve as an adjunct to surgery in lesions with poor prognostic factors, such as perineural extension, positive margins, or nodal involvement.[54] Older orthovoltage radiation machines were ideal for treatment of skin cancers because of the superficial absorption of these lower-energy beams. Indeed, skin damage from radiation treatment was one of the impetuses leading to the introduction of newer high-energy megavoltage linear accelerators. These higher energy machines can also be used to generate low-energy electrons that are better suited for treating skin cancers. Higher energy beams can be used for more deeply seated tumors. Although typically administered over multiple fractions, some investigators have demonstrated good control rates with single-fraction treatment.[142-144]

When used as a single modality, control rates for BCC and SCC are high (95% to 97% and 90%, respectively), but lesions that recur following radiation treatment tend to behave aggressively.[144] Whether this is an effect of the radiation or shows that failure to respond completely to radiation is an indicator of biologic aggressiveness is unknown, but the latter is probably more likely. In addition to its role as primary treatment, radiation therapy can play an important role in recurrent lesions as an adjunct to surgery.[144] With special shielding techniques, radiation can also be an effective tool for management of eyelid and canthal lesions, avoiding the morbidity associated with large resections of this complex area.[144] Radiation therapy generally leads to good cosmetic results following healing, but studies directly comparing radiation to surgery or other treatment modalities are lacking. In addition to its role at the primary site, radiation therapy is recommended as adjuvant therapy in cases of known nodal disease. It has been shown to improve locoregional control and survival.[115]

In contrast to other NMSCs, adjuvant radiation therapy has become standard in the treatment of Merkel cell

carcinoma. Veness et al[129] found that adjuvant locoregional radiation following surgery results in a longer median disease-free interval in Merkel cell carcinoma (23 versus 6 months) and decreased nodal relapse. This is in agreement with other studies that have demonstrated that adjuvant radiation should be considered standard therapy.[129]

Regardless of primary treatment modality, patients with skin cancer require structured follow-up for evaluation of recurrence, as well as new primary lesions.

Special Considerations

Lip Cancer

Although classified as an oral cancer, squamous cell carcinomas of the lip typically follow a different clinical course than that of typical oral squamous mucosal cancers. The behavior of lip cancers typically lies somewhere between that of oral squamous cancers and cutaneous squamous cancers. For staging purposes, the lips are defined anteriorly by the skin-vermilion junction and include the mucosal portion that comes in contact with the opposing lip. Upper and lower lips join at the commissures. The lip consists of an inner mucosal lining (more properly known as buccal mucosa), vermilion (that which touches the opposing lip), and the skin on the outer surface. Cancers involving the lip may arise from any of these areas, and determining the epicenter or point of origin is often difficult.

Most commonly the lower lip vermilion is the origin, and squamous cell cancers account for the majority of malignancies affecting the lip. Most lesions arise in an area of actinic keratosis (Figure 31-9), which can be treated with a vermilionectomy. Often it is difficult to discern the epicenter of the tumor and stage it accurately. Some cancers are so large that it is difficult to decide if they arose from the skin of the lip, the vermilion, or the buccal mucosa.

A summary of the current staging follows:

Primary Tumor

- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma in situ
- T1: Tumor less than 2 cm in greatest dimension
- T2: Tumor more than 2 cm but less than 4 cm in greatest dimension
- T3: Tumor more than 4 cm in greatest dimension
- T4a: Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face, that is, chin or nose
- T4b: Tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid artery

Regional Lymph Nodes

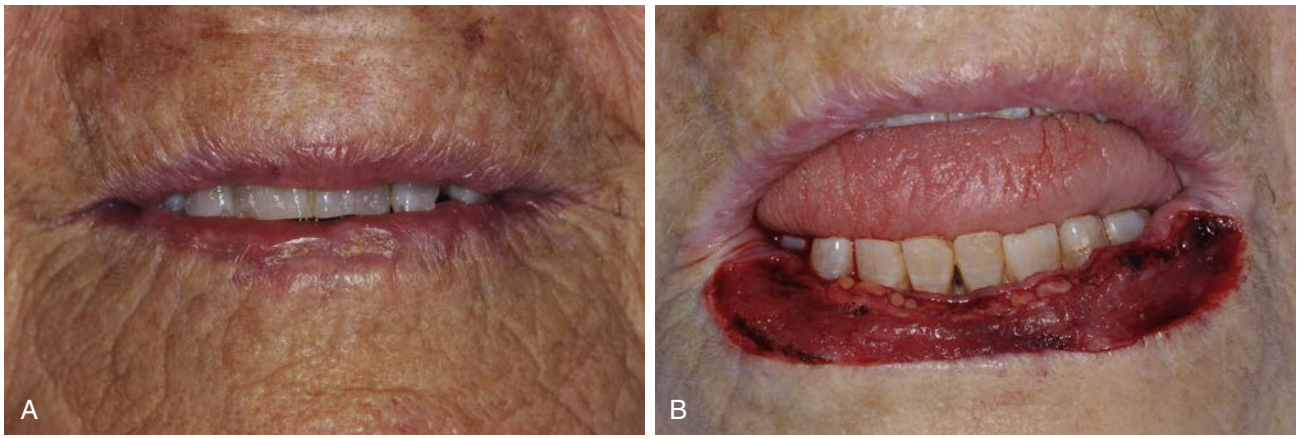
- NX: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastases
- N1: Metastases in a single ipsilateral lymph node, 3 cm or less in greatest dimension
- N2: Metastases in a single, ipsilateral lymph node, more than 3 cm but less than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral nodes, none greater than 6 cm
- N2a: Metastases in a single, ipsilateral lymph node more than 3 cm but less than 6 cm
- N2b: Metastases in multiple, ipsilateral lymph nodes, none more than 6 cm in greatest dimension
- N2c: Metastases in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
- N3: Metastases in a lymph node more than 6 cm in greatest dimension

Distant Metastases

- MX: Distant metastases cannot be assessed
- M0: No distant metastases
- M1: Distant metastases

Stage Grouping

- Stage 0: TisN0M0
- Stage I: T1N0M0
- Stage II: T2N0M0
- Stage III: T3N0M0
  - T1N1M0
  - T2N1M0
  - T3N1M0



• **Figure 31-9** **A,** Actinic keratosis. **B,** Vermilionectomy defect, which is easily closed by mucosal advancement.

- Stage IVa: T4aN0M0
  - T4aN1M0
  - T1N2M0
  - T2N2M0
  - T3N2M0
  - T4aN2M0
- Stage IVb: AnyTN3M0
  - T4bAnyNM0
- Stage IVc: AnyTAnyNM1

The primary etiologic agent for lip cancer (sun exposure) is different than for oral cancers, and the highly visible location of lip carcinomas usually leads to earlier discovery. The behavior of squamous cell cancers of the vermilion border is usually intermediate between that of SCC of the skin and that of the mucosa. The vast majority arise on the lower lip, where sun exposure plays an important etiologic role. Most lip cancers are treated surgically with resection using 0.5- to 1.0-cm margins confirmed with frozen section. Excisions typically take the form of wedge excisions, which may be combined with a lip shave procedure removing vermilion that has suffered extensive actinic damage or contains carcinoma in situ. Mohs micrographic surgery is an alternative to traditional surgical excision. There is potential for perineural invasion and/or mandibular involvement with larger lesions, which can require extensive resections and reconstructive efforts (Figure 31-10).

Certain factors are associated with more aggressive behavior in lip cancer with increased recurrence and metastatic rates. Size greater than 2 cm is associated with local recurrence and metastases more frequently than those less than 2 cm.[145] Histologic grade also influences local recurrence and metastatic rates. Well-differentiated tumors are associated with lower local recurrence rates and metastases compared to poorly differentiated tumors.[83] Perineural involvement is also associated with higher local recurrence and distant metastases, with up to 34% of patients developing distant spread.[84] Finally, age less than 40 years has been associated with increased risk of local recurrence and distant metastases.[145]

As with the cutaneous sites, there is a significant amount of controversy surrounding the need for elective neck dissection of at-risk nodal basins in lip cancer. Early investigators believed that the risk of metastasis was low, at around 0.5%,

• **Figure 31-10** **A,** 3-cm lip carcinoma with perineural invasion, extensive induration and subcutaneous spread, and palpable lymph nodes. **B,** Defect after excision. **C,** Specimen with at least 1-cm margin around palpable tumor. **D,** Reconstruction with radial forearm free flap.

but more recent investigators reported significantly higher rates of metastasis (up to 16%) with longer follow-up.[84]

Although some authors recommend elective neck dissection only in cases of clinical evidence of lymph node involvement by exam or imaging, others recommend consideration of elective treatment of at-risk nodal basins in cases with poor prognostic indicators. For clinical N0 necks, factors that should prompt consideration of elective neck dissection include T3 or T4 tumors, commissure involvement, recurrence, and perineural spread.[146] Although these guidelines exist, at this time elective treatment of the N0 neck in lip cancers is controversial.[71,73] Investigators continue to search for biologic markers and improved predictors of aggressive behavior that will better select patients requiring more intensive therapy.[72,74] Elective nodal dissection for lower lip cancers should include level I bilaterally at a minimum, although some recommend bilateral supraomohyoid dissection. Supraomohyoid (levels I to III) or modified neck dissection of levels I to V is indicated in cases of therapeutic neck dissection.[147] It should be noted that upper lip cancers account for only 10% of lip cancers and have unique characteristics. The upper lip and the commissure may metastasize to the periparotid lymph nodes, and superficial parotidectomy may be required if there are clinically enlarged nodes.[148]

Again, sentinel-node biopsy may play a role in the elective management of lip cancers when there is a question of metastatic potential.

In an effort to preserve cosmesis and function, radiation therapy, both external and brachytherapy, may be used as primary treatment in larger lesions.[149] Radiation therapy may also be indicated as an adjunct to surgery in cases of positive margins or nodal disease.

Summary

Although it makes up only 10% of the surface area of the body, the skin of the head and neck is the site for development of the majority of cutaneous malignancies because of its exposure to harmful ultraviolet radiation. Its increasing incidence associated with the significant costs of treatment will require practitioners to be well-versed in the effective and efficient management of these malignancies to limit their morbidity and costs. Oral and maxillofacial surgeons may be called upon to treat skin cancers primarily, or to reconstruct complex defects following tumor extirpation by other surgeons.

The Use of Radiation Therapy in Treatment of Head and Neck Cancer

WILLIAM L. BARRETT, MICHELLE L. MIERZWA

Almost since Wilhelm Roentgen discovered the x-ray in 1896, there has been interest in the use of radiation as treatment for malignant disease, including cancers of the head and neck. The ability of radiotherapy to reduce and sometimes eradicate cancer was appreciated in the early years of experimentation with the new modality. The use of radiation therapy for treatment of cancer of the head and neck was of particular interest because of the frequent morbidity of surgical resection of head and neck cancer with the frequent deleterious effects on speech and swallowing function as well as cosmesis associated with surgical resection. After many years of improving radiotherapy delivery methods and dose schedules, the approach remains attractive today and is frequently preferred, allowing for preservation of speech and swallowing function with eradication of disease in many cases. The modality has evolved through the years with the development of high-energy radiation machines capable of sparing superficial normal tissues; the development of effective radioisotopes for interstitial and intracavitary applications; the appreciation of biologic differences between normal tissues and tumors relative to response to radiation, allowing more optimal radiation dose schedules; the integration of systemic therapies with radiation; and the complex delivery of radiotherapy from multiple orientations and dose modifications to enhance tumor response with protection of normal tissue. The past 100 years have been extremely exciting in the evolution of radiotherapy as definitive treatment and as adjuvant therapy for patients with carcinomas of the head and neck, and the field is currently improving rapidly with continued improvements in technology.

Overview

Histologies

Squamous cell carcinoma is the most common cancer—over 90%—of the head and neck. It has been associated with chronic tobacco and/or alcohol exposure. Prognosis varies with the extent of disease present at the time of treatment, subsites involved, and technical aspects of the treatment delivery. Biologic aspects of the tumor, largely undefined to date, also affect the natural history of the disease and prognosis.

Other cancers include Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL), sarcomas of soft tissue and bone, thyroid cancers, salivary gland malignancies, and skin cancers. Mucosal melanomas are uncommon, as are carcinoids and small cell carcinomas.

Lymphomas are considered sensitive to both radiation and chemotherapy, and these modalities are used in treatment strategies for either HL or NHL. Surgery is generally not a part of the therapy regimen for these diseases. Hodgkin disease is most often managed by radiation therapy, chemotherapy, or a combination of those treatments, depending on the extent of the disease and the patient's age, gender, and comorbidities. Radiotherapy is typically delivered as once-per-day treatment with five treatments per week, with total doses typically totaling between 3000 and 4000 cGy, which is associated with high efficacy for disease eradication.[1] NHLs of the head and neck can be managed by observation, chemotherapy, and/or radiation therapy, depending on the histologic grade, extent of disease, patient age, and patient comorbidities. Most NHLs are sensitive to radiation, with doses between 3000 and 4500 cGy most often used.

Sarcomas of the head and neck are most often managed by a combination of surgical resection and radiation therapy given preoperatively or postoperatively. Typical preoperative radiation doses include 4500 cGy in 25 treatments at 180 cGy per day, and postoperative doses are typically on the order of 5940 cGy in 33 treatments with 180 cGy per day. Interstitial radiation when used alone typically entails approximately 4500 cGy delivered over 4 to 5 days, commonly with continuous iridium. When interstitial radiation

is used as a boost following preoperative radiation or before planned postoperative external radiation, the interstitial boost is typically approximately 2000 cGy over 2 days, most often with iridium.[2]

Thyroid cancers can be grossly divided into differentiated carcinomas that concentrate iodine (papillary and follicular) and poorly differentiated carcinomas that typically do not concentrate iodine, including medullary and anaplastic histologies. Papillary or follicular carcinomas of the thyroid are most often managed with surgical resection and frequently adjuvant iodine-131 (^{131}I) treatment. Indications for external radiation therapy include extracapsular extension of disease at the primary site, persistent known or suspected residual disease following ^{131}I therapy on the basis of grossly apparent disease clinically and/or radiographically, or a persistently elevated thyroglobulin level. When adjuvant radiation therapy is delivered, the radiotherapy is typically 5000 to 6000 cGy, typically 180 to 200 cGy per day with five treatments per.[3-5] Similar doses are frequently delivered postoperatively after resection of medullary carcinoma of the thyroid.[6] Anaplastic carcinoma of the thyroid has an extremely poor prognosis and is managed sometimes with surgical resection with adjuvant radiation therapy, sometimes radiation alone, and sometimes radiation with systemic therapy. Radiation doses are typically in the 6000 to 7000 cGy range at 200 cGy per day.

Mucosal melanomas are uncommon. When treated with radiation therapy definitively or as adjuvant therapy, larger fractions of typically 250 cGy or more daily are used to a total dose of 5000 cGy.[7] Cutaneous and mucosal melanomas are thought to require higher doses per treatment than squamous cell carcinomas of the head and neck because of an inherent biologic radioresistance.

Head and Neck Sites of Disease

Oral Cavity

Squamous cell carcinomas of the oral cavity most frequently involve the oral tongue and/or floor of mouth, but other potential primary sites include the lips, buccal mucosa, hard palate, gingiva, and retromolar trigone. Surgical resection is generally the first consideration if the disease is thought amenable to resection with preservation of speech and swallowing function. In the situation of technically unresectable disease or the anticipation that resection would be particularly deleterious to speech and/or swallowing function, radiotherapy as definitive treatment, with or without systemic therapy, is frequently a consideration. Adjuvant radiation delivered preoperatively or postoperatively is frequently considered in the setting of locoregionally advanced disease.

Definitive radiotherapy frequently entails external radiation directed to the primary sites and regional lymph nodes in the neck to a dose on the order of 5000 cGy in 25 treatments with subsequent localized boost radiation to the primary site and any gross adenopathy. Palpable lymph nodes typically receive an additional 2000 cGy in 10 treatments, whereas the primary disease in the oral cavity can be further treated with an electron cone on the order of 2400 cGy in eight treatments or with an interstitial implant, often with iridium delivering 2500 cGy to the tumor over 2 to 3 days. Local tumor control rates by stage of disease are listed in Table 32-1. In the absence of obvious nodal disease, the neck is generally prophylactically treated for the possibility of occult nodal disease. If the decision is made to observe the neck, the primary site can be treated with an interstitial implant alone on the order of 6000 cGy over 6 days with iridium. An oral tongue interstitial implant is pictured clinically and radiographically in Figure 32-1.

Oropharynx

Subsites of the oropharynx include the base of tongue, palatine tonsils, soft palate, and pharyngeal wall. Radiotherapy is frequently used as part or all of the treatment for patients with squamous cell carcinomas in these sites. If disease is considered technically unresectable or if resection is thought to be associated with significant morbidity, radiation therapy alone or with systemic therapy is frequently used. For advanced resectable disease, radiation is frequently delivered preoperatively or postoperatively as an adjuvant treatment. Definitive radiation therapy for tonsil, soft palate, and pharyngeal wall squamous cell carcinomas is typically external radiation throughout. Figure 32-2 demonstrates a patient treated with definitive radiotherapy for a tonsillar cancer. Base-of-tongue cancers are sometimes treated with a combination of external radiation therapy and interstitial implant with doses similar to those used for oral cavity squamous cell carcinomas. Treatment results are listed in Table 32-2.

Larynx

The larynx is typically divided into the glottis, including the true vocal cords and anterior commissure; the subglottis, just below the glottis; and the supraglottic larynx, including the epiglottis, arytenoids, aryepiglottic folds, false vocal cords, and ventricles. Squamous cell carcinomas of the larynx are frequently treated with definitive radiation therapy with or without systemic therapy in an attempt to preserve speech function. Cancers clinically confined to the glottis are thought to have low metastatic lymph node potential and are typically treated with relatively small external radiation therapy fields, as depicted in Figure 32-3. More advanced glottic cancers and supraglottic cancers are considered at risk of lymph node metastases, and lymph nodes are typically treated. A typical 3D conformal field used to

treat an advanced laryngeal cancer is shown in Figure 32-4. Patients who present with hoarseness frequently experience improvement in voice function in the first 2 to 3 weeks of the radiation course with subsequent decline in voice function as a result of mucositis and laryngeal edema, which are typically transient with typical improvement in voice function by several weeks after radiation therapy. Treatment results are shown in Table 32-3. Neoadjuvant chemotherapy prior to radiation therapy has been shown to be no worse than up-front laryngectomy and postoperative radiation therapy for locally advanced laryngeal cancer in a randomized trial,[8] but neoadjuvant chemotherapy followed by radiation therapy has been shown to be no more effective than radiation therapy alone in another randomized trial.[9] That trial did show an advantage to the addition of concurrent cisplatin with radiation for locally advanced laryngeal cancer.

TABLE 32-2 Local Control Rates at 5 years of Oropharyngeal Carcinoma by Site and Stage of Disease Treated with External Beam with or without Interstitial Radiation Therapy

Disease Site	T1	T2	T3	T4
Base of tongue[18-21]	87%-96%	74%-93%	59%-82%	28%-52%
Tonsil[22-25]	83%-95%	79%-88%	58%-74%	40%-60%
Soft palate[26-28]	90%-100%	65%-95%	50%-77%	24%-37%
Pharyngeal wall[29-31]	91%	73%-93%	82%-61%	37%

Hypopharynx

Subsites of the hypopharynx include the pyriform sinuses, post-cricoid region, and posterior pharyngeal wall. Squamous cell carcinomas of the hypopharynx are managed sometimes with surgical resection, often with preoperative or postoperative external radiation therapy, sometimes with definitive radiation therapy, and sometimes with radiation therapy with concurrent systemic therapy. Surgical resection is typically morbid relative to speech and swallowing function where larger tumors require laryngopharyngoesophagectomies. Radiation doses are similar to those discussed for cancers of the oral cavity and oropharynx. Results for treatment of cancers of the hypopharynx are shown in Table 32-4.

Nasopharynx

Cancers of the nasopharynx typically come in two general varieties. Squamous cell carcinomas of the nasopharynx behave in similar fashion to squamous cell carcinomas of other head and neck sites, typically with sequential growth at the primary site and subsequent development of lymph node metastasis and possible later hematologic metastases. The other form of nasopharyngeal cancer, sometimes referred to as lymphoepithelioma or undifferentiated carcinoma of the nasopharynx, (1) is associated with Epstein-Barr virus, (2) is much more common in the Far East than

in the Western world, (3) typically presents with large adenopathy, (4) is particularly sensitive to radiotherapy, and (5) has a high propensity for distant metastases. Radiation therapy with concurrent cisplatin and adjuvant post-radiotherapy, 5-fluorouracil (5-FU), and cisplatin has been shown to be superior to radiotherapy alone for advanced cancers of the nasopharynx.[10] Radiotherapy is typically external radiation therapy alone on the order of 7000 cGy to the primary site and gross adenopathy with 5000 cGy delivered to areas thought to be at risk for microscopic lymph node disease. Results of treatment are shown in Table 32-5.

Unknown Primary

Squamous cell carcinoma involving lymph nodes in the neck without an apparent primary lesion is an uncommon but not rare presentation. The most common management includes a careful clinical and radiographic assessment to rule out an apparent primary tumor, which typically includes a thorough examination of the skin, oral cavity, oropharynx, nasopharyngoscopy, laryngoscopy, esophagoscopy, and bronchoscopy, as well as imaging including computed tomography (CT) scan of the neck, chest x-ray, and frequently CT of the chest and positron emission tomography (PET) scan. If no primary tumor is apparent, the most common management includes neck dissection followed by radiation therapy to both necks and the most likely sites of an occult primary, including the nasopharynx, palatine tonsils, base of tongue, and pyriform sinuses. Results of treatment are shown in Table 32-6.

Treatment

Definitive Radiotherapy

Many cancers of the head and neck are amenable to definitive radiotherapy as the primary mode of treatment as a curative attempt, frequently with the preservation of function and cosmesis. Adjuvant surgery is sometimes used in a setting of advanced neck disease where neck dissection is performed before or more commonly after definitive radiation. Systemic therapy is sometimes used with definitive radiation therapy in an attempt to sensitize tumor cells to radiation and eradicate tumor cells that may not have been otherwise killed by the radiation. Definitive radiotherapy can be with external radiation therapy alone, sometimes interstitial radiation alone, or sometimes the combination of external and interstitial radiation. Definitive radiotherapy is typically used in the setting of technically unresectable disease or disease in which resection would be anticipated to cause significant morbidity, particularly relative to the patient's speech and/or swallowing function.

Preoperative and Postoperative Radiotherapy

Adjuvant or neoadjuvant preoperative radiation therapy is frequently a consideration for locoregionally advanced cancers of the head and neck. Preoperative radiation may increase

resectability of disease, and tumor cells are thought more sensitive to radiation in the preoperative setting compared with the postoperative setting because oxygenation is better before the potential surgical disruption of vascular supply. Typically, lower doses are used in the preoperative setting (i.e., 5000 cGy at 200 cGy/day) compared with the postoperative setting (i.e., 6000 cGy at 200 cGy/day) because of this difference in oxygenation and associated tumor radiosensitivity. The potential disadvantages of preoperative radiation are the possibilities of increased wound complications, delay of the definitive surgical resection during which time the tumor could potentially grow or metastasize, and the lack of detailed pathologic information regarding the extent of the disease, which is available postoperatively. In a randomized study, the Radiation Therapy Oncology Group (RTOG) found postoperative radiation to be advantageous for locoregionally advanced squamous cell carcinoma of the head and neck compared with preoperative treatment.[11]

Altered Fractionation

The most commonly used fractionation scheme for squamous cell carcinoma of the head and neck as definitive treatment has been 7000 cGy in 35 treatments over 7 weeks with typically 200-cGy fractions delivered Monday through Friday. Altered radiation fractionation schemes have been studied in

TABLE 32-7 Randomized Phase III Trials of Radiation Therapy versus Concurrent Chemoradiation

Study	Subsites Included	Treatment	3 yr LC	3 yr OS

an attempt to manipulate biologic differences between tumor and normal tissue to improve prognosis without increasing morbidity. The RTOG studied four fractionation schemes for locoregionally advanced squamous cell carcinoma of the head and neck: standard 7000 cGy in 7 weeks with five daily treatments per week; 120 cGy twice a day, 5 days per week to 7500 cGy (hyperfractionation); 3.5 weeks of once-a-day treatment followed by 2.5 weeks of twice-per-day treatment (concomitant boost); and 160 cGy twice a day for 3.5 weeks with a 2-week break, followed by an additional 2 weeks of the same treatment (hyperfractionated split course radiation). The altered fractionation schemes showed increased acute toxicity with a small improvement in efficacy compared with conventional fractionation.[12]

Radiation with Systemic Therapy

Efforts have been made for many years to optimize treatment of head and neck cancer with a combination of radiation and chemotherapy. For locoregionally advanced squamous cell carcinoma of the head and neck, several studies have suggested benefit to radiation and concurrent chemotherapy, most often cisplatin.[13] 5-FU alone and with cisplatin has been used concurrently with radiation as well, but because severe mucositis is typical with the combination of 5-FU and radiation, this is not often used. Results of randomized trials comparing radiation therapy alone to concurrent chemoradiation are noted in Table 32-7.

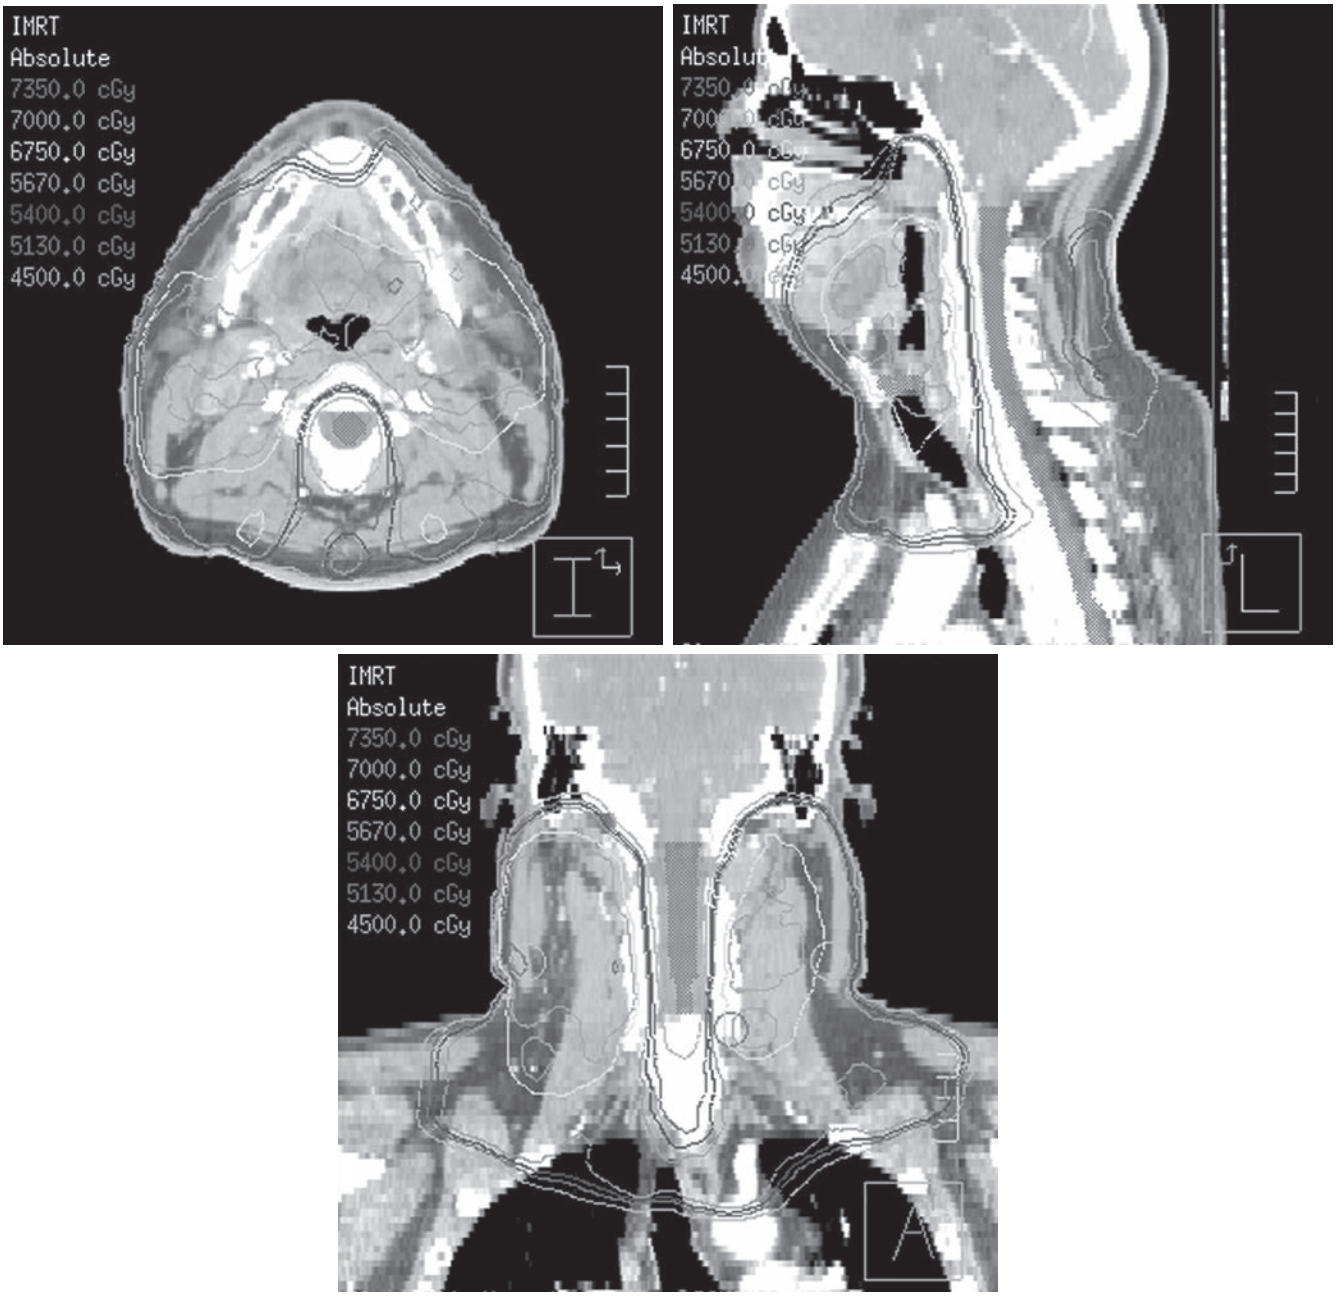
Cetuximab is a newer systemic therapy that is not chemotherapy per se and avoids many of the systemic side effects of chemotherapy. It is a monoclonal antibody to the extracellular domain of the epidermal growth factor receptor (EGFR) of cancer cells. Blocking of this receptor causes impaired cell growth. A prospective randomized trial has shown cetuximab delivered concurrently with radiation to be superior to radiation alone for locally advanced squamous cell carcinoma of the head and neck.[14] Neoadjuvant chemotherapy before definitive radiation therapy is frequently associated with dramatic tumor responses, but generally not with improved outcome in prospective randomized trials relative to radiation alone.[9,15]

Radiotherapy Techniques

Radiotherapy for head and neck cancers can be via teletherapy (external radiation) or brachytherapy (interstitial or intracavitary use of radioactive seeds). Teletherapy is the predominant form of therapeutic radiation and most commonly entails the production of high-energy photons or electrons by a linear accelerator. The radiation is typically aimed at the tumor, often from multiple orientations and with the shaping of radiation fields from each orientation to limit the volume of tissue receiving the full radiation dose. Photons have their maximal effect at a tissue depth depending on their energy, which can be varied depending on the desired depth of treatment. Whereas photons continue to pass through tissue and deposit decreasing amounts of radiation with further penetration, electrons stop more abruptly and are used to treat more superficial tumors with avoidance of more deeply seated normal tissues. Two-dimensional radiation treatment planning refers typically to radiation being directed from anterior, posterior, right lateral, or left lateral orientations where bony structures can be well recognized on x-rays taken from those orientations and the target tissue can be correlated relative to those bony structures. Three-dimensional conformal radiation refers to the use of CT scans and computers to better target tumors relative to normal tissues (see Figure 32-4). The technique involves obtaining a CT scan and putting the CT information into the computer to allow for contouring on the computer work station the target tissue to be treated and the normal tissues to be

avoided. With the help of the computer, orientations and shapes of radiation fields can be devised to better accomplish this. Intensity-modulated radiation therapy (IMRT) adds the ability to vary the amount of radiation coming through each part of each field of radiation to further conform the radiation dose to the target tissues relative to the normal tissues to be spared. Isodose patterns for the treatment of an advanced base-of-tongue cancer with IMRT are shown in Figure 32-5.

Brachytherapy can entail the permanent or temporary placement of radiation seeds directly into (interstitial) tumor-containing tissue or within an orifice adjacent to tumor (intracavitary radiation). Temporary brachytherapy is more commonly used in the treatment of head and neck cancers. Brachytherapy may have the advantage of exposing tumor cells to substantially higher doses of radiation compared with normal tissues distant from the radiation sources, thereby decreasing side effects. Temporary brachytherapy applications can be low-dose-rate radiation in which radioactive sources are typically placed for a matter of a few days, or high-dose-rate radiation in which higher-activity (strength) sources are placed for a matter of minutes. Both forms of brachytherapy are physically advantageous in placing the radiation dose at the location of the disease. The biologic differences in tumor response and normal tissue effects between continuous



• **Figure 32-5** Isodose distributions for an intensity-modulated radiation therapy (IMRT) plan used to treat an advanced base-of-tongue cancer.

low-dose-rate radiation and fractionated high-dose-rate radiation continue to be studied.

Complications of Treatment

Effects of radiation on normal tissues include acute and late effects. Acute effects occur during and immediately after a course of radiotherapy, are typically progressive in nature, and generally resolve 3 to 4 weeks after therapy. These include mucositis, hair loss, skin irritation, loss of taste, dry mouth, bone marrow suppression, and hoarseness from effects of radiation on rapidly proliferating normal tissues. In a 7-week course of daily Monday-through-Friday radiation therapy for cancers of the head and neck, acute side effects are typically noticeable beginning in the second or third week of treatment. Progression of those effects is variable and is typically counterbalanced to some extent by accelerated repopulation of normal cells in response to radiation damage. The acute side effects sometimes increase through the course of treatment as the cumulative radiation dose increases and at times plateaus because of the accelerated repopulation of normal cells. Mucositis and skin changes are typically largely resolved by 3 weeks following completion of radiation therapy. Taste typically takes a matter of months to recover, and xerostomia is frequently long lasting. The addition of concurrent chemotherapy to radiation typically augments all of the normal tissue effects and delays recovery.

Amifostine is an organic thiophosphate drug found to have normal tissue cytoprotective effects on multiple organ systems during chemotherapy or radiation therapy. It has been shown in a randomized trial to reduce acute and chronic xerostomia in patients receiving head and neck radiation therapy and to objectively increase salivary flow over placebo.[16] Unfortunately, this increase in objective salivary flow has not translated into subjective xerostomia improvements in other trials. Furthermore, amifostine is typically given as a subcutaneous injection daily during radiation therapy, and its use has been limited by toxicities including hypotension, nausea, vomiting, and allergic reaction.

Late effects of radiation on normal tissues are ischemic, in which the blood supply to normal tissues is compromised by endothelial fibrosis of small blood vessels induced by radiation. These side effects typically manifest between 6 and 24 months after radiation. Late side effects of head and neck radiation include soft tissue fibrosis of the head and neck, trismus, osteoradionecrosis of the jaw, xerostomia, and esophageal strictures. Chronic laryngeal edema and laryngeal chondronecrosis can occur as well. Osteoradionecrosis of the mandible is a potentially serious late complication of radiation therapy; however, radionecrosis of bones other than the mandible is uncommon. The complication is uncommon but is related to the volume of mandible radiated, the radiation dose delivered, radiation treatment fraction size, and dentition. Edentulous patients rarely develop osteonecrosis, and patients with poor dentition are at higher risk. It has been generally recommended that patients with poor dentition have tooth extractions before, rather than after, radiation to decrease the likelihood of developing osteoradionecrosis. With the frequent urgency to commence radiation, there may be a window for safe extractions between approximately 2 and 4 months after radiation. When teeth are extracted following radiation therapy, prophylactic hyperbaric oxygen treatment is frequently recommended, with 20 treatments before tooth extractions and 10 treatments afterward. Whether this practice is in fact necessary on a routine basis has been questioned.[17]

Second malignancies occur rarely after radiation therapy, with an average latency of 10 years. The risk increases with time after completion of radiotherapy. Criteria for second malignancy include a solid tumor within the previously treated radiation portal, tumor of a different histology than previously treated, and tumor occurring in the correct latency period.

Principles of Medical Oncology in the Management of Head and Neck Cancer

JANAKIRAMAN SUBRAMANIAN, WAHID T. HANNA

Introduction

Medical oncology is an important aspect of treatment in head and neck malignancies. Specific medical therapy in head and neck malignancy is tailored to specific cell types. More than 95% of primary head and neck tumors are squamous cell carcinomas, with adenocarcinoma representing less than 5%. This chapter focuses on squamous cell carcinoma of the head and neck (SCCHN) and on salivary gland adenocarcinomas.

Epidemiology

According to the American Cancer Society's *Cancer Facts & Figures,* approximately 45,780 new cases of cancer of the oral cavity and pharynx would be diagnosed in the United States in 2014. The incidence of head and neck cancer in men is more than twice the incidence in women. Men older than 50 years are at increased risk of developing head and neck cancer. The American Cancer Society estimated that 8,650 people would die of cancer of the oral cavity and pharynx in 2015.[1]

The trend in 5-year survival rates is improving, but a disparity still exists between Caucasian and African American individuals. Five-year survival for Caucasians was 69% in the years 2004 to 2010 compared with 57% in 1987 to 2089; 5-year survival for African Americans was 62% in 2004 to 2010, although this represented an improvement from 43% in 1987 to 1989. Survival rates for head and neck cancer also differ widely depending on the extent of disease, as would be expected. Five-year survival for localized disease is 83%, compared with 51.3% for regional involvement, and only 27.6% for distant metastases.[1] This underlines the importance of early detection, particularly in the population at high risk for development of head and neck malignancy. Screening should be performed by an individual's dentist or primary care provider during regular checkups.[1]

Risk factors for the development of squamous cell carcinoma of the head and neck are known to include tobacco use via smoking (cigarette, pipe, and cigar) and the use of smokeless (chewing) tobacco. This risk is further compounded by excessive alcohol consumption.[1]

Data suggest that passive smoking also increases the risk of development of squamous cell carcinoma of the head and neck.[2] Human papillomavirus (HPV) infection has now been identified as a risk factor for the development of oropharyngeal squamous cell carcinoma, particularly in never smokers.[3]

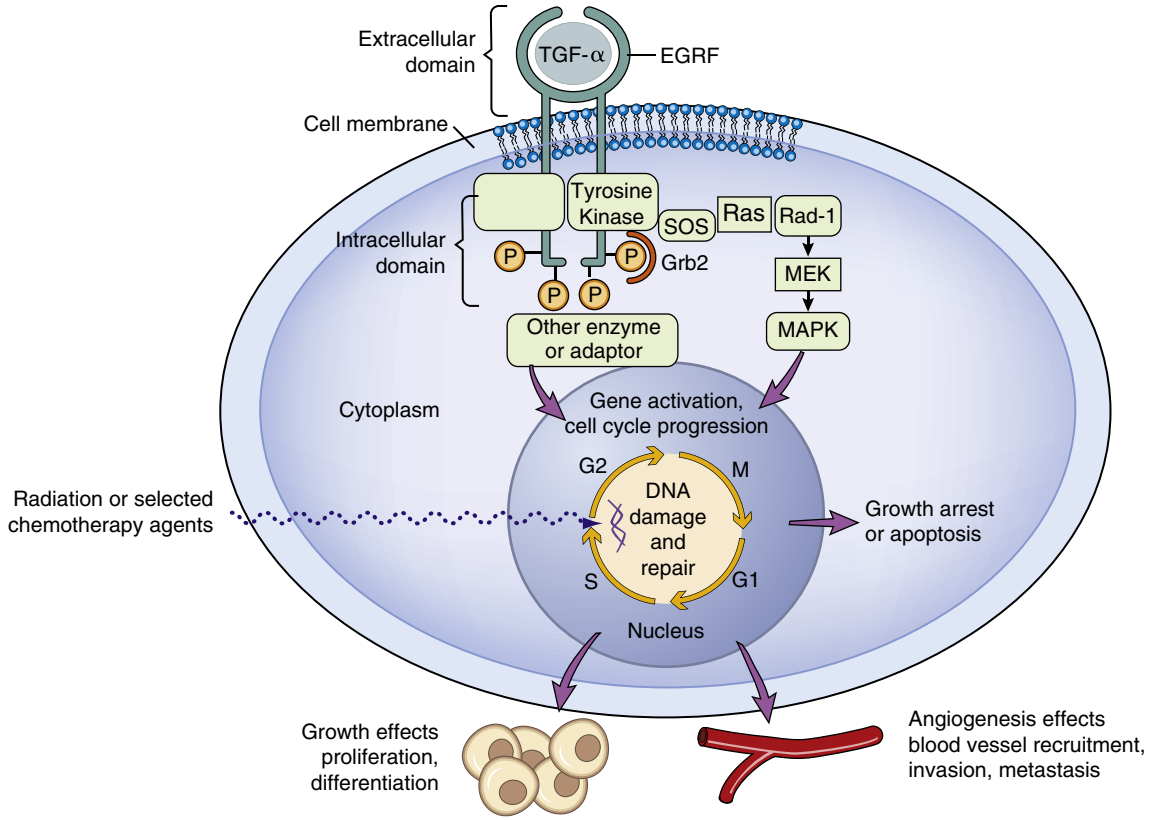
Background

The process of carcinogenesis requires multiple genetic alterations that occur over time, producing a cumulative effect on cell division and differentiation.[4] Proto-oncogenes are responsible for cell growth. When mutated, proto-oncogenes become oncogenes, which are perpetually activated to promote uncontrolled growth of the cell (Figure 33-1).

Historically, the main treatment regimen for head and neck cancer had been surgery. But with recent advances, radiation is an option in both the definitive and adjuvant treatment setting. Traditionally chemotherapy was restricted to treatment of patients with advanced-stage disease. Results from randomized trials have shown that chemotherapy in combination with radiation is effective in the definitive treatment of locally advanced SCCHN and also as adjuvant therapy after surgical resection in selected patients. Also, some randomized trials have examined the role of adding induction chemotherapy prior to chemo-radiotherapy as a treatment option for patients with locally advanced SCCHN. Recent advances in our understanding of novel molecular alterations in cancer have opened new avenues of treatment with targeted agents.

Treatment of Locally Advanced Squamous Cell Carcinoma of the Head and Neck

Patients with TNM stage III and IV SCCHN without distant metastasis are categorized as having locally advanced disease. It is associated with a high rate of disease recurrence,



• **Figure 33-1** Oncogenes implicated in head and neck cancer include cyclin D1, or the epidermal growth factor receptor (EGFR) family.

requiring a multidisciplinary treatment approach, with the site of primary tumor playing a key role in choosing treatment options. Treatment could involve surgical resection followed by adjuvant radiotherapy or chemo-radiotherapy; organ-sparing approaches with chemo-radiotherapy (CRT) alone may be an option as well. Choosing among these different treatment options will depend on various factors such as treatment availability, skill and experience of the treating physician, and the site of primary tumor.

Adjuvant Chemo-radiotherapy

Historically, surgery has been the mainstay of treatment for SCCHN. Even now for most locally advanced oral SCC, surgical resection is the preferred option. After surgical resection, patients should be evaluated for the need for adjuvant therapy. With surgery alone, locoregional control rates and 5-year survival rates have ranged between 10% and 40%.[5] Therefore efforts have been ongoing to improve local control and overall survival after surgical resection. Since the 1970s, adjuvant chemotherapy has been tested both sequentially and concomitantly with radiation treatment. The rationale for inclusion of chemotherapy in the therapeutic management of locally advanced tumors is based on three primary observations:

1. Even though 70% to 75% of patients remain free of disease at 2 years, the long-term prognosis remains poor. Five-year survival rates rarely exceed 30% to 35%.
2. Although a fairly large number of deaths are linked to intercurrent disease, metastasis can occur at a rate from 15% to 20%.
3. A variety of cytotoxic agents have demonstrated efficacy against epithelial cell cancers.[6]

The use of chemotherapy alone has proved disappointing. However, compliance has not been optimal, especially after surgery and radiation treatment. Evidence of a biologic effect was seen, in that the pattern of failure was associated with a decrease in distant metastases in selected studies; no convincing improvement in overall survival was apparent.[7,8]

To improve the prognosis for patients with stage III to IV disease, investigators began to combine chemotherapy with radiation. In an intergroup study (0034; Lawrence GE 1992), radiation treatment was administered with or without three cycles of cisplatin/5-fluorouracil (5-FU) to patients with completely resected SCCHN. This study reported no difference in overall survival (OS), disease-free survival, or locoregional failure between the two groups. A significant decrease in distant metastases was seen in the chemotherapy/radiation therapy (CRT) arm versus the radiation therapy (RT) alone arm (15% vs. 23%, respectively; P = .03). Subgroup analysis showed that patients with high-risk pathologic features (at least two positive neck lymph nodes, extracapsular extension, and/or positive surgical margins) improved more with the addition of chemotherapy than did those in the low-risk group in terms of both tumor control and survival.[8]

Starting in the early 1990s, analyses of clinical trials undertaken to compare CRT versus RT showed that CRT significantly increased locoregional control and survival rates.[9-11]

Platinum compounds and 5-FU have been used most often in prospective clinical trials.[12-15] Various studies have tested the effects of CRT and reported associated benefits.[16-18] However, considerable variability in schedule, dose, and chemotherapeutic agents used was seen in these studies. Because of this, two randomized trials conducted by the European Organization for Research and Treatment of Cancer (EORTC) and the Radiation Therapy Oncology Group (RTOG) were designed to compare the use of high-dose cisplatin (100 mg/m^2) on days 1, 22, and 43, given concurrently with radiation, versus radiation alone in patients with resected, poor-risk SCCHN of the upper aerodigestive tract (high-risk patients were more broadly defined).[19,20]

The EORTC study demonstrated a significant (P = 0.04) difference in progression-free survival (PFS). The primary end-point of overall survival favored the CRT group. Estimated median PFS was 23 months in those given RT and 55 months in the CRT group. Five-year Kaplan-Meier PFS estimates were 36% and 47%, respectively (P = 0.04). OS (P = 0.02) and locoregional control (P = 0.07) also significantly improved.[20] The RTOG study showed significant benefit for disease control with CRT over RT.

Disease-free survival and locoregional control rates at 2 years favored the CRT arm (P = 0.04 and P = 0.01, respectively). Also, a trend toward higher OS rates was seen with CRT (P = 0.19). No impact on distant control was noted. Both studies yielded positive results with regard to favorable impact of CRT on disease control. The magnitude of impact of chemotherapy on outcomes was greater in the EORTC than in the RTOG trial, but this may reflect variations in patient selection.

Data from a combined analysis of the EORTC and RTOG data indicated that CRT's benefit was primarily seen in tumors with extracapsular nodal spread (ECS) and/or microscopically involved surgical margins.[21] A trend favorable toward CRT was seen in patients with stage III to IV disease, perineural infiltrates, vascular embolism, and/or clinically enlarged lymph nodes at level IV or V associated with tumors in the oral cavity or the oral pharynx. Patients with two or more histologically involved lymph nodes who did not exhibit ECS or positive margins as additional risk factors did not appear to benefit from the addition of chemotherapy in this analysis.

Functional Organ-Preservation Approaches

In many patients with locoregional disease, even though surgical resection maybe feasible, a nonsurgical approach with concurrent CRT can be considered for functional organ preservation. In general concurrent CRT is the preferred option in this setting.

Oropharyngeal Squamous Cell Carcinoma

Several trials have examined the benefit of CRT over RT in the treatment of locally advanced oropharyngeal SCC. The most definitive evidence is provided by the Meta-analysis of Chemotherapy on Head and Neck Cancer (MACH-NC) study.[22] This analysis included studies on CRT and RT alone as well as induction chemotherapy. With 5872 patients with oropharyngeal SCC, the study concluded that regimens with chemotherapy and RT were superior to RT alone (hazard ratio [HR] 0.88; 95% confidence interval [CI] 0.82-0.93).[23] The study also reported that CRT was associated with an improvement in overall survival (HR 0.81, 95% CI 0.78-0.86) but not with induction chemotherapy followed by RT (HR 0.96; 95% CI 0.90-1.02), though it did not include the more modern trials evaluating induction with docetaxel, cisplatin, and 5-FU (TPF) followed by RT. The study also compared different chemotherapy regimens and concluded that platinum-based regimens were superior to non-platinum regimens.

Laryngeal Squamous Cell Carcinoma

Functional organ preservation for laryngeal SCC was first studied in the Veterans Affairs (VA) Laryngeal Cancer Study Group Trial.[24] In this study 332 patients with stage III or IV laryngeal SCC were randomized to surgery followed by adjuvant RT or induction chemotherapy with three cycles of cisplatin and 5-FU followed by RT. Patients who failed induction chemotherapy underwent surgery followed by RT. The 3-year survival was similar for both treatment arms (56% vs. 53%), and the larynx was successfully preserved in 64% of patients on the induction arm.

Results from the 2011 MACH-NC analysis showed that adding chemotherapy to RT versus RT alone for the treatment of laryngeal SCC (n = 3216) improved overall survival (HR 0.87; 95% CI 0.80-0.96).[23] This improvement in survival was restricted to CRT and not seen with induction or adjuvant chemotherapy. Like the MACH-NC analysis published in 2009, this study did not include the induction studies with the TPF regimen. The addition of chemotherapy to radiation was seen to improve survival in patients with hypopharyngeal SCC as well (HR 0.88; 95% CI 0.80-0.96), though the timing of chemotherapy administration, whether concurrent, induction, or adjuvant, did not appear to affect survival. Based on these data for patients with laryngeal and hypopharyngeal SCC, our experience has been to administer cisplatin 100 mg/m^2 on days 1, 22, and 43 concurrent with radiotherapy.

Induction Chemotherapy in Squamous Cell Carcinoma of the Head and Neck

The role for induction chemotherapy prior to locoregional therapy for locally advanced SCCHN has generated a lot

of discussion and controversy. The potential benefits from the induction approach are to decrease the risk of developing distant metastasis, reduce disease volume, and improve organ function, thereby allowing a more tolerable and effective locoregional therapy. Induction chemotherapy can also increase the risk of toxicity.

In locally advanced oral SCC, induction chemotherapy has been evaluated in the preoperative setting. Induction with three cycles of cisplatin and 5-FU followed by surgery versus immediate surgery was evaluated in a randomized trial.[25] Induction chemotherapy did not improve survival, but it did reduce the rate of mandibulectomy (31% vs. 52%). Also, the rate of postoperative radiation was lower in patients receiving induction chemotherapy (33% vs. 46%). More recent long-term follow-up from this trial confirmed absence of difference in overall survival between the two arms, and there was no difference in locoregional control and rates of distant metastasis. In a subsequent trial, induction with TPF prior to surgery and postoperative RT did not improve overall survival (HR 0.98; 95% CI 0.63-1.51) or disease-free survival (HR 0.97; 95% CI 0.65-1.45) when compared to surgery and RT.[26] Induction chemotherapy prior to surgery does not improve survival for locally advanced oral SCC.

The MACH-NC meta-analysis 2009 update included 31 trials with 5311 patients comparing induction chemotherapy to RT alone or surgery with or without RT and did not identify any significant difference in overall survival between these different treatment modalities (HR 0.96; 95% CI 0.90-1.02).[22] Induction chemotherapy and CRT were compared in six trials, and they showed no significant difference in overall survival between these two treatment modalities (HR 0.90; $P = 0.15$).

More recently there has been an effort to combine induction chemotherapy with CRT to maximize benefits. In the TAX 324 trial, 531 patients were randomized to receive TPF or PF (platinum and 5 FU) followed by CRT with weekly carboplatin.[27] The addition of docetaxel to platinum and 5FU was associated with an improvement in 5-year survival (52% vs. 42%; HR 0.74; 95% CI 0.58-0.94). The addition of docetaxel was also associated with increased incidence of both hematologic and nonhematologic toxicities. Subsequent trials have compared induction TPF followed by CRT to CRT alone. In the Spanish Head and Neck Cancer Cooperative phase III trial, 439 patients were randomized to receive CRT with cisplatin on days 1, 22, and 43, or two different induction regimens with TPF or PF followed by CRT with cisplatin.[28] There was no significant difference in overall survival, progression-free survival, or time to progression between the three treatment arms. Sub-analysis identified improved progression-free survival for patients receiving TPF induction who were also able to receive at least one cycle of CRT when compared to CRT alone: 20.4 months versus 13.3 months (HR 0.72, $P = 0.03$). PARADIGM and DeCIDE were randomized phase III trials that examined TPF induction followed by CRT to CRT alone.[29,30] Both studies were limited by poor accrual, and they did not show any significant survival benefit to adding TPF induction to CRT. Both studies also showed an increased incidence of adverse effects in the induction arms. The DeCIDE trial did identify a trend toward improved overall survival for patients with N2c and N3 disease, but the study was not powered to detect meaningful differences in this subgroup. Therefore we do not routinely recommend induction chemotherapy prior to CRT in patients with locally advanced SCCHN. There may still be a role for induction chemotherapy with locally advanced laryngeal cancer with tumor stage less than T4a for functional organ preservation purposes.

Chemotherapy of Patients with Recurrent or Metastatic Head and Neck Carcinoma

More than 50% of patients given a new diagnosis of SCCHN will experience a recurrence after receiving primary treatment. Patients with SCCHN have a poor prognosis once primary treatment has been unsuccessful and recurrent disease has occurred. Outcomes are poor and have not changed significantly over the past 30 years.[31,32] Several treatment options are available for patients with recurrent disease. Palliative chemotherapy has shown survival benefit over best supportive care alone in one study.[33] Multivariate analysis of data from palliative chemotherapy clinical trials has shown that time to progression and overall survival are greatly influenced by factors other than the chemotherapy agents that are used; poor performance status, prior treatments, and advanced stage of disease all are associated with poor outcomes despite chemotherapy.[34,35] Because treatment is palliative and may be associated with significant adverse effects, clinicians must be careful in selecting patients for chemotherapy treatment. The benefits must be weighed against the side effects and complications of treatment before a patient can be committed to palliative chemotherapy. Salvage surgical intervention for local recurrence has resulted in 15% to 30% long-term disease control. However, if the recurrent disease is inoperable, or if it is metastatic in nature, systemic chemotherapy and/or local radiotherapy should be considered for palliative purposes.

In the 1980s, several clinical trials compared different chemotherapeutic combinations. The outcomes of these trials are presented in Table 33-1.

Multiagent chemotherapy in general was associated with a higher response rate but also had a higher degree of toxicity. Platinum-based combination chemotherapy yielded the highest response rates, approaching 50%.[36-39] The combination of cisplatin (CDDP) plus 5-FU emerged as the most effective treatment for SCCHN in the 1980s and 1990s. In a three-arm study conducted by Clavel and colleagues, 5-FU and CDDP combinations were compared with carboplatin, methotrexate, bleomycin, and vincristine and with CDDP alone. Results with the CDDP plus 5-FU and carboplatin arms were superior to

†Majority of patients on this trial had prior therapy (excluding chemotherapy).

those with CDDP alone, with a median survival of 73 months. However, greater toxicity was encountered in all CDDP arms.[41]

Numerous single agents have been found to be effective against SCCHN (Table 33-2).[25] When taxanes became available in the 1990s, clinical trials were undertaken to evaluate these drugs. A single taxane agent, either paclitaxel or docetaxel, produced a response rate of 30% to 40%.[41-43] Because of the high rate of single-agent activity and the non-overlapping side effects seen with other agents, taxanes were used in clinical trials in combination with CDDP or carboplatin (Table 33-3).[44-49] These studies showed a response rate of 27% to 53%, with median survival of 5 to 12 months. When double-chemotherapy regimens were found to be successful, triple-chemotherapy combinations were given in an attempt to enhance response rates. Indeed, an increased response rate up to 60% and a complete response rate of 15% were attained with the combination of ifosfamide, paclitaxel, and CDDP or carboplatin.[50,51] The improvement in response rate has been consistent across other three- or four-drug combinations; unfortunately these treatment regimens resulted in significant toxicity and did not improve survival when compared to single or doublet regimens.

Epidermal Growth Factor Receptor Inhibitors in the Treatment of Squamous Cell Carcinoma of the Head and Neck

The epidermal growth factor receptor (EGFR) is highly expressed in SCCHN; both gefitinib and erlotinib have shown activity against EGFR.[52] Gefitinib has been shown to inhibit other proteins in malignant cells, and this fact could have affected study outcomes.[53,54] However, with SCCHN, it seems that these agents mainly inhibit EGFR and downstream effectors; this appears to be the primary mechanism of action.

Multiple EGFR blockade agents have been used in various clinical trials (Table 33-4).[55] Gefitinib has been studied as a single-agent treatment in SCCHN that yielded an overall response rate of 10.6%, including one patient who exhibited complete response with 1-year survival.[56] Gefitinib seems to be more active when used as first-line treatment than when administered to previously treated patients. However, this difference is not statistically significant.[57]

Erlotinib has been investigated in SCCHN.[58] A 4% partial response was reported, with 1-year survival of 20%. EGFR expression did not correlate with response to or severity of skin rash. The combination of gefitinib and erlotinib with systemic chemotherapy was investigated.

TABLE 33-3 Clinical Trials in Metastatic and Recurrent SCCHN

Agent	No. of Patients Assessable	Response Rate (%)	Survival (months)	Year of Publication
Cisplatin + fluorouracil

Note: Prior therapy represents the eligibility restrictions on patients enrolled on the trials.
EGFR, Epidermal growth factor receptor; *NA*, not available; *OS*, median overall survival; *PFS*, median progression-free survival; *RR*, overall response rate.
*After failure of a platinum-containing regimen, patients on these studies received cetuximab in combination with a platinum.

Docetaxel, cisplatin, and gefitinib showed a 50% overall response rate, with seven patients achieving complete remission.[59] Another study that studied the use of erlotinib with docetaxel and cisplatin showed an overall response of 78%, with complete response reported in 27 patients.[60]

A phase I/II study investigated the combination of erlotinib and bevacizumab-monoclonal antibodies against vascular endothelial growth factor (VEGF) in patients with recurrent and metastatic SCCHN. An overall response rate of 15% and a median survival of 6.8 months were reported.[61] The combination was well tolerated, but skin toxicity with skin rash occurred. For those patients who had not received prior treatment, objective response rate, median PFS, and median OS were 17%, 4.8 months, and 7.5 months, respectively.

Cetuximab is a human murine chimeric immunoglobulin G (IgG) monoclonal antibody that competitively binds to the extracellular domain of EGFR. This drug has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of patients with advanced SCCHN, on the basis of recent study findings.[62]

In the phase III EXTREME trial, treatment-naïve patients with advanced SCCHN were randomized to receive platinum plus 5-FU with or without cetuximab.[63] The addition of cetuximab was associated with an improvement in overall survival (median overall survival 10.1 months vs. 7.4 months; HR 0.80; 95% CI 0.64-0.99. Treatment with cetuximab was associated with increased risk for grade 3 or 4 skin rash, hypomagnesemia, sepsis, and infusion-related reactions. Other grade 3 and 4 adverse effects were similar between the two treatment groups.

As in other studies, a correlation was seen between skin rash and favorable outcomes. Cetuximab is also active in the second-line setting for platinum-refractory patients.[64] On progression during treatment with cetuximab, a platinum agent was added to the treatment and an overall response rate of 13% was reported, with five patients achieving complete response and median survival of 5.9 months. In all, 103 patients who received cetuximab progressed while receiving a platinum-based regimen.

In summary, the combination of a platinum agent plus 5-FU or platinum plus taxane are appropriate first line options for patients with advanced stage SCCHN who are chemotherapy naïve or have a prolonged period of disease control after definitive CRT and have good performance status. Adding cetuximab to this combination is an option as well. For patients who cannot tolerate combination chemotherapy or have rapid progression after definitive CRT, single-agent chemotherapy maybe a better option.

Salivary Gland Cancers

Salivary gland cancers (SGCs) make up a broader class of head and neck cancers that are relatively rare. By all accounts, less than 5% of tumors are classified as SGC.[65] Typically, these tumors arise from ductile components that are intercalated or secretory. Further classification has been distinguished by the frequency of disease site location, that is, major (parotid, submandibular) or minor (mucosal) gland. Most cases of SGC are benign and occur in the major gland. Malignancies such as adenoid cystic carcinoma (ACC), mucoepidermoid carcinoma (MEC), and salivary duct carcinoma (SDC) arise in the minor gland. Regardless of type, the therapeutic approach continues to consist of surgical intervention and radiotherapy, followed by chemotherapy in the palliative metastatic setting. Recent discoveries of targeted therapies have been advanced by the recognition of molecular abnormalities. In comparisons of healthy and abnormal samples, analysis of estrogen receptors has further opened investigation into targeted

therapies.[65] A decade of research has unveiled further histologic evidence by which these tumors can be classified into subsets, as initiated by the World Health Organization (WHO). The three predominant subtypes (ACC, MEC, and SDC) are discussed here.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (ACC) is a relatively rare, slow-growing, malignant epithelial tumor of the salivary glands. Age of onset generally ranges from 40 to 60 years.[66,67] By all accounts, ACC occurs in less than 3% of malignancies. The recommended treatment regimen includes surgical intervention and postoperative radiotherapy. However, despite these modalities, ACC has a high rate of local recurrence, with an unfortunate outcome of 10-year survival of 29% to 40%, with demise often within 2 years.[65,68] Distant metastatic (DM) events, histologically speaking, occur in solid tumor more often than tubular and cribriform subtypes. Unfortunately, metastases of this nature are due to its hematogenous disposition, which primarily involves the lungs. Chemotherapy is reserved for patients with local recurrence and for systemic disease.

Some authors have suggested that trial agents used independently, such as mitoxantrone, vinorelbine, and epirubicin, may be promising, although paclitaxel has produced no response.[65] A series of trials have investigated agents in combination, such as cisplatin-doxorubicin-cyclophosphamide (CAP) with or without the addition of fluorouracil; these have shown inconsistent outcomes. Despite immunotherapy, a combination of surgery and radiotherapy offers these patients the best chance for disease control. Analysis via immunohistochemistry (IHC) has revealed an overexpression of the proteins ErbB2[69], epidermal growth factor (EGF), and vascular endothelial growth factor receptor 2 (VEGFR-2) in the salivary glands involved by ACC. As is the case with ErbB2, trastuzumab (Herceptin) has shown widely varying results, in the range of 0% to 100%. Regimens of AEE788, a multiple-receptor tyrosine kinase inhibitor (inhibition of phosphorylation of tyrosine kinase of EGFR, VEGF2, and ERbB2), induce tumor apoptosis.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma (MEC), similar to ACC, has high rates of metastasis and locoregional tumor growth. It is the most common of the salivary gland carcinomas and, unfortunately, it exhibits a low response to therapy. In contrast to ACC, however, MEC has shown response to paclitaxel.[65] Overexpression of Her-2 displayed by IHC, EGFR, and gene amplification equates to a poor prognosis for this tumor. A phase II trial of trastuzumab objectively reported a partial response lasting 2 years. Additional studies are needed to examine tumor regression and the roles of paclitaxel, vinorelbine, and CAP in treatment.

Salivary Duct Carcinoma

Salivary duct carcinoma (SDC), the most invasive of the three malignancies, arises from the parotid gland. Its direct path of metastasis involves lymph nodes. Few data are available on the responsiveness of this tumor to chemotherapy, but in select patients, it is reasonable to use the same agents that are used for other salivary adenocarcinomas, such as CAP with or without 5-FU. Treatment regimens, as studied in phase II trials, consist mainly of palliative chemotherapy in the form of gefitinib or trastuzumab; these have resulted in stabilization of the disease for 26 to 46 weeks.[65] Other studies are ongoing with the goal of developing response of this unfortunate malignancy to multiple agents.

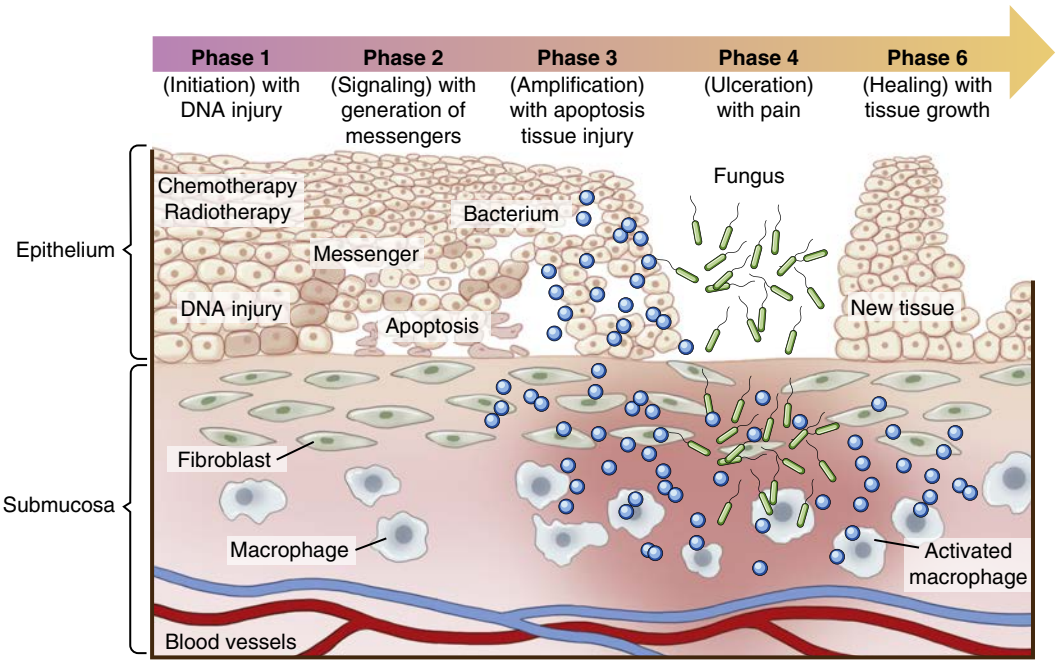
Histologically, salivary gland carcinomas must be clinically staged for identification of appropriate treatment regimens. Therapeutically, salivary gland carcinomas have a dismal prognosis; however, surgical resection and aggressive radiotherapy may provide benefit. Yet, palliative chemotherapy resides as the standard of care.

Phases of Oral Mucositis

Adoption of characterizing traits has been used to further classify mucositis into four distinct pathophysiologic phases. During the initial phase, called the inflammatory or vascular phase, tissue injury induces release of free radicals, inflammatory cytokines such as interleukin (IL)-2, prostaglandins, and tumor necrosis factor-alpha (TNF-α) via the epithelial, endothelial, and connective tissue of the oral canal. Induction of these components causes increased vascular permeability and accumulation of cytotoxic drugs.[70] The epithelial phase occurs 5 days to 1 week after treatment is initiated, or when cytotoxicity affects the dividing cells. Epithelial tissue erosion leads to fibrous exudates and forms a pseudomembrane or ulcerative tissue.[71,72] During this phase, denaturing of the epithelial mucosal lining results in the first symptoms of pain, which results from factors such as inflammation and infection attributed to microbial invasion. Epithelial destruction leads to the ulcerative phase, which can occur within 1 week after treatment is begun. The start of the pseudomembrane is seen during the epithelial phase. It becomes more prominent, leading to further destruction of the lining and ulceration. Further microbial colonization may be exacerbated by concomitant neutropenia.[73] Last, the healing phase commences on days 12 to 16. Tissue proliferation and differentiation and migration of epithelial cells restore the integrity of the mucosa (Figure 33-2).

Treatment

Investigational approaches have been used to attempt to treat or prevent mucositis.[74] It has been suggested that alpha-tocopherol, a component of vitamin E (VE), may act as an antioxidant. In clinical trials, VE has been shown to be potentially advantageous for mucosal preservation. A



• **Figure 33-2** Phases of mucositis.

double-blind randomized trial examined 54 patients with cancer of the oral cavity and oropharynx. Patients rinsed the oral cavity with an oil solution that included VE or a placebo before radiotherapy (RT) and again 8 to 12 hours later. Results indicated that VE reduced the risk of oral mucositis by 36%.[72]

Amifostine is an antioxidant cytoprotective agent that is used in cancer chemotherapy involving DNA-binding chemotherapeutic agents; it acts as a tissue-protective agent. Amifostine serves as a free radical scavenger and radioprotectant. Studies have shown that the benefit of amifostine for episodic events of mucositis is seen in patients with head and neck cancer who are undergoing usual treatment protocols. Additional studies evaluating amifostine during radiotherapy have reported a reduction in the incidence and severity of oral mucositis, but findings have been inconsistent, especially considering the tolerability of the drug and side effects such as nausea, vomiting, and hypertension. Antimicrobial agents are frequently an important adjunctive treatment for mucositis. Because the mucosa usually is colonized by a variety of microorganisms, secondary infection occurs whenever the integrity of the mucosa has been disturbed, particularly because these patients exhibit changes in the saliva and neutropenia, which cause an immunocompromised state.

Antifungal agents constitute important adjunctive treatment. Although fungal infection is not primarily involved in the development of mucositis, these agents are the most frequent causes of infection of the damaged mucosa in the immune compromised host. Prophylactic and therapeutic uses of antifungal agents, either topical (e.g., nystatin) or systemic (e.g., fluconazole), are very important in the treatment of patients with mucositis.

Second only to fungi, viruses, particularly herpes simplex virus (HSV) and varicella zoster virus (VZV), represent the most aggravating mucositis in the immunocompromised host, because of the pain and lack of response to general supportive care that they cause; these viruses respond well to antiviral agents such as acyclovir (Zovirax) or famciclovir (Famvir). Because of the severe pain that is involved, oral solutions with local anesthetics such as diphenhydramine, viscous xylocaine, lidocaine, or dicyclomine hydrochloride frequently serve as the palliative and supportive treatment required for the management of painful and damaged mucosa.

Evaluating therapeutic interventions remains difficult because of the variability of treatment regimens, the heterogeneity of patient populations, and the small number of double-blind and placebo-controlled clinical trials that have been completed.[73]

34 History of Temporomandibular Surgery

GREGORY M. NESS

Despite a vast body of supportive scientific literature reaching back into the 19th century, surgical treatment of patients with temporomandibular joint disease remains controversial in the early 21st century, perhaps in part because relatively few surgeons (or patient advocates) have examined the rich history of these operations. Certainly, reading about the history of temporomandibular joint surgery enhances our understanding of the principles behind contemporary surgical therapy. Yet, as we read the unfamiliar and dated language of individuals whose names may sometimes be known but whose faces have faded from human memory, the mists of time lift slightly and we catch glimpses of what it meant to be a surgeon 50, 80, or 100 years ago. Although this chapter can only briefly summarize the accomplishments (and failures) whose legacy is our contemporary knowledge and practice, it will fulfill its purpose if the reader is inspired to visit some of the pioneering articles themselves, seeing them in their original context among papers describing advances in general, orthopedic, or plastic surgery, and (in more recent decades) encased by advertisements for the latest and best materials, pharmaceuticals, and instruments, most of which are now long forgotten.

In fact, it is often difficult for the contemporary reader to examine outdated techniques and concepts without an anachronistic and even arrogant sense of omniscience. To understand the significance of our surgical forefathers' accomplishments, we must abandon our comparatively vast understanding of human physiology, inflammation, pain, and healing, not to mention our sophisticated technology, instrumentation, imaging capabilities, and pharmaceutical armamentarium. Imagine instead devising an approach to a temporomandibular joint that you have not imaged and whose normal structure and function are largely matters of speculation. Then, perform your operation on a patient anesthetized with an open cloth soaked in ether or chloroform. The latest textbooks discuss the comparative risks and benefits of these two anesthetic gases; both are known to have major safety and efficacy risks to patient and surgical team alike. Finally, hope that any infection afterward does not prove to be fatal, and that the operation leaves the patient better off, not worse.

Pioneers

Numerous advances notwithstanding, most fundamental surgical procedures employed in the treatment of temporomandibular joint (TMJ) disease have been known, practiced, and described in the surgical literature for a century or longer.

Thomas Annandale[1] generally is credited with the first published description of temporomandibular joint disc repair in 1887 (Figure 34-1). He describes successfully treating two patients with locking or painfully clicking TMJs using surgical disc repositioning, having correctly hypothesized that the problems lie with the "inter-articular" cartilage of the TMJ displaced "either from a sudden tearing of their connections or from a gradual stretching of them." The contemporary wisdom of the time was represented by a textbook that he quoted, which describes the disorder as "an affection occurring principally in delicate women . . . thought to depend upon relaxation of the ligaments of the joint permitting too free a movement . . . and possibly a slipping of the inter-articular cartilage."[2] This opinion may sound eerily familiar to the contemporary reader, but other 19th-century concepts are now unthinkable: Annandale's second patient was kept in hospital 10 days before her surgery and 13 days after.

Treating the temporomandibular joint was by no means a standard operation in the 19th and early 20th centuries. Annandale used a small incision comparable with a modern conservative preauricular approach. In contrast, the 1895 edition of Stimson's *Manual of Operative Surgery* describes excision of the mandibular condyle through a T-shaped incision with its horizontal arm along the inferior aspect of the zygoma about 1¼ inches in length and the vertical arm, through skin only, about 1 inch long. The "parotid, nerves and vessels" were retracted inferiorly to prevent injury.[3] In 1914, John Murphy of Chicago produced a detailed report

ON

DISPLACEMENT OF THE INTER-ARTICULAR CARTILAGE OF THE LOWER JAW, AND ITS TREATMENT BY OPERATION.

BY THOMAS ANNANDALE, F.R.S.E.,
REGIUS PROFESSOR OF CLINICAL SURGERY, UNIVERSITY OF EDINBURGH

THAT the proper movements of the temporo-maxillary joint may be interfered with by conditions inside the articulation is a fact recognised by all surgical authorities. That a displacement of the inter-articular cartilage—the "subluxation" of Sir Astley Cooper—may be one of these conditions is also recognised. But most modern works on surgery describe this affection as being generally due either to relaxation of the ligaments of the joint allowing a too free movement, or to inflammatory changes of a simple, gouty, or rheumatic nature. Heath[1] writes upon the subject thus: "It is an affection occurring principally in delicate women, and has been thought to depend upon relaxation of the ligaments of the joint permitting a too free movement of the bone, and possibly (though this is conjecture) a slipping of the inter-articular cartilage." Believing with Mr. Heath and other authors that inflammatory results may cause interference with the movements of this joint, I feel further convinced that, as in the case of the semilunar cartilages of the knee, the inter-articular cartilages of the temporo-maxillary joint may become displaced either from a sudden tearing of their connexions or from a gradual stretching of them.

But the chief object of this short paper is to advocate a new method of treating by operation cases of this condition which resist counter-irritation and the other means usually advised, and in which there are symptoms of a too free movement of one or both of these cartilages. The operation is upon the same principle as that which I have described and successfully carried out in connexion with the displacement of the semilunar cartilages of the knee-joint. The method is as follows:—An incision slightly curved, about three-quarters of an inch in length, is made over the posterior margin of the external lateral ligament of this joint, and is carried down to its capsule. Any small bleeding vessels having been secured, the capsule is divided, and the inter-articular cartilage is seized, drawn into position, and secured to the periosteum and other tissues at the outer margin of the articulation by a catgut suture. The following two cases illustrate the condition, and also the good result obtained by the operation suggested.

CASE 1.—Mary M'C——, aged thirty-eight, was admitted into my wards on March 2nd, 1886. Nine years before her admission she injured her temporo-maxillary joints during an attack of vomiting. The joints remained "locked" for a few minutes, but after a little manipulation she herself put the condition right. Ever since this time she has suffered great discomfort in the joint upon the left side, for whenever any extra movement of the jaws was made this joint became fixed, and remained so until she had practised some manipulations, when movement returned. Frequently also, when she tried to open her mouth, she found that she could only do so to a limited extent, but by using the manipulations the proper separation of the jaws was completed. On March 12th an incision was made over the left temporo-maxillary joint, and, its capsule having been divided, the inter-articular cartilage was found to be loosened from its attachments, and much more movable than usual. The cartilage, having been seized with artery forceps, was drawn into position, and a catgut suture passed through it and the periosteum and other tissues at the outer margin of the joint. The wound healed rapidly, and she left the infirmary on March 25th. At this time the movements of the joint were natural, and she could close and separate the jaws perfectly, without any locking or catch.

CASE 2.—Ann M——, aged eighteen, admitted on Jan. 20th, 1885. Two years before admission, the patient when yawning found her jaws fixed. After a little manipulation she was able to close the jaws, but with a "click" on the right side. Since then she has suffered from pain and stiffness upon the left side, and the movements of the joint were constantly interfered with by something "slipping" in it. She had been treated by blistering and other remedies without obtaining any relief. On July 23rd the usual operation was performed, and the left inter-articular cartilage, being found loosened, was stitched in position with a catgut suture, as in the former case. The wound was healed at the end of a week, and she left the infirmary on July 31st, with perfect and proper movement of the jaws.

PHOSPHATIC DIABETES.[1]

BY CHARLES HENRY RALFE, M.D. CANTAB., F.R.C.P.L.,
ASSISTANT-PHYSICIAN, LONDON HOSPITAL.

AMONG the numerous investigations that have engaged the attention of physiologists during the last fifteen years, few yield in interest and importance to the study of the part played by the inorganic constituents of the body in histogenesis, and their influence in producing the daily and hourly variations which occur in the chemical composition of the secretions. Although this branch of animal physiology is only partially developed, yet our knowledge in this direction is steadily and constantly advancing, and the advance will be more rapid when it becomes clearly perceived how greatly minute variations of the inorganic constituents conveyed by the blood plasma to the cells influence for good or evil the processes of nutrition going on in the tissues. I can here only glance at some of the more important facts that have been established in this direction, and touch only on those points which are most closely related to the subject matter of the present paper.

Twenty years ago it was stated in most text-books that inorganic substances passed unaltered through the body, and that the same weight of saline constituents was recoverable from the urine and fæces as was introduced during the same period with the food and drink. The first advance on this simple view was made when it was discovered that chloride of sodium was retained in the body, and consequently disappeared from the urine, in certain diseases attended with increased cell-formation; and that even under normal conditions only four-fifths of the common salt ingested left the body as such, the remaining fifth being decomposed and altered in constitution within the system. Further researches led to the important discovery that whilst inorganic salts pass with immense and usually uniform rapidity into the circulation, and thence to the tissues, their discharge is by no means so regular, and they are detained for very unequal periods, which apparently depends on the need of the tissue to which they are supplied. Thus both Hoffmann and Lascar have shown that, however great the tendency of the alkaline bases is to combine with acids and acid salts, these cannot be withdrawn from the alkaline blood, but are powerfully withheld to maintain its alkalinity. And this fact is illustrated by what occurs in scurvy, for, as I pointed out in 1877,[2] and it has since been corroborated by Zuelzer,[3] as soon as the alkaline carbonates cease to be supplied by means of vegetables, the alkaline phosphates begin at once to disappear from the urine, evidently to maintain the alkalescence of the blood diminished by the withdrawal of the alkaline carbonates. In connexion with this it is interesting to notice that Dr. Gee[4] has likewise called attention to the remarkable fact that in ague, on the days of the paroxysms, the phosphates almost entirely disappear from the urine; and although Dr. Gee has not attempted an explanation of the phenomenon, still it is not unlikely that this is again an instance of a salt being withheld to supply a special requirement, whilst another is being discharged in excess; for it is important to notice in connexion with this withdrawal of phosphoric acid during the ague fit that the chlorides are at that time eliminated in considerable excess. It would be easy to multiply examples, but enough has been said to emphasise the importance of the *rôle* played by the inorganic substances in the economy.

Of all inorganic constituents phosphorus has always been regarded as holding the prominent position. When first separated from the urine by Brandt (1669) it was at once hailed by the physiologists of the day as the "blood of

• **Figure 34-1** Thomas Annandale's landmark article in *The Lancet* is just over a single column in length, has no illustrations, and includes only a single formal reference citation. (From Annandale T: Displacement of the inter-articular cartilage of the lower jaw, and its treatment by operation, *Lancet* 8:411, 1887.)

on nine cases of TMJ ankylosis treated by arthroplasty with rotation of an interpositional flap of temporal fat and temporalis fascia.[4] His incision was L-shaped, with its base along the superior aspect of the zygomatic arch and a vertical arm at the posterior end, extending upward 1½ inches. Murphy claimed that keeping the horizontal incision above the zygomatic arch avoided branches of the facial nerve.

Behan published a detailed and well-illustrated description of TMJ arthrotomy in 1918, returning to the vertical preauricular approach.[5] In the same year, John Blake in Boston noted the difficulties of approaching the TMJ: "It is hard to reach for the purpose of careful detailed attack, as it lies deep below the surface, and is surrounded by good-sized arteries and nerves; a clear dry field is hard to obtain, and accurate work on the joint is consequently far from easy."[6] Even so, others pressed on: In Philadelphia, Ashhurst called Blake's concerns "undue emphasis" and reached the joint through an inverted L-shaped incision, following the zygomatic arch horizontally for 2 cm, then turning inferiorly from the posterior end for 3 cm.[7]

These early TMJ surgeons and several others in the United States, Great Britain, and Europe were pioneers in devising approaches to the TMJ and procedures to restore the joint to better function. According to contemporary standards, their incision designs range from unsophisticated to dangerous and disfiguring, but these men were hardly unsophisticated themselves. All were exceptional anatomists and broadly trained surgeons who critically reassessed the little TMJ pathophysiology known to them, brought fresh thinking to their patients' problems, and applied principles gained from experience in other operations and diseases to the TMJ in novel and perceptive ways. They were certainly aware of one another's work: Most cited one another, and nearly all referenced Annandale's article from a quarter-century before, as well as still earlier compilations of jaw dysfunction cases[8] that offered insight into the TMJ symptoms they faced, although they were of little use regarding surgical therapy.

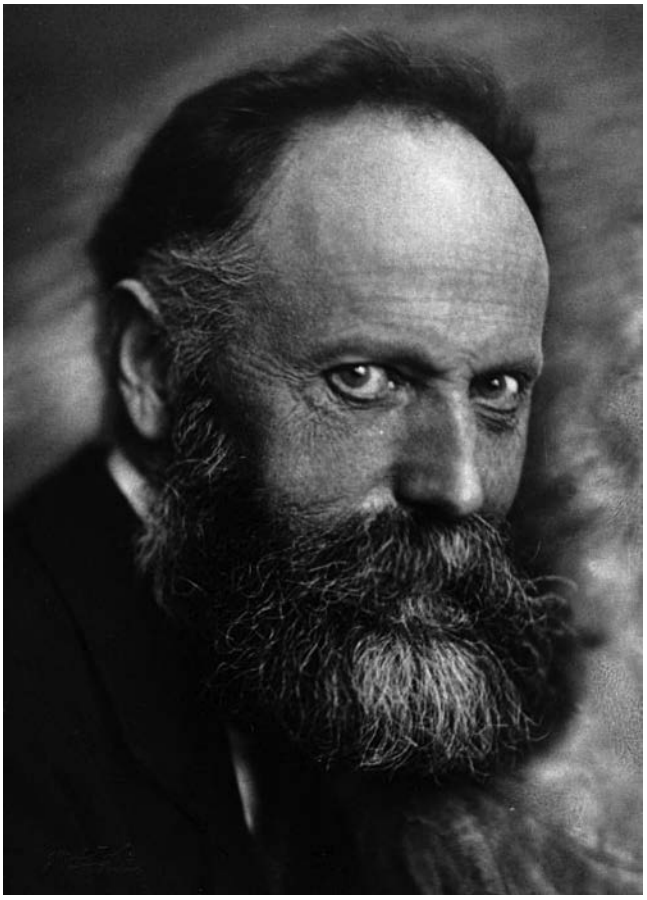
Early Arthroplasty

The Snapping Jaw

By the 1920s, a reasonable body of literature and clinical experience had accumulated regarding TMJ anatomy and function, and several distinct joint pathologies now possessed documented surgical remedies. Annandale had treated painful locking and clicking joints with disc repositioning 30 years earlier, but for many years, little more was published on surgery for this particular condition. In 1918, Behan[5] described finding either anterior or posterior disc attachments torn and he repaired them to reposition the disc. That same year, Pringle[9] hypothesized that the lateral pterygoid muscle could displace the articular disc anteriorly and medially, and treated the condition with what he believed to be the first excision of the disc. Ashhurst duplicated this operation successfully in 1921 on a 16-year-old female patient.[7] Unknown to both of them, the Swiss surgeon Otto Lanz (Figure 34-2), professor of surgery in Amsterdam, had published two cases of TMJ discectomy on an 18-year-old and a 24-year-old woman that he had performed in 1906 and 1908.[10] Lanz, who also invented the mesh skin graft during this time,[11] had reported his surgeries a decade earlier in the German-language journal *Zentralblatt für Chirurgie*.

It was Ashhurst, however, who resurrected a term first used nearly a century earlier by Cooper and christened the internally deranged TMJ the "snapping jaw," a term applied for the next several decades to a rather vaguely defined painful popping or snapping jaw that might intermittently become stuck open, closed, or something in between.

In fact, confusion reigned regarding the actual location and movement of the articular disc in normal function, not to mention its role in the intermittently locking, subluxing, dislocating, and/or snapping joint. Early on, Cooper had compared the subluxing TMJ to injured knees and hypothesized that capsular ligamentous laxity allowed subluxation, although he also believed that the disc could become displaced behind the mandibular condyle and thus prevent full mandibular closure.[8] The debate on whether capsular laxity or disc displacement was responsible for the



• **Figure 34-2** Otto Lanz, the surgeon who first treated painful locking temporomandibular joints in 1906 by removing the intra-articular disc. (Reproduced in Haeseker B: Historical notes on 50 years of plastic surgery in the Netherlands, *Eur J Plast Surg* 23:164, 2000.)

observed symptoms continued for a century and longer. Despite multiple reports of encountering the disc displaced anteriorly at surgery and repositioning it posteriorly, some authors persisted in blaming a posteriorly displaced disc or a loose lateral capsule for the pain and snapping noises in the TMJ. Some confusion may stem from inconsistent use of terminology: Many case reports were unclear on precisely what jaw mobility dysfunction was present, and the term *subluxation* seems to have been applied sometimes to the disc and sometimes to the mandible (without specifying whether the disc was thought to be malpositioned anteriorly or posteriorly). Contemporary understanding of anterior disc displacement and reduction is relatively recent, and perhaps the early confusion is understandable. If one considers the broadly diverse treatments available today for chronic subluxation/dislocation, it can be seen that we may have not progressed all that far in our understanding of this condition.

Although Lanz, Ashhurst, and Pringle directed surgery at the disc, others attempted to control "subluxation" through extracapsular procedures. Blake[6] successfully prevented recurrent dislocation in an adult male patient by wiring the coronoid process to the zygomatic arch to restrict mandibular opening. And in Germany, Nieden[12] improved on safe access to the TMJ and devised a new procedure to restrict condylar movement. He elevated an inferiorly based flap of temporalis fascia, rotated it inferiorly, and secured the free end to the lateral joint capsule to tighten it and restrict condylar movement. Several years later, this surgery was declared to be "based upon the soundest surgical principles" for treating hypermobility,[13] and the loose lateral capsule was believed to be the main point of origin for several more decades.

The story of Professor Doctor Nieden illustrates another aspect of reviewing history: Our admiration of an important figure's achievement should not automatically extend to his character. Nieden's story would not be complete without taking note of a darker side. A highly decorated military surgeon during World War I, Nieden chose a less than noble course during the National Socialist years. He joined the Nazi party early, worked with the Gestapo before and during World War II, and served in the SS. Published accounts name him as a surgeon who performed compulsory sterilization on mixed-race children in the 1930s.[14,15]

Ankylosis

Painful snapping was not the only TMJ pathology treated by operation, nor the most common. Ankylosis was perhaps the earliest TMJ condition treated surgically, although most 19th-century surgeons in Europe attempted to solve the problem with osteotomies away from the TMJ itself. In the United States, Murphy reported on nine patients with TMJ ankylosis whom he treated during the years leading up to 1914.[4] His paper is a grim reminder of the fearsome complications caused by infection in the pre-antibiotic era. Table 34-1 lists the ages of onset and causes of ankylosis for his case series.

TABLE 34-1 Age at Onset and Cause of Ankylosis in Murphy's Case Series, 1914

Case #	Onset Age	Cause
1	6 mo	Otitis media, mastoiditis
2	6 yr	Kicked in jaw by horse, angle fracture with infection
3	Birth?	Difficult delivery, facial deformity noted early in life
4	9 yr	Fall from third story, chin impact, immediate trismus
5	Birth	Unknown
6	2½ yr	Severe mastoiditis, otitis, recurrent abscesses for over 6 months
7	14	Fall from horse without direct facial injury; progressive hip, spine, and jaw immobility
8	2½ yr	Throat infection, subsequent generalized abscesses
9	17	Sepsis, osteomyelitis

Data from Murphy JB: Arthroplasty for intra-articular bony and fibrous ankylosis of temporomandibular articulation, *JAMA* 62:1783-1794, 1914.

Although some cases appear to represent congenital deformities or sequelae of direct trauma, a significant number of his ankyloses appear to be late effects of local (especially mastoiditis) or widely disseminated infection, leading to septic arthritis of the TMJ, a condition very rarely seen today. His treatment consisted of freeing the ankylosis by removing the bone in the area of the condyle and rotating a fascia and a fat flap from the temple into the gap, then propping the patient's mouth open for 2 weeks with a wedge-shaped wooden block. His purpose for this was to "prevent possible compression necrosis of the interposing flap." He reported good mandibular movement at follow-up periods of 4 to 11 months, with one recurrent ankylosis.

The Role of Dental Occlusion

During the early 20th century, intrinsic pathology of the TMJ was addressed with little apparent consideration for the state of the patient's dental occlusion. Orthopedic principles derived from greater experience in other joints were applied to the TMJ, with results reportedly satisfactory to patient and surgeon alike. By 1930, John Morris was able to present a thorough and insightful review of the state of the art in treating the snapping jaw.[13] He perpetuated the assertion that capsular laxity with consequent excessive condylar movement was responsible for the observed snapping, pain, and hypomobility. However, he recognized that posterior disc displacement was anatomically unlikely and therefore an unacceptable cause. Building on the work of Pringle,[9] he postulated that anterior displacement ultimately led to secondary joint laxity, which, in turn, produced symptoms.

• BOX 34-1 Treatment Options for "Subluxation of the Inferior Maxilla"

I. Nonoperative methods
  A. Dental technical procedures
    1. Outside mouth
      (a) Apparatus, fastened around chin and held in position by cap on head; limits chewing motion and depression of point of jaw
    2. Inside mouth
      (a) Splint, fastened to upper and lower jaw with intervening catch hinge, is adjustable to limit motion of lower jaw (Schroeder)
      (b) Hard rubber plate, fixed to upper jaw and provided with process pointing of edge of masseter muscle or coronoid process, limits excursion of latter (Fritzsche)
  B. Injection of corrosive fluids into joint (to produce shrinkage of capsule and promote adhesions)
    1. Tincture of iodine (0.75 mL tincture of iodine injected into joint posteriorly secured permanent cure in case of girl, aged 20 years, as reported by Perthes)
    2. Alcohol
II. Operative method
  A. Treatment of capsule
    1. Excision of portion of capsule is followed by suture to overcome redundancy (Perthes)
    2. Simple plication of capsule after exploration of joint takes up redundancy and tightens joint
  B. Use of fascial strip (turned down from temporal region to check excursion of head, as described by Nieden)
  C. Treatment of meniscus
    1. Fixation of disc by suture to periosteum of mandibular fossa (Haeber)
    2. Fixation of disc in vertical position in front of condylar process (Konjetzny)
    3. Removal of the articular disc (Ashhurst)

From Morris JH: Chronic recurring temporomaxillary subluxation: surgical consideration of "snapping jaw" with report of a successful operative result, *Surg Gynecol Obstet* 50:483-491, 1930.

More significantly, he summarized the contemporary treatments available for the snapping jaw (Box 34-1) and argued convincingly that joint surgery offered the best solution.

Morris's writings reflect progress made since the time of Annandale nearly half a century earlier, not only with respect to the TMJ but for all of orthopedic surgery. He decries that "standard surgical texts limit operative indications to such conditions as ankylosis, arthritis, irreducible dislocations, and a few unusual fractures. Subluxation of the joint as a surgical consideration is either dismissed as of no importance, or its existence is completely ignored." He responds by asserting that "operative indications, which were formerly limited to the more grave pathological conditions, have been gradually extended to include a variety of derangements the minor character of which did not justify the hazards imposed by the older methods. The acceptance of the minor joint lesions for radical surgical treatment indicates the highest degree of confidence in the safety and efficiency of the methods employed and offers as well the most convincing evidence of the advances made in this field."

However, within a few years, the philosophy undergirding temporomandibular joint care would turn in the opposite direction. Washington University otolaryngologist James Costen studied a large cohort of patients with varying combinations of headache, ear pain, neuralgia, glossodynia, and other less common complaints associated with abnormal jaw movement and malocclusion. He theorized that loss of posterior occlusal support (a common phenomenon of the time) led to excessive pressure on the TMJ with subsequent destruction, dysfunction, and nerve compression. His theory was ultimately published in the *Journal of the American Medical Association*[16] and gained widespread acceptance for nearly two decades; the "snapping jaw" became "Costen's syndrome."

Treatment of patients with this new syndrome, whose symptoms were correctly observed to be much more common than was previously recognized, was dental. The posterior occlusion was gradually opened; this was believed to decompress the nerves and other tissues within the TMJ and to allow healing. Most patients improved; those who did not were sometimes assumed by their treating physicians to have received poor care from their dentists.[16] In fact, Costen even advocated against removing the molar teeth in any patient with a head and neck neuralgia.

Although surgery for TMJ internal derangements did continue to be practiced, Costen's syndrome validated and energized an entire school of thought that attributed joint pathology to occlusal disharmonies. In fact, therapy following Costen's principles and the many subsequent dental refinements was reasonably effective, although probably not for the reasons cited. However, as early as 1940, some authors questioned the anatomic basis of Costen's neurologic symptoms. Dingman[17] concludes a thorough review of TMJ therapy by warning, "We must not lose sight of the fact that many of the statements made regarding this subject [Costen's syndrome] are still within the realm of speculation and need further scientific investigation for substantiation. . . . By assuming a critical attitude and proceeding in a cautious manner, the dental profession may avert severe criticism that might arise as a result of misguided therapy." His advice remains wise today.

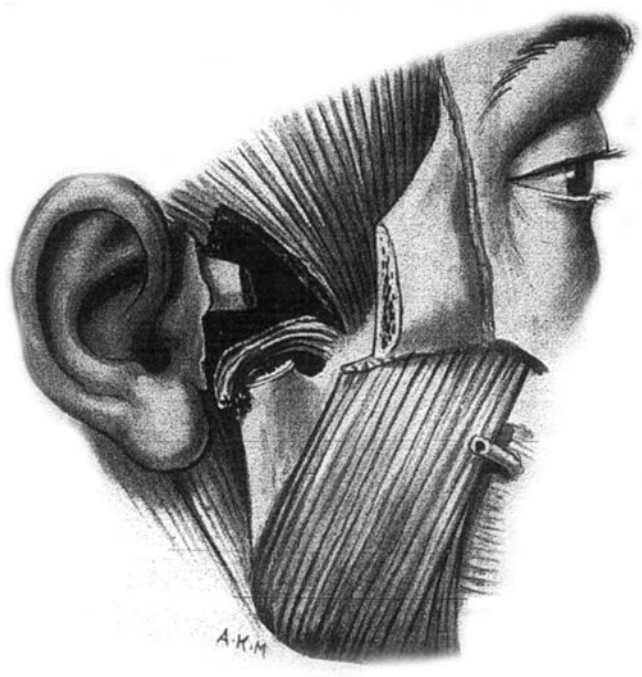
Finally, in 1948, Harry Sicher, the legendary teacher and anatomist at Loyola School of Dentistry, published a definitive anatomic study that refuted the neural compression mechanism underlying Costen's syndrome.[18] His article concludes with a balancing perspective. He notes that "destruction of the disk and degenerative and proliferative changes on the condyle and tubercle" meet "the well-defined picture of deforming arthritis. . . . The symptoms of pain, local and irradiating (referred), cracking of the joint and the restriction of movements of the joint are simply the symptoms of arthritis." Yet he does attribute TMJ arthritis to mandibular overclosure or displacement and concludes by stating, "The beneficial influence of reconstructive dentistry has to be fully recognized." Thus, the two schools of TMJ treatment, surgical and occlusal, remained established and in some tension with one

another, although perhaps forming the beginnings of a stronger scientific foundation.

The Mid-20th Century and the Science of TMJ Therapy

Professor Cecil Wakely of King's College, London, published a new review on surgery of the temporomandibular joint in 1939.[19] In a series of 38 patients (30 male and 8 female) with mandibular dislocation, he found only two whose condition was recurrent and did not operate even on those. He advocated arthroplasty with a gap for treating ankylosis and was the first to use a pedicled temporalis flap, tunneled beneath the zygomatic arch, as an interpositional tissue graft (Figure 34-3). Regarding allografts, he noted presciently, "The human body does not tolerate foreign tissue kindly."

The largest part of Wakely's paper is devoted to the displaced articular disc, a topic that he had explored a decade earlier.[20] He describes this condition as "an uncommon accident, but a much more difficult condition to treat than dislocation of the joint." He believed that synovitis resulting from displacement was in part responsible for the pain, which is perhaps the first recognition of a noninfectious, intracapsular inflammatory process as a contributing cause of the disorder. He also bluntly associated gender-related emotional issues with chronic disc displacement: "The psychologic effect of a snapping joint may be very marked, especially in females. They become introspective and nervous and are afraid to have meals in public."[19] In cases that failed "every other form of treatment" (which he does not describe), he performed discectomy and claimed good outcomes with follow-up of up to 15 years, comparing the procedure to the well-established successful operation of excising torn medial menisci from the knee.



• **Figure 34-3** Professor Wakely's temporalis flap, 1939. (From Wakely CPG: The surgery of the temporomandibular joint, *Surgery* 5:697-706, 1939.)

The following year, Reed Dingman of Washington, DC, also published a broad review of diagnosis and treatment of TMJ disorders.[17] Many of the conditions he identified are curiosities to the modern reader. Suppurative lesions of the TMJ were becoming less frequent but might still result from middle ear infection, gonorrheal ophthalmitis or urethritis (he cites a large series that found TMJ infection in 3% of gonorrheal urethritis cases), measles, scarlet fever, diphtheria, pertussis, typhoid, pneumonia, or influenza. He attributed the reduction in cases to the introduction of vaccination for many of these diseases, the use of sulfanilamide to treat infection, and the instillation of silver nitrate eyedrops to prevent gonorrhea neonatorum. He notes that without incision and drainage, a suppurative TMJ can be expected to drain preferentially into the middle ear or the external auditory canal and much less commonly to the pretragal area. Yet even with proper care, many of these cases ended in ankylosis, which remained a relatively common indication for TMJ surgery. In such cases, Dingman advocated arthroplasty with a pedicled interpositional temporalis flap, although he abandoned Murphy's mouth wedge.

Dingman also wrote at length on arthritis of the TMJ—both atrophic (rheumatoid) and hypertrophic (osteoarthritis). In either case, unless the patient developed an ankylosis or severely symptomatic disc displacement, he advocated nonsurgical care consistent with that given for other afflicted joints. He noted that TMJ arthritis previously had been thought to be rare, but its actual, more common incidence had become widely recognized. With respect to subluxation and dislocation, Dingman, like many before him, appears to have considered cases of disc displacement and condylar subluxation/dislocation as a single broad entity. He describes nonoperative treatment with intermaxillary fixation or sclerosing injections, the latter as "generally ineffectual," although he gives details of the method used by Schultz[21] with good effect. Of published surgeries for internal derangements, he concludes (although without providing evidence) that discectomy "seems to be the best and most logical procedure."[17]

Dingman and Wakely were by no means the only surgeons performing TMJ operations in the 1930s and 1940s. Caroll Silver, an orthopedic surgeon who trained in New York in the late 1930s, participated in several cases as an intern wherein mandibular hypermobility was treated by grafting a block of bone to the articular eminence. Patients were kept in a plaster head cast for 6 weeks and were fed through a straw; they reportedly did not suffer from subluxation or dislocation after healing.[22] Later in his career, Silver performed hundreds of discectomies and contributed some of the largest series of long-term outcomes in the literature.[23] In Stockholm, Karl Bowman published his doctoral dissertation entitled "Temporomandibular Joint Arthrosis

and Its Treatment by Extirpation of the Disk: A Clinical Study."[24] This landmark scientific treatise was arguably its time's most complete, well-documented compilation of knowledge regarding the TMJ and its anatomy, pathophysiology, normal and impaired function, and response to discectomy (including measured outcomes). He summarizes, saying in part the following[24]:

> Examination of a healthy material including 1350 individuals of all ages showed that symptoms of arthrosis, such as snappings, crepitations and disturbances in motion are very common and more frequent in women than in men. At least ⅓ of all grown-up persons have or have had such symptoms. They can occur already at the age of 6-8, but are more common in later ages.
>
> Contrary to information in the literature, there have been no incongruities as regards the frequency of symptoms in individuals with normal bites, straight bites and deep bites, whether the molar-premolar supports have been good or bad. In individuals with incomplete bites, down to total loss of teeth, temporomandibular joint symptoms have not occurred more frequently than in individuals without noteworthy loss of teeth. In persons without teeth, temporomandibular joint symptoms are less frequent than in denture cases. The symptoms of arthrosis are, as a rule, associated with very slight trouble. They can disappear spontaneously without leaving any clinically demonstrable traces. In exceptional cases, however, they can be associated with more severe symptoms which require treatment. . . . There is nothing to indicate a detrimental effect of the extirpation of the disk on the unoperated joint. There is no reason always to perform a bilateral extirpation of the disk, as has been recommended. In cases with bilateral symptoms, the most severely affected joint should be operated. Even the other joint is often improved thereby. There are no disadvantages of a subsequent operation on the other joint, if necessary. . . . The treatment of the temporomandibular joint arthrosis should, first and foremost, be conservative. . . . In cases with severe symptoms (constrictions, luxations, pains, disturbing snappings) which cannot be improved by conservative therapy, an extirpation of the disk is indicated. The operation offers immediate and permanent relief from these symptoms.

Nearly 70 years later, Bowman's assertions remain valid. His conclusions can hardly be better stated today.

These men and the many other surgeons they represented continued the search for better ways to treat TMJ dysfunction, applying the dramatic new medical knowledge and surgical techniques that were revolutionizing all of surgery. Their work provided the foundation for the creative treatment concepts about to emerge.

The Era of Innovation

At the end of World War II, medical and surgical innovation accelerated dramatically, and TMJ surgery received its share of attention from creative, and sometimes bold, surgeons. As Costen's influence faded and that of Wakely, Dingman, Bowman, and others grew, care of the TMJ drew renewed interest. With clearer distinction between diagnostic entities, it became easier for clinicians to choose appropriate therapies for their patients and, in turn, to assess their outcomes. The influence of basic science was felt in the world of patient care as well, not only through an exponential increase in knowledge and the resultant drugs and technologies, but also via application of scientific criteria to clinical research. It would no longer do to perform an operation a few times, declare the patient qualitatively better, describe his or her satisfaction, and publish the operation as an appropriate and successful treatment.

Nonsurgical Therapy

Not all innovations in therapy were surgical. Although occlusal equilibration continued to find acceptance, other nonoperative treatments were devised for specific conditions. Although others had attempted TMJ sclerosis using a variety of agents, Louis Schultz of Chicago had reported an improved method of reducing TMJ hypermobility with sclerosing injections in 1937, and in 1947, he published a report on 10 years' experience.[21] His method was innovative, appealing when compared with other contemporary alternatives (he mentions either surgery or mandibular fixation by head bandage for 1 to 1½ years—to be repeated if necessary), and apparently successful, although he follows the older tradition of providing no outcome data. In 1954, while treating the opposite end of the TMJ disease spectrum, Laszlo Schwartz applied the newly described concepts of myofascial pain, myalgia, and trigger areas to stiff, sore muscles in the masticatory muscle system.[25] Along with these concepts, he introduced the new therapies of local anesthetic injection and vapocoolant "spray and stretch" treatment to the TMJ literature. Of equal significance, he presented tabular data showing outcomes for a series of cases, including patients treated and those observed only. Although not blinded, randomized, placebo controlled, quantitative, or authorized by an institutional review board, his presentation of evidence was nevertheless a great leap forward from the preceding body of literature, perhaps excepting Bowman's scientifically rigorous publication.

Early Implants

Operative treatment remained the only viable alternative for severe fibrous or bony joint ankylosis, and attention was turned toward reducing the common complication of recurrence. Most surgeons used a flap of fascia, fat, or muscle in the hope of preventing bony regrowth, but with unpredictable results. In 1946, Eggers[26] reported the use of an alloplastic material, tantalum foil, to line bony surfaces at the ankylosis resection site in a 4-year-old girl. At 13 months, she had good mandibular opening, but long-term follow-up was not available. His description of the material and its use may make a contemporary surgeon who is familiar with the catastrophic failures of later alloplasts cringe: "It is a bit brittle and cracks, but satisfactory coverage can be secured

and even small pieces can be packed in areas where intervening material is desired."

Gordon,[27] when treating patients with subluxation (clicking joints), reported having 3 years' good experience placing polyethylene caps in the joint space after removing discs. His purpose was to prevent long-term malocclusion from an assumed reduction in vertical dimension at the condyle, although he admitted that in the short term, this was rarely a problem. Again, long-term follow-up was not available on this cohort of patients.

In July 1960, Sir Terence Ward lectured the Royal College of Surgeons on surgery of the mandibular joint.[28] He distilled surgical treatment of the TMJ into three operations: (1) condylectomy for pathology, (2) arthroplasty for ankylosis, and (3) condylotomy for internal derangements. His description of arthroplasty was remarkable for several innovations. He casually mentioned two advances in anesthesiology used in his cases: endotracheal intubation and controlled hypotension. These techniques were relatively new, although it is now difficult for the modern surgeon to imagine operating without them. He also illustrated the use of a rounded chrome-cobalt cap, which was inserted at surgery on a curved osteotomy into the mandibular ramus above the mandibular foramen. In this way, a new rotational joint was created below the mass of the ankylosis, and the bony surfaces separated and presumably were prevented from fusing by the chrome-cobalt cover. Ward reported "good" function following bilateral implants, without noting the duration of observation.

At the forefront of autogenous grafting, Georgiade at Duke University and colleagues reported a new application of transplanting autogenous dermis into the TMJ in 1957.[29] Tested first on dogs, the procedure was then performed on eight patients with ankylosis, and only one partial re-ankylosis was formed, although at relatively short follow-up. This landmark work gave TMJ surgeons a new biocompatible graft option that offered success at least as good as historical experience with fascia, fat, or muscle flaps.

From our vantage point a half-century later, it would be easy to fault these innovators for risking great complications or spectacular failure. However, at the time, the risks of alloplast failure could hardly seem worse than an all-too-predictable re-ankylosis, which was not only a failure but a terrible challenge to re-treat, or a malocclusion that would condemn the patient to heroic dental reconstruction or orthognathic operations that were in their infancy as well. These surgeons' contributions represented pioneering efforts to improve outcomes, and although we must surmise that these treatments failed, because they were generally abandoned, implanted materials with documented long-term success were only a few years away.

Joint Reconstruction

TMJ implants took a substantial leap forward in 1964, with Christensen's publication of a new arthroplasty technique in which a cast Vitallium glenoid fossa prosthesis was used.[30] He created a set of 20 cast prostheses based on impressions on skulls with varying anatomy, then selected the best-fitting implant for insertion into the patient.

Implants were secured with screws into the zygomatic arch, away from the occlusal surface. They were intended to provide a stable surface against which the mandibular condyle might function, preventing re-ankylosis by serving as a permanent mechanical barrier. In time, some surgeons advocated extending the indications for placement of the Christensen fossa to discectomy patients, to prevent the hypothetical but dreaded "bone-on-bone" contact and its presumed negative consequences.

The Christensen fossa implant soon was joined by a matching condylar prosthesis with a polymethylmethacrylate condylar head, thus forming the first total alloplastic temporomandibular joint prosthesis. Although other total joint replacement systems with advanced materials and engineering principles have been developed more recently, the Christensen implant remains on the market today as the first and longest used TMJ replacement system available.

Nonsurgical Treatment Revisited

Technical advances notwithstanding, surgery on the TMJ remained an imperfect and unpredictable science, facing criticism from those whose philosophy (and case study outcomes) supported nonsurgical treatment of all but tumor and ankylosis cases. During the 1960s, interest grew in the work of Schwartz and others, who believed that TMJ dysfunction was less a result of mechanical failure (either capsular or intracapsular) and more an outcome of masticatory muscle dysfunction. This in turn was attributed in large part to emotional stress and anxiety in patients, most of whom were young and female. In 1969, Daniel Laskin published an articulate paper in the *Journal of the American Dental Association* that proposed a shift of emphasis from joint to muscle pathology.[31] He provided a cogent argument for a strong psychological origin behind the physiologic muscle disorder in many patients and suggested the term *myofascial pain-dysfunction* to describe the condition.

In contrast to Costen's work, which was based to a significant extent on speculation, Laskin provided sound evidence for his theory. The paper became a lightning rod for renewed and sometimes contentious debate over the relative importance of psychological, emotional, occlusal, muscular, and intracapsular factors in patients with pain, popping and clicking joints, and stiff jaws. Unfortunately, despite its reasoned and scientific principles, the writing also reinforced the preconceptions of many clinicians who had always quietly believed TMJ disease to be a weak woman's affliction that was more "supratentorial" than organic in origin.

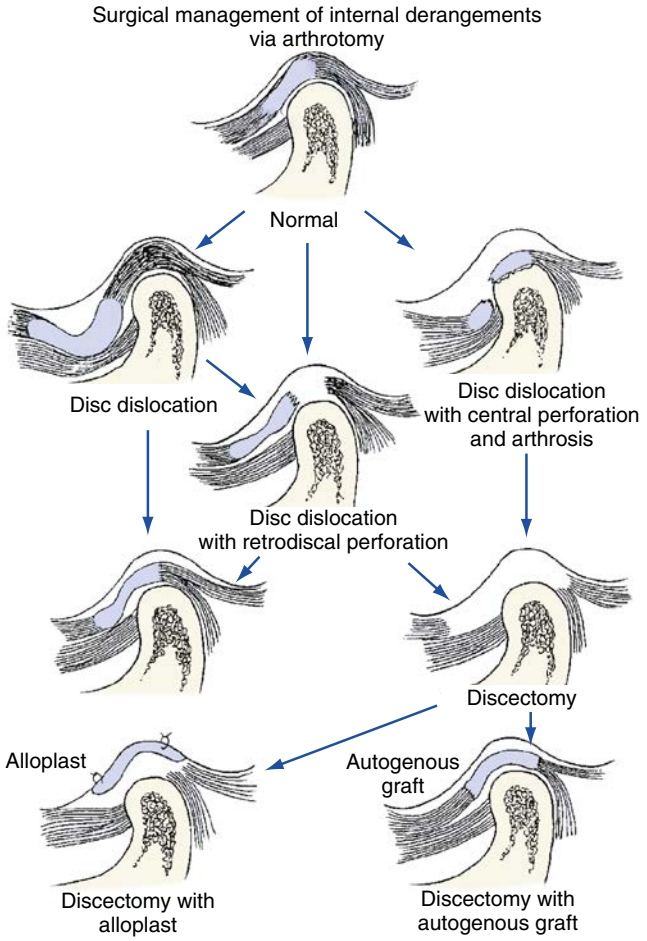
For a time, TMJ surgery was unpopular. Even so, amid the controversy and renewed interest in occlusal and muscle therapy, a new generation of surgical pioneers prepared the next round of advances.

The Return of the Operation

Open Joint Surgery

In the 1970s and 1980s, Wilkes brought new understanding to TMJ surgery, advancing interpretation of imaging, creating a clinical and radiographic staging system for characterizing TMJ internal derangements, and even developing new instrumentation for open TMJ surgery.[32,33] McCarty and Farrar,[34,35] Dolwick and colleagues,[36] and many others promoted a more complete understanding of the normal and abnormal function of the articular disc, leading to a resurgence of interest in disc surgery. Although discectomy continued to be performed, new techniques for disc preservation surgery were widely promoted by these and other authors (Figure 34-4).

The preauricular approach became standard, with modifications in skin incision placement behind the tragus by Kiehn[37] and widely cited improvements based on research by Al-Kayat and Bramley.[38] Indresano and Mobati have written an excellent summary of advances in TMJ surgery, particularly during the late 20th century.[39]



• **Figure 34-4** A schematic of options for temporomandibular joint disc surgery, 1989. (From Braun T, Kent J: Temporomandibular joint surgery, part II: partial and total joint reconstruction and osseous procedures, *Selected Readings Oral Maxillofac Surg* 1:1-24, 1989.)

The wide resurgence of interest in TMJ surgery contributed to a tragic chapter in its history. With disc surgical procedures being performed in great numbers, attention was directed to finding a suitable disc replacement. Autogenous grafts, including Georgiade's dermal graft, were widely used, although evidence for their improving outcomes was minimal. However, many surgeons turned to alloplastic materials for implantation. By the mid 1980s, two commonly used implants—silicone sheeting and a Teflon-Proplast implant specifically developed as an articular disc replacement—proved to be poor choices. The Teflon-Proplast implant in particular was prone to fragmentation and evoked an intense and locally destructive foreign-body giant cell reaction, resulting in catastrophic local destruction and, in many cases, consigning the patient to a lifetime of intractable pain. The manufacturing company withdrew it from the market (Figure 34-5), was subject to extensive litigation, and ultimately went bankrupt. Silicone sheeting was also subject to degeneration and foreign body reaction, but with less intense local destruction.

The TMJ implant debacle brought repercussions well beyond those felt by the unfortunate patients who received them. Critics of surgical therapy for TMJ internal derangement renewed their attacks. Insurance companies, alarmed by disastrous and expensive outcomes in their affected clients, simply wrote blanket exclusions for any TMJ-related care into most of their policies. Furthermore, a large cohort of patients with iatrogenically created chronic pain now joined the TMJ surgeons' caseloads, bringing complex long-term medical management issues into practices that were more comfortable providing acute surgical care to a relatively straightforward patient population. As a result of these forces, many surgeons stopped providing TMJ care in their practices, thereby reducing patient access to interested and qualified TMJ surgeons—a situation that persists to the present day.

Total Joint Replacement

The 1980s were a time of new developments in alloplastic total joint reconstruction. Although relatively few patients required total joint replacement, a small number with severe rheumatoid arthritis, traumatic joint destruction, failed reconstruction with autogenous grafts (most commonly costochondral grafts), or ankylosis had few other reasonable alternatives. The Christensen implant system remained the state-of-the-art total joint replacement technique throughout the 1970s, but then advances in materials, biomechanical engineering, and understanding of joint pathophysiology dramatically altered joint reconstruction in general orthopedics. Joint replacement for knees, hips, and other joints had become frequent and predictably successful surgery, and oral and maxillofacial surgeons began working to bring the same contemporary technologies to the TMJ. Kent and others[40,41] developed a joint reconstruction system with a polymeric fossa prosthesis and a metallic condylar head—the opposite of Christensen's design,

VOLUNTARY SAFETY ALERT

PRODUCT: VITEK TEMPOROMANDIBULAR JOINT (TMJ) INTERPOSITIONAL IMPLANT (IPI) - ALL LOTS

Dear Doctor:

The purpose of this letter is to inform you of the following reported concerns which affect the Vitek TMJ IPI. The corresponding product catalogue numbers are 912.71, 912.72, 912.74, 912.76, 912.77 and 912.78. Vitek's IPI's may fragment, delaminate or otherwise be damaged or punctured. Debris in the joint from alloplastic implants can contribute to progressive bone degenerative changes and to giant cell reaction. All patients, including asymptomatic patients, should be monitored closely to assure proper patient maintenance. This monitoring should include clinical and radiographic examination. The radiographic examination may include transcranial or tomographic x-rays, CAT scans or bone scans.

As you know, the 1984 AAOMS criteria for meniscus surgery recommends continuing postsurgical follow-up. Because it is often difficult to distinguish between normal bone remodeling changes that can occur and long term extensive bone resorption in presently asymptomatic patients who have received alloplastic implants such as the TMJ IPI, it is strongly recommended that these patients be followed indefinitely. Please inform all your patients who have received a Vitek IPI of the importance of follow-up.

The prophylactic removal of Vitek's IPI is not recommended.

Additionally, do not implant any more of these devices if you have any of them in your possession. These implants should be returned for credit. Return these implants to the address below in their original boxes with, if available, a copy of the corresponding shipping memorandum.

For our records, we would appreciate your completion and return of the enclosed postage paid, self-addressed postcard.

If you have any questions, concerning this notification, please call Sue Tellkamp at the telephone numbers given below.

Thank you for your assistance and cooperation.

• **Figure 34-5** The letter distributed to oral and maxillofacial surgeons announcing the recall of the Vitek Teflon-Proplast implant. By the time of its distribution, many surgeons were already well aware of the implant's risks for patient safety.

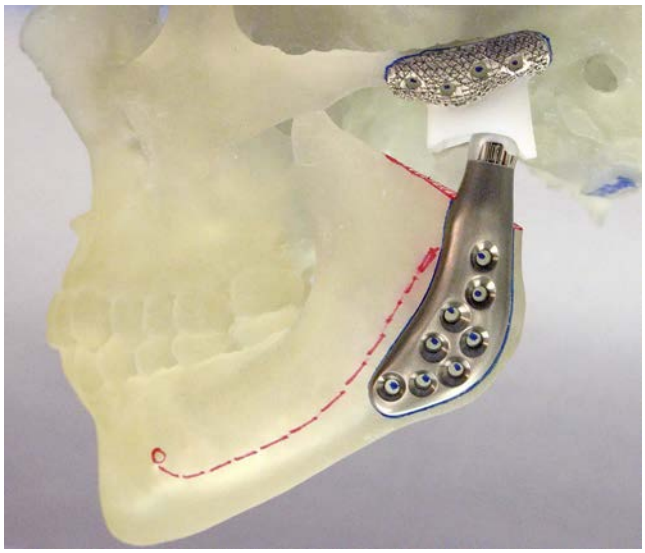
but consistent with contemporary biomechanical research. This system was used successfully in many cases, but it was manufactured by the ill-fated Vitek Corporation and disappeared from the market with that company's collapse. Several other investigators and large manufacturers developed TMJ implant designs, but in the aftermath of the Teflon-Proplast debacle, a combination of relatively few potential patients (compared with the market for large orthopedic joints) and a particularly—and understandably—harsh regulatory climate brought nearly all to a halt before production or while still in early clinical trials. Ironically, many of the patients most in need of total alloplastic reconstruction were those with severe iatrogenic joint destruction from failed fossa implants.

Ultimately, one TMJ reconstruction system completed rigorous trials and was approved by the FDA for use in limited indications in the mid-1990s. This system uses a computer-aided design/computer-aided manufacturing (CAD-CAM) design with custom-fitted fossa and condylar implant that differed from prior systems, which allowed selection from a set of stock sizes and configurations. Computed tomography (CT)-derived data are used to construct a full-size model of the patient's jaw and skull base, which in turn is used to design and manufacture the implants (Figure 34-6).

Their custom-fitted nature eliminated the need to shim or backfill the implants, particularly the fossa component, with polymethylmethacrylate or other materials, and resulted in a stable prosthesis without micro-movement, even in patients with severely mutilated joints. This system remains on the market today, with numerous reports of good function and stability generated over a decade or longer.[42-44] A second total TMJ replacement system, designed using similar principles and materials, offers standard-sized, as opposed to custom, components. Nevertheless, a well-documented and significant drawback to these and all TMJ reconstruction technologies available to date is their inability to predictably reduce or eliminate pain, even when movement and function are improved.

Minimally Invasive Treatment

In 1975, Ohnishi published the first description of arthroscopy of the temporomandibular joint in the Japanese literature.[45] Until that time, arthroscopes were too large for the TMJ, but Watanabe developed a suitably thin instrument for small joints. Ohnishi and Murakami developed a protocol for TMJ arthroscopic lysis and lavage, which they successfully used in the treatment of internal derangements. A large series of results was published in the English literature in 1986,[46] and TMJ arthroscopy rapidly became popular in North America as an alternative to open surgery, with lower costs and less morbidity. Early adaptors included Sanders and McCain, both of whom published extensively on the technique,[47-51] including the development of elegant and sophisticated advanced operative techniques.[52] A large multicenter retrospective study was published in 1992 by several leading authorities to document high success rates for the procedure.[53]



• **Figure 34-6** The TMJ Concepts Patient-Fitted Implant. The components are shown here on the laser stereolithographic model derived from computed tomography data and used in their fabrication. (Courtesy of TMJ Concepts Inc., Ventura, CA.)

Arthroscopy itself represented a major advance in TMJ surgery, allowing minimally invasive treatment for patients who would otherwise be candidates for open surgical procedures. However, critical evaluation of the success and outcomes of arthroscopic lysis and lavage led to new theories about the mechanical basis of TMJ disease. In 1990, Nitzan, Dolwick, and Heft published an article in which they questioned the direct primary role of disc displacement in TMJ symptoms, based on strong evidence that arthroscopic surgery was highly successful clinically but failed to reduce discs to the "normal" position in all but a few cases.[54] In 1991 Nitzan, Dolwick, and Martinez described a novel technique for treating patients with acute closed lock of the TMJ, which they called *arthrocentesis*.[55] Moreover, they postulated that anterior disc displacement in the TMJ might better represent an anatomic variant than a true pathology. They offered alternative hypothetical explanations for mandibular hypomobility not dependent on mechanical obstruction of the condyle by an anterior disc.[56] These theories remain somewhat controversial to the present day, but they represent a further evolution in our understanding of the pathophysiologic mechanisms underlying TMJ symptoms.

TMJ arthroscopy and arthrocentesis have given researchers the tools with which they can sample healthy and diseased joints and gather clues on the molecular basis of TMJ disease. Scientist clinicians, as represented by Milam[57,58] at the University of Texas in San Antonio, are essential allies of the current generation of surgeons. Today they bring the tools of molecular biology to bear on the diseases Cooper struggled to describe 165 years ago.

Summary

Diseases of the temporomandibular joint have been recognized in the Western medical literature for 200 years or more, and they have been treated with surgery since the latter part of the 19th century. The earliest operations were pioneering efforts by early general surgeons, whose solutions for the most seriously debilitating problems were, in many cases, not dissimilar to contemporary operations. Advances in the early 20th century paralleled those in other arenas of medicine and surgery, including the introduction of minimally invasive surgery near the end of the century.

Surgical management of TMJ disease, particularly internal derangement, has been provided with varying degrees of tension with nonsurgical therapy almost since the beginning. Over the 20th century, expert opinion and clinical practice swung between the two poles, and some confusion and dogma persist on both sides to the present day. As scientific study has improved our knowledge about the origin and natural course of internal derangements and has clarified the outcomes a clinician might expect from a given treatment, both types of therapy have found their place in the contemporary surgeon's armamentarium.

Perhaps the most critical lesson to be learned by reviewing the history of treatment for temporomandibular joint disease is that we can still learn from the errors of our predecessors. It is remarkable how little is truly new in TMJ arthroplasty, for example, and the surgeon who is considering a clever "innovation" probably should examine the literature from longer ago than he or she might have thought necessary before declaring the idea new. Perhaps the direction most likely to yield truly new knowledge and therapies will be molecular medicine. Even with this, future scientists likely will wish to read the works of contemporary arthroscopists and surgeon-scientists, or they will risk re-invention rather than true innovation.

Structure and Function of the Temporomandibular Joint

ROBERT GASSNER

Providing motion is the central function of the craniomandibular or temporomandibular articulation, where mandible and cranium are connected as the temporomandibular joint (TMJ). As part of the stomatognathic system, the TMJ allows simple and complex movements such as free movement during phonation, gesticulation, swallowing, and breathing, as well as different types of load-bearing movements during incision and chewing. Although all other bony segments of the head are fused via synostoses, only the three ossicles within the middle ear also show articulations. Therefore, the description of the phylogenetic development of the TMJ is helpful for an understanding of its structure and function.[1-8]

Developmental Perspective of the Craniomandibular Articulation

In mammals, the articulating bony parts of the TMJ are derived from membrane bone. These are formed directly from intramembranous centers of ossification. These developing bones, the squamous portion of the temporal bone, and the condyles of the mandible become completely surrounded by periosteum, including areas that eventually form the articular surfaces of the TMJ and build the "secondary" TMJ there.[9,10] In contradistinction to that is the development of the "primary" TMJ of nonmammalians, deriving from cartilage. In bony fish, reptiles, and birds, the proximal parts of the mandible constitute the TMJ, which is actually the primary TMJ. In mammals, the primary or primitive TMJ is subjected to complex changes, also ultimately forming the joints for three ossicles within the middle ear. The secondary TMJ in humans starts to develop by the 10th week of gestation from mesenchymal condensations of two separate blastemas for the mandibular condyle and the temporal bone.[5,10-12] The condylar and temporal mesenchymal cells differentiate into osteoblasts, which lay down membrane bone. The periosteum that lines these articular surfaces gradually is transformed during its early development into the dense fibrous articular tissues of the TMJ.[6] In the center of the condyle, cartilage develops and becomes the growth center, with subchondral bone formation by an enchondral mechanism.[13] Superior to the condylar blastema, a band of mesenchymal cells develops that differentiates into the disc, which is considered as deriving from an extension of lateral pterygoid muscle.[5,9,14,15] The configuration and shape of the TMJ are also related to the development of dentition. During infancy, the articular fossa is a flat furrow with almost no eminence. Eruption of the primary dentition increases the groove, forming a fossa. The final adult formation of the TMJ is associated with eruption of the permanent dentition. Articular forces acting through the TMJ play an important role in this gradual transformation.[6,16] Depending on the preservation of the dentition, the TMJ may maintain a stable form throughout life. Edentulism of the jaws again causes secondary changes within the TMJ, with flattening of the articular fossa and eminence. The configuration and shape of the TMJ depend on skeletal and dental relationships of the maxilla and mandible. For example, a deep bite is correlated with a steep eminence.[4,9]

Most synovial joints have hyaline cartilage that lines their articulating surfaces, because bones of typical synovial joints are endochondrally formed bones that are initially preformed in hyaline cartilage. In contrast, articulating surfaces of the TMJ are lined by dense, avascular, fibrous connective tissue. Most of this cartilage eventually is calcified and then is replaced by bone, although the cartilage that lines the articular surfaces persists in a modified form. Thus, the lack of hyaline cartilage on the articular surfaces of the TMJ reflects its unique ontogenetic and phylogenetic development; although it is not a hyaline cartridge-covered joint, it is capable of bearing loads. Although a secondary cartilage is present in the condyle of the growing mandible, this

• **Figure 35-1** Lateral view of human cranium and mandible.

• **Figure 35-2** Basal view of human cranium.

cartilage does not form part of the articular surface because the periosteum-derived articular tissues cover it.[17,18]

Surgical Anatomy and Histology

The mandible and cranium make up the craniomandibular articulation, which frequently is referred to as the *temporomandibular articulation.* This articulation of the mandible consists of two synovial joints: left- and right-sided TMJs. The bony components include the mandibular condyles below and the squamous temporal bones above (Figure 35-1). The articular space of each TMJ is divided into upper and lower compartments because of the interposition of the fibrous articular disc between the temporal bone and the mandible. Gliding or translatory movements occur primarily in the upper compartment, while the lower compartment functions primarily as a hinge or rotary joint.[1,4,6,18-23]

Glenoid Fossa—Articular Eminence

The *glenoid* or *mandibular fossa,* is the concavity within the temporal bone that houses the mandibular condyle. Its anterior wall is built by the articular eminence of the squamous temporal bone and its posterior wall by the tympanic plate of the temporal bone, which also forms the anterior wall of the external acoustic meatus. The bony roof of the glenoid fossa is thin and often appears translucent when transilluminated (Figure 35-2).

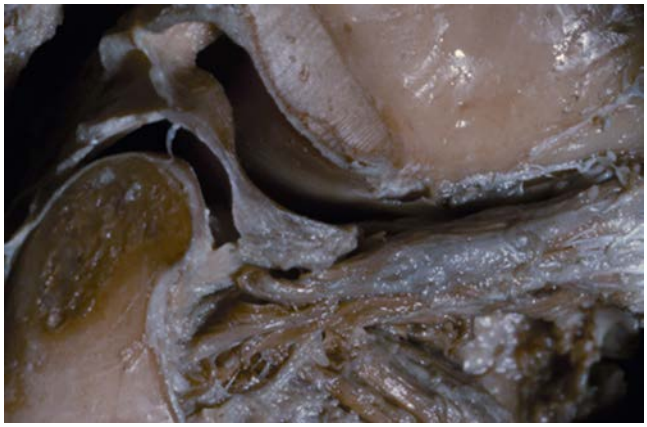
It is important to note that the term *articular fossa* refers to the particular portion of the glenoid fossa that is covered by articular tissues. It is built entirely by the squamous portion of the temporal bone (see Figure 35-1). The posterior part of the articular fossa is elevated to a ridge called the *posterior articular lip.* In most individuals, the posterior articular lip is higher and thicker at its lateral end and thus is visible from the side as a cone-shaped process between the articular fossa and the tympanic plate. This structure is the postglenoid process. The lateral border of the articular fossa sometimes is marked by a narrow, low ridge or crest.

In the posterior and lateral parts of the *glenoid fossa,* a fissure separates the articular and nonarticular portions of the glenoid fossa. This fissure, called the *tympanosquamosal fissure,* also separates the tympanic portion from the squamous portion of the temporal bone. Medial to this fissure, a bony plate of the petrous portion of the temporal bone, the tegmen tympani, protrudes between the tympanic and squamous portions. Therefore, instead of a tympanosquamosal fissure along the medial aspect of the glenoid fossa, an anterior petrosquamosal fissure and a posterior petrotympanic fissure occur. The petrotympanic fissure is slightly widened laterally to permit passage of the chorda tympani nerve and the anterior tympanic blood vessels. These neurovascular structures are located within the glenoid fossa, but not within the articular fossa (see Figure 35-2).

The *articular eminence* is the transverse bar of dense bone that forms the posterior root of the zygomatic arch and the anterior wall of the articular fossa. It has a large articular surface. It is strongly convex on a side view and moderately concave when viewed from the front or back. The degree of this convexity and concavity is highly variable. Fine bony ridges often outline the medial and lateral borders of the articular eminence. Although a thin layer of fibrous tissue covers the roof of the articular fossa, the fibrous tissue that covers the articular eminence is thick and quite firm. Moreover, different from the roof, the articular eminence is made up of a fairly thick layer of dense bone. Lateral to the articular eminence, a small bony projection, the *articular tubercle,* is located. The articular tubercle is not an articular surface. Instead, it serves as the attachment area for portions of the temporomandibular ligament (TML).[24-26]

Articular Disc—Disc Ligaments

The *articular disc* is a firm, oval, fibrous plate that is positioned between the mandibular condyle and the articular fossa and eminence (Figure 35-3). Its central part, the



• **Figure 35-3** Parasagittal section of temporomandibular joint disc area and lateral pterygoid muscle.

• **Figure 35-4** Parasagittal section of temporomandibular joint disc area.

intermediate zone, is considerably thinner than its periphery—the anterior and posterior bands. Anteriorly, the disc continues as the anterior attachment and is fused to the capsule of the TMJ. Posteriorly, the disc continues as the posterior attachment or bilaminar zone—a thick double layer of vascularized connective tissue. The bilaminar zone splits into two parts: (1) an upper fibroelastic layer that attaches to the postglenoid process, posterior articular lip, and tympanosquamosal fissure; and (2) a lower fibrous layer that attaches to the posterior portion of the condylar neck immediately below the articular tissues. Posteriorly, these two layers are separated by the intermediate layer, which contains loose connective tissue that attaches to the posterior wall of the joint capsule. The posterior attachment has a profuse supply of nerves and blood vessels.[11,12,27-30]

Unlike its anterior and posterior attachments, the disc is not attached to the capsule laterally or medially. Instead, it is tightly bound directly to the medial and lateral poles of the mandibular condyle. The position of the disc relative to the condyle also is influenced by the pull of the superior head of the lateral pterygoid muscle because a small portion of this muscle often attaches to the disc (Figure 35-4). Because the superior head of the lateral pterygoid also attaches to the mandibular condyle, and the disc is tightly bound to the medial and lateral poles of the condyle, this muscle arguably may have no special influence on movements of the articular disc relative to the condyle.[31,32]

Ontogenetically, the articular disc derives from a mesenchymal block of tissue that also gives rise to the capsule of the TMJ and the lateral pterygoid muscle.[33] This tissue mass is located between the developing squamous temporal bone and mandibular condyle. In adults, the uppermost part (or superior head) of the lateral pterygoid muscle often retains its original connection to the capsule and articular disc of the TMJ.

Blood vessels and nerves are absent in the intermediate zone, that is, the firm central region of the articular disc, as well as in the avascular fibrous layers that cover the mandibular and temporal articular surfaces of the joint. A lack of these neurovascular structures is compatible with the hypothesis that a considerable reaction force occurs along this portion of the joint. It has been suggested that one main function of the articular disc is to reduce stress concentrations between the articular surfaces of the mandibular condyle and the squamous temporal bone—that is, the compliant nature of the disc helps to distribute reaction force more evenly along these joint surfaces.[7,20,34-36]

Condyle

The articular surface of the mandible is the upper and anterior surface of the condyle (Figure 35-5). The adult human condyle is about 15 to 20 mm from side to side and 8 to 10 mm from front to back. Its long axis lies at right angles to the plane of the mandibular ramus. Because of the flare of the ramus, however, the long axes of the left and right condyles cross approximately at the anterior margin of the foramen magnum, forming an obtuse angle varying from 145 to 170 degrees.[37]

The articular surface of the condyle is strongly convex when viewed from the side and less so when viewed from the front. The articular surface faces upward and forward, so that in side view, the condylar neck is bent forward. As seen from the front, the articular convexity often resembles a tentlike configuration that is divided into medial and lateral slopes by a variably prominent crest. The lateral pole of the condyle extends slightly beyond the outer surface of the ramus and is roughened for the attachment of the articular disc and the TML.[19] The medial pole of the condyle protrudes considerably beyond the inner surface of the ramus and also is slightly roughened for the attachment of the articular disc. Variations in the shape of the condyle are frequent. Irregularities of the bony articular surfaces are obscured and smoothed by the thick covering of fibrous tissue that is derived from and directly continuous with the periosteum of the mandible.

• **Figure 35-5** Mandibles with different condylar head shapes and angles.

Synovial Membrane

The synovial membrane, a highly vascularized layer of connective tissue, lines all structures of the articulation that do not experience compressive forces. The largest area of synovial lining covers the upper and lower surfaces of the posterior attachment, including the loose connective tissue that binds the posterior border of the disc to the capsule. Synovial tissue also lines the inner aspect of the fibrous capsule. When the condyle is positioned in the glenoid fossa, the synovial membrane forms rather heavy folds posteriorly (see Figure 35-4). When the condyle is protruded toward the summit of the articular eminence, the folds disappear as the synovial tissues are stretched.[38]

• **Figure 35-6** Lateral view of temporomandibular joint capsule and position of maxillary artery.

Capsule—Extracapsular Ligaments

The articular capsule is quite thin anteromedially, medially, and posteriorly, but it is thick anterolaterally and laterally, where it attaches to the articular tubercle.[39] This reinforced lateral portion of the capsule is the temporomandibular ligament. The capsule attaches to the squamous portion of the temporal bone along the outer limits of the articular surface of the articular eminence, fossa, and preglenoid plane. Posteriorly, the capsule arises from the postglenoid process, the posterior articular lip, and the tympanosquamosal fissure (Figure 35-6).

The anatomy of the capsule and that of the TML show considerable variability.[16,40-43] The TML can be split into two layers: a wide, fan-shaped superficial portion, and a narrow deep portion. The broad origin of the superficial portion along the articular tubercle and its narrower insertion along the condylar neck account for its somewhat fan-shaped morphology. Its anterior fibers run from the articular tubercle obliquely down and back; the posterior fibers have a more vertical orientation. Fibers of the deep portion are oriented horizontally (anteroposteriorly), attaching along the lateral pole of the mandibular condyle and extending to a crest situated along the articular tubercle. This deep horizontal band sometimes is named the *lateral polar ligament.*[19,39]

The fibrous capsule of the TMJ and the TML allows and limits jaw movements. The vertical fibers control distraction movements of the condyle from the articular eminence and fossa, the horizontal fibers (polar ligaments) prevent excessive retrusive movements of the condyle, and the posterior portion of the capsule limits protrusive movements. The anterior part of the capsule and the anterolateral part of the TML may limit condylar rotation during jaw opening, although most of this limitation is imposed by the stretched jaw-closing muscles.[19,39]

Accessory Ligaments

The sphenomandibular and the stylomandibular ligaments are considered accessory ligaments of the temporomandibular articulation (Figure 35-7).

• **Figure 35-7** Posterior view of temporomandibular joint capsule and ligaments.

• **Figure 35-8** Masseter muscle: superficial and deep parts.

Sphenomandibular Ligament

The sphenomandibular ligament arises from the spine of the sphenoid bone and is directed downward and outward, inserting on the mandible at the mandibular lingula, which is located along the upper border of the mandibular foramen. It is derived from Meckel cartilage. In most individuals, the sphenomandibular ligament is a thin layer of connective tissue with indistinct anterior and posterior borders that protects the blood vessels and nerves passing through the mandibular foramen from additional tensile stress during jaw opening and closing.[44] It normally has no influence on mandibular movement.

Stylomandibular Ligament

The stylomandibular ligament is a reinforced sheet of cervical fascia that extends from the styloid process and the stylohyoid ligament to the region of the mandibular angle. Many of its fibers are attached to the back edge of the lower part of the mandibular ramus; others continue onto the deep fascia along the medial surface of the medial pterygoid muscle. The upper border of the stylomandibular ligament normally is a thickened cordlike structure.

This ligament is relatively loose when the jaws are closed and when they are wide open; it is tensed only when the mandible is maximally protruded. Thus, apparently this ligament can limit excessive protrusive movements.

Muscles

Various muscle groups of the face, tongue, palate, and hyoid are involved in TMJ motion. In addition to the four powerful masticatory muscles (masseter, temporalis, medial pterygoid, and lateral pterygoid), the morphology and function of other important muscles that play a role in mandibular movements are described here.[45,46]

Masseter Muscle

The masseter muscle reaches as a rectangular plate from the zygomatic arch to the lateral surface of the mandibular ramus (Figure 35-8). It is divided into a superficial and a smaller deep portion. The superficial masseter arises from the lower border of the zygomatic arch as strong tendinous fibers. The most anterior fibers may arise from the outer corner of the zygomatic process of the maxilla. Posteriorly, the origin of the superficial portion ends along the zygomaticotemporal suture. The superficial masseter is covered on its outer surface by a strong tendinous layer that extends down from the zygomatic arch over the upper third or half of the muscle.

In a frontal view, these fibers are directed downward and medially. In a side view, the muscle fibers of the superficial masseter are directed downward and backward to insert along the angle of the mandible. The mandibular attachment of the superficial masseter extends along the lower one third of the posterior border of the ramus and along the lower border of the mandible anterior to the third molar; it covers, more or less, the lower half of the lateral surface of the ramus. The field of insertion has ridges into which the tendons insert, as well as grooves between the ridges into which the fleshy fibers insert.

Posteriorly, the fibers of the superficial masseter wrap around the posterior and inferior aspects of the angle of the mandible, joining fibers of the medial pterygoid muscle in a tendinous raphe. This muscular arrangement is called the *pterygomasseteric sling.* The deep and superficial portions of

the masseter fuse anteriorly, but posteriorly, the two can be separated. Fibers of the deep masseter arise from the entire length of the zygomatic arch up to the anterior slope of the articular eminence. Some of its fibers also may arise from the lateral wall of the TMJ capsule.[31,47]

The deep masseter inserts above the superficial masseter along the mandibular ramus as a triangular insertion field. The base of this triangle faces posteriorly, and the apex faces anteriorly. In the side view, the fibers of the deep masseter, which have a near vertical alignment, pass downward at an angle of about 30 to 40 degrees to the fibers of the more obliquely aligned superficial masseter.

The masseter muscle is a powerful elevator of the mandible. A lateral view reveals that the deep masseter exerts primarily a vertical force on the mandible. In contrast, the superficial masseter exerts a vertical and slightly anteriorly directed force on the mandible that is approximately perpendicular to the occlusal plane of the molars. The entire masseter also exerts a lateral component of force on the mandible.[48]

Temporalis Muscle

The temporalis muscle has a fan-shaped origin along the lateral surface of the skull and the dense fascia overlying this muscle (Figure 35-9). The bony attachment field, the temporal fossa, is encircled above by the inferior temporal line. This attachment field includes a narrow strip of the parietal bone, the greater part of the temporal squama, the temporal surface of the frontal bone, and the temporal surface of the greater wing of the sphenoid bone. Muscle fibers and tendons also arise from the postorbital septum, which is the bony partition that separates the temporal fossa from the orbit. Both the zygomatic and frontal bones and the greater wing of the sphenoid contribute to the formation of the postorbital septum. The bony field of origin of the temporalis muscle reaches downward to include the infratemporal crest of the sphenoid.

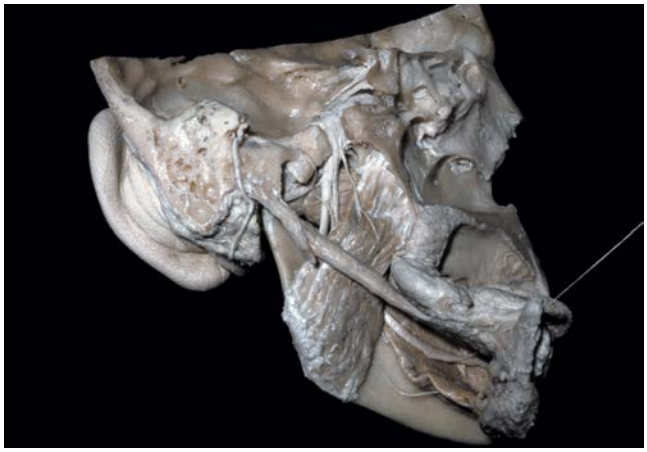
Many of the temporalis muscle fibers originate from the medial surface of the temporalis fascia. The temporalis fascia attaches to the superior temporal line and the upper border of the zygomatic arch. Passing downward from the superior temporal line, the temporalis fascia thickens considerably and then splits into two layers; the superficial layer continues into the periosteum of the zygomatic arch along its lateral surface, and the deep layer extends into the periosteum of the zygomatic arch along its medial surface.

The bundles of the temporalis muscle converge toward the opening located between the zygomatic arch and the lateral surface of the skull (temporal foramen). The tip of the coronoid process projects into this opening. The anterior fibers of the temporalis muscle, which form the major bulk of the muscle, are largely vertical; the fibers in the middle part of the muscle are increasingly oblique. The most posterior fibers run forward almost horizontally, bend around the posterior root of the zygomatic arch in front of the articular eminence, and pass downward vertically to the mandible.

The middle and posterior portions of the temporalis muscle, respectively, are attached along the apex of the coronoid process and along its posterior slope to the deepest point of the mandibular notch. The more superficial fibers of the anterior temporalis muscle insert along the apex of the coronoid process, the anterior surface of the coronoid process, and the mandibular ramus. The deeper fibers of the anterior temporalis attach along the medial anterior surface of the mandibular ramus.

• **Figure 35-9** Temporalis muscle.

Similar to the masseter muscle, the temporalis muscle mainly elevates the mandible. Its fan-shaped morphology indicates that its direction of pull varies considerably, depending on which portions are mechanically active. Superficially, it appears that its most posterior fibers retract the mandible because of their horizontal orientation along the side of the skull; however, as previously noted, when the condyle is situated in the mandibular fossa, the fibers of the posterior temporalis are bent around the posterior root of the zygomatic arch at a sharp angle and thus are oriented vertically. Therefore, this portion of the temporalis muscle exerts primarily an upward force on the mandible during normal



• **Figure 35-10** Medial view of medial pterygoid muscle.

• **Figure 35-11** Medial view of medial and lateral pterygoid muscle.

• **Figure 35-12** Oblique view of lateral pterygoid muscle.

closure. When the condyle is translated anteriorly into a more protruded position, these posterior fibers likely cause the mandible to retrude because, in this instance, the posterior temporalis is aligned more horizontally. Because its most posterior fibers pass very close to the condyle, the posterior temporalis probably also functions as a stabilizer of the TMJ.

The middle and obliquely aligned portion of the temporalis muscle is capable of exerting a vertical and retracting force on the mandible. Most of the anterior portion is capable of a vertical pull on the mandible. That portion of the anterior temporalis that originates from the postorbital septum, however, likely pulls the mandible upward and forward. Finally, the deep fibers of the anterior temporalis that originate along and just above the infratemporal crest pull the mandible upward and somewhat medially. Thus, the morphology of the entire temporalis muscle indicates that its fibers are capable of considerable variability in their direction of pull.

Medial Pterygoid Muscle

The medial pterygoid muscle is situated on the medial side of the mandibular ramus as a powerful rectangular muscle (Figure 35-10). Its main origin is the pterygoid fossa, a depression that is located between the back edges of the medial and lateral pterygoid plates of the sphenoid bone. The deepest fibers arise from strong tendons; others arise directly from the medial surface of the lateral pterygoid plate. A flat tendon covers the medial surface of the muscle at its origin, and it is as wide as the tensor veli palatini, with which it is in contact.

The most anterior fibers of the medial pterygoid arise from the outer and inferior surface of the pyramidal process of the palatine bone and from adjacent parts of the maxillary tuberosity. These fibers, which are referred to as the superficial head of the medial pterygoid, are positioned lateral to the lateral pterygoid muscle. The remaining and largest portion of this muscle, the deep head, is positioned medial or deep to the lateral pterygoid muscle.

The fibers of the medial pterygoid muscle run downward, backward, and laterally and are inserted along the medial surface of the angle of the mandible. The field of insertion is approximately triangular and is located between the mandibular angle and the mylohyoid groove. As noted earlier, the fibers of the medial pterygoid muscle often meet fibers of the masseter in a tendinous raphe behind and below the mandibular angle (the pterygomasseteric sling). Because of the overall fiber orientation of the medial pterygoid muscle, it is primarily an elevator of the mandible (Figure 35-11).

Lateral Pterygoid Muscle

The lateral pterygoid muscle arises from two heads (Figure 35-12). The inferior head is about three times larger than the superior head.[49,50] The superior head (sometimes called the *superior pterygoid*)[51] originates from the infratemporal surface of the greater wing of the sphenoid medial to the infratemporal crest. From its origin, the fibers of the superior head run almost horizontally backward and laterally in close relation to the external surface of the cranial base. The inferior head originates from the outer surface of the lateral pterygoid plate. Although the fibers of the inferior head also run backward and laterally, they pass upward at an angle of about 45 degrees relative to the superior head.

The two heads of the lateral pterygoid muscle are separated at their origins by a wide gap but fuse in front of the TMJ. The fibers of the superior head are attached

• **Figure 35-13** Digastric muscle and mylohyoid muscle.

primarily to a roughened fossa on the anteromedial surface of the condylar neck. This fossa is called the *pterygoid fovea.* In addition, a small portion of the superior head frequently is attached directly to the anteromedial part of the TMJ capsule and extends into the anteromedial part of the articular disc. All fibers of the inferior head insert into or along the periphery of the pterygoid fovea. This description of the lateral pterygoid is based on the work of numerous authors.[16,27,31,32,39,47,49,52-54]

The lateral pterygoid muscle also consists of two functionally distinct parts. The superior head contracts during jaw closing, and the inferior head contracts during protraction, opening, and shifting of the jaw to one side.[55-58] The superior head of the lateral pterygoid stabilizes the mandibular condyle against the articular eminence during biting and mastication.[16,59] Bilateral contraction of the lower head of the lateral pterygoid muscle creates a protruding mandibular movement. Unilateral action of the inferior head shifts the midline of the mandible to the opposite side (lateral excursion). Finally, if either or both heads of the lateral pterygoid muscle are actively recruited during mandibular closure, this muscle must experience an eccentric or lengthening contraction.[14,39] Under these conditions, the lateral pterygoid muscle exhibits considerable stiffness; this also facilitates joint stability by controlling or limiting condylar movements.[6,32,60]

Digastric Muscle

As the name implies, the digastric (two-bellied) muscle consists of an anterior belly and a posterior belly (Figure 35-13). The posterior belly arises from the mastoid notch medial to the mastoid process; the intermediate tendon is held to the body of the hyoid bone by a fascial loop. The anterior belly attaches to the digastric fossa of the mandible. This fossa is located at the lower lingual border of the mandible slightly lateral to the midline. In the side view, the two bellies of the muscle form an obtuse angle. The posterior belly is much longer than the anterior belly and is only slightly flattened in the mediolateral direction.

If the hyoid is fixed by the action of the infrahyoid muscles, contraction of the digastric muscles pulls the front of the mandible back and down and thus facilitates retrusive and opening movements of the mandible.[61,62] If the teeth are held firmly in occlusion (by the jaw-closing muscles), then contraction of the entire digastric elevates the hyoid as long as the infrahyoid muscles are relatively relaxed.

Mylohyoid Muscle

The mylohyoid muscle builds a muscular diaphragm or floor for most of the oral cavity (see Figure 35-13). It is a flat, continuous, pentagonal sheet of muscle located deep to the anterior belly of the digastric. The base of this pentagon attaches to the body of the hyoid bone, and the two adjacent sides of the base have a free edge. The remaining two sides attach to the medial or lingual aspect of the left and right mandible corpora along the mylohyoid line. The apex of this pentagon attaches to the midline lingual surface of the mandible. It also attaches to a midline mylohyoid raphe that connects the body of the hyoid with the lingual midline surface of the mandible. This raphe divides the mylohyoid into left and right sides.

The mylohyoid slightly raises the hyoid (and tongue) and floor of the mouth. Moreover, if the mandible is stabilized, it can also pull the hyoid forward. In the event that the hyoid is stabilized or is being pulled down and/or backward, this muscle also can depress the mandible.

Geniohyoid Muscle

The geniohyoid muscle is a strap-shaped muscle that runs from the ventral surface of the body of the hyoid to the lingual aspect of the mandible immediately lateral to the midline (Figure 35-14). It is located superficial to the mylohyoid. The muscle is made up of nearly parallel muscle fibers that run straight from origin to insertion. The anatomy of the geniohyoid indicates that if the mandible is stabilized in occlusion, these muscles can slightly raise the hyoid (and tongue) during contraction, and it can pull these structures forward. Conversely, in the event that the hyoid is pulled downward and/or backward, the geniohyoids can depress the mandible. The geniohyoid muscles are not branchial arch derivatives. These muscles are the serial homologs of the musculi rectus abdominis; this is why they are often described as belonging to the "rectus cervicis" group—the straight muscles of the neck.[63]

Innervation and Blood Supply

The sensory nerves of the *capsule* for proprioception and pain are branches of the auriculotemporal, deep temporal,

• **Figure 35-14** Geniohyoid muscle.

• **Figure 35-15** Lateral view of trigeminal nerve when condyle is removed.

and masseteric nerves. The blood supply to the capsule and disc is provided mainly by branches from a maxillary artery. Nerves (Figure 35-15) and blood vessels are numerous in the posterior portions of the articular disc and fibrous capsule.[4,6]

The *masseter muscle* is derived from the first branchial arch and therefore is innervated by the trigeminal nerve (cranial nerve V). More specifically, the masseteric nerve, a small branch of the mandibular or third division of the trigeminal nerve (V_3), innervates the masseter muscle. This nerve passes above the lateral pterygoid muscle and then, after passing through the mandibular notch behind the tendon of the temporalis muscle, enters the medial surface of the deep masseter muscle. The masseteric nerve supplies the deep masseter, perforates it, and then enters the superficial masseter.

The *temporalis* muscle is innervated by the deep temporal branches of the anterior trunk of V_3. Of the three deep temporal nerves ordinarily present, the posterior and middle branches arise as separate filaments from the anterior trunk immediately after the trigeminal nerve emerges through the foramen ovale. The anterior branch initially is united with the buccal nerve; this common trunk, which lies in a sulcus adjacent to the foramen ovale, runs anteriorly and laterally, close to the base of the skull. It is held in place by a ligament that bridges the sulcus. If this ligament ossifies, it contributes to the formation of the temporobuccal foramen.

The anterior temporal nerve usually separates from the buccal nerve after the latter has passed between the two heads of the lateral pterygoid muscle. Its most anterior portion, however, is not positioned nearly as far forward as the anterior portion of the superficial masseter.

The nerve to the *medial pterygoid* arises from V_3 immediately before it divides into its anterior and posterior trunks. The medial pterygoid nerve, which also innervates the tensor tympani and tensor veli palatini muscles, reaches the medial pterygoid muscle at its upper posterior border.

The nerve to the *lateral pterygoid muscle* is usually a branch of the buccal nerve, which is a branch of the anterior trunk of V_3.

The bellies of the *digastric muscle* are derived from the first and second branchial arches and are innervated by the mandibular division of the trigeminal (V_3) and facial nerves (cranial nerve VII), respectively. The mylohyoid nerve, which is a branch of the inferior alveolar nerve, innervates the anterior belly, a first-arch derivative. A branch of the facial nerve supplies the posterior belly, a second-arch derivative.

V_3 innervates the *mylohyoid muscle* via the mylohyoid nerve. Occasionally, the anterior belly of the digastric is fused to the ventral surface of the mylohyoid. This fusion reflects the embryologic origin of these two muscles from a common muscle mass derived from the first branchial arch.

The *geniohyoids* are innervated by ventral rami of the first and second cervical nerves. These nerve fibers connect to the left and right hypoglossal nerves (cranial nerve XII) to reach the floor of the mouth.

TMJ Function

Comprehending TMJ function requires consideration of the relationship of fossa, disc, and condyle during motion. If a finger is placed just in front of the tragus of the ear, the forward and downward sliding of the mandibular condyle can be felt. Soft tissues behind the moving condyle

sink in slightly, and a shallow groove often becomes visible during jaw opening. If a finger is introduced into the external acoustic meatus, it is easy to feel the prominence of the lateral pole of the mandibular condyle on the cartilaginous anterior wall of the meatus and the widening of this passage when the mouth is opened. Differences due to active and passive motion-free (or empty) movements of the mandible, which are those that occur without food in the oral cavity, are distinguished from incision and mastication movements, which are associated with biting and chewing of food (Box 35-1).[1-6,64-76]

The muscles of the TMJ combine in various patterns to execute movements of the mandible. A muscle may act synergistically with different muscles at different times. Moreover, antagonistic muscles may act simultaneously to control jaw movements. Muscles that affect the movements of the mandible are divided into groups. These include elevators—the temporalis, masseter, and medial pterygoid muscles; depressors—the digastric, mylohyoid, and geniohyoid muscles; and protractors—the lateral pterygoid muscles (see Box 35-1). Retractors of the mandible do not constitute an independent group; they are the digastric muscles and the obliquely aligned fibers of the temporalis muscles. When the stylohyoid and infrahyoid muscles fix the hyoid, the mylohyoid and geniohyoid also may help to retract the protruded mandible. The fibers of the deep portion of the masseter also help in this. Thus, both elevators and depressors can function as retractors of the mandible. The infrahyoid muscles function to control hyoid movements; therefore, their action is important during both jaw opening and jaw closing.

Free Movements of the Mandible

Two basic movements of the mandible can occur: (1) the rotary or hinge movement, which consists of rotation of the mandible around a transverse axis that passes through the centers of the mandibular condyles, and (2) the translatory or sliding movement, which involves bodily movement of the mandible in the anteroposterior and/or mediolateral direction. Whereas rotating movement occurs mainly between the disc and the condyle in the lower joint compartment, anteroposterior and mediolateral translatory movements occur mainly between the articular eminence and the disc (and mandible) in the upper compartment of the temporomandibular articulation. Sometimes, the translation movements are not symmetric between the left and right joints. Generally, translation occurs simultaneously with rotation, so during normal rotary movements, the center of rotation is not located within the mandible or the condyle.[66]

Free movements of the mandible, which combine rotation and translation, include opening and closing, protrusion and retrusion (symmetric forward and backward movements), and lateral shifts of the mandible. The extreme or outer limits of the various combinations of these movements make up what have been called the border movements of the mandible.[67,68]

Opening

Although highly variable, on average, a nearly equal or linear combination of translation and rotation is observable in the opening and closing movements of the mandible.[66] Translation brings the disc and the condyle forward and downward along the posterior slope of the articular eminence. The condyle and disc may even move anterior to the greatest height of the articular eminence onto the preglenoid plane. The opening movement is so extensive that normally the opening between the maxillary and mandibular incisors easily accommodates three fingers (40 to 60 mm).

The opening movement is caused by gravity, relaxation of the elevator muscles, and a combined action of the lateral pterygoid, geniohyoid, mylohyoid, and digastric muscles. If the opening movement occurs without resistance, the depressors act without any great force. If the amount of opening is only slight, relaxation of the elevators and the force of gravity can accomplish this movement. When wide opening occurs, the protracting force of the inferior head of the lateral pterygoid muscles, which act on the condyles and discs, combines with the depressing and retracting forces of the geniohyoid, digastric, and mylohyoid muscles, which act on the chin and body of the mandible.

Closing

The elevators of the mandible execute the closing movement. If the mouth is opened to its maximal extent, timing of the activation and relaxation of different parts of these muscles may be important for proper closure. During maximum opening, each disc and condyle glides anterior to the summit of the articular eminence onto the preglenoid plane. At the beginning of mouth closure, the discs and condyles are moved back from this anterior position. The elevators execute this phase of the closing movement. This action returns the jaw to the rest or occlusal position.

Protrusion

During protrusion, the mandible is pulled forward, with the mandibular teeth slightly separated from or in light contact with the maxillary teeth. The mandibular condyles are pulled forward together with the articular discs at this time. Therefore, movement occurs primarily in the upper compartment of the TMJ, and it is symmetric.[19] Protrusion of the mandible is primarily the result of contraction of the inferior heads of the lateral pterygoid muscles, although slight activity of the masseter and medial pterygoid muscles also is noted at this time. The temporalis muscle usually is not active during this movement, and the depressors are only slightly active. The lateral pterygoid muscles pull the mandibular condyles (and discs) forward and downward along the articular eminences, while the elevators and depressors apparently stabilize the position of the mandible relative to the maxilla. Contraction of the elevators and the depressors in an unresisted forward thrust often is not noticeable on palpation. However, if the mandible is moved to the extreme forward position, contraction of the superficial masseters can be felt. The forward and backward movements of the mandible are mainly, but not exclusively, translatory.

Retrusion

The reversal of the forward movement, retrusion, is also mainly translatory. These forward condylar movements, which can be confirmed easily by palpation, are limited by the posterior portion of the joint capsule.[43] Most people with a relatively normal masticatory apparatus can retrude the mandible 1 to 2 mm from the full occlusal position or centric occlusion. The capsular and polar ligaments of the TMJ limit retrusion from this position. This retruded position beyond centric occlusion (referred to as centric relation) is not reached during normal jaw movements in humans, although by definition, it falls along the border movements of the mandible. When the condyles are situated in the mandibular fossa, the obliquely aligned middle fibers of the temporalis muscle combine forces with the depressors so as to retrude the mandible, while the remaining elevators exhibit varying amounts of activity. From the maximum protruded position, the posterior temporalis assists the middle temporalis during mandibular retrusion.

Lateral Shift

A lateral shift of the mandible (e.g., a shift to the right) results if the condyle and disc on the opposite or left side are pulled forward, downward, and medially along the articular eminence. In this instance, the left side is often called the *balancing side (b-s) condyle,* whereas the right side is called the *working-side (w-s) condyle.* The w-s condyle, sometimes called the *resting condyle,* executes very limited movement at this time. This movement consists primarily of a rotation of the mandible around a nearly vertical axis located within or immediately behind the w-s condyle. This movement also results in a slightly transverse translation of the two condyles toward the working side.

Lateral shift of the mandible results from an asymmetric variation of protrusion, that is, the b-s lateral pterygoid muscle combines forces with the slightly active elevators. The middle portion of the w-s temporalis muscle must assist in this movement by holding the w-s condyle and preventing it from deviating anteriorly to any great extent. Continued rotation of the w-s condyle is prevented as the lateral polar ligament is pulled straight. Under guidance of this ligament, the center of the w-s condyle is forced to move slightly forward and laterally. The lateral component of this movement often is called the *Bennett movement.* As noted, the different movements of the w-s and b-s condyles can be palpated easily.

Masticatory Movements of the Mandible

The two basic mandibular movements, namely, rotation and translation, combine during masticatory jaw movement. Two general types exist: a cutting movement, as occurs when a piece of food is bitten off, and a crushing and grinding movement, which is used to comminute a piece of food. The cutting of food into bite-sized pieces, often referred to as *incision,* is carried out mainly by the incisors. The rhythmic and repetitive crushing and grinding of food, termed *mastication,* is carried out almost exclusively along the premolars and molars. When mechanically resistant foods are eaten, chewing usually occurs unilaterally, that is, chewing takes place on only one side of the dental arch.[75-89]

Incision

Incision consists of three parts, namely, (1) opening, (2) closing, and (3) power strokes.[69,70] (1) Starting from the rest or occlusal position, depression of the mandible opens the mouth, and the extent of opening is primarily dependent on the size of the food object. (2) The mandible is elevated or closed. An upward and forward movement of the mandibular incisors occurs along with an upward and backward movement of the mandibular condyles during jaw closure, and this part of the incision continues until the maxillary and mandibular incisors contact the food object. (3) Following food contact, the jaw continues to close with the simultaneous application of force on the food object. In many instances, the closing stroke does not occur simply, because when the food object is large (e.g., a whole apple), the amount of jaw opening is just enough to accommodate this object between the maxillary and mandibular incisors.[6]

Mastication

Similar to incision, mastication or chewing consists of three basic parts: opening, closing, and power strokes,[71] which combine to make up a single chewing cycle. All chewing cycles associated with the mastication of a single piece of food are referred to as a *chewing sequence.* A chewing cycle begins with opening of the mouth. During the opening stroke, the amount of opening varies from one chewing cycle to the next, and this depends in part on the size and

consistency of the food object. The closing stroke starts from the position of maximum opening. The mandibular incisors then are moved upward, forward, and away from the midline toward the working side. Completion of the closing stroke leads to the power stroke, which is the forceful contact of the food between the occlusal surfaces of the molar and premolar teeth. The w-s teeth posterior to the canine are moved back toward the midline during the power stroke. With the exception of those movements associated with contact between the maxillary and mandibular teeth, mandibular incisor movements during mastication are well within the border movements.

When tough, mechanically resistant foods are chewed, the power stroke of mastication often ends before the maxillary and mandibular teeth make contact. This type of power stroke is called *puncture crushing.* However, a power stroke often does involve direct contact between the maxillary and mandibular teeth; this type of power stroke is called *tooth-tooth contact.*[77-83] When a large food object suddenly breaks during incision, the holding force and stiffness of each lateral pterygoid muscle prevent uncontrolled posterior and upward displacement of the mandibular condyles, as the condyles and discs are situated precariously near the summit or along the posterior slope of the articular eminence.

Summary

Clinicians constantly are challenged to deal more effectively with their patients' TMJ problems when they do arise. Moreover, the very narrow definitions of ideal intraindividual and interindividual TMJ morphology and mandibular function may divert clinicians to regard otherwise normal variability in asymptomatic populations as a pathologic condition that requires treatment. This chapter has provided insights into the structure and function of the craniomandibular articulation. In keeping with the evolutionary history of this articulation, which is reflected in its early ontogeny, unique aspects of the TMJs were highlighted. The articulating surfaces are covered by fibroelastic tissue distinct from hyaline cartilage in other synovial joints. The TMJs as load-bearing joints always must function bilaterally and are influenced by dental occlusion. The articular discs are interposed between articular fossae and condyles, allowing complex rotational and translatory movements, especially during incision and mastication. In conclusion, the craniomandibular articulation within the stomatognathic system has an enormous capacity to function in a wide variety of patterns and displays great ability to adapt to different functional demands.

Acknowledgment

The author is grateful to Professor Helga Fritsch, MD, PhD (Rector of the Medical University of Innsbruck and previous Head of the Institute of Anatomy at the University Hospital of Innsbruck, Innsbruck, Austria) and in particular to Axel Pomaroli, MD, DMD, PhD, retired Professor of Anatomy, and Stefano Longato, MD, Anatomist, for their excellent support in providing the figures for this chapter.

Assessing Temporomandibular Disorders

GARY M. HEIR

This chapter discusses the assessment of pathology and abnormal function of the temporomandibular joint (TMJ). In order to comprehend pathologic processes resulting in pain and dysfunction of the temporomandibular joints, a clear understanding of normal anatomy and biomechanics is essential. Assessment of the temporomandibular joint, typically performed on a symptomatic patient, requires an understanding of the various clinical conditions that encompass temporomandibular disorders.

Research in the field of temporomandibular disorders is limited in its utility because of a lack of consistency in the standardized nomenclature, in definitions of the various disorders that might affect the masticatory system, and in the quality of research.[1] In an attempt to better define temporomandibular disorders, the International RDC/TMD Consortium Network and Orofacial Pain Special Interest Group has recently published validated diagnostic criteria of the assessment of the temporomandibular joint.[2] A persistent problem appearing in the literature, addressed by the Diagnostic Criteria for Temporomandibular Disorders (DC/TMD), is use of "Temporomandibular Disorders (TMD)" as a comprehensive term incorporating all aspects of masticatory pain, regardless of etiology or severity. The DC/TMD addresses this by separating out two categories of painful TMD: myogenous, or muscle-generated pain, and arthrogenous, or joint-generated pain. The DC/TMD further subdivides myogenous and arthrogenous TMDs into subgroups of local pain with and without referral, disc displacement disorders, degenerative joint disease, and subluxation[3] (Table 36-1). Non–TMJ-related topics are beyond the scope of this chapter, but familiarity with these diagnostic entities and techniques is encouraged.

Temporomandibular Disorders

Temporomandibular disorders are defined as clinical problems involving the masticatory musculature, the temporomandibular joints and associated structures, or both. Articular disorders of the TMJ often coexist with masticatory muscle pain, and a clear differential diagnosis is necessary, especially when surgery is a possibility. Articular disorders include disc displacement disorders, arthritic or degenerative changes, and neoplasm.[4] Other conditions that may affect the temporomandibular joints include congenital disorders, inflammatory conditions, and systemic disease.

TMDs are considered the most common cause of musculoskeletal orofacial pain. Common features of a TMD include: (1) pain with mandibular function, (2) limitation of mandibular movement, and (3) joint sounds. One, two, or all three conditions, when present, may represent signs of chronic adaptation of the anatomy of the joint that require no treatment interventions, or may reveal symptoms of dysfunction that may affect the activities of daily life due to dysfunction and/or pain.

Although pain in the masticatory system can arise from the muscles of mastication or can be referred to the orofacial region from remote musculoskeletal structures, a discussion of muscle pain is not within the scope of this chapter. However, it is important to consider that myogenous pain occurs more frequently than pain arising from articular disorders.[4]

A differential diagnosis of myogenous pain and dysfunction, as opposed to a true internal derangement or temporomandibular *joint* dysfunction, is essential to successful treatment.[5] For the purpose of classification, temporomandibular disorders will be considered as pain or dysfunction of the musculoskeletal system involving the temporomandibular joints and the masticatory muscles.

With myogenous pain, the patient typically provides a history of regional pain, a sense of muscle weakness, easy fatigability of the masticatory muscles, and a limited passive mandibular range of motion. A palpatory examination of the masticatory muscles often reveals myofascial trigger points and muscle tenderness, which also can produce referral patterns to the region of the temporomandibular joints.

TABLE 36-1 Detailed and Validated Diagnostic Approach to Temporomandibular Disorders as Proposed by the DC/TMD

Disc Displacement with Reduction (ICD-10 M 26.63)

Description	An intracapsular biomechanical disorder involving the condyle-disc complex. In the closed mouth position, the disc is in an anterior position relative to the condylar head and the disc reduces upon opening of the mouth. Medial and lateral displacement of the disc may also be present. Clicking, popping, or snapping noises may occur with disc reduction. A history of prior locking in the closed position coupled with interference in mastication precludes this diagnosis.
History	Positive for at least one of the following: 1. In the last 30 days,* any TMJ noise(s) present with jaw movement or function; OR 2. Patient report of any noise present during the exam.
Exam	Positive for at least one of the following: 1. Clicking, popping, and/or snapping noise during both opening and closing movements, detected with palpation during at least one of three repetitions of jaw opening and closing movements; OR 2a. Clicking, popping, and/or snapping noise detected with palpation during at least one of three repetitions of opening or closing movement(s); AND 2b. Clicking, popping, and/or snapping noise detected with palpation during at least one of three repetitions of right or left lateral, or protrusive movement(s).
Validity	Without imaging: sensitivity 0.34; specificity 0.92. Imaging is the reference standard for this diagnosis.
Imaging	When this diagnosis needs to be confirmed, TMJ MRI criteria are positive for both of the following: 1. In the maximum intercuspal position, the posterior band of the disc is located anterior to the 11:30 position and the intermediate zone of the disc is anterior to the condylar head; AND 2. On full opening, the intermediate zone of the disc is located between the condylar head and the articular eminence.

Disc Displacement with Reduction with Intermittent Locking (ICD 10 M 26.63)

Description	An intracapsular biomechanical disorder involving the condyle-disc complex. In the closed mouth position, the disc is in an anterior position relative to the condylar head, and the disc intermittently reduces with opening of the mouth. When the disc does not reduce with opening of the mouth, intermittent limited mandibular opening occurs. When limited opening occurs, a maneuver may be needed to unlock the TMJ. Medial and lateral displacement of the disc may also be present. Clicking, popping, or snapping noises may occur with disc reduction.
History	Positive for both of the following: 1a. In the last 30 days,* any TMJ noise(s) present with jaw movement or function; OR 1b. Patient report of any noise present during the exam; AND 2. In the last 30 days,* jaw locks with limited mouth opening, even for a moment, and then unlocks.
Exam	Positive for both of the following: 1. Clicking, popping, and/or snapping noise detected during both opening and closing movements, detected with palpation during at least one of three repetitions of jaw opening and closing movements; OR 2a. Clicking, popping, and/or snapping noise detected with palpation during at one of three repetitions of opening or closing movement(s); AND 2b. Clicking, popping, and/or snapping noise detected with palpation during at least one of three repetitions of right or left lateral, or protrusive movement(s).
Validity	Without imaging: sensitivity 0.38; specificity 0.98. Imaging is the reference standard for this diagnosis.
Imaging	When this diagnosis needs to be confirmed, the imaging criteria are the same as for disc displacement with reduction if intermittent locking is not present at the time of imaging. If locking occurs during imaging, an imaging-based diagnosis of disc displacement without reduction will be rendered and clinical confirmation of reversion to intermittent locking is needed.
Note	Although not required, when this disorder is present clinically, examination is positive for inability to open to a normal amount, even momentarily, without the clinician or patient performing a maneuver to reduce the lock.

Disc Displacement without Reduction with Limited Opening (ICD 10 M 26.63)

Description	An intracapsular biomechanical disorder involving the condyle-disc complex. In the closed mouth position, the disc is in an anterior position relative to the condylar head, and the disc does not reduce with opening of the mouth. Medial and lateral displacement of the disc may also be present. This disorder is associated with persistent limited mandibular opening that does not reduce with the clinician or patient performing a manipulative maneuver. This is also referred to as “closed lock.” This disorder is associated with limited mandibular opening.
History	Positive for both of the following: 1. Jaw locked so that the mouth would not open all the way; AND 2. Limitation in jaw opening severe enough to limit jaw opening and interfere with ability to eat.

TABLE 36-1 Detailed and Validated Diagnostic Approach to Temporomandibular Disorders as Proposed by the DC/TMD—cont'd

Exam	Positive for the following: 1. Maximum assisted opening (passive stretch) movement including vertical incisal overlap <40.
Validity	Without imaging: sensitivity 0.80; specificity 0.97. Imaging is the reference standard for this diagnosis.
Imaging	Maximum assisted opening of <40 mm is determined clinically.
Note	Presence of TMJ noise (e.g., click during opening) does not exclude this diagnosis.

Disc Displacement without Reduction without Limited Opening (ICD 10 M 26.63)

Description	An intracapsular biomechanical disorder involving the condyle-disc complex. In the closed mouth position, the disc is in an anterior position relative the condylar head and the disc does not reduce with opening of the mouth. Medial and lateral displacement of the disc may also be present. This disorder is NOT associated with current limited opening.
History	Positive for both of the following in the past: 1. Jaw locked so that the mouth would not open all the way; AND 2. Limitation in jaw opening severe enough to limit jaw opening and interfere with ability to eat.
Exam	Positive for the following: 1. Maximum assisted opening (passive stretch) movement including vertical incisal overlap ≥40 mm.
Validity	Without imaging: sensitivity 0.54; specificity 0.79. Imaging is the reference standard for this diagnosis.
Imaging	When this diagnosis needs to be confirmed, TMJ MRI criteria are the same as for disc displacement without reduction with limited opening. Note: Maximum assisted opening of ≥40 mm is determined clinically.
Note	Presence of TMJ noise (e.g., click during opening) does not exclude this diagnosis.

Degenerative Joint Disease (ICD 10 M 26.69)

Description	A degenerative disorder involving the joint characterized by deterioration of articular tissue with concomitant osseous changes in the condyle and/or articular eminence.
History	Positive for at least one of the following: 1. In the last 30 days,* any TMJ noise(s) present with jaw movement or function; OR 2. Patient report of any noise present during the exam.
Exam	Positive for the following: 1. Crepitus detected with palpation during at least one of the following: opening, closing, right or left lateral, or protrusive movement(s).
Validity	Without imaging: sensitivity 0.55; specificity 0.61. Imaging is the reference standard for this diagnosis.
Imaging	When this diagnosis needs to be confirmed, then TMJ CT criteria are positive for at least one of the following: Subchondral cyst(s), erosion(s), generalized sclerosis, or osteophyte(s). Note: Flattening and/or cortical sclerosis are considered indeterminate findings for degenerative joint disease (DJD) and may represent normal variation, aging, remodeling, or a precursor to frank DJD.

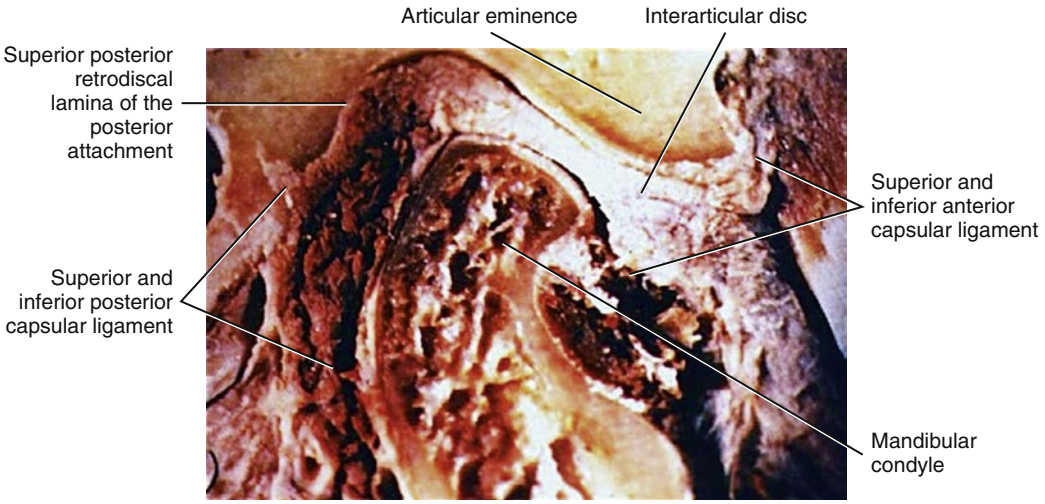
Subluxation (ICD 10 M 26.69)

Description	A hypermobility disorder involving the disc-condyle complex and the articular eminence: In the open mouth position, the disc-condyle complex is positioned anterior to the articular eminence and is unable to return to a normal closed mouth position without a manipulative maneuver. The duration of dislocation may be momentary or prolonged. When the patient can reduce the dislocation himself/herself, this is referred to as subluxation. When the patient needs the assistance of the clinician to reduce the dislocation and normalize jaw movement, this is referred to as luxation. This disorder is also referred to as "open lock." The sensitivity and specificity have been established for only subluxation.
History	Positive for both of the following: 1. In last 30 days,* jaw locking or catching in a wide open mouth position, even for a moment, so could not close from the wide-open position; AND 2. Inability to close the mouth from a wide-open position without a self-maneuver.
Exam	Although no exam findings are required, when this disorder is present clinically, examination is positive for inability to return to a normal closed mouth position without the patient performing a manipulative maneuver.
Validity	Without imaging and based only on history: sensitivity 0.98; specificity 1.00.
Imaging	When this diagnosis needs to be confirmed, imaging criteria are positive for the condyle positioned beyond the height of the articular eminence with the patient unable to close his/her mouth.

*Validity for assessing selected biomechanical intra-articular disorders is in "the last 30 days"' since the stated sensitivity and specificity of these criteria were established using this time frame.

CT, Computed tomography; *DJD,* degenerative joint disease; *ICD-10,* International Classification of Diseases 10th Revision; *MRI,* magnetic resonance imaging; *TMJ,* temporomandibular joint.

Adapted from Schiffman E, Ohrbach R, Truelove E et al: Diagnostic Criteria for Temporomandibular Disorders (DC/TMD) for clinical and research applications: recommendations of the International RDC/TMD Consortium Network and Orofacial Pain Special Interest Group, *J Oral Facial Pain Headache* 28:6-27, 2014



• **Figure 36-1** Cross-sectional anatomy of the temporomandibular joint. (Courtesy Dr. Peter Neff.)

Included in the myogenous pain group are conditions such as myositis or muscle inflammation, which often result from local trauma or infection. Upon palpation, muscles with myositis may also be tender and feel swollen and warm.

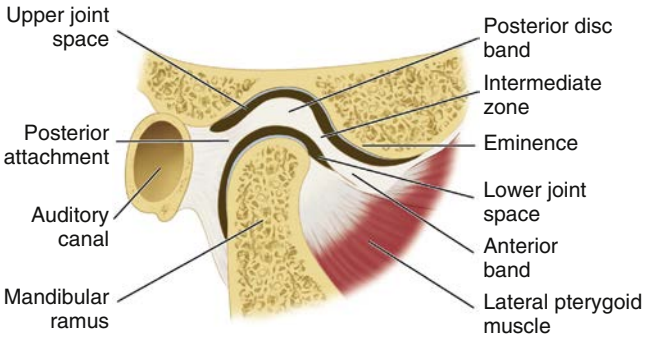
Myospasm is an often-overused diagnostic term that describes an involuntary muscle contraction. The patient with myospasm may present with a restricted mandibular range of motion that must be differentiated from an internal derangement of the joint, because this condition also can restrict mandibular movement. Spastic muscles may be tender to palpation. True myospasm may be secondary to a neuromuscular disorder and can be diagnosed by needle electrode electromyography.

With time, masticatory muscles exhibiting chronic contraction or other local myopathies may develop myofibrotic contracture. This may not be a painful condition, but will also limit the mandibular range of motion. For this reason, a differential diagnosis requires a detailed history and thorough evaluation. Myofibrotic contracture may be characterized by local tenderness and may be differentiated from other forms of muscle disorders via needle electrode electromyography.

Anatomy

The temporomandibular articulation is among the most complex in the body. It is a synovial joint that has two joint compartments and four articular surfaces, contains vascularized tissue within the joint capsule, and has articular surfaces of fibrous rather than chondrocartilage.

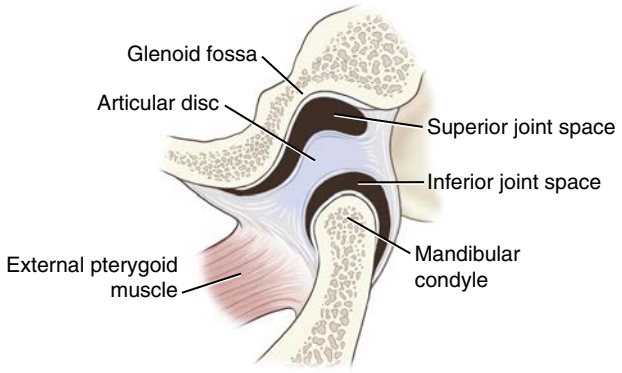
The temporomandibular joint functions within the glenoid or temporomandibular fossa of the skull. The fossa is located in the temporal bone bilaterally, just anterior to the external auditory meatus. The TMJ fossa is not so much a precise socket as a depression in the base of the skull, within which the mandibular condyle functions.



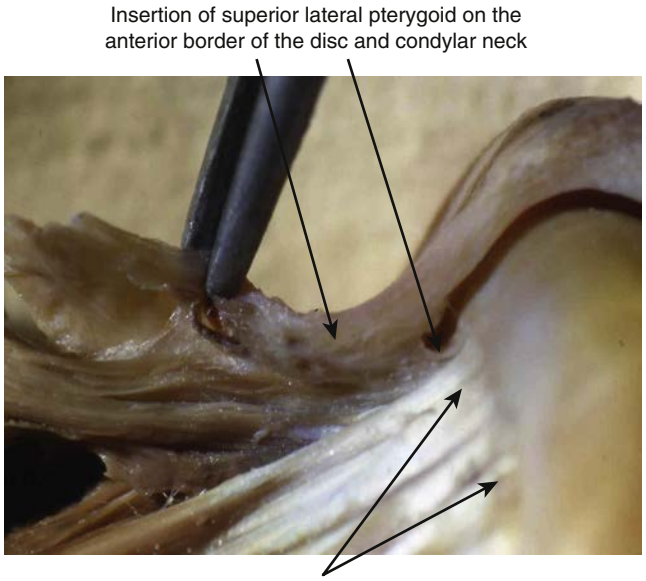
• **Figure 36-2** Articular disc and associated structures. (From Nelson SJ: *Wheeler's dental anatomy, physiology and occlusion*, ed 10, St Louis, 2015, Elsevier.)

The mandibular condyle is a spheroidal structure that is capable of a wide range of anterior, posterior, and lateral movements. The fibrocartilaginous articular surfaces of the condyle and fossa function against the fibrous interarticular disc that is interposed between these two bony structures (Figure 36-1). The disc is attached to the mandibular condyle by lateral and medial collateral ligaments and blends into the capsule anteriorly. Posteriorly, the disc attaches to the complex retrodiscal tissues. Although the disc is avascular and is not innervated, the retrodiscal tissue is highly vascularized and richly innervated (Figure 36-2). Therefore, intracapsular pain may be due to injury or inflammation of the retrodiscal tissue (retrodiscitis).

Like any synovial joint, the temporomandibular joint is encapsulated and stress bearing. The disc and its circumferential attachments separate the joint into upper and lower joint spaces. The disc-condyle complex and the mandibular fossa are enclosed within the capsular ligament, which is lined by synovial tissue with collateral ligaments that blend into the capsule. The TMJ lateral ligament complex arises from the articular eminence and attaches to the posterior aspect of the neck of the condyle (Figure 36-3). The lateral ligament complex functions to limit lateral movement.



• **Figure 36-3** Components of the temporomandibular joint.



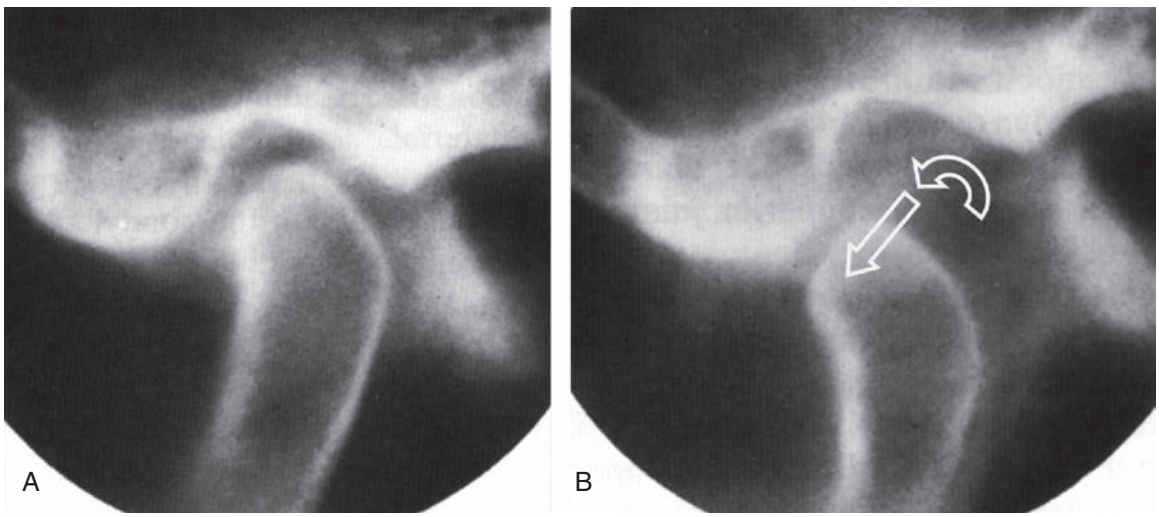
• **Figure 36-4** The superior and inferior lateral pterygoid muscles insert on the condylar neck. The inferior lateral pterygoid protrudes the mandible, whereas the superior lateral pterygoid contracts during mandibular closure. Some fibers of this muscle attach to the anterior border of the disc and contract eccentrically to stabilize the disc against the posterior slope of the articular eminence during closure. (Courtesy Thomas M. Wilkinson, BDS, MSO.)

Normal Biomechanics

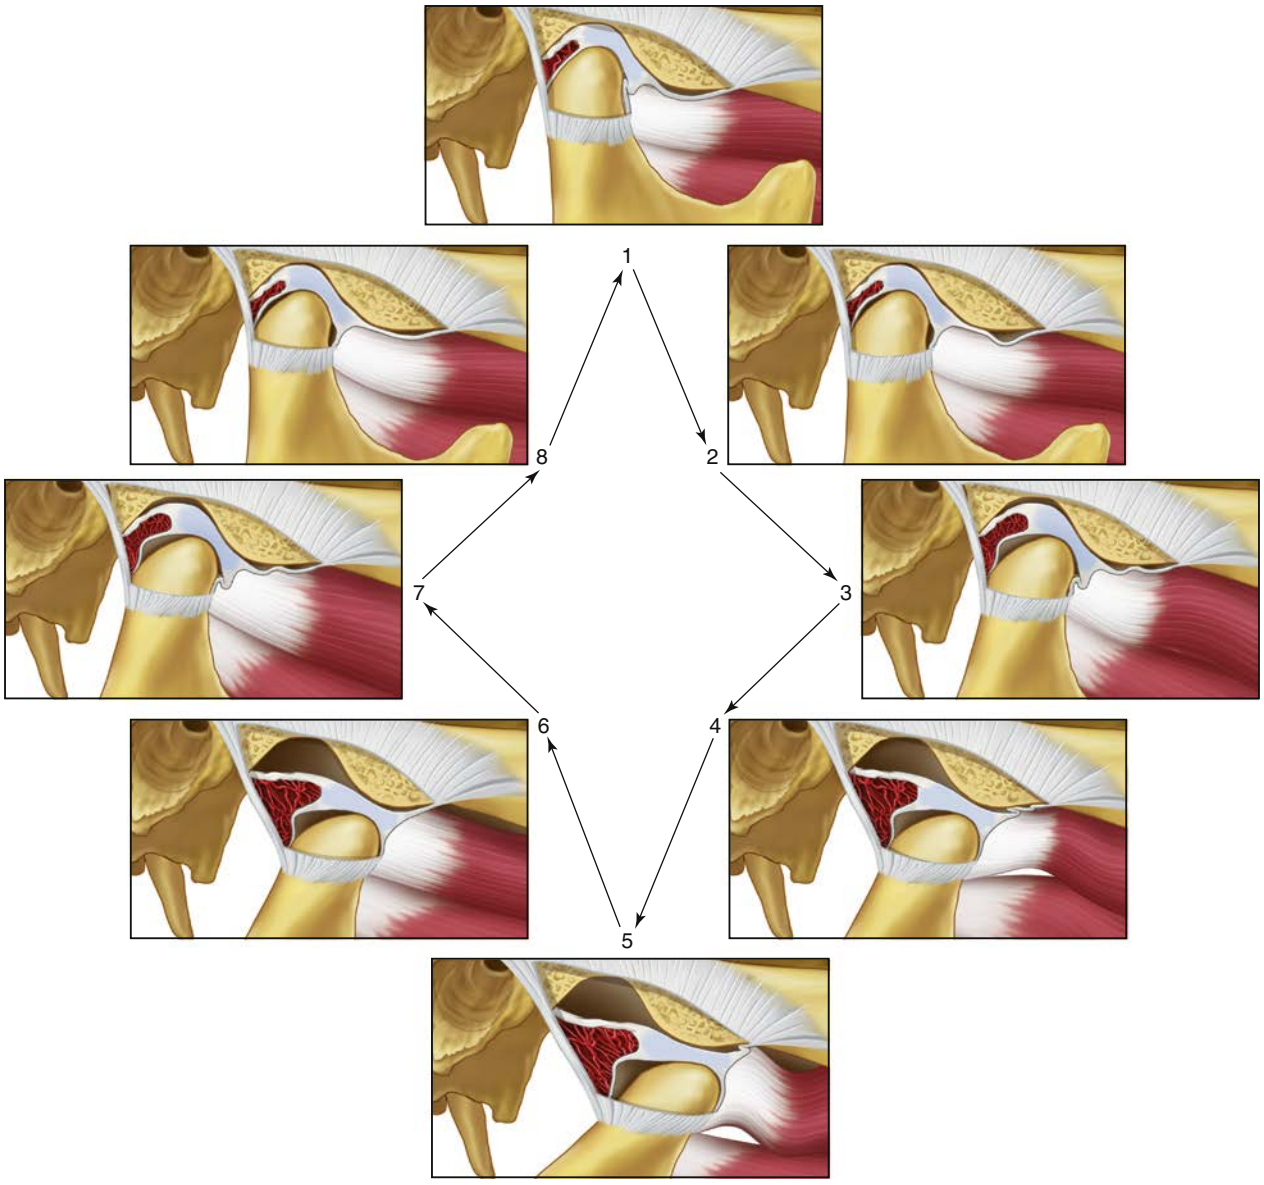
The TMJ is a ginglymoarthrodial joint that is capable of both rotational movements in the inferior compartment and translational movements in the superior compartment (Figure 36-4). During function, the lateral and medial discal collateral ligaments allow for rotational movement of the condyle on the inferior surface of the disc, and the superior surface of the disc translates or slides along the posterior aspect of the articular eminence. Biomechanically, the TMJ exhibits significant mobility. The mandibular condyle freely rotates on the inferior surface of the interarticular disc, and the disc-condyle complex moves within the fossa and translates unimpeded along the posterior slope of the articular eminence. In addition, limited lateral movements are possible. During all of these movements of a normal temporomandibular joint, the interarticular disc is always positioned between the fossa/eminence and the condyle by the action of the superior lateral pterygoid muscle and the uppermost elastic properties of the posterior attachment known as the posterior, superior retrodiscal lamina of the retrodiscal tissue. Translation of the condyle occurs as a result of the action of the inferior lateral pterygoid muscle, which protrudes the mandible, acting in concert with other mandibular depressors of the infrahyoid and suprahyoid musculature. Movement of the disc is also controlled by a second structure. The superior, posterior retrodiscal lamina acts passively to pull the disc posteriorly during opening as the condyle translates anteriorly. The superior lateral pterygoid muscle contracts eccentrically during closure to stabilize the disc against the distal slope of the articular eminence (Figure 36-5). Normal disc/condyle/fossa relationships are demonstrated in Figure 36-6.

Abnormal Biomechanics

Smooth and coordinated opening and closing, in the absence of pain or joint sounds, characterize normal function of all synovial joints, including the TMJ. Signs of a TMD therefore include limited or irregular jaw movements, discomfort, and/or sounds emanating from the joint during function.



• **Figure 36-5** Tomographic imaging of normal translation of the temporomandibular joint. **A,** Closed mouth position. **B,** Open mouth position after rotational and translatory movements.



• **Figure 36-6** Normal functional movement of the condyle and disc during the full range of opening and closing. Note that the disc is rotated posteriorly on the condyle as the condyle is translated out of the fossa. The closing movement is the exact opposite of opening. (From Okeson JP: *Management of temporomandibular disorders and occlusion*, ed 7, St Louis, 2013, Elsevier.)

Impediments to normal joint movement can be extracapsular or intracapsular. A temporomandibular joint assessment must differentiate between the two.

As was previously discussed, extracapsular conditions that affect joint movement typically are caused by muscle dysfunction, although osseous anomalies also may interfere with mandibular movement. These include coronoid hypertrophy, calcified styloid processes, osteochondromatosis, or other bony abnormalities (Figures 36-7 through 36-9).

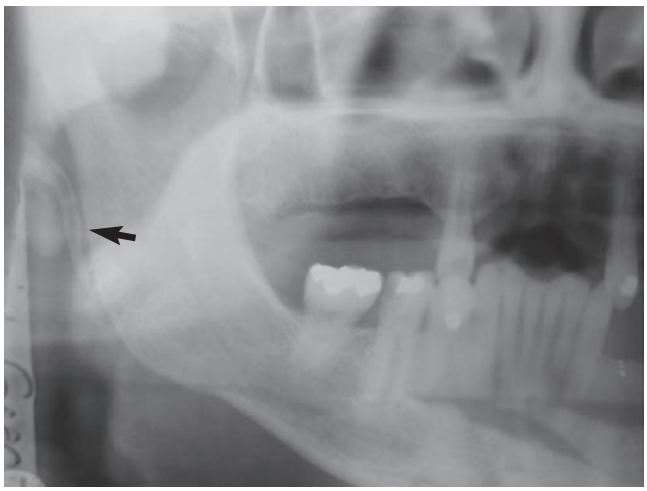
Synovial chondromatosis is an uncommon arthropathy, but it is one that should be considered in the differential diagnosis of TMJ-pain dysfunction syndrome[6] (Figure 36-10). Limitation of mandibular function caused by calcified bodies found within the TMJ capsule may displace the mandibular condyle, impede mandibular function, and mimic disc displacement or disc interference disorders.

Myofascial pain, myositis, myalgia, and muscle contracture not only can limit mandibular depression but also can result in pain during movement.[7] Myofascial trigger points of the masticatory musculature can refer pain to the TMJ.[8] Care must be taken during the history and physical examination to clearly define the source of the problem. If mandibular dysfunction is not due to extracapsular or myogenous causes, attention should be directed at possible intracapsular disorders.

Intracapsular Pathofunctional Disorders

Intracapsular pathofunctional disorders include anterior disc displacement with and without reduction.

• **Figure 36-7** Hypertrophic hamulus preventing normal mandibular opening.



• **Figure 36-8** Calcified styloid process growing along the posterior border of the ramus, preventing normal mandibular depression.

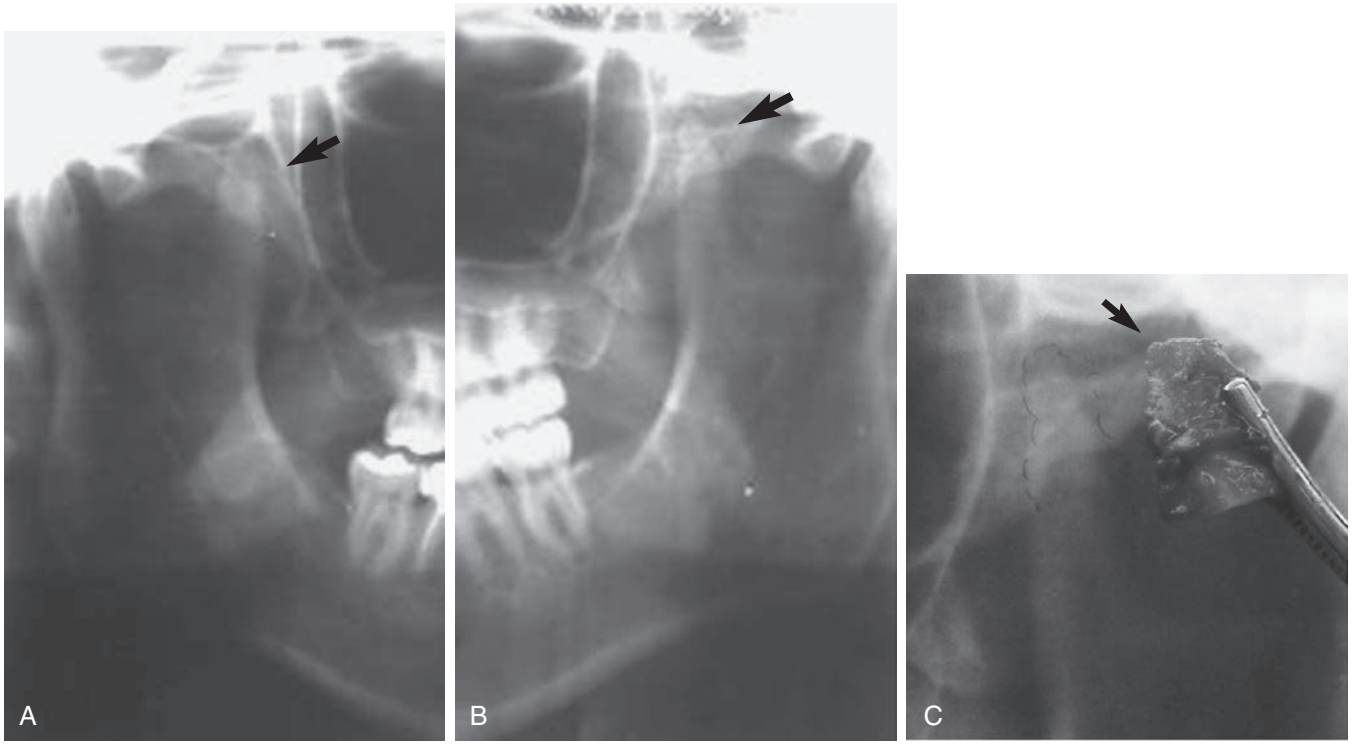
Anterior disc displacement is a partial anterior or anteromedially displaced disc, characterized by joint sounds during function that occur at variable points during mandibular movement (Figure 36-11). Chronic anterior disc displacement may occur for a variety of reasons and may be an adaptive change that occurs within the joint as a result of functional demands (Figure 36-12). Adaptation should not be presumed to be pathologic. Some research indicates that a large segment of the general population, perhaps 90%, exhibits mild disc displacements similar to those of patients seeking treatment. Nearly one third were asymptomatic—that is, without pain or dysfunction—and had documented discal displacement. Therefore, the occurrence of disc displacement is common in the general population, and caution is necessary in differential diagnosis and in determining the need to initiate treatment for asymptomatic individuals based merely on an asymptomatic adaptive disc displacement.[9]

Differential diagnosis involves a physical examination in which the mandibular range of motion is measured, the gait of movement is observed, and the joint is auscultated. Assessing the mandibular range of motion is an important factor in the evaluation for TMDs. A limited mandibular range of motion may be a sign of a biomechanical dysfunction, muscular restriction of movement, extracapsular mechanical factors interfering with movement, or a variety of systemic conditions.

When assessing the mandibular range of motion there is an assumption that normal opening is 40 to 55 mm; however, there are no supporting validated studies. A review of published literature finds that maximal opening varies greatly and is described by several authors as, for example, 39 to 69 mm[10] or 46.9 to 60 mm.[11-13] These data are observational reports only, not taking into account the variations in individual anatomy that might be predictors of an individual's maximum opening. Methods for measuring the mandibular range of motion are also inconsistent; for example, maximum mandibular opening is often measured as the interincisal distance while opening as wide as possible, but inclusion of overbite in the measurement is not consistent.[10] Other literature suggests measurement should begin at the alveolar crest.[14] The lack of standardization in measuring the mandibular range of motion may account for these range discrepancies.

Even accepting a normal range of motion of 40 to 55 mm, as multiple authors have done,[4,15,16] does not eliminate confusion. The normal range of motion is reported anecdotally as less in women, and decreasing with increasing age.[15] Furthermore, range of motion may depend on the height of the patient. A young male of small stature might have a mandibular range of motion of less than 40 mm, while a tall and older female might approach 60 mm. A more accurate measure of normal opening might involve assessment of condylar translation to the crest of the articular eminence. This may be demonstrated radiographically, but the use of x-ray or magnetic resonance imaging (MRI) for this purpose is not suggested; it would be considered overuse of diagnostic imaging.

In anterior disc displacement, soft tissue imaging such as MRI can reveal a displaced disc with improved position during jaw opening. Hard tissue imaging may show an absence of degenerative changes, even though adaptive remodeling of the articular surfaces may occur. Disc displacement with reduction also may be accompanied by pain with joint movement and deviation of the mandible during



• **Figure 36-9** **A-B,** Hypertrophic coronoid processes are visualized radiographically. The surgical specimen has been removed and is shown next to the radiograph **(C).** (Courtesy Dr. Cibele Nasri.)

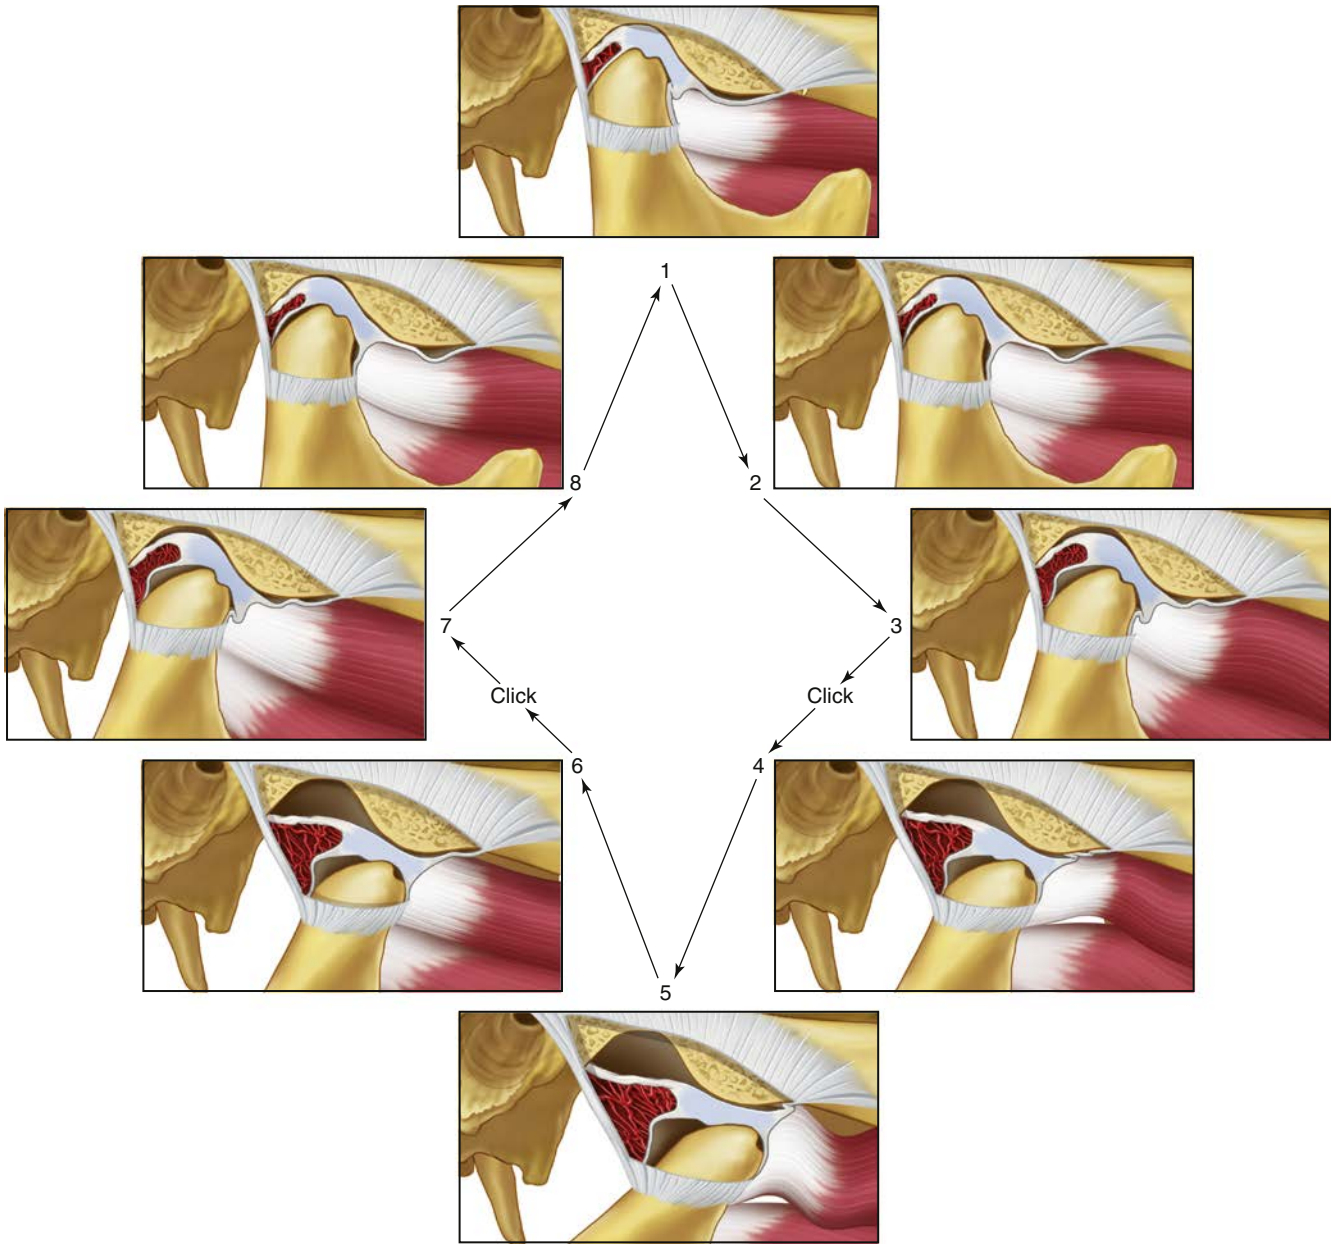
opening, possibly coinciding with a click as the displaced disc returns to normal. No restriction is placed on mandibular movement despite the possibility of an episodic and momentary catch during jaw movement. An abnormal disc/condyle relationship is characteristic of disc displacement with reduction.[4]

Anterior disc displacement without reduction is the state in which the anteriorly displaced disc is maintained in this position throughout translation. This is often referred to as a closed lock. Essentially, the disc no longer allows the condyle to translate along the articular eminence. Thickening of the disc or damage to the posterior attachment may contribute to the disc getting caught or interfering with condylar movement.[4] Disc displacement without reduction is typically chronic, but initially presents as an acute problem. Some patients with anterior disc displacement with reduction evolve to nonreducing disc displacement. However, it is impossible to determine which patients will evolve to more advanced dysfunction.

Although a patient with disc displacement without reduction frequently reports a history of clicking during mandibular movement, a nonreducing disc displacement typically

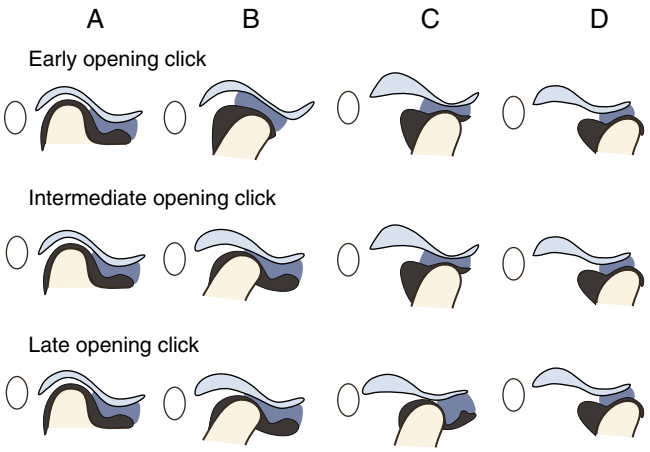


• **Figure 36-11** In position 1, the structural defect (alteration in form) in the condyle and disc. Between positions 3 and 4 the condyle moves out of the defect, creating a click. The condyle returns to this defect between positions 6 and 7. The opening and closing click occurs at the same degree of opening. (From Okeson JP: *Management of temporomandibular disorders and occlusion*, ed 7, St Louis, 2013, Elsevier.)

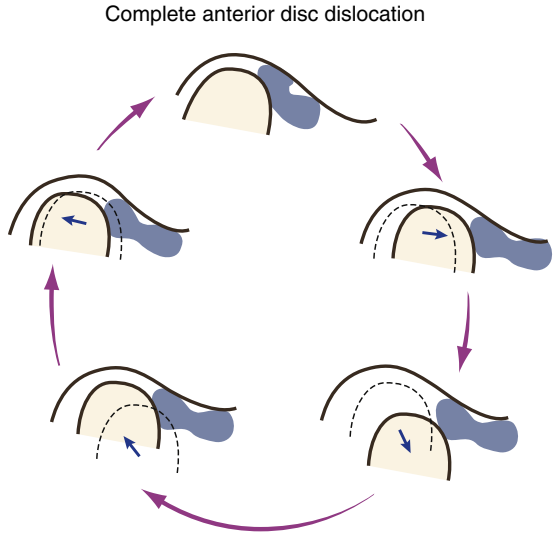
occurs in the absence of joint sounds. Therefore, the presence or absence of joint sounds may not be diagnostic. In fact, patients with chronic anterior disc displacement may have a normal mandibular range of motion with no joint sounds. Soft tissue imaging reveals a displaced disc that does not improve its position during jaw opening. Hard tissue imaging may show degenerative changes. An acute closed lock or nonreducing anterior disc displacement has a sudden onset with nearly immediate limited mouth opening of less than 25 mm. The mandible deflects to the affected side, and lateral movement to the opposite side is limited. Soft tissue imaging reveals the displaced disc, although hard tissue imaging may be normal.[4]

Chronic anterior disc displacement without reduction or chronic closed lock typically includes a history of sudden onset of limited mouth opening with continued limitation of opening for longer than 4 months. Soft tissue imaging shows the displaced disc without reduction. Typically, arthritic or degenerative changes are not extensive[4] (Figure 36-13).

Another post-traumatic condition that may affect mandibular and TMJ function involves intracapsular adhesions. As was previously described, the TMJ functions within a capsular ligament. This ligament exhibits varying degrees of toughness, with the strongest portion at the medial aspect of the superior joint space. The superior/anterior TMJ capsular



• **Figure 36-12** Diagrammatic representation of anterior disc displacement with reduction during early, intermediate, and late condylar translation. **A,** Closed. **B,** Partial translation. **C** and **D,** Full opening. (Adapted from Farrar W, McCarty WL Jr: *A clinical outline of temporomandibular joint diagnosis and treatment*, Montgomery, AL, 1982, Normandie Press.)



• **Figure 36-13** Disc displacement without reduction of the temporomandibular joint. (Adapted from Farrar W, McCarty WL Jr: *A clinical outline of temporomandibular joint diagnosis and treatment*, Montgomery, AL, 1982, Normandie Press.)

ligament is comparatively fragile. A sudden hypertranslation or condylar subluxation could allow the condyle to traumatically encroach on this structure. If injured, bleeding may occur into the superior joint space, resulting in the organization of fibrous bands known as adhesions. These intracapsular adhesions can prevent normal translation of the disc and, while giving the appearance and history of chronic disc displacement without reduction, can actually fixate the disc to the roof of the fossa. MRI or computed tomography (CT) may demonstrate the disc in a normal, closed position.

Another explanation for what appears to be a clinical closed lock in the presence of a normal discal position has been described. A sudden and persistent severely limited mouth opening associated with a total lack of disc translation along the articular eminence may be due to adhesion of

• **Figure 36-14** End-range, bilateral subluxation resulting in a deviation first to the left as the right condyle subluxates, then to the right as the left condyle does the same. After bilateral subluxation, the mandible returns to the midline position. Subluxation may be accompanied by a joint sound that should not be confused with a disc interference disorder.

the disc to the articular eminence secondary to joint overloading. In view of the fact that it is promptly released by lavage (arthrocentesis) of the upper joint space, inefficient lubrication of the joint is hypothesized. It has been postulated that overloading may reduce lubrication and may be responsible for this adhesion of the disc to the fossa and/or eminence. This also may explain the immediate release of the disc following arthrocentesis.[17]

In contrast to hypomobility caused by disc interference or muscle contraction is the chronic subluxation or hypermobility that is seen when, because of laxity of the supporting ligaments, the mandibular condyle translates beyond the articular eminence. Subluxation of the condyle will result in a soft or hard click as the condyle passes beyond the articular eminence at maximum opening. This is accompanied by unilateral or bilateral deflective movements at the end of the opening range. The joint sound associated with a subluxation should not be confused with that of a disc interference disorder (Figure 36-14).

Aside from mechanical dysfunction of the TMJ, inflammation that may accompany abnormal joint mechanics may contribute to the patient's discomfort. Intracapsular swelling from inflammation also may impede joint movement. Inflammation of the joint capsule (capsulitis) or inflammation of the joint lining (synovitis) can result in pain with jaw movement. Intracapsular edema my result in disocclusion of posterior teeth and referred otalgia.

Trauma to the highly innervated and richly vascularized retrodiscal tissue, as might occur with a blow to the jaw that drives the condyle upward and backward, can impart a

• **Figure 36-15** Panoramic view shows mild degenerative changes in the mandibular condylar articulation.

direct trauma to this tissue, resulting in swelling and pain. Pain within the joint may result in secondary muscle splinting or protective guarding of the joints that may cause a more limited mandibular range of motion and pain. Inflammatory mediators within the injured joint may perpetuate pain and dysfunction. Central pain mechanisms may be initiated, resulting in pain referral patterns extending beyond the temporomandibular joints.[18] Synovial fluid may be diminished in quality and/or quantity; this compromises nutrition of the articular surfaces and diminishes protection and lubrication of the joints. Although the quality of synovial fluid within an inflamed joint may be poor, a tendency for excessive synovial fluid formation may result in increased intracapsular pressure, which may lead to further dysfunction and pain.

Evaluation

Regardless of the cause, pain, dysfunctional movements, and sounds during function characterize a TMD. Although trauma may have been the precipitating event leading to the onset of the patient's complaints, other contributing factors may result in lengthier and less productive treatment, if they are not recognized and eliminated. Therefore, the first goal in implementing a well-defined management program is to identify contributing factors. This involves addressing physical, emotional, and psychological factors.

History

A comprehensive evaluation must include a detailed history that reviews the following:

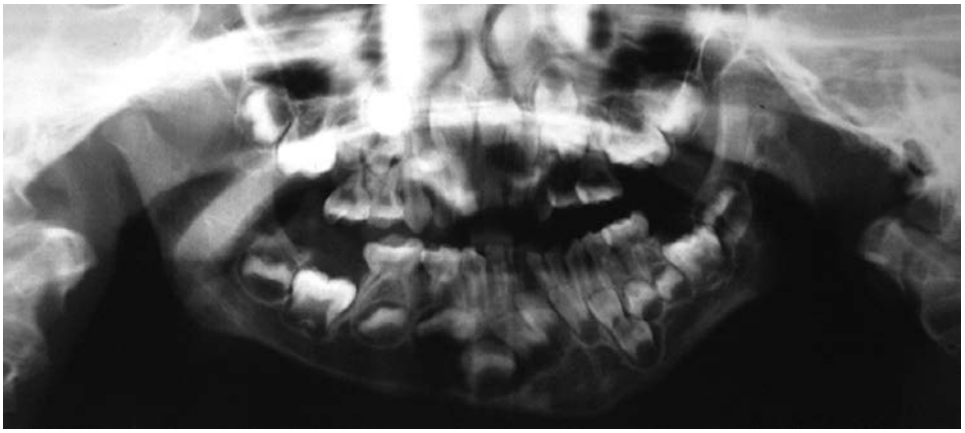
- Chief complaint
- History of the present illness
- Chronology of onset
- Description of any trauma
- Patient's medical and dental histories
- Prior history of joint dysfunction
- Has this individual ever been treated for a similar problem?
- What were the results of that treatment?
- Are any comorbid systemic disorders present?
- Findings of the clinical examination include the following:
  - Evaluation of the muscles of mastication and the supporting muscles of the neck and shoulders
  - Conditions found within the oral cavity that might be contributing to the patient's pain complaints (i.e., an evaluation of the soft tissues, periodontium, and teeth)
  - Myofunctional and/or parafunctional habits
  - Mandibular range of motion measurements
  - Auscultation of the temporomandibular joints during movement
  - Radiologic findings

Diagnostic Imaging

Temporomandibular disorders often involve displacement or dislocation of the interarticular disc and arthritic changes in the bony components of the joint. These alterations from normal anatomy and function may result from various causes, including trauma, degenerative joint processes, developmental anomalies, and neoplasm. It is acceptable to include some form of diagnostic imaging in a temporomandibular joint evaluation to facilitate diagnosis. Various methods of radiologic imaging are available.

Hard Tissue Imaging

The most readily available diagnostic radiograph used in the dental office is the panoramic radiograph. This type of study often is all that is necessary to identify fractures, gross arthritic changes, or hard tissue abnormalities, such as tumors, bone cysts, or malformations (Figures 36-15 and 36-16).



• **Figure 36-16** Condylar aplasia in a 9-year-old child seen on panoramic radiograph.

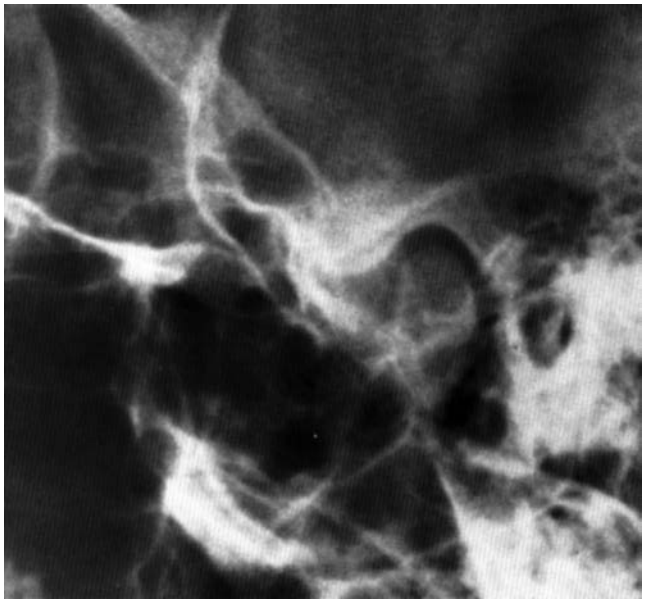
An alternative radiographic study, which is also easily performed in a dental office, is the transcranial view. This study, which uses standard dental x-ray equipment, normally includes views of each condyle in the open, closed, and rest positions. Transcranial radiographs provide information concerning the contours of bony elements. Transcranial radiographs often are inappropriately used to determine condylar position in the fossa—a determination that is not possible with this type of study. As with the panoramic radiograph, transcranial radiographs may be useful in ruling out gross arthritic changes, as well as fractures. Although greater detail is offered on transcranial radiographs, the information provided is similar to that seen on the panoramic radiograph (Figure 36-17).

Tomography offers an evaluation of the osseous structures (Figure 36-18). It is a more accurate study in that it can focus on planes ("cuts") that are only several millimeters thick. This ability enables a tomographic study to evaluate a temporomandibular joint similarly to a loaf of bread, that is, to evaluate one slice at a time. Greater detail of the articular surfaces is rendered. More accurate information regarding condylar displacement and arthritic changes also may be attained.

Cone-beam computed tomography (CBCT) provides superior reliability and greater accuracy than standard tomography and TMJ panoramic projections in the detection of condylar cortical erosion.[19] Although earlier studies reported that CBCT had not been shown to offer significant differences in diagnostic accuracy from that available with conventional tomograms,[20] enhanced osseous detail is obtained with the use of three-dimensional CT (Figure 36-19). In a study comparing imaging from patients diagnosed with osteoarthritis or closed lock of the TMJ to records of non-TMD patients, there were significant correlations between CBCT findings and a clinical diagnosis of TMD.[21]

Soft Tissue Imaging

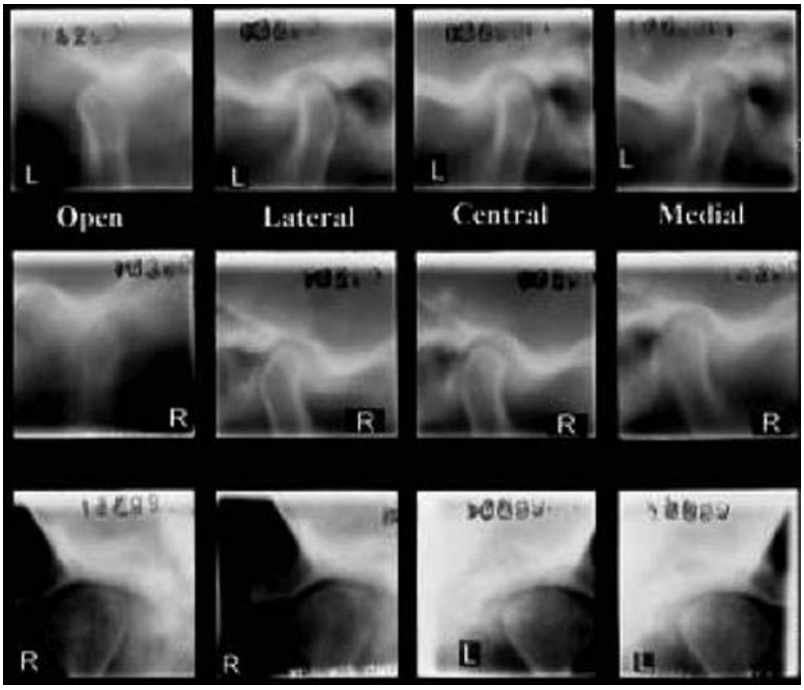
Although transcranial, tomographic, and cone-beam studies are acceptable for evaluating hard tissues of the temporomandibular joints, they do not demonstrate the



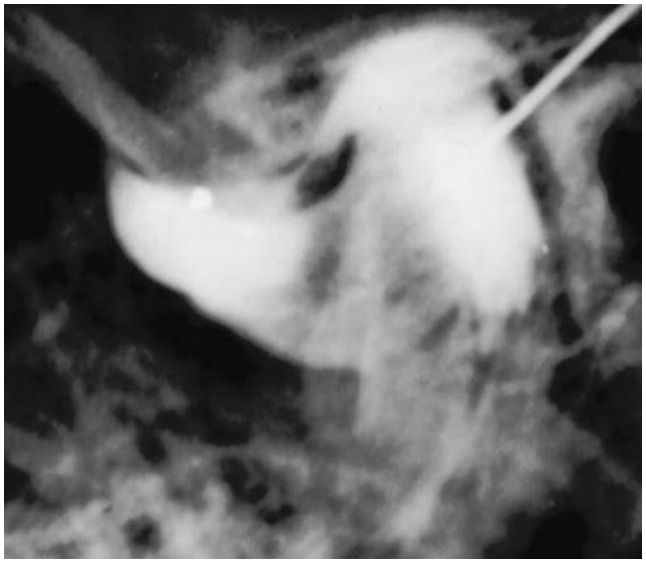
• **Figure 36-17** Transcranial view of the temporomandibular joint, demonstrating normal bony configuration.

interarticular disc. Various imaging techniques may be used to determine the position of the disc. Arthrography is an excellent method of imaging disc position. This test has been replaced by MRI and is now rarely used, but is of historic value. It is performed by injecting a small amount of radiopaque material into the inferior and/or superior joint compartment. The radiopaque solution outlines the disc (Figure 36-20). This procedure, which may be combined with video fluoroscopy, provides a great deal of information. Difficulties associated with this type of radiographic study include the following: (1) It is often painful for the patient, (2) it requires a great degree of expertise on the part of the radiologist, and (3) it exposes the patient to a significant amount of radiation.

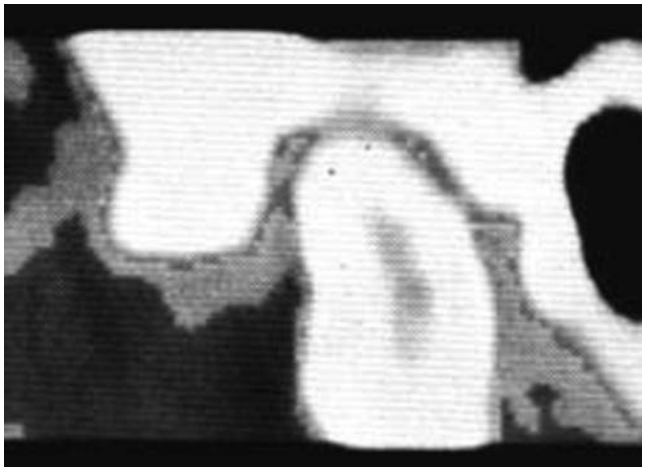
Noninvasive imaging studies include CT scan and MRI. Computed axial tomography has the capacity to image not only the hard, bony tissues but soft tissues as well. Through computer analysis of the x-ray signal, soft tissues



• **Figure 36-18** Tomographic study of a normal temporomandibular joint. Assessment of bony architecture and condyle/fossa relationship is possible on tomographic cuts. Lateral, central, and medial refer to the depth of the cut in each example.



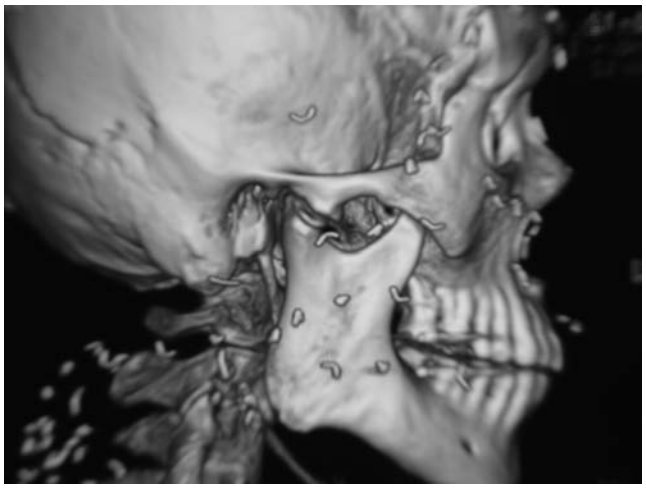
• **Figure 36-19** Radiopaque material injected into the inferior joint space permeates into the superior joint space during an arthrography demonstrating discal perforation.



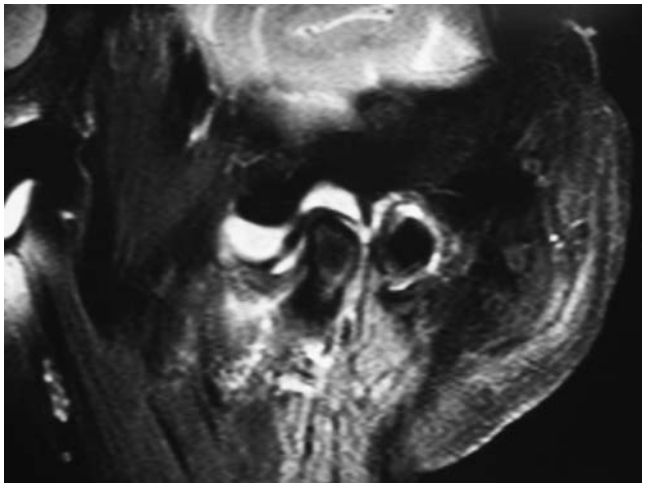
• **Figure 36-20** Computed axial tomography shows anterior disc displacement.

such as the temporomandibular joint disc can be visualized (Figure 36-21). This procedure has proved fairly accurate in its depiction of discal position, although the image often lacks detail. On the negative side is the fact that with this test, as with arthrography, the patient is exposed to substantial radiation.

MRI represents the current gold standard for soft tissue diagnostic imaging technology. It does not use radiation; the image is produced through computer analysis of signals emitted by the oscillation of molecules of water contained within bodily tissues. These signals are produced by placing the patient into a strong magnetic field. MRI is quite effective. The detail of soft tissues revealed by an MRI study is often quite remarkable. Not only can MRI allow visualization of the TMJ interarticular disc, often in more detail than former studies, it also can reveal scar tissue and inflammation (Figure 36-22). In addition, the muscles of mastication can be imaged. No side effects or radiation are associated with MRI. The study is noninvasive and provides a maximum amount of information with the smallest risk.[22-24] The patient experiences no discomfort. A drawback is the cost of this study. Also,



• **Figure 36-21** Three-dimensional computed axial tomography shows degenerative changes in the right condyle and fossa.



• **Figure 36-22** Nonreducing anterior disc displacement seen on T2-weighted magnetic resonance imaging during condylar translation. Note effusion in upper and lower joint spaces.

patients with claustrophobia may have difficulty with the MRI technique, but this has been overcome by the innovation of open MRI.

In cases in which it is necessary to determine the position of a suspected displaced disc, or when confirmation of intracapsular adhesions is necessary, CT or MRI studies may be considered appropriate. Conversely, these imaging studies should not be done routinely for every patient or as initial diagnostic tests. Although panoramic radiographs, transcranial studies, or tomographic images may be considered acceptable initial diagnostic tests, the use of more sophisticated imaging studies should be restricted to those cases for which they are indicated.

Adjunctive Diagnostic Testing

Numerous diagnostic aids may be employed in the evaluation of a TMD. These include movement and sound recording devices, as well as those that monitor muscle activity. Because the diagnosis of a TMD is best made via a meticulous history and clinical evaluation, the use of adjunctive testing devices is not discussed here. Suffice it to say that any adjunctive testing should be secondary to a well-taken history and thorough clinical examination. Adjunctive tests should be used judiciously, and the type of adjunctive diagnostic testing employed should be individualized for the specific patient's need. Consideration of their use depends on the potential for adding significant information to determine a diagnosis or formulate a treatment plan, as well as the cost effectiveness of the test.

• Box 36-1 A Screening Questionnaire for Temporomandibular Disorders

Do you have difficulty, pain, or both when opening your mouth, for instance, when yawning?	Yes ☐ No ☐
Does your jaw "get stuck," "lock," or "go out"?	Yes ☐ No ☐
Do you have difficulty, pain, or both when chewing, talking, or using your jaws?	Yes ☐ No ☐
Are you aware of noises in the jaw joints?	Yes ☐ No ☐
Do your jaws regularly feel stiff, tight, or tired?	Yes ☐ No ☐
Do you have pain in or about the ears, temples, or cheeks?	Yes ☐ No ☐
Do you have frequent headaches, neck aches, or toothaches?	Yes ☐ No ☐
Have you had a recent injury to your head, neck, or jaw?	Yes ☐ No ☐
Have you been aware of any recent changes in your bite?	Yes ☐ No ☐
Have you been previously treated for unexplained facial pain or a jaw joint problem?	Yes ☐ No ☐

From de Leeuw JR, Klasser G, editors: *Orofacial pain: guidelines for assessment, diagnosis and management*, Chicago, 2013, Quintessence.

Assessment of Orofacial Pain Disorders

Because musculoskeletal disorders are the most common sources of orofacial pain, all patients should be screened for TMD and other orofacial pain disorders during a general dental examination. A brief review of the history and use of a screening questionnaire and examination may lead to the diagnosis of a variety of musculoskeletal disorders. The need for a comprehensive history and clinical examination will depend on positive findings and their clinical significance. One option for a screening questionnaire is shown in Box 36-1, and a second option for screening is shown in Box 36-2. Any single positive finding may be enough to prompt a comprehensive examination.

• Box 36-2 TMD—Pain Screener

1. In the last 30 days, how long did any pain last in your jaw or temple area on either side?
   a. No pain
   b. Pain comes and goes
   c. Pain is always present
2. In the last 30 days, have you had pain or stiffness in your jaw on awakening?
   a. No
   b. Yes
3. In the last 30 days, did the following activities change any pain (that is, make it better or make it worse) in your jaw or temple area on either side?
   A. Chewing hard or tough food
      a. No
      b. Yes
   B. Opening your mouth or moving your jaw forward or to the side
      a. No
      b. Yes
   C. Jaw habits such as holding teeth together, clenching, grinding, or chewing gum
      a. No
      b. Yes
   D. Other jaw activities such as talking, kissing, or yawning
      a. No
      b. Yes

• Box 36-3 Recommended Screening Examination Procedures for Temporomandibular Disorder

- Measure range of motion of the mandible on opening, right, and left lateral movement. (Note any uncoordinated movements.)
- Palpate for preauricular temporomandibular joint (TMJ) tenderness.
- Auscultate and/or palpate for TMJ sounds (i.e., clicking or crepitus).
- Palpate for tenderness in the masseter and temporalis muscles.
- Note excessive occlusal wear, excessive tooth mobility, buccal mucosal ridging, or lateral tongue scalloping.
- Inspect symmetry and alignment of the face, jaws, and dental arches.

From de Leeuw JR, Klasser G, editors: *Orofacial pain: guidelines for assessment, diagnosis and management*, Chicago, 2013, Quintessence, p 26.

The screening examination should include the information in Box 36-3.

TMJ Evaluation

Minimal requirements for the examination of the TMJ include the following:

- Measurement of mandibular range of motion
- Evaluation of mandibular gait
- Auscultation
- Palpation

A description of these examination techniques follows; however, there is a tendency to focus on symptoms and chief complaints, passing over often important steps in the examination and diagnostic process. This can only be avoided by following an examination outline in order to ensure that all etiologic possibilities are assessed. Inconsistent data reporting has been mentioned as problematic when attempting to review the literature. The same may hold true for the examination; inconsistent evaluation of patients may be problematic for attempting to arrive at a diagnosis. Carefully following examination instruments such as the DC/TMD may play an important role in a systematic documentation of symptoms and clinical findings as well as a means by which to monitor a patient's progress.

Clinical observation and the use of a millimeter ruler is the most common method for assessing the mandibular range of motion and gait. Stethoscopic auscultation is the most common technique for detecting joint sounds, although more sophisticated "listening" devices are available.

Range of Motion

As previously noted, the normal mandibular range of motion is generally accepted as 40 to 55 mm,[25-27] but this varies extensively with stature, gender, craniofacial form, and other factors.[28,29] A limited mandibular range of motion, or hypomobility, can result from intracapsular or extracapsular disorders. Intracapsular disorders may include internal derangements (e.g., disc displacement with and without reduction, calcified bodies within the joint space), fibrosis, fracture, ankylosis, and tumor. Extracapsular disorders that limit range of motion include muscle dysfunction, especially dysfunction of muscles involved in mandibular elevation, hypertrophy of the coronoid processes, fractures, and capsular scarring.

Hypermobility with translation of the mandibular condyle beyond the articular eminence may or may not represent a clinical disturbance. Radiographic correlation for clinically evident hypermobility or hypomobility is helpful and is assessed by the relationship of the translated condyle to the crest of the articular eminence.

Mandibular range of motion is the measurement of vertical and sagittal opening and lateral movements of the mandible. Three vertical opening measurements are suggested: (1) maximum comfortable opening, (2) full, unassisted opening, and (3) assisted opening.[30] Several techniques and aids for assessing mandibular range of motion are available, ranging from a millimeter ruler to elaborate electrodiagnostic measuring systems.

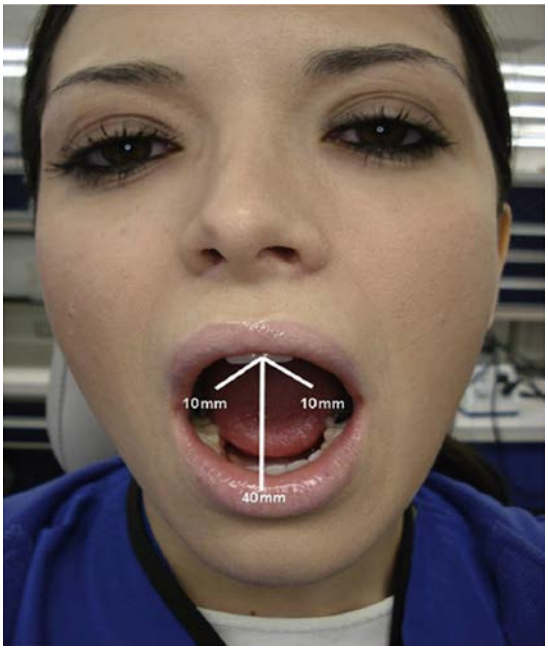
Maximum comfortable opening is assessed by asking the patient to open the mouth within a comfortable range. The distance between the maxillary and mandibular incisors, that is, the interincisal distance, is measured.[22] Adding overlap to the measurement is suggested. In the edentulous patient, measurement from the crest

of the alveolar ridge is suggested, noting the absence of dentition.

A full, unassisted range of motion is attained by asking the patient to open the mouth as widely as possible regardless of pain. This is called the active range of motion (AROM).

Assisted opening is assessed by asking the patient to open as widely as possible. The clinician then applies gentle, steady force to determine whether further opening is possible. This measurement, also referred to as passive range of motion (PROM), demonstrates the joint "end feel." To test end feel, light force is applied in an attempt to depress the mandible. If additional opening is possible, the joint end feel is classified as "soft." If, however, the sensation perceived by the clinician is firm and no further mandibular depression is possible, the joint "end feel" is classified as "hard." Although the joint end-feel might be noted, this test has poor reliability and is difficult to interpret.[23,24]

The location of pain provoked when AROM and PROM are tested should be noted. Although this is a reliable sign,[25] the patient's perception of reduced movement, or change in movement, may be more useful than actual measurements.[26]



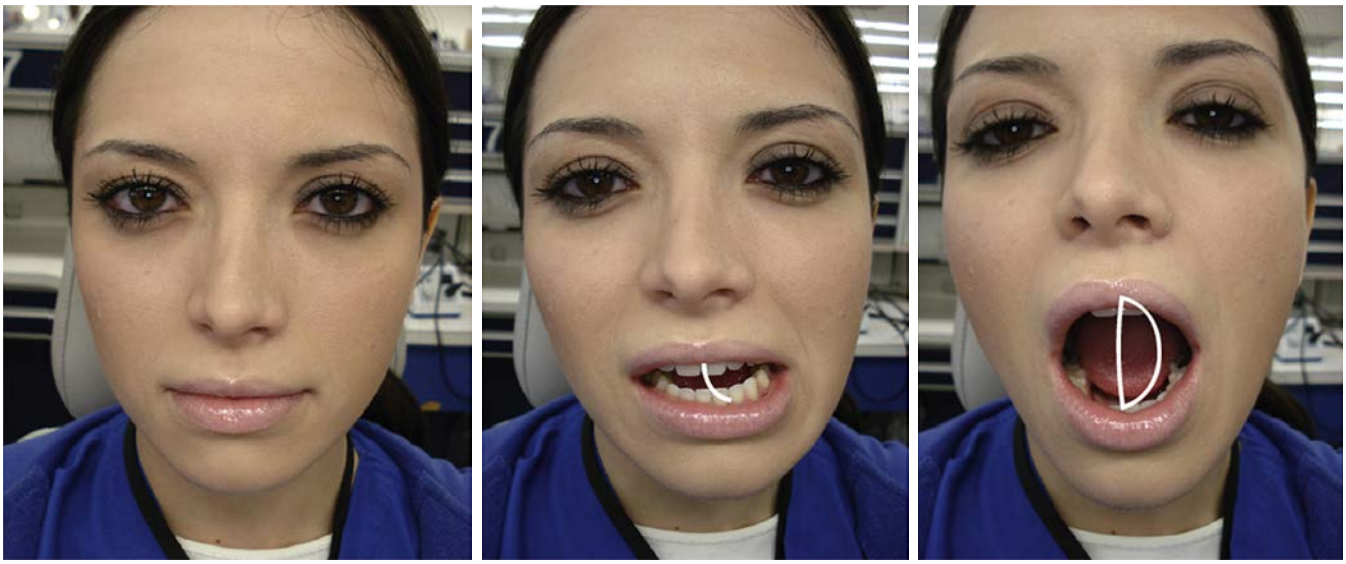
• **Figure 36-23** The normal opening-to-lateral movement ratio is typically 4:1. Opening should be smooth, pain free, and coordinated, and with an absence of joint sounds.

Gait

Gait is the pattern, direction, and quality of mandibular movements. Abnormal mandibular gait arises from intracapsular and extracapsular disorders. The presence and time of occurrence (early, middle, or late opening and/or closing) of clicking, crepitus, or interference with jaw movement should be documented.[27] Normal opening should be smooth, coordinated, sound and pain free (Figure 36-23). Abnormal or uncoordinated movements are easily observed clinically (Figure 36-24).

Assessment of the opening gait can aid in determining the status of temporomandibular joint biomechanics. The following section is adapted from *A Clinical Outline of Temporomandibular Joint Diagnosis and Treatment,* by William Farrar, DDS, and William L. McCarty Jr., DMD, of the Normandie Study Group for TMJ Dysfunction (Normandie Press, 1982). Although somewhat dated, the observations of Drs. Farrar and McCarty are still relevant.

When the opening-to-lateral movement ratio is observed, 4:1 is considered within normal limits. This would indicate



• **Figure 36-24** Example of deflection of mandibular movement during opening. The mandible deflects to the left, consistent with a left disc interference disorder, preventing normal condylar translation. After reduction of the disc, the condyle is free to translate, and the mandible returns to the midline.

that an opening of 40 mm should be accompanied by lateral movements of 10 mm (Figure 36-25).

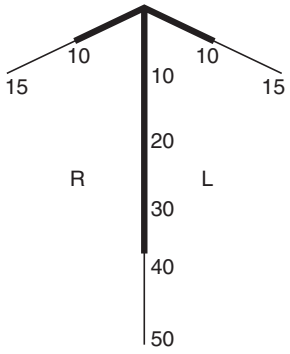
Disc interference disorders often result in a deflection to the affected side during movement with a return to the midline if the disc reduces to a normal or noninterfering position during translation (Figure 36-26). After reduction (the opening click), lateral movements are normal, that is, the 4:1 ratio. The diagram represents disc displacement with reduction of the right TMJ and normal opening that follows a click or disc reduction at approximately 10 mm of opening.

Disc dislocation without reduction that impairs normal translation will result in a lack of lateral movement away from the affected side and a deviation toward the locked joint. Figure 36-27 represents an anterior disc displacement of the left joint that prevents normal translation of that side. Lateral movement away from the locked joint is not possible, and during opening, the mandible deviates toward the locked joint. Note that the sagittal opening is limited to approximately half of the normal opening range, consistent with rotational (hinge) movement only.

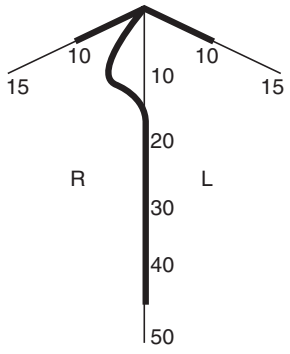
As a disc dislocation becomes more chronic, the opening-to-lateral movement ratio may increase. The opening range may even approach normal, but a deviated opening may still be observed (Figure 36-28).

As a chronic lock enters later stages, the mandibular range of motion may once again approach normal, reassuming the 4:1 opening-to-lateral movement ratio. At this point, the joint or joints may have gone through various adaptive changes, which may be demonstrated on soft tissue imaging.

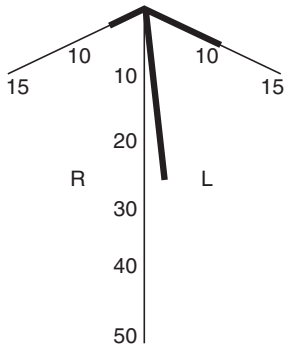
A subluxation occurs when the mandibular condyle translates beyond the crest of the articular eminence. This is considered a hypermobility disorder and may be associated with joint sounds similar to those of a disc interference disorder. As shown in Figures 36-29 and 36-30, this is characterized by unilateral or bilateral deflection of mandibular movement at the end of the opening range.



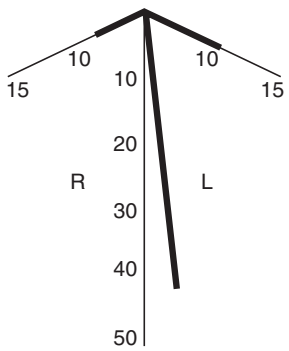
• **Figure 36-25** Normal opening-to-lateral excursion ratio. In this illustration, 40 mm of opening and bilateral movement of 10 mm, or a 4:1 ratio, is considered normal. The opening range and lateral movements may vary with the patient's stature, but the 4:1 ratio should remain.



• **Figure 36-26** Early disc interference. The opening gait in this case demonstrates a sharp, early deflection to the right, followed by a return to midline. Opening beyond that point is seen along the midline. The opening-to-lateral movement ratio is normal, but the deflection with return to midline at the same moment as a click of the right temporomandibular joint is consistent with anterior disc displacement with reduction.

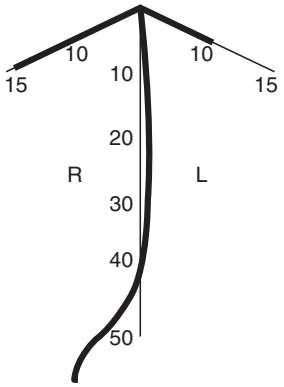


• **Figure 36-27** Nonreducing disc displacement. This illustration maps jaw movement that is limited in opening to approximately 25 mm. The mandible deflects to the left at maximum opening. Lateral movement to the left is normal at 10 mm but is limited to 3 to 5 mm to the right. This is consistent with a nonreducing disc displacement of the left temporomandibular joint. The opening is limited by the nonreducing disc, which causes the mandible to deflect to the affected side. Lateral movement is possible to the side of disc displacement but is limited to the opposite right side because of limited left condylar translation, which prevents movement away from the disc displacement.

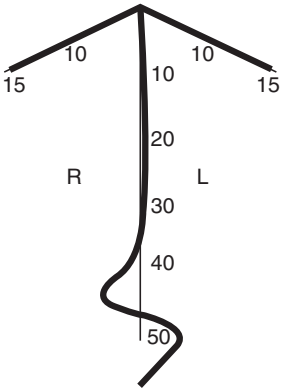


• **Figure 36-28** Chronic anterior disc displacement. If the condition of acute, nonreducing anterior disc displacement seen in Figure 36-27 persists, it may enter a phase of chronic anterior disc displacement without reduction. As the retrodiscal tissues and capsular and collateral ligaments become permanently stretched and the interarticular disc becomes deformed, mandibular range of motion may return to a normal opening-to-lateral excursion ratio. Disc interferences, deviations, and deflections of movement and joint sounds consistent with possible degenerative joint changes may be evident.

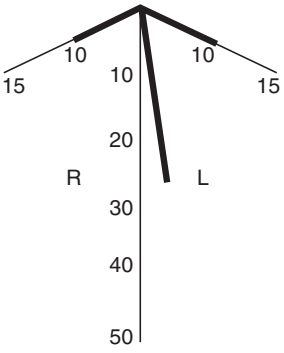
A patient with limited opening and normal lateral movements likely will have an extracapsular source of limited mandibular opening such as muscle dysfunction. In Figure 36-31, the mandibular range of motion demonstrates normal lateral movements and a limited opening with deflection to the left, possibly consistent with left masticatory muscle dysfunction.



• **Figure 36-29** Unilateral subluxation of the left condyle.



• **Figure 36-30** Bilateral subluxation, first left, then right.

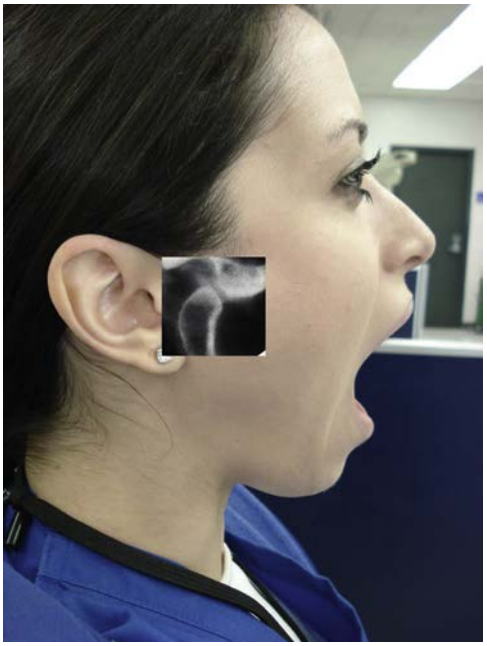


• **Figure 36-31** Muscular restriction of mandibular movement. Another cause of limited mandibular opening is illustrated in this diagram. Lateral movements are normal, but mandibular opening is limited. This opening-to-lateral excursion ratio is 2.5:1, consistent with contracture of jaw elevator muscles. Normal bilateral translation is possible and disc displacement therefore is not likely. Sagittal opening is restricted by mandibular elevator muscle dysfunction.

Auscultation

Intra-articular joint sounds may result from mandibular movement. Joint sounds may be signs of intracapsular pathology such as internal derangement, degenerative processes, or architectural defects of articulating surfaces.

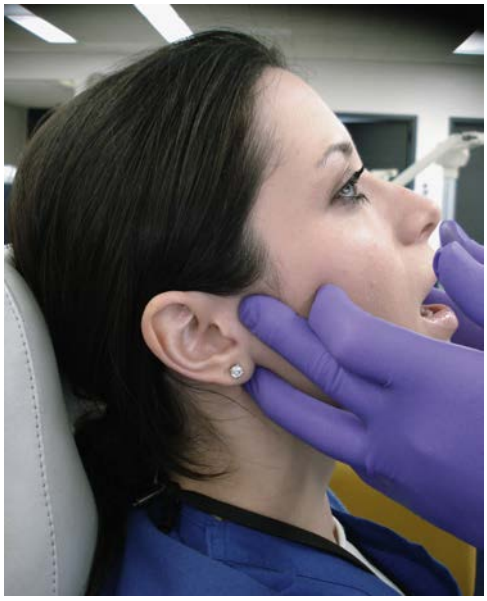
• **Figure 36-32** In the closed mouth position, the condyle is illustrated within the central portion of the temporomandibular joint fossa, behind the posterior slope of the articular eminence. Space for the interarticular disc and retrodiscal tissues is adequate.



• **Figure 36-33** During normal mandibular depression or jaw opening, the condyle rotates on the inferior surface of the interarticular disc. The disc-condyle complex translates forward along the articular eminence. This movement takes place between the posterior slope of the articular eminence and the superior surface of the disc. This illustration shows normal opening with the crest of the condyle approaching the lowest point of the articular eminence.

Sounds may correlate with pain or pathologic function or may be due to functional adaptations not associated with pain or dysfunction. Joint sounds are common among the general population and must be evaluated within the context of other presenting signs and symptoms.[31] Nonpainful joint sounds not associated with impairment of mandibular function do not require treatment.

Auscultation of the temporomandibular joints should discern the presence and timing of early, middle, or late opening and/or closing, clicking, and crepitus, as well as their correlation with interference with jaw movement. Joints sounds, that is, clicking, crunching, grinding, or grating noises classified as crepitus, have not been validated as consistent with clinical findings.[2]

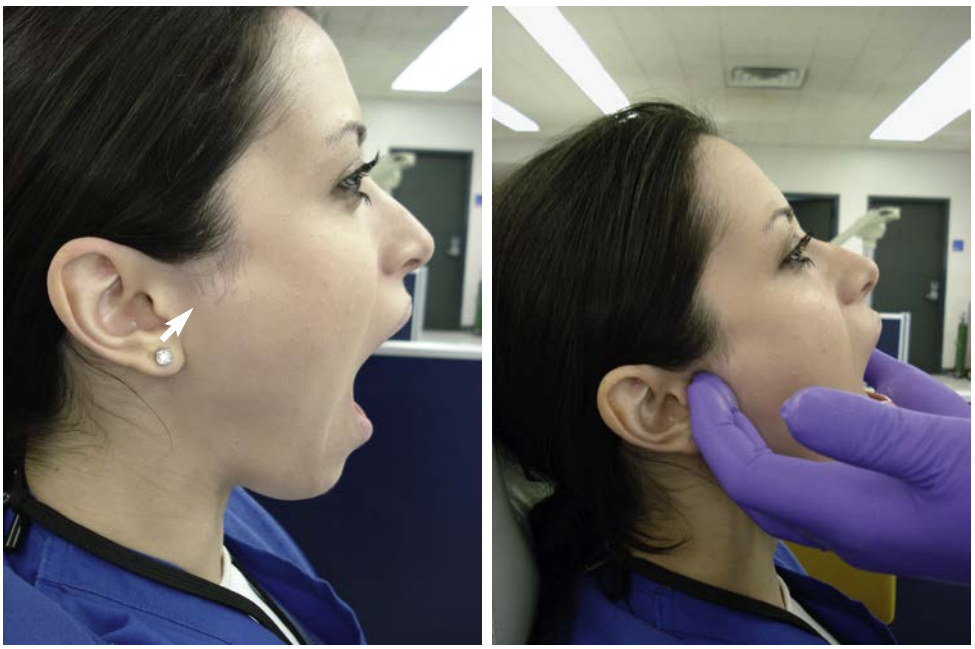


• **Figure 36-34** With the mouth partially open (early translation), palpate the lateral pole to assess capsular tenderness.

Palpation

The temporomandibular joints are palpated bilaterally so that patterns of condylar movement, tenderness, pain, and swelling can be perceived. Temporomandibular joints may be palpated for assessment of tenderness consistent with inflammation of the joint capsule and retrodiscal tissue. Although the predictive value of joint palpation is low in asymptomatic populations,[32,33] positive findings may have clinical significance in symptomatic patients.[34]

During a palpatory examination, movement patterns, tenderness, pain, and swelling are evaluated. The temporomandibular joints should be assessed by direct, gentle palpation of the lateral pole of the condyle (preauricular), as well as the posterior aspect of the condyle in the region of the posterior attachment or retrodiscal tissue (Figures 36-32 through 36-34). Intrameatal palpation achieved by placing the fingers in the external auditory canals and pressing forward during mandibular function may produce artifactual jaw movement and discomfort. The recommended technique has the patient with the mandible in a mild protrusive position and the tip of the index finger gently positioned in the depression formed posterior to the translated condyle. Mild pressure in a forward direction will allow palpation of the posterior-lateral aspect of the condyle and the lateral portion of the retrodiscal tissue (Figure 36-35).



• **Figure 36-35** Full opening (maximum condylar translation) results in the formation of a depression posterior to the translating condyle *(arrow)*. Digital pressure in an anterior direction can be used to assess for posterior capsular pain.

Muscle Evaluation

Local myalgia, myositis, myospasm, muscle contracture, and myofascial pain are conditions that affect all muscles in the body, including the masticatory muscles. These structures must be evaluated for sources of mandibular pain and dysfunction.

The muscles of mastication are palpated bilaterally so that equality of size and firmness can be determined; however, tenderness to palpation is the most important information derived from palpation. The temporalis, deep and superficial masseter, medial pterygoid, and suprahyoid muscles should be examined. Palpation of the lateral pterygoid muscle is difficult in that this muscle is difficult to approach intraorally.[35,36] Evaluation of the lateral pterygoid may be accomplished by functional manipulation and by challenging the muscle to contract against resistance.[37] Myalgia may be exacerbated during this maneuver.

Pressure algometry has been shown to provide reliable measures of muscle and TMJ tenderness[37-39] but is not often used in a clinical setting. Calibration training for finger pressure and site location also can produce reliable data. Palpation pressure for women should be less than that for men[38] and should be adjusted for stature.

Needle electrode electromyography detects abnormal muscle unit firing as in neuromuscular diseases, and it is used to assess innervation of a muscle or groups of muscles.[39,40]

An organized approach to a clinical evaluation is recommended. A suggested data collection form for orofacial pain and temporomandibular disorder evaluation is provided in Box 36-4.

Table 36-2 summarizes this text and offers a guide to the most common temporomandibular disorders.

A summary of various stages of disc interference disorders is presented in Figure 36-36.

Summary

Dysfunction of the temporomandibular joints and associated structures can be a source of acute and chronic orofacial pain and masticatory dysfunction. Successful treatment depends on an accurate assessment of these disorders. Therefore, the treatment plan must be based on a comprehensive evaluation and accurate diagnosis.

Disorders that may affect the TMJ are similar to those involving other synovial joints; therefore, treatment of patients with TMD should be consistent with that provided to patients with any other musculoskeletal disorder. A clear understanding of the anatomy, biomechanics, and pathologic processes that may afflict the TMJ is necessary if an acceptable course of treatment is to be determined.

An organized approach to the assessment of orofacial pain and of patients with TMD, as well as an accurate diagnosis, is essential. This chapter is intended to provide some basic tools that can be used in assessment of the patient with TMD.

Acknowledgment

Appreciation to Dr. Cibele Nasri-Heir for her invaluable assistance in the preparation of this manuscript and to Dr. Adi Ram Adini her assistance assessing the mandibular range of motion literature.

Imaging of the Temporomandibular Joint

ANITHA POTLURI, ADITYA TADINADA

The temporomandibular joint (TMJ) has a complex joint architecture comprising the mandibular condyle, temporal bone, and an articular disc. This hard and soft tissue combination has a unique joint orchestra that makes it very difficult to image. Clinical examination alone cannot provide a complete picture of the multitude of challenges associated with the joint. Imaging plays a critical role in the diagnosis, treatment planning, and outcomes assessment associated with the joint. Conventional imaging of the joint with two-dimensional (2D) imaging offers limited information regarding the joint. Advancements in image capture technology and evolution of postprocessing image algorithms are changing the way the TMJ is being imaged and evaluated. Significant developments in imaging technology and evolution of faster acquisition techniques that reduce motion artifacts have paved the way to a more holistic imaging approach. The radiation dose associated with ionizing radiation is a perennial challenge, but good clinical practice strikes a balance between dose and diagnostic-quality images. Various techniques have been described in the literature with specific indications and contraindications.[1] The evolution of lower-dose, three-dimensional (3D) imaging modalities such as cone-beam computed tomography (CBCT) and the ability to modify the acquisition protocols have brought a paradigm shift in the radiographic analyses of the osseous components of the joint.[2,3]

The scope of TMJ disorders includes myofascial pain that involves discomfort or pain in the muscles that control jaw function, internal derangement of the joint, or arthritis, which refers to a group of degenerative/inflammatory joint disorders.[4]

The logical diagnostic approach to this complex group of conditions includes clinical and radiologic correlation. A comprehensive history and clinical exam and a 2D screening exam such as a panoramic radiograph will allow for task-specific evaluation and guide the clinician in choosing the appropriate advanced imaging modality, when indicated, to further evaluate the joint complex.

This chapter provides an overview of existing imaging modalities and their indications and contraindications.

Conventional Imaging

Conventional radiography is the most common 2D imaging modality used to examine the TMJ. It serves as a cost-effective, low-dose diagnostic tool that provides an overview of the joint and is easily accessible to the practitioner. Various projections are used to view specific areas of the TMJ. The objective is to obtain nondistorted, possibly superimposition-free diagnostic radiographs with clear visibility of anatomic detail. With the ubiquitous availability of 3D imaging, the use of 2D imaging is declining, but it is important to appreciate the value of these projections and their use. Routine projections include transcranial, transmaxillary, panoramic, pseudo-tomographic, lateral oblique, submentovertex (basal), and reverse Towne views. A combination of these projections is typically used to evaluate the joint based on clinical symptoms. In addition, conventional linear or multidirectional tomography may be used for sectional imaging of the TMJ.

Film-based imaging continues to be routinely employed in clinical practice. However, the benefits of digital imaging have resulted in an exponential increase in the use of this technology. Many imaging options are available now; their use is facilitated by faster and more efficient digital sensors with higher quantum efficiency, which enables direct or indirect capture of images.[5] The most commonly used technological devices include solid-state sensors such as charge-coupled device (CCD)-based units, complementary metal oxide semiconductor (CMOS)-based units, and others such as photostimulable phosphor (PSP)-based sensors that are widely used in high-volume settings such as a hospitals and trauma centers. Advantages of using digital imaging include reduced doses in

• **Figure 37-1** Transcranial view: Note the superimposition of overlying anatomy on the temporomandibular joint. Only one joint can be imaged at a time. The series shows the position of the condyle during mouth opening. The *arrows* are pointing to the condyle position in relation to the eminence in closed, open, and widely open views.

comparison with earlier-generation film-screen systems; the ability to process images to tease out the signal of interest (postprocessing) without having to re-expose the patient for possible retakes; the ability to transmit, archive, and retrieve images efficiently and in a timely manner with no change in image quality; and the ability to synthesize or reformat images in other planes with the use of image processing algorithms. Such processing and synthesis of 3D volumes are not possible with film-based images unless they are digitized. All advanced imaging modalities use direct-capture electronic sensors.

Conventional imaging modalities are less expensive and more easily accessible than advanced modalities, and they entail lower radiation doses when compared with modalities such as computed tomography (CT). However, image acquisition in two dimensions does not provide a spatial perception of depth. Regional anatomy superimposed on the regions of interest precludes complete evaluation of the TMJ. In addition, image distortion, nonuniform magnification, and the generation of artifacts and other processing errors are potential challenges. Multiple radiographs generally are acquired using differing projection geometry in order to visualize the entire joint and to localize pathology. A single radiograph is seldom diagnostic because the information that is captured is limited to two planes as dictated by the specific projection geometry. The cumulative addition of radiation dose often equals or surpasses the more modern low-dose advanced imaging options such as CBCT.[6]

Transcranial

This method was very popular before the advent of advanced imaging modalities that use low radiation doses, such as CBCT. A transcranial image serves to provide a better view of the lateral aspect of the TMJ than the medial or central portion by virtue of projection geometry. However, most osseous lesions are known to start in this region. Significant superimposition of the mediolateral poles of the condyle occurs in this 2D projection, in addition to other overlying anatomy in the path of the beam as it traverses the skull. Adequate contrast and density are critical for obtaining a diagnostically acceptable image. The lateral portion of the condyle is nearer to the plane of the film and hence appears with relatively greater clarity (Figure 37-1).

• **Figure 37-2** Transmaxillary or transorbital view: Coronal view of the temporomandibular joints. (Courtesy James C. Pettigrew Jr, University of Florida.)

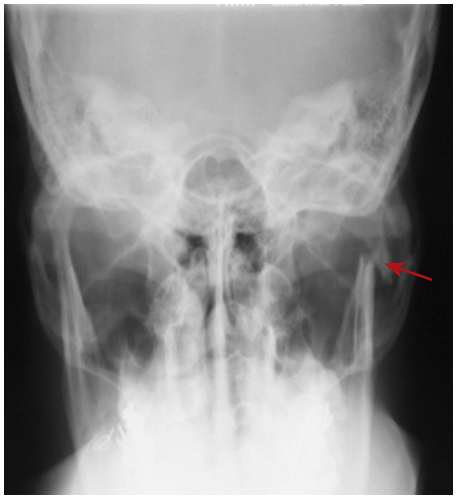
Transmaxillary or Transorbital

In order to better view the medial and central portions of the condyles, it is recommended that an additional coronal view of the TMJ be acquired. This can be achieved with the use of transmaxillary or transorbital projections. Anteroposterior projection geometry places the TMJ closer to the plane of the receptor (Figure 37-2).

Reverse Towne Projection

Another projection that is commonly used to evaluate the condyle is reverse Towne projection, which is a posteroanterior

(PA) projection.[7-9] A PA view is preferred because of the relative proximity of the condyles to the plane of the receptor (film or digital sensor), which results in an image with relatively greater detail. The patient opens the mouth, allowing translation and rotation of the condyle out of the glenoid fossa. This motion may be limited in trauma. However, if obtained accurately, the view facilitates acceptable evaluation of the medial and lateral poles of the condyle without a corrected axis view, but with a good overview of the subcondylar and upper ramal regions to help rule out fractures. Localization of fractures is facilitated because any displacement along the mediolateral axis can be evaluated (Figure 37-3).



• **Figure 37-3** Reverse Towne projection: Open-mouth view enables visualization of the condyles as they translate and rotate out of the glenoid fossa. This view enables bilateral comparison of the two condyles. Note the *arrow* pointing to the left condylar neck fracture.

Submentovertex (SMV) Projection

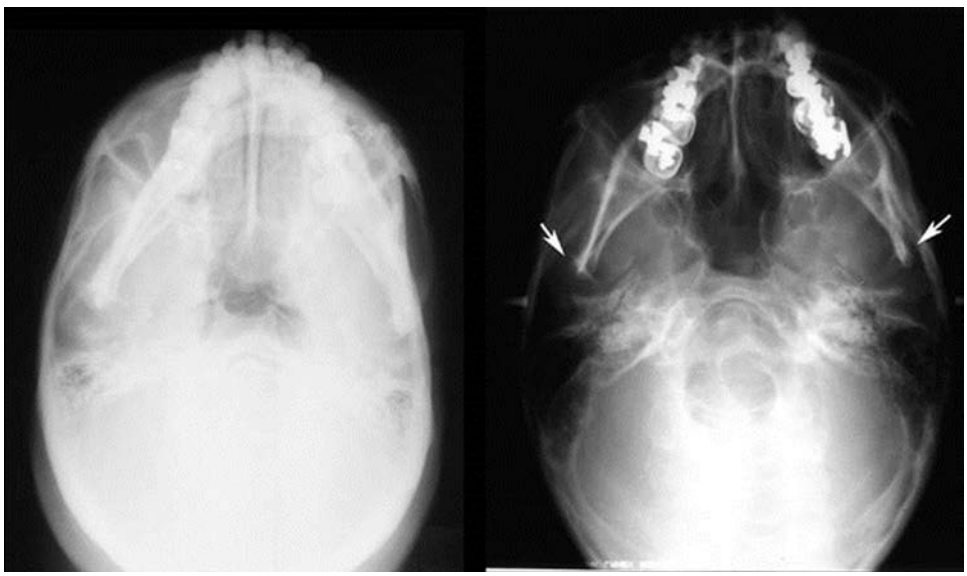
The angulation of the condylar axis with respect to the midsagittal plane can be determined with use of the basal projection, also known as the SMV.[10] The base of the skull is imaged, and the condyles are captured on this projection. However, significant superimposition of the floor of the middle cranial fossa onto the TMJ does not permit a meaningful evaluation. This projection has limited TMJ applications and is most commonly used to acquire corrected-axis tomograms of the TMJ. The mediolateral axes of the condyles are plotted in conventional tomography software to assist with generation of slices parallel to the long axes (Figure 37-4).

Lateral Oblique Views

The lateral oblique view of each condyle/ramus, a commonly used projection before the introduction of panoramic radiography, can capture relatively good images of the TMJs, one at a time. In the absence of a panoramic imaging unit, this view provides an excellent option for viewing the condyles and the ramus. The glenoid fossa usually is superimposed by overlying anatomy. The central beam is directed at the midpoint of the ramus (Figure 37-5).

Panoramic Radiography

Panoramic radiographs are used as screening images to evaluate the TMJ. The inherent distortion, magnification, presence of superimposing ghost artifacts, double shadows, and so on prevent a thorough and quantitative examination of the osseous components of the TMJ.[11,12] However, this view allows bilateral visualization of both TMJs, enabling a reasonable comparative evaluation. The patient's position in the focal trough of the panoramic unit, as well as



• **Figure 37-4** Submentovertex view: Also known as the basal view or jug handle view. Enables visualization of the condyles along their mediolateral axis, so the angle with the midsagittal plane can be determined for generation of corrected axis tomograms. *Left* image is showing the right zygomatic arch fracture. The *arrows* are pointing to the zygomatic arches bilaterally.

the choice of imaging parameters such as the configuration of the focal trough itself, are of paramount significance in this context to reduce uneven magnification of the areas of interest. Alterations in imaging geometry have been implemented in some panoramic units to limit exposure to the TMJ. Variable magnification of the images in all three axes has been documented to severely impair the ability to make measurements for diagnosis or for treatment planning purposes. Soft tissue components of the TMJ are not captured adequately, and direct visualization of these structures is not possible, as on any other conventional 2D radiographs. Because panoramic radiographs are "Mercator" projections of the area of interest, it is challenging to accurately assess the anatomic area being imaged, but because pantomography has been around for a long time and the focal trough and technique have evolved over time, the depiction of joint anatomy is now well understood.[12]

Modifications of the focal trough, as well as changes in the configuration of motion of panoramic imaging units, have been introduced to generate local views of TMJs, as well as pseudo-tomograms. Pseudo-tomograms are full-thickness images that appear very similar to tomograms. Many modern panoramic units offer various TMJ imaging options, including true linear tomographic capabilities with corrected axis acquisition capabilities. However, these usually are time-consuming procedures that require limited stabilization and positioning devices; in addition, they generate artifacts that may be seen on linear tomography (Figure 37-6).

When the clinical examination suggests some form of pathology, panoramic imaging is recommended for initial TMJ screening by the American Academy of Pediatric Dentistry, the American Academy of Orofacial Pain, and the American Academy of Oral and Maxillofacial Radiology.[12] Although panoramic imaging is extensively used in routine clinical practice and is valuable as a screening exam, the coming of multiple field of view (FOV) CBCT machines is changing the imaging approach to TMJ evaluation.

Panoramic imaging is a very good screening imaging modality. With the advent of newer machines with TMJ specific protocols, pseudo-tomogram–like images can be obtained. Significantly less radiation exposure occurs compared to advanced imaging modalities. Major disadvantages of this imaging are altered image geometry and variable magnification in all three axes. Because of the 2D aspect of the imaging, anatomic relationship cannot be evaluated with accuracy. Only osseous components with limited and incomplete depiction of the joint can be evaluated. No soft tissue evaluation can be done.

Conventional Linear and Multidirectional Tomography

Conventional tomography was extensively used before the advent of CBCT, but the coming of newer 3D imaging modalities has made these methods redundant. Conventional tomography[9-11] is a process by which slices of regions of interest are generated, one at a time, through different types of simultaneous motion of the x-ray source and the receptor (film or digital). Synchronous movement of these two elements about a center of rotation effectively captures a slice of the region of interest placed at this point. Slice thickness varies inversely with the angle circumscribed by the x-ray source during translational or rotational motion. The more complex the motion, the more effective will be the blurring of superimposing anatomy, thus improving visualization detail. However, it should be borne in mind that a decrease in slice thickness beyond a certain value (2-3 mm) will adversely affect contrast as the thickness of imaged tissue lessens. Artifacts are known to degrade image quality in simple motion configurations such as the linear mode. Many panoramic units offer this basic capability for generating linear tomograms. The procedure is very technique sensitive and time consuming, as only one slice is generated at a time. However, it does provide an accurate evaluation of the osseous components of the TMJ. Most panoramic units with true tomographic imaging capabilities offer special positioning devices and programs to correct for the mediolateral angulation of the condylar axis, in order to help generate a true orthogonal view of the anatomy. The condylar angle is assessed with respect to the midsagittal plane with the use of an SMV view that is acquired first.

Multidirectional tomography units use complex motions such as tri-spiral, hypocycloidal, and figure of eight to generate tomographic slices with minimal artifacts and smaller slice thicknesses (Figure 37-7). Computer-driven platforms are used for this purpose. Laser positioning lights and the

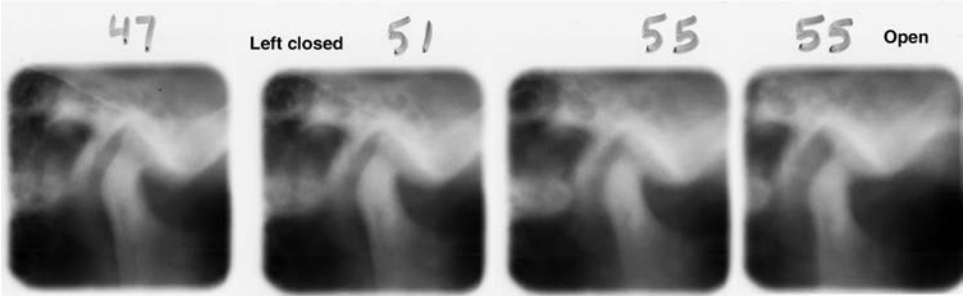
registration of appropriate coordinates in the *x, y,* and *z* axes are possible with such units. This is advantageous for long-term follow-up studies, for which some reproduction of imaging geometry may be required. An SMV may be generated and imported into the software with a flatbed scanner to compute the correction needed to generate orthogonal tomograms. Conventional tomography permits accurate measurement of the regions of interest because magnification is known a priori and stays constant over the entire image.



• **Figure 37-7** Conventional tomograms: Sagittal slices through the temporomandibular joint. Note the condyles in open- and closed-mouth positions.

Advanced Imaging Modalities

Three-dimensional imaging finds numerous applications in diagnostic TMJ imaging, owing to its capability of demonstrating depth-specific information in an interactive manner. Most such imaging is done to evaluate internal derangement, a common problem in about 50% of the population.[13,14] Anterior disc displacement is more common and is followed by anterolateral positioning. Disc displacement patterns vary to a large extent, which is very well depicted with magnetic resonance imaging (MRI). Other pathologic entities such as degenerative joint disease, ankylosis, tumors, and developmental anomalies often necessitate 3D imaging. In addition, soft tissue components can be adequately visualized with MRI and the use of appropriate techniques in CT. Advanced imaging modalities provide diagnostic information that also can be quantified to characterize pathology and thus determine the optimal mode of intervention.

CT is also used as a basis for therapeutic options such as patient-fitted total joint replacement. The evolution of better materials and more refined radiographic imaging for preoperative planning has changed the landscape of this procedure. The DICOM data from the scan is used to create an accurate 3D plastic model of the TMJ and associated jaw structures. Stereolithography, CAD-CAM fabrication, or more recently 3D printing technology is used to make a functional 3D model, to best restore the patient to normal joint function. The new joint is created based on this model.[15]

Computed Tomography

Computed tomography (CT) uses an image-forming algorithm to reconstruct a 3D image data set from multiple 2D images of the TMJ. The patient is positioned on the gantry; the x-ray sources and the electronic detector array rotate around the patient and undergo translation as images are continuously acquired. Direct acquisition in most units occurs in an axial plane, but coronal acquisition can also be achieved.[1] The patient will have to be placed in an uncomfortable position for direct coronal capture to occur. However, images can be synthesized or reformatted in any plane such as sagittal or coronal.[1] This process is referred to as multiplanar reconstruction (MPR). An entire region of interest thus can be examined in a single acquisition. MPR reduces the resolution of images slightly, but contemporary techniques yield adequate imagery for diagnosis. Earlier generations of CT units used less efficient modes of image collection, resulting in longer study times and the potential for motion artifact. Later generations of imaging units are capable of much quicker image generation, such as spiral CT, in which the gantry continues to translate as the x-ray sources and detector array rotate around the patient, thus generating a spiral motion and significantly reducing image acquisition times. Newer units have superior detector technologies and are capable of relatively high spatial resolution. The contrast resolution offered by CT is the highest that can be achieved. Examination of osseous structures with CT, therefore, is considered optimal. However, spatial resolution is still lower than that of digital radiography (DR) in that pixel sizes of the sensors in a CT unit are larger.

CT data can be visualized interactively, in static or dynamic modes, with the use of different display settings. MPR facilitates the generation of images in the coronal and sagittal planes. Scout images are generated first to ensure that the patient has been positioned appropriately in the gantry, and appropriate slices are selected for image generation. The images are displayed as shades of gray that are based on attenuation of the x-ray beam as it passes through the tissues of interest. This value, which is expressed as the attenuation coefficient of the tissue, is compared with the attenuation coefficient of water and is expressed as a logarithmic ratio, resulting in a value commonly referred to as a Hounsfield unit (HU). HU values of different tissues have been identified, thus yielding a range of values that are best for viewing different types of tissue. Further image processing through windowing and leveling of data results in display of desired shades of gray on the image based on the specific diagnostic task. Osseous tissues thus can be best visualized in a bone window setting. Likewise, soft tissue window settings are ideal for viewing such components of the TMJ and adjacent anatomy. The disc usually is difficult to visualize with the use of CT, especially if it is thin and small.[1] Larger discs and posterior attachments may present as areas of differential attenuation, permitting some visualization. Anterior displacement of the disc also may permit visualization. Indirect localization of the disc may occur through observation of displacement of the fat pad adjacent

to the lateral pterygoid muscle attachment to the condylar head. Windowing and leveling can be interactively carried out at the workstation.

For TMJ imaging, closed- and open-mouth views are generated, allowing examination of translation and rotation of the condyles and the dynamic range of motion. The patient must be immobilized during image acquisition by biting down on an object in the open position. CT also allows examination of the glenoid fossa, morphologic alterations or erosions of the condyles, and the articular eminentia and trauma. Perforation of the glenoid fossa into the middle cranial fossa also can be visualized well. If the disc is visualized, sagittal views render the disc much more visible in open and closed positions than do coronal and axial views. However, medial or lateral displacement of the disc may be noted in the coronal view.

CT imaging provides multiple advantages, because 3D information is captured and displayed interactively as a stack of 2D slices in any desired plane through MPR. In addition, 3D volumes can be displayed as surface rendering and volumetric rendering. Surface rendering, as the term implies, generates a surface-only 3D image; volumetric rendering generates the entire volume by making the superficial pixels transparent on the basis of their attenuation properties. In addition, CT is an excellent imaging modality for visualizing osseous components of the TMJ. CT also permits visualization of soft tissue components of the TMJ to some extent, although soft tissue examination is best performed by MRI. CT of the TMJ exposes the patient to higher radiation doses than do conventional techniques. The artifacts in CT may require that the study be repeated or that another modality be chosen. The most commonly seen artifacts include: (1) those induced by metallic fixtures or prostheses in or near the TMJ, (2) restorations such as amalgam and stainless steel crowns that produce a starburst pattern, and (3) motion artifacts induced by patient movement, especially in pediatric patients or those with involuntary movements. Adequate modes of stabilization or a sedation protocol should be used in these instances (Figures 37-8 through 37-10).

Magnetic Resonance Imaging

MRI is being used increasingly for TMJ imaging and has largely replaced invasive arthrography, because it offers three major advantages: (1) It does not entail the use of ionizing radiation, (2) it provides excellent images of soft tissue components of the TMJ and permits direct visualization of inflammatory changes and the presence of effusion, and (3) it can be acquired in any desired plane. However, bone is not directly visualized on MRI. Detection of joint effusion and osseous changes of varying degrees is well documented,[16] and long-term prospective imaging studies have been advocated to track changes over time.[17] Such studies are useful for evaluating morphologic alterations and remodeling following surgical intervention, or in cases where only nonsurgical therapy is adopted. MRI has also been shown to be the optimal imaging modality in cases where no evidence of effusion, osteoarthritic changes, or internal derangement can be found.[17] Furthermore, changes in bone marrow signals can be detected with accuracy on MRI.[16] Studies have also shown that MRI and CT can detect occult fractures of the articular eminentia and the glenoid fossa.[18] These

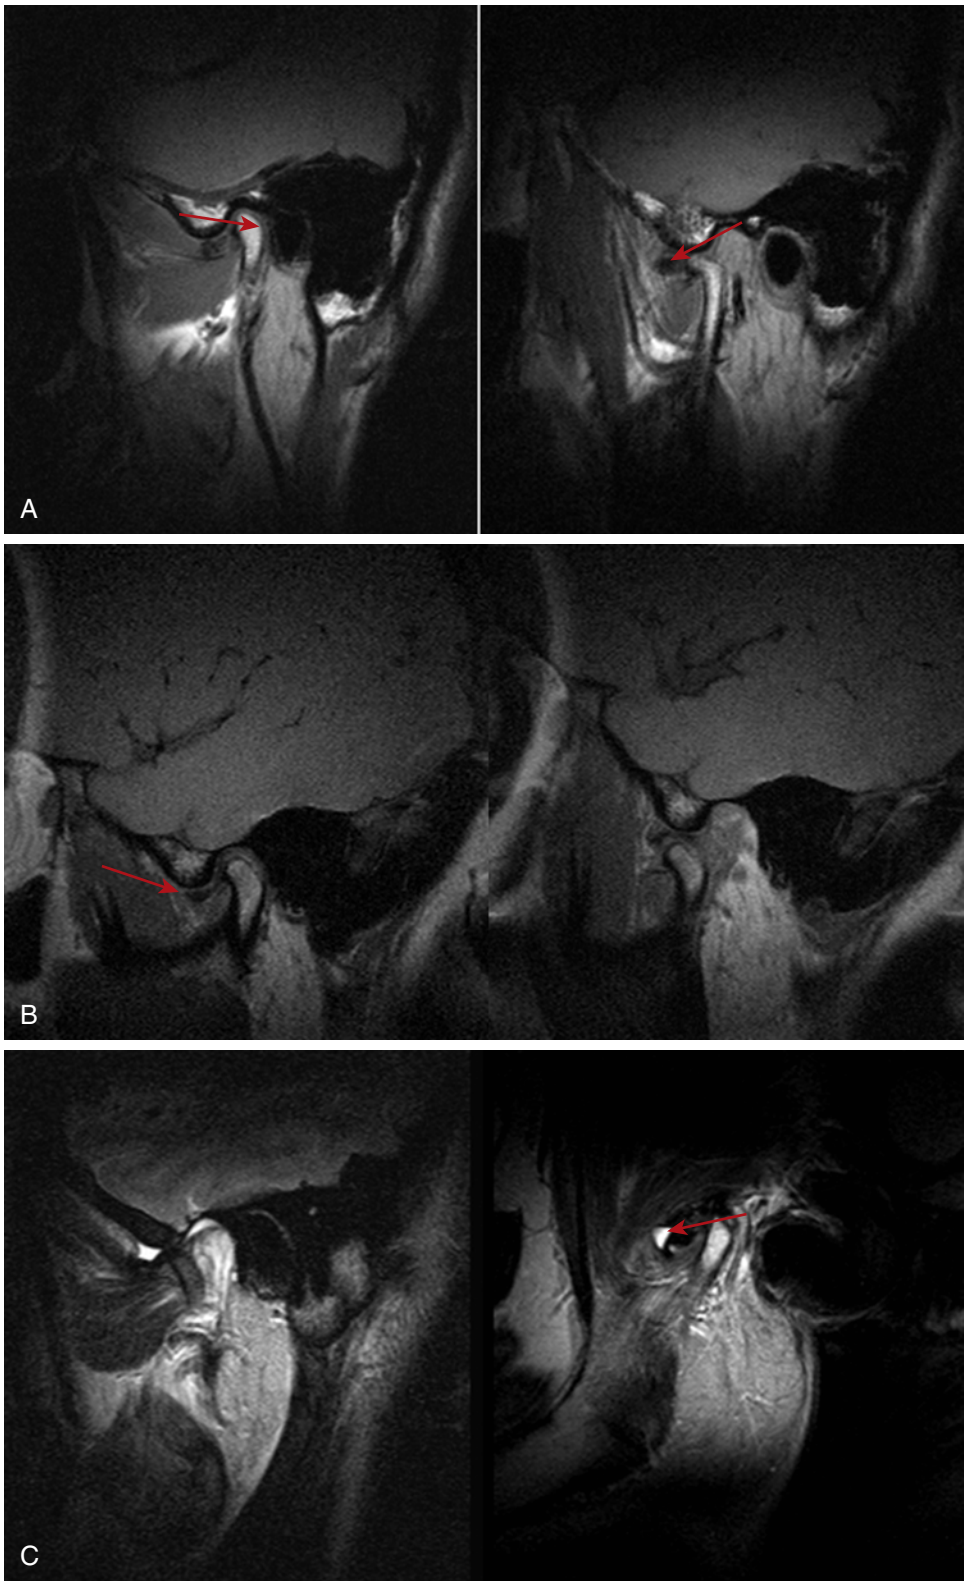
distinct advantages for several applications make MRI an indispensable tool for diagnosis and treatment planning.

Magnetic resonance images are generated via the magnetic properties of hydrogen atoms in water molecules under the influence of powerful external magnetic fields. Radiofrequency (RF) pulses are delivered at a certain frequency and time interval to the region of interest that helps flip the protons within hydrogen atoms by a certain degree from their original axis of spin. Relaxation of hydrogen atoms upon termination of the RF pulse results in emission of the signal, which then is interpreted by the algorithm and displayed as the signal. Various protocols for MR imaging are based on pulse sequences that are determined by the diagnostic task. Image property varies according to method of acquisition. Differential response of different tissue types in normal and unhealthy states enables the generation of signals that facilitate interpretation of MR images. Image weighting is achieved by alteration of the time of repetition (TR) of the RF pulse and the time of echo (TE) of the signal from tissues of interest. Commonly used weighting includes T1, T2, and proton density. T1 images provide anatomic details, with fat enhancing as a bright signal. Bone appears dark on MRI as hydrogen atoms are tightly bound, failing to generate a signal. T2-weighted images, on the other hand, are appropriate for visualizing inflammatory changes in the capsule, as well as the presence of effusion. Proton density–weighted images provide excellent anatomic detail in that the position of the disc is more clearly outlined in relation to surrounding osseous and soft tissue structures.[1]

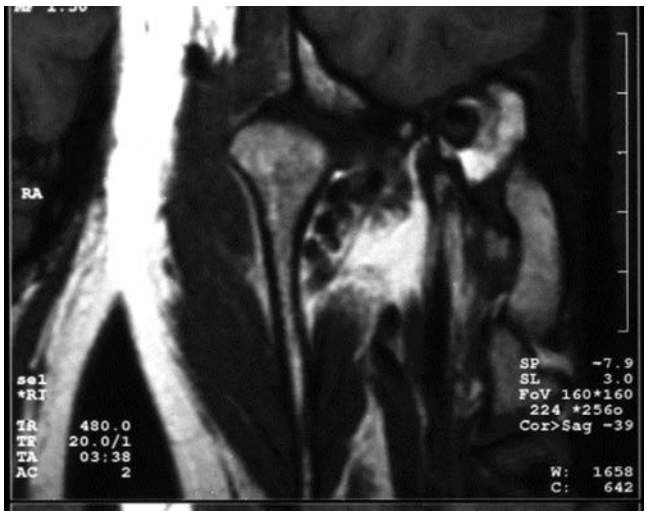
Open- and closed-mouth views are generated in MRI studies. The relative positions of the disc and its attachments can be studied at different positions of translocation[17,18,19] of the mandible, thus documenting TMJ dynamics.[17,19] Assessment of disc recapture can be made in suspected cases of internal derangement.[20] Images in any plane can be acquired directly without the need to reformat images from axial projections, as is done in CT. Patients do not have to be positioned differently. Scout images are acquired initially for slice location planning purposes.

MRI of the TMJ yields information that is not captured by any other modality, directly and in a noninvasive pattern.[21-30] MRI imaging of the TMJ provides hard tissue and soft tissue details along with functional information without using ionizing radiation. Extraction of signals of interest within a reconstructed volume using specific exposure and image processing parameters results in the collection of unique data that then can be viewed interactively. MRI thus continues to be routinely used in instances where (1) clinical signs and symptoms warrant such examination for effective definitive diagnoses,[24] particularly in relation to delineation and evaluation of soft tissue components, and (2) other imaging modalities including arthrography[28] are not considered appropriate. Arthrography has been shown to be relatively insensitive for the detection of medial and lateral displacements.[25] Disc degeneration has been shown on MRI to start in the retrodiscal attachment complex.[26]

TMJ imaging by MRI continues to evolve with improving technology. For TMJ imaging, special circular polarized transmission and receiver coils (surface coils) are used to emit and receive signals to enhance resultant image quality.[26,28] One or two coils may be used to capture the signals. Slice thickness of 3 mm or less is used with interslice spacing of 0.3 to 1.5 mm. MRI must be used to determine disc recapture in patients with internal derangement during splint therapy. Preoperative and postoperative images permit evaluation of the functional efficiency of the splint. Studies have shown that the use of high-quality, superconducting receiver coils significantly enhances image quality on low-field and other open scanners[28] (Figures 37-11 and 37-12).



• **Figure 37-11** Magnetic resonance imaging (MRI): Imaging of soft tissue detail, as well as effusion and inflammatory processes, is possible. **A,** T1-weighted parasagittal slices through the temporomandibular joint (TMJ) showing disc displacement without reduction: optimal for visualization of anatomy, condylar and disc position. Note the bright white signal *(arrow on the right side)* representing the joint space effusion.



• **Figure 37-12** Magnetic resonance imaging (MRI): T1-weighted paracoronal slice through the TMJ.

There are multiple advantages that are unique to MRI. MRI imaging yields information that is not captured by any other imaging modality, noninvasively and with no radiation to the patient.[29] Functional and physical evaluation of the joint and joint space components is facilitated by more accurate images.[30] Evaluation of pathologic conditions with inflammation can be done at high resolution.[31] Various imaging protocols are available that can be used to enhance desired tissue with unique interactive data.[32] Disadvantages include potential for artifact generation from field distortions caused by ferromagnetic metallic objects, prostheses, and implants in the maxillofacial region[33] and an inability to image patients with implanted cardiac pacemakers[34] or aneurysm clips in the brain,[35] as well as patients with claustrophobia.[36] However, open units are available for patients with claustrophobia. Such units generally use magnets with lower field strengths, resulting in lower signal-to-noise ratios.

Tuned-Aperture Computed Tomography

Tuned-aperture computed tomography (TACT) is an imaging modality that was developed from the basic principles of tomosynthesis. However, none of the limitations of tomosynthesis apply to TACT. Multiple conventional images of the volume of interest are acquired from different loci in space, resulting in 2D radiographs. Software is used to reconstruct 3D volume with these data. 2D slices then can be generated, or the entire volume can be examined interactively at the workstation in static or dynamic modes. The stack of slices lends itself to image processing like CT (see Figure 37-11). Before the advent and wide availability of cone-beam volumetric imaging, TACT was a promising new modality to get 3D images in less time than conventional tomography and with fewer artifacts compared to CT. TACT was evaluated for TMJ arthroplasty, as it provided images with fewer metal and streak artifacts to evaluate the joint after arthroplasty. Disadvantages include the time required to acquire and reconstruct the images. TACT continues to be evaluated for a variety of diagnostic tasks and is used in medical applications such as mammography.[37,38]

Cone Beam Computed Tomography (CBCT)

CBCT is a relatively new 3D diagnostic imaging modality in dentistry that is finding numerous applications in maxillofacial imaging.[38-43] It uses an x-ray source that delivers a cone-shaped beam, resulting in exposure of the entire volume of interest at the same time and not just one or more slices of the tissue at a time. The result is a faster image acquisition process with significantly lower radiation doses. The linear accuracy of measurements from CBCT scans is very reliable, as the image acquisition is done using isotropic voxels. Because CBCT has poor contrast resolution, scatter artifacts from metallic structures are significantly fewer. First-generation CBCT units were designed to acquire the scan in a supine position, but most current CBCT units are designed to image the patient in a seated or standing position. Most standing and chairless units accommodate patients in wheelchairs. Numerous units are in use, most of which use sensors with high spatial resolution capabilities. Reconstruction times vary according to the unit, but some vendor software can achieve real-time secondary multiplanar reconstructions. Panoramic and other dental modes of view are available in the reconstruction schemes. Field of view and voxel size play a key role in the detection of subtle osseous changes and can help in early diagnosis of arthritic changes; research in this area is emerging and is helpful in developing imaging protocols for evaluation of the TMJ.[44] A new area of emerging research is the ability of CBCT scanners to acquire 3D information using fewer basis projections by modifying the acquisition protocol to do a 180-degree rotation as compared to the conventional 360-degree rotation. This modified acquisition technique is showing promising results in the detection of small and large arthritic lesions associated with the TMJ.[45] This is largely due to the evolution of postprocessing algorithms and small voxel sizes that deliver high-resolution images and better sensors. Newer sensors have resulted in 14-bit capture of data in the recent past and provide an opportunity to postprocess images to glean more valuable diagnostic information. Efforts to achieve 16-bit capture are ongoing. The definitive advantage of increased bit depth in the absence of soft tissue visualization remains to be proved. Cone-beam acquisition does not permit diagnostic imaging of most soft tissue such as muscle attachments and fascial planes, as is seen in conventional CT. Contrast imaging and soft tissue imaging using CT are still best achieved through conventional CT. CBCT does, however, facilitate evaluation of some soft tissue structures such as airway spaces outlined by regional soft tissue, a profile of the patient's face for orthognathic or other reconstructive operative needs, and imaging of subtle calcifications within soft tissue entities. Also available are units that could generate images of selected regions

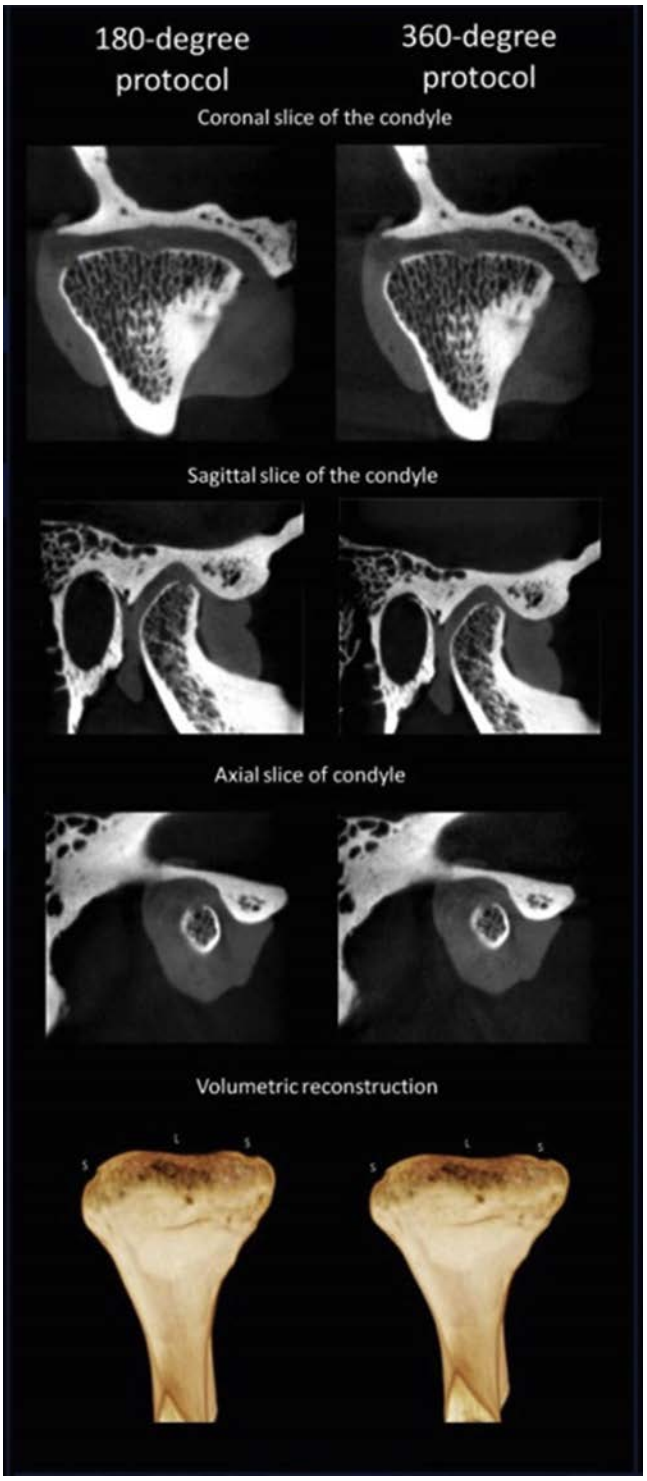
of the patient's anatomy with the use of smaller detectors and tightly collimated beams, resulting in significantly higher spatial resolution levels. However, these are limited area views, and only a small portion of the anatomy can be captured.

Surface and volumetric reconstructions can be done with CT data for treatment planning purposes. Surface reconstruction yields an image with surface pixels processed to show the exterior of the region of interest; volumetric reconstruction facilitates visualization of internal anatomic details. This is especially useful for reconstructive surgical treatment planning, simulation procedures, and establishment of visual treatment objectives[46] (Figures 37-13 through 37-17).

A major advantage of CBCT imaging is that it is a low-dose 3D imaging modality with high spatial resolution for imaging the hard tissues in the maxillofacial region. It has a significantly lower radiation dose, lower cost, and smaller footprint compared to multi-slice CTs. A major disadvantage of CBCT in comparison with multi-slice CTs is its poorer contrast resolution, which depicts soft issue details poorly. Other disadvantages such as patient motion artifact and metal artifacts are similar between both imaging modalities.

Functional Imaging

All of the image generation techniques discussed previously fall under the category of morphologic imaging modalities. Functional imaging modalities capture images that provide information on the functional integrity of the region of interest.[47-57] Applications in TMJ imaging are very limited. Examples include evaluation of functional changes following orthopedic treatment,[47] pre-splint and post-splint therapy imaging,[48] condylar hyperplasia,[49] necrosis of the condyle, chronic craniofacial pain refractory to treatment,[50,51] craniofacial osteomyelitis,[52] solid tumor invasion, and so forth. Thus, in instances where such information is needed to evaluate the presence of primary or secondary lesions in the TMJ, functional imaging is used in conjunction with morphologic imaging. These methods include scintigraphy, positron emission tomography (PET), and single photon emission computed tomography (SPECT), among others. Radioactive isotope-labeled tracer agents with short half-lives are administered intravenously, followed by image capture with the use of specialized cameras. Anatomic entities are not well outlined on the resultant images; however, those areas within the volume of interest that take up more of the tracer agent as a result of increased metabolic activity present as bright signals and vice versa. Although the sensitivity of this technique has increased with the use of SPECT, specificity is rather low, leading to false-positive results. Therefore, functional studies should be interpreted with caution. Increased physical activity just prior to imaging is known to generate signals in regions of hyperactivity that may not necessarily result from pathologic activity. In addition, internal radiation doses are delivered when this procedure is followed. Therefore, this imaging modality is not selected without prior acquisition of morphologic imaging through CT or MRI; it should be advocated only in those instances where an undisputed indication for such functional assessment exists.



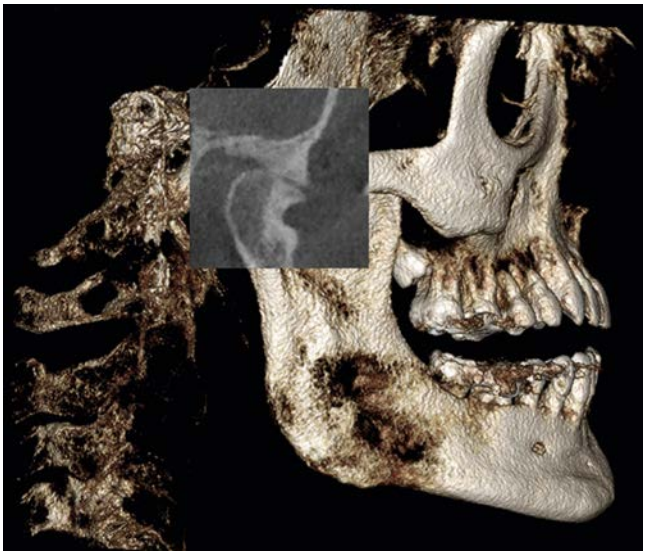
• **Figure 37-13** Cone-beam computed tomography (CBCT): Modified and conventional small-volume, low-dose scans: sagittal, coronal slices and volumetric rendering through condyles. Note the condylar surface erosion and defects in both coronal slices and volumetric rendering images through condyles consistent with degenerative changes.

• **Figure 37-14** Cone-beam computed tomography (CBCT): Lateral reconstruction with maximum intensity projection (MIP).

• **Figure 37-15** Cone-beam computed tomography (CBCT): Postero-anterior open-mouth reconstruction with maximum intensity projection (MIP).

Fusion Imaging

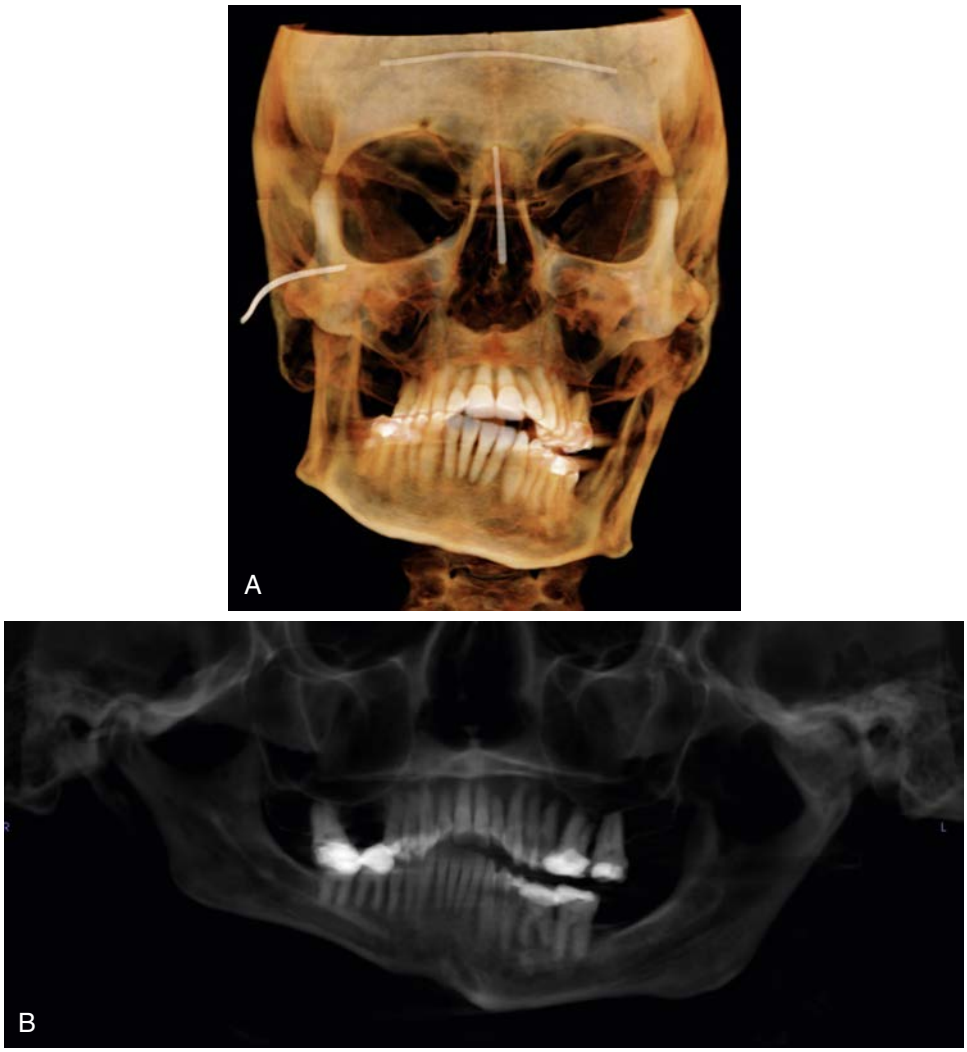
The concept of fusion imaging arose from the need to correlate findings on morphologic and functional imaging studies in a meaningful manner in 3D space. PET/SPECT-CT thus was introduced as a fusion imaging modality.[53-57] Images acquired with the use of the unit would contain both CT and PET/SPECT components, resulting in visualization of data that have been spatially correlated within the volume. It is thus easier to localize areas of increased or decreased metabolic activity to slice planes without compromising visualization of regional anatomy. Post-acquisition fusion of images from two different modalities can be done but is often not as accurate as when images are acquired together. Functional imaging is thus an invasive procedure that has the potential for false-positive results; it must be used only in conjunction with morphologic imaging modalities.[50]



• **Figure 37-16** Cone-beam computed tomography (CBCT): Lateral volumetric reconstruction in a bone window with x-ray window overlapping the right condyle. Note joint space reduction and osteophyte formation on right condyle.

Ultrasonography

Ultrasonography (US) is a noninvasive, inexpensive morphologic imaging procedure that can provide valuable information about TMJ components.[58-61] It may be used as a screening tool to evaluate the osseous contours of joints and may be used to evaluate joint spaces. Good diagnostic accuracy and reliability depend on appropriate use of this technique. The procedure can be completed in a short time. TMJ components present as hyperechoic areas of differing signal intensity, making them distinguishable from each other. Correlation of US findings with results of other imaging modalities such as MRI has shown that morphologic changes can be detected with some accuracy, including measurement of joint spaces as an indication of the presence of effusion as seen on MRI. Effusions present as hypoechoic or anechoic areas on US. Other applications include detection of disc position and dynamic evaluation of TMJ components in motion. More powerful transducers, positioning and size of the transducer for image acquisition, and the expertise of the operator have a direct bearing on image quality. However, it should be noted that evaluation of the medial aspect of the joint continues to be a problem. Some challenges to the routine use of US in diagnostic imaging of the TMJ have arisen, but the future seems to be bright as the technology continues to evolve.



• **Figure 37-17** Cone-beam computed tomography (CBCT): **A**, 3D volumetric rendering showing left condylar hyperplasia. **B,** Panoramic reconstruction from CBCT showing left condylar hyperplasia, joint space reduction, and ankylosis.

Summary

With recent advances in imaging technology and the introduction of newer imaging modalities, noninvasive evaluation of the TMJ has become a more efficient process. Static and dynamic observation of TMJ components is being done with significant reduction of radiation dose and, when necessary, by fusing or co-registering two imaging modalities together. The ideal imaging modality for a specific diagnostic task must be determined on the basis of clinical signs and symptoms, in consultation with a radiologist, because imaging protocols and acquisition schemes constantly change with technological upgrades.

Pathology of the Temporomandibular Joint

ROBERT GASSNER

This chapter on the pathology of the temporomandibular joint (TMJ) consists of three parts. The first part deals with joint physiology and pathophysiology. The second part assesses the plethora of TMJ arthritides. Finally, the last part provides insight into the occurrence of benign and malignant tumors of the TMJ.

Joint Physiology and Pathophysiology

Motion is a fundamental event throughout biology.[1] It is an especially powerful modulator of cellular events, altering and interfering with effects of cytokines and growth factors in the musculoskeletal system.[2] Until recently, mechanical effects on joint tissue, especially the activation of cells such as chondrocytes, synovial fibroblasts, and osteoblasts, were considered beneficial only in disease-free tissue and were regarded as detrimental in the presence of inflammatory disease. When assessing the literature on the TMJ, usually in place of *motion*, the term *mechanical stress* is used in association with breakdown of joint function.[3,4]

This provides a small glimpse of results and work of the past 10 years regarding the interaction of motion and inflammation in articular tissue in vitro and in vivo.[5-12] It reveals how motion provides anti-inflammatory effects even in inflamed articular tissue through intracellular mechanisms. It further outlines how motion-based therapies such as continuous passive motion exert beneficial effects in various states of inflamed joint tissues. The in vitro model compares chondrocyte behavior when chondrocytes are subjected to four different conditions: (1) inflammation (interleukin-1 [IL-1]), (2) motion (cyclic tensile strain[CTS]), (3) inflammation and motion, and (4) experimental control. The in vivo model compares inflamed cartilage behavior when cartilage is subjected to two different conditions: (1) immobilization (IMM), and (2) motion (continuous passive motion [CPM]).

Understanding this can help in the clinical decision-making progress regarding therapeutic regimens of medical, surgical, and/or physical therapy interventions used in the treatment of temporomandibular disorders (TMDs). It can also help in understanding the molecular basis of joint diseases.

Interplay of Cytokines, Growth Factors, and Mechanical Signals

Articular cartilage maintains normal TMJ function through a specialized, hydrated extracellular matrix.[13] The major constituents of fibro-cartilage include type-II collagen fibrils providing tensile strength, and aggregating proteoglycans (aggrecans), nonaggregating proteoglycans, and water providing compressive resilience.[14] Less abundant components, types IX and XI collagen[15] and small proteoglycans,[16] also influence matrix organization.

Glycosaminoglycans are the polysaccharide side chains attached to the core proteins of proteoglycans. The distribution of proteoglycans close to the inferior and superior surfaces[14,17] in a given articular tissue is not uniform.[13,17] Chondroitin sulfate is evenly distributed in cartilage; dermatan sulfate is largely concentrated in the periphery and keratan sulfate in the middle of TMJ discs.[13,17] This may reflect different loading patterns in various regions of the TMJ disc.

Chondrocytes embedded in the articular cartilage express distinct functional properties in development and aging, while maintaining homeostasis in the mature organism and during cartilage remodeling after traumatic or inflammatory injury.[18] Physiologically, these responses lead to the formation or restitution of cartilage extracellular matrix (ECM). Dysregulation of these responses can lead to qualitatively or quantitatively abnormal formation or degradation of ECM, resulting in impaired joint function.[14]

Additionally, mechanical stimuli affect articular chondrocyte metabolism. During normal daily activity, a variety of mechanical forces including stresses, strains, and pressures is distributed within the joint; the long-term stability of the cartilage matrix depends mainly on the response

of chondrocytes to mechanical stimuli [6,19] and their limited capability to balance between anabolic and catabolic processes.[20-22]

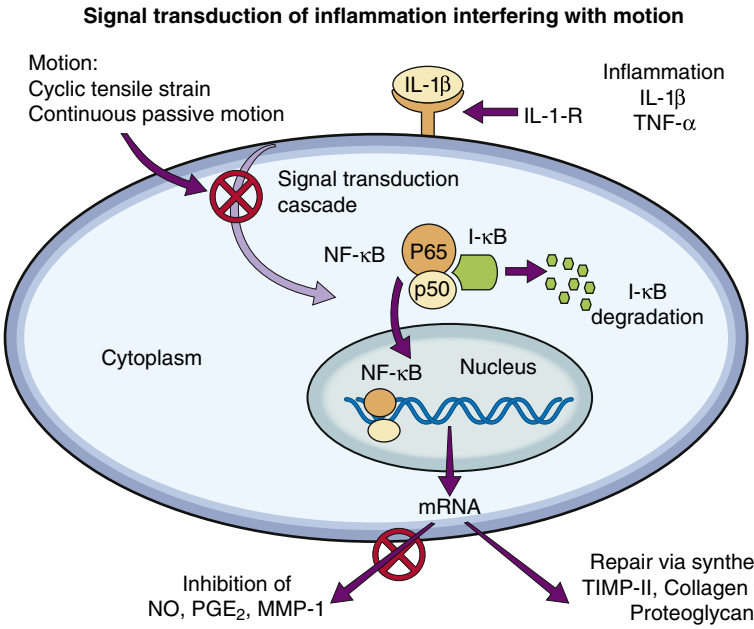
Chondrocyte activation and the induction of anabolic or catabolic responses are thought to be primarily the function of cytokines and growth factors. The catabolic cascade is induced by proinflammatory stimuli such as interleukin-1 (IL-1) and tumor necrosis factor alpha (TNF-α) and is characterized by the secretion of proteases, suppression of matrix synthesis, and inhibition of chondrocyte proliferation. The anabolic process is associated with the secretion of antagonistic cytokines, synthesis of protease inhibitors, production of extracellular matrix, and cell replication.[18]

During inflammation in degenerative TMJ diseases, proinflammatory cytokines such as IL-1 and TNF-α decrease synthesis and increase degradation of proteoglycans and collagens.[19,20,22] Growth factors such as transforming growth factor beta (TGF-β) are unable to stimulate chondrocyte synthesis of collagens and proteoglycans and ultimately reduce the activity of IL-l–stimulated proteinases.[23-25]

It is most important to note that mechanical signals generated by tensile strain of low magnitude (TENS-L) are anti-inflammatory, whereas tensile strain of high magnitude (TENS-H) is proinflammatory and catabolic.[5-8] Both low and high magnitudes of mechanical strain exploit nuclear factor NF-κB as a common pathway for transcriptional inhibition/activation of proinflammatory genes and catabolic processes as described for the intracellular mechanism of action of applied tensile forces in osteoblast-like cells.[26] TENS-L is a potent inhibitor of IL-1β-induced I-κBβ degradation and prevents dissociation of NF-κB from cytoplasmic complexes and thus its nuclear translocation. This leads to sustained suppression of IL-1β-induced NF-κB transcriptional regulation of proinflammatory genes. In contrast, TENS-H is a proinflammatory signal that induces I-κBβ degradation, nuclear translocation of NF-κB, and transcriptional activation of proinflammatory genes (Figure 38-1).

Articular chondrocytes synthesize copious amounts of the free radical nitrous oxide (NO) following activation by IL-l.[21] NO is generated by the NO synthase (NOS) group of enzymes, which synthesize NO by combining molecular oxygen with the terminal guanidino nitrogen of the amino acid L-arginine, yielding L-citrulline as a coproduct.[27] Under aerobic conditions, NO spontaneously oxidizes to its stable metabolites, nitrate (NO_3) and nitrite (NO_2). Because the half-life of NO is on the order of seconds, NO production is assessed indirectly by measuring the conversion of ^{14}C-labeled L-arginine to L-citrulline in tissue homogenates or by measuring the accumulation of the stable NO metabolites NO_3 and NO_2 in biological fluids such as the synovial fluid.[6,20-22,28] To date three distinct isoforms of NOS have been identified: a neuronal form (nNOS) initially isolated from brain, an endothelial form (ecNOS) initially isolated from the endothelium, and an inducible form (iNOS) initially isolated from macrophages.[20,22]

The iNOS pathway is principally regulated at the transcriptional level. Proinflammatory cytokines and endotoxin are potent inducers of iNOS in a wide variety of cell types, whereas glucocorticoids and the anti-inflammatory cytokines IL-4, IL-10, and the growth factor TGF-β suppress NO production. NO, acting as a endogenous mediator of catabolic actions, inhibits proteoglycan synthesis directly,[20-22] whereas TGF-β suppresses that NO production, reversing the NO-mediated inhibition of proteoglycan synthesis.[22]



• **Figure 38-1** Scheme: Interaction of inflammatory cytokine interleukin-1 (IL-1) and motion (cyclic tensile strain/CTS; continuous passive motion/CPM). *NO,* Nitrous oxide; *PGE_2,* prostaglandin E_2; *TNF-α,* tumor necrosis factor alpha.

The synovial fluid of arthritic TMJs also contains inflammatory mediators such as IL-1β, TNF, NO, leukotriene B_4, and prostaglandin E_2. Elevated levels of IL-1 and NO in the pathogenesis of arthritic conditions signal downstream events including the induction of matrix metalloproteinases (MMPs), eventually leading to the destruction of stromal tissue.[10]

Matrix metalloproteinases represent a family of structurally and functionally related enzymes responsible for the proteolytic degradation of extracellular matrix. They have been traditionally subdivided into three classes based on their substrate specificity: collagenases, gelatinases, and stromelysins. Their substrates include fibrillar collagen, collagen type IV or denatured collagen (gelatin), and other extracellular matrices (proteoglycan, laminin, fibronectin, casein), respectively. MMPs have been detected in TMJ synovial fluid aspirates and lavage collections, confirming that MMPs are involved in the degenerative component of TMJ disorders.[10,12]

To treat acutely and chronically inflamed joints, both immobilization and mobilization are used as therapeutic measures, with variable success.[29-31] This is partly due to the fact that mechanisms by which these two differing treatments exert their effects remain unclear. Recent in vitro studies demonstrate that biomechanical signals are potent anti-inflammatory signals that attenuate proinflammatory gene induction in chondrocytes. These signals act on chondrocytes in a magnitude-dependent manner. At low magnitudes, biomechanical signals inhibit IL-1β- or TNF-α-induced transcriptional activation of COX-2, MMPs, IL-1β, and other proinflammatory molecules.[32-35] These mediators are involved in cartilage destruction, and by blocking their gene expression, biomechanical signals can potentially attenuate cartilage destruction. Additionally, biomechanical signals upregulate expression of proteins associated with cartilage repair, such as aggrecans, collagen type II, and sulfated glycosaminoglycans. Not surprisingly, mechanical signals intercept the IL-Iβ-signaling pathway and inhibit nuclear translocation of NF-κB and subsequent transcriptional activation of genes under its control.[34,36] Because NF-κB transactivation occurs within a few minutes following activation of chondrocytes with IL-1β or TNF-α, the actions of biomechanical signals are rapid and can be observed within a few hours. Moreover, biomechanical signals act on cells in a sustained manner and can be observed in the presence of an inflammatory stimulus.[34,36] Additionally, mechanistic analysis of the actions of biomechanical signals in vivo is indicated to understand the biological basis of motion-based therapies that may contribute significantly to the healing of inflamed joints.

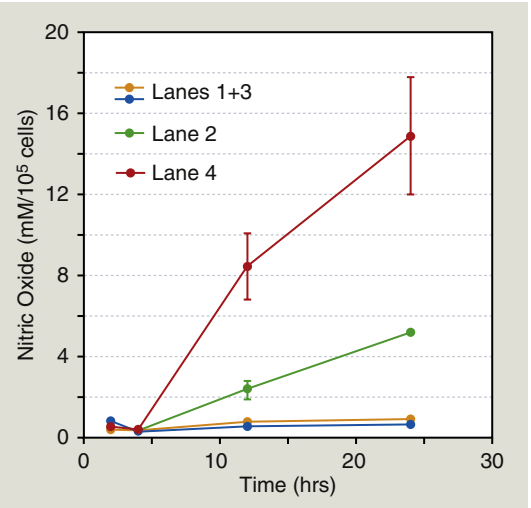
The Arthritic Condition and Cyclic Tensile Strain in Vitro

CTS vs. CTS+IL-1 vs. Experimental Control Group vs. IL-1 Alone

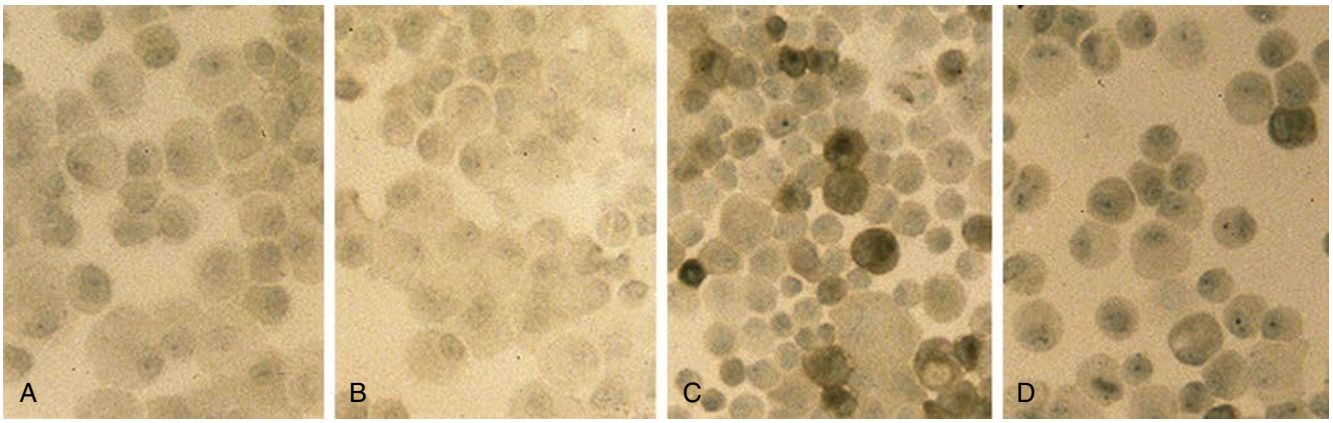
Mimicking the arthritic condition in in vitro chondrocyte function has to be assessed under at least four different conditions: (1) motion (CTS), (2) motion and inflammation (IL-1), (3) inflammation (IL-1) alone, (4) and experimental control (Figure 38-2). Exposure of chondrocytes to the proinflammatory cytokine IL-1 leads to upregulation of presence of iNOS mRNA and iNOS protein and NO itself via activation of IL-1 receptor on the cell surface and following dissociation of NF-κB from cytoplasmic complexes and thus its nuclear translocation (lane 4). In particular, Figure 38-2 shows that CTS itself does not induce the inflammatory cascade for NO (lane 1), while CTS is clearly downregulating the inflammatory pathway of NO (lane 2). Resting chondrocytes in the control group do not show activation of the proinflammatory NO signaling cascade (lane 3).[5,36]

Chondrocytes in the tangential layers of cartilage are most responsive to IL-1β and synthesize high levels of iNOS as compared with chondrocytes in the deeper layers.[20,21] As shown in Figure 38-3, immunochemical staining for iNOS shows the distinct presence of inflammatory response in chondrocytes following exposure to inflammatory signals alone in comparison to simultaneous exposure to mechanical and inflammatory signals. Absence of the iNOS-protein occurs in control groups and during CTS alone (see Figure 38-3, *A* and *B*). About 35% of all chondrocytes are iNOS-positive cells representing the cells derived from the tangential layer of articular cartilage (see Figure 38-3, *C*). This population of chondrocytes is most likely the one that is also responsive to CTS, showing a 62% decrease of iNOS protein immunostaining (see Figure 38-3, *D*).

These in vitro findings provide evidence that mechanical signals play an important and critical role as modulators of inflammatory joint diseases. CTS functions as a potent effector mechanism for suppressing pathologic effects of IL-1β in vitro through inhibition of inducible



• **Figure 38-2** Nitric oxide (NO): A marker of inflammatory cell response during (*lane 1*) motion (cyclic strain), (*lane 2*) motion and inflammation (interleukin-1 [IL-1]), (*lane 3*) experimental control, and (*lane 4*) inflammation (IL-1) alone. (From Gassner R, Buckley M, Studer R, et al: Cyclic tensile stress exerts antiinflammatory properties by inhibiting iNOS induction in chondrocytes, *J Immunol* 163:2187-2192, 1999.)



• **Figure 38-3** Immunochemically stained protein inducible nitric oxide synthase (iNOS) (brown color) during **(A)** control – no motion, **(B)** motion alone, **(C)** inflammation alone (interleukin-1 [IL-1]) alone, and **(D)** motion and inflammation (IL-1 IL-1β. Motion inhibits inflammation.). (From Gassner R, Buckley M, Studer R, et al: Cyclic tensile stress exerts antiinflammatory properties by inhibiting iNOS induction in chondrocytes, *J Immunol* 163:2187-2192, 1999.)

NO production.[5] It is likely that in vivo mechanical signals may exert their effects on arthritic joints in a similar manner by inhibiting the inflammatory effects induced by IL-1β via interruption of iNOS expression. In turn, this would limit the production of NO and its catabolic effects on cartilage. Furthermore, mechanical signals do not only inhibit NO production, but also upregulate proteoglycan synthesis at concentrations of IL-Iβ frequently observed in inflamed arthritic joints, suggesting that the actions of mechanical signals are clinically relevant in suppressing the sustained effects of pathological levels of IL-1β in vivo. Maintaining anabolic capabilities of chondrocytes within inflamed joint tissue is an additional anti-inflammatory asset for the treatment of arthritic conditions.

The Arthritic Condition and Continuous Passive Motion in Vivo

Immobilization versus Continuous Passive Motion

Destruction of cartilage integrity is a hallmark of arthritic conditions as evidenced in a rabbit model of antigen-induced arthritis (AIA).[12] The histopathogenesis of AIA has been well characterized, and the model demonstrates many features of human rheumatoid arthritis (RA), including joint inflammation and damage to articular cartilage via both increased breakdown and decreased synthesis of cartilaginous matrix.[32-34] To evaluate the molecular basis of interaction between motion and inflammation, the in vivo model compares inflamed cartilage behavior where cartilage is subjected to either of two different conditions: (1) IMM or (2) motion (CPM). Given that maintenance of cartilage integrity is due to chondrocyte function, regulation and control of proinflammatory molecules in inflamed cartilage depends on the presence of biomechanical signals. Mobilization clearly prevents cartilage degradation. CPM protects matrix integrity in AIA-afflicted articular cartilage. Inflammation is mainly driven by monocytic cells in immobilized knees as compared with CPM knees. CPM downregulates the proinflammatory cytokine IL-1β mRNA expression and synthesis in inflamed chondrocytes (Figure 38-4). CPM suppresses COX-2 synthesis in inflamed cartilage (data not shown). Finally, CPM suppresses MMP-1 synthesis in inflamed chondrocytes (Figure 38-5). CPM upregulates IL-10 synthesis in inflamed cartilage (Figure 38-6).

Joint mobilization is suggested to disseminate the inflammatory exudates, whereas IMM is suggested to create a stagnant environment in the synovium, leading to increased inflammation and cartilage damage. Although these effects of mobilization and IMM cannot be excluded, the fact that mechanical signals directly interfere with the proinflammatory gene induction in chondrocytes suggests that mechanical signals regulate inflammation at the intracellular level. The in vitro and ex vivo data demonstrate that chondrocytes are mechanosensitive cells and respond to mechanical signals in a magnitude-dependent manner.[33-38] For example, cyclic tensile or compressive forces, in the presence of inflammatory signals, induce matrix synthesis in chondrocytes and fibrochondrocytes.[35-38] The in vivo findings confirm the in vitro and ex vivo data and demonstrate that mechanical signals act directly on chondrocytes to prevent cartilage destruction due to inflammation. Appropriate mechanical signals play a profound role in attenuating localized joint inflammation in vivo. These signals act on inflamed chondrocytes by two equally important mechanisms. First, these signals are potent inhibitors of proinflammatory gene induction and inhibit expression of catabolic mediators, such as IL-1β, COX-2, and MMP-l. Second, these signals induce expression of the anti-inflammatory cytokine IL-10. Together, the results demonstrate that biomechanical signals have profound effects in minimizing cartilage destruction in a severe

proinflammatory environment and provide continuing evidence that motion-based therapies are more efficacious than perceived earlier.[12]

Arthritides of the Temporomandibular Joint

More than 10% of the population suffers from arthritic diseases leading to pain, loss of function, disabilities, and joint replacement and economically measured as major loss of human productivity and especially early retirement.[5,6,12] In the United States alone, more than 40 million people suffer from some form of arthritis; among these, 12 million have osteoarthritis (OA) and 8 million have RA. Arthritis is also the most common disease affecting the TMJ. All of the arthritic forms that involve other joints in the body occur in this joint, too. Therefore, these conditions are to be considered in the differential diagnosis whenever a patient presents with chronic TMJ pain and dysfunction.[39-45]

Arthritic diseases of the TMJ are inflammation-derived alterations of the synovium, cartilage, and surrounding structures such as the capsule, bursa, tendons, and bone. Similarities of signs and symptoms of the many variants of arthritis necessitate the establishment of a working differential diagnosis based on the patient's history, physical examination, and radiographic evaluation distinguishing these conditions from other causes of TMJ symptoms.

Patient evaluation includes questions regarding swelling, redness, pain at rest, duration of symptoms, rate of onset, location of involved joints, pattern of joint involvement, preceding events such as trauma, and time of day when symptoms are worse. Discussion of medications influencing symptoms and a thorough review of organ systems follows.[39-41,46] Physical examination extends beyond the involved joints, as the skin, heart, lungs, and mucous membranes are often affected by the same disease process. Involved joints are observed for deformity, symmetry, and proximity. Palpation of these areas assesses pain, temperature, and range of motion.

Diagnostic studies also include radiologic studies (magnetic resonance imaging [MRI], computerized tomography [CT] scan, and bone scans), laboratory tests, and synovial fluid analysis.[39-41,43,46] Normal synovial fluid is clear or straw colored and viscous from hyaluronic acid. Viscosity is reduced in inflammatory arthritides, and the synovial fluid flows like water—unlike the stringing produced by normal synovial fluid. Evaluation of cell counts, clot formation, and differences between serum and synovial glucose levels can aid in the diagnosis and differentiate arthritic conditions.

The presence of crystals and evaluation of their size, shape, and compensation under polarized light can be useful in the diagnosis of metabolic arthritides.[39-41]

Classification of Arthritis

Symptoms and signs of the different arthritic diseases are similar. Yet, clinically individual conditions can be distinguished.

1. Traumatic arthritis
2. Degenerative (osteo)arthritis
3. Inflammatory arthritis:
   a. Rheumatoid arthritis
   b. Juvenile rheumatoid arthritis
   c. Psoriatic arthritis
   d. Ankylosing spondylitis
   e. Reiter syndrome
4. Infectious arthritis:
   a. Gonococcal arthritis
   b. Syphilitic arthritis
   c. Tuberculous arthritis
   d. Lyme disease–associated arthritis
5. Metabolic arthritis:
   a. Gout
   b. Pseudogout
6. Arthritides associated with connective tissue diseases: systemic lupus erythematosus, scleroderma, chronic inflammatory bowel disease, reflex sympathetic dystrophy, and sarcoidosis.

Traumatic Arthritis

The immediate intra-articular response of the joint tissues to single or repetitive episodes of acute trauma is release of proinflammatory cytokines starting a cascade of inflammatory events.[46] This response, traumatic arthritis, is manifested in the form of pathologic and clinical states, the nature of which is generally determined by the magnitude of the trauma sustained by the joint tissues.[39,40] *Minor trauma* to the joint tissue may result in compression, or shearing of the retrodiscal tissue and capsule or dislocation of the disc.

Moderate trauma may cause damage to the synovial lining, resulting in subsequent edema and mild serohemorrhagic effusion that can cause hemarthrosis and an inflammatory response in the synovial membrane. This inflammation may eventually result in a hypertrophic synovial response and fibrosis, causing cicatricial contractions and adhesions between the joint components and even fibrous ankylosis. In children, traumatic arthritis can cause growth abnormalities, malocclusion, and facial asymmetry. *Severe trauma*, short of producing a condylar fracture, can cause damage to the articular surfaces, subchondral bone, or both, eventually predisposing to or causing degenerative joint disease.

Clinical Findings

Acute traumatic arthritis presents with severe jaw pain both at rest and with movement. The joint is tender to palpation, is occasionally swollen, and has a decreased range of motion. Effusion in the joint space and edema or hemorrhage in the retrodiscal tissue can cause an increased distance between the articulating components on the traumatized side that results in a posterior open bite. The acute symptoms usually subside within a few days or weeks.[47] In cases of severe trauma, however, the condition may eventually progress to persistent limitation of motion, ganglion formation, intra-articular disc derangement, or degenerative joint disease.

Imaging Findings

As a result of edema and swelling, the intracapsular and capsular structures can increase in thickness. This can be reflected radiographically as an increased distance between the roof of the glenoid fossa and the condylar surface in the closed-mouth position. Late severe traumatic changes in the joint may be manifested as degenerative joint disease or as bony ankylosis.

Diagnosis

A thorough history must be taken and a careful physical examination of the TMJ must be performed after injury to exclude presence of condylar or other mandibular fractures. The diagnosis of traumatic arthritis of the TMJ is based on a history of trauma and on the absence of the characteristic features of the other forms of arthritis. Trauma to the TMJ can aggravate the inflammatory status of other preexisting forms of arthritis. The use of arthroscopy to evaluate the intra-articular disc and for lavage of the joint after condylar trauma has been reported, but the long-term benefit of such a procedure is still uncertain.[48,49]

Degenerative (Osteo)arthritis

Osteoarthritis is the most common form of arthritis affecting the human skeleton and is related to increased mechanical loading, physical stress, and traumatic injury of the joint. Consequently, the joints most often affected are the weight-bearing joints such as the hips, spine, and knees. Hand joints are also commonly affected, especially in women. Systemic, genetic, endocrinologic, metabolic, and/or vascular factors, in combination with local mechanical factors, influence the development and progression of the disease.[39-41]

OA is also the most common disease affecting the TMJ. Radiographic evidence of OA of the TMJ occurs in 14% to 44% of symptom-free individuals, and histologic evidence of the disease occurs in 40% to 60% of studied populations.[50] However, clinical evidence of the disease occurs in only 8% to 16% of the population. OA of the TMJ has a strong predilection for women and affects patients at any age, but is more prevalent beyond the age of 40 years. Generally OA is unilateral, although bilateral involvement does occur; in these cases, one side usually shows greater severity.[39-42]

OA characteristically affects the articular cartilage of synovial joints and is associated with simultaneous remodeling of the underlying subchondral bone and secondary

involvement of the synovium. Synonymous terms such as osteoarthrosis, arthrosis, and arthritis deformans are commonly used in Europe, whereas osteoarthritis, degenerative joint disease, and degenerative arthritis are the most commonly used terms in North America.

Clinical Findings

The large weight-bearing joints are predominantly affected by OA. A gradual onset is followed by a chronic course. When the TMJ is affected, the patient usually complains of pain and tenderness in the joint and masticatory muscles. The patient may also complain of jaw muscle fatigue, stiffness and tiredness, difficulty opening the mouth, reduced range of motion, and crepitation during mandibular movements.[51] Osteoarthritis is usually characterized by a lack of morning jaw stiffness; if present, this stiffness lasts no more than 30 minutes.[39,40] The TMJ symptoms may be present in the absence of similar symptoms in other joints of the body. Because of the bony thickening and marginal osteophyte formation in the mandibular condyle, a palpable swelling may occur over the joint.

Although radiographic changes in the TMJ may be observed bilaterally, symptoms may be unilateral. Other associated symptoms include referred head and neck pain and earache. OA may affect the TMJ primarily (primary OA) as a result of the normal wear and tear of the joint components that occur with aging. This form of OA usually begins in the fifth decade of life, with slow onset, and runs a course of mild symptoms. The other form of OA of the TMJ is secondary and is usually associated with macrotrauma or chronic microtrauma. This form affects patients 20 to 40 years old and produces more symptoms than the primary form. In these patients, the symptoms may be associated with chronic myofascial pain and dysfunction (MPD) or intra-articular disc derangement.[39-42,52]

Articular cartilage receives its nutrition from the synovial fluid, not the subchondral bone. After maturity of the epiphyseal plate, perforating vessels can no longer supply the cartilage with nutrients or remove waste products. Changes in the synovial fluid therefore influence the metabolism of the cartilage.[53,54]

Many hypotheses regarding the initial event triggering OA have been postulated, including mechanical, inflammatory, and chemical insults that release collagenases and proteolytic enzymes, causing degradation of the cartilage. Abnormal and repetitive mechanical stresses may exceed the functional capacity of normal articular tissues. The result is a decreased collagen stiffness, leading to increased hydration of the proteoglycan-water gel.[53] Other hypotheses suggest that cartilage breakdown is the result of weakness of the subchondral bone secondary to microfractures from excessive loading. Inflammatory mediators and waste products are also likely causes of degeneration. Alterations of synovial fluid or reduced quantities, causing improper lubrication and nutrition of the cartilage, may also play a role. These phenomena lead to friction of the cartilage and collagen destruction.[55]

Early in OA and chondromalacia, which are indistinguishable, the water content of the cartilage matrix is increased from swelling and breakdown of the collagen fibrils.[41,51,56] Proteoglycans are depleted, and chondrocytes cluster while proliferating in an attempt to repair. These histologic findings are manifested mostly in the deeper layers of cartilage, sparing the superficial layer until advanced disease develops, which may take years.[57] As the disease progresses, chondrocytes degenerate and synovial cells destruct, releasing proteolytic and collagenolytic enzymes; this results in more degradation. As the process advances, tissues lose integrity, and the cartilage splits and fibrillation occurs. This leads to adhesions as the cartilage thins. The marrow contained within the subchondral bone then fibroses. Macroscopic changes identifiable on radiographs include osteophyte formation, sclerosis, surface erosions, subchondral cysts, and deformations. Extra-articular responses such as muscle pain and atrophy may be evident as the mandible length is altered and the occlusion changes.[58]

Although OA may develop without disc displacement, internal derangements are highly correlated with TMJ OA.[39-41,59,60] Cartilage degradation, altering the sliding properties of the joint surfaces, and alterations of the synovial fluid, giving rise to increased friction and adhesive wear, impair disc movement.[45] Degradative products from the OA cartilage are then released into the synovial fluid. When it is produced in large quantities, it cannot be reabsorbed by the synovial membrane or cleared. Mediators of inflammation are also released in response, causing synovitis. The osteoarthrosis and synovitis is termed osteoarthritis. The synovial membrane is not innervated, but the mediators of inflammation produced by the synovium stimulate capsular nociceptors.[61] This leads to joint tightness and continued stretching and elongation of the attachments, causing anterior displacement. Limitation of the mandibular opening can then ensue from the malpositioned disc. The peridiscal tissues, such as ligaments and muscles, are also subject to alteration from the changes in the articular surface. As the posterior attachment elongates, the nociceptors within the tissue are stimulated, causing pain. As the ligaments are subjected to tensile forces from the altered frictional capacity and elongation, they extend beyond their span of elasticity and deform. As they elongate, the collagenous component of the ligament is disrupted and the tissue may rupture or lacerate. It is these ligamentous attachments of the disc that keep it anchored to the condylar head and resist displacement. As the functional limits of the ligament are exceeded, nociceptors are stimulated, causing sprains and pain.[58] Anteriorly displaced discs are also subject to compressive loads placed on their posterior attachment. Maladaption, inflammation, and perforation are then possible as the inflammatory process continues. However, these are not the only adaptive changes that occur. There can be decreased vascularity and elastin content as collagen increases and fibrosis occurs. This can act as a pseudodisc and withstand compressive loads. Autopsy studies revealed that 50% of elderly patients had joint degeneration, although no disc

problems were reported in life. Eighty percent of patients with displaced discs had similar findings. This may suggest that displaced discs are a sign of OA, not a cause of OA.[62]

Classification and findings of TMJ OA should include the stage of cartilage destruction and the grade of synovitis rather than the degree of internal derangement. As reported by Dijkgraaf and others,[63] TMJ cartilage degeneration can be separated into four stages. In the *first stage* of OA, the initial repair stage, an imbalance of synthesis and degradation of extracellular matrix by chondrocytes is encountered. Growth factors, including insulin-like growth factor I, become evident in this stage.[63] Electron microscopy reveals increased metabolic activity, with increased DNA synthesis evident in chondrocytes and increased synthesis of the extracellular matrix. In the *second stage* of OA, the early stage, extracellular matrix synthesis increases but is exceeded by degradation from the increased activity of proteases. Cartilage swelling ensues, resulting in an irregular surface and a net loss of articular cartilage.[40,58] Characteristic clusters of chondrocytes with increased metabolic activity in the swollen areas are also seen. Chondrocyte and cartilage necrosis follow in all cell layers, leaving attempts at repair disorganized.[59] Synovial fluid analysis during this early stage reveals metabolic products of arachidonic acid, IL-1, IL-6, TNF-α, and other proteases. Arthroscopic examination reveals swelling, softening, and fibrillations. Common clinical complaints during this phase include pain and limited range of motion. In the *third stage* of OA, the intermediate stage, articular cartilage is lost as synthesis is exceeded by degradation. Histologic evaluation reveals thinning, vertical splitting, and fibrillations of the cartilage as clusters of chondrocytes continue to necrose. Staining of proteoglycan continues to be reduced, and the collagen network becomes more haphazard. Biochemical markers such as cytokines and fibronectin continue to fill the joint space. Arthroscopically, cartilage continues to thin, and a displaced disc may be evident. Pain with limited range of motion continues and can now be accompanied by joint clicking. In the *fourth stage* of OA, the late stage, increased degradation exceeds synthesis or reduced degradation equals decreased synthesis. Histologically, fibrillations are extensive, bone becomes denuded, and proteoglycan staining is nearly lost. Extracellular matrix synthesis is reduced, whereas protease activity can be reduced or increased if residual OA is occurring. Arthroscopic evaluation is remarkable for severe fibrillations, exposed bone, disc displacement, and possibly angiogenesis.[39-41]

Imaging Findings

Radiographic studies of OA of the TMJ reveal an incidence of 40% in patients older than 40 years and 100% in patients older than 80 years. Approximately 50% of the population has radiographic changes, but only 30% of these patients are symptomatic.[39,40] Because OA affects the articular cartilage first, the early changes may escape radiographic detection, or the radiograph may only show a reduced joint space, indicating loss of the articular cartilage and/or perforation of the disc. The most common early radiographic change in the condyle is subchondral bone sclerosis because of thickening of the subchondral bony plate. As the disease progresses, there may be flattening and marginal lipping of the condyle and flattening of the articular eminence. In the late stages of the disease, the changes are in the form of erosion of the cortical plate, osteophyte formation, or both. Occasionally, in the late stages of the disease, subchondral bone breakdown may also occur, causing the formation of a bone "cyst" within the condyle.[39,40]

MRI of the TMJ with OA may reveal perforation, damage, or displacement of the articular disc, whereas osseous changes are best delineated by computed or linear tomography.[28,89] High-resolution ultrasonography may also be a valuable diagnostic aid for the detection of abnormal condylar morphology in OA.[64]

Laboratory Findings

A combination of arthroscopy and synovial fluid analysis is useful as an important diagnostic modality for the early detection of OA. Recent studies using synovial fluid analysis have shown a correlation of pain and disease progression with TNF-α, interleukin 1β, stromelysin, and bradykinin.[65-68] Keratan sulfate levels in the synovial fluid are higher in joints that had arthroscopic evidence of early OA than in normal joints.[65]

The synovial fluid aspirate may show a slight elevation of white blood cells (often less than 2000/μL) and fewer than 30% polymorphonuclear cells, and rheumatoid factor is usually absent.[40] The ESD is usually normal or only slightly elevated, and high values may only be present when the disease has an acute inflammatory component.

Diagnosis

The diagnosis of OA is based mostly on clinical findings and radiographic studies and is usually easy to make when the typical features of the disease are present. The most difficulty is encountered in differentiating OA from early MPD and from RA. Therefore, the differential diagnosis of OA of the TMJ should include RA and its variants, MPD, and various forms of intra-articular disc derangement. Features distinguishing OA from MPD include the more localized nature of the pain, the frequent presence of joint tenderness, and the presence of joint crepitation in the former. When both conditions are present concurrently, as is often the case, the history may help determine which is the primary condition.[40,42]

Inflammatory Arthritis

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic inflammatory disease that primarily affects the periarticular structures such as the synovial membrane, capsule, tendons, tendon sheaths, and ligaments. It secondarily involves the articular cartilage and subchondral bone. The prevalence of RA among the general population is about 2% to 2.5%, with a female-to-male predilection ratio of 2.5 to 3.0:1 and a peak onset of the

• BOX 38-1 Classification Criteria for Rheumatoid Arthritis

Morning stiffness (>1 hour)
Swelling (soft tissue) of three or more joints
Swelling (soft tissue) of hand joints (PIP, MCP, or wrist)
Symmetric swelling (soft tissue)
Subcutaneous nodules
Serum rheumatoid factor
Erosion and/or periarticular osteopenia, in hand or wrist joints, seen on x-ray

The first four of the listed criteria must be continuous for 6 weeks and observed by a physician. Diagnosis requires at least four criteria.

Approximately 50% to 75% of patients with rheumatoid arthritis have involvement of the temporomandibular joint during the course of the disease.[40,57,70-72]

disease between the patient ages of 40 and 60 years.[69,70] To guarantee uniformity in investigational and epidemiologic studies, the American College of Rheumatology has developed classification criteria (Box 38-1).

Clinical Findings

The disease often has an insidious onset and runs a slow, chronic course with progressive destruction of the articular soft tissues and eventual destruction of the cartilage and bone. It has asymmetric, polyarticular involvement, and the small peripheral joints are affected first (wrists, elbows, and ankles). It then progresses symmetrically toward the central skeleton, involving the knee, shoulders, and cervical spine. In the advanced stages, when the inflammatory tissue infiltrates the articular cartilage and bone, erosion and destruction of the articular disc, cartilage, and subchondral bone result.[73]

Such total destruction causes joint deformity and loss of joint function. Joint deformity may also result, in part, from involvement of the tendons, muscles, and ligaments.[39-41,46] RA also has characteristic extra-articular and systemic features that include ocular involvement such as episcleritis, iritis, and keratoconjunctivitis; pulmonary features such as pleurisy, pleural effusion, and fibrosis; cardiac features such as pericarditis and cardiac arrhythmias; vasculitis causing skin ulcerations and osteoporosis; and the presence of subcutaneous nodules in pressure and friction areas in 20% to 25% of patients. Systemic signs and symptoms of RA include fatigue, weight loss, fever, and anemia.[40] When RA is present in combination with anemia, neutropenia, thrombocytopenia, and hypersplenism, the condition is called *Felty syndrome*.[40,74]

A close relationship exists between involvement of the TMJ and the severity of the systemic disease. When the TMJ is involved, it is bilateral in 34% to 75% of those patients.[72] Signs and symptoms of TMJ involvement include deep, dull, aching pain in the preauricular area, especially during function; muscle tenderness with decreased bite force; limited range of motion; crepitation or clicking; and morning joint stiffness.[55,75-77] The pain is occasionally referred to the temporal region and angle of the mandible. As the disease progresses, the condylar bone is resorbed and scar tissue is formed between the joint surfaces and within the joint capsule. This causes further limitation of movement of the jaw.[39,40]

Mandibular movement may be severely limited in the late stages of the disease. This is usually caused by fibrous ankylosis and rarely by bony ankylosis.[78] Perhaps the most striking feature of advanced RA affecting the TMJ is development of a progressive class II malocclusion and anterior open bite deformity with impairment of chewing and phonation. This deformity is caused by loss of normal ramus height secondary to destruction of the mandibular condyles.

Imaging Findings

Because RA is primarily a soft tissue disease, the early stages are characterized by the absence of radiographic changes. Even when these changes are present, they lack specificity and are difficult to interpret. However, with the use of MRI, changes such as disc destruction and/or displacement, condylar cortical bone erosion, joint effusion, and cartilage irregularity and thinning can be seen.[79,80] Once bone is involved in the later stages of the disease, radiographic changes in the TMJ occur in 19% to 84% of patients[55,71]; the incidence and severity of these changes are related to the duration of the disease.

The radiographic features of RA of the TMJ include loss of joint space, condylar destruction, and flattening and anterior positioning of the condyle. This may be accompanied by flattening and anterior positioning of the condyle as well as flattening of the articular eminence and erosion of the glenoid fossa.[81-83] In advanced stages of the disease, the radiographic changes may include a sharp, pointed condyle, osteophyte formation, lipping, shortened posterior ramus length causing premature posterior occlusion, an anterior open bite, and deepening of the antegonial notch.[39,40]

Laboratory Findings

RA has an autoimmune component, with 80% of RA patients testing positive for an immunoglobulin (Ig) directed at the Fc region of IgG known as rheumatoid factor (RF). High titers of RF have been correlated with severe joint destruction and subcutaneous nodules. Testing for RF by latex agglutination or sensitized sheep cell agglutination detects IgM antibodies, although IgG, IgA, IgE, and IgD antibodies have been described. IgM antibodies have the ability of complexing with five IgG molecules and are believed to be the cause of synovial inflammation. Smaller molecules, such as IgG antibodies, are believed to participate in the systemic manifestations and vasculitis common to this disease. Despite the strong association of RF with RA, it is not found only in this disease state. Chronic antigen presentation, as seen in diseases such as bacterial endocarditis, tuberculosis, viral infections, and advanced age, has also resulted in the formation of RF. None of these states is associated

with HLA-DR4, suggesting that the etiology may result from a combination of RF with the genetic antigen.[41,60] Other test results that are less specific for RA include a decreased serum albumin level and the presence of antinuclear antibody (ANA) in 15% of RA patients. HLA-Dw5 and HLA-DRw antigens are also both positive in 50% of RA patients.[39-42,46]

The preliminary diagnosis of RA is frequently based on clinical and radiographic findings, and laboratory tests are used to confirm the diagnosis. The most commonly used test is for RF, which is positive in 70% to 80% of patients with RA. Although the test is not totally diagnostic, it has a good diagnostic and prognostic value when the factor is present in high titers (above 1:1280). In these patients, the disease has a more severe and progressive course. However, the test is also occasionally positive in patients with one of the rheumatoid variants and in approximately 5% of healthy subjects.[84]

The Westergren erythrocyte sedimentation rate (ESR), although not a highly specific test for RA, is elevated in approximately 90% of patients during active stages of the disease, and the test often is used to follow the course of the disease.[77] The complete and differential blood cell counts frequently show a normal white blood cell count, although leukocytosis or leukocytopenia can occur in patients with RA. An elevated platelet count may accompany the stages of high activity of the disease, while mild anemia is reported in approximately 25% of patients. Most of the latter patients have a normochromic or slightly hypochromic, normocytic anemia. Synovial fluid aspirated from a joint with RA is usually cloudy; the viscosity is reduced and the white cell count is high (greater than 20,000/μL).

Diagnosis

The criteria for diagnosis of generalized RA are based on the presence of several clinical, radiographic, and laboratory findings for at least 6 weeks.[39,40,46] The diagnosis of RA of the TMJ is frequently less difficult because involvement of the TMJ often occurs in the advanced stages of the disease and, at that point, the diagnosis of RA has already been established. In these instances, the signs and symptoms, along with the positive radiographic findings, form the basis for diagnosing involvement of the TMJ by the disease.[84] However, in the absence of an already established diagnosis, the differential diagnosis of TMJ involvement should include psoriatic arthritis (PA), ankylosing spondylitis (AS), gout, and OA.

Differentiation of RA from the rheumatoid variants is based on factors such as age of the patient, pattern of involvement (symmetry), number and type of joints involved (polyarticular and peripheral joints), presence of rheumatoid nodules, and, to a lesser degree, laboratory findings (positive RF). Differentiation of RA from OA is less difficult and also is based on the clinical and radiographic findings and, to a greater extent, on some of the laboratory tests.[85]

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA; also juvenile rheumatoid arthritis, JRA) is a chronic inflammatory involvement of the joint lining that has an onset before the age of 16 years. The overall prevalence of JIA is uncertain, but estimates of the number of children affected in the United States range from 30,000 to 250,000.[86] The disease occurs predominantly in girls, with a female-male ratio of 2:1 to 3:1, and it has two peaks of onset, one between the ages of 1 and 3 years and the other between the ages of 8 and 12 years.[39-41]

The reported TMJ involvement in patients with JIA varies considerably, mostly because of the difference in the methods of examination in different studies. Nonetheless, up to 41% of children with JIA have TMJ involvement, with significant adverse effects on occlusion, oral health, and facial growth.[87-89]

Clinical Findings

Based on the manifestations of the disease during the first 6 months and a number of other factors, JIA is classified into three major subtypes: systemic, polyarticular, and pauciarticular. The latter two are often further subdivided into two subtypes.[46]

Systemic JIA, called *Still disease,* occurs mostly in boys 5 years of age or younger, can affect any joint, and is usually accompanied by several systemic signs, including high fever, a rheumatoid rash, cardiopulmonary involvement, lymphadenopathy, and hepatosplenomegaly. The major complication of this disease is cardiac failure, but the majority of patients go into remission with minimal or no residual articular complications. Generally, patients in this subtype are seronegative for both RF and ANA.

Polyarticular JIA involves more than four joints and has fewer systemic signs. This subtype can be seropositive for RF and ANA in 50% of patients. The major complication of this subtype is the long-term possibility of deformity and disability from the polyarthritis.[74]

Pauciarticular JIA affects girls more often than boys, involves four or fewer joints, and has fewer systemic signs. This subtype usually affects large joints such as the knee, hip, and sacroiliac, but patients rarely experience severe arthritis. Patients in this group are generally seronegative for RF, but the ANA test is positive in 60% to 80% of patients.[40,90] The major hazards of this subtype are iridocyclitis and blindness. The prognosis for articular disability is greater than with the other two forms of JIA.

Although the TMJ can be involved in any of these subtypes, it is mostly affected by the polyarticular subtype. The clinical features of JIA of the TMJ include pain, joint tenderness, crepitation, stiffness, and decreased range of motion.[87-89] Some patients may even develop fibrous or bony ankylosis.

A characteristic feature associated with advanced JIA of the TMJ is a combination of micrognathia and a Class II skeletal deformity[91,92] and is frequently referred to as bird-face deformity. This deformity is a result of the impaired growth of the mandible caused by destruction of the

condylar growth site. Alterations in the soft tissues adjacent to the TMJ, such as scarring of the capsule and ligaments and changes in muscle strength, also can interfere with the normal growth processes of the mandible. The prevalence and severity of such deformity in patients with JIA of the TMJ are influenced by the age of onset and the duration of the disease. The prevalence of this deformity ranges from 0% to 38%.[78,92]

Imaging Findings

The early radiographic changes of JIA of the TMJ may not be visible on a conventional radiograph. However, these changes can be detected on MRI and include cortical bone erosion, disc thinning and perforation, reduction of the joint space, and pannus and effusion in the joint.[92-94] The radiographic changes usually appear late, and the severity of these changes is generally related to the duration of the disease. The radiographic findings in JIA of the TMJ in general resemble those of the adult disease and include erosion of the superior surface of the condyle (leaving a flat, horizontal, or inclined articular surface). The eminence may be eroded and flattened to the same degree as the condyle.

In advanced stages of the disease, these changes may significantly affect growth of the mandible and face. The mandible appears micrognathic, with a downward and backward rotation of the chin and an anterior open bite. This deformity is associated with radiographic evidence of deepening of the antegonial notch.[47,95,96]

Laboratory Findings

Laboratory findings in patients with JIA are not consistent and, when present, the abnormality varies with the mode of onset. RF is positive in 5% to 20% of patients with JIA, mostly with the pauciarticular and polyarticular subtypes, while the ANA test is positive mostly in patients with the pauciarticular subtypes (60% to 80% of these patients). Other laboratory findings, including low-grade anemia, leukocytes, thrombocytopenia, and elevated ESR, may also vary according to the subtype of JIA.

Diagnosis

A diagnosis of JIA of the TMJ is often not difficult to make because involvement of the TMJ usually occurs in the later stages. Because of the presence of fever and generalized arthralgia with the onset of systemic JIA, the differential diagnosis should include bacterial infection, viral polyarthritis, traumatic arthritis, infectious arthritis, and joint involvement with rheumatic fever.

Psoriatic Arthritis

Psoriasis is a dermatologic disease that affects approximately 1% to 2% of the general population. It is characterized by a rash of silvery scales affecting the elbow, scalp, and back. Approximately 5% to 7% of patients with psoriasis develop psoriatic arthritis.[97-99] In 75% of these patients, skin lesions appear before the joint symptoms, whereas arthritis appears first in 10% to 15% of patients; in another 10% to 15% of patients, the symptoms appear simultaneously.[100] PA is an inflammatory, mostly asymmetric, oligoarticular, seronegative arthritis that affects a limited number of joints including those of the hand, knee, and foot.

Reports on the disease incidence relative to sex differ from a predilection for males to equal predilection for males and females.[49,50] The onset of the disease is usually between the ages of 35 and 45 years. PA affecting the TMJ was first described by Franks.[101]

The cause is probably multifactorial, but histocompatibility studies support a propensity for the condition to be associated with several other systemic conditions such as Crohn disease; Reiter, Behçet, and Sjögren syndrome; and aortic incompetence.[46] Heredity and a history of trauma are significant factors in the development of PA.[40,100,102]

Despite the prevalence of PA in other joints, fewer than 35 cases of PA of the TMJ have been reported in the English literature.[103-105] However, some authors suggest that involvement of the TMJ with PA is more common and could be as great as 20%.[106] When PA affects the TMJ, the onset of symptoms occurs by the fourth decade of life and is usually associated with a history of trauma.[107,108]

Clinical Findings

The arthritic changes of PA are mostly limited to the distal interphalangeal and metacarpophalangeal joints, but occasionally may extend to the proximal interphalangeal joints, producing characteristic sausage-shaped digits. Systemic symptoms of PA include fever, fatigue, myalgia, weight loss, and malaise. Joint symptoms include morning stiffness and pain, swelling, and limitation of motion. Other associated symptoms may include nail dystrophy in the form of pitting and oncolysis in 80% of patients, and eye symptoms including conjunctivitis, iritis, and uveitis.[98]

Based on the presence of different clinical features, four distinct patterns of PA are currently recognized: (1) arthritis affecting mostly the distal interphalangeal joints; (2) severe arthritis affecting single or multiple joints, with widespread bone destruction and ankylosis; (3) seronegative polyarthritis that may be difficult to distinguish from seronegative RA; and (4) arthritis that is characterized by the presence of sacroiliitis, spondylitis, and peripheral joint involvement, as well as the presence of HLA-B27 antigen.[40,46]

PA of the TMJ often is unilateral, has a sudden onset, is episodic in nature, and may have a spontaneous remission. Symptoms include pain and tenderness of the joint area and the muscles of mastication, morning stiffness, tiredness in the jaws, joint crepitation, occasional painful swelling of the TMJ capsule, and painful mandibular movements associated with a progressive decrease in the interincisal opening.[103] In severe cases, ankylosis of the TMJ may occur.[104]

Imaging Findings

Radiographic changes associated with PA may be seen in as many as 82% of patients with affected TMJs and include erosion, flattening, osteoporosis, loss of joint mobility, and extreme joint space narrowing. Subchondral bone cysts,

subluxation, and ankylosis are also observed occasionally.[79,106,108,109] The radiographic changes are nonspecific and cannot be easily distinguished from those of other types of arthritis, particularly RA and AS.

Diagnosis

Because the symptoms of TMJ involvement are generally nonspecific, the diagnosis of PA of the TMJ is difficult and is made mainly on the basis of the systemic presentation of the disease. In general, the diagnosis is based on a triad of (1) psoriasis, (2) radiographic evidence of erosive polyarthritis, and (3) a negative serologic test for RF. However, even in the presence of a skin rash, the diagnosis of PA cannot be absolutely confirmed. The differential diagnosis of PA should always include entities such as RA, Reiter syndrome, AS, and gout.

Ankylosing Spondylitis

Ankylosing spondylitis is a disease known by many other terms, but two of the most commonly used are *Marie-Strümpell disease* and *seronegative spondylitis*. It is a chronic and usually progressive inflammatory disease that primarily affects the axial skeleton, most commonly the sacroiliac joint and the vertebral column. When the disease spreads to the peripheral joints, the most commonly affected are the hips, shoulders, knees, wrists, hands, and TMJ. The disease has a prevalence of 0.4% to 1.6% among whites, with a strong familial tendency.[45] It affects both sexes, with a predilection for men up to 10 times greater that for women, and has an onset between the ages of 20 and 30 years.[40,46,110]

When affected, the TMJ is usually involved several years after the onset of the systemic disease and frequently during the late stages of spinal and peripheral joint involvement. Although only sporadic case reports of AS of the TMJ have been published, involvement with AS is reported to occur in 4% to 50% of such patients.[111-113]

Clinical Findings

The clinical signs and symptoms of AS generally arise from chronic inflammation of the synovial tissues and joint capsule and sites of insertion of ligaments and tendons. The inflammation later progresses to ossification and eventually causes limitation of joint motion. In the spine, this results in low back pain and stiffness that are usually worse in the morning but that can be alleviated by mobility and exercise. In the late stages, fusion of the adjacent vertebrae and fixation of the back in extreme flexion causes decreased spinal mobility, lumbar lordosis, and increased thoracic and lumbar kyphosis with limitation of chest movement. The back pain may be referred to the buttocks and the posterior aspect of the leg. Extra-articular manifestations of AS include iritis or anterior uveitis and cardiac symptoms such as aortic insufficiency and conduction defects.[46]

When the TMJ is affected, pain, stiffness, limitation of jaw movements, and, in advanced cases, ankylosis of the joint may occur.[114-116] Often the severity of the TMJ involvement correlates with the severity of the spinal and peripheral involvement, although TMJ symptoms have been reported in patients with only a slightly affected spine.

Imaging Findings

The radiographic features of the disease usually include ossification of ligaments and tendons and sclerotic fusion between the vertebrae. In the late stages of the disease, calcification of the annulus under the paraspinal ligaments gives rise to the characteristic "bamboo spine" appearance. The pelvic radiographs usually show fusion of the sacroiliac joint and sclerotic widening of the margins of the pubic symphysis.[114]

The radiographic features of AS in the TMJ are nonspecific and are observed in 30% of patients. These features usually involve erosive changes in the condyle and fossa, subchondral sclerosis, and osteophyte formation. In the later stages of the disease, narrowing of the joint space and radiographic evidence of restricted anterior translation of the condyle may be detected.[114,115,117]

Laboratory Findings

AS characteristically has a hereditary component; the incidence of occurrence of HLA-B27 antigen is higher in patients with AS than in patients with any other disease of the inflammatory arthritis group. An elevated ESR is reported in as many as 70% of patients with AS, although the test is generally nonspecific and serves only as a rough gauge of the disease. Tests for RF are generally negative.[40,41,46]

Diagnosis

Because of the similarities among RA, PS, and AS, the differential diagnosis should include these entities. However, some features exist that may be helpful in distinguishing AS from the other two conditions. These include involvement of the sacroiliac joint, which, although possible with any of the other types, is only common in AS and is rare in RA. Furthermore, whereas AS may involve peripheral joints, it usually spares the small joints of the hands and feet. Although radiographically apparent erosive changes and narrowing of joint space and osteophyte formation are common in all three diseases, localized or extensive sclerosis is more common in AS, whereas cortical erosion and subcortical bone cyst formation are more common in RA.[39,40,45]

Reiter Syndrome

Classically, Reiter syndrome (RS) is a triad of arthritis, conjunctivitis, and urethritis occurring mostly in men between the ages of 20 and 30 years. More recently, additional frequent features of the disease have been recognized, including mucocutaneous lesions and cardiac and central or peripheral nervous system involvement. The exact cause of the disease is unknown, but the frequent presence of HLA-B27 alloantigen in the patient population has been established. The disease occurs mostly in young men after venereal infection and in both men and women after dysenteric infection.[70] Hans Reiter first described RS in 1916, when a lieutenant in the Prussian army developed the three typical features.[118]

The arthritis in Reiter syndrome often involves multiple joints (resembling RA), but affects mainly the lower extremities. Involvement of the TMJ is rare, but some authors believe its incidence may be grossly underreported because of the lack of specific clinical or histologic features of the disease.[119,120]

Clinical Findings

The manifestations of the disease include development of urethritis, conjunctivitis, and finally arthritis either sequentially or simultaneously. Fever, fatigue, weight loss, and lymphadenopathy often accompany the arthritis. Both the urethritis and the conjunctivitis can develop and resolve without sequelae, or they can cause long-lasting urologic and ocular complications. Skin lesions, known as keratoderma blennorrhagica, may occur on the palms, soles, and glans penis. As many as 80% of patients with Reiter syndrome may show oral lesions in the form of 1- to 10-mm papules on the lips, gingivae, buccal mucosa, and tongue.[107]

When the TMJ is affected, the symptoms are generally acute and asymmetric and include tenderness, erythema, and warmness of the joint.[119]

Imaging and Laboratory Findings

Radiographically, bony changes in the joints affected by Reiter syndrome are only observed in the late stages and consist of erosion of the condyle and loss of the joint space.[119,120] The laboratory findings are mostly nonspecific and may include an elevated ESR, leukocytosis, mild anemia, and negative tests for RF and ANA. Serologic evidence of recent infection and an HLA-B27 marker may be present.[70]

Diagnosis

The diagnosis of Reiter syndrome is clinical and is based on the triad of symptoms that are present in 70% of patients in the first 10 days. However, only the presence of seronegative, oligoarticular, asymmetric arthritis and urethritis is adequate for diagnosis of the syndrome. The differential diagnosis should include PA and other forms of reactive arthritis, such as those associated with ulcerative colitis and regional enteritis and that occurring after intestinal bypass surgery.

Infectious Arthritis

General

Although infectious or septic arthritis of the TMJ is frequently considered a possible complication of such systemic diseases as tuberculosis, syphilis, and gonorrhea, only 22 cases have been reported.[40,121] Some authors attribute the small number of reported cases to misdiagnosis or underreporting and suggest that misdiagnosed septic arthritis in children may account for a significant percentage of cases of mandibular ankylosis.[122,123]

Infectious arthritis can involve the TMJ by direct extension of local odontogenic infections via the pterygomandibular space, from osteomyelitis of the mandible (Figure 38-7), or from parotid, ear, or throat infections.[124] Direct infection can also occur as a result of inoculation of organisms into the joint space during traumatic injury or joint surgery.[125]

The other major route of infection of the TMJ is from a systemic disease such as gonorrhea, syphilis, tuberculosis, or actinomycosis.[40] Risk factors for TMJ infection include the presence of RA, diabetes mellitus, intravenous drug abuse,[126] burn wounds,[127] sexually transmitted diseases,[128] preexisting joint disease,[129] trauma, and steroid therapy.[40,46]

Despite the decreased incidence of some of the systemic infectious diseases known to predispose to septic arthritis, an increase in the frequency of septic arthritis can be expected in the future because of the large number of immunocompromised patients with acquired immunodeficiency syndrome (AIDS) and the wider use of immunosuppressive agents. This form of septic arthritis may be either bacterial (including chlamydia) or fungal in origin.[78,130] Another form of infectious arthritis that can have serious consequences involves infection of a joint prosthesis. Such infection can occur immediately after implant placement or later from hematogenous dissemination of bacteria.[46] However, despite several reports of such infections in the orthopedic literature, only two cases involving the TMJ have been reported.[126]

Clinical Findings

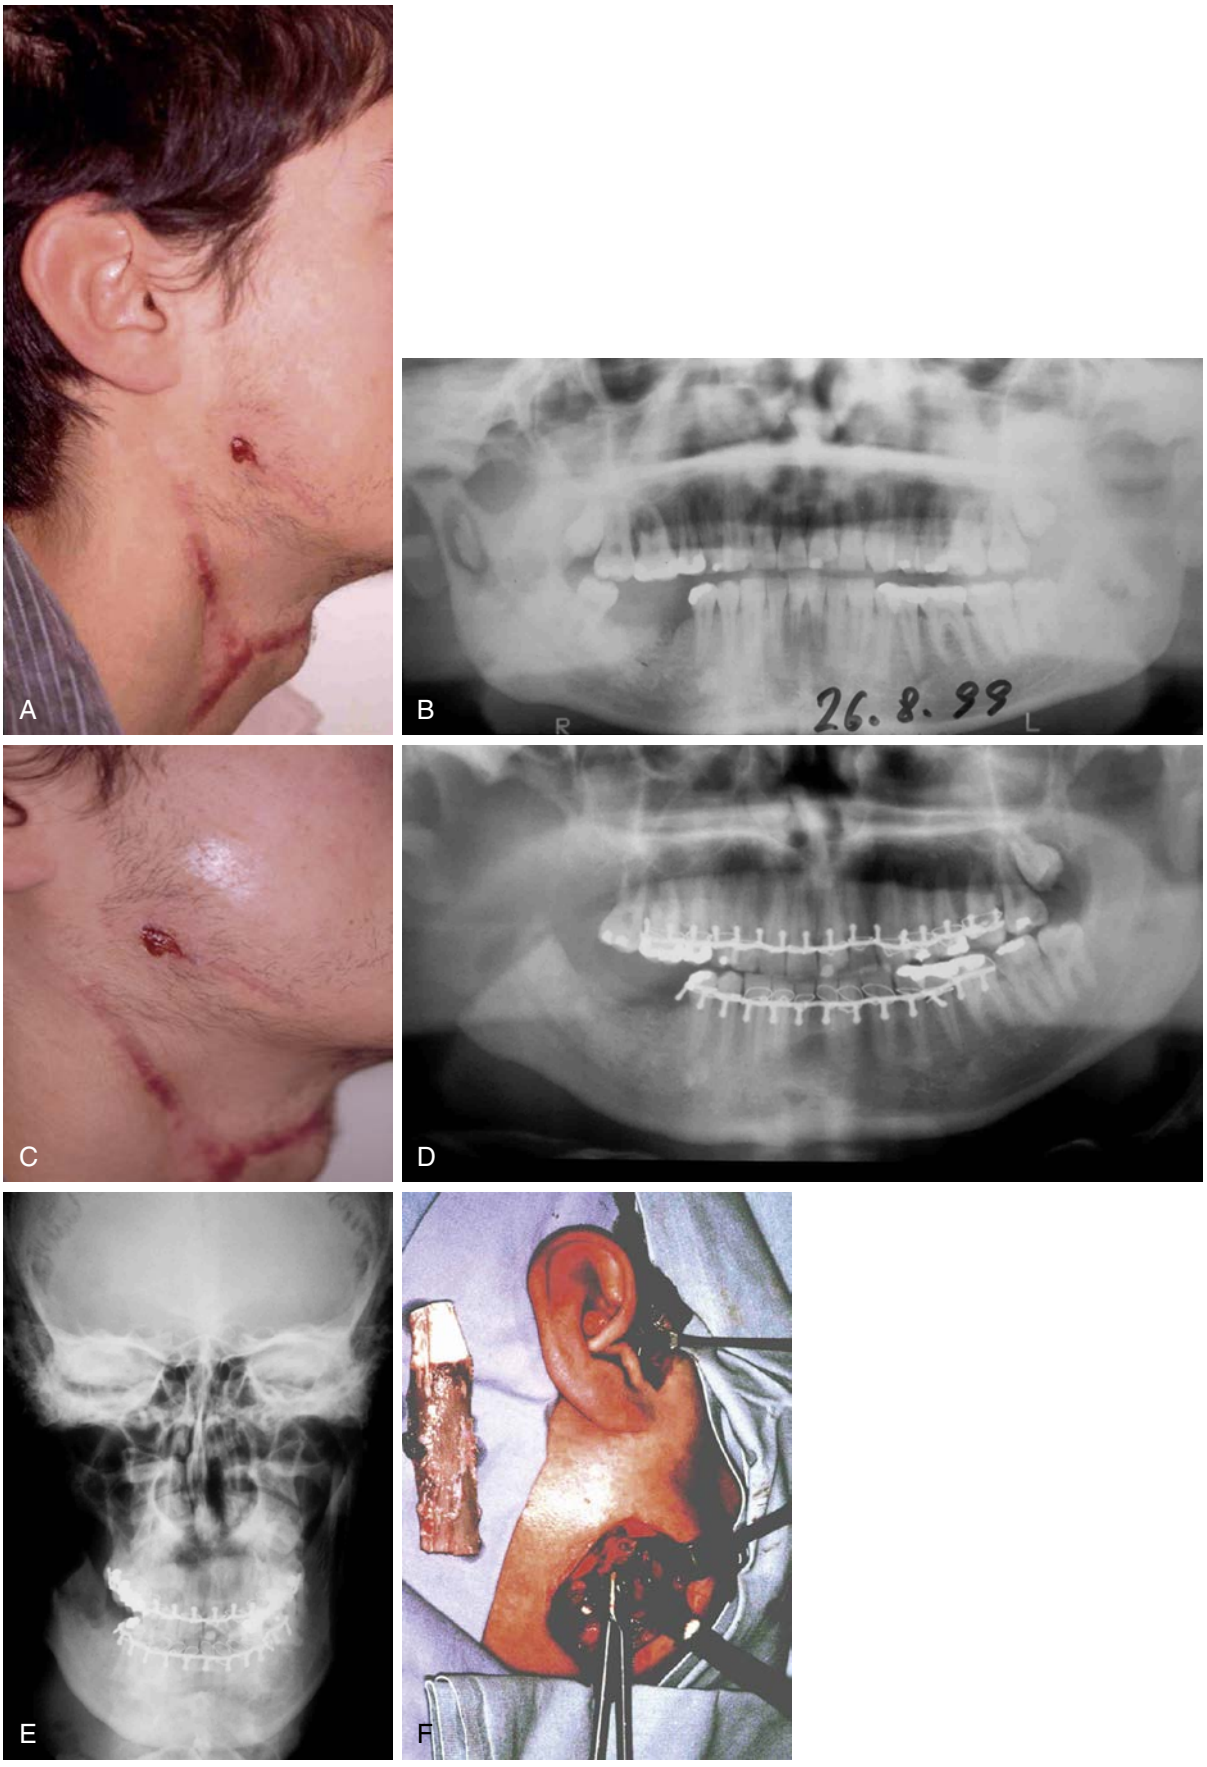
When the cause of the infectious arthritis is systemic, the joint symptoms may be preceded by a prodromal period of symptoms of the primary disease. The acute presentation of septic arthritis includes signs of malaise, fever, chills, sweating, and regional lymphadenopathy. The affected joint (usually one side) is painful, tender, swollen, warm, and erythematous. Movement of the mandible is usually limited and typically elicits severe pain. Occasionally, malocclusion, deviation of the mandible to the contralateral side, and a posterior open bite will occur secondary to the increased amount of joint fluid.

Fluctuation may be present in the region of the joint if the fluid collection is not drained. If septic arthritis is left untreated, it may progress to complete destruction of the condylar cartilage and bone, causing ankylosis, which in children may cause underdevelopment of the mandible and facial asymmetry later in life.

Imaging Findings

Because no bony involvement occurs in the first 7 to 10 days of infectious arthritis, radiographic changes are not demonstrable.[78] However, because of accumulation of intra-articular fluid or pus, a separation of the articular surfaces, in which the mandibular condyle is in a more anteroinferior position, can be seen on either a panoramic radiograph or CT scan of the joint. Later, if the infection is left untreated, bony changes range from destruction of the articular cartilage to total destruction of the joint.

MRI can be used to detect intra-articular pus or accumulation of exudate,[39,40] although it is not helpful in



• **Figure 38-7** Clinical case of infectious arthritis deriving from molar dental infection followed by live threatening mediastinitis and proceeding into condyle osteomyelitis. **A,** Side view of patient with incision scars at the right submandibular neck and pus drainage at the mandibular angle. **B,** Preoperative panoramic radiograph with affected right condyle and TMJ. **C,** Close-up side view. **D,** Panoramic radiograph after resection of right condyle. **E,** Anteroposterior radiograph after resection of right condyle. **F,** Osteochondral rib graft, preauricular and submandibular access.

distinguishing infection from inflammatory, traumatic, or degenerative processes in the joint.[40] A bone scan usually shows an increased uptake in the joint capsule in the presence of septic arthritis, and it can detect bone changes sooner than other imaging studies.[121]

Laboratory Findings

Laboratory tests for septic arthritis in the presence of systemic signs should include a complete blood cell count, a differential cell count, ESR, C-reactive protein determination, and blood culture. Joint fluid should be aspirated for analysis and culture whenever feasible. The aspirated fluid should be examined with a Gram stain, culture, and antibiotic sensitivity testing, a complete blood cell count, and a differential cell count. Glucose and hyaluronic acid levels also should be analyzed. These levels are usually decreased. Typically, the aspirated fluid from an infected joint contains cloudy exudate and sometimes pus. The number of leukocytes is elevated, and the cells are predominantly of the polymorphonuclear type.

Although bacterial growth is obtained in only 62% of cases,[121] when positive it confirms the diagnosis of septic arthritis. The most commonly isolated organism from patients with septic arthritis of the TMJ is *Staphylococcus aureus*,[131,132] although isolation and growth of other organisms, such as gonococci[128] and viruses,[133] have also been reported.

Diagnosis

The diagnosis of septic arthritis should be considered in all cases of monoarthritis associated with high-grade fever, acute severe pain, and tenderness of the TMJ. The diagnosis is confirmed by identification of the organism in the joint aspirate. In the absence of such a laboratory finding, the clinical presentation, radiographic features, other positive laboratory values, and response to antibiotic therapy should provide a basis for the diagnosis.[40,41,134] The differential diagnosis should include RA with acute exacerbation, JIA, PA, traumatic arthritis, viral polyarthritis, disseminated malignancy, and gout.

Lyme Disease–Associated Arthritis

Lyme disease (named after the town of Lyme, CT) is a multisystem disorder that involves the skin, joints, nervous system, and heart. It is caused by the spirochete *Borrelia burgdorferi* and is mostly transmitted by the tick *Ixodes dammini*.[135] Although the disease usually affects only one or two large joints, often the knee, the TMJ can also be involved.[136,137]

Clinical Findings

The initial presentation of the disease is marked by the appearance of a characteristic skin lesion called erythema chronicum migrans (ECM), a clinical marker for Lyme disease. ECM begins as a red macule or papule at the site of a tick or insect bite. Days to a month later, the lesion expands to an average diameter of 10 cm (range, 8 to 68 cm), with partial clearing of the center of the lesion. The outer borders become red and generally flat, while the center is indurated, vesicular, or necrotic. The lesions are usually warm but not painful. They are frequently associated with constitutional symptoms such as fever, malaise, headaches, and regional lymphadenopathy.[138] Generalized lymphadenopathy and splenomegaly are less common findings.

Within a few days to months of the onset of ECM, secondary lesions develop. These lesions are similar in appearance to the ECM but are usually smaller, migrate less, lack the indurated centers, and are not associated with tick bite sites. In some patients, the secondary lesions are associated with a malar rash, conjunctivitis, or, rarely, with a diffuse urticaria.[46] Other systemic signs include neurologic involvement, which appears at the same time as the ECM or weeks to months later. They also include meningoencephalitis, vertigo, short-term memory loss, numbness or tingling of the extremities, atypical facial pain, and bilateral facial nerve paralysis. Cardiac abnormalities are less common, can last from a few days to several weeks, and may be recurrent. They include atrioventricular block, myopericarditis, and cardiomegaly.[138]

Musculoskeletal involvement by Lyme disease occurs in approximately 60% of patients and appears from a few weeks to 7 years after the onset of the disease. The arthritis is usually manifested as a migratory polyarthritis or myalgia

associated with joint swelling. Months to years later, frank arthritis occurs, characterized by intermittent attacks of painful swelling of one or two large peripheral joints such as the knee. The pain is often episodic and of short duration, followed by periods of complete remission and then recurrence. The affected joints are usually swollen and may be warm but are rarely erythematous. Occasionally, joint involvement is polyarticular and symmetric, including the small joints of the hands and feet.

In approximately 10% of patients with arthritic signs of Lyme disease, the condition evolves into chronic arthritis, causing deformity and disability.[46]

Diagnosis

Because many of the signs and symptoms of Lyme disease are nonspecific and may mimic TMJ involvement from other causes, the diagnosis can be difficult, especially in the early stages. Therefore, these conditions should be included in the differential diagnosis. The diagnosis of Lyme disease can be facilitated by a history of tick bite and skin rash. In the absence of such a history, the diagnosis is more difficult, but the presence of an immunoglobulin M antibody to spirochetes may be a helpful diagnostic test.

B. burgdorferi has also been cultured from the skin lesions of ECM and from several body fluids, including the synovial fluid of affected joints.[138,139] Lyme arthritis that persists after antibiotic treatment is correlated with persistence of the spirochete in the synovial fluid.[138,139] Other laboratory findings useful in the diagnosis include an elevated white blood cell count in the synovial fluid (approximately 25,000/μL) that consists mostly of neutrophils, and an elevated serum aspartate aminotransferase.[40,46]

Metabolic Arthritis

Gout and Pseudogout

Gout (uric acid arthritis) and pseudogout (pyrophosphate arthropathy, chondrocalcinosis articularis, and calcium pyrophosphate dihydrate arthropathy) are the two main types of metabolic arthritis affecting the TMJ.[78,140] They are characterized by inflammation of the joint tissues caused by deposition of microcrystals in the synovium. In gout these crystals are sodium urate, and in pseudogout they are calcium pyrophosphate dihydrate.

Gout is characterized by an increase in the serum level of uric acid, generally arising from an inherited anomaly that causes an increase in purine (and uric acid) production and/or a decrease in the excretion of uric acid in the urine. However, it may also be caused by an increase in uric acid production resulting from blood dyscrasias (where cells rich in purine are broken down) or by use of certain medications, such as diuretics.

Pseudogout is regarded by some as an independent disease that often occurs in association with other metabolic diseases, such as hyperparathyroidism and diabetes mellitus.[78] Gout is uncommon in men and women younger than 40 years. It mostly affects men older than 40 years. A suggestion of genetic inheritance exists, with a family prevalence that varies from 40% to 60%. The disease is often associated with tophi (urate deposits) in and around the ear and joints of the extremities, renal disease, uric acid nephrolithiasis, and some degree of renal failure. Although the prevalence of gout is 5% among men 65 years and older and 2% among women of the same age,[140] only a few cases of TMJ involvement have been reported.[140,141] The exact prevalence of pseudogout in the TMJ is uncertain, but it frequently affects persons after the age of 40 to 50 years and has an equal sex predilection.[141,142]

Clinical Findings

The clinical presentation of a metabolic arthropathy is quite characteristic. The onset is usually sudden and is most often monoarticular, affecting the proximal interphalanx of the great toe, the ankle, and the wrists and causing pain and swelling in about 50% to 70% of patients. The affected joint is usually erythematous, warm, and extremely tender. In the acute presentation of the disease, the patient may feel ill and feverish.

When the TMJ is involved, the patient's ability to open the mouth wide and masticate is significantly decreased.[140,142-144] Occasionally, the onset and presentation may be less dramatic in the TMJ than in other joints, and the signs and symptoms are less severe. The latter include mild pain, limited mouth opening, and noise in the joint.

Imaging Findings

Radiographic changes do not become apparent in the joint until several years after the onset of gout. Although no specific radiographic features exist for gout, the changes in the advanced form of the disease have been described as bony erosion, "punched-out" cystic lesions of the bone, bone spurs, and exostoses.

In the case of pseudogout, osseous tophi within the joint and calcification of the disc may be demonstrable in the radiographs. The crystal deposits may have a punctate or linear appearance.[78,142]

Laboratory Findings

Typically, the serum uric acid level is elevated in gout. Aspiration of joint fluid reveals an opalescent fluid. Monosodium urate crystals are present when the fluid is examined under the polarizing microscope. Acute attacks are generally associated with leukocytosis and an elevated ESR. In pseudogout, the serum uric acid is increased in only 30% of patients.[78]

Diagnosis

The diagnosis of gout can be readily made if the disease presents in its acute form. If the symptoms are mild, determination of the serum uric acid level may be helpful. Because the serum uric acid level may also be increased in numerous other conditions, the diagnosis can only be confirmed by identification of uric acid crystals in the synovial fluid or in the surgical specimen. The monosodium urate crystals are needle shaped and have a strongly negative birefringence

when examined by compensated polarized light microscopy. In the absence of such findings, a past history of acute synovitis (especially in the great toe), a history of renal colic, and a family history of gout make the diagnosis more likely. The differential diagnosis of gout should include septic arthritis, pseudogout, acute RA, PA, OA, and local trauma.

Arthritides Associated with Connective Tissue Diseases

Systemic lupus erythematosus (SLE) is a chronic autoimmune multisystem disease arising from a combination of genetic and environmental factors that interact to cause a state of immune hyperactivity. Systems that SLE commonly may affect include the brain and peripheral nervous system, skin, joints, kidneys, lungs, serous membranes, and components of the blood, but other organs of the body also may be affected. The characteristic immune response is caused by certain self-antigens and involves both T- and B-cell activity. One of the most common symptoms of SLE is symmetric polyarthritis, most frequently occurring in the fingers, knees, and wrists. TMJ involvement has been found in a few studies.[45,145,146] In a controlled study of SLE patients, one third had subjective TMJ symptoms, 22% had clinical signs, and 11% had radiographic changes.[45,146]

Scleroderma

Progressive systemic sclerosis is a generalized disorder of connective tissue recognized clinically by thickening and fibrosis of the skin (scleroderma) and specific forms of involvement of organs including the heart, lungs, kidneys, and gastrointestinal tract. Scleroderma occurs in all racial groups and in all geographic regions, showing the highest onset between the ages of 30 and 50 years. The disease is three to four times more frequent in women. Because better diagnostic techniques are now available, the prevalence may be higher than previously recognized. The precise incidence remains undefined, but most studies suggest between 4 and 12 subjects per million per year.[147] Characteristic oral manifestations that may complicate dental treatment include limited mouth opening, TMJ dysfunction, mucogingival problems, xerostomia, telangiectasia, increased periodontal ligament width, and osseous resorption of the mandible.[148,149]

Mixed Connective Tissue Disease

Mixed connective tissue disease (MCTD) is a disorder showing overlapping features with a number of different connective tissue diseases. Because of the various overlapping features that have been reported, the existence of MCTD as a distinct disease entity has previously been considered controversial. Today, however, it is regarded as a distinct rheumatoid disease, although the exact prevalence is not known.[150] Clinical manifestations of MCTD often include concurrent development of features of SLE, scleroderma, polymyositis, dermatomyositis, and RA, but the overlapping features usually occur sequentially. Because of these overlapping features, it often takes several years to verify the most appropriate diagnosis. Early symptoms include fatigue, myalgia, arthralgia, and Raynaud phenomenon. Nearly all patients have joint pain and stiffness.[150] In a series of 10 patients with MCTD analyzed for signs and symptoms in the masticatory system, all 10 patients showed symptoms or signs of temporomandibular disorders, and 7 had radiographic changes in the TMJ.[151] In five patients with normal-appearing mucosa, histologic examination revealed chronic inflammation.

Sjögren Syndrome

Sjögren syndrome (SS) is a systemic autoimmune disease of unknown etiology and pathogenesis leading to xerostomia and dry eyes.[152] These "sicca" ("dry") symptoms result from an autoimmune process that often may affect other organs, such as neural systems, skin, mucosa, lungs, and kidneys. SS also can develop as a secondary phenomenon, in which the sicca symptoms are associated with RA, SLE, or scleroderma. The prevalence of primary SS, judging from blood donor subjects, has been estimated to be 0.08%. SS is sometimes associated with polyarthritis, and thus the TMJ may also be affected.[45]

Summary

More than 100 heterogenous acute and chronic conditions, some with multisystem involvement, can affect the musculoskeletal system. Clinically, the most important of these conditions that affect the temporomandibular joint (TMJ) complex are the systemic diseases of the musculoskeletal system and the systemic connective tissue disorders. The more common systemic diseases affecting the TMJ are seropositive rheumatoid arthritis and juvenile rheumatoid arthritis. Far less common diseases and disorders are ankylosing spondylitis; psoriatic arthritis; Reiter syndrome, also known as reactive arthritis; gout and calcium pyrophosphate deposition disease; systemic lupus erythematosus; scleroderma; mixed connective tissue disease; and Sjögren syndrome, chronic inflammatory bowel disease, reflex sympathetic dystrophy, and sarcoidosis.

Tumors

Tumors of the TMJ are rare. They may develop from the disc, the synovial membrane, and the articular capsule but also the articulating bones, that is, the glenoid fossa and especially the mandibular condyle. As in most other sites benign proliferations are more common than malignancies. As in other bones, the most frequently occurring malignancy is metastatic carcinoma (Figure 38-8). Despite metastatic lesions, consideration should be given to locally invasive proliferations of lymphocytic, parotid, or middle ear origin.[153-155]

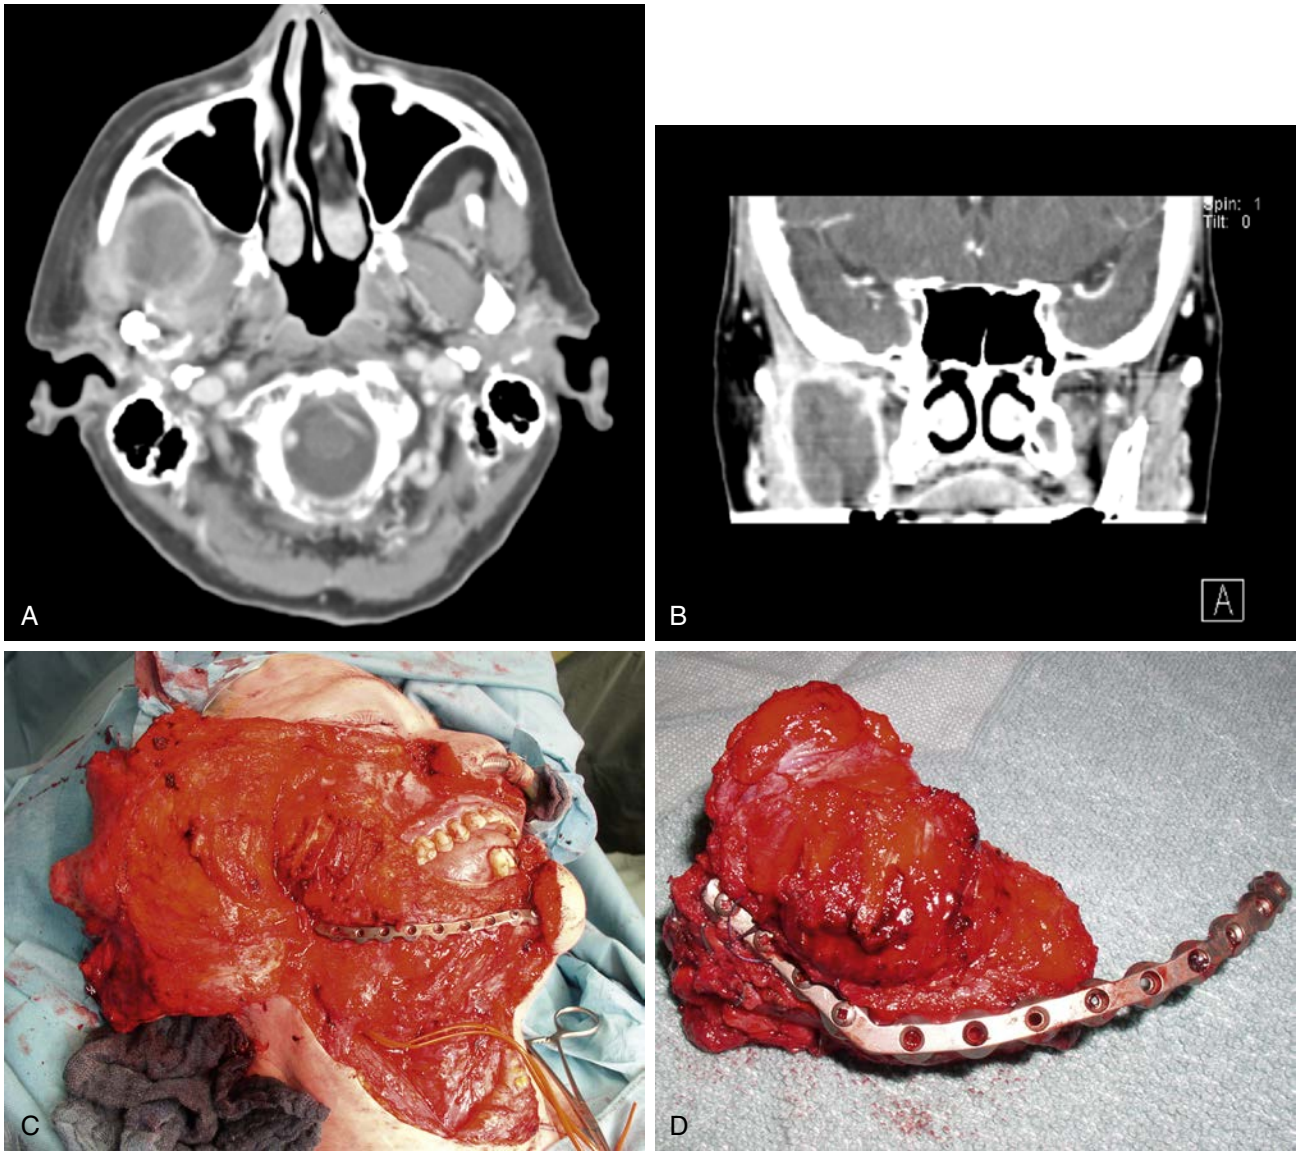
Space-occupying lesions of the TMJ may present with preauricular swelling, pain, trismus, deviation of mandibular motion, and malocclusion. All these symptoms also correlate with far more common entities within the plethora of

temporomandibular disorders. Therefore immediate correct diagnosis of neoplasms in the TMJ is demanding and can be delayed. Radiographic examination and interpretation is necessary, and CT and MRI techniques are often helpful. When clinical and radiographic examinations suggest the presence of a tumor, arthroscopy or open arthrotomy is warranted to obtain tissue for histologic evaluation and diagnosis.[153-158]

Although early symptoms are consistent with findings attributable to internal derangement such as limited mouth opening, jaw deviation, and clicking or popping joint sounds, the following signs are indicative of advanced disease. The tumor mass may extend into the middle cranial fossa through the roof of the glenoid fossa. It may also invade through the glenoid fossa posteriorly and present as a lesion of the external auditory canal or middle ear. Growing laterally, it may mimic a parotid neoplasm, creating a preauricular swelling. Anteromedially it can extend into the infratemporal and pterygopalatine fossae and produce symptoms of cranial nerve involvement. Pathologic fracture with sudden onset of pain may also occur.[153-155]

When formulating a differential diagnosis for any jaw lesion, it is helpful to organize the pathologic entities into several categories and then compare the characteristics of the presenting lesions with those of lesions in each category. In the field of oral and maxillofacial surgery, jaw lesions are suggested to be organized into the following six categories[155-159]:

1. Developmental cysts
2. Odontogenic cysts



• **Figure 38-8** Clinical case of tumor of the temporomandibular joint (TMJ): recurrence of an oral squamous cell carcinoma in the infratemporal region involving the right TMJ. **A,** Axial view on patient's CT scan—recurrence, right infratemporal region. **B,** Coronal view on patient's CT scan—recurrence, right infratemporal region. **C,** Access via soft tissue degloving and temporary zygoma resection. **D,** Resected tumor specimen including TMJ and attached mandibular reconstruction plate from previous surgery.

3. Benign odontogenic tumors and lesions
4. Benign non-odontogenic tumors and lesions
5. Inflammatory, metabolic, and genetic disorders
6. Malignant and locally invasive lesions

The presence of developmental cysts, odontogenic cysts, and benign odontogenic tumors in the condyle or TMJ is rare and generally represents an extension of a process that initiated in the tooth-bearing segments of the mandible. Diagnosis and management of those lesions are covered elsewhere and are not discussed here. The benign conditions that are considered here do not all represent neoplasms. Some are cystic lesions but are important in differential diagnosis. Others may be reactive or hyperplastic proliferations, in which the distinction from a benign neoplasm is often unclear.

Benign Tumors, Cysts, and Cystlike Lesions

Condylar Hyperplasia

The articular surface of a normal condyle is composed of fibrocartilage that exhibits appositional growth in contrast to endochondral ossification. Histologic sections of hyperplastic condyles demonstrate the abnormal presence of hyaline cartilage that undergoes ossification and results in abnormal growth. Therefore condylar hyperplasia can have presenting symptoms similar to those of space-occupying benign or malignant lesions, which can displace the condyle from the fossa and cause asymmetry with malocclusion. The etiology of this disorder is not well understood.

Condylar hyperplasia is categorized into two types. The type I deformity, or *hemimandibular elongation*, is the most

Figure 38-8, cont'd **I,** Intraoral soft neopalate of patient 3 years after surgery. **J,** Image of patient 3 years after surgery.

common variant. The mandible is asymmetric, with deviation of the chin to the contralateral side and a concomitant dental crossbite. In patients with the type II deformity, or *hemimandibular hypertrophy*, deviation of the chin is not a prominent feature, but a marked vertical open bite is present on the ipsilateral side of the hyperplasia.[160,161]

Condylar hyperplasia is not a truly neoplastic process but actually a self-limited disorder. Radionuclide bone scans with technetium-99m can be useful in differentiating between active and inactive disorders. Some surgeons favor the use of a high condylar shave to remove the zone of abnormal tissue if the disorder is diagnosed early in its active stage. Removal of only 5 or 6 mm of the most superior condylar surface is usually adequate, and condylectomy is unnecessarily aggressive.[162,163]

Recontouring of the inferior border and angle of the mandible is sometimes necessary to correct the inferior component of the asymmetry. When a bone scan indicates that the process is inactive, orthognathic procedures, such as a vertical subsigmoid osteotomy, can be useful in correcting an open bite while maintaining a functional joint articulation.[162,163]

Chondroblastoma

These tumors develop in the medullary cavity of a bone and are thought to arise from the cartilage of the growth plates. Thus, most cases occur prior to skeletal maturity; the vast majority occur in patients aged 10 to 20 years.

Chondroblastomas usually involve the epiphysis of the distal femur and proximal tibia. These sites are followed in frequency by the proximal humerus and proximal femur. When the tumors develop in more unusual locations, the patients are usually older. Thus, the mean age of patients with tumors of a long bone is 16 years, whereas the mean age in patients with flat and short tubular bone involvement is 28 years.[164] In the mandibular condyle the reported age range has been from 27 to 41 years,[165] and there is a 2:1 male predilection.

Pain is the dominant symptom in the extremities, but swelling or limited motion is prevalent with condylar tumors. Radiographically, they produce a well-defined radiolucency with a sclerotic margin. Flocculent radiopacities may be seen within the lesion.

Chondroblastomas of the skull and facial bones are very uncommon, but it is interesting to note that among the 30 cases reported in a single series, three arose in the mandibular condyle. Twenty-one patients had tumors in the temporal bone, and two of these also extended into the TMJ.[166]

The chondroblastoma is a benign tumor of immature cartilage cells with foci of cartilage matrix formation. The proliferating cell is believed to be a chondroblast. The cells are round to oval, with central or eccentric round to oval nuclei that may have a longitudinal cleft. These cells may be densely packed, and scattered multinucleated giant cells are usually prominent. Interspersed areas show cartilage differentiation and an immature cartilaginous matrix, which appears as an amorphous pinkish tissue. The proportion of these two types of tissue is quite variable. Calcifications tend to form a fine, "chicken wire" pattern around

the chondroblastic cells, although a coarser pattern may be present. Aneurysmal bone cysts develop in about 20% of cases.

Aneurysmal Bone Cyst

Several cases of aneurysmal bone cyst have been reported in the TMJ.[167] These lesions are not actually cysts but rather tumors in which there are widely dilated, blood-filled spaces that are not lined by endothelium. Frequently these tumors occur as a secondary phenomenon within a preexisting pathologic process, most often a giant cell tumor, but also with other conditions such as osteoblastoma, chondroblastoma, and nonossifying fibroma. There is a near-equal distribution between the sexes, and the majority arise in individuals younger than 20 years. In 32 cases in the mandible reported by Trent and Byl,[168] only 2% occurred in the condyle.

The histories concerning the cases in the condyle have varied from rapidly expanding, destructive lesions to incidental findings. The majority of patients had experienced previous trauma.

Pseudocysts

Pseudocysts of the mandibular condyle are asymptomatic radiolucencies with corticated margins. They are seen in the anterior aspect of the condyle and are the result of cupping of the pterygoid fovea; the margins are formed by the dense medial and lateral condylar ridges.

The image is the result of a radiographic distortion when the central x-ray beam does not pass through the condyle at right angles but rather passes obliquely in the horizontal plane and superiorly in the vertical plane. Consequently, the medial ridge is projected posteriorly and superiorly, and the lateral ridge is projected anteriorly and inferiorly. These "lesions" are thus not pathologic processes.

In a Veterans Affairs population of 507 patients aged 22 to 96 years, 9 (1.8%) such cases were found.[169] In a population of 1193 patients aged 18 years and younger, 18 (1.5%) such cases were found.[170]

Idiopathic Bone Cavity (Traumatic Bone Cyst, Hemorrhagic Bone Cyst, Simple Bone Cyst)

Idiopathic bone cavities in the jaw usually are located in the body or symphysis. Approximately 10 cases have been reported in the TMJ.[171] These are essentially asymptomatic lesions. When associated symptoms have occurred, they have usually been caused by a pathologic fracture.

The diagnostic criteria for an idiopathic bone cavity include the presence of a single lesion, the absence of an epithelial lining, and the absence of infection. The lumen should be empty save for some fluid or air. The wall is bony, although a scant amount of fibrous tissue may be present. Many of these cavities appear to undergo spontaneous regression. Similar lesions may be observed in association with other entities, such as florid osseous dysplasia and other fibro-osseous processes.

Central Giant Cell Granuloma

Central giant cell granulomas represent fewer than 7% of all benign jaw tumors; of these, 70% occur in the mandible. The body of the mandible is the area of predilection. There is a female preponderance, and the majority of patients are younger than 30 years. The condyle is an unusual location, although several eases have been reported.[172]

In the condyle, both unilocular and multilocular lesions have been described. Some have been asymptomatic, without functional impairment, even in the presence of preauricular swelling. Histologically, these tumors consist of randomly scattered multinucleated giant cells within a cellular fibrous stroma that also contains extravasated blood. The giant cells are osteoclastic cells, so these lesions represent an osteoclastoma.

A more aggressive giant cell lesion, referred to as a *giant cell tumor,* has been described in the jaws and facial bones but not in the mandibular condyle.[153]

Ganglion and Synovial Cysts

The literature does not always clearly distinguish these two lesions. Whereas the synovial cyst is a true cyst with an epithelial lining, the ganglion cyst is not. *Ganglion cysts* arise in a joint capsule as a consequence of myxoid degeneration of the connective tissue, possibly secondary to a deficiency in the vascular supply. They are not connected to the joint cavity. There is a female predilection with an age range of 30 to 50 years. These lesions are very rare in the TMJ area; only about 10 cases have been reported.[173]

They present as a preauricular swelling, and there may also be joint dysfunction, pain, and tenderness. Bone scans will reveal an increased uptake of technetium-99m. Histologically, these lesions are lined by fibrous tissue and contain a gelatinous material.

Synovial cysts are also uncommon in the TMJ. Five cases have been reported, two of which were associated with a history of trauma.[174] These lesions also present as a preauricular swelling. They are lined by flat or cuboidal cells, which are of synovial origin, and the lumen contains a gelatinous material. These cysts may be the consequence of herniation of the synovium or possibly the result of displacement of tissue during embryogenesis. Following trauma, increased intracapsular pressure may cause degeneration of the adjacent connective tissue.

Hemangioma

Intraosseous Hemangioma

Only five cases of intraosseous hemangioma in the TMJ have been reported.[175] Hemangiomas of bone are found most frequently in the vertebrae and are uncommon in the jaws, where their usual location is in the body of the mandible. These lesions have a 2:1 female-to-male ratio, and there is an age predilection for the second decade.

Among the patients with a lesion involving the TMJ, one was asymptomatic. The others presented with joint pain,

aggravated by movement of the mandible, as well as tenderness over the joint and restricted mouth opening.

Synovial Hemangioma

Synovial hemangiomas are rare lesions, occurring predominantly in the knee joint. They are most unusual in other sites. There is a predilection for female children and young adults.

The findings are typically recurrent, long-standing pain, decreased range of motion, and a spongy, compressible mass over the joint. They may be localized and well circumscribed or diffuse and infiltrative. These hemangiomas are of the cavernous type, with large, dilated, blood-filled vessels that are separated by an edematous, myxoid, or focally hyalinized matrix. Inflammatory cells may also be present. The synovium may develop villous projections, with hemosiderin deposition in the synovial cells.

These lesions may be juxta-articular, intra-articular, or mixed. The intra-articular type is the most frequent, and the tumor is lined by a synovial membrane. The mixed type originates from the synovium and lies both juxta-articularly and intra-articularly, whereas the juxta-articular type is located adjacent to the joint without actual involvement of the synovial membrane.

Radiographs usually reveal nonspecific radiolucencies or opacities. However, the presence of phleboliths is a helpful diagnostic feature.

TMJ involvement has been reported.[176] The case was that of a 43-year-old woman who had been treated for 3 years for masticatory myalgia associated with localized intermittent preauricular pain, restricted motion, and deviation on opening. However, there was no muscle tenderness and no preauricular mass, although there was a painful preauricular depression. Aspiration was not productive. A CT scan showed a soft tissue mass in the posterior portion of the joint. Grossly it was confluent with the synovial membrane.

Arteriovenous Malformation

Facial vascular anomalies are not uncommon findings in maxillofacial surgical patients. Many of these vascular anomalies, such as port wine stains, have a benign course. However, the subset of anomalies classified as arteriovenous malformations (AVMs) has significant morbidity and mortality. Intraosseous AVMs are particularly difficult to diagnose, may not present until adolescence or early adulthood, and often present with symptoms that mimic periodontal disease. Mandibular AVMs account for approximately 1% of all facial AVMs. A small percentage of these present in the TMJ. Death secondary to intractable hemorrhage is reported to occur in approximately 8% of patients.[155]

Treatment of these malformations continues to provide a clinical challenge. Because of the poor prognosis of untreated AVMs, radical cure is mandatory. Treatment modalities used in the past have included radiation therapy, sclerosing therapy, cryosurgery, selective embolization, and surgical resection. Resection of the malformation and the surrounding bone is considered the optimal treatment to prevent recurrence. However, profound surgical hemorrhage and significant postoperative deformity have prompted clinicians to pursue alternative treatments that may have a lower morbidity and mortality. A major advance in the treatment of these malformations has been the development of selective embolization. Selective embolization can serve as the only treatment but is often used as a surgical adjunct to provide preoperative devascularization. Reznik and colleagues[160] and Flandroy and Pruvo[161] described a technique for the treatment of mandibular AVMs in which embolization is performed through direct transosseous puncture. This technique has been further modified to perform the embolization with transosseous microcatheters.

Histologically, AVMs consist of numerous medium- to large-caliber arteries and veins that are directly connected without intervening capillary-size vessels. These vessels are supported by a variable collagenous stroma.

Fibrous Dysplasia

Fibrous dysplasia most commonly presents as an asymptomatic, slow enlargement of the involved bone. Monostotic fibrous dysplasia accounts for up to 80% of reported cases. Jaw involvement is common in this form of the disease. The entire ramus-condyle complex can be involved and present as facial asymmetry.[155] Often the clinical presentation is difficult to distinguish from that of condylar hyperplasia. The radiographic presentation is sometimes similar to that of Garre osteomyelitis.

Following a variable period of growth, fibrous dysplasia frequently stabilizes. Growth typically slows significantly after the onset of puberty. Once pathologic diagnosis is confirmed by biopsy, the only treatment required may be periodic follow-up. However, if significant cosmetic or functional deformity has occurred, surgical intervention with osseous recontouring may be undertaken.[155]

The histologic findings in fibrous dysplasia consist of a cellular, fibrous connective tissue proliferation that contains foci of irregularly shaped trabeculae of immature bone. A relatively constant ratio of fibrous tissue to bone throughout a given lesion has been described as characteristic. The collagen fibers may completely lack orientation or, alternatively, may be arranged in a storiform pattern of interlacing collagen bundles. The fibroblasts exhibit uniform spindle- to star-shaped nuclei. The bony trabeculae assume bizarre, irregular shapes, likened to Chinese characters. These trabeculae do not display any apparent functional orientation. The bone is predominantly woven bone that appears to arise directly from the collagenous stroma without prominent osteoblastic activity. In a mature fibrous dysplasia lesion, lamellar bone may be found. Aneurysmal bone cysts have been reported in association with fibrous dysplasia. It should be noted that fibrous dysplasia shares many microscopic features with the ossifying fibroma.

Nonossifying Fibroma (Fibrous Cortical Defect)

This is a common benign lesion that is generally noted as an incidental radiographic finding in the metaphyses of long bones in skeletally immature patients. It appears to be a self-limiting process that is related to incomplete ossification. It is found almost exclusively in children and adolescents. The lesion frequently resolves spontaneously. The lower extremity is the site of predilection; the distal femoral metaphysis is the most frequent site, followed by the proximal tibial metaphysis.

Occasionally these lesions are multifocal and symmetric. Multiple lesions have been associated with neurofibromatosis and are also found in Jaffe-Campanacci syndrome.

Nonossifying fibromas are typically asymptomatic, but when large, they may cause some expansion and even a pathologic fracture. When found in its typical location, the radiographic appearance is pathognomonic. It appears as an eccentric cortical-based radiolucency with scalloped sclerotic margins. The overlying cortex may be considerably thinned and slightly expanded.

Involvement of the TMJ is extremely rare. Several cases have been reported in the neck of the condylar process.[177-179] These lesions have not caused joint dysfunction and are typically asymptomatic. The jaw lesions appear to be more common in females, whereas in the long bones more males are affected.

Histologically, the lesion consists of a cellular fibroblastic stroma with a storiform pattern. Some multinucleated giant cells and foci of foamy histiocytes are present, and hemosiderin is visible in the stromal cells. Some mononuclear inflammatory cells are usually present.

Cystic change, hemorrhage, and necrosis may occur, and secondary aneurysmal bone cysts have developed. The nonossifying fibroma tends to stabilize at puberty and heals by peripheral sclerosis or solid opacification.

Osteochondroma (Osteocartilaginous Exostosis)

The osteochondroma constitutes about 35% of all benign bone tumors. It is a hamartomatous proliferation that arises from endochondral bone and is thus usually found in the long bones, most frequently the distal metaphysis of the femur and proximal metaphysis of the tibia. Patients are usually younger than 20 years, and there is a 2:1 male predilection. Tumors of the mandibular condyle occur over a much wider age range and have a 2:1 female predilection.

Seventy-five percent are solitary lesions, and 25% are multiple lesions. Multiple osteochondromatosis is an autosomal-dominant hereditary disorder. In these cases, about 11% undergo sarcomatous change, in contrast to 1% of solitary lesions. However, no cases of sarcomatous change have been reported in the mandibular condyle.

Osteochondromas occur infrequently in the mandibular condyle. They form an exophytic mass emanating from the cortex that may cause limited mouth opening, jaw deviation, and unilateral open bite. The radiographic appearance of an osteochondroma of the condyle is pathognomonic. A tapering radiopaque mass extends from the anteromedial aspect of the condyle along the tendon of the lateral pterygoid.

Histologically, the bony mass is covered by a cap of fibrocartilage and hyaline cartilage of varying thickness and cellularity, which is surrounded by the fibrous tissue of the perichondrium. In the deepest aspect of the cartilage, where it interfaces with bone, endochondral ossification occurs.

Spontaneous regression of an osteochondroma has occurred in rare instances.[180] This is most likely due to cessation of growth of the cartilage cap and subsequent resorption and incorporation of the lesion into the cortex through appositional growth. Cessation of growth may also be the consequence of a pathologic fracture. It is also possible that involution of the cartilage cap may result in the lesion resembling an osteoma.

Osteoma

Osteomas occur in several clinicopathologic guises, and frequent sites of involvement include the cranium, mandible, facial bones, orbit, and paranasal sinuses. In the condyle, osteomas usually appear as spherical or lobular enlargements. They may even have a pedicle. They generally consist of dense lamellar cortical bone that is well circumscribed, but a cancellous form also has been described. Although usually occurring as single, isolated lesions, osteomas may also arise in the condyle as part of Gardner syndrome.[153]

Osteoid Osteoma

These tumors are very uncommon in the jaws. One case has been reported in which the inferolateral aspect of the mandibular condyle was involved.[181] The patient was a 21-year-old woman who experienced trismus and spontaneous pain that, in the classic presentation of this tumor, occurred essentially at night. The radiographic appearance was also classic, in that it appeared as a subcortical nodule, 0.8 cm in diameter, with a sclerotic border.

Osteoid osteomas consist of active osteoblasts that deposit abundant osteoid to form a small nidus within normal bone. The lesion generally does not exceed 1.0 cm in diameter.

In general, osteoid osteomas are found in the 10- to 25-year age group, and there is a 3:1 male predilection. About half the cases involve the lower extremity. They have a limited growth potential and may undergo spontaneous regression.

Benign Osteoblastoma

Osteoblastomas do not occur frequently in the jaws. In this region, the most common site is the body of the mandible, but several cases involving the TMJ have been reported.[182]

Most osteoblastomas arise in the vertebrae and long bones, with a 2:1 male-to-female ratio. The average age of patients is 17 years, and the age range is from the first through eighth decades. The sex and age distributions of TMJ lesions are similar to those in other locations.

They are typically well-circumscribed, solitary lesions that expand within the medullary cavity and exceed 1 cm in diameter. They often produce a tender swelling. When osteoblastomas occur in the TMJ, there is often a history of trauma and, as in other locations, a tender swelling is the frequent presentation. In some cases, there is not only an expanding deformity of the condyle but also a secondary deformity of the glenoid fossa.

These neoplasms, as in the osteoid osteoma, consist of active osteoblasts that lay down abundant osteoid. The osteoblasts are concentrated along the osteoid seams. The fibrous stroma is very vascular with numerous dilated capillaries. Because of the vascularity of the lesion, angiography and scintigraphy are diagnostically useful.

Pigmented Villonodular Synovitis

This term is applied to a group of fibrohistiocytic lesions that involve joints, tendon sheaths, bursae, and adjacent fascial and ligamentous tissues. They are believed to represent a reactive inflammatory process. However, the fact that there may be bone destruction and a significant rate of recurrence suggests a locally aggressive neoplastic process.[183]

Essentially, these are destructive lesions that produce villous and nodular protrusions of the articular and extra-articular synovial membranes. They have been divided into intra-articular (diffuse and localized) and extra-articular (diffuse and nodular) forms. However, the nomenclature and classification involving these lesions have not been consistent.

They are relatively rare lesions, constituting fewer than 5% of all primary soft tissue tumors, and occur over a wide age range, with a peak in the third and fourth decades. Most are located intra-articularly. Eighty percent of cases involve the knee (including both diffuse and local types). The nodular extra-articular form (also called *pigmented villonodular tenosynovitis* or *giant cell tumor of tendon sheath*) is seen predominantly in the finger, carpal, and metacarpal joints.

These lesions are very rare in the TMJ. The majority are extra-articular, although this cannot always be confirmed. Although only about 22 cases have been reported in the literature, approximately a third of them have extended into the temporal bone and middle cranial fossa.[184]

Among the presenting symptoms, preauricular swelling is the most frequent. Hearing loss and tinnitus arising from compression of the auditory canal, as well as pain, trismus, and clicking, may also be present. Some cases have occurred in conjunction with synovial chondromatosis.

Histologically, the lesions consist of fibroblasts, mononuclear histiocytic cells, and irregularly interspersed multinucleated giant cells. Scattered and clustered foamy histiocytes are present, giving the lesion its yellow color, and there is abundant hemosiderin, responsible for the brown color. The hemosiderin may be found in the synovial cells and macrophages or lying free in the proliferative connective tissue, associated with multinucleated giant cells. The irregular villi are covered by thickened synovium or may be denuded. The histiocytes and giant cells are of monocyte-macrophage origin.

The histologic components of the different fibrohistiocytic lesions under this rubric are similar; the distinction is in the clinical presentation and behavior. Localized lesions are well circumscribed and may be partially encapsulated, whereas the diffuse lesions exhibit infiltrative and destructive growth. Thus the overall prognosis is more favorable for localized disease. This issue has not been addressed directly in the reported TMJ cases, but it is clear that many of these cases did behave in an aggressive fashion.

Synovial Chondromatosis

This uncommon entity has generally been considered to represent a non-neoplastic, metaplastic process. However, certain characteristics suggest the possibility that it may be neoplastic. The evidence of monoclonal chromosomal changes has given this theory strong support.[185] In addition, not only may synovial chondromatosis (SC) recur, but also the cartilaginous component may exhibit atypia. Synovial chondrosarcoma has also developed within preexisting SC.[186] In some cases, SC reaches considerable size and behaves in a destructive fashion.[187] SC may develop as a primary lesion or may arise secondary to trauma or another disease process such as osteoarthritis. The aggressive neoplastic features appear to be associated with the primary disease. Thus, it is possible that the primary type is neoplastic and the secondary form is metaplastic.[188]

SC usually affects the joints of the knee, hip, elbow, and ankle; approximately 70% of cases occur in the knee. It is rare in the TMJ; slightly fewer than 100 cases have been reported in the literature. In at least one reported case, the lesion developed from the disc. In the TMJ, SC occurs more frequently in females than in males and usually in the fourth through sixth decades. At other sites, there is a male preponderance and presentation generally occurs two decades earlier.

Pain is the most frequently cited symptom, followed by swelling, clicking, mandibular deviation, and limited mouth opening. CT scans and MRI can be very helpful diagnostically, although the presence of loose bodies in the joint space is not pathognomonic, because they may also be seen with intracapsular fractures and the osteoarthroses.

Initially, the lesion develops within the synovium as a proliferation of undifferentiated cells. Then fibroblast-like cells form a chondroid matrix from which cartilaginous nodules develop. This early phase has been called *stage 1.* Subsequently the nodules begin to lose their attachment and extrude into the joint cavity. The synovial fluid helps to maintain their nutrition and growth. *Stage 2* is the transitional phase, in which there is synovial involvement and detached nodules are found in the joint space. The cartilaginous foci within the synovium and joint space may calcify or even ossify, at which time the term *osteochondromatosis* is appropriate. This process commences at the periphery of the nodule and progresses inward. Eventually the nodules may coalesce to form an

irregular mass. *Stage 3* is advanced disease in which there is no longer synovial involvement and all the nodules have detached. Although the nodules or masses are typically confined to the joint space, in some cases they may erode the underlying bone or joint capsule and invade the periarticular tissues.

Cellular atypia is not unusual in SC, where large cells and binucleated cells may be observed. However, this does not indicate aggressive behavior. The most important consideration in the differential diagnosis is chondrosarcoma.[153]

Malignant Neoplasms

Chondrosarcoma

The majority of reported sarcomas arising in the TMJ have been chondrosarcomas. However, because this amounts to some 14 cases, this is still a very rare occurrence.[189] The age and sex of the patients were not known in three cases. Among the others, the age ranged from 17 to 75 years; four cases arose in the patient's fifth decade. Six patients were female and three were male.

Swelling was a consistent finding and, in most instances, pain or discomfort was also noted. Limited mouth opening and diminished hearing have also been described. Overall, chondrosarcomas constitute about 25% of primary bone sarcomas, with only 1% to 3% arising in the facial bones and jaws.

These tumors develop from mesenchymal stem cells, which show partial chondroblastic differentiation. They are typically slow-growing tumors, and the majority are low grade. They tend to show a lobular growth pattern with hypercellularity. The cells are often pleomorphic and may be binucleated. Malignant cartilage is formed but, in distinction to the osteosarcoma, no osteoid is formed directly from the malignant stroma.

High-grade tumors may metastasize to regional lymph nodes. Low-grade tumors have an excellent prognosis, but recurrences can develop, often after many years.

Synovial Chondrosarcoma

These tumors may arise as a primary malignancy of the synovium or secondarily in a preexisting synovial chondromatosis. They are rare occurrences, and only 21 cases have been reported in the literature. The knee, hip, and ankle are the sites of predilection. The age range of the patients is 30 to 70 years, and two thirds occur in the fifth to seventh decades. There is a female preponderance. The tumors form a soft tissue mass associated with pain and joint dysfunction.

Only six cases occurring in the TMJ have been reported.[190-195] Because there are very close similarities in the clinical, radiologic, and histologic aspects between synovial chondromatosis and synovial chondrosarcoma, the diagnosis may be difficult. Local recurrence and invasion of bone and surrounding soft tissue are clinical features that are also shared by these two entities. Radiographically, in addition to the presence of a soft tissue mass, clumps of ca1cification may be seen within the lesion, and there may be marginal erosion of the articular bone. As in synovial chondromatosis, nodules may be seen grossly, lying free within the joint space and/or the soft tissues.

The histology may also be ambiguous because cytologic atypia is common in synovial chondromatosis. The following histologic criteria are suggested to recognize malignancy:

1. Qualitative differences in the cartilage in different parts of the tumor, in which a clustering pattern is juxtaposed with abundant matrix and tumor cells arranged in sheets
2. Myxoid changes in the matrix
3. Hypercellularity, with crowding and spindling of the nuclei at the periphery
4. Necrosis
5. Permeation of trabecular bone, with "filling up" of marrow spaces rather than a pushing margin[2]

In the series reported by Bertoni and colleagues,[186] the nine patients available for follow-up, in whom the tumors occurred in the lower extremity (knee, hip, and ankle), all developed recurrences following local excision with "lesional margins." In spite of aggressive follow-up surgery, five patients developed metastases.

Synovial Sarcoma

These tumors represent about 5% to 10% of all soft tissue sarcomas. They are the fourth most frequently occurring soft tissue sarcoma, following malignant fibrous histiocytoma, liposarcoma, and rhabdomyosarcoma. They arise near tendons and tendon sheaths and next to joint capsules. They do not arise from mature synovial cells but rather from pluripotential mesenchyme.

Joint involvement per se is very uncommon, occurring in less than 5% of cases. Usually they occur in periarticular areas of the extremities, particularly around the knee, but approximately 9% occur in the head and neck, where the perivertebral structures give rise to most of the tumors, which then present in the pharynx, larynx, or esophagus. The tumors are generally rather slow growing. Up to 50% show calcifications radiographically, a helpful finding diagnostically.

Most cases occur in patients in the 15- to 40-year age range. The four patients with lesions in the TMJ ranged in age from 22 to 57 years.[174] At this site they have tended to present with a preauricular mass, which was painless in some instances.

Histologically, two types of synovial sarcoma may occur: biphasic and monophasic. Both types have occurred in the TMJ. The biphasic tumor consists of plump, uniform spindle cells that resemble a fibrosarcoma but lack a herringbone pattern, and cuboidal to columnar epithelial-like cells that line spaces or clefts and form nests. There also may be a pseudoglandular pattern. Both the spindle and epithelial-type cells stain positively for cytokeratin and epithelial membrane antigen. Mitoses are infrequent, and calcifications may be present.

The monophasic form is usually of the fibrous type, and most of the spindle cells exhibit the same immunohistochemistry as the biphasic form. A monophasic epithelial

form also exists but is very rare. Synovial sarcomas are associated with the chromosomal translocation t (X:18) (p11.2;q11.2).

About half of cases of synovial sarcoma will have local recurrences, even after wide surgical excision and a neck dissection. Most recur within the first 2 years, but recurrence may also take place many years later. Although the lung is the most frequent metastatic site, synovial sarcoma is one sarcoma that may metastasize to the lymph nodes (20% of cases).

Osteosarcoma

Osteosarcomas represent about 30% of all primary bone malignancies, and 6% to 13% involve the craniofacial bones. The maxilla and mandible are involved with almost equal frequency. It is unusual for these tumors to originate in the TMJ.[196] The age of patients with such tumors has ranged from 17 to 69 years.

Patients generally complain of pain, often mild; limited mouth opening; and altered occlusion. Radiographically, the lesions show extensive destruction.

These tumors arise from pluripotential mesenchymal stem cells and may thus show considerable histologic diversity. This includes chondroid and fibrous differentiation. The diagnosis rests on the identification of osteoid formed directly from a malignant stroma.

Lung metastases may occur early in the course of the disease.

Multiple Myeloma

Multiple myeloma represents about 43% of malignant tumors of bone. Most cases arise in individuals older than 60 years, and there is a slight male preponderance.

There appear to be seven cases of multiple myeloma reported in the literature in which there was a mandibular condyle lesion.[197] These patients ranged from 41 to 70 years in age, which is typical for this disease. Two patients had pathologic fractures. The most frequent finding was pain, usually associated with trismus. One patient had a tender preauricular swelling. In some patients, additional bone lesions were found at time of presentation, but in others no additional bone lesions were identified.

Multiple myeloma is a plasma cell dyscrasia in which sheets of proliferating plasma cells form bone tumors. Radiographically, the lesions are typically well-defined radiolucencies that lack a sclerotic rim.

Langerhans Cell Histiocytosis

Approximately 13 cases of Langerhans cell histiocytosis have been reported in the mandibular condyle.[198] The majority were solitary lesions. One patient was found to have additional bone lesions at presentation, and another developed an additional lesion in the bone within 6 months. Four patients were female and nine were male. Three cases occurred in the patients' first decade, three in the third, four in the fourth, and three in the fifth.

All patients had pain in the area of the TMJ. Most had preauricular swelling, and limited mouth opening was also frequently reported. At least four patients developed pathologic fractures. In all cases, a lytic lesion could be identified radiographically within the condyle.

Histologically these tumors consist of sheets of histiocytes with focal collections of eosinophils. Some plasma cells and lymphocytes may also be present. The proliferating histiocytic cells can be identified as Langerhans cells by staining for S100 protein and more definitively by immunostaining for CD1a antigen, as well as by ultrastructural examination and identification of cytoplasmic Birbeck granules.

Although there is still some controversy concerning the nature of these lesions, the finding that these are clonal proliferations suggests that they are indeed neoplasms.

Metastatic Carcinoma

Metastatic carcinoma is the most frequently occurring malignancy of bone. However, the jaws are an uncommon site for metastases, and the condyle is an even less frequent location. In a review of 390 cases of metastatic tumors to the jaws, Hirshberg and colleagues[199] reported that 81% occurred in the mandible but only 11 cases (3.5%) involved the condyle. They also noted that overall there was a female preponderance, probably accounting for the fact that the breast was the most prevalent primary tumor site. Other reported primary sites with metastases to the condyle have included lung, prostate, liver, pancreas, uterus, rectum, and skin of the toe. One particularly unusual report involved a testicular teratoma with metastases to both condyles.[200]

The most prevalent presentation of metastases to the condyle was TMJ dysfunction, but a pathologic fracture may also be found. Although in most cases the patient has a known primary lesion, in some series condylar metastasis was the first sign of a neoplasm in as many as half of the patients. Unfortunately, patients with these metastases have a very poor prognosis, and treatment is generally palliative.

Hypotheses regarding the paucity of metastases to the condyle include the scant amount of red marrow; the separate blood supply from the circular penetrating branches of the maxillary and superficial temporal arteries; the slow circulation; and the limiting osseous plate that shuts off the condylar marrow cavity from the spongiosa of the rest of the mandible.

Other Tumors

Many other tumors have been described as occurring within the condyle. Most of these have been single cases. They have included nodular fasciitis,[201] neurofibroma,[202] malignant schwannoma,[203] leiomyosarcoma,[204] malignant fibrous histiocytoma,[205] fibrosarcoma,[206] and Ewing sarcoma.[207]

Inflammatory, Metabolic, and Genetic Disorders

The inflammatory-metabolic-genetic category accounts for a small percentage of TMJ pathology and includes acromegaly, Garre osteomyelitis, hemifacial hypertrophy, hemifacial microsomia, heterotopic bone formation, phantom bone disease, and septic arthritis. The characteristics of hemifacial microsomia, hemifacial hypertrophy, and acromegaly are well outlined elsewhere in this text and are not discussed in this chapter.

Garre Osteomyelitis

Garre osteomyelitis can be considered a variant of chronic osteomyelitis with a concomitant prominent periosteal inflammatory reaction. This type of osteomyelitis is uncommon. It has been described in the tibia and in the maxillofacial region. In the mandible, it most commonly results from a periapical abscess associated with a molar. It has also been associated with pericoronal infections and infections following tooth extraction.[155] Rarely, this process may involve bone in the area of the TMJ. Patients typically present with a bony hard swelling of the posterior mandible. The overlying skin and mucosa characteristically appear normal. Occasionally the swelling may be tender.

The radiographic appearance is that of a centrally mottled radiolucency similar to chronic osteomyelitis. The peripheral periosteal reaction provides a distinctive radiographic appearance. The mandibular cortex is expanded, with concentric opaque layers (onion skin) noted on occlusal radiographs or CT scans. The clinician must differentiate Garre osteomyelitis from benign mandibular neoplasms. Radiographs are helpful to rule out certain neoplasms, but the radiographic presentation of fibrous dysplasia is often similar. Biopsy for histopathologic examination and bone culture is useful.

Removal of the etiologic agent is of paramount importance in the treatment of Garre osteomyelitis. Some surgeons advocate additional treatment with antibiotic therapy. Others advocate wide exposure of the affected area with perforation of the mandibular cortex to allow for capillary ingrowth.

Heterotopic Bone Formation

Heterotopic ossification is a condition in which mature lamellar bone is formed in tissues that do not normally ossify. Heterotopic ossification is considered to occur in three basic forms: traumatic, neurogenic, and myositis ossificans progressiva. It has also been described, although rarely, following tetanus, burns, poliomyelitis, and some forms of carcinoma. It is a well-recognized entity following injuries such as total hip arthroplasty and internal fixation of acetabular fractures.[155] It rarely occurs in the TMJ.

The onset of heterotopic bone formation usually occurs approximately 2 weeks after injury, although symptoms may not present until 8 to 10 weeks later. A diminished range of motion of the joint is a hallmark characteristic and is often the earliest sign. Patients may also complain of pain, swelling, and local tenderness. Management includes arthroplasty and physiotherapy. Radiotherapy and pharmacologic therapy with agents such as bisphosphonates and nonsteroidal anti-inflammatory drugs have been advocated as prophylaxis to prevent heterotopic bone formation.

Phantom Bone Disease

Phantom bone disease, also known as vanishing bone disease or massive osteolysis, is a rare clinical entity, with approximately 70 cases reported since its initial description in 1838. Only 15 cases have been reported in the maxillofacial region. The clinical course is characterized by a slowly progressive localized destruction of bone. Although the disease is progressive, its course can vary. With time, the bone destruction may spontaneously abate, or the bone may gradually disappear. No effective treatment is known for phantom bone disease.[155] Recently, controversy has developed as to whether this process represents a distinct entity or is a misinterpretation of other pathologic processes. Practitioners are encouraged to consider other pathologic entities when presented with a condition diagnosed as "phantom bone disease."

Conclusion

In the study of temporomandibular disorders, much emphasis has been placed on the commonly occurring conditions such as masticatory myalgia and internal derangements. Practitioners must approach such patients with an open mind, because many other conditions can produce similar signs and symptoms. These include arthritides and neoplasms. Although most neoplasms of the TMJ are benign, features that may suggest the possibility of malignancy include swelling, paresthesia, paresis, trismus, and occlusal changes. In addition, there may be auditory changes, including tinnitus and vertigo secondary to eighth nerve involvement and decreased auditory acuity secondary to eustachian tube involvement. When occlusal changes are of sudden onset, the immediate cause may be a pathologic fracture. The development of symptoms of myofascial pain and jaw dysfunction later in life (i.e., beyond the typical 20- to 40-year age range for patients with masticatory myalgia), or failure of the initial treatment for this condition, should make clinicians suspicious of more serious problems.[153-158,208]

The use of good radiographs and other imaging studies is of paramount importance in developing a correct diagnosis. Although the diagnosis is frequently suggested by the clinical and imaging information, in most cases the final diagnosis will only be made by microscopic tissue examination. However, histologic analysis alone is not sufficient. Only by assessing the clinical, radiographic, and histologic information together can the clinician achieve an accurate diagnosis.

Nonsurgical Management of Temporomandibular Joint Disorders

A. THOMAS INDRESANO, CHAN M. PARK

Introduction

Temporomandibular joint (TMJ) disorders are a diverse collection of problems involving the joint itself and/or the surrounding masticatory system. This masticatory system includes the muscles of mastication, their nerve supply, the surrounding afferent neural tracts, central oromotor control, and the maxillary and mandibular dentoskeletal relationship. Given this diversity and the complex cause of the disorders, management is equally diverse. Treatment regimens can be divided into two broad categories: surgical and nonsurgical management. Surgical modalities will be discussed elsewhere in this text.

Accurate diagnosis of the particular TMJ disorder is paramount in determining a treatment regimen. For example, intracapsular joint disorders will be treated differently than musculoskeletal disorders. With virtually all TMJ disorders, however, numerous nonsurgical therapies are part of a treatment regimen (Box 39-1, Figure 39-1).

Philosophies of Treatment

The treatment of TMJ disorders involves philosophical differences among patients and practitioners. These differences often involve what one individual believes is the most appropriate course of treatment. Several treatment philosophies are universally accepted, including the use of a multidisciplinary approach, the use of reversible therapies first, and management of pain by alteration of the disease process.

Multidisciplinary Approach

TMJ disorders, as discussed earlier, involve a variety of diagnoses. The disorders also influence multiple aspects of patients' lives. For example, depression has been positively associated with TMJ complaints, especially painful symptoms.[1-4] Because of this, a sole-practitioner approach to treating TMJ disorders is often inappropriate. A "team" approach is often necessary, using multiple specialties. Professionals from diverse disciplines, such as general dentistry, oral and maxillofacial surgery, orthodontics, physical therapy, occupational therapy, psychiatry, and neurology, are often needed for thorough treatment.

Reversible Versus Nonreversible Treatment

A widely held philosophy is that the most appropriate disease therapy is the least invasive therapy that provides a positive outcome. A large reason for this is that the least invasive therapies are often reversible. Once the therapy is completed, the patient's physiology is not significantly altered. Nonsurgical TMJ therapies often, but not always, fall into this category of reversible treatment.[198] For example, long-term splint therapy can alter disc position and condylar morphology.[5-8] After reversible therapies have been attempted and it has been determined that a disease process has not been adequately interrupted, nonreversible modalities should be initiated.

Pain Management Versus Disease Therapy

Most patient's complaints of TMJ disorders involve pain.[9] Clear delineation must be made within the therapy of TMJ disorders between palliative pain management and a therapy used to *treat* a disease process. Pain can be managed in multiple ways, but the most effective is with removal of the offending stimulus or disease process. During this process, however, medicinal pain management may be necessary. Patients must be educated in the nature of the disease process and what impact each treatment modality will have on that process.

Splint Therapy

The use of occlusal splint therapy for the treatment of TMJ disorders dates back to Kingsley in 1877.[10] Occlusal splints

have, over the years, been advocated for the use of a variety of purposes. It follows that the design of the splints has been modified for each purpose. For example, Sved, Block, and Christensen used occlusal appliances to restore the vertical dimension of occlusion.[11-13] In the 1940s, Thompson advocated mandibular repositioning using intraoral appliances.[14] This form of treatment was postulated to "unload" the condyle. In the 1960s, Ramfjord popularized the use of splint therapy for patients with muscular dysfunction by using electromyographic studies.[15] Further attempts were made to "unload" the condyle in the 1970s and 1980s with anterior repositioning appliances.[10]

Splint therapy remains a popular method of treating TMJ disorders.[16,17] Several studies have concluded that splint therapy is often an effective therapy, but the type of splint used seems to have little consequence.[18-22] This is likely because the exact mechanism of action of splint therapy is not well understood. This section will highlight the different splints used and their specific uses (Box 39-2).

• BOX 39-1 Nonsurgical Options for Treating TMJ Disorders

Splint therapy
Pharmacotherapy
Occlusal management
Physical therapy
Adjunctive therapies (acupuncture, acupressure, botulinum toxin A, etc.)

Types

- Stabilization splints: Stabilization splints are the most commonly used splints to treat myofascial pain[23] (Figure 39-2). They consist of acrylic full coverage of the maxillary or mandibular occlusal shelf. Most commonly, there is interdigitation with one arch, but little to no interdigitation with the other arch. Balanced, bilateral occlusal contacts are a must. If any interdigitation

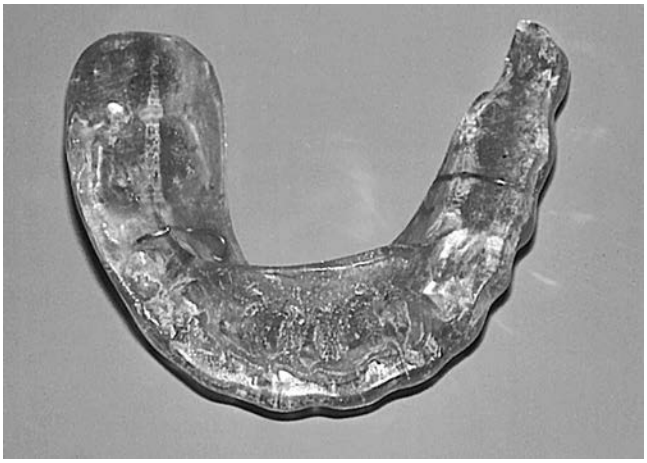
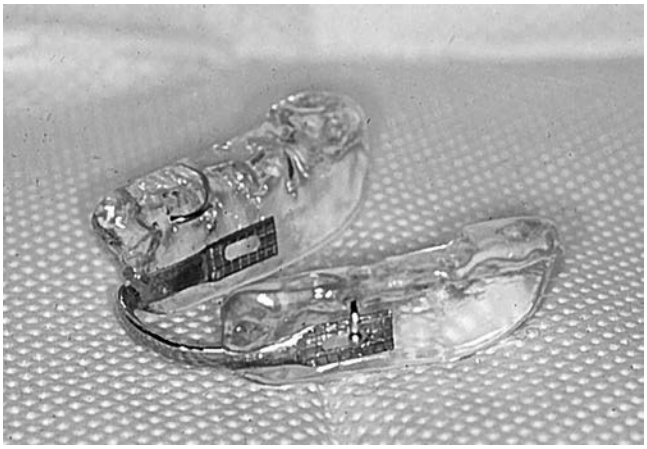
exists, anterior disclusion and canine guidance or group function is established. Stabilization splints are usually constructed in a centric relation. They have been shown to be moderately successful in reducing pain in longitudinal studies.[24] Studies of full-coverage stabilization splints have been shown to have favorable results in symptoms related to joint, muscular, and motion pain, but demonstrate poor results at decreasing joint noise.[25,26] Schmitter et al recently determined that patients treated with stabilization splints were treated more effectively than those with distraction splints.[27] A recent Cochrane Database review of studies using stabilization splints concluded that there was insufficient evidence to support or discourage their use.[28,29] This highlights the need for further well-controlled studies examining their efficacy.

- Repositioning splints: Repositioning splints are primarily used to alter the condylar position at occlusal contact and to recapture a displaced disc (Figure 39-3). They are constructed out of hard acrylic for the maxillary or mandibular arch with cuspal interdigitation or inclines to guide the mandible to a predetermined position. Repositioning splints became popular in the early 1980s with promising results shown to decrease pain and joint noise in patients with anteriorly displaced discs with reduction.[30-32] This initial enthusiasm, however, dwindled with controlled long-term studies showing a high rate of joint noise returning and progressive pain.[33,34] Other studies have shown a significant improvement in pain, but marginal success in "recapturing" discs.[35]

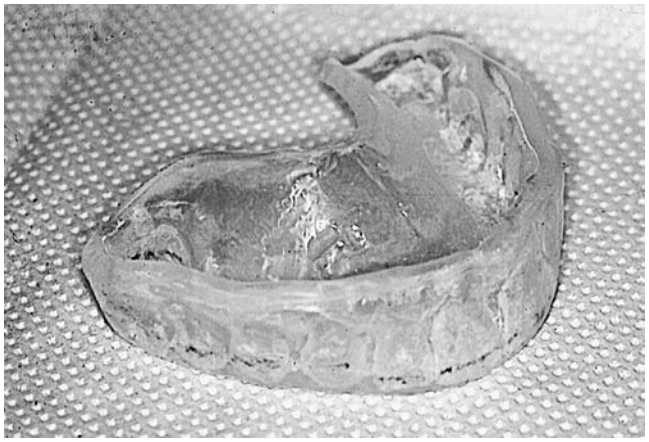


• Figure 39-3 Maxillary anterior repositioning appliance worn unsupervised for 2 years.

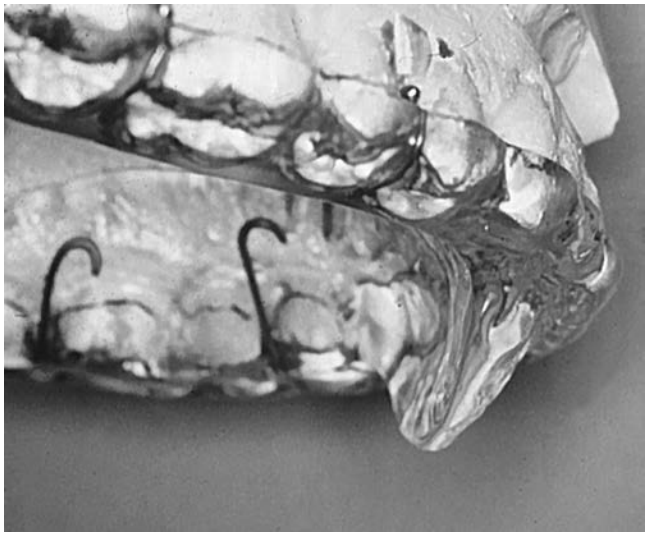


• Figure 39-4 A pivot splint. Note that posterior acrylic blocks are thought to gently distract the condylar head when patient is in centric occlusion.

- Pivot splints: First described by Goodwillie in 1881, these splints are designed to "unload" the TMJ and to mildly stretch the joint[10] (Figure 39-4). They can be made for the mandibular or maxillary arch and made unilateral or bilateral depending on the involved joint(s). They were theorized to be useful in patients with intracapsular inflammation. Unfortunately, the elevator muscles of the mandible lie on or posterior to the most distal portion of the dentition. Without the use of a chin cup or other orthopedic device, unloading of the joint is difficult to achieve.[36]
- Soft splints: Soft, or resilient, splints are made from a pliable material and are often effective for immediate results in patients with myofascial pain[37,38] (Figure 39-5). They have an advantage of low cost and ease of fabrication. It is believed, however, that hard splints are superior to their soft counterparts, especially in cases of bruxism.[39,40]
- Bite plane splints: Bite plane splints are used to disrupt mandibular proprioception, thereby decreasing muscle activity[41] (Figure 39-6). They are constructed by indexing only the anterior teeth with no posterior contact.



• **Figure 39-5** Soft splint.



• **Figure 39-6** Lateral view of maxillary anterior repositioning appliance. Note that resting of lower incisors is anterior to this flange.

Prolonged use can cause occlusal discrepancies (Figure 39-7), and stabilization splints are more effective in bruxism cases.

Uses

Myofascial Pain

Numerous studies have shown that splint therapy is effective for myofascial pain. Stabilization splints are the most common splints used.[23] Other forms of splints have been advocated for myofascial pain with similar value; these are effective in 70% to 90% of cases.[10] The exact reason why splint therapy is effective in myofascial pain is not yet determined. Numerous electromyography (EMG) studies have shown a short-term decrease in muscle activity, especially the temporalis and masseter muscles.[42-44] Long-term EMG studies, however, have shown ambiguous results.[45-47] This may be due to a traditionally cyclic nature of symptoms related to myofascial disorders.[48]

A study by deLeeuw et al determined that patients with myofascial pain had a decrease in symptoms with splint usage compared with a control group. These patients were also shown to have a decrease in depression and an increase in the use of planned actions and rational thinking.[49] It is not clear, however, if the reduction in symptoms caused a decrease in depression or if a decrease in depression caused a reduction in symptoms.

• **Figure 39-7** Patient's occlusion after 2 years of unsupervised wear. Note open posterior malocclusion.

The effectiveness of splint therapy for myofascial pain has been brought into question by a study by Dao et al. In a parallel randomized controlled blinded study, patients were divided into three groups: brief splint usage only at recall appointments, palatal splint usage 24 hours a day (no occlusal coverage), and stabilization splint usage 24 hours a day. All three groups demonstrated a decrease in symptoms, with no statistically significant difference between the groups.[50] The findings of this study support the theory of other authors who suggest that cognitive awareness and positive patient expectations may have an as large or larger role in treatment of TMJ disorders than the biomechanical impact of occlusal appliances.[18,51-53]

The exact reason why splint therapy is effective for myofascial pain is yet to be determined. Further controlled studies are needed to validate any number of theories. The most effective type of splint used is also yet to be definitively determined. It is important, however, to use conservative and reversible appliances because some splints can have adverse effects on a patient's occlusion.[54]

Bruxism

Bruxism can cause several deleterious effects. First, bruxism can cause irreversible wear on the dentition.[55,56] Second, bruxism can also cause moderate hypertrophy of the masticatory muscles, most notably the masseter.[57] Third, bruxism can result in alteration of the TMJ anatomy over time.[58] Lastly, the link between bruxism and myofascial pain is strong and quite possibly causative in many cases.[59,60] Therefore if a patient with bruxism has a myofascial pain component, the same rationale for splint therapy applies.

EMG studies have shown a significant decrease in masseter and temporalis muscle activity with splint use in patients exhibiting nocturnal bruxism.[39,61-63] These studies also

show that the effect of splint therapy is not maintained once splint usage is halted.[61,62] Muscle activity often returned to the pretreatment levels within several weeks after cessation of treatment. Further, a recent study by Raphael et al found pain to improve in patients with bruxism, but the splint therapy had little effect on the severity of the bruxism.[64] This raises questions of the exact mechanism of splint therapy and if there is an exact causative nature of bruxism and myofascial pain.

Internal Derangement

Splint therapy has been used extensively for various intracapsular TMJ disorders with little definitive evidence indicating their therapeutic value. In attempting to treat anterior displaced discs with or without reduction, splints have been hypothesized to "recapture" a displaced disc into its natural position over the condylar head, especially during function. Cohen and MacAfee submitted that a proper meniscal-condylar position is essential to prevent future degenerative joint disease.[65] This theory, however, has not been supported by further studies. Studies show that recapturing the disc with the use of splints is marginally effective in the short and long term.[66-69] Furthermore, the use of repositioning splints can permanently alter the patient's occlusion. The most effective use is in relation to pain symptoms, where likely the joint is "unloaded" leading to a decrease in inflammation. A decrease in inflammation may result in an increase in the range of motion.[67,70,71]

In the case of anterior displaced discs *with* reduction, the theory is that a "joint unloading" will allow the disc to resume its natural position over the condylar head. Consistent repositioning of the disc has not been proven, but splint therapy has been shown to result in a decrease in joint loading. Nitzan studied the intraarticular pressure within the TMJ with and without an intraocclusal appliance. During clenching there was a decrease in intraarticular pressure of 81.2% with the occlusal appliance in place versus without it.[71] Pivot splints have also been used for joint unloading and have shown that a fulcrum at the second molar area results in 1 to 3 mm of condylar lowering.[70]

Similarly, splints have been used to treat anterior displaced discs *without* reduction. Their effectiveness, however, has been brought into question. A similar "joint unloading" phenomenon has been reported with a decrease in pain.[72,73] It is theorized that over time the retrodiscal tissue becomes more fibrotic, with a decrease in vascularity and innervation.[74-76] A study by Lundh et al, however, found no statistical benefit in pain or range of motion with the use of splints in patients with anterior disc displacement without reduction.[77] Conversely a study by Ohnuki et al observed that pain symptoms improved with splint therapy with patients with anterior disc displacement without reduction. Post-treatment magnetic resonance imaging (MRI) studies, however, revealed that splint therapy had minimal effect on the disc's position.[78]

It is therefore reasonable to conclude that a definitive role of splint therapy in patients with internal derangement is yet to be determined. Splints do have a role in decreasing joint load, which may lead to an improvement in pain symptoms. Given the lack of a conclusive role, splint therapy, if chosen, should remain conservative and not cause irreversible changes to the occlusion or TMJ anatomy.

Degenerative Joint Disease

Degenerative joint disease includes osteoarthritis and rheumatoid arthritis. Splint therapy has been shown to have a favorable therapeutic index to treat symptoms related to muscle activity and inflammation in the joint as a result of overload. If a patient is exhibiting pain in association with degenerative changes, splint therapy may be effective at treating the symptoms. Splint therapy, however, has not been shown to alter the course of degenerative joint disease.[79,80]

Pharmacotherapy

The treatment of TMJ disorders is often not effective with one modality alone. A complete treatment regimen involves multiple types of treatment reflective of the multifactorial nature of the disease process. Pharmacologic therapy quite often plays a central or adjunctive role in the treatment of TMJ disorders.

Pharmacologic therapy can be divided into two main categories: medications used to treat a certain disorder and medications used to palliate symptoms associated with the disorder. Several types of medication are used for both purposes. Imperative is a detailed discussion with the patient regarding the reason(s) why a certain medication is being prescribed and what is the desired end point. Continuing a medication, especially an analgesic, for an extended period of time is not a desirable method of treating TMJ disorders. Dependency, tolerance, or adverse side effects may occur. Furthermore, giving medications on an "as needed" basis should be avoided as much as possible. Instructions to take a medication "as needed" require the symptom to be present.[72,81,82] This leads to an oscillating or cyclical process to the patient's symptoms. More appropriate is to give medications on a schedule to prevent these variations in symptoms. The goal is to develop an individualized regimen that relieves the symptoms for a period of time, hopefully breaking the disease process and causing permanent improvement.

The categories of various pharmacologic treatment modalities are listed in Box 39-3. The choice of one type of medication over another depends on the TMJ diagnosis

• BOX 39-3 Categories of Medications Used to Treat TMJ Disorders

NSAIDs
Corticosteroids
Analgesics
Muscle relaxants
Antidepressants
Anxiolytics

and the severity of the patient's symptoms. It is not uncommon to use medications from several categories to treat an individual's disease process.

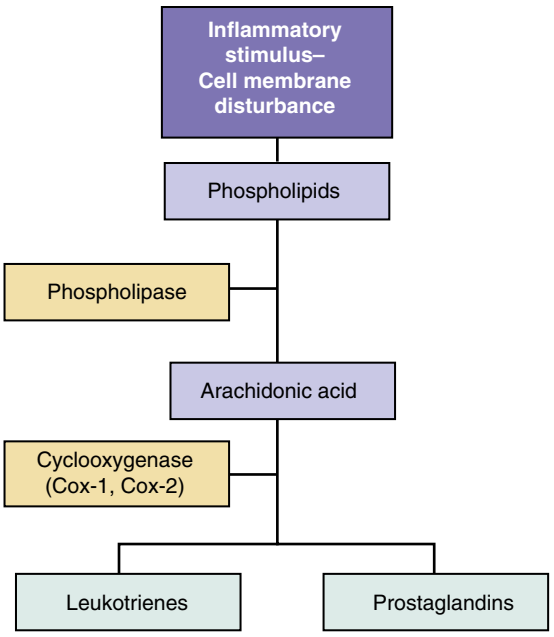
Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs are used to treat TMJ disorders by two mechanisms: their analgesic effects and anti-inflammatory properties. NSAIDs have been used in myofascial pain syndrome, synovitis, osteoarthritis, and symptomatic disc displacement.[83] NSAIDs' mechanism of action is to inhibit cyclooxygenase from converting arachidonic acid into prostaglandins and thromboxane. Arachidonic acid is released from cell membrane phospholipids in response to noxious stimuli. Prostaglandins promote multiple physiologic effects, including both inflammation and pain (Figure 39-8).

NSAIDs act by temporarily preventing the binding of arachidonic acid to the cyclooxygenase enzyme. The exception to this is aspirin, where the cyclooxygenase enzyme is acetylated. Aspirin's effects take longer to wear off because production of new cyclooxygenase molecules is needed to restore baseline function.[84]

Two different cyclooxygenase enzymes (Cox-1 and Cox-2) produce prostaglandins. Cox-1 is a constitutive enzyme that is stimulated by normal physiologic processes and is always present. It affects platelet aggregation and renal blood flow, protects stomach mucosa, and regulates vasomotor tone.[84,85] The Cox-2 enzyme is increased dramatically with the action of macrophages. This results in the formation of multiple prostaglandins that result in pain, increased swelling, and increased temperature.[86,87]

All NSAIDs are active against Cox-1 and Cox-2, but the degree of effect that a particular NSAID has on either enzyme varies greatly. For example, aspirin is highly selective for Cox-1, whereas naproxen has a relatively equal effect on both enzymes.[86] In general, the greater the effect that a particular NSAID has on Cox-1, the greater side effect profile it has. Most notably, this manifests as gastrointestinal irritation. It follows that NSAIDs should be chosen to maximize their Cox-2 effects and decrease their impact on Cox-1. This idea, though still believed, has been brought into question by reports of selective Cox-2 inhibitors causing various cardiovascular problems.[88,199] Commonly prescribed NSAIDs are shown in Table 39-1. Currently, ibuprofen and naproxen are the most prevalent, after usage of the selective Cox-2 inhibitors has decreased.



• **Figure 39-8** The cyclooxygenase pathway.

Corticosteroids

Various corticosteroids used in TMJ disorders are shown in Table 39-2. Corticosteroids interrupt the inflammatory cascade by completely blocking the formation of arachidonic acid by blocking phospholipase (see Figure 39-8). This results in a greater effect on the formation of prostaglandins than that found with NSAIDs. Their effect on acute TMJ pain and hypomobility is therefore greater than that found with NSAIDs. Long-term use of corticosteroids for the treatment of TMJ disorders, however, is contraindicated. It has been shown that usage of prednisone more than 10 to 20 mg a day for 2 weeks can cause suppression of the hypothalamic-pituitary-adrenal axis.[89] This can result in a Cushing's-like disease process, acute adrenal crisis, hypotension, electrolyte abnormalities, and diabetes. Chronic steroid administration can also result in the formation of osteoporosis including the TMJ. This is because the mandibular condyle has a reduced ability to withstand stress and may go through destructive changes.[90-92]

The use of intracapsular corticosteroid injections is discussed elsewhere in this text. The use of oral corticosteroids should be reserved for significant acute TMJ discomfort or for diagnostic purposes. The course of drug administration should be short and repeated as infrequently as possible. A typical regimen is a tapering dose lasting 5 to 7 days.

Analgesics

Practitioners have a wide array of opinions regarding the role of analgesics in TMJ disorders. Prescribed duration and dosage vary significantly. Patients' attitudes toward analgesics are also variable. Patients must be aware that the use of analgesic medications likely will not "cure" their TMJ disorder. It is permissible for patients to use analgesics for symptomatic relief, but they must be aware that by taking the medication the disease process is not halted.

The use of analgesics in TMJ disorders can be divided into two main categories: narcotic and nonnarcotic analgesics. The primary nonnarcotic medications used are the NSAIDs, which were discussed previously. Acetaminophen is another commonly used nonnarcotic analgesic. Acetaminophen does have some anti-inflammatory properties, but is mainly used for pain relief. High dose or long-term

TABLE 39-1 Nonsteroidal Anti-inflammatory Drugs Used in TMJ Disorders

Category	Generic Name	Brand Name	Usual Dosage	Relative Specificity Ratio of Cox-1 to Cox-2
Salicylates	Aspirin (acetylsalicylic acid) Diflunisal	Bayer Dolobid	650 mg qid (EC) 250 mg bid	166

Oxicams	Piroxicam Meloxicam	Feldene Mobicox	20 mg qod 7.5 mg qod	250 –3.0
Pyranocarboxylic acids	Etodolac	Ultradol	300 mg bid	0.1
Naphthylalkanones	Naburnetone	Relafen	1 g qod	
Cox-2 inhibitors	Celecoxib Profecoxib Valdecoxib	Celebrex Vioxx Bextra	200 mg qod 25 mg qod 20 mg qod	0.003 0.026

TABLE 39-2 Oral Corticosteroids Used in TMJ Disorders

Drug	Alternative Name	Relative Potency	Usual Dose
Hydrocortisone	Hydrocortone	1	20-240 mg/day
Prednisone	Deltasone, Orasone	4	5-60 mg/day
Prednisolone	Delta-Cortef	4	5-60 mg/day
Dexamethasone	Decadron	25	0.75-9.0 mg/day
Betamethasone	Celestone	25	0.6-7.2 mg/day

usage of acetaminophen can cause liver dysfunction. It is contraindicated in patients with liver disease or moderate alcohol consumption.

Opioid analgesics are a class of phenanthrene alkaloids with a first known use in sixteenth century Egypt.[93] Multiple opioid receptors have been discovered over the years, but the *mu* receptor has been found to be the principle receptor involved in analgesia.[94] Opioid analgesics act at sites in the brainstem for descending pain inhibition, elsewhere in the brain raising the threshold to a painful stimulus, or peripherally in peripheral nociceptors.[95-99] Opioid analgesics have adverse effects, including decreased gastrointestinal motility, respiratory depression, urine retention, sedation, and nausea and vomiting.

A large drawback to the use of opioids is a potential tolerance to the medication with chronic usage. Physical and psychological dependence on opioids is possible with repeated administration. Commonly used opioid analgesics are shown in Table 39-3 with their relative risk of causing dependence. The tolerance and dependence are both reversible, but the psychological dependence is the most difficult to completely resolve.

If prescribing opioid analgesics for patients with TMJ disorders, it is important to educate the patient on the proper use of the medications and potential risks. Further, a patient's medication intake should be monitored as closely as possible to decrease the abuse potential. Opioids should be prescribed for short durations during times of acute discomfort.

Muscle Relaxants

Muscle relaxants have been used for many years in treating symptoms associated with TMJ disorders. Proper diagnosis is paramount to determine if muscle relaxants are indicated.

TABLE 39-3 Commonly Used Opioid Analgesics in TMJ Disorders

Drug	Alternative Name	Therapeutic Dose	Abuse Potential
Codeine		30-60 mg	Low
Pentazocine	Talwin	50 mg	Low
Propoxyphene	Darvon	32-65	Low
Tramadol	Ultram	50-100 mg	Low
Hydrocodone	Dicodid, in Vicodin	5-10 mg	Moderate
Meperidine	Demerol	50-100 mg	Moderate
Methadone	Dolophine	5-15 mg	Moderate
Morphine	MS Contin	20-60 mg	Moderate
Hydromorphone	Dilaudid	2-4 mg	High
Levorphanol	Levo-Dromoran	2-3 mg	High
Oxycodone	In Percodan	5-10 mg	High

Symptoms associated with myofascial pain, bruxism, and hyperactivity of the masticatory musculature can benefit from muscle relaxants.[100,101] It follows that muscle relaxants will have minimal effects on meniscal disorders. Muscle relaxants are divided into two categories: centrally acting or peripherally acting.

Most commonly, centrally acting muscle relaxants are used to treat TMJ disorders. Antianxiety medications do have centrally acting muscle relaxation properties, but will be discussed elsewhere in this section. Centrally acting muscle relaxants act by diminishing nerve output to voluntary muscles. They involve several areas of the CNS, including the brainstem, thalamus, and basal ganglia. The most commonly used centrally acting muscle relaxants are cyclobenzaprine (Flexeril), carisoprodol (Rela, Soma), and methocarbamol (Robaxin) (Table 39-4).

The most common peripherally acting muscle relaxant is baclofen (Lioresal). Baclofen is an analogue to γ-aminobutyric acid (GABA), which binds to GABA receptors and reduces the release of excitatory amino acids, thus reducing motor tone.[102] Baclofen has been used in traumatic spinal cord injuries, multiple sclerosis, and trigeminal neuralgia in addition to TMJ disorders. Baclofen is reserved for use in patients who are experiencing marked muscle spasms or pain stemming from a neurogenic origin.

An additional method of muscle relaxation is the use of botulinum toxin A (Botox).[103-105] Botulinum toxin A functions by inhibiting the release of acetylcholine from cholinergic neurons, which decreases the transmission of the neural stimulus to the muscle. Botulinum toxin A has been used extensively to treat various dystonic syndromes.[106] Administration of botulinum toxin A requires direct injection into the affected muscle. Most precise administration is accomplished with the use of EMG-guided needles. Repeat dosing of botulinum toxin A is delayed for approximately 6 months, giving time for the botulinum toxin A to defuse from the acetylcholine receptors. Repetitive dosing can result in a tolerance in the recipient muscle.[106] Often botulinum toxin A administration will decrease muscle activity enough that the patient's disease cycle is broken, resulting in an improvement of symptoms for a period of time after the medication has worn off. Some have used botulinum toxin A for treatment of TMJ clicking with success.[200-202]

TABLE 39-4 Commonly Used Muscle Relaxants in TMJ Disorders

Generic Name	Brand Name	Usual Dosage
Centrally Acting		
Cyclobenzaprine	Flexeril	5-30 mg/day
Methocarbamol	Robaxin	1500-4500 mg/day
Carisoprodol	Rela, Soma	1000-1400 mg/day
Chlorzoxazone	Paraflex	750-3000 mg/day
Peripherally Acting		
Baclofen	Lioresal	15-80 mg/day
Botulinum toxin A	Botox	20-100 units/ 6 months

Antidepressants

Several classes of antidepressant medications exist, including tricyclic antidepressants, monoamine oxidase (MAO) inhibitors, and selective serotonin reuptake inhibitors. In general, antidepressants are used to treat a variety of disorders, including depression, eating disorders, chronic pain syndromes, obsessive-compulsive disorders, and sleeping disorders. It is well known that there is a complicated link between chronic pain and depression, and treatment of both entities is often necessary.[107] Magni reported that nearly all patients (97%)

with a chronic pain syndrome without an organic lesion causing the pain were found to have a psychiatric condition compared with 39% of patients with chronic pain resulting from an obvious cause.[108] The majority of patients with TMJ disorders have demonstrated evidence of depression on presentation or through the course of the disorder.[109,110]

For TMJ disorders, tricyclic antidepressants (TCAs) are the most commonly used class of antidepressant medications. TCAs have not only antidepressant properties but have been shown to possess analgesic potential.[111] Amitriptyline, the most commonly used TCA for TMJ disorders, has analgesic properties at low doses, much lower than the therapeutic levels to achieve significant antidepressant effects. Numerous studies have demonstrated their effectiveness in treating chronic pain from TMJ disorders.[112-114] Common side effects include xerostomia, sedation, constipation, and orthostasis[115] (Table 39-5).

Anxiolytics

Anxiolytic medications are occasionally used to treat patients with TMJ disorders. They decrease the anxiety related to the disease process, which often accompanies the depression characteristics. Anxiolytic medications also serve to decrease insomnia and decrease muscle activity, which is often associated with nocturnal bruxism. Anxiolytic medications are often not the only line of treatment for TMJ disorders, but function well as periodic adjunctive therapy.

The most commonly used anxiolytic medications are benzodiazepines (Table 39-6). Their popularity stems from a high selectivity for treatment of anxiety and a larger margin of safety than other medications (e.g., barbiturates). The benzodiazepine receptors in the CNS are coupled with the inhibitory neurotransmitter GABA receptors, leading to an increase in chloride influx. This leads to membrane hyperpolarization and neural inhibition.[116] Benzodiazepines, especially diazepam, have muscle relaxant properties, which can be very effective at treating symptoms associated with nocturnal bruxism. Adverse effects of benzodiazepines include somnolence, muscle weakness, confusion, apathy, and dependency. It is recommended to not use benzodiazepines to treat TMJ disorders for long periods of time. Syrop recommended usage for a maximum of 3 continuous weeks for the treatment of nocturnal bruxism.[83]

Buspirone (BuSpar) is an azaspirodecanedione medication used for anxiolysis. It is not related to benzodiazepines, but has the same anxiolytic properties, without the sedative, anticonvulsant, and muscle relaxant characteristics. It also does not result in physical dependence, as is the case with benzodiazepines. The major disadvantage to using buspirone is a delayed onset to clinical effect of 1 to 3 weeks.

Several other medications are occasionally used for anxiolysis. For example, meprobamate was commonly used before the advent of benzodiazepines, but its popularity has decreased substantially. Antihistamines are used for both their anxiolytic and sedative properties. They have a relatively low toxicity and minimal abuse potential.

Occlusal Management

For many years, dentistry has maintained the position that the cause of TMJ disorders is multifactorial, which usually implies that the profession is unsure about the specific cause. Dental and skeletal occlusion is at the center of a complete maxillofacial examination. This likely has lead to the historical thought that occlusion is the most important etiologic factor in the development of TMJ disorders. Presently, there are no studies that suggest that orthodontics, restorative dentistry, or oral and maxillofacial surgery prevents an individual from developing symptoms or promotes the development of symptoms. The rationale for the treatment of TMJ disorders in association with skeletal malocclusions using orthognathic surgery will be discussed elsewhere in this text.

Anterior Overjet, Overbite, and Open Bites

Numerous sources have suggested that an increase in both the anterior overbite and overjet can predispose individuals

TABLE 39-5 Commonly Used Antidepressant Medication for TMJ Disorders

Class	Generic Name	Brand Name	Usual Dose
TCA	Amitriptyline	Elavil	10-100 mg/day
	Nortriptyline	Pamelor, Aventyl	2.5-75 mg/day
	Doxepin	Sinequan	50-150 mg/day
	Imipramine	Tofranil	10-40 mg/day
	Desipramine	Norpramin	50-150 mg/day
Serotonin modulator	Trazodone	Desyrel	25-50 mg/day
SSRI	Fluoxetine	Prozac	1-20 mg/day
	Paroxetine hydrochloride	Paxil	5-20 mg/day
	Sertraline	Zoloft	50-200 mg/day

TABLE 39-6 Commonly Used Anxiolytic Medications in TMJ Disorders

Class	Generic Name	Brand Name	Usual Dosage
Azaspirodecanedione	Buspirone	BuSpar	15-30 mg/day
Antihistamine	Hydroxyzine	Vistaril	75-300 mg/day
	Promethazine	Phenergan	25-50 mg/day
Carbamate	Meprobamate	Miltown	1.2-1.6 mg/day
Benzodiazepine	Alprazolam	Xanax	0.75-4 mg/day
	Lorazepam	Ativan	2-6 mg/day
	Oxazepam	Serax	30-90 mg/day
	Temazepam	Restoril	15-30 mg/day
	Triazolam	Halcion	0.125-0.5 mg/day
	Chlordiazepoxide	Librium	15-100 mg/day
	Diazepam	Valium	8-40 mg/day
	Flurazepam	Dalmane	15-30 mg/day
	Prazepam	Verstran, Centrax	30-60 mg/day

to mandibular dysfunction.[117-120] There are not, however, suitable studies to support this claim definitively. Many of the currently available studies do not have sufficient numbers, controls, or longitudinal data.

Pullinger et al demonstrated a small but significant correlation between increased horizontal overjet and TMJ disorders.[121] A recent longitudinal study by Pahkala and Qvarnstrom supported this conclusion. Excessive overjet was the only variable that correlated with an increased risk of TMJ disorders.[122]

Definitive data regarding anterior open bites are not available. Numerous studies suggest that there is a higher percentage of open bites in patients with TMJ disorders.[121,123,124] No longitudinal studies, however, have determined that the open bite is the *cause* of the TMJ disorder. More likely, the open bite is a result of the TMJ disorder, possibly because of an alteration in the disc position or condylar resorption.

Therefore minimal conclusions can be made in regard to overjet, overbite, and open bites. There is likely a slight increase in TMJ disorders in patients with an increase in horizontal overjet. Therefore a treatment recommendation *may* be made to correct excessive horizontal overjet. Further longitudinal studies are necessary to completely describe the role, if any, overjet, overbite, and open bites play in TMJ disorders.

Angle's Classification and Anterior Contact

As discussed in the previous section, an increase in horizontal overjet may correlate with a small increase in TMJ disorders. It follows that this increase in horizontal overjet is often associated with an Angle's class II, division 1 occlusion. Studies have found that there is a small increase in TMJ disorders in Angle's class II patients compared with the overall population.[125-128]

The question of the superiority of one type of anterior contact (canine versus group function) over another has been debated in the literature. There is no scientific evidence regarding the impact of these occlusal schemes on either the success or failure of restorative dentistry treatment outcomes or on the prevention of TMJ disorders.

A study by Okano et al demonstrated a decrease in electromyographic activity in the masseter muscles with a canine-guided occlusion compared with group function and balanced occlusions. This study, however, used overlay-constructed occlusal patterns, not patients' natural occlusions.[129] Conversely, Belser and Hannam found there to be no significant change in muscle activity between group function and canine-protected occlusions.[130] Further, numerous studies have shown that occlusal splints have had minimal change on bruxism long term when splint usage is discontinued.[62,131] Therefore an alteration in occlusal scheme (i.e., usage of an occlusal splint) does not significantly decrease muscle activity long term. These results suggest that altering the occlusal scheme probably has little effect on oral habits or the development of intraarticular TMJ disorders.

Missing Posterior Teeth

Historically, it was believed that missing posterior teeth lead to TMJ disorders and the associated pain and dysfunction. Restoring the posterior occlusion would treat these symptoms.[132-134] Many studies have investigated whether missing posterior teeth increased the risk of intraarticular TMJ

disorders or increased the risk of symptoms and if restoring posterior occlusion would treat TMJ disorders.

Loss of posterior teeth has been positively correlated with osteoarthritic changes.[135-138] Tallents et al also found an association between missing mandibular molar teeth and the presence of disc displacement.[139] This has not, however, correlated with the development of symptoms.[140,141]

Several studies have shown that restoring missing posterior teeth does not decrease the prevalence of TMJ disorders.[121,142,143] A longitudinal study by Witter et al demonstrated that loss of posterior teeth did not increase the risk of TMJ disorders.[144] They also suggested that removable partial dentures do not prevent TMJ disorders and do not improve oral function. Lederman and Clayton found dysfunction in 68% of patients with fixed partial dentures in all posterior quadrants.[145] These observations pose two concerns: restorative dentistry to restore posterior occlusion is not justified as a solution to prevent TMJ disorders, and even if a symptomatic patient is restored, he or she may continue to have pain. There are other possible causes for facial pain in a patient with missing posterior teeth.

Centric Relation Versus Maximal Intercuspation

A widely debated question is whether a discrepancy between initial occlusal contact and maximal intercuspation increases the risk of developing TMJ disorders. Numerous epidemiologic studies have been done investigating the degree of TMJ disorders in relation to centric relation and/or maximal intercuspation slides.[125,127,146] The current literature does not strongly support the role of dental occlusion as an etiologic factor in TMJ disorders from the standpoint of centric relation and/or maximal intercuspation slides.[147] Several studies, however, have been done showing that alteration of the vertical dimension or introducing occlusal interferences (i.e., with "high" restoration) can incite pain and synovial changes.[148-150]

It follows that occlusal adjustments should not be used to treat TMJ disorders.[151,152] Most telling was a Cochrane Database publication concluding that there is an absence of evidence that occlusal adjustment treats or prevents TMJ disorders and cannot be recommended for the management or prevention of TMJ disorders.[153] Therefore occlusal adjustments are only recommended when TMJ pain symptoms have been introduced by recent restorative dentistry or occlusal changes. The traditional recommendation to eliminate centric relation and/or maximal intercuspation slides for the treatment of TMJ disorders has little merit.

Physical Therapy

Throughout the history of treating TMJ disorders, physical therapy modalities have been widely used. Virtually all treatment regimens for TMJ disorders involve physical therapy. The primary focus is to treat neuromuscular conditions relating to the TMJ. Physical therapy incorporates many different treatment modalities. They include stretch and/or range of motion exercises, massage, thermal treatments, ultrasonography, and electrical stimulation.

These therapies can be delivered in several manners. Trained dental professionals can carry out the therapy themselves or teach the patient the proper technique, interval, and duration of the treatment. However, physical therapists trained in caring for TMJ disorders are often necessary and highly beneficial. The physical therapists' primary goal is to treat impairments and functional limitations that are related to the patients' disability, which may or may not have a correlation to the medical diagnosis. This does not limit the necessity for an accurate diagnosis so that a proper and complete treatment regimen can be established. Table 39-7 illustrates the functional limitation and the treatment modality that can be used to improve the impairment.

Exercise Therapy

It is well established throughout the orthopedic literature that synovial joints need movement to maintain function. Early mobilization, even during the inflammatory phase after an injury, is widely accepted in the rehabilitation of other joints.[154] These same principles apply to the TMJ.[155] To maintain proper function and joint integrity, full joint motion is necessary. Furthermore, hypomobile TMJs require range of motion exercises. Exercise therapy is best used when hypomobility exists in one or both TMJs or as a result of surrounding soft tissues.[156] Conflicting opinions exist concerning the degree of hypomobility that warrants exercise therapy, but a maximum incisal opening of less than 30 mm is often used as a cutoff. Hypomobility resulting from periarticular tissue tightness and a disc displacement without reduction responds the best to exercise therapy.

The technique of joint mobilization can be done in either an active or passive manner. The active jaw motion technique involves the activation of the mandibular depressor muscles. Passive joint mobilization is a more popular technique where the musculature is relaxed and the jaw is opened manually (finger pressure, tongue blades, mandibular opening devices). Often some degree of distraction technique is necessary for proper passive mobilization. This can include medicinal therapy in extreme cases.

TABLE 39-7 Physical Therapy Treatment Concerns and Treatment Modalities to Consider

Treatment Concerns	Physical Therapy Treatment Modality
Inflammation	Heat, cold, ultrasound, TENS, iontophoresis
Hypermobility	Awareness, yawning, tongue control
Hypomobility	Heat, exercise therapy
Masticatory muscle hyperactivity	Massage, exercise therapy, ultrasound, iontophoresis

Two passive joint mobilization techniques are often used. First is to have the mandible stretched open and the position held for a short period of time (5 to 15 seconds). This is repeated 5 to 10 times in a session and can be repeated several times throughout the day. The second technique uses a low-load prolonged stretch. This technique has been demonstrated effective in laboratory studies to stretch tendinous soft tissues.[157,158] Heat therapy is often coupled with this technique because it produces greater elongation of the treated tissues. Continuous passive motion is often used after surgical procedures to maintain a proper range of motion.[159] The jaw is stretched open for approximately 10 minutes one to three times per day. It is important to not forget lateral excursive and protrusive movements during passive joint mobilization.

Exercise therapy is also often recommended for symptoms associated with masticatory muscle hyperactivity (resulting in myofascial pain). These therapies are often isometric where there is minimal movement of the mandible. The theory is that contracting one muscle group will cause the antagonist muscle(s) to relax. Therefore contraction of the mandibular depressor muscles will cause the elevator muscles (muscles of mastication) to relax.[160] Care must be taken, however, because excessive exercise and stretching of the masticatory muscles may worsen the myofascial pain.

Exercise therapy used to recapture displaced discs has been found to be minimally effective. Kurita et al found that only 9% of permanently anteriorly displaced discs can be reduced by mandibular manipulation.[161] It is important to remember that exercise therapy is not used to treat the disease process, but to minimize the sequelae. A recent study by Maloney et al concluded that exercise therapy is effective in both joint (intracapsular) and muscle (extracapsular) disorders to relieve pain and increase the range of motion.[162] Exercise therapy may therefore be used to alleviate painful symptoms and maintain functional integrity.

Massage

Minimal research has been done on the effectiveness of massage therapy on symptoms related to TMJ disorders. Massage therapy is only effective in cases involving a muscular component. Techniques, duration, and intervals of massage of the muscles of mastication vary depending on the clinician. Patients can also be instructed at self-massage if they think that it is effective for them. It has been speculated that acupressure techniques are effective at relaxing trigger points within the musculature.[163,164]

Thermal Therapy

Thermal agents are often used in the symptomatic management of TMJ disorders. Patients often express an improvement in symptoms when exercise therapy is incorporated with thermal agents. The use of heat and cold therapy is best used when an inflammatory component is present or with hypomobile TMJs. If marked inflammation is present, heat therapy may be contraindicated.

Superficial heating of the TMJ or surrounding musculature results in an elevation of the pain threshold, increases nerve conduction velocity, and decreases muscle tension.[165-167] No benefit has been cited between moist and dry heat. Heat therapy in the form of a moist washcloth or heating pad is typically applied for approximately 20 minutes to the effected area(s). Application of heat often allows for a greater range of motion with a decrease in pain.

Cold therapy, or cryotherapy, is helpful at decreasing inflammation by causing vasoconstriction and a decrease in tissue metabolism. Furthermore, a *decrease* in nerve conduction velocity has been shown to cause and increase the pain threshold.[168] The "spray and stretch" method has been described to decrease pain while attempting to increase maximal incisal opening.[169] Travell and Simons theorized that stimulation of afferent delta fibers (detecting temperature) produced a decrease in C fiber stimulation (detecting pain).[170] Many clinicians believe that the pain originates from "trigger points" in myofascial pain and the "spray and stretch" technique is effective at decreasing their sensitivity.[171-173]

Ultrasound

Ultrasound has been used widely in various fields of medicine as an additional method of delivering heat to tissues. Unlike superficial heating, however, the tissue interaction is 1 to 5 cm below the skin surface. The deep heat functions similar to superficial heating, intended to decrease pain, increase tissue perfusion, and allow for greater mobility.[174]

In addition to heating the tissues, ultrasound decreases inflammation by increasing cell membrane and vascular wall permeability.[175] Success has been reported in the orthopedic literature when exercise therapy is applied in conjunction with ultrasound.[176] In addition to causing a temperature rise and increased tissue permeability, ultrasound causes an increase in the viscoelastic properties of collagen and hyaluronic acid.[177] This results in greater joint and soft tissue laxity in case of TMJ hypomobility. Care must be taken to perform ultrasound with a proper acoustic conductive gel and use continuous motion so as not to overheat the tissues. Furthermore, ultrasound should not be used over areas of active bone growth; it may cause further aberrant growth.[178]

Electrical Stimulation

The most commonly used method of electrical stimulation is transcutaneous electrical nerve stimulation (TENS). The TENS unit is a small, portable low-voltage electrical device used in an outpatient setting or as a home therapy. The frequency, pulse width, and amplitude of the alternating current can be adjusted. The electrodes are placed over symptomatic areas, areas of inflammation, muscle hyperactivity, or trigger points.[179,180] TENS is most effective

in myofascial pain, resulting in pain relief and muscle relaxation.[181]

The exact mechanism of action of TENS is not known, but it likely involves a counterstimulation of the afferent nerves and controls pain based on the gate control theory.[182] The gate control theory postulates that the pain perception is blocked because the larger proprioceptive afferent fibers are selectively stimulated, inhibiting the smaller nociceptive fibers.[183] TENS has also been shown to produce vasodilation, which increases circulation and lymphatic drainage.[184] Contraindications to TENS treatment include epilepsy, demand-type pacemakers, a history of transient ischemic attacks, or a history of cerebrovascular accidents.[185]

Another method of using electrical stimulation is iontophoresis. Iontophoresis shifts water-soluble ions through the skin to the underlying soft tissue.[186-188] Commonly used ionizing drugs are dexamethasone, methylprednisolone, lidocaine, and salicylates. Medications administered by iontophoresis have been shown to have higher tissue levels than medications taken enterally, but lower tissue levels than achieved by injection.[189] Further research is required on the medication levels achievable in the TMJ. Several studies have shown minimal improvement of pain with the use of iontophoresis, but have shown an improvement in mandibular function.[190,191]

Summary

TMJ disorders are a complex combination of bone disorders, articular problems, inflammatory reactions, connective tissue breakdowns, myalgias, and neural ailments. This can seem quite daunting and has created a stigma against treating TMJ disorders for some clinicians. This has lead to the unfortunate circumstance of specialization of a few clinicians, and the alienation of many others, treating these disorders. As illustrated throughout this chapter, TMJ disorders are quite often multifactorial and require several forms of treatment. This treatment is often best carried out by several members of a team, rather than one individual. Ideally, after an accurate and complete diagnosis has been made, there would be one clinician who is a "team leader" who refers to appropriate specialists (such as orthodontists, oral and maxillofacial surgeons, physical therapists, psychologists, etc.).[192,193]

One method of treatment of TMJ disorders is often ineffective. Common reasons why the treatment of TMJ disorders fails include an inaccurate initial diagnosis and treatment plan, poor patient compliance with treatment, coexisting morbidities, or significant psychosocial problems.[194] It is commonly believed, however, that the treatment should begin with nonsurgical management in the majority of cases. If the initial course of treatment proves to be insufficiently effective, consideration should be made to add additional treatments, surgical or nonsurgical, and to reevaluate the original diagnosis. Nonsurgical management of TMJ disorders, however, has been shown to be quite effective. Okeson reviewed the long-term studies using conservative therapy and found that there was a reported 70% to 95% success rate.[72] The majority of cases have no surgical intervention. Longitudinal studies have shown that patient symptoms fluctuate over time, but the majority improves with a reported remission rate of 31%.[195-197]

Arthrocentesis of the Temporomandibular Joint

VINCENT B. ZICCARDI, SAMI A. NIZAM II

Introduction

Arthrocentesis is a safe and rapid procedure used to treat a multitude of disorders affecting the temporomandibular joint (TMJ). The popularity of this procedure followed the success of arthroscopic surgical procedures with the initial application for treatment of disc displacement without reduction. Since that time, arthrocentesis has been described for other clinical indications; however, it is not indicated for all temporomandibular joint disorders. This procedure does not change the shape or position of the disc or the anatomic structure of the mandibular condyle and glenoid fossa. Pathology involving bony degeneration, osteophytes and bone spicules, disc perforation or fibro-osseous ankylosis are not amendable to arthrocentesis. Treatment with arthrocentesis is generally indicated when other nonsurgical and pharmacologic methods have failed to alleviate TMJ pain and dysfunction.[1]

The etiology of pain associated with the TMJ is multifaceted. Possible sources of pain include impingement, compression and inflammatory changes in the retrodiscal tissues, inflammatory changes in the synovial membrane with joint effusion, and capsulitis. Biochemical investigations of TMJ synovial fluid obtained through arthroscopic lavage and arthrocentesis have yielded information regarding the pathophysiology of pain in the TMJ. Lysis and lavage of the joint space allows for removal and dilution of inflammatory mediators which may contribute to reduction of pain. Elevated protein levels in synovial fluid parallel the degree of inflammation due to increased permeability of the synovial membrane to plasma proteins. Joint effusion as detected on T2 weighted magnetic resonance images reflects hypertrophic synovial lining and exudation from inflamed tissues. Joint effusion is also observed in joints at a more advanced degree of internal derangement.[2]

Prior to performing arthrocentesis, patients must undergo appropriate diagnosis and treatment planning. This is based on medical history, visual analogue pain scales if indicated, and clinical and radiographic findings. Clinical examination should include interincisal opening, lateral excursions, deviation on opening, and documentation of any occlusal discrepancies. Auscultation of the joint may be performed to ascertain any clicks or crepitus which may indicate disc displacement or degenerative joint disease, respectively. Radiographic imaging should minimally include a panoramic screening film followed by other imaging modalities including tomography, computed tomography, magnetic resonance imaging or nuclear medicine studies, as indicated based upon the clinical and physical findings for the specific patient.

Nonoperative management for TMJ disorders may include physical therapy, avoidance of traumatic behaviors such as clenching or gum chewing, dietary changes, nonsteroidal anti-inflammatory drugs, muscle relaxants, and occlusal appliances. Patients who fail conservative measures may be considered as candidates for arthrocentesis. Nonsurgical management for internal derangement without reduction improves symptoms comparably to surgical intervention; however, improvement takes a longer period of time. Patients with TMJ internal derangements without reduction who do not respond to nonsurgical management benefit from arthrocentesis or arthroscopic lysis and lavage.[3]

TMJ internal derangements have been described to progress through clinical stages that initially present as clicking with normal interincisal opening to limited opening lacking translational movement where clicking ceases due to a nonreducible disc. Excessive loading on the joint with a nonreducible, anteriorly displaced disc that restricts the ability of the condyle to translate on the articular surfaces can be treated effectively with arthrocentesis of the superior joint space. When originally described by Nitzan, arthrocentesis was limited to patients with closed locked TMJs. Today, due to its ease and low morbidity, arthrocentesis has found an expanded list of clinical indications including:

1. Acute closed lock due to anteriorly displaced disc
2. Acute open lock due to condyle entrapped anterior to the disc after the more common pathology involving anterior translation past the eminence has been ruled out[4]
3. Palliation of acute episodes of degenerative or inflammatory osteoarthropathies
4. Evacuation of hemarthrosis after traumatic injury[5]
5. Fluid sampling and lavage of septic joints[6]

Contraindications to TMJ arthrocentesis would include those patients who have not undergone appropriate nonsurgical and pharmacologic treatment, demonstrate bony or fibrous ankyloses, or exhibit extracapsular sources of pain such as myofascial or neuropathic pain.[7] Interestingly, some literature has called into question the need for initial conservative therapy, and found better initial pain control and mobility when arthrocentesis was used in place of nonsurgical management, although both study groups ultimately had similar outcomes at 26 weeks.[8]

Pathophysiology of TMJ Dysfunction

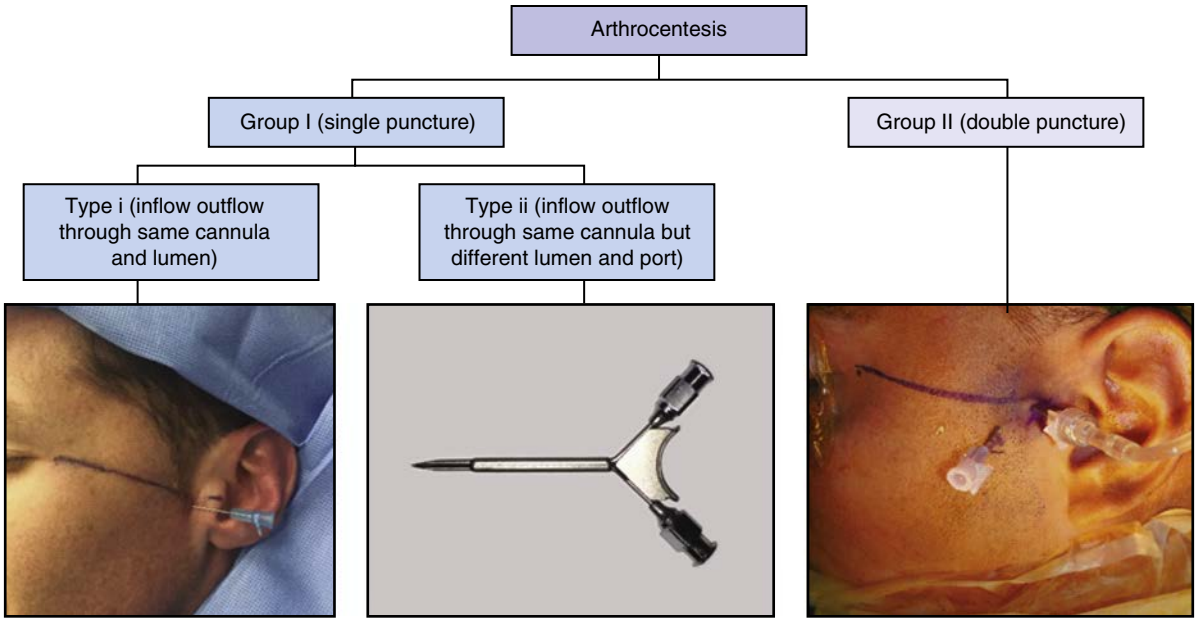
There are several sources regarding the development of pain and dysfunction within the TMJ including the musculature, bony structures, synovium, and discal tissues. Past interest has been directed at the changes observed in the shape and position of the articular disc. More recent research has focused on the biomechanical and biochemical processes involved in TMJ dysfunction. Anchored disc phenomenon as described by Nitzan is a sudden onset of limited mouth opening with deviation of the mandible toward the affected side. Forced opening of the mouth may provoke pain. The disc will appear to be stuck to the fossa with the condyle sliding underneath the disc on MRI studies. This is in distinction to disc displacement without reduction where the patient tends to evolve through stages with intermittent popping and clicking leading to internal derangement with reduction and eventual development of limitation of opening with internal derangement without reduction.[9]

The suction cup effect is one of the forces possibly responsible for maintaining the articular disc adherent to the fossa in anchored disc phenomenon. In an earlier study, greater negative pressures were measured in the upper joint space of patients with anchored disc phenomenon compared to normal joints. The negative pressure was thought to be strong enough to keep the disc from sliding in a normal manner. Insertion of a needle into the superior joint space would reduce the negative pressure; however, other factors may contribute to this condition.[10] Joint overloading may cause collapse of the lubrication system through increased intra-articular pressure and hypoxia that is compensated by re-oxygenation on termination of overloading. The hypoxia-reperfusion cycle can lead to the release and production of reactive oxygen species, which can result in the degradation of hyaluronic acid (HA) and a marked reduction in synovial fluid viscosity.[11] Within the TMJ, surface-active phospholipids function as boundary lubricants and protectors of the articular surfaces. Lysis of these surface-active phospholipids by phospholipase A_2 can result in a significant increase in friction and adhesion between articular surfaces. HA plays a role in joint lubrication through its protection of the surface-active phospholipids from lysis by phospholipase A_2. Injection of hyaluronic acid after arthrocentesis/arthroscopy has been postulated to contribute to a boundary layer of lubrication after surgery so that patients may immediately begin with their postoperative physical therapy.[12]

Temporomandibular joints with internal derangements may be painful as well as demonstrate restricted mobility. Proinflammatory cytokines, which are induced by inflammatory stimuli, may be involved in the pathogenesis of internal derangements. Interleukin-1-beta (IL-1-β) and tumor necrosis factor-alpha (TNF-α) are responsible for destruction of cartilage through degradation of proteoglycans. IL-6 may act to protect cartilage through promotion of the production of tissue inhibitors. It has been suggested that IL-1-β and IL-6 in synovial fluid may be associated with the development of osteoarthritis and the presence of IL-6 may be an index of synovitis. Patients with internal derangements treated with arthrocentesis underwent analysis of synovial fluid aspirates for the assessment of proinflammatory cytokines. It was determined that the detection of IL-6 and IL-1-β in synovial fluid may be an indicator for possible unsuccessful treatment after arthrocentesis for internal derangement of the TMJ.[13] Therefore, techniques aimed at increasing joint function, palliation of pain, and halting the progression of disease should be used. What follows is a summary of current TMJ arthrocentesis techniques described in the literature, indications, contraindications, and adjunctive therapies used to address the pathophysiology and better tailor treatments to each patient using an evidence-based approach.

Technique of Temporomandibular Joint Arthrocentesis

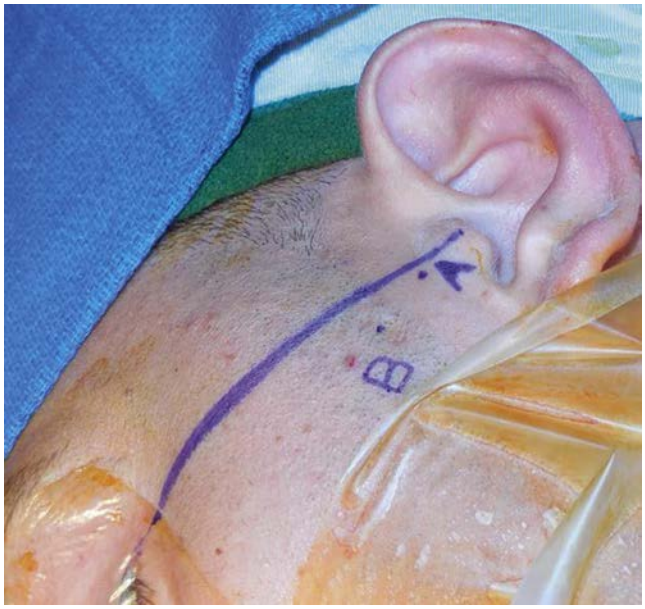
As with any surgical procedure, new techniques and modifications are proposed in the literature, which can cause confusion if there is no universally accepted classification system. Senturk and Cambazoglu created a simple classification system in 2015, taking into account the published techniques for TMJ arthrocentesis. They divided the procedure into two groups: group 1, single puncture arthrocentesis, in which a single needle is inserted into the joint space; and group 2, double puncture techniques in which two needles are placed into the joint at two separate sites. Group 1 is further subdivided into type i, in which inflow and outflow is through the same cannula and lumen, and type ii, in which inflow and outflow are through the same cannula but different lumens and ports.[14] Figure 40-1 presents a simplified diagram of this categorization scheme and can be referenced when comparing and contrasting techniques in the following text.



• **Figure 40-1** Classification scheme of arthrocentesis as devised by Senturk and Cambazoglu. (Senturk MF, Cambazoglu M: A new classification for temporomandibular joint arthrocentesis techniques, *Int J Oral Maxillofac Surg* 44(3):417–418, 2015.)

Double Puncture Technique (Group 2)

Arthrocentesis of the TMJ may be performed under local anesthesia, sedation, or general anesthesia, depending on the surgeon and patient preferences. It is most conveniently performed with the patient in the office suite in a semi-reclined position. The hair is pulled from the surgical field and retracted using a combination of sterile surgical towels and antibiotic ointment. The external auditory canal should be protected from fluid and blood accumulation using an antibiotic-impregnated cotton pledget. A canthal-tragal line is drawn from the midpoint of the tragus to the lateral canthus of the ipsilateral eye. A point is made 10 mm forward from the tragus and 2 mm inferior to the line. This 10-2 point approximates the posterior extent of the articular fossa. This should be confirmed by palpation with the patient opening and closing the mouth. A second point corresponding to the height of the articular eminence can be marked at 20 mm anterior to the midtragal point and 10 mm below the tragal-canthal plane. This can function as a landmark for the placement of the second portal for the outflow of irrigant (Figure 40-2).



• **Figure 40-2** Canthal-tragal line with entry points marked at 10-2 and 20-10.

An auriculotemporal block and infiltration to the preauricular area for joint penetration are completed with local anesthesia. The superior joint is then entered with an 18-gauge needle directed in an anterior-medial-inferior direction at the 10-2 entry point, aiming for the posterior aspect of the articular eminence or anterior recess. Alternatively, some surgeons prefer to gently touch the zygomatic arch and gently walk the needle into the superior joint space. Once the joint space is entered, it may be insufflated with saline or lactated Ringer's solution. Several milliliters of solution can be injected rather passively into the joint space to the end point where there is rebound of the syringe pressure with jaw movement. With the needle in place, the syringe is removed and either a larger syringe can be attached for irrigation or connection to an intravenous fluid bag may be performed (Figure 40-3). A second needle must be inserted for the outflow portal at either the 20-10 point or slightly anterior to the initial needle placement. The joint is then lavaged, maintaining good outflow to confirm maintenance of the needles in the intra-articular space (Figure 40-4). After the procedure is completed, the joint can be manipulated by the assistant who is not part of the sterile field and has a gloved hand in the patient's mouth, going

• **Figure 40-3** System of IV tubing with syringe attached to provide high flow pressure irrigation.

• **Figure 40-4** Same system in use showing maintenance of outflow to confirm intra-articular positioning of the needle.

through opening, protrusive, and excursive movements. A goal of 30 to 40 mm interincisal opening should be achieved at the completion of the arthrocentesis procedure.

This technique can be used for all indications of arthrocentesis because it allows copious volumes of fluid to be flushed in an expedient manner. In particular, it is helpful for palliation of exacerbations of the inflammatory arthropathies, irrigation of a septic joint, or washing out hematoma after trauma.

Single Puncture Technique (Group 1 Type i)

As noted previously, arthrocentesis can be carried out with the use of one needle. The landmarks and procedure remain the same as in the two needle technique, however only the 10-2 posterior point of entry is used. The patient is asked to open his or her mouth and the needle is introduced. The patient then closes the mouth and small aliquots of irrigant are introduced with removal of the irrigating device to allow passive efflux of fluid. This increased hydrostatic pressure is postulated to expand the joint space and break up adhesions. The procedure is repeated several times until more passive movement of the jaw is observed.[15,16]

Insertion of only one needle posteriorly reduces the potential complication of penetrating the frontal branch of the facial nerve. In joints with advanced degenerative changes, the single puncture technique avoids the difficulty often seen with insertion of a second needle. This remains a good option if multiple attempts at second needle insertion have failed and avoids the trauma of multiple punctures to not only the joint capsule but also the glenoid fossa. If a steroid or hyaluronic acid solution is being injected postoperatively, the single needle technique theoretically allows more to stay within the joint space because there is no second perforation of the capsule allowing these substances to leak out. These considerations make the single puncture technique a good option for joints with significant hypomobility from adhesions, especially those with advanced degenerative changes. Of interest, a recently conducted randomized clinical trial demonstrated no statistically significant difference between single and double needle techniques when looking at range of motion (ROM), patient perceived improvement in pain, and surgical procedure tolerability.[17]

Single Puncture (Group 1 Type ii)

This group of techniques makes use of either commercially available needles such as the Shepard Cannula (Normed, Germany) or custom fabricated needles inserted through one puncture site, which combines the advantages of group 1 and 2. Needle entry is again obtained at the 10-2 point as in the previously described techniques. The disadvantages are related to problems with the device itself such as dulling, rusting after sterilization, and a potentially more difficult access due to the larger gauge of the device. Additionally, some have theorized that these devices may not allow adequate pressure for joint distentsion and lysis of adhesions.[5] However, this could be obviated simply by periodically blocking the outflow port.

Irrigant Volume

Because one of the goals of arthrocentesis is to wash out inflammatory mediators responsible for inflammation within the joint, it would be necessary to provide adequate volume to irrigate the joint space and meet that purpose. Repeatedly injecting solution into the joint will increase pressure to release adhesions, but not necessarily eliminate the inflammatory mediators. It was observed that 200 mL of perfusate was sufficient to achieve a statistically significant reduction in protein, bradykinin, and IL-6 concentrations. An ideal lavage volume between 300 to 400 mL perfusate resulted in no detectable level of protein and bradykinin.[18] Previous recommendations were for 100 mL of perfusate to effectively decrease the concentration of protein in synovial fluid and provide therapeutic lavage. Recommendations should probably be for a minimum of 100 mL of total

arthrocentesis volume to achieve therapeutic lavage of the superior joint space of the human TMJ and, if feasible, up to 300 to 400 mL solution.[19]

In 2009 Alkan and Kilic described use of the irrigation pump on self-irrigating surgical motors to provide higher pressures and reduce treatment time, allowing more infusion. They described the two needle technique, confirming outflow before they attached the pump and then irrigating the joint space in 2 minutes with 300 mL of effluent. They cautioned that if outflow stops or rapid swelling occurs, the procedure should cease immediately and an outflow obstruction should be suspected. No mention of actual pressures achieved in the joint were described.[20]

Irrigant Pressure

Arthrocentesis of the TMJ under low pressure with an elevated infusion bag or syringe has been reported to be effective in treating patients with acute closed lock of the TMJ.[21] Irrigation and lavage under sufficiently high hydraulic pressure has also been postulated to widen the joint space and potentially remove adhesions to improve mandibular mobility. This can be an effective procedure for treating patients with chronic closed lock and adhesions in the superior joint space. High-pressure infusion using the infusion with a maximum pressure of 40 KPa, may offer wider application of arthrocentesis for patients other than those patients with acute closed lock.[22]

Number of Treatment Sessions

In 2012 Manfredini et al. reported an overall positive trend with no statistical significance in clinical outcomes using a protocol of 5 weekly sessions utilizing the two needle technique with HA injection.[23] This was tested in 2015 in a randomized clinical trial evaluating three treatment protocols: two group 1 type i single needle procedures (one group with medium molecular weight HA and the other with high molecular weight HA), each utilizing one session, and one group 2 traditional two needle technique utilizing five sessions with HA at each session. This trial did show a significant improvement on visual analog scale at 6 months, however, other variables such as patient perceived effectiveness and maximal incisal opening remained unchanged.[24] The issues when evaluating these studies are the confounding variable of HA addition and use of different arthrocentesis techniques (group 1 vs. group 2). The authors also commented that further research utilizing a three-session protocol should be attempted to maximize cost/benefit ratio. At this time it does seem that a multitreatment session protocol may be more effective when combined with HA, although the specific number of sessions remains in question.

Adjunctive Substances

Steroids have been the most commonly injected adjunctive agent administered after arthrocentesis. Most protocols make use of betamethasone, dexamethasone, or methylprednisolone. They have been shown either alone or in conjunction with arthrocentesis to decrease pain and provide increased MIO for up to a year, although other studies have found no difference.[25] Steroids remain a good adjunctive treatment, due to their availability and marginal cost.

Hyaluronic acid has been one of the recent focuses of literature because it contributes to joint function by maintaining lubrication, minimizing mechanical wear, and playing a role in the nutritional support of the avascular portion of the disc and condylar cartilage.[26] Most injections consist of 0.5- to 2-mL injections. A Cochrane systematic review of the literature through 2010 found that although HA was effective for treating internal joint derangements when compared to placebo, it was no better than intra-articular steroid injection or oral appliances.[27] Unfortunately, most studies looked at use of HA after arthrocentesis, introducing confounding variables. To further investigate, Triantaffillidou and Venetis performed a randomized clinical trial comparing saline placebo with five sessions of HA alone. They found no statistically significant changes at 1 month, but at 6 months and 1 year, all parameters studied were significantly better, including MIO.[28] Another randomized trial performed in 2014 demonstrated single HA injection performance was statistically significantly superior at 1 and 6 weeks when compared to tenoxicam and betamethasone.[29] No difference has been found in using low molecular weight (600 kDa) and medium molecular weight (1200 kDa) formulations.[30] It seems that hyaluronic acid does have proven superiority to other supplemental joint injections, especially when viewed over longer periods of time, and should be contemplated despite its cost when an adjunctive medication is considered.

Intra-articular injection of opioids holds promise as adjunctive therapy and has been studied in two randomized clinical trials. One study compared use of 5 and 10 mg of morphine versus saline and Marcaine and assessed pain relief at 1 week. Although the levels of pain relief drastically fell off after 48 hours for saline placebo and Marcaine 5 mg, 10 mg of morphine had lasting pain relief at 1 week.[31] Another trial comparing lactated Ringer's placebo, 50 mg tramadol, and 1 mg morphine injected intra-articularly after standard arthrocentesis, found a statistically significant improvement in pain up to 6 months postoperatively with morphine. This pain relief was attributed to more potent agonist at the μ opioid receptor.[32] Of note, neither of these studies demonstrated statistically significant increases in oral opening.

The relationship between muscle activity and TMJ dysfunction is not always precisely defined. Many cases of TMJ dysfunction have a component of muscle hyperactivity which can lead to joint overloading and promotion of inflammation and the potential for development of internal derangements. It has been suggested that injection of Botox-A into the muscles of mastication as an adjunct to TMJ arthrocentesis may be more effective at prolonging the improvement of symptoms compared to arthrocentesis

alone by addressing both the joint and the musculature simultaneously. The positive effect may be attributed to the result of mechanical unloading of the joint or possible anti-inflammatory properties of the Botox-A.[33]

Regenerative medicine using growth factors and stem cell therapy is an area of interest. Many studies have found beneficial properties to the use of growth factors throughout the human body. Hanci et al. conducted a trial comparing the injection of platelet rich plasma (PRP) to arthrocentesis and found that PRP had statistically significant increases in maximum opening, decreased joint sounds, and decreased pain when compared to a control group consisting of arthrocentesis alone.[34] As growth factors and stem cell processing units become more popular, these treatments will undoubtedly see increased application.

The literature has clearly shown benefit to all of the described adjunctive treatments in addition to arthrocentesis. Questions remain as to specific formulations, treatment protocols, and superiority of one modality versus another. Selection should be based on the evidence-based findings and combined with known pathophysiology of different internal derangements of the TMJ. For instance, if the patient's chief complaint is limitation in opening, steroids may be selected and combined with a high pressure arthrocentesis to lyse adhesions and provide long-lasting gains in function. If pain is the chief complaint in an end stage joint, intra-articular opioids can be given to provide long-lasting relief and combined with group 1 single needle procedures for ease of insertion.

Outcome Assessment of Arthrocentesis of the Temporomandibular Joint

Nitzan et al. reported that arthrocentesis is a valuable modification of arthroscopic lavage. They demonstrated that arthrocentesis was very effective in the treatment of closed lock with regard to lack of recurrence of symptoms and significant improvement in pain and jaw function within a year of treatment. Furthermore, the authors recommended that arthrocentesis should be performed without delay in those patients in whom attempts at releasing the closed lock by nonsurgical means have failed. Additionally, it was noted that approximately 30% of the joints presented with no history of clicking, implying that the disc became anchored without the presence of an internal derangement, providing clinical evidence that disc displacement without reduction does not always follow disc displacement with reduction.[35]

Carvajal and Laskin[36] reported an overall success rate of 88% in their retrospective review of 26 patients (39 joints) with mean follow-up of 48.7 months after undergoing arthrocentesis. The authors stated that arthrocentesis can reduce pain and dysfunction in patients with anterior disc displacement both long- and short-term. Patients with disc displacement with both reduction and nonreducing discs have interrelated symptoms including pain, which leads to decreased opening, which in turn causes increased dysfunction. Increasing joint mobility may be more important for restoring physiologic function rather than repositioning a disc. Arthrocentesis has been found to be particularly effective in treating patients with disc displacement without reduction, possibly through release of adhesions reducing the obstruction of the displaced disc and by elimination of inflammatory mediators within the joint. For patients with anterior disc displacement with reduction in whom adhesions play a lesser role, the benefits may be derived from the reduction of inflammation and inflammatory mediators.

Kunjur et al.[37] performed a retrospective audit of 298 patients over a 10-year period that had undergone arthrocentesis for refractory TMJ pain. The pain was assessed at 1, 6, and 12 months after the procedure. A significant reduction in their pain score was found and 90% of the patients stated the procedure was beneficial. All patients in this study had failed to respond to conservative therapy including soft diet, physiotherapy, and oral appliances. The joints in these procedures were lavaged with 50 mL of normal saline followed by infusion of 10 mg of morphine and gentle manipulation. These results were reported by the investigators to demonstrate significant improvement in TMJ pain and were recommended as a first-line intervention with patients with TMJ pain refractory to conservative treatment.

Alpaslan[38] reported a 5-year retrospective evaluation of TMJ arthrocentesis patients with a mean follow-up of 22 months. Included patients completed questionnaires as part of the analysis. At long-term follow-up, 26% of the patients were pain free and 88% of patients had decreased pain. There was a significant increase in the maximal mouth opening postoperatively that persisted long-term. Pain and dysfunction levels at follow-up were significantly lower than preoperative levels. A greater reduction in dysfunction with improvement in maximal mouth opening was noted in nonbruxers. Duration of symptoms before undergoing arthrocentesis did not affect outcomes in this study. The authors concluded that arthrocentesis would continue to be a valuable treatment modality for TMJ internal derangements based on its reliable and predictable outcomes with minimal invasiveness.

In a meta-analysis of surgical treatments for patients with TMJ disorders, Reston et al.[39] reported that in patients refractory to nonsurgical management, surgical arthrocentesis and arthroscopy were most reliably effective for patients with disc displacement without reduction. This study reviewed 1,600 journals and included 22 articles that met their criteria of including at least 10 patients, diagnosis of disc displacement with or without reduction, report on the use of a surgical procedure, as well as other factors. In a reappraisal of the study, Ng et al.[40] performed a systematic review of the data using additional inclusion criteria of follow-up duration of 12 months or longer and improvement based on increased maximal mouth opening. The authors discussed the lack of published prospective randomized studies with long-term results to assist the surgeon in selecting a particular surgical option. Their results

indicated that arthrocentesis provided the greatest degree of improvement after intervention compared to the historical controls of discectomy and disc repair. The number of patients enrolled in studies was greater for arthroscopy compared to arthrocentesis, however, it was concluded that arthrocentesis and arthroscopy are effective for patients with disc displacement without reduction.

Prognostic and Predictive Factors for the Effectiveness of Arthrocentesis

Prognostic factors for successful arthrocentesis have been analyzed. Nishimura[41] reviewed 103 TMJ arthrocentesis procedures performed on 100 patients and evaluated the effectiveness of treatment in terms of maximal mouth opening and degree of pain on a visual analogue scale. Other prognostic factors also were evaluated, including age, gender, duration of symptoms, presence of clicks, and radiographic imaging. There were statistically significant differences noted between successful and unsuccessful cases immediately and 1 week after the procedure in maximal mouth opening and visual analogue pain scales. There were no statistically significant differences noted in age, gender, range of preoperative opening, duration of painful locking, and report of preoperative clicking before locking. The degree of condylar deformity on magnetic resonance imaging was statistically lower in successfully treated cases. Pain on the visual analogue scale was significantly lower in the successful cases, which may be related to increased inflammation reducing the effectiveness of the arthrocentesis procedure. In summary, severe preoperative pain, relapse of maximal mouth opening within 1 week after treatment, and the preoperative presence of condylar deformation may be indicators of potentially unsuccessful outcome following TMJ arthrocentesis.

Clinical pain and TMJ dysfunction have been linked to magnetic resonance imaging of internal derangements and osteoarthritis. There was a high rate of MRI confirmed changes in patients with symptomatic internal derangements, which may support the concept that internal derangements of the TMJ may be significantly involved in the production of TMJ pain and dysfunction and, in fact, osteoarthritis and internal derangements of the TMJ may be closely related entities. Internal derangements may be associated with radiographically evident degenerative changes including condylar flattening, sclerosis, and exophyte formation. Comparison of pretreatment versus 2-month post-treatment magnetic resonance images demonstrated no change for those patients with internal derangements, and slight increase in those patients with osteoarthritis. At 2-month follow-up, clinical examination confirmed a significant reduction in pain during function, significant reduction in the clinical diagnosis of internal derangement without reduction, and a significant increase in mandibular range of motion. It was concluded that although clinical pain may be related to TMJ magnetic resonance imaging findings of internal derangements and osteoarthritis, these disorders were not linked to the therapeutic outcomes from TMJ arthrocentesis and hydraulic distention as related to pain and mandibular range of motion.[42]

Patients with successful outcomes from arthrocentesis were more likely to be associated with a magnetic resonance image finding of osteoarthritis compared to those patients with unsuccessful outcomes. Patients with a clinical diagnosis of internal derangement without reduction and concomitant magnetic resonance imaging finding of disc displacement without reduction had a higher rate of osteoarthritis. The presence of osteoarthritis on magnetic resonance imaging is related to clinical finding of pain and osteoarthritis may be an important prognostic determinant of successful arthrocentesis. Osteoarthritis is significantly involved in the production of TMJ pain and dysfunction, although it is not always associated with TMJ pain and dysfunction. This observation emphasizes the fact that prediction of treatment outcomes is not a matter of simple linearity involving only one risk factor. Treatment plans should be based on identified risk factors to optimize outcomes with successful surgical treatment.[43]

TMJ internal derangements and osteoarthritis are frequently cited as causes of TMJ pain and dysfunction. Osteoarthritis is a noninflammatory joint disease characterized by deterioration of the articular surface with subsequent bony remodeling. Internal derangements and osteoarthritis have been recognized as closely related clinical entities with internal derangements described as associated with degenerative changes including surface irregularities, flattening, sclerosis, and osteophyte formation. Arthrocentesis has been demonstrated to be less successful in patients with chronic pain of duration greater than 6 months in regards to outcome of pain reduction. Patients with osteoarthritis were reported to receive greater benefit from arthrocentesis with respect to the elimination of internal derangements compared to non-osteoarthritic patients. TMJ patients with pain associated with internal derangements without reduction were associated with a higher rate of osteoarthritis. This further supports the concept that prediction of outcomes is not based on individual factors, but rather a complex interaction among different variables. As duration of pain increases, the condition becomes more refractory to traditional medical treatments.[44]

Successful intervention based on risk factors may have important implications with regards to the management of TMJ disorders. It has been demonstrated through logistic regression analysis that a significant increase in the benefit of successful outcomes occurred with age less than 25 years, visual analogue pain scale of greater than 75 mm, and range of motion of less than 25 mm preoperatively. The ages of patients in the unsuccessful group were significantly higher than those patients with a successful outcome. Patients with a successful outcome had a higher visual analogue scale pain level and more restricted range of motion compared to those with an unsuccessful outcome. It was hypothesized that these cases may have a more severe inflammatory process

associated with altered constituents in the synovial fluid which was effectively treated with the lavage of arthrocentesis. Predictive modeling may help identify patients who may benefit from arthrocentesis to initiate specific treatments earlier.[45]

Conclusions

Arthrocentesis of the TMJ has been shown to be an effective initial surgical treatment modality for the management of a variety of TMJ disorders in patients who do not respond to conservative nonsurgical management. It has great utility in the treatment of internal derangements without reduction, but also has applicability to other acute and chronic disorders affecting the TMJ. The physical action of lysis and lavage is thought to break down adhesions and remove inflammatory mediators, including cytokines and interleukins, which may lead to chronic pain. It allows a port for deposition of therapeutic medicaments, which are backed by a growing body of literature. These attributes lead to relief of pain, resulting in increased opening and decreased dysfunction. Arthrocentesis can be performed effectively as an outpatient procedure with minimal potential morbidity and should be considered as a first-line intervention and when other noninvasive modalities have not been successful. Outcomes have been reported to be very successful for those cases that are appropriate for this surgical intervention and should be considered prior to open arthrotomy surgical procedures except in those cases where open surgery is the only option.[46]

Arthroscopy of the Temporomandibular Joint

A. THOMAS INDRESANO, CHAN M. PARK

History

Tagaki performed the first arthroscopic examination in 1918. He used a cystoscope to look at a cadaver knee.[1] Several further attempts to look into the knee joint were made, but the equipment was problematic. Watanabe then developed several working arthroscopes and described their use in various joints in 1957.[2] Fiberoptic lighting was incorporated in the 1970s, which allowed for reproducible examination. In 1975, Ohnishi used a Watanabe small-joint arthroscope to enter the temporomandibular joint (TMJ).[3]

Sanders brought the Japanese techniques to the United States, and others, like Holmlund in Sweden, developed diagnostic uses for the arthroscope.[4,5] Murakami published descriptions of the arthroscopic anatomy and pathology in 1982.[6] The main operative usage of arthroscopy in the United States became the lysis and lavage procedure popularized by Sanders and others.[7,8] Operative arthroscopy in the TMJ was first limited by the size of the joint and the lack of miniaturization of instruments that had been developed for the knee.[9] The use of fiberoptic laser delivery in the 1980s by Indresano and Braderick and by Koslin advanced operative capabilities.[10,11] McCain developed suturing techniques that allowed operative arthroscopy to rival open arthroplasty for disc stabilization.[12] Later Dolwick and Nitzan showed that a simple procedure known as arthrocentesis, and performing a lysis and lavage without putting the arthroscope into the joint, gave similar results.[13] Today, therefore, arthroscopic lysis and lavage has been all but replaced by arthrocentesis.[14] Operative arthroscopic arthroplasty is used for more advanced maneuvers by those able to perform them. A modern surgical algorithm for internal derangement will generally include arthrocentesis and may use operative arthroscopic surgery or open surgery as the next step. This has decreased the volume of arthroscopic procedures that were performed in the 1980s and early 1990s.[15]

Anatomic Considerations

The general anatomy of the TMJ is described in Chapter 35. There are several special anatomic concerns that must be mentioned pertaining specifically to arthroscopy. Anatomic landmarks, first enumerated by Murakami, added new terms to those anatomic structures established from dissection.[6]

The volume of fluid in the upper and lower compartments is important to understand. The volume of the normal upper joint space is about 2 mL, but it can increase to as much as 6 mL with pathology. The lower space volume is about 1 mL and can increase to 2 mL. Knowing this is essential to prevent a capsular tear when the initial joint puncture and joint insufflation is attempted.

The joint functions with a complex rotation and sliding motion. The upper compartment is involved in the sliding motion, and most mechanical hindrances and pathologic entities occur here. This is the reason that most arthroscopic surgery is performed in the superior joint space. Since inferior joint space arthroscopy is much more technically difficult to perform, it is quite fortunate that the upper space is where arthroscopy can achieve desired results.

In either the upper or the lower compartment, one must verify that sufficient joint space exists to establish and maintain fluid flow and to accept arthroscopic portals. The ligamentous and capsular structures are thin in the normal joints and can easily be violated by too many puncture attempts, or from too much fluid distention. Attempts to pass an arthroscope in severely fibrosed or bony ankylosed joints are subject to major complications. With pathologic changes, these structures are much more substantial and can be difficult to traverse.

It is imperative that the anatomy of the region specific to arthroplasty be understood before attempting arthroscopic surgery. The bony roof can be interrupted by a sharp trocar in the deep superior portion of a thin mandibular fossa. The proximity of the external auditory canal must be considered. In a large patient, the mandibular fossa position may be topographically difficult to differentiate from portions

of the external and even the middle ear. The temporal vessels and the facial nerve are also of great concern during the puncture maneuver. Injuries to these structures will be described under the section, *Complications*.

Finally, arthroscopy should not be attempted by anyone not capable of performing open joint surgery. If bleeding occurs or instruments break, it may be necessary to surgically explore the joint. One should always be prepared and have informed consent for that eventuality.

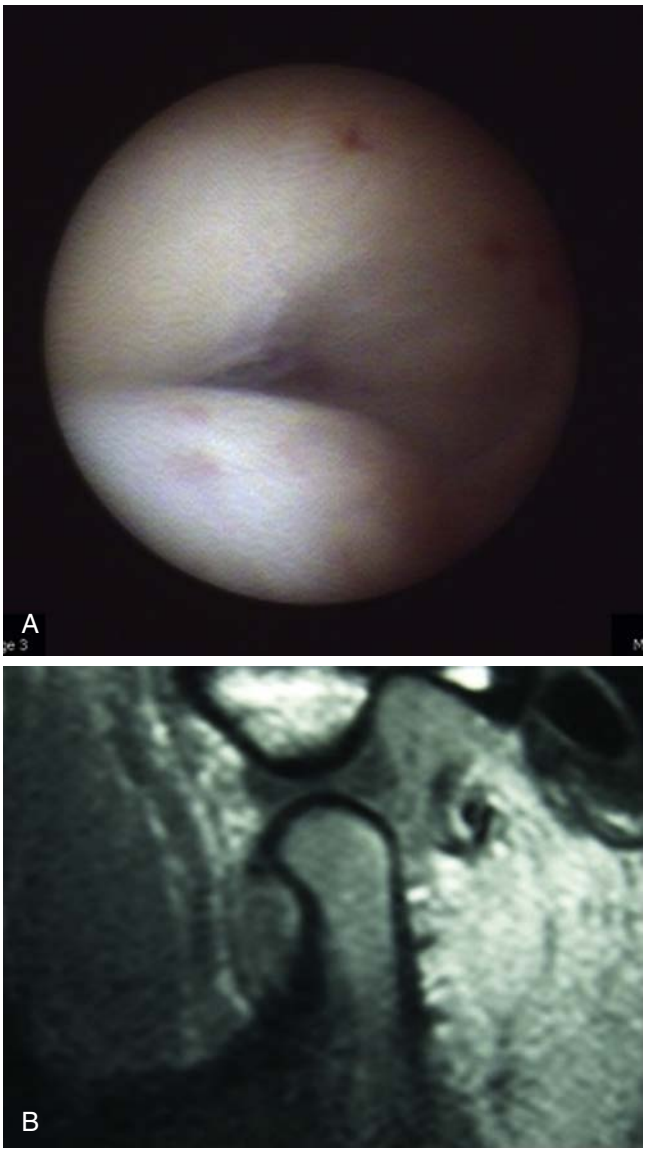
Normal Arthroscopic Anatomy

Superior (Upper) Compartment

Puncture places the arthroscope in the superior space, showing the medial capsule. The synovium is glistening white with a shiny consistency. Posteriorly the synovium folds over the posterior attachment, which is richly vascular, but the vessels are crisp and discrete. When inflammation is present, however, the vascular region is diffuse and blurred. In the normal joint, the posterior band of the disc is raised and glistening but not vascular. The normal disc is white and smooth with no visible vascularity. A folded posterior attachment has been labeled the oblique protuberance and signifies a ligamentous band. The anterior wall is reflected over the pterygoid muscle and is very thin and translucent. Posteriorly and medially the medial capsule is seen. The consistency changes from thin to thick as one moves more posteriorly. The lateral capsule is not easily seen from the inferolateral approach.[17] Figure 41-1 shows a typical posterior recess as viewed arthroscopically, with the corresponding normal MRI appearance.

Inferior (Lower) Compartment

Generally, vascularity is not seen in the lower compartment. The surfaces are glistening and smooth, as is the condylar cartilage cap. Because of the small volume and narrow recesses, generally not much is seen and one must be suspect that the scope itself may cause seemingly pathologic changes.



• **Figure 41-1** Normal joint. **A,** Normal view of upper joint space with arthroscopy. **B,** Corresponding normal MRI.

Diagnostic Uses

When temporomandibular joint arthroscopic examination was first performed, its diagnostic usefulness was felt to be the primary benefit. After more than 20 years used as a common tool, direct visualization of the joint is not routinely needed for diagnosis. Although many forms of joint pathology can occur in the TMJ, there may be no correlation with changes in the synovial or cartilage surfaces. Therefore diagnostic arthroscopy must be used in conjunction with history, clinical signs, and imaging to formulate a diagnosis in the TMJ patient.

The main abnormality seen in the temporomandibular joint is the internal derangement/osteoarthritis continuum categorized by the Wilkes classification.[18] Arthroscopy can be most useful in staging this disease and determining treatment options.

Other arthritides are seen, with rheumatoid arthritis being the most common, but arthroscopy is rarely, if ever, the deciding factor in diagnosis. Diagnosis and treatment of traumatic conditions may be helped by arthroscopic evaluation. Biopsy is essential if dealing with the very rare tumor that may occur.

Pathology

Internal Derangement

Although the most common condition to be treated with arthroscopy, internal derangement shows various levels of nonspecific changes that are mostly attributed to inflammation. Increased vascularity in the posterior

attachment, vessels encroaching onto the avascular disc, and blurring of vascular markings may all be seen. Signs of cartilage degeneration in later stages may also be seen. This information may direct the operative therapy when performing arthroscopic surgery, such as the use of laser, anti-inflammatory medications, or lubrication therapy. It might also indicate the need for an open procedure if an undiagnosed perforation of the disc is seen. Figure 41-2 depicts various pathologic conditions as encountered by arthroscopy.

Fluid Analysis

Analysis of joint fluid has brought a greater understanding of the degradation process in internal derangement as well as theories for the causation of pain emanating from the joint. Substances such as interleukin-6 (IL-6) and IL-10 have been shown to be markers predicting outcome in lysis and lavage for chronic closed lock.[19] Fluid analysis will be discussed elsewhere.

Equipment

There is much written about arthroscopic equipment, especially at the advent of its use.[20,21] Figure 41-3 shows a typical equipment set-up. Telescopes run from 0.7 to 2.7 mm in diameter. The angle of view can range from zero to 35 degrees. Generally an angled arthroscope is better for visualization of all areas, and a zero-degree arthroscope is better for operative techniques that include triangulation. Various light and camera systems are available. A complex three-chip camera will give the best video reproduction. There has not been much research and development in TMJ arthroscopic equipment recently. Manufacturers have concluded that there is not a large market for this equipment in the United States. With most joint lavage now being accomplished through arthrocentesis, only a few changes in arthroscope design have occurred. These have been accomplished in Japan, and much of the newer equipment is not exported to the United States.

Arthroscopic Puncture—The Inferolateral Technique

Arthroscopy is very technique-sensitive. There is a large learning curve to master before feeling comfortable performing this procedure effortlessly. Partly, this is due to the process of learning to operate while watching a monitor and making very minor hand movements to achieve objectives, and partly from complications that can occur if not performed skillfully.

Arthroscopy can be undertaken with the patient receiving a local anesthetic, but this is usually a single-puncture observation of the joint, possibly with biopsy. Most often it is performed with the patient receiving a general anesthetic in an operating room, especially if multiple punctures are used and operative equipment such as lasers are required.

Peri-operative antibiotics directed to prevent skin contamination and glucocorticoids for edema management are often used. The patient is placed in the supine position on the operating table and receives nasal endotracheal intubation. Preparation of the skin with povidone iodine or comparable antibacterial solution is performed. After the surgical field is isolated, circular holed aperture (eye) drapes are affixed anteriorly over the ear to provide an isolated field in front of the ear. Neurosurgical drapes may be helpful in keeping the copious irrigating fluid off the floor and shoes.

Lidocaine with epinephrine may be injected subcutaneously for hemostasis at the puncture site. It is controversial as to whether epinephrine should be injected directly into the joint space because it may affect visualization of synovial vascularity. The pattern and character of synovial vessels may indicate the level of inflammation present. After the initial evaluation, vasoconstrictor may also be added for hemostasis.

Several different size syringes are needed on the field. Ringer's lactate solution is the preferred irrigant, but normal saline may also be used. It is injected into the superior joint capsule using a 3-mL syringe, so that back-pressure can be felt when the joint space is entered. After a successful circuit is achieved, a large syringe (30 to 60 mL) should be used for irrigation. Some operators suspend a bag of fluid under pressure for this purpose. The drawback to this method may be fluid extravasation.

Puncture using the sharp trocar of a 1.9- to 2.3-mm arthroscope should be along the tragocanthal line approximately 1 cm anterior of the midtragus. As the operator becomes more experienced, the topographic measurement will often give way to palpation to establish the entrance point. The inferolateral approach described by Murakami is standard[8] (Figure 41-4). Moses described an endaural approach that can be used for visualizing the lateral capsule, but it is rarely used.[22] Once the capsule is entered the blunt trocar is used to establish the position inside the joint space. An 18-gauge needle is used as an outflow port temporarily while the arthroscope is inserted and a methodic examination around the superior space is performed. Most diagnoses can be established in this first sweep. Once done, the arthroscope is positioned in the anterior recess, so that a second puncture is performed to provide fluid outflow and triangulation. By measuring the length of the first trocar, the second puncture point can be established. If the lights are dimmed the arthroscope light will transilluminate the position in a thin patient. The second puncture is performed at 90 degrees to the first. The operator should be able to see the entrance of the second trocar in the field in the anterior recess. Now, the operator is prepared to perform any surgical maneuver necessary. Operators who do not instrument the joint, but only observe and lavage the joint, may be able to use only an outflow needle, which simplifies the procedure greatly.

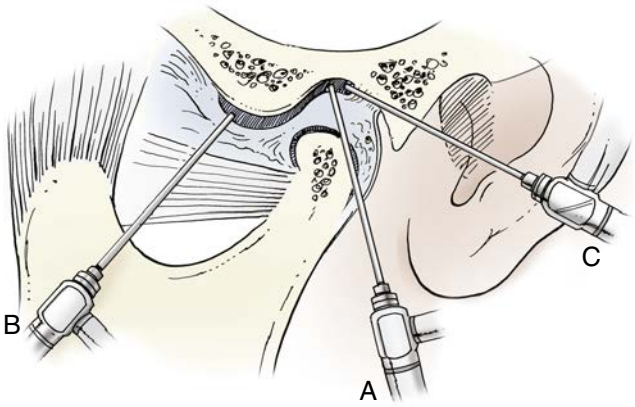
Operative Arthroscopy

The goals of arthroscopic surgery vary with the diagnosis, but generally follow several paths.

Various arthritides may require diagnostic observation and biopsy. Anti-inflammatory medications can be directly applied by lavage, or by direct needle placement for injection into the pathologic tissues. Laser energy can be used to remove pathologic tissue or to contract redundant or hypermobile tissues.

However, internal derangement is the disorder most often encountered. The goals of therapy depend on the diagnostic stage. Usually the surgery is directed to increasing motion and function. These goals can be obtained by stretching the capsular tissues with probes, cutting the restrictive capsular elements with knives or laser, removing scarred or hyperplastic tissues with shavers or laser, removing adhesions, or placing anti-inflammatory agents with direct needle injection.



• **Figure 41-4** Puncture direction for the upper compartment of the temporomandibular joint. **A,** Inferolateral approach. **B,** Anterolateral approach. **C,** Endaural approach.

• **Figure 41-5** A zero-degree telescope suitable for arthroscopic surgery. Small-diameter scissors and forceps must be of high quality.

More severe degenerative joint disease may require the ablation and resurfacing of the joint surfaces. This can be attained with mechanical shavers or laser, and application of medications (Figure 41-5).

Arthroscopic Lysis and Lavage

Joints with surface breakdown caused by mechanical injury or arthritides may benefit from lavage with a suitable fluid.[4-9] Lavage is a normal part of all arthroscopic procedures. The fluid can be used as a mechanical dilator in the joint space, releasing some adhesions through distention or breaking the "suction cup" effect described by Nitzan.[25] Fluid is also used to wash out cytokines, interleukins, and other pain mediators and breakdown products of cartilage damage and arthritic destruction. Milam has also determined that the greater volume of lavage fluid removes the larger molecules more effectively.[28]

Lysis of adhesions may be performed with the arthroscopic "sweep" described by Sanders,[4] with surgical instruments or

• **Figure 41-6** Lysis of fibrotic bands using the blunt trocar in sweeping movements from anterior to posterior.

with laser[10] (Figure 41-6). This technique is usually part of all arthroscopic surgery, and is used to free the superior joint space to gain increased motion. Lysis and lavage was the first arthroscopic procedure described and was the predominant procedure for internal derangement in the late 1980s. The success rate of this procedure is reported to range between 70% and 90%.[15,27] Since the procedure included several components, it was difficult to ascribe success to any specific part of the procedure. The evolution of arthrocentesis, with lavage and manipulation alone, brought into question whether arthroscopy with visualization was necessary as a routine procedure.[23-26]

Arthroscopic Arthroplasty

The addition of miniaturized hand instruments, mechanical shavers, and lasers to the armamentarium created arthroscopic arthroplasty of the TMJ. Procedures performed previously only in open arthroplasty could now be performed arthroscopically. These techniques increased the difficulty of the procedure, requiring increased technical ability. Consequently, the pool of surgeons performing arthroscopic arthroplasty decreased, with the majority performing arthrocentesis.

Arthroscopic Removal of Adhesions

Superior joint space adhesions can be released with the sweep of a surgical probe. More definite and thick bands require sharp or laser dissection. Multiple severe adhesive bands may require a mechanical shaver, but can also be lysed using a holmium laser fiber.

Capsular Releases

Generally, joint restriction resulting from internal derangement may be improved by anterior or lateral capsular release.

Anterior Capsular Release

The arthroscope is placed into the anterior recess and the anterior wall may be stretched using a probe or released using sharp dissection or laser (Figure 41-7). Immediate widening of the anterior wall is achieved. This may have a profound effect on joint translation.

Lateral Release

Lateral capsular release, described by Moses,[29] increases translation and lateral excursion. The release is performed by stretching with probes or sharp laser dissection. The Moses elevator was designed for this procedure.

Disc Repositioning

The efficacy of open disc repositioning in internal derangement has been questioned,[30,32] but it was once the mainstay of surgical treatment with success rates of about 85%.[31] Arthroscopic repositioning can be achieved by performing anterior release and contracting the posterior attachment by either using laser, injecting sclerosing agent, or performing a suturing maneuver as described by McCain[33] (Figures 41-8 through 41-11). There does not seem to be any difference when compared with open arthroplasty with suturing. Successful disc repositioning that has been maintained over time has not been reported. When using laser, there is no pretense of repositioning the disc to normal position, but this combination technique has been shown to be successful in a prospective study.[15] It should be recalled that success is based on return to normal function with minimal pain, not based on the preconceived notion of restoring normal anatomic position. Arthroscopic suturing is technically difficult and requires a high level of expertise. It is, therefore, employed by very few surgeons.[34]

The holmium:YAG laser is most often used, although any laser with fiberoptic delivery can be potentially used. Holmium has the advantage of being precise and safe. With a small amount of energy, the laser can perform pinpoint cutting or the beam can be defocused to contract tissues and ablate blood vessels (Figures 41-12 through 41-14). The laser is of little use on bony surfaces, where it is inefficient at cutting and may char the surface. Electric cautery can be used for contraction of tissues, but it has been replaced by the laser for ease of use and safety.[35]

Both Ohnishi and Merrill studied the use of chemical sclerosants as a means of limiting motion in a hypermobile joint.[36,37] Several agents (Sotradeccol, sodium morrhuate) have been injected into the posterior attachment under direct vision. The technique is underutilized, but is successful at stabilizing loose joint tissues.

Complications

The complication rate for arthroscopic temporomandibular joint surgery is small,[38,45] but the arthroscopist must be able to perform all open procedures in order to assure safety. Extravasations of fluid are possible with extensive procedure time, multiple failed punctures, or excessive pressures. The swelling can usually be controlled with pressure dressings, but possible airway compromise must be considered when large volumes of fluid extravasate.

• **Figure 41-12** Anterior release through disc to the underlying pterygoid muscle.

Vascular damage was seen in about 2% of patients in a study by Carter.[16] Hemorrhage can be controlled in the superficial vessels with pressure or with ligation. Intraoperatively, deep hemorrhage from within the posterior attachment can usually be treated by retruding the condyle to put direct pressure on the posterior attachment for at least 5 minutes. In the rare instance that bleeding cannot be controlled, arthrotomy must be performed. Rarely, an arteriovenous fistula may occur, in which case the patient will be bothered by a whooshing sound that occurs several days post surgery. Arthrotomy with direct ligation of the vessel or endovascular treatment may then be required. [44]

Broken instruments are rare and can often be removed with a magnetic probe or with a biopsy forceps.[39] It is imperative that visualization of the instrument be maintained from the time it is broken. If it cannot be removed, then fluoroscopically guided open surgery may be necessary.

Otic injuries are the result of instrument positioning errors and can result in external, middle ear complications or intracranial injuries, all of which are quite rare. Infection occurs in less than 0.5% of cases.[12]

• **Figure 41-13** Posterior tissue after laser treatment.

• **Figure 41-14** Posterior synovial hyperplasia with pain.

Postoperative Care

Immediate postoperative care is directed to controlling swelling and pain. A pressure dressing is usually applied short term, and may be removed in the recovery room before discharge. Peri-operative antibiotics may be given during surgery with a second dose before discharge. Dexamethasone is also administered at the beginning of the case and before discharge. Other medication schedules exist, but there is generally no rationale for long-term antibiotics or steroids. Moderate pain medication is prescribed for home use.

Postoperative Physical Therapy

Postoperative physical therapy is often the most important part of the overall treatment plan, especially if joint restriction is present. A regimen of 1 hour 3 times a week with a therapist is necessary until goals are met, which usually occurs in 2 to 4 weeks. Specific goals of maximum incisal opening, protrusion, and excursions are established by the surgeon as they apply to each patient. A decrease in pain to a level that the patient can tolerate with nonnarcotic pain medicine and a return to a normal diet are also therapeutic goals.

Evidence

Published arthroscopic results have been mostly retrospective case series, with varying techniques and populations. They are difficult to compare and many have no controls. Retrospective studies that report results as "excellent" or "successful" provide the preponderance of these results. [46] Success is usually defined as increased mobility and function and decreased pain and disability. Authors often mix the use of lysis and lavage with other operative techniques, and apply medicines described in one generic term of "arthroscopy," which makes comparisons difficult. However, the volume of case series from around the world accentuates the results. When most reports agree that "success" rates are 80% to 90%, one has to conclude that the technique is achieving the results indicated. It is difficult to design prospective, controlled studies with surgical options that might have to be withheld to satisfy the design.

In 1993 Sanders and Buonchristiani reported 86% excellent results and 9% good results for 306 patients who had undergone lysis and lavage and were followed for 5 years.[39] McCain and colleagues reported a multicenter study in 1992, the largest study to date; this study had a 6-year follow-up on 1114 patients, with an overall success rate of 91% using multiple techniques.[12] The study by White[40] in 2001 reported on 100 patients who had received lysis and lavage and were followed for 13 years; 94% of these patients were greatly or moderately improved.[41] Indresano reported on 400 patients using lysis and lavage and later laser operative arthroscopy, with 80% success results over 5 to 8 years, making comparisons between the two techniques.[41]

Generally, the reported procedure may be divided into two groups: lysis and lavage or arthroscopic arthroplasty, which may include either mechanical or laser manipulations. Arthroscopic placement of medications is more difficult to track since many surgeons use medicinal adjuncts to arthroscopic surgery. It may be impossible do distinguish the effects of these agents without specific studies such as that published by Kopp.[42]

More research must be done in the area of therapy directed to joint lubricaton.[43] The advent of high molecular weight hyaluronate compounds has only added to the need for research into the loss of lubrication and how replacement may contribute to joint health. Arthroscopic lysis and lavage has been shown to provide most of the benefits of more complex operative arthroscopic surgery in many TMJ patients. However, arthrocentesis may often achieve these same goals with less risk, and it has significantly reduced performance of arthroscopy. The more complicated procedures, such as operative arthroscopy, are increasingly limited to few surgeons.

Surgery for Internal Derangement of the Temporomandibular Joint

WILLIAM CHUNG, ALEJANDRO J. ALMARZA

The term temporomandibular joint disorder (TMD) describes a condition that involves temporomandibular joint (TMJ) pain and dysfunction. TMD may arise from a muscular disorder or may involve the joint itself or any of its associated structures. Effective management of TMD becomes more critical, and potentially complex, when a patient presents with both myofascial pain and articular disease. DeBont et al created a detailed classification system for the articular disorders of the TMJ[1] (Box 42-1).

The earliest recognized and reported dysfunction of the TMJ involved joint ankylosis or dislocation. Another articular condition, internal derangement (ID), was first described by Hey and Davies in 1814.[2] ID involves an abnormality of the disc-fossa relationship resulting in a mechanical disorder that creates irregular joint noises and prohibits normal, smooth condylar movements. A staging system for ID was created by Wilkes, which describes the clinical and radiographic characteristics of this disorder (Box 42-2).[3] Stage I is clinically consistent with painless clicking but no limitation of jaw opening. In Stage II the patient experiences occasional painful clicking and intermittent joint locking. As the patient progresses to Stage III, more significant joint pain on function occurs along with restricted jaw opening. In Stage V, the patient's exam is positive for crepitus, episodic and variable joint pain, and restriction of opening.

The presence of parafunctional oral habits, concomitant medical and/or psychological conditions, and other past and present treatment need to be carefully identified and considered prior to pursuing surgery. Proper patient selection is also a fundamental and essential aspect of TMJ surgery. Although nonsurgical, conservative therapies should be undertaken, and often exhausted, before pursuing surgery, certain pathologic disorders of an articular origin are best treated by surgery, specifically TMJ dislocation, ankylosis, certain condylar fractures, neoplasms, and degenerative joint disease.

The evolution of surgery for ID is well documented in the literature. In 1887 Annandale reported the first intracapsular procedure for ID,[4] while in 1909 Lanz reported the first use of a discectomy for painful joint dysfunction.[5] An array of procedures ranging from minimally invasive techniques to arthrotomy have been used to treat ID, and the benefits of each have been clearly documented.[6-14] The use of TMJ arthrography was instrumental in establishing disc pathology as a factor in TMD,[15,16] and studies by Dolwick elaborated on the role of various disc surgeries, such as repositioning and repair, in the treatment of ID.[17-19] Yet the exact role of surgery for the management of ID remains controversial. Detractors of surgery for ID are quick to point out that amidst progressive anatomic degenerative changes, TMJ pain and dysfunction can still decrease in the absence of any treatment.[20,21]

This chapter discusses key elements in a patient's history and physical exam that assist the surgeon in selecting the proper surgical candidate. The chapter also lists the goals of surgery for ID and the role of diagnostic imaging in treatment planning. Only open arthrotomy techniques are reviewed, as other minimally invasive procedures used to treat ID and TMD are covered elsewhere in this text. Lastly, complications of surgery and the importance of postoperative physical therapy will be discussed.

History and Physical Examination

The diagnosis of ID is achieved through a thorough history and detailed clinical examination, and an accurate diagnosis is paramount in determining either the most appropriate surgical technique or the need for surgery altogether. However, establishing the patient's diagnosis can be an obstacle for the surgeon because each patient's symptoms are highly individualized. Additionally, the patient may not always accurately report or describe his or her symptoms. Focused questionnaires regarding TMJ pain

• BOX 42-2 Wilkes Classification of Internal Derangement of TMJ

Stage I Early

Clinical—Painless clicking
No limitation of opening
Radiographic—Mild disc displacement with early reduction
Normal disc morphology

Stage II Early/Intermediate

Clinical—Occasional painful clicking
Intermittent locking
Radiographic—Mild to moderate disc displacement with late reduction
Mild disc deformity

Stage III Intermediate

Clinical—Joint tenderness
Limited opening
Frequent pain
Radiographic—Displaced, *nonreducing* disc
Disc deformity

Stage IV Intermediate/Late

Clinical—Chronic pain
Limited opening
Radiographic—Severe displacement, without reduction
Deformity of disc
Degenerative osseous changes

Stage V Late

Clinical—Variable joint pain
Joint crepitus
Radiographic—Nonreduction of disc with perforation of disc attachment or disc
Degenerative osseous changes

and dysfunction can be completed by the patient to help the surgeon rule out certain subtypes of TMDs that may not be amenable to surgery. If the patient reports a history of painful joint noises and pain on mandibular function, a diagnosis of ID is likely and surgery may be indicated. One scenario that should cause concern for the surgeon is a recent resolution of a patient's history of painful joint noises in lieu of continued joint pain. This clinical picture may indicate acute disc perforation. Physical exam findings consistent with ID include:

1. Pain on palpation directly over the TMJ, particularly during joint loading
2. Limitation in joint range of motion
3. Deviation on opening, if unilateral
4. Joint noises consistently associated with pain
5. Joint crepitus

If concomitant myofascial pain or dysfunction exists, it must be specifically addressed in the comprehensive treatment of the patient. Myofascial pain may develop secondarily in patients with ID, and ID may develop secondarily in patients with myofascial pain. In cases of disc dislocation with reduction, a patient may experience significant pain while trying to move past the obstructing portion of the disc. When a patient has a unilaterally dislocated disc, the mandible will deviate to the affected side during rotation and then correct its path toward the midline once the condyle has moved past the obstruction and has reduced itself into the disc. In bilateral disc dislocation with reduction, the mandible will deviate to one side and then click. The mandible may deviate to the contralateral side and then click again.

Pathogenesis

Recent studies have related the molecular biology of the joint to the pathogenesis of ID. An imbalance favoring catabolic over anabolic processes has been implicated in the development of degenerative disease. Milam proposed that mechanical stresses in the joint make the TMJ susceptible to formation of free radicals that are thought to contribute to the production of other metabolites and enzymes that promote degenerative changes.[22] One specific free radical, nitric oxide, has been formed in increased levels in

arthritic joints. Nitric oxide also promotes the formation of enzymes and prostaglandins that lead to inflammation and tissue breakdown within the joint.[23] Nitzan hypothesized that free radical formation leads to oxidative stress, which subsequently may impair the lubrication system of the joint.[24] The ultimate disruption of joint lubrication leads to increased friction within the joint space. Nitzan and Etsion suggested that this increased friction due to a lack of disc lubrication is what causes disc dislocation as the disc is repetitively pressed against the articular surfaces.[25]

Synovial fluid analysis of the TMJ has shed light on the role of cytokines, proteinases, and other substances in the development of ID. Interleukins are specific cytokines that mediate inflammation and have been detected in both ID and osteoarthritis (OA) of the TMJ.[26] Cytokines appear to contribute to tissue damage by inducing the release of proteinases and collagenases. Gruber et al[27] reported on the possible role of one such marker, matrix metalloproteins (MMPs) produced by synoviocytes and articular chondrocytes, as mediators of cartilage degradation. Kubota et al[28] compared the TMJ synovial fluid between asymptomatic patients and those with established ID or OA for differences in interleukin-1 (IL-1β) and IL-6 levels to determine whether the IL levels would reflect the pathogenesis of ID. Results indicated higher levels of IL-1β in the synovial fluid of joints with ID or OA compared to the normal, asymptomatic group. IL-1β and IL-6 levels were also significantly higher in the OA group than in the ID group. This study concluded that elevated levels of cytokines can be potential markers for cartilage degradation in the TMJ. The findings from the above-mentioned studies lend support to the role of arthrocentesis or arthroscopy as the initial surgical intervention for ID such as closed lock, as lavage of inflammatory mediators and lysis of adhesions can be accomplished by either technique. Other past and more recent studies continue in their attempts to establish the role of molecular biology of the TMJ with ID.[29-33]

Goals and Criteria for Surgery

Surgery is reserved for patients whose TMJ pain and dysfunction are refractory to conservative nonsurgical modalities and when symptoms result in significant impairment.[34,35] The goal of surgery is to preserve the articular tissues while returning the patient to a more regular diet and reestablishing a normal range of motion to the jaw. Individualized goals of surgery are discussed with each patient before undertaking any form of surgery. The American Association of Oral & Maxillofacial Surgeons (AAOMS) published the first guidelines for disc surgery in 1984 based on a literature review and the general consensus of surgeons.[36] This document was succeeded by another in 1990 stating the standards and criteria for TMJ surgery.[37] TMJ arthrotomy is performed for TMJ ankylosis, trauma, previous surgery, severe degenerative disease, growth disturbances, and neoplasms.[38-44] As recently as 2005, a study by Hall et al compared the outcomes of four commonly used techniques in treating ID.[6]

Two reports by Holmlund and The Second International Consensus Meeting in 1992 have stated criteria for successful TMJ disc surgery.[45,46] These criteria include:

1. Mild, brief, or infrequent pain of no concern to the patient
2. A vertical range of motion greater than 35 mm and lateral range of motion greater than 6 mm
3. Ability of patient to eat a regular diet, at worst avoiding tough or hard foods
4. Stabilization of possible degenerative imaging changes
5. Absence of symptoms for at least 2 years
6. Absence of significant complications

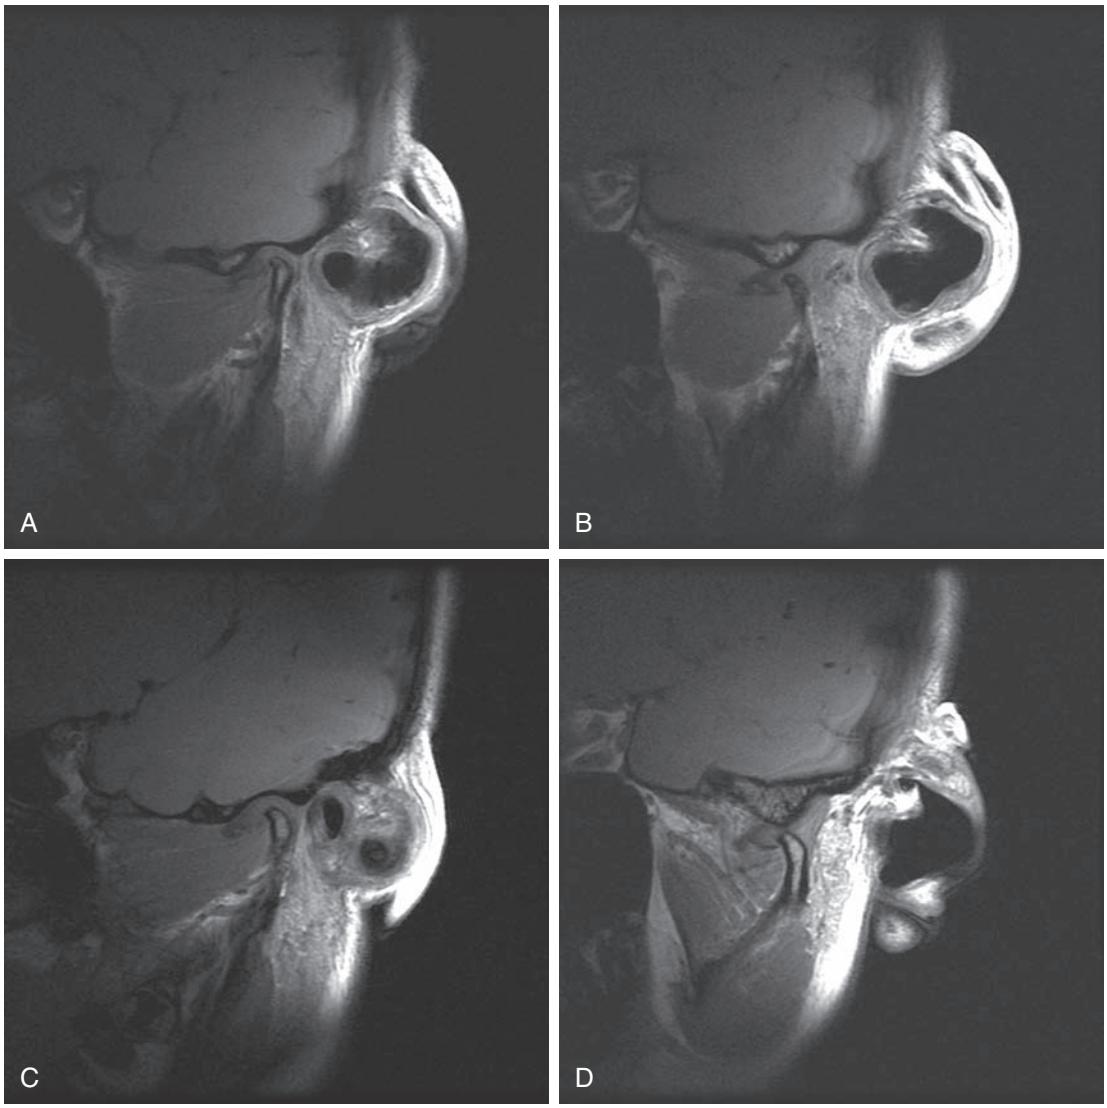
A common form of ID is closed lock. This condition is associated with either an acute or chronic anterior disc dislocation without reduction. When TMJ arthroscopy is undertaken for this condition, adhesions are often noted in the superior joint space. These adhesions can subsequently be removed by arthroscopic techniques. Adhesions can be noted in the superior joint space particularly during diagnostic arthroscopy and then subsequently removed by arthroscopic surgery.[47-51] Arthrotomy is performed for closed lock if arthroscopic techniques fail to correct the mechanical disturbance.

Diagnostic Imaging

Hard tissue abnormalities of the TMJ are most readily identifiable by plain films and computed tomography (CT) scans.[52-54] Panoramic radiographs best serve as a screening tool to identify any gross bony abnormalities, while CT scans are superior to plain tomography in evaluating hard tissues. CT scans provide only limited evaluation of the soft tissues surrounding the TMJ, particularly the disc. Soft tissue disorders of the joint can be determined by arthrography.[54,55] However, an MRI is the study of choice to evaluate ID. MRI studies differentiate the variable proton density within a given tissue volume and then use variable pulse sequences to configure images. The TMJ disc has a low signal pattern and appears black due to its low proton density. Tissues that are higher in either water or proteins appear white on an MRI, which may be indicative of tissue edema. No direct correlation has been definitively reported linking higher signal intensities of TMJ discs with perforations or other surface damage.

Studies of disc displacement or degenerative changes of the condyle have been clearly demonstrated in asymptomatic patients.[56-58] Thus, one must avoid over-emphasizing radiographic findings so as to prevent unnecessary or overly aggressive treatment. Figure 42-1, *A* and *B* show an MRI that displays anterior disc displacement without reduction. This patient was involved in a motor vehicle accident and sustained a whiplash-type injury and developed a unilateral TMD. Figures 42-1, *C* and *D* illustrate how the same patient can manifest the identical anatomic abnormality on the contralateral side. However, this patient reported no symptoms from the contralateral side.

When ordering an MRI for ID, the surgeon should request both sagittal and coronal views to accurately depict



• **Figure 42-1** **A,** Direct sagittal magnetic resonance image (MRI) of an anteriorly dislocated disc in the closed mouth position. The disc is located anterior to its normal position relative to the condyle and articular eminence. **B,** Direct sagittal MRI of patient in part **A** in the open mouth position. The nonreducing dislocated disc is situated at the bottom of the articular eminence with the condyle articulating against the posterior attachment of the disc. **C,** Direct sagittal MRI of contralateral disc in the closed mouth position in the same patient. The disc is anteriorly dislocated. **D,** Direct sagittal MRI of the same disc in the open mouth position. The disc is severely dislocated without reduction.

the three-dimensional aspect of ID. Sagittal views alone may not depict medial or lateral disc displacement. Liedberg and Katzberg have reported the diagnostic value of coronal MRI views in verifying disc displacement.[59,60] An MRI should also be ordered in both T1- and T2-weighted images. T1-weighted images best depict the anatomy of the TMJ, while T2-weighted images allow for visualization of joint effusions. No studies have been able to consistently or accurately determine disc perforations.

Preoperative Therapies

Nonsurgical, conservative therapies used in the treatment of TMD are covered in greater detail in other chapters of this text. Non-steroidal anti-inflammatory drugs, a soft diet, physical therapy, splint therapy, and behavioral therapy when indicated are among the various nonsurgical, conservative therapies that are typically implemented, and sometimes exhausted, before surgery is considered in the treatment of ID. When myofascial pain exists concurrently with ID, splint therapy may relieve one pain but aggravate another. If an anterior repositioning splint is implemented because of the presence of the ID, the patient's myofascial pain may be aggravated. If the more common maxillary stabilization splint is fabricated, the myofascial pain may be improved, but joint pain may still exist, especially if the patient is functioning on the posterior attachment of the disc.

Surgical Approaches

A variety of open surgical techniques exist for the treatment of ID. These include the following:

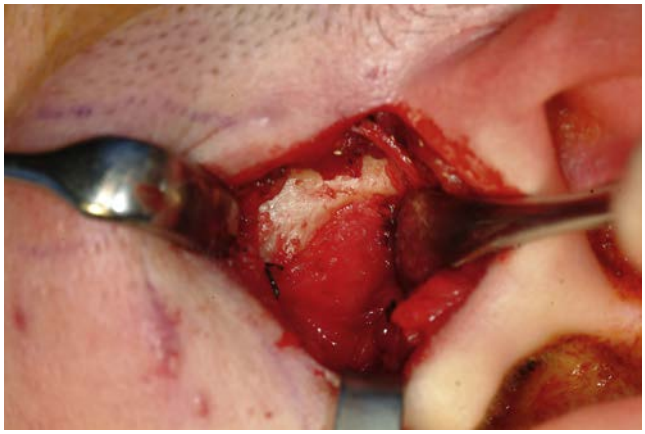
1. Disc repositioning
2. Disc repair
3. Discectomy alone
4. Discectomy with autologous graft replacement
5. Condylotomy

The above-mentioned procedures are all performed through either a preauricular, endaural, or postauricular skin incision. Regarding grafting procedures, this chapter will discuss only those techniques that use autologous tissue sources, as numerous studies have concluded that the use of alloplastic graft materials in TMJ surgery is unsupported.[61-66] The specific arthrotomy technique chosen is usually dependent on the surgeon's skills and experiences. The procedure should also result in the fewest complications, such as facial nerve injury, permanent occlusal changes, and relapse of joint pain and dysfunction. Another consideration is if a second surgical site is required for procurement of an autologous graft.

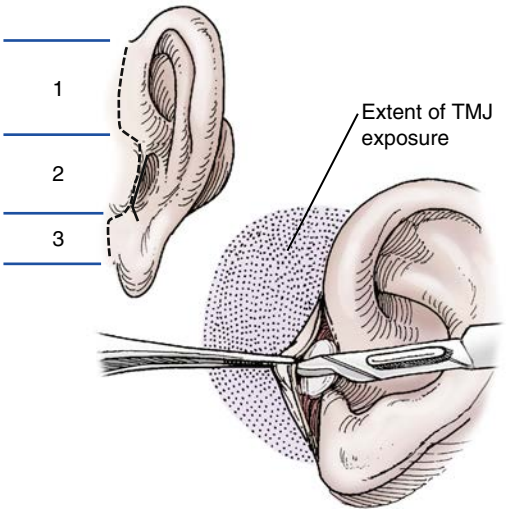
Preauricular Incision

The preauricular incision is commonly used and a modification of an incision designed by Blair.[67] The incision provides maximal lateral and anterior access to the joint space. The preauricular incision is approximately 3 cm long and has a superior and inferior component, which meet at a point level with the superior aspect of the tragus. The incision is placed within a preauricular skin crease that lies posterior to the superficial temporal vessels and the auriculotemporal nerve. The vessels can be avoided by following the preauricular cartilage during the dissection. Sufficient surgical access in the inferior portion of the incision can be easily achieved by carrying the incision to a point just below the tragus, but the incision can be extended inferiorly to the level of the lobule.

The skin and subcuticular tissues are sharply incised with a No. 15 blade. The superior portion of the incision is progressively dissected with mosquito hemostats down to the intensely white temporalis fascia. The inferior portion of the incision is dissected down to the lateral TMJ ligament. Since the external auditory canal is angled nearly 45 degrees anteromedially to the skin surface, the inferior portion of the dissection follows the pretragal pocket to avoid perforating into the external auditory canal. Small retractors are placed into the superior and inferior pockets. A sharp, curved Metzenbaum scissors is placed on top of the temporalis fascia and used to connect the superior and inferior pockets, and the overlying tissues are sharply incised. A flap is reflected anteriorly and superiorly, clearly exposing the temporalis fascia. This flap is then retracted anteriorly away from the tragus. A No. 15 blade is used to make a vertical incision through the temporalis fascia, then the dissection proceeds down to the root of the zygomatic arch. A full-thickness flap is then elevated anteriorly off of the arch until the articular eminence is visualized.



• **Figure 42-2** Preauricular incision with exposure of the articular eminence and TMJ capsule.

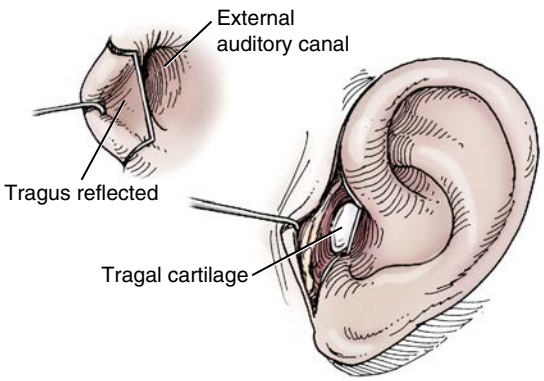


• **Figure 42-3** Endaural incision. Although the skin incisions are made in creases to hide them, the deeper dissection hugs the cartilage of the pinna or external auditory canal cartilage. The shaded area is that which is eventually exposed.

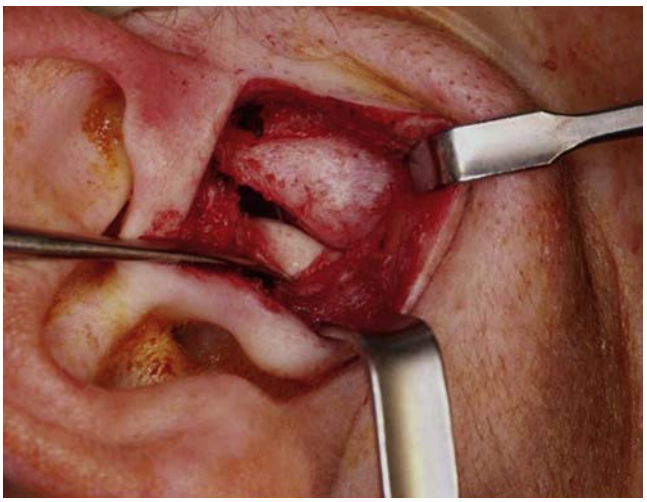
The mandible can be manipulated through a sterile drape, allowing the surgeon to become oriented and possibly identify the lateral pole of the condyle. The overlying tissues are bluntly dissected with Metzenbaum scissors until the lateral capsule is identified (Figure 42-2). Small Obwegeser right angle retractors can be used inferiorly and anteriorly to expose the articular eminence and the lateral capsule. A superior extension of the preauricular incision allows access to the temporalis muscle if a temporalis muscle flap must be harvested for reconstructive purposes. The primary disadvantage of the preauricular incision is the risk of injury to the superficial temporal vessels.

Endaural Incision

The endaural incision described by Rongetti is a modification of an endaural approach first reported by Lempert for treatment of otosclerosis.[68] The endaural incision is more esthetic because the incision is made in the external auditory



• **Figure 42-4** The skin incision inside the tragus connects the superior and inferior portions of the endaural incision at right angles to facilitate reapproximation and closure. A supraperichondrial dissection is continued on the anterior aspect of the tragal cartilage deep into the wound following the contour of the cartilage.



• **Figure 42-5** Lateral capsule incised and an intact, shiny, white, and firm disc is visualized.

canal (Figure 42-3). However, this incision does carry the disadvantage of possible perichondritis. The superior portion of this incision begins at the junction of the face and pinna and extends to the top of the tragus. The incision is made at a 90-degree angle to the skin surface just anterior to the pinna, following the cartilage of the pinna. The inferior portion of the incision begins at the base of the tragus and extends to the junction of the lobe and the face. The tragus is retracted anteriorly and an incision is made 2 to 3 mm inside the crest of the tragus, connecting the superior and inferior incisions (Figure 42-4). The skin is dissected off of the tragal cartilage without creating a perforation of the skin while it is being reflected over the cartilage.

Metzenbaum scissors are used at the superior extent of the incision to bluntly dissect down to the temporalis fascia. The superficial temporal vessels can be avoided by closely following the cartilage of the pinna. The dissection anterior to the tragus follows a supraperichondrial plane, over the cartilage that forms the anterior wall of the external auditory canal. An important landmark during this dissection is the bony postglenoid tubercle, which is located anterior to the cartilage of the external auditory canal. The dissection along the anterior portion of the cartilaginous canal must stop at the postglenoid tubercle because the tympanic membrane is attached to the cartilaginous canal near the junction of the cartilaginous and bony canal. If the bony canal is perforated, the tympanic membrane can be injured. The plane of dissection follows that of the cartilage of the canal rather than the skin surface, or the parotid gland may be violated. Inferiorly, the dissection proceeds down to the skin just beneath the lobe. Sutures can be placed through the tragal cartilage and the superior flap to assist in retraction.

Other Skin Incisions

Alexander wrote on the postauricular approach for TMJ surgery.[69] More recently, Politi described a deep subfascial approach to the TMJ or zygomatic arch.[70] The incision is a modification of the preauricular incision that follows a deep subfascial dissection, passing deep to both layers of the temporalis fascia. No injuries to the facial nerve were reported with this incision and it was not necessary to ligate any superficial temporal vessels except an occasional posterior branch of the superficial temporal artery. The deep subfascial approach was recommended in second procedures of the TMJ or in delayed surgery. The specific incision used is ultimately determined by the surgeon's experience, as no studies have indicated that the incision affects the intended goals of the surgery.

Capsular Incisions

Once the lateral capsule is identified, the mandible can be distracted through a sterile drape, enabling the lateral pole of the condyle to be palpated through the capsule. The capsule can be incised through any number of different incision designs to gain access to the superior joint space. The most commonly used incisions involve making an incision either over the lateral rim or just below the lateral rim of the glenoid fossa (Figure 42-5). The superior joint space is insufflated with 2% lidocaine with 1:100,000 of epinephrine-impregnated local anesthesia through the lateral capsule. The local anesthesia will rapidly escape once the capsule is either dissected off of the rim with a periosteal elevator or incised with a No. 15 blade. In the case of the latter design, the incision is extended anteriorly and posteriorly with a pair of sharp scissors. The surgeon should excise any adhesions within the superior joint space, but should not be overly aggressive with removing tissue from the undersurface of the fossa, as the synovial lining may be inadvertently removed.

Care must be taken not to damage the posterior attachment of the disc while dissecting the capsule. If the surgeon must access the inferior joint space, the capsule can be incised off of the disc and the periosteal elevator can reflect a flap to expose the condyle. Vertical reduction of the articular eminence can be performed to maximize the surgeon's view of the superior joint space. Reduction typically involves removal of 4 to 5 mm of bone on the most lateral aspect of the eminence along the lateral tubercle. If necessary, an

• **Figure 42-6** The endaural incision is closed in layers. The skin immediately anterior to the tragal cartilage is sutured before skin closure to prevent tenting of the skin over the tragus, obliterating the natural depression in the face anterior to the tragus. The skin is closed with interrupted sutures at the corners of the endaural incision with 5-0 monofilament sutures. The inferior portion is closed with interrupted sutures, while the superior portion is closed with a continuous subcuticular 5-0 monofilament "pullout" suture.

additional 1 to 3 mm of bone can be removed from the medial aspect of the eminence to optimize movement of the condyle within the fossa during the arthroplasty.

Wound Closure

Regardless of the specific incision design used, the wound is closed in layers. If the capsule is incised below the lateral aspect of the zygomatic arch, the capsule can be reapproximated and closed with interrupted 4.0 vicryl sutures. The deeper tissues that lie over the capsule and the subcuticular layer are also closed with interrupted 4.0 vicryl sutures. In a preauricular incision, the skin is closed with a running 5.0 monofilament suture. Closure of an endaural incision begins by suturing the corners of the tragal portion of the incision with interrupted sutures (Figure 42-6). Then interrupted sutures are placed to close the inferior portion of the incision by the lobe. The superior portion of the incision is closed with a continuous subcuticular suture.

Arthrotomy Procedures

Disc Repositioning

In 1979 McCarty and Farrar first reported surgery to reposition the disc into its normal anatomic relationship relative to the condyle and fossa.[71] Disc integrity, or deformity, must be carefully assessed if repositioning is to be contemplated. The chances of successful repositioning increase if the disc has maintained its normal appearance (white, shiny, firm) and length, and is minimally displaced. The posterior aspect of the disc is positioned over the superior portion of the condyle in a normal, healthy joint. If the disc is severely displaced and does not reduce, loading by the condyle increases on the retrodiscal tissues, making them hypovascular. Both the condyle and articular eminence can undergo remodeling, and a "pseudodisc" may eventually form. However, an MRI may not be able to distinguish the pseudodisc from remnants of the true disc.

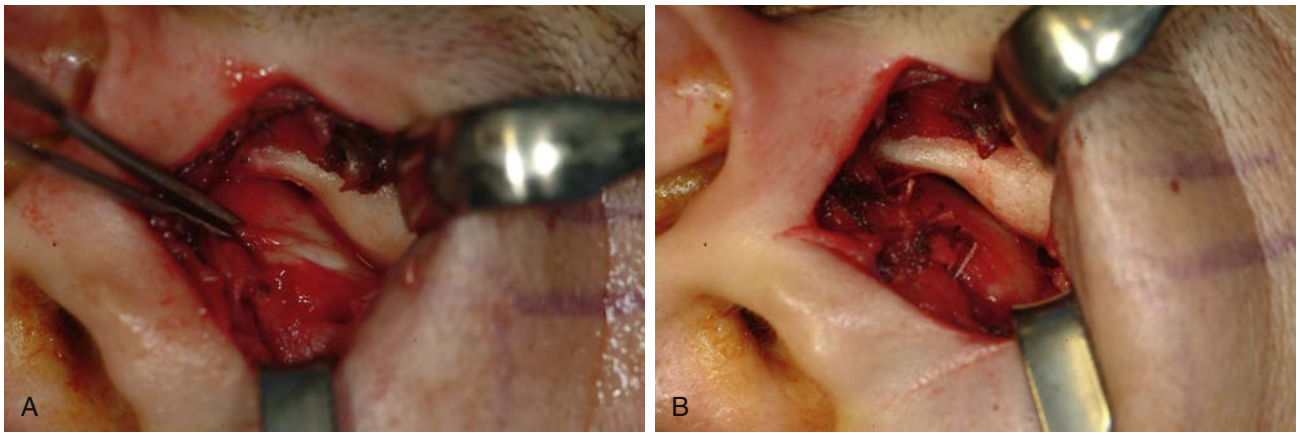
One must closely inspect the disc before proceeding with its repositioning. The disc should not be distorted or placed under tension during posterior repositioning. Dense adhesions that result from longstanding disc displacement often require releasing incisions in the anterior and/or medial regions of the disc. If a releasing incision must be performed on the medial aspect of the disc, it must be made with caution because of the risk of significant hemorrhage. Violation of the medial capsule, lateral pterygoid muscle, or internal maxillary artery can contribute to hemorrhage in this region. Intraoperatively, if the disc is amenable to repositioning, it is plicated posteriorly or posterolaterally to return the anteromedially displaced disc to its more normal anatomic location.

Hall described a partial-thickness plication of the disc if the disc can be repositioned without entering the lower joint space.[72] If a situation exists where the inferior joint space must be entered, such as osseous recontouring of the condyle, then a full-thickness plication should be performed as described by Dolwick and Sanders.[73] Numerous studies have reported disc repositioning success rates based on the reduction of TMJ pain and an increased range of motion, of 80% or more[19,71,74-76] (Figure 42-7). Weinberg and others have reported how an eminectomy or condyloplasty may also facilitate improved disc repositioning.[77-79]

After disc repositioning is completed, the patient should be educated on the possibility of recurrent joint noises. The patient should not worry about either continued joint dysfunction or progression of the ID as long as the joint noises are not accompanied by pain. Further surgery is not recommended for the treatment of unremitting postoperative pain.[46]

Disc Repair

When indicated, perforations of the disc can be managed by reparative techniques.[17,80] For smaller perforations, the disc can be undermined from the surrounding soft tissue for a tension-free primary closure with a non-resorbable suture. Osteophytes and bony overgrowths are commonly found under disc perforations. Any necessary arthroplasty of the condyle can be conveniently performed during disc repair procedures through the perforation. Larger perforations of a dislocated disc require a more extensive repair, because the disc is unlikely to reduce after the margins of the perforation are excised due to more dense adhesion formation and scarring. If the disc cannot be adequately repaired, then the surgeon must make the decision to replace the disc with either an autologous or homologous graft, or perform a discectomy.



• **Figure 42-7** **A,** Disc repositioning through a preauricular incision. Adhesions have been removed from the undersurface of the fossa. The disc is without perforations and is white, shiny, and firm. The disc is being repositioned with Adson tissue forceps. **B,** Disc from part **A** has been plicated posteriorly.

Discectomy

Intraoperatively, if a surgeon believes that a deformed disc is not beyond repair, a discoplasty can be performed. However, if a deformed disc is determined to be unsalvageable, a discectomy is considered. Additionally, if the disc is anatomically amenable to repositioning and/or repair but prohibits the fluid, smooth movement of the condyle, the disc should be excised. First described by Lanz in 1909,[5] discectomy is indicated in several instances: irreparable disc perforation; complete loss of elasticity of the disc; or persistent pain and dysfunction even after disc repositioning. Excising the irreparable disc allows the jaw to move without an impediment. Both partial and total discectomies have been described.[81,82] Kondoh described a procedure referred to as disc reshaping, which is a modification of a partial discectomy.[80] Only that portion of the disc and posterior attachment deemed unsalvageable is excised to eliminate diseased tissue and remove any obstacle for smooth condylar movement.

During a discectomy, all remnants of the disc do not need to be removed to avoid unnecessary, significant hemorrhage, particularly in the highly vascular retrodiscal or medial regions of the joint space. After the disc and posterior attachment are excised and a smooth motion of the condyle can be consistently repeated intraoperatively, the condyle can be conservatively recontoured to remove any irregularities or osteophytes (Figure 42-8). Intact articular cartilage should not be removed from either the condylar head or the fossa. Excessive removal of articular cartilage may predispose the joint to heterotopic bone formation and subsequent ankylosis.

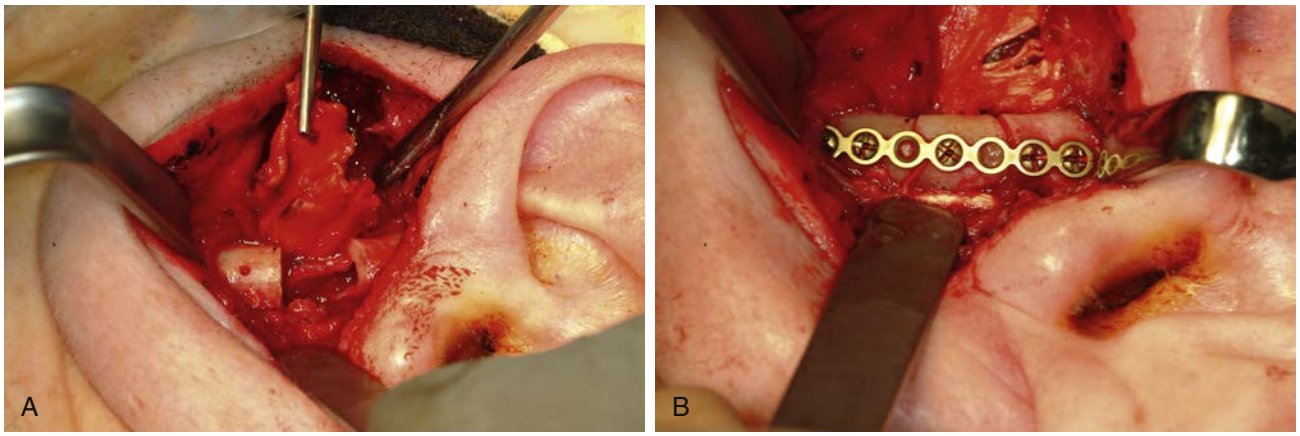
Both short-term[83,84] and long-term[85,86] favorable results from discectomy have been documented. Most patients from these studies were pain-free and had little in the way of dietary restrictions. Takaku and Toyoda's study followed 39 discectomy patients over an average of 20 years after surgery.[87] All but two of their patients had no pain and none experienced masticatory disorders. Mouth opening of 35 mm was attained by 38 of the patients. Eriksson and Westesson's long-term evaluation of 15 discectomy patients with a mean follow-up of 29 years also revealed successful results.[85] All patients were free of pain and none had reported mandibular dysfunction. Only one of the patients could not open beyond 39 mm.

• **Figure 42-8** Large perforation through the disc. The top of the condylar head can be seen through the perforation.

Of interest is the significant bony remodeling as evident by the flattening of the fossa and condyle that has been reported with discectomy.[88,89] These changes were noted to stabilize after just 2 years and were not viewed as degenerative due to a lack of symptomatology.[90-92] Post-discectomy physical therapy is essential because the therapy helps the patient reestablish an adequate range of motion. Additionally, in unilateral cases, it assists the patient in compensating for the expected deviation of the mandible to the operated side. When bilateral discectomies are performed, an anterior open bite may occur because of posterior displacement of the condyles. Use of "light" elastics for a period of 6 weeks may prevent this.

Discectomy with Replacement

Intuitively, a surgeon may feel compelled to replace a disc to avoid a scenario where a patient's TMJ is allowed to



• **Figure 42-9** **A,** Partial-thickness temporalis muscle flap. The patient's zygomatic arch was preplated with a 1.2-mm miniplate. The miniplate and screws were removed and the osteotomies completed. The zygomatic arch was removed to gain access to the temporalis muscle. **B,** Temporalis muscle flap inset into the fossa and secured with sutures. The arch is placed back with the miniplate and screws.

function against the bony fossa without any intermediary tissue. The rationale behind disc replacement with a graft was to protect the articular surfaces from further degenerative changes and to deter joint adhesion formation. The graft material was to create a scaffold for synovial tissue in-growth, and some studies have reported this process to partially occur.[93,94] Yet clinical uncertainty still surrounds performing a discectomy without replacement versus disc replacement.

Animal studies have suggested that autogenous graft placement after discectomy is beneficial.[93] Thyne et al investigated the changes that occur to the joint tissues following the use of temporalis muscle as an interpositional graft following discectomy in sheep.[95] The results revealed that although the temporalis muscle in sheep underwent avascular necrosis and subsequent displacement, the condyle and fossa could still remodel. A study by Tucker et al evaluated the histologic changes in primate TMJs after autogenous auricular cartilage grafts were placed following discectomy.[93] Viable auricular cartilage was found in each of the sacrificed monkeys. A variable amount of fibrous connective tissue was found in all grafts, and one graft was fused to the glenoid fossa, while a second graft was fused to the condyle. Regardless of the positive results reported by these and other animal studies, Takaku et al[89] and McKenna[96] have reported long-term evaluations in humans with discectomy alone that surpass those short-term results of discectomy with grafts.

Reports by Wagner, Westesson, Ryan, Heffez, Dolwick, and others have clearly documented the poor clinical outcomes of alloplastic materials such as silastic, silicone, and Proplast-Teflon for disc replacement.[61-66] Autogenous tissues have been used as both disc replacement material following discectomy and as an interpositional material in the treatment of joint ankylosis. Autogenous sources such as temporalis muscle flaps, auricular cartilage, and dermal grafts have proven far better options for disc replacement than their alloplastic counterparts.[97-100]

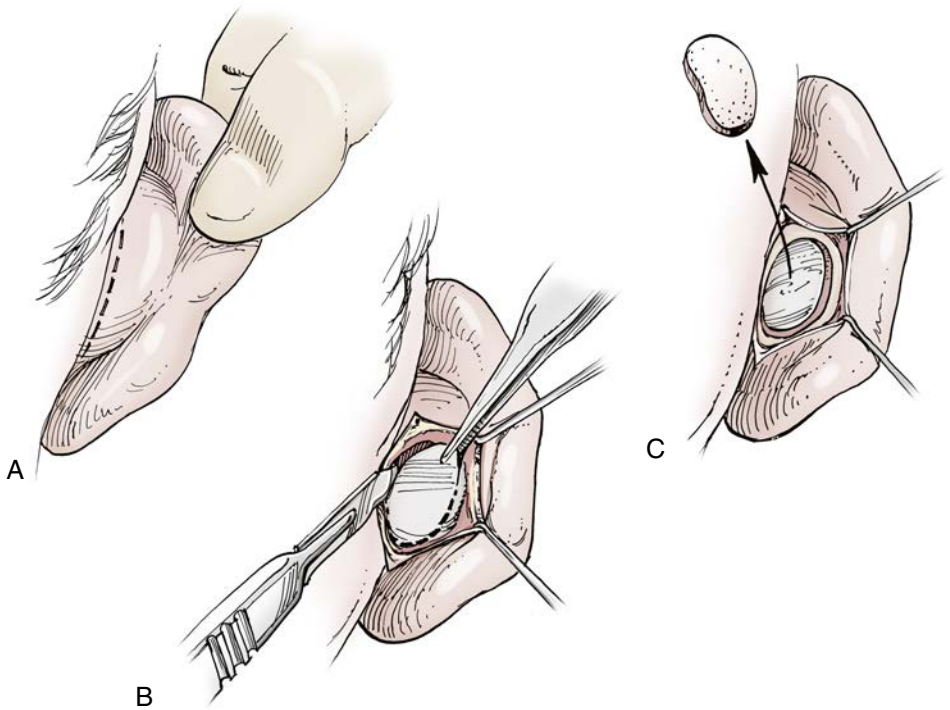
Temporalis Myofascial Flaps

The primary uses for a temporalis myofascial flap are as an interpositional graft in the TMJ to avoid ankylosis and to reconstruct a joint with significant degenerative remodeling. Temporalis myofascial flaps can also be used as a replacement material after discectomy. In choosing the type of autogenous tissue material, remote or adjacent donor site morbidity is a consideration. Avoiding a separate, remote donor site is one advantage of the temporalis flap. It also has the distinct advantage over other autogenous sources of being a vascularized flap, maintaining a viable blood supply. Umeda et al reported that the muscle tissue in the flap maintained its viability with only some fibrosis for 15 months.[101]

The temporalis myofascial flap owes its versatility to its ability to be harvested in variable thicknesses to allow for reconstruction of defects of variable sizes. A flap 3 to 4 cm wide is usually sufficient to adequately cover the fossa. The zygomatic arch can be preplated prior to it being osteotomized if the surgeon desires to place the myofascial flap under the arch and over the eminence (Figure 42-9). The procedure has also been described by placement of the flap over the arch.[102] In unilateral cases of ID where the disc is determined intraoperatively to be unrepairable, a temporalis flap can minimize or avoid a posterior open bite that can occur on the non-operated side. Disadvantages of this flap include possible flap necrosis and fibrosis or adhesion formation within the joint space. The temporalis muscle flap is similar to other arthrotomy techniques in its risk of postoperative decreased interincisal opening.

Auricular Cartilage Grafts

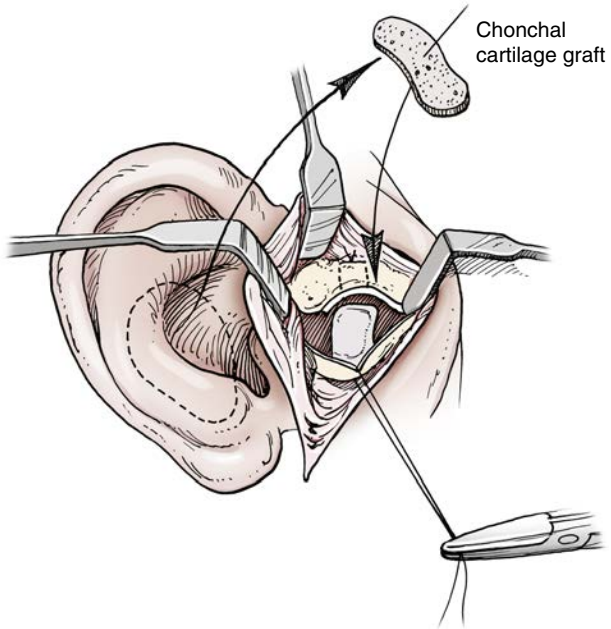
The auricular cartilage graft is procured with the intent to use it as an interpositional material after discectomy and occasionally in the treatment of ankylosis. It is most commonly harvested through a posterior approach to the ear (Figure 42-10). A vertical incision is made on the posterior side of the conchal bowl. A supraperichondrial dissection is performed on the convex side of the cartilage. The cartilage



• **Figure 42-10** **A,** Auricular cartilage is harvested via a vertical incision on the posterior aspect of the concha. **B,** The cartilage is exposed, and the desired size of the graft is outlined. The perichondrium is left on the convex surface of the cartilage. **C,** The outlined portion is excised so the perichondrium is not removed with the graft. The graft should only have perichondrium on the convex side and none on the concave side.

is incised parallel to the helix. A subperichondrial dissection is created on the concave side of the cartilage. Sufficient cartilage must remain to support the ear. The skin is then closed primarily. The graft is sutured with several horizontal mattress sutures to the surrounding tissues (Figure 42-11).

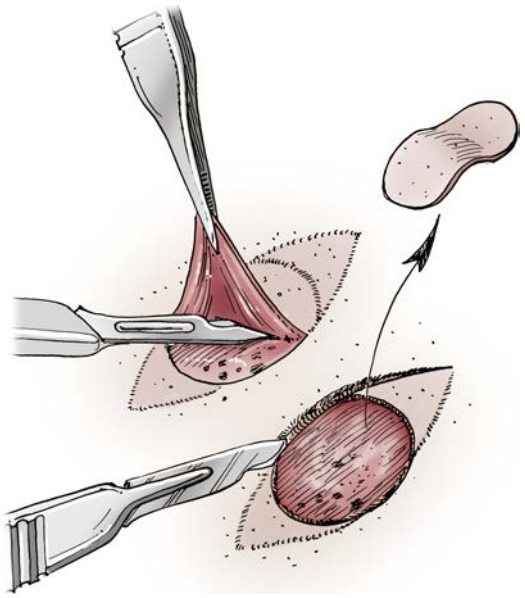
Although not commonly used at the present time, the auricular cartilage graft was previously used to replace a failed alloplastic graft when alloplasts were still widely used. It is important to recall that if an auricular cartilage graft is being considered, the perichondrium is left intact on the convex side of the graft, which opposes the glenoid fossa. Auricular cartilage grafts do not induce a foreign-body reaction and appear to resist most occlusal loading forces. However, histologic analysis in both animal and human studies has shown that dense adhesions or a fibrous fusion occurs between the graft and either the fossa or condyle.[94,95,104] A disadvantage of the auricular cartilage graft is that it requires a second donor site, although it is in close proximity to the primary surgical field. Reported complications related to auricular cartilage grafts include the graft becoming prematurely displaced and infections of the graft.



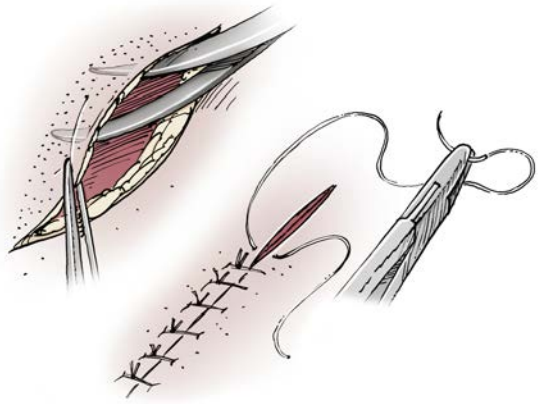
• **Figure 42-11** The graft is sutured to the fossa and the posterior slope of the eminence with either wires or heavy sutures.

Dermal Grafts

Dermal grafts have been used for disc replacement but are more commonly used for repair of disc perforations and as an interpositional material in cases of TMJ ankylosis. The most common sites from which to harvest dermal grafts for TMJ surgery include the upper lateral thigh, buttock, and groin. Dermal grafts are harvested as either partial-thickness or full-thickness grafts. A dermatome is used to obtain a partial-thickness graft. Complete removal of the epidermis from the graft is preferable to avoid leaving epithelial remnants on the graft, which may lead to epithelial cyst formation on the condyle from the undersurface of the graft. A



• **Figure 42-12** Dermal harvest includes removal of epidermis over an ovoid area of skin. The epidermis is discarded.

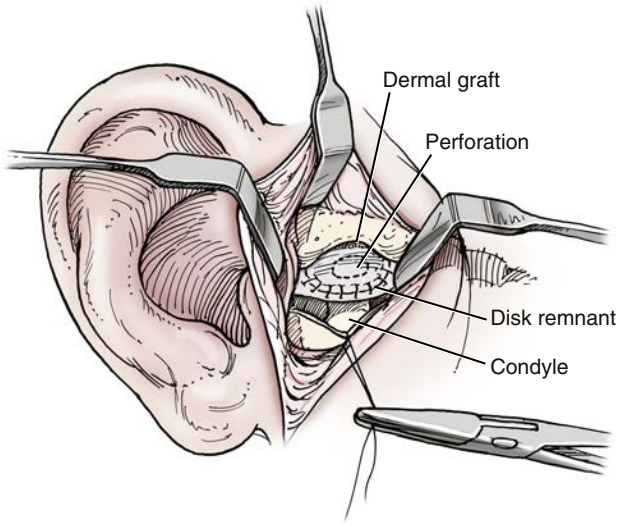


• **Figure 42-13** The oval is converted to a full-thickness fusiform shape, three times longer than wide. The split-thickness oval, along with the remainder of the fusiform, is excised down to the subcutaneous fat. The full-thickness ends are excised. The wound is then undermined and closed primarily.

thin film of antibiotic ointment is coated over the donor site, and a transparent, occlusive wound dressing is placed over the area.

Full-thickness grafts begin by drawing a fusiform outline of the desired graft on the skin (Figure 42-12). A circular area of epidermis is removed from the center of the fusiform outline. Next, the entire outlined area is excised down to the subcutaneous fat. The graft site is undermined and closed primarily (Figure 42-13). The dermis alone is excised from the central portion of the fusiform-shaped graft, and then defatted by hand with either a No. 15 blade or scissors (Figure 42-14). Removal of fat from the dermal graft assists in revascularization of the graft by capillary in-growth from the tissues in the recipient bed. An animal study by Tucker et al indicated that vascular perfusion of dermal grafts placed

• **Figure 42-14** The dermal graft being defatted by hand.



• **Figure 42-15** The dermal graft sutured in place.

in the TMJ occurred soon after its placement.[105] The graft appears to remain viable as a free graft.

When dermal grafts are harvested for disc repair, the margins of the perforation should be freshened. The harvested graft should be approximately twice the diameter of the measured defect to allow for anticipated contraction of the graft (Figure 42-15). The dermal graft should also extend well beyond the extent of the perforation to avoid exposure of the condylar head if the dermal graft were to migrate. Postoperative physical therapy will help to prevent possible fibrous adhesion formation within the joint space. One disadvantage of the dermal graft is that it requires a remote donor site. Additionally, dermal grafts, much like auricular cartilage grafts, can result in fibrous tissue formation with subsequent fibrous ankylosis.

Regenerative Medicine Alternatives for Future Treatment of Disc Perforation

Epidemiologic surveys report that 20% to 25% of the population has TMD symptoms,[106] while patient studies show that 3% to 4% of the population seeks treatment.[107] The TMJ disc is relatively avascular and does not spontaneously regenerate or repair itself in vivo.[108] It has been shown that almost 70% of patients with TMDs suffer from disc displacement,[109] a finding that identifies the TMJ disc as a key structure in the cascade of events that lead to progressive

pathology and morbidity. A novel, effective treatment for disc regeneration may signal a paradigm shift in the treatment of perforated TMJ discs and prevent the inevitable consequence of degenerative articular surface damage with subsequent total joint replacement.

Tissue Engineering Strategies

From 2004 through 2008, Almarza et al[110,111] published 13 articles describing the use of porcine TMJ disc cells for creating a tissue-engineered TMJ disc in vitro. These studies optimized monolayer culture conditions, scaffold selection, seeding density and technique, growth factor regimens, and biomechanical stimulation regimens, but the ability to create a TMJ disc with properties that matched the native disc was limited. More recently, a series of studies has been published in which costal cartilage was evaluated as an autologous cell source for a tissue-engineered disc.[112-114] This autologous tissue would be appealing as many craniofacial surgeons also have experience replacing the mandibular condyle with a rib graft. However, this procedure has variable results and significant questions remain regarding cell source, scaffold choice, and stimulation regimen.

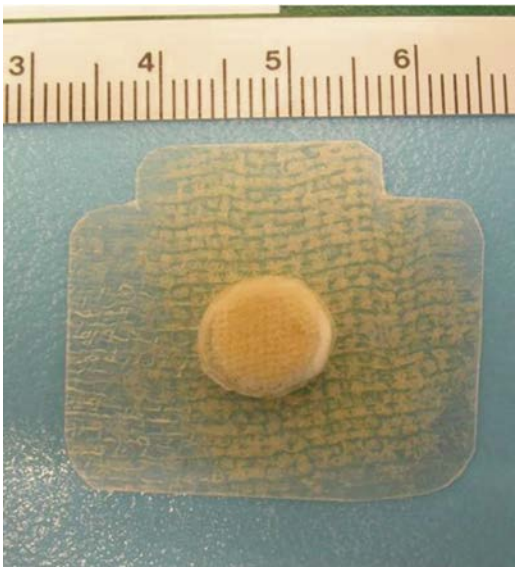
The latest work with extracellular matrix (ECM) scaffolds by the collaborative group of Chung, Badylak, Brown, and Almarza[115,116] represents a novel regenerative medicine approach for TMJ disc replacement and a departure from purely in vitro strategies. The approach involves recruitment of progenitor cells with local modulation of the host innate immune response by promoting an M2 versus M1 macrophage phenotype. These processes are centered on the use of a biologic scaffold material composed of xenogeneic ECM.

Macrophage Phenotype as a Predictor of Constructive Remodeling

Badylak and co-workers have shown that the phenotype of macrophages that participate in the remodeling of ECM scaffolds plays a critical role in determining whether the events follow a pro-inflammatory course leading to fibrosis and scarring, or a constructive remodeling course resulting in deposition and organization of site appropriate tissue.[117-119] Macrophages have been classified as having either an M1 or an M2 phenotype, based on their biologic function.[120] The causes and effects of this macrophage dichotomy toward a given phenotype have been studied in the context of tissue engineering. It was shown that M1 and M2 macrophages have distinct effects on the recruitment of progenitor stem cells, a cell population believed to play a critical role in repopulating the ECM scaffold material.[121] M2 macrophages promote the chemotaxis/recruitment of these cells, while M1 cells inhibit the chemotaxis of these stem cells.

Canine Unilateral Discectomy Model

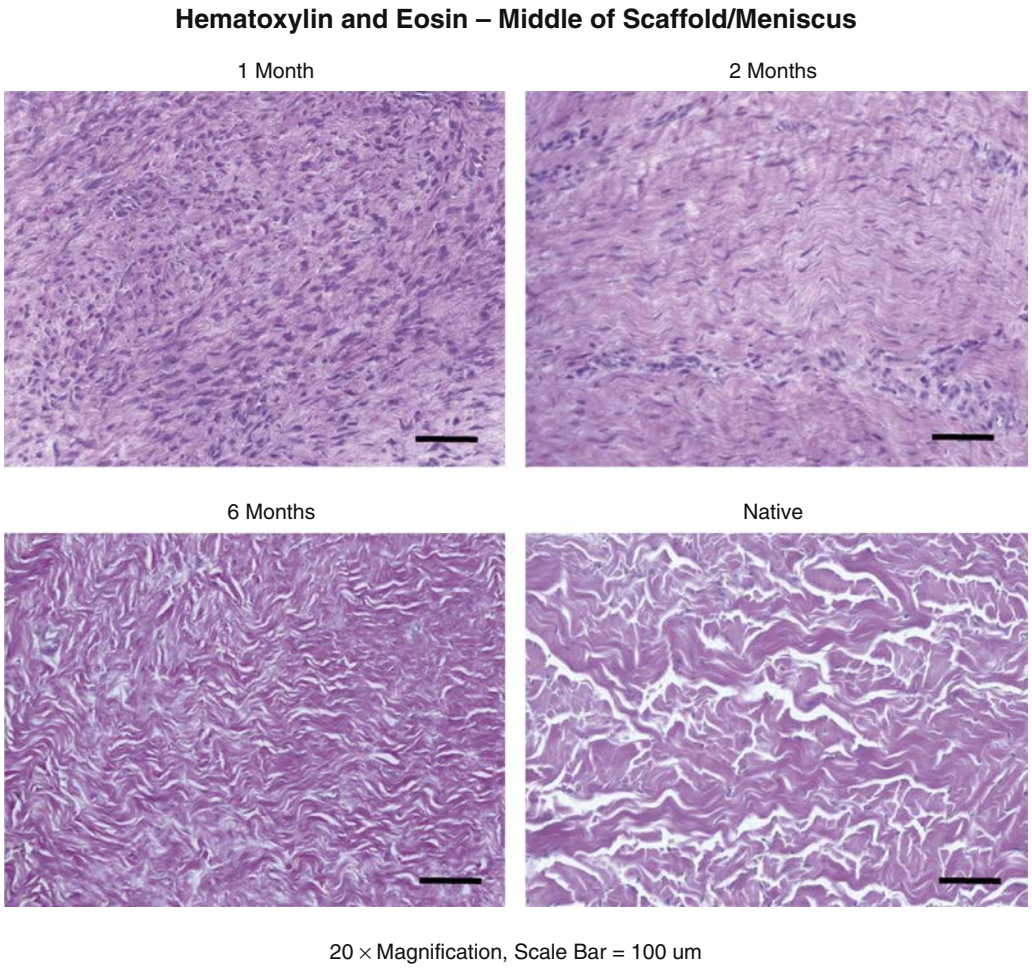
A prototype ECM derived from porcine urinary bladder mucosa (UBM) was first evaluated as a scaffold for TMJ disc reconstruction in a canine model.[115] Five dogs were subjected to unilateral resection of the native disc and subsequent replacement with the UBM-ECM (Figure 42-16). Analyses were performed at 3, 4, 8, 12, and 24 weeks in this pilot study. Macroscopically, the scaffold remodeled rapidly, and it was indistinguishable from newly deposited host tissue at all time points, including the 3-week time point. Microscopically, remodeling was characterized by intense vascularization during the first 2 months, and a dense infiltration of predominantly CD68+ mononuclear cells (i.e., macrophages) and smooth muscle actin (SMA)+ large, round cells at early time points. The cell population changed over time to a sparse population of SMA spindle-shaped cells resembling those of the native TMJ disc (i.e., fibrochondrocytes) (Figure 42-17). Furthermore, the remodeling process showed deposition of predominantly collagen type I (as determined by Herovici staining),[122] the density and organization of which resembled that of the native disc by the 6-month time point. In-growth of skeletal muscle tissue was observed at the interface of the remodeled UBM with the host periarticular musculature. No adverse changes in the articulating surfaces of the condyle or fossa were observed, thus confirming the protective function of the remodeled scaffold. Results of this pilot study suggest that the xenogeneic ECM scaffolds have the potential to provide an effective interpositional material while serving as a template for host-driven reconstruction of the TMJ disc. The number of samples at each time point was only one and therefore prompted the following study.



• **Figure 42-16** Macroscopic image of the pre-implantation UBM-ECM device. The central "pillow" consists of a fine particulate form of the same ECM that encases the deformable pillow. The encasing sheets serve as the brim for attachment to the joint capsule.

Canine Bilateral Discectomy Model

In light of the promising findings in the pilot study described above, a more definitive study was conducted in which 10 dogs were allowed to survive for 6 months following UBM implantation.[116] It was decided that confirmation of the long-term (6 month) remodeling events was needed.



• **Figure 42-17** Histologic appearance of the remodeling process at 1, 2, and 6 months. The dense cell infiltrate at 1 month transforms into a fibrocartilaginous tissue very similar to the native TMJ disc *(lower right)*. Recall that the original implant is totally acellular.

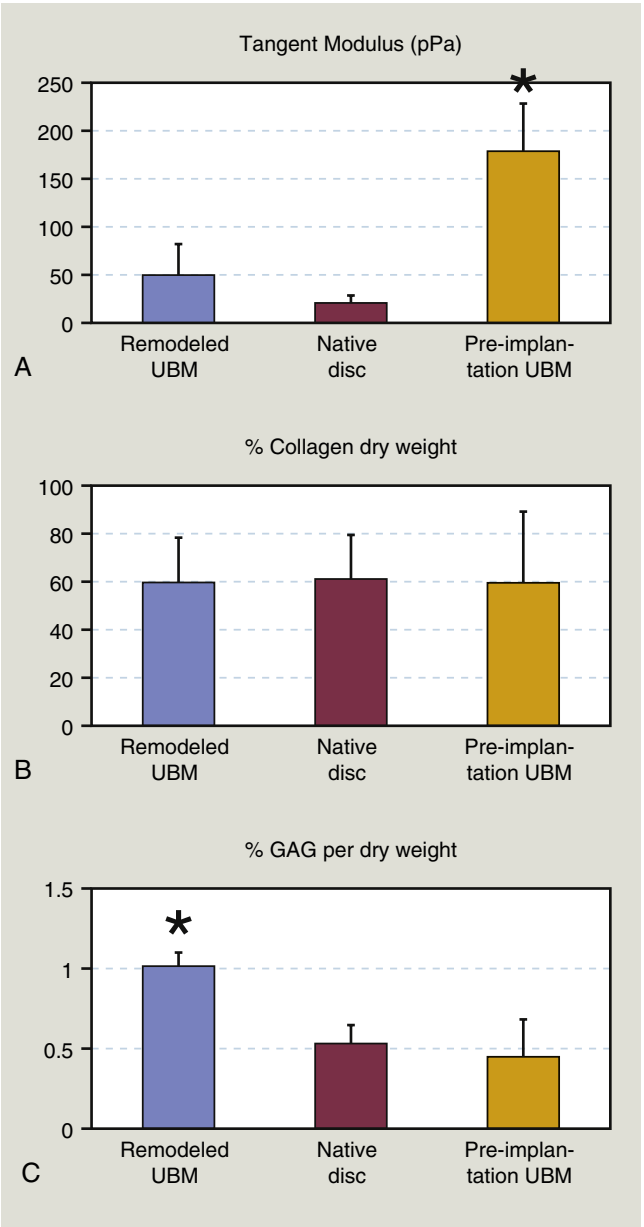
The goal of this study was to examine the 6-month gross morphologic and histologic outcome in a more comprehensive manner than the initial pilot study and to evaluate the biomechanical properties and biochemical content of the remodeled tissues at 6 months post-implantation.

Unlike the pilot study, a bilateral discectomy was performed in this trial with one side being treated with the xenogeneic UBM and the opposite side serving as a control and left empty. The results in 9 out of the 10 dogs showed excellent remodeling of the scaffold with articular surface protection while the contralateral, untreated control side clearly displayed pitted articular surface irregularities within 6 months and no regrowth of the TMJ disc tissue.

Gross morphologic findings showed little to no change in the articulating surfaces of the temporal fossa or the mandibular condyle following placement with the UBM device, again confirming the protective effect of the ECM device even during the remodeling process. Consistent with the pilot study results, the UBM in the second study was replaced with a dense collagen fiber structure that resembled the native TMJ disc by the 6-month post-surgery time point in 9 of 10 animals. The one animal in which the ECM scaffold did not remodel in a constructive manner showed degeneration and scar tissue deposition at the site of UBM, the cause of which is unknown.

Immunolabeling for CD31 showed that the number and size of blood vessels within the remodeled device at 6 months were similar to those of the native disc. Immunolabeling for CD68 was negative, indicating that the macrophages present at early time points were replaced with a population of cells that resembled those of the native disc.

Biomechanical testing showed that the pre-implantation ECM device had a higher maximum stress, equilibrium stress, and tangent modulus than did the native TMJ disc tissue and a lower percentage of relaxation. By 6 months post-implantation, however, the mechanical properties values of the remodeled UBM and the native disc were indistinguishable (Figure 42-18). Biochemical testing showed that both the pre-implantation UBM device and the remodeled UBM had collagen and water contents that were similar to those of the native disc tissue (see Figure 42-18, *B*). The remodeled UBM had higher glycosamino glycans (GAG) content than both the pre-implantation device and the native tissue (see Figure 42-18, *C*).

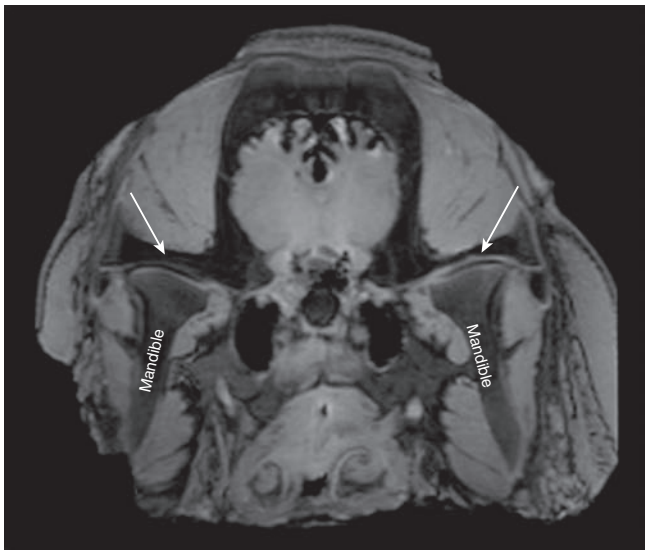


• **Figure 42-18** Biomechanical and biochemical results of the second study. The first group (*blue*) is the remodeled ECM scaffold after 6 months of implantation (N=5). The second group (*red*) is native canine TMJ disc (N=6). The third group (*orange*) is the pre-implantation ECM scaffold (N=6). **A,** Tangent modulus in kPa from stress-strain behavior, with pre-implantation ECM scaffold significantly higher than the other two groups. **B,** Collagen content per dry weight basis, with no differences found. **C,** GAG content per dry weight basis, with remodeled ECM scaffold showing higher values than the other two groups.

In summary, the tissue into which the UBM scaffold material had remodeled showed remarkable morphologic, biochemical, and mechanical similarity to the native TMJ disc tissue.

Porcine Bilateral Discectomy Model

Current efforts are being shifted to adapt the bilateral meniscectomy procedure to a porcine model (Figure 42-19), a species in which the structure and function of the TMJ disc is more like human than other species.[123-125]



• **Figure 42-19** MRI of adult porcine skull from a recent study showing bilateral TMJ discs *(arrows)*.

The pig is thought to be the most suitable non-primate model of human TMJ anatomy and function.[123-125] Berg[123] examined pigs, sheep, calves and dogs, and noted that the pig was best suited for experiments in replacing the TMJ disc. Bermejo et al[124] also concluded that the pig was the only suitable experimental animal model after comparison to dogs, cats, rabbits, rats, cows, sheep, and goats. Similarities of the pig to human include the size of the articular structures, shape of the disc, and the omnivorous diet. Ström et al[125] recommended the domestic pig as a useful model in the investigation of masticatory system function. Thus, it has been established that pig and human TMJs have similar gross morphology, size, and structure of each TMJ component, including the disc, which will prompt further studies in this model.

Data from these two novel studies show a dramatic and rapid change from an acellular ECM scaffold to a fibrocartilaginous tissue in the dog discectomy model. Additional work shows that ECM remodeling includes a process of cellular infiltration that involves M2 macrophages, multipotential stem cells, and transient vascularization. Chemical crosslinking of ECM scaffolds shifts the macrophage response to a proinflammatory M1 phenotype in soft tissue applications[126] and markedly inhibits degradation and release of bioactive peptides.[118] The temporospatial pattern of remodeling is largely unexplored and the relative contribution and importance of factors such as scaffold degradability, the innate immune response, and the mechanical loading are unknown, especially in an intra-articular environment. Therefore, in the future these different aspects of ECM remodeling will be studied in the porcine model.

Condylotomy

The principal indication for condylotomy is reduction of pain in disc displacement with reduction, but it can be

used for any Wilkes stages I-III. Studies have reported favorable outcomes with a condylotomy for painful ID but no restricted range of motion.[127,128] The condylar sag that results from the condylotomy creates increased joint space and decreased articular pressure. This procedure has also been used for treatment of recurrent TMJ dislocation. Campbell described the first condylotomy, a closed procedure, which was performed with a Gigli saw.[129] Nickerson modified the procedure in 1983 by changing the osteotomy to one that resembles an intraoral vertical osteotomy.[130]

Several technical aspects of importance exist when performing the condylotomy for ID. The first important technical aspect is the location of the osteotomy. The vertical ramal osteotomy must be performed just posterior to the antelingular prominence to avoid the mandibular canal and unnecessary injury to the inferior alveolar nerve and vessels. The surgeon also needs to avoid placement of the inferior portion of the vertical osteotomy through the posterior border. The osteotomy should be carried through the inferior border of the mandible to allow for the desired condylar sag and better control of the condylar (proximal) segment.[132,133] Additionally, if the inferior portion of the osteotomy is made too far posteriorly along the ramus, the tip of the proximal segment may be either palpable or visible after resolution of the surgical edema. This result can be avoided by removing the tip of the proximal segment at the time of surgery with a rongeur.[134]

The amount of condylar sag is estimated by the distance created between the tip of the proximal segment and the inferior border. Factors such as the amount of medial pterygoid muscle attachment on the proximal segment and joint laxity determine the amount of condylar sag and proximal segment mobility. Proximal segment mobility can be appreciated by pushing up on the inferior portion of the proximal segment with a gauze director. A 3- to 4-mm step at the inferior border implies adequate condylar sag.

A second technical aspect of importance is the amount of bone removed along the osteotomy site. Nickerson and Veaco first described the modified condylotomy with a forward position of the proximal segment.[130] The proximal segment is placed slightly anterior and lateral to the distal segment by creating a step in the medial edge of the proximal segment. Hall later stated that forward positioning of the proximal segment was not necessary.[132] He advocated creation of a butt joint between the proximal and distal segments and encouraged creation of a medial step on the proximal segment only if a greater anterior positioning of the proximal segment was necessary.

The primary proposed advantage of the condylotomy over other arthrotomy procedures is less intra-articular scarring because the condylotomy is an extra-articular procedure. Less scarring in the joint space results in an increased range of motion, and the disc and posterior attachment remain unaltered. Maxillo-mandibular fixation (MMF) via Erich arch bars is used for 1 week in a unilateral condylotomy and for 2 weeks for bilateral condylotomy followed by application of light training elastics for an additional 4 to 5 weeks in either case to avoid an anterior open bite.[132] Active range of motion exercises are initiated 4 weeks after surgery to restore a normal range of motion. A regular diet can be reinstituted in 6 to 8 weeks.

The most significant complication associated with condylotomy is malocclusion as a result of condylar sag and changes in ramal segment position. Hemorrhage; injury to the inferior alveolar, lingual, or long buccal nerves; infection; and condylar dislocation are among the other complications.[131]

Controversy still surrounds the use of the condylotomy in the treatment of ID, and the procedure has both its strong advocates as well as opponents.[131,132,134] Proponents of the condylotomy are quick to point out how the normal disc-condyle relationship is restored and pain relief is achieved to a greater degree and more quickly than with other arthrotomy procedures. Various studies by Nickerson and Veaco,[130] Upton,[134] and McKenna[135] all showed significant decreases in pain after modified condylotomies for ID.

Complications

The common complications associated with all arthrotomy procedures include hemorrhage, auriculotemporal nerve and facial nerve injury (particularly of the temporal branch), fibrous adhesion formation, persistent pain, and occlusal changes.[136] The inferior alveolar, lingual, and long buccal nerves can also be at risk for injury from surgical retraction or manipulation of the condyle. Complications more likely with a discectomy involve heterotopic bone formation and joint ankylosis. Infection rarely occurs with TMJ arthrotomy.

Postoperative Therapies

The 1990 AAOMS standards and criteria of surgical procedures (for TMJ surgery) list a number of factors that impact a patient's postoperative course.[37] Several of these factors are issues remote from the intrinsic joint pathology, such as concomitant facial pain from other sources, poorly controlled parafunctional habits, psychological disorders, and systemic disease affecting the muscles, ligaments or bone. Myofascial pain and dysfunction can also exist concurrently with ID. If these issues are not addressed both preoperatively and postoperatively, a patient will not attain the goals of the surgery.

Postoperative therapy involves a combination of physical therapy, pharmacologic management, and occasionally splint therapy, each playing an integral role in enabling the patient to achieve an acceptable postoperative pain level and condylar range of motion. Patients who have undergone discectomy are encouraged to begin conservative range of motion exercises shortly after surgery. Disc repositioning or repair patients are typically instructed to begin conservative stretching exercises within a week after surgery. Many who undergo an arthrotomy procedure regain a normal, or close to normal, range of motion in 2 to 3 months with a

regimented course of postoperative physical therapy. A Therabyte (ACTOS Medical) appliance is routinely prescribed as a part of the patient's physical therapy. Patients who do not exhibit a decreased range of motion preoperatively should regain a normal range of motion postoperatively without much difficulty. However, patients who had a poor range of motion preoperatively will have a more difficult time attaining a normal, or even near normal, range of motion postoperatively. Thus, strict adherence to a regimented physical therapy program becomes critical.

The role of physiotherapy on the recovery of patients undergoing surgery for ID has been reported by Oh.[137] The study compared a treatment group of 22 patients who received postoperative physiotherapy versus a surgery-only group of an identical size. The groups were evaluated for two characteristics: pain intensity and temporomandibular joint function. Both groups were evaluated at three intervals: before surgery, 6 weeks after surgery, and 7 months after surgery. The group receiving physiotherapy reported less pain and dysfunction after each postoperative interval than the surgery-alone group.

Splint therapy can be beneficial in maintaining a stable postoperative occlusion. More importantly, a splint is necessary if the patient resumes any documented preoperative parafunctional habits that may cause delayed pain reduction in the postoperative phase. The splint may require adjustment as postoperative changes in the soft and hard tissues of the joint occur. Postoperative joint noises that are asymptomatic should not create any concern for either the patient or surgeon.

Summary

The literature has clearly documented the benefits of surgery for ID.[6-14] Numerous studies have documented the success of minimally invasive techniques such as arthroscopy and arthrocentesis in the treatment of ID.[22-33,138-140] Although arthrotomy is not indicated for all cases of ID, nonsurgical treatment or other less invasive techniques may not always be indicated or even be considered better alternatives in some situations. Determining an accurate diagnosis is a critical first step, and obtaining the diagnosis is often marred by the challenge of the patient's lack of understanding of his/her own symptoms. Strict adherence to surgical treatment algorithms for ID is not always beneficial or possible because each patient's underlying disorder and symptoms are unique and must be treated as such. The surgeon must avoid overemphasizing radiographic findings when determining if arthrotomy will effectively treat the ID and not cause any unnecessary morbidity. Regardless, careful patient selection is a fundamental and essential factor prior to pursuing surgery, particularly arthrotomy.

Temporomandibular Joint Replacement

LOUIS G. MERCURI

Introduction

Temporomandibular joint (TMJ) total joint replacement (TJR) presents unique problems because of the integral and complex role the TMJ plays in establishing and maintaining proper form and function within the stomatognathic system. The TMJ not only acts as a secondary growth center for the mandible in prepuberty, but its integrity is vital to the functions of mastication, speech, airway support, and deglutition in both children and adults.

Prior to the mid-1980s, the primary indications for TMJ TJR were the management of developmental maxillofacial deformities, ankylosis, severe inflammatory joint disease, or TMJ replacement after ablative tumor surgery or trauma.

Thereafter, along with these form and function challenges, there arose a group of patients requiring TMJ TJR who had previously undergone multiple failed TMJ surgical procedures. Many of these patients' joints were anatomically distorted and functionless secondary to the failure of interpositional materials such as Proplast-Teflon (Vitek, Houston, TX) and/or Silastic (Dow-Corning-Wright, Arlington, TX) (Figure 43-1).

Considering not only function and form, but also a patient's neurologic and psychological issues, surgeons developed physiologically reasonable, biologically rational, technically achievable outcome objectives based on decades of orthopedic joint replacement experience.

The following TMJ replacement goals were developed:[1]

1. Improvement of mandibular function and form
2. Reduction of further suffering and disability
3. Containment of excessive treatment and cost
4. Prevention of further morbidity

End-stage disease and/or pathology with accompanying anatomic form and physiologic function distortions dictate the need for TMJ TJR. Due to the complex nature of its anatomic and masticatory muscle functional relationships, it is unreasonable to expect that a TMJ TJR will return a patient to their premorbid mandibular functional status. Therefore, as with orthopedic joint replacements, there will always be some functional disability after TMJ replacement.

Further, in multiply operated, anatomically distorted patients, chronic neuropathic and centrally mediated pain often play a major role in their disability. Therefore it is important that both the surgeon and the patient understand that the primary goal of TMJ replacement is the restoration of mandibular function and form, and that any subjective pain relief achieved must only be considered as a secondary benefit.[2]

Historic Perspective of TMJ Replacement

Autogenous TMJ Replacement

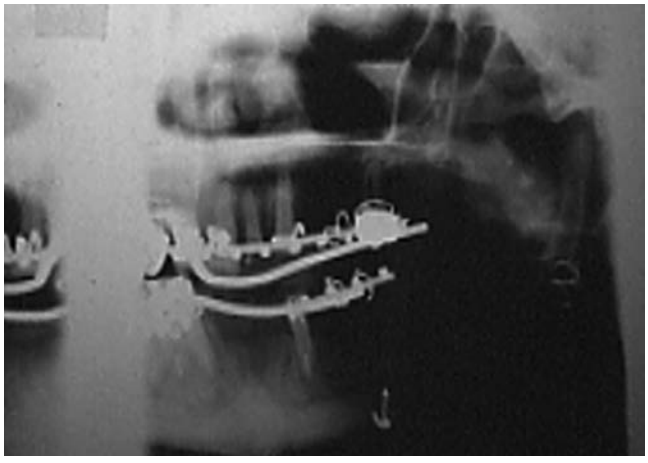
Bone—Vascularized and Non-vascularized

Earliest TMJ replacement involved the use of autogenous tissues. In 1909 Bardenheuer[3] performed a mandibular condyle replacement with the fourth metatarsal. This technique was also reported in 1920 by Gillies.[4] The use of an autogenous metatarsal head to reconstruct the mandibular condyle was also reported by Dingman[5] in 1964, Glahn[6] in 1967, and Spiessl[7] in 1972. Use of a non-vascularized metatarsophalangeal joint to correct a facial deformity was reported by Entin[8] in 1958 (Figure 43-2). Datillo[9] in 1986, and Dierks[10] in 2000 reported the use of a vascularized metatarsophalangeal joint to replace the TMJ.

TMJ replacement has also been performed using vascularized rib[11,12] and iliac crest.[13] Other autogenous tissues such as fibula[14,15] and iliac bone free grafts,[16-20] clavicle, and sternoclavicular joint have been used.[21-23] However, none of these reports provided long-term follow-up.

The non-vascularized costochondral free graft has been the most frequently recommended autogenous bone for TMJ replacement because of its conjectured ease of adaptation to the recipient site, its ostensibly gross anatomic similarity to the mandibular condyle, its low morbidity at the donor site, and its theoretic growth potential in juveniles[24-29] (Figure 43-3).

• **Figure 43-1** Anatomically distorted and functionless left TMJ attributable to Proplast-Teflon foreign body giant cell reaction. Note the osteolysis of the temporal zygomatic arch, articular eminence, glenoid fossa, and mandibular condyle.



• **Figure 43-2** Non-vascularized fifth metatarsal graft reconstruction of the left TMJ.

Tissue—Vascularized and Non-vascularized

A number of different autogenous tissues—temporalis fascia,[30-34] masseter, temporalis muscle flaps,[35-54] dermal grafts,[55-59] and fascia lata[60,61]—have been advocated as a replacement for the TMJ articular disc. However, the vascularized local temporalis muscle flap remains the most popular.

Vascularized Temporalis Muscle Flap

The advantages of the temporalis muscle flap are its proximity to the TMJ and its reliable blood supply.[51,52,54] Feinberg and Larsen[47] stated that one of the most important roles of the temporalis muscle flap is the maintenance of TMJ functional movements. These authors state that since the flap is attached to the coronoid process, when the mandible translates, the movement of the mandible pulls the muscle flap in an anterior direction, simulating the natural functional movements of the articular disc (Figure 43-4). Investigators reported that follow-up studies on patients with temporalis muscle replacement discovered the presence of viable muscle tissue within the joint.[51-53]

Tong and Tideman[62] reported the re-formation of a disc-like interpositional structure, after 18 months, with use of the pedicled temporalis muscle flap after TMJ discectomy in four Rhesus monkeys with osteoarthritis. They also reported a milder degree of osteoarthritis was observed histologically in three of the four monkey joints where the muscle flaps survived.

Henry and Wolford[63] offered the following contraindications for the use of the temporalis muscle/fascia graft: failed Proplast-Teflon (Vitek, Houston, TX) or Silastic (Dow-Corning-Wright, Arlington, TX) with continuing foreign body giant cell reaction;[64-66] rheumatoid arthritis or other high-inflammatory connective tissue diseases;[67] progressive osteoarthritis;[67] and two or more prior surgeries.[67,68]

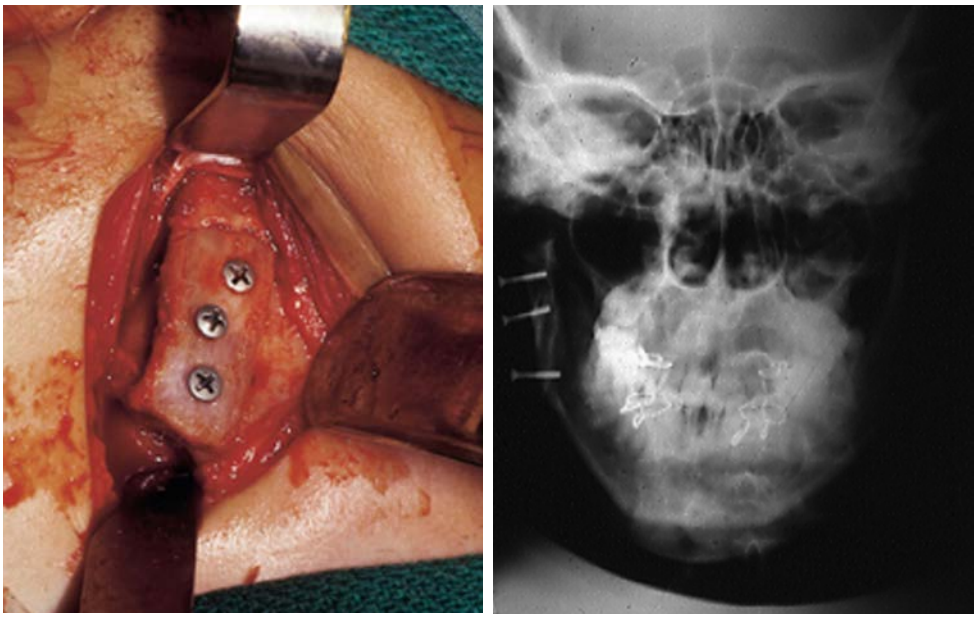
Auricular Cartilage

Ioannides and Maltha[69] reported use of autogenous auricular cartilage as a TMJ disc replacement in 1988. However, Takatsuka et al.[70] studied the use of auricular cartilage after discectomy in the rabbit TMJ. On histologic examination, these authors found fibrous adhesion of the grafted auricular cartilage to the condyle and the presence of a fibrous layer containing fragmented cartilage at the articular surface. They concluded that auricular cartilage did not appear to be an ideal material for disc replacement. Other investigators reported similar findings.[71,72]

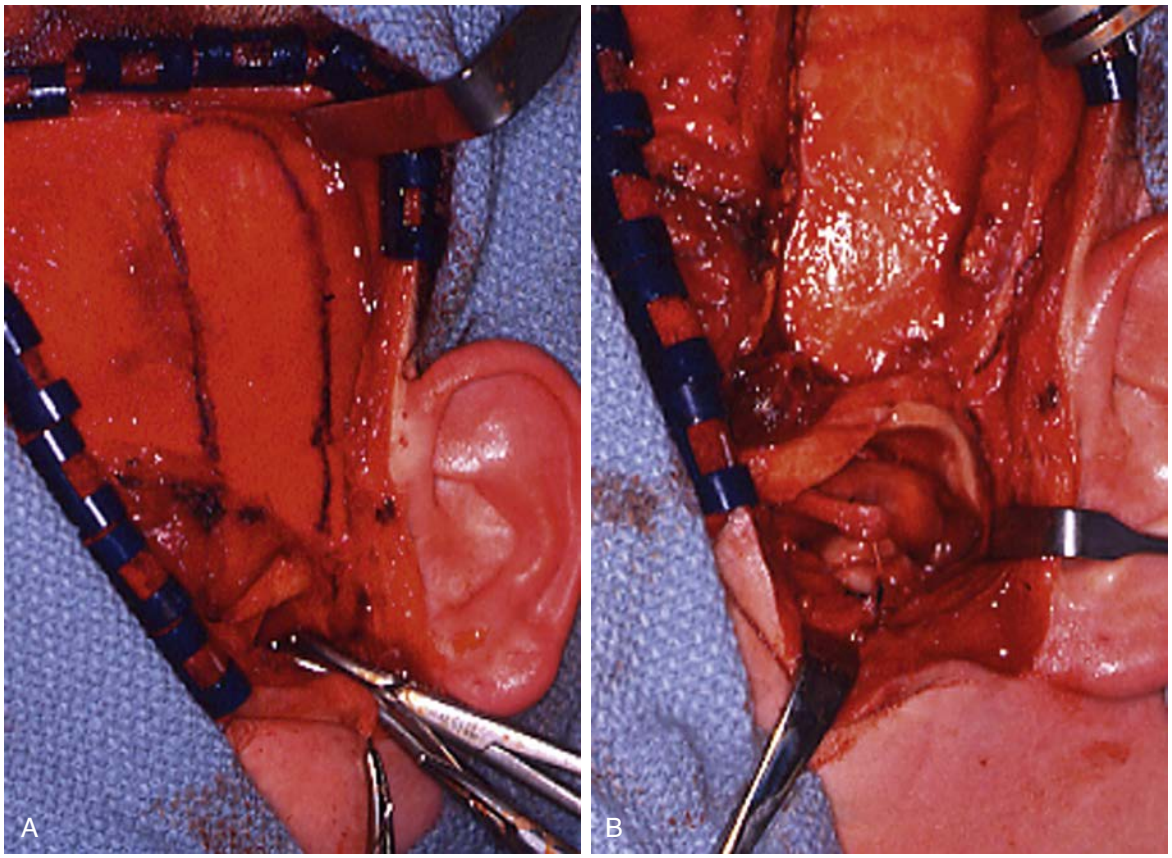
In the past, autogenous tissue has been called the "gold standard" for management of primary, uncompromised TMJ replacement. However, because of the potential morbidity associated with harvest of autogenous tissues, the inability of these tissues to survive either the transplantation process or the functional demands of the forces applied to them, and for the reasons discussed below, there arose the need for the development and use of alloplastic materials to replace the anatomically and functionally impaired TMJ. This is a similar course followed by orthopedic surgery in replacement of other end-stage diseased body joints.

Alloplastic TMJ Replacement

John Murray Carnochan,[73] a New York surgeon, was credited with the idea of interposing alloplastic material between the surfaces of diseased, excised joints in an attempt to prevent ankylosis and promote function. In 1840 he reported an attempt to mobilize a patient's ankylosed TMJ by placing a small block of wood between the raw bony surfaces of the residual mandible after gap arthroplasty.[73]



• **Figure 43-3** Non-vascularized costochondral graft reconstruction of the right TMJ.



• **Figure 43-4** Temporalis muscle flap. **A,** Outline of flap. **B,** Flap fed under temporal process of zygoma and into the glenoid fossa.

Tracing the use of alloplastic materials for the management of severe anatomic end-stage TMJ disease and associated mandibular dysfunction, ankylosis was the primary problem that led patients to surgery. Every new material developed was used in an attempt to manage any joint ankylosis, including the TMJ.[74-133]

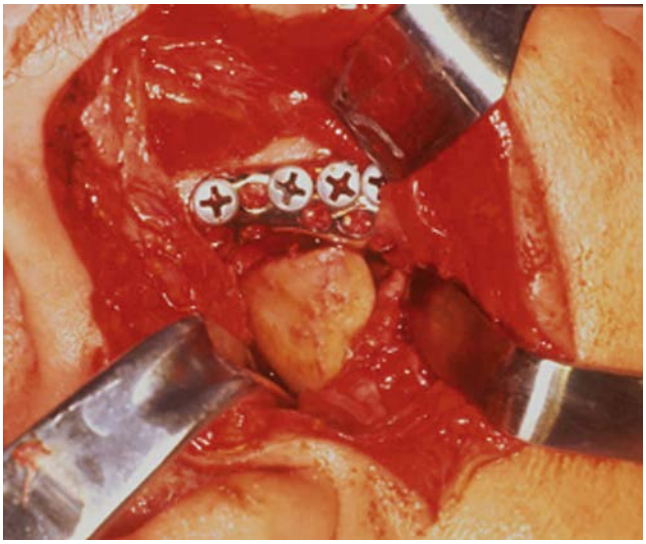
In 1960 Sir John Charnley reported the development of a total alloplastic prosthetic hip replacement system composed of a metal-backed polyethylene acetabular cup articulating with a metal femoral head, attached to a metal femoral shaft which was cemented into place with polymethylmethacrylate.[134] Modifications of Charnley's device have become

the "gold standard" for hip, knee, and shoulder total joint replacement devices in orthopedic surgery.[135]

In 1963, 1964, and 1970, Christensen[84-86] reported the use of a thin cast vitallium fossa-eminence prosthesis for management of TMJ ankylosis (Figure 43-5). He later added a cast vitallium ramus-condyle with a polymethylmethacrylate head to create a total joint device (Figure 43-6).

Between 1974 and 1985, a number of reports were published involving the use of partial and total alloplastic TMJ replacement devices. These were typically case reports with small numbers of patients for whom the diagnosis was ankylosis or reconstruction after ablative malignant neoplasia surgery.[95-99,106-123] Of these, the two most significant reports were those by Kiehn[111,112] and Kummoona.[117]

In 1985[119] and again in 1990[120] S. Sonnenburg and M. Sonnenburg reported the use of a TMJ TJR device consisting of a cast chromium-cobalt-molybdenum ramus-condyle component articulating against an ultra–high-molecular-weight polyethylene fossa, mimicking the materials and geometry used in the design of alloplastic joint devices by orthopedic surgeons.



• **Figure 43-5** Alloplastic thin cast vitallium fossa-eminence device (TMJ Inc., Golden, CO), right TMJ.

Hinds, Homsy, and Kent[107] in 1974 reported the use of a Proplast-Teflon-coated vitallium ramus-condyle component for hemi-articulation reconstruction of the TMJ. Kent, in 1983, reported the use of a Dacron/Proplast-Teflon (VK-I) and later a Dacron/Proplast-Teflon/ultra–high-molecular-weight polyethylene (VK-II) fossa.[108,109] The ramus-condyle and fossa components were then used as TMJ TJR devices (Vitek, Houston, TX). In 1993 Kent et al.[110] reported a long-term follow-up study using these devices (Figure 43-7).

From 1990 to 1995, reports surfaced regarding the development and use of alloplastic partial and total TMJ replacement devices. The indications for use ranged from ankylosis to reconstruction after ablative surgery and trauma to the unsuccessfully managed, multiply operated patient.[124-130]

In 1993 Henry and Wolford[66] reported prospective results with the use of the Techmedica (Camarillo, CA; now TMJ Concepts, Ventura, CA) computer assisted designed/computer aided manufactured (CAD/CAM) TMJ TJR device used to manage end-stage TMJ disease in 26 patients followed a mean of 46 months with anatomically divergent, functionless TMJs after Proplast-Teflon exposure and failure. Wolford, Cottrell, and Henry[23] then reported in 1994 the use of the same device in 56 multiply operated TMJ patients followed for a mean of 30 months. Mercuri et al.[130] in 1995 reported the preliminary results in a prospective multicenter clinical study with the Techmedica device in 215 patients followed for a mean of 4 years. In 2004 Mercuri et al.[131] published a 10-year follow-up study; and in 2006 Edibam et al.[132] reported a 14-year follow-up study of these

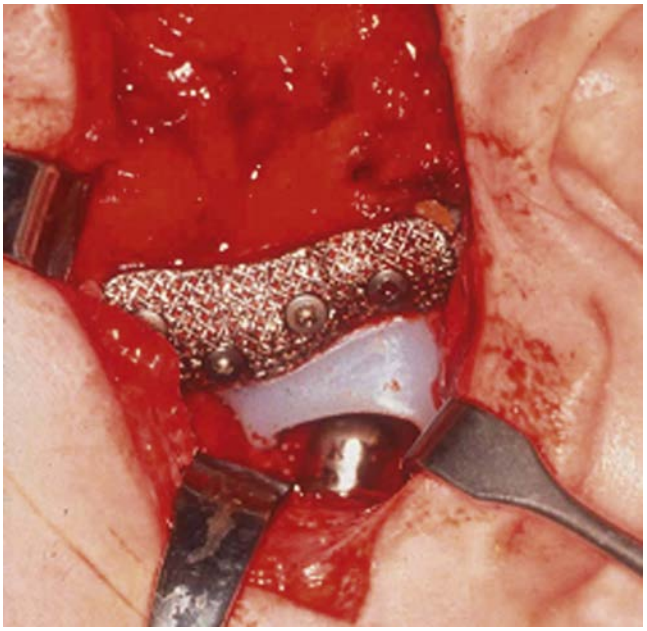
patients (Figure 43-8). In 2015, Wolford et al. reported a 20-year follow-up of 99 Techmedica/TMJ Concepts TMJ TJR devices. The results indicated that these devices continue to function well and patients showed sustained improvement in TMJ pain, jaw function, ability to eat solid food, and quality of life.[133,134]

In 1995 Chase et al.[87] reported retrospective results with the use of the Christensen (TMJ Inc., Golden, CO) TMJ TJR device in 21 patients followed for a mean of 2.4 years. Garrett et al.[88] reported the use of a custom modification of the standard Christensen total TMJ device employed in 20 multiply operated patients followed for a mean of 7.5 months. In 2000 Gerard and Hudson[135] reported on the use of the modified metal-on-metal Christensen TMJ device implanted in 23 patients followed for a mean of 26 months (Figure 43-9).

Wolford et al.[136] presented the first comparison of pre- and postoperative subjective and objective domains from similar groups of patients implanted with two different TMJ TJR systems: Techmedica (Camarillo, CA; now TMJ Concepts, Ventura, CA) and TMJ, Inc. TMJ TJR device (Golden, CO; now Nexus CMF, Salt Lake City, UT). These authors found statistically significant better outcomes in both domains in patients implanted with the Techmedica TMJ TJR device than the TMJ, Inc.

All implanted alloplastic devices (dental implants, orthopedic, and TMJ TJR) depend on the principle of osseointegration of their fixation components for their ultimate stability and longevity. Osseointegration implies the direct incorporation of the implant fixation into the bone without the preliminary phase of fibrous tissue in-growth. The requirements for osseointegration are



• **Figure 43-8** Wrought alloyed titanium ramus, cobalt-chrome-molybdenum condyle, and commercially pure titanium and ultra–high-molecular-weight polyethylene fossa components of a patient-fitted alloplastic total TMJ device (Techmedica, Camarillo, CA).

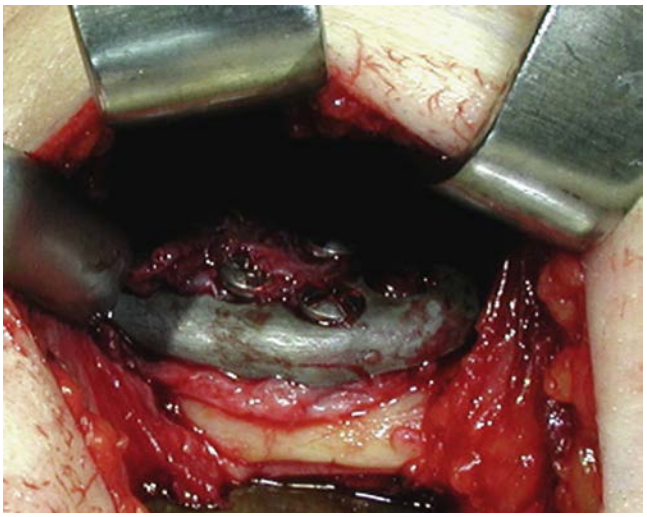
essentially the same as for primary fracture healing: the transmission of forces from the implant to the bone and vice versa must occur without relative motion or without intermittent loading.[137] Therefore, just as with a dental implant, the most important principle in TMJ TJR is primary stability of the device fixation and components from the moment they are implanted.

In orthopedic surgery, TJR devices can be initially stabilized by press-fitting or, now less frequently, cementation of the components into the host bone. In the case of the TMJ, the anatomy of both the mandible and the temporal glenoid fossa does not provide for such a fixation option. Therefore screw fixation of both TMJ TJR fossa and the ramus/condyle components must be utilized to provide initial fixation and stabilization.

Compounding the normal TMJ stability issues are patients who have distorted anatomy following prior surgical and/or material failures, or the result of local or systemic pathology. This makes it extremely difficult to replace the TMJ with an "off-the-shelf" or so-called "stock" device and obtain primary component stability.

Using TMJ TJR stock devices, the surgeon may be tempted to bend, shim with bone or alloplastic cement, or remove precious host bone to make them fit. Any of these maneuvers can lead to component material fatigue or overload, promoting micromotion or breakage.

Micromotion or movement under functional loading leads to the formation of a fibrous connective tissue interface between any mobile TMJ TJR component and the host bone. This can result in early loosening of that component and potential early catastrophic or later premature device failure (Figure 43-10).



• **Figure 43-10** Failed "stock" alloplastic total TMJ device. Note loose screws and fibrous connective tissue interface between the ramus component and the host mandibular bone caused by micromotion under function, right TMJ.

Therefore a patient-fitted or custom-made TMJ TJR device appears to be the most appropriate solution for such complex cases.[130-134] Patient-fitted or custom TMJ TJR devices, designed and manufactured for each specific anatomic situation, conform to any unique anatomic condition. They require no alteration or supplementation to achieve initial implantation stability. The screw fixation of TMJ TJR custom devices secures the components with accuracy to the host bone, mitigating any chance for micromotion while maximizing the opportunity for osseointegration of the fixation screws (Figure 43-11).

• **Figure 43-11** Wrought alloyed titanium ramus, cobalt-chrome-molybdenum condyle, and commercially pure titanium and ultra–high-molecular-weight polyethylene fossa components of a patient-fitted alloplastic total TMJ device (TMJ Concepts, Ventura, CA) on a CT-generated stereolithographic model.

When calculating procedural costs, it is important not only that the price of the TMJ TJR device is considered, but also that all factors associated with its implantation should be evaluated. The major advantage of alloplastic TMJ TJR over autogenous TMJ replacement is that alloplastic TMJ TJR does not require a second surgical site. Therefore, the potential morbidity of the second surgical donor site, associated intraoperative time, and postoperative hospital expenses are all greatly decreased. Despite the fact that TMJ TJR devices can be expensive, the relative costs involved with their use overall is either equal to or ultimately less than costs for autogenous TMJ replacement procedures.

Indications For TMJ Replacement

TMJ TJR is indicated to manage any of the following conditions,[1] each of which is described in detail in the following sections:

1. Inflammatory arthritis involving the TMJ not responsive to other modalities of treatment
2. Recurrent fibrosis and/or bony ankylosis not responsive to other modalities of treatment
3. Failed tissue grafts (bone and soft tissue)
4. Failed alloplastic joint reconstruction
5. Loss of vertical mandibular height and/or occlusal relationship attributable to bony resorption, trauma, developmental abnormalities, or pathologic lesions

Inflammatory Arthritis Involving the TMJ

In 1988 Lindqvist[138] presented a clinical 10-year mean follow-up study of 16 of the 60 patients he previously reported. Of the 16, all were unilateral and 4 had the preoperative diagnosis of "severe TMJ arthritis." There was no indication whether the 4 "severe TMJ arthritis" patients suffered from low-inflammatory or high-inflammatory arthritis. However, based on the symptoms described, one might surmise that these patients had low-inflammatory TMJ arthritic disease (osteoarthritis), which demographically is more common unilaterally than is high-inflammatory TMJ arthritis. The authors concluded that their long-term clinical results utilizing autogenous costochondral TMJ grafting in adult patients were "fairly good."

Obeid,[139] in a mean 5-year (range 2 to 11 years) retrospective follow-up study, reported results with autogenous costochondral TMJ grafting in 22 patients (14 unilateral). He concluded that autogenous costochondral grafting was a successful method for replacement of the TMJ, despite a 10% infection rate and an unpredictable growth rate in the younger patients, all of whom required later corrective osteotomies.

In 1994 Perrott[140] presented a retrospective study of TMJ autogenous costochondral grafting in 26 patients, 7 growing and 19 nongrowing, with a mean follow-up of approximately 4 years. One of the non-growing patients had a diagnosis of "autoimmune arthritis" (high-inflammatory arthritis) and two others "DJD" (degenerative joint disease, that is, osteoarthritis). When reviewing the follow-up data, the "autoimmune arthritis" patient demonstrated on radiographic measurement significant bilateral loss of posterior mandibular vertical dimension, and the only incidence of a decrease in maximum interincisal opening (MIO). However, follow-up data for the two "DJD" patients revealed that their radiographic measurements and MIO corresponded with the other nonarthritic pre-reconstruction diagnoses. These authors concluded that their results indicated that costochondral grafting may be used to successfully replace the TMJ.

MacIntosh[141-143] discussed a rationale and provided clinical examples for the use of autogenous costochondral grafting in the management of the functional and esthetic consequences of TMJ osteoarthritis, rheumatoid arthritis, and juvenile arthritis, but provided no clinical data upon which to evaluate his clinical results. He advocated disc preservation in early-stage high-inflammatory arthritic disease and two-stage autogenous temporalis flap and autogenous costochondral grafting in late-stage high-inflammatory TMJ arthritic disease.[142] MacIntosh[142] stated, "Absolute guidelines for determining the appropriate time to operate on the rheumatoid arthritis patient do not exist. The author has found a quiescent period of 2 years, during which the number of affected body articulations remain stable (although not normal), and imaging of the temporomandibular joint and status of jaw position-occlusion remain unchanged, to offer reasonable expectations for postsurgical stability." However, again, no data were provided to support this observation or his management recommendations.

Frietas et al.[144] reported 12 arthritic, adult patients (24 joints) requiring TMJ TJR. Six were managed utilizing autogenous sternoclavicular or costochondral grafts, and six with TMJ TJR devices. These groups were followed for a

mean of 48.8 months and 58.5 months respectively. The authors reported that based on the study criteria, the TMJ TJR device patients demonstrated statistically significantly better subjective and objective domain outcomes than did those replaced with autogenous bone. In light of these results, the authors concluded that TMJ TJR devices were more appropriate for the management of patients with end-stage low- or high-inflammatory arthritic disease. TMJ TJR avoided the need for another operative site and its potential morbidity, decreased the operating room time, and allowed for simultaneous mandibular advancement, all with predictable long-term results and stability.[145]

Troulis et al.[146] studied 10 patients (17 joints) followed a mean of 17 months (range 8 to 38 months) who underwent endoscopic condylectomy and autogenous costochondral grafting. They reported satisfactory clinical results with low morbidity over the short period of this initial study and stated they would be pursuing long-term follow-up studies. To date neither longer follow-up nor any further studies have been reported.

Saeed and Kent[147] retrospectively reviewed 76 TMJ costochondral grafts (57 patients) with a mean follow-up of 53 months (range 24 to 161 months). Nine patients (three with ankylosis and six without ankylosis) had a preoperative diagnosis of arthritis. They never stated whether it was a low-inflammatory or a high-inflammatory arthritic condition. They concluded that in patients with no previous TMJ surgery, arthritic disease, or congenital deformity, the costochondral graft performed well. However, a preoperative diagnosis of ankylosis was associated with a high complication rate, suggesting caution when using the autogenous costochondral grafts in ankylosis patients.

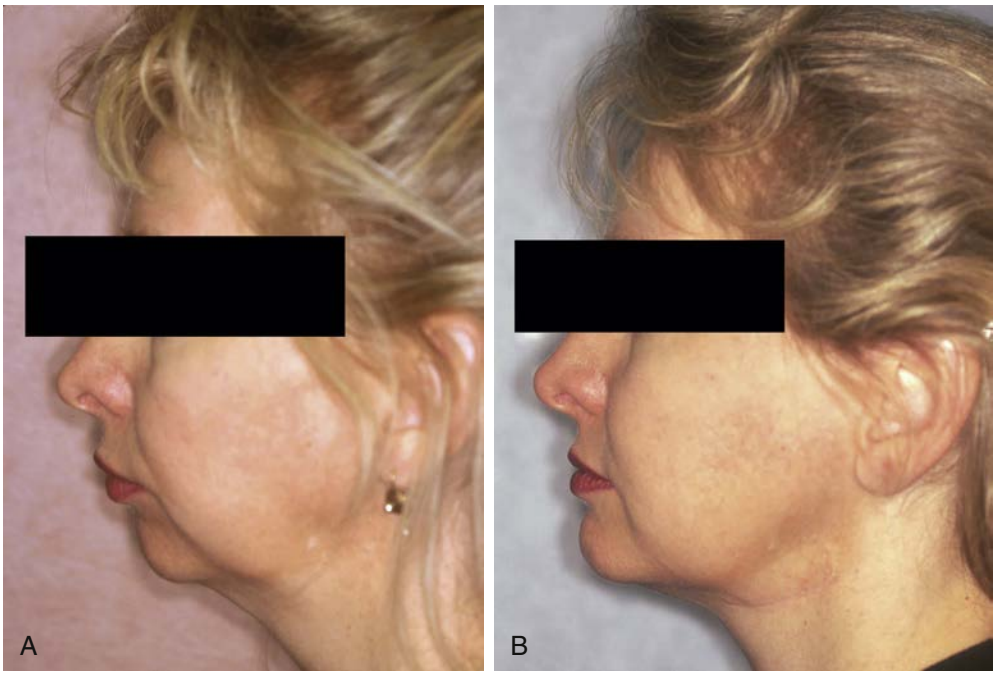
Neither orthopedic textbooks nor journal articles published recently discuss the use of autogenous bone in the replacement of any joint in the adult patient affected by either end-stage low- or high-inflammatory arthritic disease. Alloplastic total joint replacement is the recommended management modality when orthopedic joint replacement is required in such cases[148,149] (Figure 43-12).

Other high-inflammatory arthritic conditions affect both the upper and the lower compartment of the TMJ. This may account for the poor performance of costochondral grafting resulting in ankylosis often experienced in these cases.

The role of TMJ TJR in the management of juvenile idiopathic arthritis (JIA) has not been studied.[150] Despite the many clinically successful applications of the costochondral graft, its use in children has been associated with excessive cartilaginous growth, resulting in malocclusion and facial deformity.[155-158]

Peltomäki,[159] in the marmoset, and Ellis,[160] in the monkey, studied the growth of the mandible after costochondral grafting with emphasis on the amount of cartilage included in the graft. Peltomäki found that depending on the amount of cartilage in the unilateral costochondral graft, the mandible shifted toward the nonoperated side. This occurred during the entire period of growth, which the authors concluded indicated a strong hormonal influence.

Ellis compared the use of sternoclavicular grafts to costochondral grafts and concluded that both behaved similarly with regard to growth/over-growth in the monkey. Ellis suggested that in growing patients, maintenance of biomechanical architecture and reasonably normal function may be more important than the nature of the autogenous graft used for condylar replacement. Further, Ellis recommended



• **Figure 43-12** Rheumatoid arthritis. Bilateral patient-fitted alloplastic TMJ reconstruction. **A,** Preoperative. **B,** Postoperative.

retaining as little cartilage as possible to prevent over-growth when replacing the mandibular condyle with a costochondral graft in growing individuals.

In light of the data supporting the reports by Frietas,[144] Mehra,[145] Saeed et al.,[161,162] and the orthopedic experience in other synovial joints,[148,149] it appears that autogenous costochondral grafting should be re-evaluated for use in adult patients afflicted with low- and high-inflammatory TMJ arthritis requiring TMJ replacement.

Recurrent Fibrosis and/or Bony Ankylosis

The traditional management of complete bony TMJ ankylosis has been gap arthroplasty with autogenous tissue graft replacement or alloplastic hemiarthroplasty. While the autogenous grafting techniques can lead to improved mandibular function and form, function is delayed due to the healing process required. Since graft micromotion during healing will jeopardize its incorporation into the host environment by compromising neovascularization, early mandibular mobility often leads to graft/host interface failure. Matsuura[163] reported a high incidence of failure and ankylosis of autogenous TMJ costochondral grafts in sheep after condylectomy if the jaws were only partially immobilized.

Saeed and Kent[164] reported a high incidence of re-ankylosis in patients with ankylosis who underwent TMJ autogenous costochondral replacement. They advised caution when employing this technique for ankylosis cases. For the patient with re-ankylosis, placing autogenous bone into an area where reactive or heterotopic ossification has occurred intuitively makes no sense. In similar situations in other joints, orthopedic surgeons will opt for total alloplastic joint replacement.[148,149]

In light of the biologic facts and the orthopedic experience, TMJ TJR should be considered in the management of recurrent fibrosis and bony ankylosis of the TMJ (Figure 43-13, Table 43-1).

Failed Tissue Grafts

The success of any autogenous tissue graft requires a rich vascular bed at the recipient site. Scar tissue that inevitably develops around the TMJ in the multiply operated patient does not provide an environment conducive to the predictable success of an autogenous tissue graft. Marx reports that capillaries can penetrate a maximum thickness of 180 to 220 μm of tissue, whereas scar tissue surrounding previously operated bone averages 440 μm in thickness.[165] This fact may account for the clinical observation that free, non-vascularized autogenous tissue grafts, such as cartilage, costochondral, and sternoclavicular grafts, often fail in the case of the multiply operated patient or those patients with severe anatomic architectural discrepancies resulting from pathology (e.g., failed autogenous materials).

Reitzik[166] reported, in an analogous situation to autogenous costochondral grafting, cortex-to-cortex healing after vertical ramus osteotomy in monkeys required 20 weeks and probably 25 weeks in humans. Typically in patients reconstructed with costochondral grafts, maxillo-mandibular fixation is maintained for only 4 to 6 weeks to prevent ankylosis. Despite screw/plate fixation, micromotion of these non-vascularized free grafts will invariably occur after this short period of immobilization based on Reitzik's work. Early mandibular function results in shear movements of the graft that lead to poor neovascularization, nonunion, and/or failure.[167] This, along with the compromise in vascularity discussed previously undoubtedly accounts for autogenous costochondral graft failures. Therefore, in light of the fundamental biologic and mechanical issues discussed, TMJ cases involving multiply operated patients—especially those exposed to failed autogenous tissue grafts and/or those with anatomically distorted and severe intra-articular end-stage pathology—should be managed with TMJ TJR devices to achieve optimal functional and esthetic outcomes (Figure 43-14).

Failed Alloplastic Materials

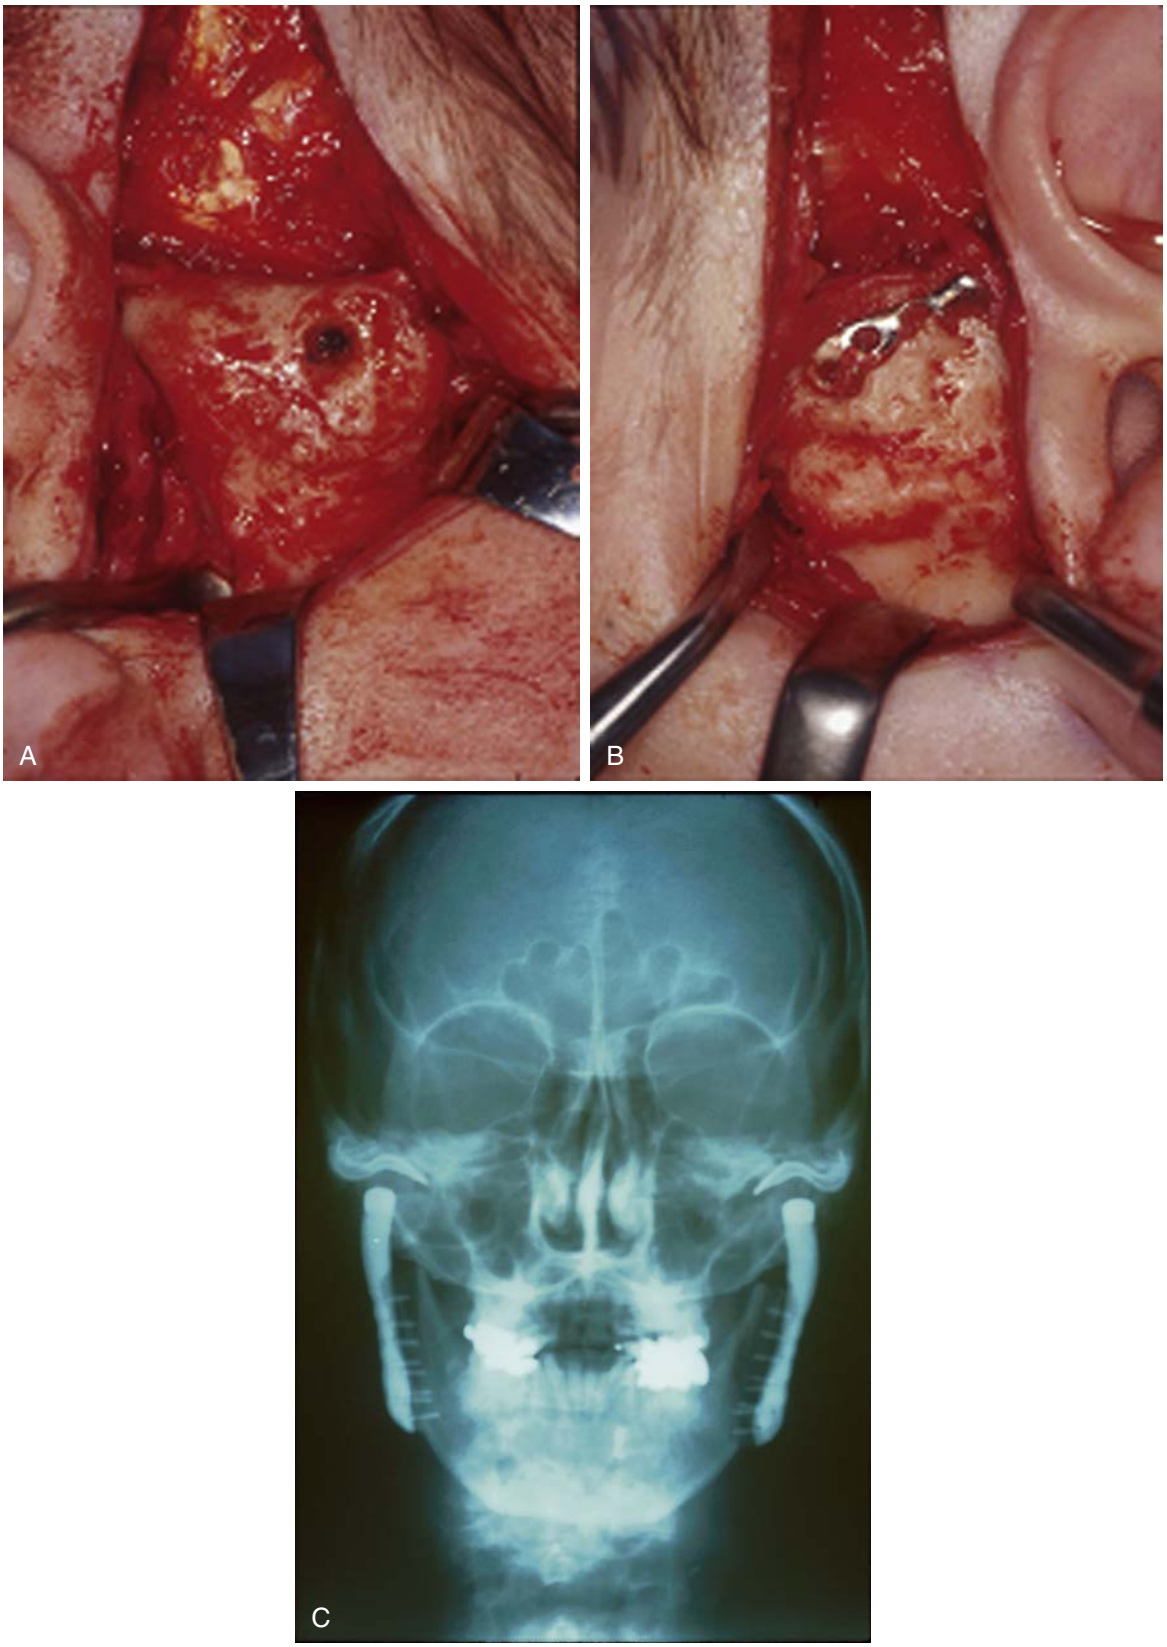
As a result of the osteolysis around failed TMJ replacement alloplasts and the resultant host bone architectural discrepancies, it is difficult to adapt and fixate replacement TMJ TJR devices stably to the bony remnants of either the fossa or the ramus. As discussed above, the foreign body giant cell reactions associated with failed or failing devices provide a poor vascular environment into which to introduce an autogenous graft.[66]

Mercuri and Giobbe-Hurder[131] discussed this issue at length in a report where they evaluated long-term outcomes with TMJ TJR in patients with prior exposure to failed Proplast-Teflon and/or silicone rubber. They found that the TMJ TJR devices remained functional long-term (60.2 months mean), but that patients exposed to failed materials had lower subjective domain improvement scores (pain, jaw function, diet consistency) when matched to a TMJ TJR group of patients never exposed to failed TMJ alloplasts. Therefore, based on the available literature, it appears appropriate to replace TMJs affected by prior failed alloplasts with TMJ TJR devices rather than autogenous tissues (Figure 43-15).

Orthopedists and biomedical engineers have been studying the effect of failed and failing devices on the long-term outcomes of future implanted alloplastic devices. There is now evidence that failure of a prior implanted device in some patients results in a cell-mediated immune response that bodes poorly for the outcomes of any future implanted alloplast.[168-171]

Loss of Vertical Mandibular Height and/or Occlusal Relationship

Loss of TMJ bone stock leading to decreased posterior mandibular vertical dimension is caused by developmental abnormalities, pathology, or traumatic injury. This condition results in maxillomandibular form and function discrepancies. These situations should be managed



• **Figure 43-13** Bilateral TMJ ankylosis. **A,** Preoperative right TMJ. **B,** Preoperative left TMJ with embedded fossa-eminence device. **C,** Postoperative bilateral patient-fitted alloplastic TMJ reconstruction.

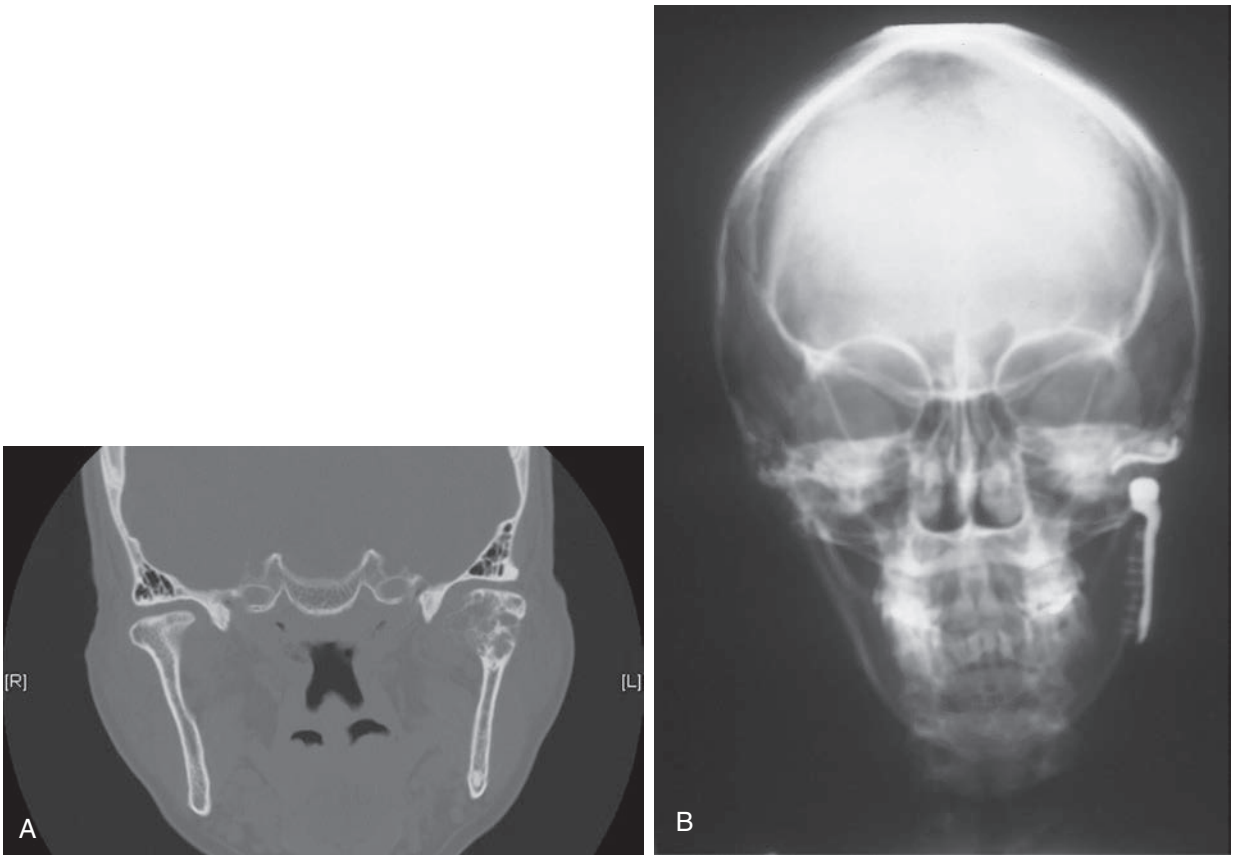
by identifying the etiology of the problem and correcting it at the site directly affected by the pathology. In the case of a primary TMJ etiology (i.e., high-inflammatory arthritis, benign neoplasia), TMJ TJR rather than osteotomy should be considered. The surgeon must understand the nature of the pathology leading to the loss of vertical mandibular height, the patient's prior local surgical history, and the state of the host bone architecture before deciding on the type of TMJ replacement best suited to the situation (Figure 43-16).

Further, there is always a component of counterclockwise mandibular rotation in the surgical management of loss or posterior mandibular vertical height. Expecting a free, non-vascularized autogenous costochondral graft, or end-stage disease affected compromised condyloid process remnant to withstand functional loading forces generated after orthognathic surgery or distraction is fraught with the relapse potential.[172] The long-term stability using patient-fitted TMJ TJR in such cases is well documented.[173-176]



• **Figure 43-16** **A,** Low-grade fibrosarcoma of the left TMJ, preoperative. **B,** Patient-fitted alloplastic reconstruction of the left TMJ, postoperative.

The Skeletally Immature Patient

Theoretically, in growing patients, autogenous costochondral grafts will "grow with the patient." However, the growth potential of costochondral grafts used to replace the TMJ in growing patients has been reported to be unpredictable or result in ankylosis. Either or both can occur as the consequence of graft and/or fixation failure or the uncooperative nature of the young patient with regard to the rigorous physical therapy required after surgery.[139,177-180] Some studies have even questioned the necessity for using a cartilaginous graft to restore and maintain mandibular growth.[15,160]

Long-term reports of mandibular growth in children who underwent autogenous costochondral TMJ TJR reveal that excessive growth on the treated side occurred in 54% of the 72 cases examined and growth equal to that on the opposite side occurred in only 38% of the cases.[140,181-185] Furthermore, Peltomäki et al., in an investigation of mandibular growth after CCG, supported previous experiments with regard to the inability of the graft to adapt to the growth velocity of the new environment.[159, 186-187]

Reported unreliability of autogenous costochondral TMJ TJR in children includes graft failure, unpredictable growth, ankylosis, and potential for donor-site morbidity. On the basis of the orthopedic experience and success reported with alloplastic TJR in improving the quality of life of growing patients with severe anatomic and functional joint disorders,[188] it seems reasonable to consider alloplastic TMJ TJR for the following conditions in children:

1. High-inflammatory TMJ arthritis unresponsive to other modalities of treatment
2. Recurrent fibrosis and/or bony ankylosis unresponsive to other modalities of treatment
3. Failed tissue grafts (bone and soft tissue)
4. Loss of vertical mandibular height and/or occlusal relationship because of bony resorption, trauma, developmental abnormalities, or pathologic lesions

To continue to re-operate children with failed, overgrown, or ankylosed costochondral grafts employing the same autogenous tissues that failed when there may be an appropriate solution available seems myopic. These patients would be better managed with TMJ TJR devices understanding that, depending on growth, revision and/or replacement surgery may be required in the future. This would appear to be a sounder option rather than incurring continued autogenous tissue failures that will also very likely require future surgical intervention.[188]

Future Considerations

Distraction Osteogenesis

Distraction osteogenesis, which induces new bone formation along the vector of pull without the use of a bone

graft, has been employed as a reconstruction method for mandibular defects.[189-191] Stucki-McCormick et al.[192,193] reported the application of transfer osteogenesis to reconstruct the mandibular condyle in two patients. Cavaliere et al.[194] reported using similar methods to manage hemifacial microsomia patients with 1- and 2-year follow-up. The long-term growth potential for the use of this modality in the reconstruction of prepubescent cases also has yet to be determined.

Despite the short-term promising clinical results, the histomorphologic changes in the associated joint structures (i.e., cartilage, disc, and masticatory musculature) have not been elucidated completely. Experimental studies with rabbits and monkeys addressing this issue are appearing in the literature.[195,196]

Based on their animal experiments, Hu et al.[196] list several potential advantages of mandibular condyle reconstruction using transport distraction over conventional autogenous bone grafting:

1. Donor site morbidity is avoided.
2. The rigid distraction device allows for immediate postoperative physical therapy, which allows for the formation of a pseudo-arthrosis and prevents ankylosis.
3. The risk of bone graft necrosis and resorption is greatly reduced compared to non-vascularized free bone grafts (e.g., costochondral) because the transported bone in this technique retains its internal muscle and periosteal blood supply.

However, these experimental studies were carried out in animals with normal temporomandibular joints, and extrapolation of these data to patients with compromised temporomandibular joint anatomy caused by prior surgery or pathology remains a question and concern when using this technique.

Tissue Engineering

Mandibular condyle tissue engineering has been proposed to address limitations of both autogenous and alloplastic reconstructions.[197] A tissue-engineering strategy would incorporate a biodegradable scaffold delivering biologics such as cells, genes, and/or proteins to regenerate the bone/cartilage tissues of the mandibular condyle. Tissue engineering could be applied to regenerate localized defects or, theoretically, the entire articulating condylar surface. Implementation could take one of three approaches: (1) ex vivo growth of tissue on the scaffold/biologic composite in a bioreactor before implantation on the mandible, (2) implantation of the scaffold/biologic composite at a secondary surgical site before implantation on the mandible, and (3) direct implantation at the mandible site.[198]

While this modality holds the potential to revolutionize TMJ reconstruction in the future, there are many biologic, physiologic, mechanical, regulatory, and ethical issues that must be tested and addressed before it becomes a reality.

Summary

At the present time, based on the available published clinical data, TMJ TJR appears to provide the most predictable functional and esthetic outcomes for patients with end-stage low- and high-inflammatory TMJ arthritis, re-ankylosis, failed alloplastic TMJ replacements, and loss of posterior mandibular vertical dimension.[199-200]

Soft tissue (temporalis muscle) appears to have limited use in TMJ replacement surgery as an interpositional material in the initial management of ankylosis.

Osteodistraction may supplant autogenous bone grafting in the future as more long-term studies are reported. Tissue-engineered TMJ replacement, while still in its infancy, may ultimately provide an answer for TMJ cases in the future. However, both osteodistraction and tissue engineered TMJ replacements suffer from the same local and systemic biologic and pathologic issues as autogenous tissue grafting discussed above.

Chronic Facial Pain: Evaluation, Differential Diagnosis, and Management Strategies

JAMES Q. SWIFT, MARYANN (MA'ANN) C. SABINO, HADAS LEHMAN-NAAMAN

Introduction

According to the National Health Interview Survey (NHIS) conducted by the Centers for Disease Control and Prevention (CDC) in 2005, approximately 7% of Americans suffer from facial pain each year.[1] The term facial pain may be used to describe any unpleasant, annoying, or descriptive sensation in the facial region, including those emanating from the oral cavity, dentition, maxilla, mandible, sinus, orbital, cranial, and nasal regions of the head and neck. While it is clear that facial pain is mediated primarily by nerve fibers of trigeminal nerve origin, other sensory nerves and nerve fibers may also play a role in facial pain transmission. In order to understand facial pain, one must first understand the neurophysiology of pain: from the release of pain-producing neurotransmitters and the interaction with receptors on peripheral nerve fibers innervating head and neck structures to the complex cortical reorganization and processing that occurs in chronic pain. This chapter will highlight the key neurophysiologic mechanisms that underlie both acute and chronic facial pain entities.

Chronic facial pain is one of the most challenging entities for a clinician to diagnose and treat. It is usually of greater than 6 months' duration, unrelenting, and recalcitrant to conventional modes of pharmacotherapy and/or surgical intervention.[2] The chronic pain patient who relies on chronic opioid therapy poses a particular challenge to the oral and maxillofacial surgeon from an intraoperative and postoperative pain management standpoint. This chapter will discuss differential diagnoses of chronic facial pain, treatment recommendations, and barriers that currently exist for the management of the chronic facial pain patient. Identifying the barriers and eliminating them through discussions with the patient and health care providers will allow for effective pain management and abolition of biases that currently affect many chronic pain sufferers.

Facial pain, like other types of pain, can be complex and multidimensional and therefore clinical evaluation becomes an important aspect in the diagnosis of the facial pain patient. Many clinical specialties play a role in the diagnosis and management of facial pain. These include anesthesiologists, dentists, endodontists, oral and maxillofacial surgeons, facial pain experts, otolaryngologists, neurologists, neurosurgeons, physical therapists, psychiatrists, psychologists, and chemical dependency physicians. In complex cases of facial pain, a team approach is usually taken, resulting in improved therapeutic outcomes.[3] With an understanding of the complex neurophysiology that exists in the facial pain patient, an idea of how to delineate the correct facial pain diagnosis, and an understanding of the alternative treatment modalities that currently exist, the clinician will be enabled to manage one of the most complex and challenging pathologic entities—a patient with chronic facial pain.

Neurophysiology of Pain

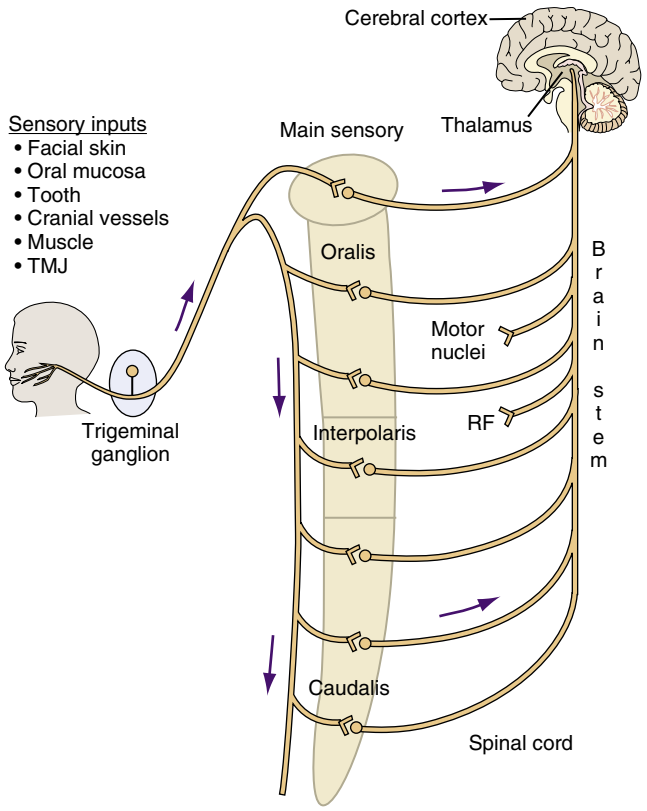
Trigeminal Anatomy

A thorough understanding of neuroanatomy and neurophysiology is imperative to fully appreciate the complex nature of facial pain. While it is clear that other sensory fibers are important in the transmission of painful information from the head and neck (e.g., cervical spinal nerves, sympathetic fibers), the majority of pain in the head and neck is transmitted via branches of the fifth cranial nerve—the trigeminal nerve. The trigeminal nerve is considered the largest of the cranial nerves. The primary sensory neurons (also known as first-order neurons) of the trigeminal nerve are located within the largest ganglia in the human body—the trigeminal ganglia. The trigeminal ganglia are housed within the petrous portion of the temporal bone in the middle cranial fossa in close proximity to the internal

carotid artery and cavernous sinus. It is considered a bipolar neuron in that its primary afferent (peripheral nerve) fibers terminate within the head and neck while its central fibers terminate within the medullary dorsal horn and cervical spinal cord. Its extensive distribution highlights the amount of sensory input the head and neck receives.

The trigeminal sensory fibers synapse with second-order neurons located within the spinal trigeminal nuclear complex. The trigeminal brainstem nuclear complex is subdivided into the (1) chief main sensory nucleus, (2) spinal trigeminal nucleus oralis, (3) spinal trigeminal nucleus interpolaris, and (4) spinal trigeminal nucleus caudalis. The spinal trigeminal nucleus caudalis has been implicated as the main nucleus that receives painful or nociceptive input from peripheral targets. There is a significant convergence of non–trigeminal nerve fibers arising from the cervical spine and vagus and glossopharyngeal nerve terminals onto trigeminal nuclei. The large convergence of cranial and spinal nerves explains the presence of referred pain to non–head and neck structures in the facial pain patient.

Neurons within the spinal trigeminal sensory nuclear complex project to higher brain centers such as the *thalamus* and *reticular formation.* The pathways are known as the trigeminothalamic and trigeminoreticular tracts, respectively, and they project to higher-order neurons located within the somatosensory cortex and anterior cingulated cortex. The processing of both discriminative (quality, severity, and location) and affective (emotional) components of pain occurs at these cortical levels[4] (Figure 44-1).



• **Figure 44-1** Trigeminal nerve pain pathway. Pain information within the head and neck is transmitted via the branches of the trigeminal nerve (cranial nerve V), whose sensory neurons are located in the trigeminal ganglion. Information is further processed as it courses through second-order neurons in the spinal trigeminal nuclear complex within the brainstem, thalamus, and cerebral cortex. (From Sessle BJ: Acute and chronic craniofacial pain: brainstem mechanisms of nociceptive transmission and neuroplasticity, and their clinical correlates, *Crit Rev Oral Biol Med* 11(1):57-92, 2000.)

Peripheral Mechanisms of Pain

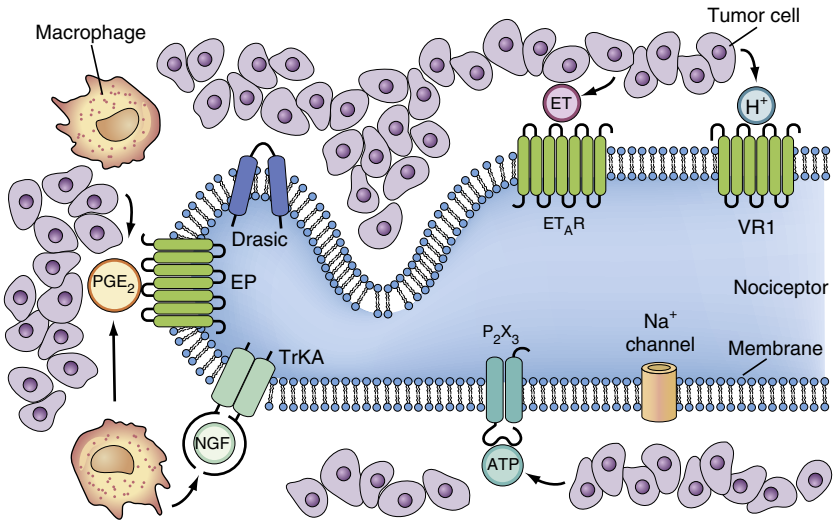
Considerable advances have been made in the past 2 decades in identifying cellular and molecular mechanisms involved in facial pain transmission. Injury to peripheral tissues certainly occurs during oral and maxillofacial surgical procedures. Pain generally occurs during tissue damage and is a result of release of neurotransmitters, cytokines, and factors from damaged cells, adjacent blood vessels, and nerve terminals. Prostaglandins, substance P, calcitonin gene–related peptide (CGRP), bradykinins, histamine, interleukin-1 and interleukin-6, and serotonin are examples of proinflammatory mediators that are involved in the generation of the inflammatory state that accompanies tissue destruction.[5-7]

Pain transduction occurs when these proinflammatory mediators interact with channels and receptors expressed on the peripheral nerve membrane. These are specialized structures that detect a diversity of chemical and thermal stimuli (Figure 44-2). During minor tissue damage, proinflammatory mediators are released and bind to their respective receptor or channel, and pain transduction occurs and resolves over time. Peripheral sensitization occurs when the peripheral nerve becomes sensitized because of constant stimulation and activation. This may be in the form of decreased excitation thresholds, upregulation of receptors and/or channels in both nerve terminals and sensory neurons, or recruitment of previously silent pain receptors or nociceptors.[8-9]

Neurophysiology of Peripheral Nerve Fibers

Peripheral nerve fibers, also known as primary afferent nerve fibers, are generally classified according to degree of myelination and conduction velocities. The A beta (Aβ) fibers are myelinated and have fast conduction velocities (35-120 m/sec). These fibers transmit mechanosensory information and have specialized terminals called Meissner's, Pacinian, Merkel's, and Ruffini's corpuscles located within skin.[10] Although this fiber type does not transmit painful information, current studies have now demonstrated their role in chronic pain states. Nerve fibers that transmit pain and thermal information are known as A delta and C fibers and are lightly myelinated and unmyelinated, respectively. The A delta (Aδ) fibers have relatively fast conduction velocities (5-30 m/sec) when compared to C fibers (0.5-2 m/sec). Both Aδ and C fibers terminate in skin, bone, muscle, and joints as free nerve endings.

Peripheral nerve fibers that innervate the head and neck arise from the ophthalmic (V1), maxillary (V2), and mandibular (V3) divisions of the trigeminal nerve (cranial nerve V [CN V]) as well as cutaneous inputs from cervical spinal nerves as far caudal as spinal C7.[4,11] The extensive rostrocaudal input of painful information from the head



• **Figure 44-2** Interaction between inflammatory mediators and receptors. Schematic diagram of a peripheral pain fiber expressing receptors and ion channels. Interaction between neurotransmitters and inflammatory mediators and their cognate receptor results in pain transduction and signaling. (From Mantyh PW, Clohisy DR, Koltzenburg M, et al: Molecular mechanisms of cancer pain, *Nature Rev Cancer* 2(3):201-209, 2002.)

and neck as well as significant convergence of input from other cranial and spinal nerves (e.g., CN X, CN XII, cervical spinal nerves) may in part explain the referral patterns in the chronic pain patient.[12]

Central Mechanisms of Pain

Centrally mediated pain is defined as pain initiated or caused by a primary lesion or dysfunction in the central nervous system. While it is rare in practice to see patients with primary CNS lesions, it is not uncommon for chronic facial pain patients to be first evaluated by an oral and maxillofacial surgeon. The primary mechanism for chronic pain lies in neuroplastic changes that occur within the central nervous system in response to chronic painful stimuli.[13] Much of the research in central pain mechanisms is related to other chronic pain conditions such as traumatic neuropathy and diabetic neuropathy in both animal and human models.[14] Certainly animal models of chronic facial pain exist that have increased our understanding of the pathophysiology of centrally mediated chronic facial pain.[4]

Central Sensitization

Central sensitization refers to the heightened reactivity of central nervous system neurons in the face of sustained peripheral neural input. While this may occur within the thalamus and cortex, research has been primarily focused on the dorsal horn of the spinal cord. Electrophysiologic and anatomic studies have demonstrated a change in the activity and responsiveness of dorsal horn neurons in response to persistent painful stimulation.

Persistent stimulation of unmyelinated C fibers results in the increased activity and responsiveness of spinal neurons that receive input from the stimulated unmyelinated C fiber. This increased responsiveness is of short (10 sec) duration and is known as *wind up*. Sensitization can also occur when persistent stimulation results in phenotypic changes in neurons that do not receive persistent painful stimulation, but are adjacent to neurons that do receive painful input. Typically these neurons receive input from Aβ fibers that normally do not transmit painful stimuli. However, once sensitized, these neurons are capable of transmitting both nonpainful and painful information. Central sensitization is mediated in part by glutamate, substance P, prostaglandins, and growth factors. These receptors/ion channels are known as *N*-methyl-D-aspartate (NMDA), neurokinin-1 (NK-1), EP, and tyrosine kinase B (trkB), respectively. Upregulation of transient receptor potential (TRPV1) and sodium channels has also been reported in central sensitization. Pain evoked from a stimulus that normally does not evoke pain (allodynia) may result from central sensitization.[4,13]

Descending Inhibitory Control

A protective mechanism exists in which adrenergic and serotoninergic fibers arising from the hypothalamus and periaqueductal gray matter descend and terminate in the medulla and superficial dorsal horn. This descending pathway controls or dampens painful sensory input from primary afferent fibers arising from the periphery. Chemical denervation of the inhibitory pathway results in an increased response to a stimulus that is normally painful (hyperalgesia). Inhibitory receptors have also been shown to be reduced in animal models of chronic pain. Thus disruption of inhibitory pathways that are normally tonically active may also result in chronic pain.[15]

The constant barrage of neurochemicals that are implicated in pain transmission results in changes in the activity and phenotype of nerve fibers and neurons within the

peripheral and central nervous system. These changes result in a chronic and debilitating condition that is recalcitrant to many conventional modes of acute pain therapy. The chronic pain patient has a "pain portrait" that is distinct from the acute pain patient and its management reflects this difference. However, not all chronic facial pain entities are alike. Diagnosis of the facial pain patient requires meticulous investigation and educated elimination of other pain entities.

Evaluation of the Facial Pain Patient

The chronic facial pain patient poses one of the most challenging cases to the oral and maxillofacial surgeon. One major reason is because pain is primarily subjective in nature. It is difficult to measure pain objectively because it cannot be seen nor is it palpable on clinical exam. The clinician is required to gather clinical and historical information, formulate a list of differential diagnoses, and systematically eliminate least likely entities until a final diagnosis is achieved. To formulate a list of differential diagnoses assumes that the most common and simplest forms of pain have been eliminated. A thorough assessment of the patient's history of present illness can be obtained by asking pointed questions that may identify the etiology or etiologies of the patient's facial pain. Questions regarding incidence, character, and duration as well as treatment modalities—particularly those that have already been employed to treat the pain—may also assist in the diagnosis of facial pain. The key to successful diagnosis of the chronic facial pain patient lies in comprehensive and accurate inquiry aimed to identify and answer key questions to develop a list of differential diagnoses.

Chief Complaint

The patient's chief complaint should always be documented in his/her own words with the use of parentheses. The severity of the patient's pain at time of examination must be documented. The two most frequently used methods to assess pain intensity are the visual analogue scale (VAS) and the numeric pain rating scale (NPRS). In the VAS the patient marks a line to indicate pain severity which will be measured in centimeters from 0 (no pain) to the patient marked rating on a horizontal or vertical 10-cm line.[16] The NPRS is different in that the patient verbalizes a number corresponding to the extent of his/her pain: 0 is no pain and 10 is the worst pain imaginable.

History of Present Illness

Pain onset and duration are important to determine whether the onset was acute in nature or developed gradually over time. This is a particularly challenging task with most facial pain patients. In general, there is an association made with an event, procedure, or circumstance that may not have a role in the generation of the symptoms. If the facial pain is acute, one must further question the events surrounding its onset. If the facial pain is chronic, one must further question acceleration and remission periods. A history of previous surgical and nonsurgical therapies to treat facial pain must also be elucidated to establish a diagnosis, assess prognosis, and define a surgical plan if indicated.

The location, quality, character, and radiation of pain should be assessed in the facial pain patient. Diffuse or localized pain will identify whether the pain is isolated to a single anatomic entity or whether multiple structures are involved. The patient must be asked to indicate, by one finger pointing to the area, where the pain is most severe. Descriptions of pain character such as "dull and throbbing" or "sharp and stabbing" will help to identify what dominant peripheral nerve fiber type is involved, which will assist in determining type of facial pain entity. Facial pain may radiate or be referred to adjacent muscular structures and the forehead, sometimes suggesting generalized myofascial pain disorder.

The pain impact on the patient's sleeping, function, and quality of life is very significant for numerous reasons. Sleep disturbance may imply an acute dental condition such as irreversible pulpitis or acute dentoalveolar abscess.[17] Sleep disturbance may result in generalized muscle pain, reduced pain thresholds, and reduced coping ability. Sleeping and daily function can influence treatment protocols and prognosis.[17]

The patient should be asked about analgesics used in attempts to alleviate facial pain and whether these analgesics are efficacious. The chronic use of opioids, spasmolytics, and antidepressants to manage facial pain is typically seen in patients with a preexisting diagnosis of chronic facial pain. Questions should be directed towards identifying therapies or medications that relieve pain. For example, if nonsteroidal anti-inflammatory drugs and heat packs relieve pain, the patient likely suffers from mild inflammation of the muscle and/or joint. Habits should also be assessed to determine if the etiology of facial pain arises from parafunctional habits such as repetitive jaw motion or extreme jaw forces from gum chewing or clenching, respectively.

Past Medical History Related to the Facial Pain Patient

The review of a patient's medical history is always important; however, it is clear that certain systemic conditions are commonly observed in the chronic facial pain patient. It is important to determine whether anxiety, depression, and/or other psychogenic disorders are present and appropriately managed. Clearly, facial pain patients with concomitant depression derive benefit from antidepressant medication. Fibromyalgia is another chronic pain entity that affects 4% of Americans. It is generally associated with diffuse generalized pain and fatigue and occurs in approximately 15% to 20% of facial pain patients.[12] Other systemic disorders that are commonly observed in the chronic facial pain patient include autoimmune diseases such as osteoarthritis, rheumatoid arthritis, and

migraine symptoms and headaches.[18] The concomitant comorbidities of systemic disease and chronic facial pain add to the complexity of the diagnosis and management of this challenging condition.

Clinical Examination

A thorough dental examination must be performed to rule out odontogenic sources of pain and avoid unnecessary dental treatments (Figure 44-3). In most clinical practice, the referring general dentist or clinician will have diagnosed the most common entities that cause pain: dental caries and infection. Facial pain may be referred from teeth and/or supportive structures and therefore pathology associated with such structures must be ruled out.

The most common and frequently seen pathology that results in facial pain includes the following:

- Tooth fractures
- Caries
- Temporomandibular disorders (TMDs)
- Salivary gland disease
- Ulcers
- Infection
- Neoplasms

Although the clinical examination and radiologic findings associated with these pathologies are beyond the scope of this chapter, it is important to exclude these entities to obtain the diagnosis of chronic facial pain. In addition, patients with no observable etiology of facial pain cannot be dismissed as hypochondriacs. Some insidious neoplasms, both benign and malignant, develop slowly. Pain may be the first sign that a neoplasm is present before progressing to a size that is detectable by either clinical evaluation or imaging.

The clinical examination of the chronic facial pain patient is very challenging because there is no visible entity that can easily be seen or felt. Instead, the clinical examination should focus on the following aspects to derive a list of differential diagnoses:

- Location
  - Identify etiology of pain by location (sensory nerve innervation).
  - Does the pain arise from dental, gingival, dentoalveolar or other structures?
  - Does the pain arise from stimulation of a specific sensory nerve distribution?
  - Is the pain limited to a specific sensory distribution?
  - Does the pain radiate to other structures within or beyond the head and neck?
  - Do the involved structures demonstrate abnormalities in color, temperature, turgor, or sensation?
- Duration
  - Identify whether the pain is intermittent or constant.
  - If evoked, identify the type of stimuli that causes the pain.
  - Is the pain sharp and stabbing when stimulated?
  - Is the pain reproducible and consistent?
  - Does the pain spontaneously resolve?
- Character
  - Identify the general pain sensation.
  - Is the pain sharp, dull, or lancinating?
  - Is the pain a burning sensation?
  - Are there any sensations other than pain that coexist (for example, tingling, numbness, formication)?
- Presence of sensory or motor deficits
  - Quantitative clinical neurosensory testing must be performed for all patients with documented sensory deficits.[19]

• **Figure 44-3** Panoramic radiograph of a facial pain patient who underwent multiple root canal therapies to treat her facial pain. Following referral to an appropriate facial pain specialist, the patient was properly diagnosed and medically managed. (Courtesy Donald Nixdorf, University of Minnesota.)

- Level A testing assesses spatiotemporal sensory discrimination using two methods: brush stroke directional testing and two-point discrimination. Both methods assess the discriminatory competency of myelinated Aβ fibers.
- Level B testing assesses static sensory discrimination using Semmes-Weinstein nylon monofilaments of graded thicknesses. Electronic versions are available.
- Level C testing assesses sharp-dull discrimination and pain thresholds. Specialized equipment such as calibrated thermodes or pain algometers is available although a sharp instrument (e.g., needle) may be used. This level of testing assesses the competency of unmyelinated C fibers and lightly myelinated Aδ fibers.
- Responses to interventions
- Are there any modalities, activities or action that reduces or eliminates the pain?
- Is the pain diminished, changed or resolved by pharmacologic agents, including over the counter interventions, opioids, or other analgesics?

Pain Descriptors

A sensory map should be developed based on the clinical neurosensory examination. In unilateral cases, both sides of the head and neck should be evaluated; the contralateral side may serve as an internal control. Based on the clinical findings and patient interview, the facial pain entity may now be described using conventional pain terminology (Table 44-1). Following the patient interview and clinical examination, the clinician is now able to describe the facial pain entity. Utilization of appropriate terminology will improve communication between health care professionals, assist in formulating a list of differential diagnoses, and assess the progress of both the pain condition and the treatment rendered.

Imaging Modalities

Appropriate imaging studies may be necessary to allow the clinician to derive a list of differential diagnoses and exclude certain conditions. Depending on the source, character, and complexity of pain, multiple imaging modalities may be considered. While it is appropriate to consider imaging studies, chronic facial pain is difficult to diagnose with imaging studies as there is a lack of definitive abnormalities that are characteristic or pathognomonic for facial pain.[20]

- Orthopantomogram: The orthopantomogram is the most common screening film used in the oral and maxillofacial surgery practice. It is both economical and practical in its use and provides minimum radiation exposure to the patient. Additionally, patients often have panoramic radiographs that predate the consultation visit or date of onset of pain that can be used as a reference or baseline image. While panoramic imaging may not establish the clinical diagnosis, it has its utility as a screening tool before requesting more advanced imaging.[21]

TABLE 44-1 Pain Definitions

Type of Pain	Definition
Allodynia	Pain evoked with stimulus that normally does not provoke pain
Analgesia	Absence of pain in response to stimulation that would normally be painful
Causalgia	A syndrome of sustained burning pain, allodynia, and hyperpathia after a traumatic nerve lesion, often combined with vasomotor and sudomotor dysfunction and later trophic changes
Dysesthesia	An unpleasant abnormal sensation, whether spontaneous or evoked
Hyperesthesia	Increased sensitivity to stimulation
Hypoesthesia	Diminished sensitivity to stimulation
Hyperalgesia	Increased pain from a stimulus that normally provokes pain
Hypoalgesia	Diminished pain in response to a normally painful stimulus
Hyperpathia	A painful syndrome characterized by an abnormally painful reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold
Neuralgia	Pain in distribution of nerve or nerves
Neuropathic pain	Pain caused by a lesion or disease of the somatosensory nervous system
Neuropathy	A disturbance of function or pathologic change in a nerve: in one nerve, mononeuropathy; in several nerves, mononeuropathy multiplex; if diffuse and bilateral, polyneuropathy
Paresthesia	An abnormal sensation, whether spontaneous or evoked

From Merskey H, Bogduk N, editors: IASP Task Force on Taxonomy. In *Classification of chronic pain,* ed 2, Seattle, 1994, IASP Press, pp 209-214.

- Computed tomographic (CT) imaging including cone beam CT scans (CBCT): Although CT imaging is not a standard modality for chronic pain, newer techniques that use CT technology are being used for facial pain patients. CT imaging is useful mostly to evaluate the bony elements of the TMJ. 3D CT and a stereolithography model fabrication are crucial in the processing of planning complex reconstructive surgeries.
- The role of single photon emission computed tomography with technetium 99m methylene diphosphonate (SPECT with 99mTc-MDP) and computed tomography (CT) to diagnose facial pain has been reported.[22] This technology uses radiolabeled technetium to identify areas of increased bone metabolism and uses diphosphonates, which display strong affinity to hydroxylapatite crystals within bone. Using SPECT technology, data are acquired in all three planes (axial, coronal, and sagittal planes) to allow for three-dimensional mapping. When used in conjunction with conventional CT data, functional anatomic mapping is obtained, which allows for 3D rendering. Advantages include (1) low radiation requirements (0.00675 Gy per 70-kg adult) and (2) high sensitivity. Disadvantages include (1) the need for specialized equipment and staff, (2) cost, and (3) poor specificity. SPECT in conjunction with CT is currently being used in oncology as a surveillance tool.
- Magnetic resonance imaging (MRI): Clinical evaluation of the TMJ can be nonspecific due to overlap of symptoms between internal derangement and myofascial pain and dysfunction. MRI should be part of the standard evaluation when an internal structural joint abnormality is suspected. The MRI imaging allows for a detailed evaluation of the anatomy as well as biomechanics of the joint through open and closed mouth imaging.[23] It is also used as a tool to eliminate any intracranial lesion that can mimic craniofacial pain symptoms.
- Functional magnetic resonance imaging (fMRI) is an indirect method used to assess neural activity within the central nervous system. It utilizes the BOLD effect, or changes in blood oxygenation, by quantifying the relative concentrations of oxyhemoglobin and deoxyhemoglobin. An increase in blood flow and, hence, neural activity results in a decrease in deoxyhemoglobin level. These changes are then mapped onto previously obtained anatomic maps of the patient's brain. Functional MRI has been used in studies of headache, acute dental pain, trigeminal neuropathy, and atypical facial pain to examine areas within the cortex that are involved in pain processing.[20,24] Both discriminative and affective components of pain have been mapped to the somatosensory cortex and anterior cingulate cortex, respectively, based on fMRI studies. While its utility in examining treatment success has been reported, its diagnostic capabilities remain limited because of a relative paucity of neuroimaging studies on trigeminal pain pathways.[24]

Differential Diagnosis

After establishing the character, duration, quantity, and quality of the facial pain entity, the clinician must eliminate more common facial pain causation or etiology. Then, augmenting information gleaned from the patient interview and exam with appropriate imaging modalities, the clinician is able to derive a list of differential diagnoses of chronic facial pain entities. While the differential diagnoses are only a partial listing of all chronic facial pain states, these are the most commonly encountered and the most challenging to diagnose.

Complex Regional Pain Syndrome (CRPS)

Complex regional pain syndrome (CRPS) is a pathology that has been described as occurring almost always in an appendage. However, there are patients in whom the face, head, and neck are affected. Very few patients were found to meet the International Association for the Study of Pain criteria for this disease. The clinical characteristics were similar to those of CRPS elsewhere in the body, with the main features being burning pain, hyperalgesia, and hyperesthesia starting after a trauma to the craniofacial region.[25] The diagnosis of CRPS is based almost exclusively on clinical examination. Two types of CRPS exist: type I or reflex sympathetic dystrophy (RSD) and type II or causalgia. Based on the 2005 consensus meeting of the International Association for the Study of Pain (IASP), the diagnosis of CRPS can be made if the following criteria are fulfilled:

- The presence of a noxious initiating event without nerve damage (type I: reflex sympathetic dystrophy) or with nerve damage (type II: causalgia)
- Spontaneous pain or hyperalgesia that is disproportionate to the inciting event and that extends beyond a single nerve territory
- Autonomic dysfunction: edema, cutaneous blood flow changes (increased or decreased), motor changes, and/or trophic changes
- All other diagnoses are excluded.

Nearly 75% of patients with CRPS type I or RSD will demonstrate pain that is described as aching, burning, or pricking in nature. Sometimes the pain can be "shooting" in character. All will describe some type of hyperalgesia to innocuous mechanical stimuli that may extend beyond the site of injury. This finding highlights the central sensitization that occurs in RSD. Muscle weakness or tremors may be observed in as high as 75% of RSD patients. Autonomic disturbances, such as edema and thermal cutaneous dysregulation, and trophic changes, such as disruptions in hair growth and skin atrophy, are seen in more severe cases of RSD.[14]

CRPS II or causalgia is distinguished from RSD if nerve damage is present. Similar to other neuropathic pain conditions, pain resulting from causalgia is described as electrical or shooting pain. Some patients may also exhibit areas of simultaneous hypoesthesia and extreme allodynia. Autonomic and motor disturbances similar to those seen in RSD are present.[26]

Management of CRPS should be aimed at reducing pain and enabling function. Pharmacologic treatment with tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), anticonvulsants, gabapentin, steroids, and opioids has been described.[27] In the head and neck region a treatment including a series of stellate ganglion anesthetic blocks was reported to have a good outcome.[25]

Neuralgia-Inducing Cavitational Osteonecrosis (NICO)

Since first described, the concept of NICO has been questioned by some clinicians.[28-30] NICO has been defined as a syndrome of chronic neuralgia-like facial pain associated with intraosseous cavity formation and long-standing cancellous bone necrosis of the jaws with minimal regenerative capabilities.[31] The pathophysiology of NICO is not clear. Multiple etiologies have been suggested including infection, bone marrow ischemia, coagulation related factors, and autoimmune concept based on antibodies to peripheral nerve myelin.[30,31] From an epidemiologic standpoint the prevalence of this condition is unknown. Patients with NICO complain of continuous or paroxysmal pain that is sharp, stabbing, burning, and lancinating in character. The location of pain is primarily at the site over the alveolar bone of a previously extracted tooth site. Symptoms have been reported to be unilateral or bilateral and involve both the maxillary and mandibular tooth-bearing areas. The symptoms may be referred to a larger area, often crossing midline structures.

Diagnosis requires a multifaceted approach that includes palpation, diagnostic anesthesia testing, radiographs, computed tomography scan, MRI (looking for chronic bone marrow ischemia), and Tc-99 scan. According to Bouquot, between 75% and 79% of patients with atypical facial neuralgia pain will demonstrated hot spots with technetium-99 scan.[28,30]

A definitive diagnosis of NICO is clinically difficult to establish and recommended treatment is moderately invasive. Treatment of NICO lesions has been primarily debridement of cavitary lesions with removal of cortical bone and exploration of medullary bone until "bone cavities" are identified. Long-term management includes either gauze-impregnated packing or injectable antibiotics for up to 9 weeks' duration. Approximately 70% of patients report decreases in pain after surgery; however, recurrence in pain symptoms is often seen. Management of NICO with warfarin and stanozolol has been reported; however, pain relief and side effect profiles limit their utility.

Persistent Idiopathic Facial Pain (Atypical Facial Pain)

Atypical facial pain (AFP) or persistent idiopathic facial pain (PIFP) is primarily a diagnosis of exclusion that is based primarily on history and clinical examination. Like many chronic facial pain entities, atypical facial pain cannot be diagnosed based on laboratory and/or radiologic findings as these are typically normal. AFP has an incidence of 1 in 100,000, affects mainly adults, and is equally distributed between men and women. The etiology of PIFP remains unknown. This syndrome consists of mostly unilateral long-lasting facial pain that lasts most of the day, and is described as a severe ache, burning, or crushing sensation. The level of the pain is mild to severe, and no autonomic abnormalities are noted.[32] According to the International Headache Society's 2004 classification, PIFP is "Persistent facial pain that does not have the characteristics of the cranial neuralgias and is not attributed to another disorder."[33]

There are four criteria to be met for the diagnosis:

1. There is pain in the face present for most of the day or all day and occurring daily.
2. Initially, the pain may be confined to a portion of the face, but is poorly localized and deep.
3. It is not associated with other physical signs or loss of sensation.
4. Workup in terms of imaging is unrevealing of an obvious anatomic or structural cause.

It may follow an operation or trauma to the face, teeth, or gums, but persists without a known local factor.

The treatment modalities can include pharmacologic treatment such as tricyclic antidepressants or anticonvulsant drugs. Topical anesthetic agents, Botulinum toxin A, and cannabis have been suggested as a treatment as well.

Atypical Odontalgia

Atypical odontalgia (AO) is one of the most challenging conditions an oral and maxillofacial surgeon will face. To fulfill the diagnostic criteria for atypical odontalgia, the following conditions must be met:

- Pain is located in the mouth or face.
- Pain is described as a constant, deep, and dull ache.
- Onset of pain is associated with a dental procedure (e.g., extraction, endodontic therapy) and develops within 1 month of the procedure and persists for more than 4 months.
- Sleep is undisturbed.
- The area of hyperalgesia associated with trauma is surrounded by an area of less hyperalgesia.
- Local anesthetic injections are equivocal.
- Radiographic and laboratory tests are negative.

Atypical odontalgia can occur in as many as 6% of patients who have undergone endodontic therapy and has a reported incidence rate of 25% within the chronic facial pain community.[34] It has a female predilection and occurs in the fourth decade of life. Psychogenic, neurovascular, and

neuropathic etiologies have been hypothesized. An association between atypical odontalgia and concomitant depression and/or personality disorder was shown in as many as 66% of sufferers. However, a deafferentation injury to trigeminal nerves appears to be the most accredited theory. Trauma to dentoalveolar structures has been hypothesized to result in both peripheral and central sensitization, resulting in allodynia and hyperalgesia commonly found in AO. Management of AO is primarily pharmacologic as dental intervention only worsens the condition.[35] The patient's psychogenic background should always be considered in the treatment and/or management of AO.[9]

Stomatodynia (Burning Mouth Syndrome)

Stomatodynia or burning mouth syndrome (BMS) is characterized by a burning mucosal pain with no evidence of mucosal pathology, often accompanied by dysgeusia and xerostomia. It commonly affects women more than men (7:1) in the age range of 38 to 78 years. The incidence of BMS worldwide ranges from 0.7% to 14.8% depending on diagnostic criteria used.

Inclusion criteria include the following:[16]

- Oral pain or dysesthesia of a burning quality
- Present daily and persisting most of the day
- Oral mucosa is of normal appearance
- Unremitting pain for at least 3 months
- Pain does not interfere with sleep

The pain associated with stomatodynia is described as a prolonged burning, tingling, and numbing pain, onset of which does not generally coincide with an inciting event. However, previous dental procedures have been implicated in some cases of stomatodynia. The pain never worsens from, but may be relieved by, eating or drinking. The duration of pain is typically greater than 3 months and may persist beyond 12 years. Spontaneous pain remission is rare. The pain is often accompanied by dysgeusia and/or xerostomia; more than half of stomatodynia patients complain of persistent taste alterations that are characterized as bitter and/or metallic. Xerostomia and salivary dysfunction are also a common finding in the stomatodynia patient.[13] BMS can be associated with mood changes or disruptions in personality traits.

The etiology of stomatodynia is poorly understood and remains elusive to many facial pain experts. It may be due to psychogenic, nutritional, and neuronal disturbances. The current neuronal disturbance etiology supports two main theories: a sensory neuropathy either peripheral and/or central or disturbance in the balance between the gustatory and sensory system. Systemic nutritional factors should be identified and corrected. Patients with stomatodynia and concomitant psychologic disturbances should be referred for appropriate management. Medical management of stomatodynia with systemic[36] and topical[11] capsaicin are described. Systemic and topical benzodiazepines (most frequently Clonazepam) were used with variable success.[37-41]

Medical management of stomatodynia with topical capsaicin, anticonvulsants, and tricyclic antidepressants has been proposed; however, these treatment options remain unsatisfactory. No definitive cure exists.

Nerve Injury From Dental Procedures

Chemical or traumatic nerve injury may occur following endodontic therapy, placement of endosseous implants, mandibular third molar extractions, and administration of local anesthetics. These types of nerve injuries may also occur in association with facial trauma and their subsequent treatment as well as during orthognathic surgery, particularly sagittal split ramus osteotomy. Nerve injury associated with trauma and orthognathic surgery is less likely to result in complaints of chronic facial pain compared to dentoalveolar procedures. Sensory disturbances may vary from partial anesthesia or paresthesia, to complete anesthesia, to dysesthesia with or without anesthesia. Multiple hypotheses regarding the pathophysiology of nerve injury exist and are dependent on the mode of injury.

- Direct surgical trauma/nerve manipulation (induced nerve injury): It is clear from review of the literature that the most likely common surgical procedure that results in temporary or permanent nerve injury is surgical removal of mandibular third molars. The incidence rates are as follows although some have opined that these rates of injury are a likely underestimation of true incidence: [42]
  - Inferior alveolar nerve (IAN) permanent injury: 4 per 1000 cases
  - Lingual nerve permanent injury: 1:1000 cases
  - 80% of IAN injuries have a known cause.
  - 57% of lingual nerve injuries have an unknown etiology.

Endosseous implant placement is a potential source of surgically induced nerve injury. Similar to third molar extraction, the inferior alveolar nerve canal and lingual nerve are adjacent to the surgical sites during mandibular implant osteotomy and placement. This proximity increases the likelihood of damaging the adjacent peripheral nerves. The prevalence of temporary sensory disturbances ranges from no damage to 43% while permanent damage may be as high as 13% of patients undergoing implant placement.[43,44] Prompt management is recommended if nerve damage is directly visualized.

When known, the likely etiology for both extraction-induced and implant placement–induced nerve injury is direct trauma to the neurovascular bundle (IAN) or nerve (lingual). The reader is directed to the dentoalveolar chapter for further information regarding surgical management of nerve injury.

- Endodontic therapy–induced nerve injury: The inferior alveolar nerve is more commonly damaged during endodontic therapy than the lingual nerve. Nerve injury is likely due to chemical injury from extrusion of root canal–filling materials beyond the apex of the root.[45,46] Materials such as paraformaldehyde-containing Sargenti

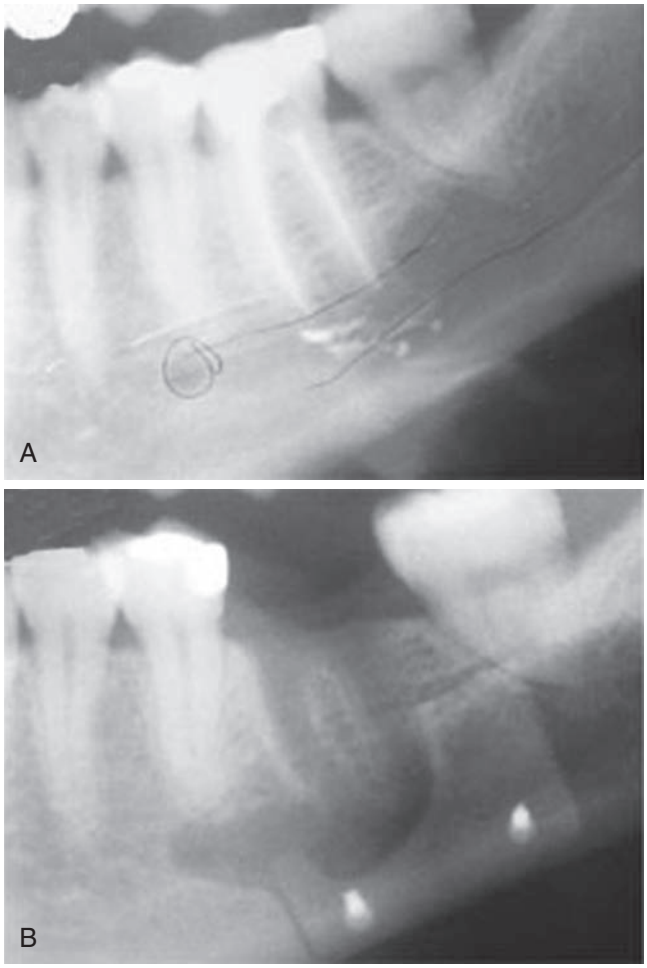
paste[47] (Figure 44-4) and inert gutta-percha[45] have been reported to cause painful dysesthesias following root canal treatment. Neurologic disturbances such as hyperesthesia and dysesthesias in the distribution of the IAN are commonly observed. Hyperesthesia is rarely seen. Surgical management in the form of careful debridement and decompression of the nerve with conservation of teeth has been reported.[46]

- Mandibular nerve block–induced nerve injury: Recent attention has focused on nerve injuries following administration of local anesthetics via the mandibular nerve block. The prevalence of temporary sensory deficits following block anesthesia ranges from 0.15% to 0.54% whereas permanent damage occurs with a much larger range: from as low as <0.01%[48] to as high as 3%.[49]

Many hypotheses exist regarding the etiology of nerve injury from mandibular block anesthesia. Direct fascicular damage to the nerve sheath has been proposed. This may be due to either direct needle penetration within the nerve or tearing of the epineurial sheath with a barbed needle. It has been well documented that the lingual nerve is more commonly injured during mandibular blocks. This may be due to the lingual nerve being ensheathed within the interpterygoid fascia, therefore being unable to deflect during needle contact. An electrical shock during initial needle placement has been reported in over 50% of patients with nerve injury[49] and further supports the direct injury theory.

Alternatively, the type and concentration of local anesthetic delivered have been examined.[5,48,50] In these studies, the most common local anesthetics associated with permanent sensory deficits were 4% articaine and 3% prilocaine with vasoconstrictors. Such high concentrations have been shown to cause microstructural damage to neural architecture in an experimental model; however, no gross structural abnormalities were observed clinically.[49] The volume of local anesthetic did not appear to influence onset or severity of nerve injury. Of the patients with sensory nerve deficits from mandibular block anesthesia, 85% to 94% will have symptoms that resolve spontaneously, and this occurs over an 8-week period. Of those who do not spontaneously resolve, more than two thirds will have permanent sensory impairment. Surgical intervention does not appear to resolve symptoms and may in fact worsen the clinical course.

It is difficult to determine or predict which patients with direct nerve injury will suffer from chronic pain. The patient who exhibits symptoms of paresthesia or anesthesia in conjunction with chronic facial pain symptoms may be a daunting diagnostic and treatment challenge. Treatment must be focused on goals of restoring sensation while at the same time controlling or eliminating pain. Many patients with facial pain will choose sensory deficit over facial pain if given a choice or ultimatum.



• **Figure 44-4** **A,** Panoramic radiographs of a patient who underwent endodontic therapy with Sargenti paste to tooth #19. Note the opaque material within the area of the inferior alveolar nerve canal. The patient complained of significant burning and shooting pain. She subsequently underwent multiple surgical procedures including lateral corticotomy, debridement, nerve decompression, and translocation, **B,** without resolution of her symptoms.

Facial Pain of Cardiac Origin

Case reports describing facial pain of cardiac origin have been documented[51-53] and may occur in as many as 18% of cardiac patients who complain of jaw and tooth pain.[53] This pain is primarily due to pain as a result of cardiac ischemia. The neurophysiologic basis for this occurrence is due to significant convergence of vagal nerve fibers arising from cardiac smooth muscle within the same spinal segments (medullary dorsal horn and cervical spinal cord) as trigeminal sensory neurons. Orofacial pain of cardiac origin most often will be described as burning and oppressive toothache that occurs spontaneously, usually in relation to exercise, and can be bilateral; the pain decreases with nitroglycerin tablets and is usually associated with chest pain, anterior neck pain, and/or shoulder pain, although it can also manifest as an isolated case. Toothache of cardiac origin may occur as a single clinical manifestation in the oral cavity, affecting adults as well as the elderly and children. There are also other craniofacial regions where this "heterotopic pain" (a pain in this region even though the source may be located elsewhere in the body) of cardiac origin can manifest in isolation as the paranasal sinuses, head, mandibular area, and

the temporomandibular joint region, though mainly it will be located in the mandible and throat. It can radiate to other craniofacial structures.[54] Clinicians should consider cardiac ischemia as a potential etiology of chronic constant or recurring facial pain without obvious dental or orofacial etiology. Prompt referral for cardiac evaluation is recommended.

Eagle's Syndrome

Eagle's syndrome is characterized by an elongated styloid process or calcified stylohyoid ligament and facial pain; this syndrome affects women more than men. The pain is variable and can be complex. Pain can be constant within the throat, ear, or temporal region or it can be elicited with changes in head position or palpation of the styloid process. Eagle divided his syndrome into two subgroups: classic type and carotid type. The most common symptoms of classic type are as follows: [55]

- Vague pain in neck
- Foreign body sensation
- Throat pain
- Pain on swallowing
- Pain on changing head position

In the carotid type, compression over the internal carotid artery can cause pain in the parietal region of the skull or in the superior periorbital region. Dizziness, transient visual loss, syncope, stroke, Horner's syndrome, headache during exercise and straining, and even sudden death have also all been described as a consequence of internal carotid artery compression.

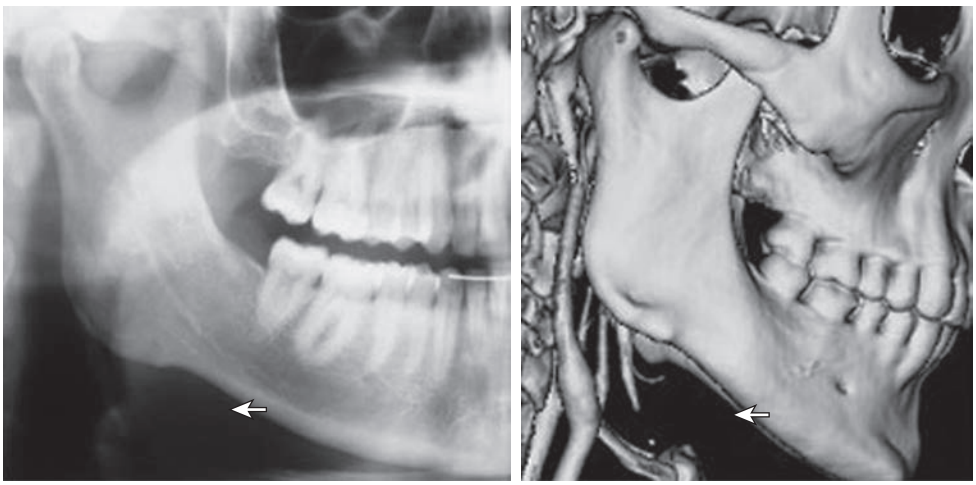
Eagle's syndrome is diagnosed based on the following criteria:

- Patient symptoms
- Palpation of the elongated styloid process overlying the tonsillar pillar
- Temporary relief of symptoms following administration of local anesthetic
- Radiographic evidence of an elongated styloid process or calcified stylohyoid ligament

The syndrome was seen most frequently in women in their fourth and fifth decades. Occasionally, Eagle's patients described prior styloid chain trauma (including tonsillectomy).[56]

The average length of the styloid process is approximately 20 to 30 mm and approximately 4% to 20% of the general population will demonstrate radiologic evidence of an elongated styloid process or mineralized stylohyoid ligament. Of those who present with an enlarged styloid process, less than 0.5% will report painful symptoms, suggesting a poor correlation between patient symptoms and radiologic findings.[57] Panoramic radiographs remain the most common radiologic modality to identify an elongated styloid process. However, lateral skull films, Towne's view radiographs, lateral oblique mandibular radiographs, and CT have all been utilized[58] (Figure 44-5). Because of the character of pain, it is important that the oral and maxillofacial surgeon rule out temporomandibular disorders because TMDs have been found in patients with Eagle's syndrome.[57]

The pathophysiology of Eagle's syndrome is likely caused by (1) impingement of the glossopharyngeal nerve, vagus nerve, or branches of the trigeminal nerve, (2) impingement of the carotid vessels, or (3) inflammation of the tendinous portion of the stylohyoid ligament. Management is by surgical excision of the elongated styloid process via a transoral or transcutaneous approach. Advantages of a transoral approach include that this approach has minimal scar formation, is safe, and is less time-consuming; also, a cutaneous scar is avoided. Disadvantages include poor visibility, risk for possible deep neck infection, and proximity to major vessels. The advantages of a transcutaneous approach include excellent visibility; however, risk for facial nerve injury and a neck scar are possible. While surgical excision remains the standard for managing patients with Eagle's syndrome, facial pain recurs in as many as 20% of



• **Figure 44-5** Reformatted 3D CT and panoramic radiograph of patient with Eagle's syndrome. Note the calcified stylohyoid ligament *(arrow).* Patient complained of vague neck and shoulder pain and dizziness with rotation of his head.

patients who have undergone surgery. Noninvasive management has been described to result in temporary relief of symptoms.

Facial Pain From Osteonecrosis

Radiation exceeding 6000 cGy and chronic intravenous antiresorptive therapy including bisphosphonates have been associated with the development of osteonecrosis of the maxilla and mandible. While the pathophysiology and surgical management of these entities can be found in other chapters within this text, it is important to understand the management of the chronic pain associated with these conditions. Radiation therapy and surgery is the most common treatment regimen used to treat oral cancers. However, it has a clear impact on the cancer survivor's quality of life from a functional, esthetic, and pain perspective. Patients may undergo dental and surgical reconstruction to reestablish masticatory, speech, and facial harmony; however, chronic pain may remain poorly treated.[59] Current pharmacologic strategies using nonsteroidal anti-inflammatory drugs (NSAIDs) and opioid analgesics have only little to moderate benefit. Physical therapy is suggested to be a useful adjunct to manage chronic pain as some patients have shown modest improvement.[59]

Medication-Related Osteonecrosis of the Jaw

Medication-related osteonecrosis of the jaw (MRONJ) is a relatively newly diagnosed clinical entity that has had the medical and dental community concerned.[60,61] MRONJ refers to osteonecrosis cases associated with either bisphosphonates or other antiresorptive and antiangiogenic therapies. It is clear that these therapies improve survival and quality of life in this patient population. However, because of the prolonged life span and, subsequently, prolonged duration of treatment, clinicians must also consider how to manage the sequelae of the chemotherapeutic agent. Diagnostic criteria were established for MRONJ, and patients are considered to have MRONJ if all of the following characteristics are present:[62]

- Current or previous treatment with antiresorptive or antiangiogenic agents
- Exposed bone or bone that can be probed through an intraoral or extraoral fistula in the maxillofacial region that has persisted for longer than 8 weeks
- No history of radiation therapy to the jaws or obvious metastatic disease to the jaws

Similar to other chronic pain conditions, the management of pain associated with MRONJ revolves around the use of NSAIDs and opioid analgesics. Depending on the presence of peripheral neuropathy, adjuvant medication can be considered. While the use of hyperbaric treatment to manage MRONJ remains under scrutiny, several reports have demonstrated its analgesic efficacy and it should be considered.[63-66]

Barriers to the Management of the Chronic Facial Pain Patient

The management of the chronic pain patient has been under scrutiny in recent years resulting in the development of chronic opioid therapy guidelines by the Centers for Disease Control in 2016. The guideline is intended to ensure that clinicians consider the safest and most effective drug therapies, while minimizing the development of adverse effects and/or side effects related to chronic opioid therapy.[67]

Multiple barriers exist between oral and maxillofacial surgeons and the adequate management of the chronic pain patient. Certainly concerns over addiction, tolerance, and side effect profiles of medication all play an important role in pain management strategies. Addiction is defined as a primary chronic disease with psychosocial and environmental factors that influence its development. Addictive behaviors include inability to control drug use, inability to discontinue use despite harmful sequelae, compulsive use of the drug, and craving of the drug. This is not to be mistaken for dependence, an adaptive state whereby discontinuation of drug results in specific withdrawal symptoms related to specific drug cessation or disruption. Finally, tolerance is an expected outcome during chronic drug therapy whereby chronic exposure to drug results in diminished drug effects, potentially necessitating increasing dosages for adequate pain relief. This may also relate to the side effect profile.[68]

In the management of the chronic pain patient, one must expect that dependence and tolerance will occur because of the chronicity of the pain disorder. It should be noted that in most cases, increasing analgesic requirements reflect more about the progression of disease rather than development of tolerance. Tolerance to the respiratory and CNS depressant effects and nausea from chronic opioid use has been observed. However, tolerance to other side effects such as constipation does not occur. Certainly, side effect profiles should not prevent surgeons from adequately treating pain. Such side effects should and can be managed with appropriate pharmacotherapy including antiemetics, promotility agents, and stool softeners.

It is critically important that surgeons discuss the postoperative pain management strategy with the chronic pain patient before surgery. This not only provides the patient with some satisfaction that his/her pain needs have been thoroughly considered, but also provides the platform for establishing an opioid contract.[69] For chronic pain patients who are managed by their primary care physician (PCP), a trilateral opioid contract may be made involving the patient, surgeon, and PCP.[70] The opioid contract should include the following:

- Address issues related to improper use of opioid (including overdosing, seeking medicines elsewhere, selling medicine, or abruptly stopping medicine)
- Terms for disciplinary action (including abuse, missing appointments, violating contract, inappropriate behavior)
- Establish limitations for replacing medications or changing prescriptions

- Inform surgeon of relevant information (e.g., side effects, changes in medical history)

Pain Management Considerations in the Substance Abuser

The substance abuser requires special consideration from a controlled substance pain management standpoint. Opioid and illicit drug abuse is seen in as high as one third of chronic pain patients receiving treatment for chronic pain.[68] The most common illicit drugs abused are marijuana, cocaine, and methamphetamines, occurring in 11%, 5%, and 2% of chronic pain patients, respectively. Approximately 50% of patients who are current illicit drug abusers have had a history of illicit drug abuse and 16% of them also abuse opioids. A history of illicit drug abuse, however, is not correlated with opioid abuse. The concern for substance abuse is a major barrier in the management of the chronic pain patient; however, it should not deter the surgeon from appropriately managing the pain.

Diversion of controlled substances can occur through illegal Internet pharmacies, drug theft, prescription medication forgeries, or through doctor shopping. Doctor shopping remains the most common way physicians believe their patients obtain controlled substances. The following key measures can be taken to help prevent diversion and abuse of controlled substances:

- Ensure that a single physician/surgeon/pain specialist manages all controlled substances.
- Establish an opioid contract.
- Obtain a thorough history including medication use and illicit drug use. Include type, duration, and chronicity of use.
- Obtain medication prescription history before long-term pain management. Discussions with previous physicians and pharmacists should be considered.

Treatment Modalities for Chronic Facial Pain

Currently 70 million Americans suffer from chronic pain and chronic pain results in $100 billion in lost productivity annually. The importance of pain assessment and management is highlighted in The Joint Commission's (TJC) statement mandating that pain be the "fifth" vital sign. Many states now require health care providers to provide appropriate pain management and have even reprimanded health care providers who fail to treat pain.[71] In the new era of chronic pain management, emphasis is placed on graded polypharmacy and utilization of nonpharmaceuticals to augment treatment strategies.

Physical Therapy

The benefits of physical therapy as an integral part of the multidisciplinary management of the facial pain patient are clear. Physical therapy modalities include cautious isometric and repetitive muscle stretching and relaxation exercises, joint mobilization, iontophoresis of specific muscle groups with corticosteroids, continuous or pulsed ultrasound, hot and cold therapy including vapocoolant spray to release taut bands, and transcutaneous electrical neural stimulation (TENS). The main goals for physical therapy include decreasing or eliminating pain, increasing range of motion in patients whose myofascial pain limits mandibular opening, and returning masticatory function. Benefits include cost-effectiveness, reversibility, and noninvasiveness. Indeed, the success of physical therapy relies on the compliance of the patient. Thus patient education becomes critically important. Patients must understand that physical therapy is reversible and therefore they will require both short-term professional therapy and long-term home therapy.[72,73]

Opioid Therapy

For acute breakthrough pain, opioid analgesics may be used. Opioids remain the gold standard drug for the management of moderate to severe pain. They exert their analgesic effects by interacting primarily with mu (μ) receptors, but there are also kappa (κ) opioid receptors located in spinal sites. Expression of μ receptors in peripheral nerve fibers suggests peripheral actions of opioids as well.[74] Side effects of opioid analgesics are related to dosing and patient sensitivity and include nausea and vomiting, sedation, respiratory depression, constipation, and physical dependence. Unfortunately, the concern for abuse and physical dependence has unnecessarily limited clinicians in their willingness to prescribe opioids. Opioids commonly used for acute pain management include codeine, hydrocodone, and oxycodone.

For the chronic pain patient, it is clear that management strategies must be altered compared to managing acute pain. First, a stepwise approach must be initiated where scheduled (or "round the clock") medications are given for the constant pain while rescue medications are given for breakthrough pain. Dose escalation can then be performed by the practitioner until pain is appropriately controlled (Table 44-2). Long-acting opioids should always be used instead of short-acting opioids for round the clock dosing. Morphine sulfate is the most common orally available opioid used for the management of chronic pain.

Fentanyl is an opioid derivative that is 80 times more potent than morphine. It is available in injectable, transdermal, and transmucosal forms, the latter two being more commonly used for chronic pain management.[75] Fentanyl should NOT be used in opioid-naïve patients. Opioid-tolerant individuals are defined as those who require at least (1) 60 mg of oral morphine daily, (2) 30 mg of oral oxycodone daily, or (3) 8 mg of oral hydromorphone daily (Duragesic prescribing information pack, Janssen Pharmaceutica Products, Titusville, NJ). Calculations for transdermal fentanyl (Duragesic) dose conversion are based on the following:

1. Calculate the previous 24-hour analgesic requirements (mg/day).

TABLE 44-2 Management of Chronic Pain With Orally Available Morphine Sulfate

Steps	Morphine Sulfate Immediate Release: Scheduled	Morphine Sulfate Immediate Release: Rescue	Morphine Sulfate Controlled Release: Scheduled	Morphine Sulfate Controlled Release: Rescue
I	10 mg q4h	5 mg q1h	30 mg q4h	7.5 mg q1h
II	15 mg q4h	7.5 mg q1h	60 mg q4h	15 mg q1h
III	30 mg q4h	15 mg q1h	90 mg q4h	15 mg q1h
IV	45 mg q4h	22.5 mg q1h	100 mg q4h	30 mg q1h

Adapted from Lee KF, Ray JB, Dunn GP: Chronic pain management and the surgeon: barriers and opportunities, *J Am Coll Surg* 193(6):689-701, 2001.

TABLE 44-3 Conversion Table for Common Oral Opioids to Transdermal Fentanyl Patch

Current Analgesic	Daily Dosage (mg/d)			
Oral morphine	60-134	135-224	225-314	315-404
IM/IV morphine	10-22	23-37	38-52	53-67
Oral oxycodone	30-67	67.5-112	112.5-157	157.5-202
Oral codeine	150-447	448-747	748-1047	1048-1347
Oral hydromorphone	8-17	17.1-28	28.1-39	39.1-51
IV hydromorphone	1.5-3.4	3.5-5.6	5.7-7.9	8-10
IM meperidine	75-165	166-278	279-390	391-503
Oral methadone	20-44	45-74	75-104	105-134
	⇓	⇓	⇓	⇓
Recommend DURAGESIC dose	25 mcg/h	50 mcg/h	75 mcg/h	100 mcg/h

Table 44-3 should not be used to convert from DURAGESIC to other therapies because this conversion to DURAGESIC is conservative. Use of Table 44-3 for conversion to other analgesic therapies can overestimate the dose of the new agent. Overdosage of the new analgesic agent is possible. DURAGESIC (fentanyl transdermal system), CII Prescribing Information. Janssen Pharmaceuticals, Inc. April, 2014.

2. Convert amount to equianalgesic oral morphine dose (mg/day).
3. Use manufacturer-recommended conversion table (Table 44-3).

The transdermal fentanyl patch has an elimination half-life of 20 to 27 hours and therefore may take as many as 6 days to achieve steady-state concentrations. During the first 16 hours of transdermal therapy, analgesics must be prescribed for chronic breakthrough pain and to prevent withdrawals. The transdermal patch is replaced every 72 hours and should never be cut as this will result in a rapid release and absorption of a potentially fatal dose of fentanyl. Fentanyl patches are commercially available in 12, 25, 50, 75, and 100 mcg/hr systems. These patches are not indicated for the management of acute pain associated with surgical procedures.

Gaining a clear appreciation of the extent of the patient's pain and an understanding of pain management including "round the clock" and "breakthrough" rescue dosing with opioids, using adjunctive pharmacologic and behavioral therapies, and, most importantly, ensuring management of all medications by a single clinician will ensure the most appropriate treatment for the chronic pain patient.[68-70]

Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are generally used to treat the inflammatory component of facial pain. NSAIDs exert their actions by inhibiting prostaglandin biosynthesis in the arachidonic acid cascade. There are two main types of NSAIDs, nonselective and selective. The terms nonselective and selective refer to different NSAIDs' ability to inhibit specific types of cyclooxygenase (COX) enzymes. Nonselective NSAIDs inhibit both COX-1 and COX-2 enzymes. Examples of nonselective NSAIDs commonly used are ibuprofen (Advil, Motrin, Nuprin), and naproxen (Aleve). Selective NSAIDs inhibit COX-2. The

TABLE 44-4 Pharmacotherapy for the Management of Acute and Chronic Facial Pain

Drug (Proprietary Name)	Initial Dose (Maximum Daily Dose)	Maintenance Dose Range (Maximum Daily Dose)
NSAID and Opioid Analgesics for Acute Pain		
Ibuprofen (Advil, Motrin)	200-400 mg q6-8h	400-800 mg q6-8h (2400 mg)
Naproxen (Naprosyn, Aleve)	250-375 mg bid	500 mg bid
Celecoxib (Celebrex)	100 mg bid or 200 mg once a day	up to 400 mg daily
Hydrocodone/acetaminophen 5/500 mg (Vicodin)	1-2 tablets q4-6h prn breakthrough pain (4 g acetaminophen)	Not to be used as maintenance drug
Oxycodone/acetaminophen 5/325 mg (Percocet)	1-2 tablets q4-6h prn breakthrough pain	Not to be used as maintenance drug
Antidepressants		
Amitriptyline (Elavil)	10-25 mg nightly	75-100 mg nightly
Venlafaxine (Effexor XR)	37.5 mg /day	75-225 mg/day
Duloxetine	20-40 mg/day	60-120 mg/day
Anticonvulsants		
Gabapentin (Neurontin)	100-300 mg nightly or tid	1200-2400 mg per day
Pregabalin (Lyrica)	50 mg tid or 75 mg bid	50-100 mg tid or 75-150 mg bid up to 300mg/day
Muscle Relaxants		
Clonazepam (Klonopin)	0.25 mg nightly or bid	0.5-1.0 mg qid max
Cyclobenzaprine (Flexeril)	10 mg nightly or tid	10-20 mg nightly or tid max
Diazepam (Valium)	5 mg nightly	5 mg tid max
Tizanidine (Zanaflex)	2-4 mg nightly to qid	36 mg/day max
Corticosteroids		
Betamethasone (Celestone)	6 mg IM	9 mg/day max
Methylprednisolone (Depo-Medrol)	10-80 mg IM	Dose interval 1-5 weeks
Dexamethasone (Decadron)	4-16 mg IM	Dose interval 1-3 weeks
Topical Medication		
Capsaicin cream (Zostrix)	0.075% qid topical	Dose interval up to 8 weeks

role of COX-2 in peripheral inflammation and in development of central hyperalgesia had been demonstrated,[76] and these NSAIDs are less likely to cause gastrointestinal injury. Celecoxib (Celebrex) is a selective NSAID that is available in the United States. Other selective NSAIDs that can be found elsewhere in the world include etoricoxib (Arcoxia) and lumiracoxib (Prexige). Selective COX-2 inhibitors were initially promoted for chronic use in patients with osteoarthritis, rheumatoid arthritis, dysmenorrhea, and dental pain. However, an increased risk for significant adverse effects on cardiovascular and renal systems was noted when compared to NSAIDs and controls.[77] Because of these recent findings, Merck withdrew rofecoxib (Vioxx) from the market in September 2004 and Pfizer has placed a "black box warning" on celecoxib (Celebrex) and suspended sales of valdecoxib (Bextra) in both the United States and European Union as of April 2006.

Chronic use of NSAIDs is discouraged because of the risk for developing upper gastrointestinal complications, major vascular events, renal toxicity and/or failure, and abdominal pain and cramping. Therefore, for chronic use, if necessary, close monitoring is recommended. Suggested dosing regimens are listed in Table 44-4.

Antidepressants

Tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) have been shown to be useful in many chronic pain states including fibromyalgia and those related to clinical depression. It is particularly useful in myofascial pain patients with sleep disturbances and in those with a neuropathic pain component. Although the mechanism of action of TCAs is poorly understood, it is believed to be the inhibition of reuptake of norepinephrine,

dopamine, and serotonin. In contrast, the SSRIs selectively block the reuptake of serotonin only. The analgesic efficacy of TCAs and SSRIs in facial pain appears to be independent of its antidepressant properties and is supported by reduced dose requirements to alleviate facial pain.[78] TCAs provide effective pain relief for a period of 2 to 8 weeks whereas SSRIs provide effective pain relief for a period of 3 to 6 months.[79] If used clinically as an antidepressant, clinicians trained in the diagnosis and treatment of depression should be responsible for its prescription. Adverse effects include sedation, xerostomia, constipation, dizziness, and confusion.

Venlafaxine was initially developed as an antidepressant, although it is now used as a neuropathic agent. It is considered a bicyclic antidepressant as it prevents the reuptake of serotonin, dopamine, and norepinephrine. Although used primarily to treat anxiety and depression, it has been used off-label to treat migraines and diabetic neuropathy. It is only modestly efficacious in the treatment of facial pain.[80] Side effects include headache, nausea, sedation, xerostomia, dizziness, insomnia, and sexual dysfunction.

Anticonvulsant drugs, including gabapentin (Neurontin), pregabalin (Lyrica), topiramax (Topamax), and carbamazepine (Tegretol), are often tried in chronic neuropathic pain and are thought to be indicated especially when the pain is lancinating or burning. Their molecular mechanisms are varied, but typically involve action at the level of cell membrane ion channels. They have narrow therapeutic indices and are therefore best applied by knowledgeable practitioners.[32]

Anticonvulsant Agents

Gabapentin (Neurontin) and pregabalin (Lyrica) have been used as adjuvants to manage both neuropathic and myofascial pain disorders. The exact mechanism of action of gabapentin is unknown. The molecular structure of gabapentin resembles the inhibitory neurotransmitter gamma-aminobutyric acid (gaba), although it does not bind to the gaba receptor; rather, it is believed that gabapentin interacts with the $\alpha_2\delta$ subunit of the voltage-gated calcium channel[81] within the central nervous system to disrupt calcium ion conduction, resulting in inhibition. Gabapentin is not considered a controlled substance and has little to no abuse potential. The $\alpha_2\delta$ calcium-channel antagonists provide effective neuropathic pain relief for assessment periods ranging from 5 to 12 weeks and are recommended for patients with neuropathic pain. Common side effects include dizziness, sedation, ataxia, and peripheral edema.[79]

Muscle Relaxants

Muscle relaxants are used to reduce muscle hyperactivity and tone and are commonly prescribed to manage TMDs. Their mode of action is primarily disruption of spinal reflexes within the brainstem and spinal cord to inhibit firing of motor neurons. Some relaxants such as cyclobenzaprine have been found to be particularly efficacious when prescribed with an NSAID and physical therapy.[82] In contrast, diazepam is efficacious when used alone.[83] Although no randomized controlled studies have been performed, tizanidine (Zanaflex), an α_2-adrenergic agonist, appears to be effective in treating muscle spasms. Because of their activity within the central nervous system, muscle relaxants have CNS side effects including sedation, somnolence, and cognitive dysfunction. Chronic use should be avoided.

Therapeutic Injections

Injections of aqueous solutions of local anesthetics, corticosteroids, and/or physiologic normal saline into target muscle groups have been performed with some success. The basis for local injections is to disrupt the afferent and efferent neural pathways within the contracted muscles to allow for muscle elongation. Combination local anesthetic with corticosteroid injections can be used; however, combination injection is not clinically superior to local anesthetic or steroid injection alone.[84] Injection of normal saline (0.9%) appears to be as efficacious as local anesthetics in reducing myofascial pain.[85]

Local anesthetics commonly used are 0.5% to 2% lidocaine without vasoconstrictor or 0.25% to 0.5% bupivacaine without vasoconstrictor. Local anesthetics exert their actions via blockade of sodium conductance through sodium channels located on peripheral nerve fibers. Disruption of sodium conductance results in blockade of action potentials and thus sensory and motor activity. Side effects include CNS depression, seizures, tinnitus, and dysrhythmias and are related to exceeding maximum single daily dose. In addition, risks associated with injection technique have been discussed, including soft tissue infection, necrosis, and, less commonly, accidental intrathecal injection resulting in respiratory depression and hemiplegia requiring endotracheal intubation.[86] Careful aspiration before injection is recommended. Local anesthetic injections may also be used as a diagnostic tool to rule out neuropathic central pain syndromes including trigeminal and glossopharyngeal neuralgias.

Implantable pump systems such as the On-Q Pain Management System, the Pain Buster Pain Management System, the Don Joy Pain Pump, and the Stryker Pain Pumps are commercially available that allow for controlled amounts of local anesthetics to be administered in a specific anatomic area for postoperative pain management. Medication is delivered directly to the surgical wound site or in close proximity to the nerves associated with the surgical area. These systems are used for the management of acute postoperative pain and remain implanted for 3 to 7 days depending on the system used. Although a paucity of data exist in the oral and maxillofacial surgery literature, such systems have been found to be efficacious in the plastic and reconstructive, gastrointestinal, and orthopedic literature. Common side effects include wound infection, toxicity of drug, and accidental premature removal.

Corticosteroid injections either alone or in combination with local anesthetics have been advocated. Steroids exert their analgesic effect by inhibition of phospholipase A_2 production within the arachidonic acid cascade. This blocks the formation of the proinflammatory mediators prostaglandin and leukotriene within damaged or traumatized tissues. Commonly used corticosteroids include methylprednisolone (Depo-Medrol), dexamethasone (Decadron), and betamethasone (Celestone), and each differs based on solubility. Betamethasone is the most soluble injectable corticosteroid and therefore has the least risk for development of muscle wasting, fat atrophy, hypopigmentation, and tendon rupture. The more insoluble methylprednisolone has greater duration of action than either dexamethasone or betamethasone. Adverse reactions include facial flushing, insomnia, dizziness, and nervousness. Use steroids with caution in patients with poorly controlled diabetes, active infections, ulcerative colitis, severe gastroesophageal reflux disease, renal disease, and congestive heart failure. Chronic steroid injections are not recommended because of related systemic side effects. Repeat dosing intervals of 1 to 5 weeks are generally recommended to decrease risk of side effects.

Botulinum Toxin Injections

Botulinum toxin is produced by the bacterium *Clostridium botulinum,* and eight distinct types exist (types A, B, C1, C2, D, E, F, and G). Two types—botulinum toxin A (BTA, Botox, and Botox Cosmetic, Allergan Inc., Irvine, CA) and botulinum toxin B (BTB, Myobloc, Elan Pharmaceuticals Inc., New York, NY)—are commercially available in the United States. Primary indications for BTA are treatment of blepharospasms, strabismus, tension headaches, hyperhidrosis, spasmodic dysphonia, oromandibular dystonia, torticollis, cosmetic treatment of facial rhytides, myofascial pain that is resistant to physical therapy and oral pharmacotherapy, and muscle spasticity related to cerebral palsy, cerebrovascular accidents, and multiple sclerosis.[87] The mechanism of action is disruption of acetylcholine release from the neuromuscular junction. This prevents the repetitive and consecutive muscular contraction and development of local tissue ischemia.

Botox is supplied in 100 mouse unit vials and must be reconstituted with unpreserved saline before use. One unit is equal to the amount that would be lethal in 50% of mice. The human lethal dose for Botox is 3,000 units or 40 to 50 units/kg. Flaccid paralysis occurs after 3 days and lasts for 3 to 5 months. Typically, 1 mL of unpreserved saline is carefully injected into the vial and gently mixed so as not to incorporate bubbles. A 1-mL tuberculin syringe with a 30-gauge 1-inch needle is then used to draw up the solution with a final concentration of 10 units per 0.1 mL. Other authors have advocated using 6 mL of unpreserved saline and placing the solution into six 1-mL tuberculin syringes with a final concentration of 1.7 units/0.1 mL.[88] The manufacturer recommends using Botox within 4 hours of reconstitution although it may be stored refrigerated for up to 1 week. A dose of 10 mouse units per muscle group is recommended but may be higher in larger muscle compartments.[89] The maximum dose in a single muscle is 25 units with a maximum 30-day cumulative dose of 200 units.

The most common side effects associated with Botox injection are postinjection ecchymosis, bruising, and unwanted temporary paralysis of the facial muscles of expression. If possible, patients should refrain from platelet inhibitors such as aspirin and NSAIDs 7 to 14 days before injections. Contraindications for Botox injections include pregnancy (category C) and breastfeeding, prior allergic reaction, and injections into sites of infection or inflammation. Use with caution in patients with neuromuscular diseases such as myasthenia gravis, amyotrophic lateral sclerosis, and Lambert-Eaton syndrome. Approximately 6% of patients will develop neutralizing antibodies against botox A and become nonresponsive to treatment. In this population, botox B (Myobloc) may be used.[90] Myobloc is supplied in 2500-unit to 10,000-unit vials and is not equivalent to Botox. One unit of Botox is equivalent to 50 units of Myobloc. Injection doses exceeding 4500 units of Myobloc have been associated with an increased incidence of side effects including ptosis, burning on injection, visual disturbances, xerostomia, xerophthalmia, headache, and facial muscle weakness. Paralysis lasts for 7 weeks and increases to 8 weeks with higher doses.

Botulinum toxin may be used to treat myofascial pain and for neuropathic pain with presumed local pain generation as third-line therapy mainly because of insufficient evidence of therapeutic benefit.[79]

Topical Capsaicin

Topical capsaicin is used for a variety of chronic pain conditions including causalgia, herpetic neuralgia, diabetic neuropathy, osteoarthritis, and rheumatoid arthritis.[91] The compound capsaicin, alkylamine with the chemical formula C18H27NO3 found in various chili peppers, has long been known to produce a hot, burning, stinging sensation, whether on ingestion of spicy food or when applied to the skin. As somewhat of a paradox, capsaicin has also been known to provide superficial pain relief despite, again, an initial unpleasant sensation. Although this has been known for a century, the molecular target and mechanism for capsaicin's effects have only relatively recently been investigated and brought to light. Modern scientific technique has allowed for a more complete characterization of not only capsaicin and its action but also of its target—the TRPV1 receptor—itself and the class of receptors to which it belongs.[92]

High-concentration topical capsaicin (8%) can be used to treat postherpetic neuralgia and HIV neuropathy.[93] Topical capsaicin has been available for some time in a low dose (i.e., less than 1%). Many studies have been published in an attempt to evaluate its efficacy and safety. Again, it is important to note that "low-dose capsaicin" here actually refers to two different concentrations: 0.025% and 0.075%.

According to meta-analysis of randomized controlled trials to determine the efficacy of topical (0.075%) capsaicin in the treatment of chronic pain from neuropathic and musculoskeletal disorders, it is efficacious in at least 50% pain reduction in 60% of patients with painful neuropathies when used for an 8-week period and in 57% of patients when used for a 4-week period; of note, the placebo effect was estimated as 42% in both groups. In musculoskeletal conditions the efficacy was slightly lower but the capsaicin concentration was lower as well. With manipulation of those data for neuropathic conditions, in patients using topical capsaicin 0.075%, for approximately every six patients, one would achieve at least a 50% reduction in pain in patients who would not have experienced pain reduction if given placebo.[94]

Winocur et al. in a double-blind 4-week study on 30 TMD patients found that capsaicin cream (0.025%) produced no statistically significant influence on measured variables when compared to placebo.[95]

The Cochrane review by Derry et al.[93] based on the existing data available, concluded that there are insufficient data to draw any conclusions about the efficacy of low-concentration capsaicin cream in the treatment of neuropathic pain. The data do suggest that low-concentration topical capsaicin is without meaningful effect beyond that found in placebo creams. Local skin irritation, which was often mild and transient but may lead to withdrawal, was common. Systemic adverse effects were rare.

Thus, although the majority of available data do seem to suggest that low-dose capsaicin for neuropathic or musculoskeletal pain is not an effective treatment option, there are some data to suggest that in some patients low-dose capsaicin may be a reasonable therapeutic option when others have failed to provide sufficiently complete pain relief and quality of life improvement.

Surgical Intervention

Chemical denervation with potent preservatives such as alcohol or glycerol has been reported as a treatment regimen for chronic facial pain, especially trigeminal neuralgia. Performed as a transcutaneous gasserian block, each compound is delivered via a spinal needle at a volume of 0.2 to 0.5 mL. Although many patients report symptomatic relief hours after injection, recurrence may occur within 1 year following injection. Injections are performed in an operating room or clinical setting (depending on surgeon experience) with immediate video fluoroscopy for confirmation of needle placement. Side effects include permanent or temporary cutaneous hyperesthesia, dysesthesia or anesthesia, anesthesia dolorosa, cutaneous necrosis, risk for corneal abrasion (for permanent V1 anesthesia), pain recurrence, and failure to achieve relief.[7,96]

Surgery may be considered in the facial pain patient who remains refractory to conventional nonsurgical modalities and is often viewed as the "last resort." Surgical techniques such as nerve transection, microvascular decompression, thermorhizotomy, and stereotactic gamma knife radiosurgery have all been described in the literature for treating chronic facial pain.[97] The latter three surgical techniques are commonly used for managing trigeminal neuralgia and are beyond the scope of this chapter. However, nerve transection may be performed for intractable pain developing from branches arising from the trigeminal nerve. While success rates are minimal, many chronic facial pain patients are willing to give up somatic sensation if pain is even slightly diminished. As to be expected, complete anesthesia in the distribution of the transected nerve is expected with no recovery of sensation. Diagnostic tests in the form of local anesthetic blockade are necessary before proceeding with surgical denervation to ensure that central sensitization has not occurred. Surgical or chemical denervation will not successfully resolve chronic pain disorders that have a central pain component.

Clinically Based Comprehensive Pain Management Programs

Many clinical specialties play a role in the diagnosis and management of facial pain. For more complex cases, a team approach is usually considered.[3] In all chronic pain conditions, the more severe cases involve some degree of psychologic disturbance.[98] It is unclear whether, for example, the depression that accompanies many chronic pain states is a result of or contributes to the underlying disease process. Because it is clear that pain has both a discriminatory and an affective component, focusing treatment on one aspect will have less successful results. The multidisciplinary approach to chronic pain management ensures all aspects of the pain disorder are treated. The pain clinic team may be comprised of psychologists, psychiatrists, physical therapists, anesthesiologists, TMD specialists, oral and maxillofacial surgeons, neurologists, neurosurgeons, and integrative medicine specialists. There is evidence demonstrating the psychologic ramifications that chronic facial pain has on diagnosis and treatment outcomes[99,100] and the need for the multidisciplinary approach.

Future Directions in Pain Management

Pain research has significantly improved our understanding of acute and chronic pain mechanisms. By highlighting key molecular mechanisms involved in pain transmission, new drugs are currently being investigated as potential novel and selective therapies. Currently available medications such as opioids are certainly fraught with side effect profiles that may limit their clinical utility. Research is now focused on specific receptor or channel targets within the nervous system that limit systemic complications. It appears from the available data that while low-dose capsaicin is generally ineffective as an analgesic in either musculoskeletal or multiple forms of chronic neuropathic pain in adults, high-dose capsaicin has shown efficacy in certain forms of chronic neuropathic pain. A logical evolution in research into investigation of TRPV1 agonism, then, most likely ought to

focus on either 8% topical capsaicin in musculoskeletal pain or forms of chronic neuropathic pain not yet investigated, be it diabetic peripheral neuropathy, or distal painful polyneuropathy. Further investigation into TRPV1 antagonists may continue to yield fruitful results

Growth factors are important in the differentiation, maturation, and plasticity of cells within the nervous system. Key growth factors that have been implicated in pain include nerve growth factor (NGF), glial-derived growth factor (GDNF), and brain-derived growth factor (BDNF).[101] Receptors for such growth factors are expressed on C fibers and Aδ fibers that terminate within the spinal cord. In animal models of chronic pain, NGF levels are elevated in damaged peripheral tissues. Neutralizing antibodies against NGF are effective, at least in animal models, in reducing and, in some cases, preventing chronic pain. Interestingly, administration of NGF has also been shown to reduce neuropathic pain. Phase III clinical trials are currently underway assessing the efficacy of recombinant NGF to treat diabetic neuropathy. BDNF has been implicated in the modulation of central sensitization as its expression is increased in nociceptive neurons in models of peripheral neuropathy. BDNF sensitizes C fiber activity, resulting in hyperalgesia and allodynia. Inhibition of BDNF and its cognate receptor trkB results in decreased C fiber firing and a reduction in pain behaviors. Finally, GDNF is important in the survival of sensory neurons and supporting cells. Neuropathic pain behaviors commonly observed in animal models of chronic pain are prevented or reversed following GDNF administration. The timing of administration determined whether treatment was protective or therapeutic in nature.

Other directions for further investigation could include randomized controlled trials of the effectiveness of botulinum toxin injections. Further trials measuring the safety and the efficacy of autologous administration of stem cells for neuropathic trigeminal pain reduction may offer a viable treatment option.[102] Evaluation of neuromodulation with electrical stimulus to treat atypical neuropathic pain refractory to other treatments also may prove to be of value. Development of novel compounds to improve safety and tolerability of NSAIDs may also be beneficial in the treatment of chronic facial pain.

Temporomandibular Muscle Disorders: Diagnostic and Management Considerations

JAMES FRICTON, GREGORY M. NESS

Intrinsic pain of the masticatory muscles is sometimes perceived by oral and maxillofacial surgeons as a vaguely defined syndrome managed by somewhat mysterious—but definitely nonsurgical—treatment. In fact, myogenous temporomandibular disorders (TMDs), or masticatory myalgias, are characterized by pain and dysfunction arising from a number of well-defined, distinct pathologic and functional processes in the masticatory muscles. These include myofascial pain (MFP), myositis, muscle spasm, and muscle contracture.[1] The surgeon who would operate on the temporomandibular joint (TMJ) must also be familiar with the diagnosis and nonsurgical management of these muscular problems. This chapter defines these disorders and suggests effective and evidence-based therapies for each.

MFP is the most common muscle pain disorder.[2] It is an acute to chronic condition that includes the presence of regional pain associated with tender areas called *trigger points* (TrPs), which are expressed in taut bands of skeletal muscles, tendons, or ligaments. Although the pain most often occurs in the region over the TrP, pain can be referred to areas distant from the TrP (e.g., the temporalis referring to the frontal area and the masseter referring into the ear and/or the posterior teeth). Reproducible duplication of pain complaints with specific palpation of the tender area is often diagnostic.

Myositis is an acute condition with localized or generalized inflammation of the muscle and connective tissue and is associated with pain and swelling overlying the muscle. Most areas in the muscle are tender, with pain in active range of motion. The inflammation is usually due to local causes such as overuse, excessive stretch, drugs (e.g., ecstasy), local infection from pericoronitis, trauma, or cellulitis. Myositis is also termed *delayed onset muscle soreness* in cases of acute overuse.

Muscle spasm is also an acute disorder characterized by a brief involuntary tonic contraction of a muscle. It can occur as a result of overstretching of a previously weakened muscle, from protective splinting of an injury, as a centrally mediated phenomenon such as prochlorperazine (Compazine)-induced spasm of the lateral pterygoid muscle, or through overuse of the muscle. A muscle in spasm is acutely shortened and painful, causing limited range of motion in the affected joint. Lateral pterygoid spasm on one side can also cause a shift of the occlusion to the contralateral side.

Muscle contracture is a chronic condition characterized by continuous gross shortening of the muscle with significant limited range of motion. It can begin as a result of factors such as trauma, infection, or prolonged hypomobility. If the muscle is maintained in a shortened state, muscular fibrosis and contracture may develop over several months. Pain is often minimal in the process from protection of the muscle.

Etiology and Epidemiology

Prevalence

Muscle pain disorders are the most common cause of persistent pain in the head and neck, affecting about 50% of a chronic head and neck pain population.[3] They are also a common cause of pain in the general population, with 20% to 50% of people having muscle pain disorders and about 6% having symptoms severe enough to warrant treatment.[4,5]

Etiologic Factors

Onset factors for myogenous TMDs include both direct or indirect macrotrauma to the muscle and repetitive strain activities.[6] Macrotrauma includes a direct blow to the jaw and opening the mouth too wide or for too long a period during activities such as undergoing dental work, eating, yawning, or engaging in sexual activity. Indirect trauma due to a whiplash-type injury may initiate muscle pain in some cases. Local infection and trauma may cause myositis and lead to muscle contracture if not resolved. Occupational and repetitive strain injury may result in MFP and, if acute, muscle spasm. Sleep disturbance and nocturnal habits can contribute to MFP. Psychosocial stressors such as relationship conflicts, monetary problems, feelings of hurriedness, overscheduling, and poor pacing skills can also play an indirect role.

Postural strain caused by a forward head posture, increased cervical or lumbar lordosis, some occlusal abnormalities, and poor positioning of the head or tongue have also been implicated in MFP; so have static postural problems such as unilateral short leg, small hemipelvis, occlusal discrepancies, and scoliosis or functional postural habits such as forward head, jaw thrust, shoulder phone bracing, and lumbar lifting. In a study of postural problems in 164 head and neck muscle pain patients, poor sitting and standing posture in 96%, forward head in 84.7%, rounded shoulders in 82.3%, lower tongue position in 67.7%, abnormal lordosis in 46.3%, scoliosis in 15.9%, and leg length discrepancy in 14.0% were found to contribute to muscle pain.[2]

Oral parafunctional muscle tension produces habits such as teeth clenching, jaw thrust, gum chewing, and jaw tensing. Nocturnal bruxism is often cited as a common cause of MFP but probably is better thought of as a perpetuating cofactor.

Pathophysiology and Mechanisms

Because there are no specific anatomic changes in the myogenous pain, there are no conclusive mechanisms identified in nontrauma cases. Therefore there are several processes that may explain the development and persistence of masticatory myogenous pain.[6]

Repetitive Strain Hypothesis

Repetitive strain from oral parafunctional habits contributes to localized progressive increases in oxidative metabolism and depleted energy supply (decrease in the levels of adenosine triphosphate [ATP], adenosine diphosphate [ADP], and phosphoryl creatine and abnormal tissue oxygenation). The result is changes in the muscle nociception, particularly with type I muscle fiber types associated with static muscle tone and posture. Tenderness and pain in the muscle are mediated by type III and IV muscle nociceptors, which may be activated by locally released noxious substances such as potassium, histamine, kinins, or prostaglandins, causing tenderness.

Neurophysiologic Hypothesis

Tonic muscular hyperactivity may be a normal protective adaptation to pain instead of its cause. Phasic modulation of excitatory and inhibitory interneurons supplied by high-threshold sensory afferents may be involved.

Central Hypothesis

Convergence of multiple afferent inputs from the muscle and other visceral and somatic structures in the lamina I or V of the dorsal horn on the way to the cortex can result in perception of local and referred pain.[7]

Central Biasing Mechanism

Multiple peripheral and central factors may inhibit or facilitate central input through modulatory influence of the brainstem. This may explain the diverse factors that can either exacerbate or alleviate the pain, such as stress, repetitive strain, poor posture, relaxation, medications, temperature change, massage, local anesthetic injections, and electrical stimulation.

Clinical Presentation

The major characteristics of masticatory myalgia include pain, muscle tenderness, limited range of motion, and other symptoms such as fatigability, stiffness, and subjective weakness. Comorbid conditions and complicating factors are also common and discussed. Each will be discussed for the different subtypes.

Pain

The common sites of pain in the masticatory system include jaw pain; facial pain; temporal, frontal, or occipital headaches; preauricular pain; earache; and neck pain. The pain is often a constant steady dull ache that fluctuates in intensity and can be acute to chronic. The duration may vary from hours to days.

Muscle Tenderness

In MFP the tenderness is in a deep, localized (2 to 5 mm), taut band of skeletal muscle, a TrP, which is associated with consistent patterns of pain referral. In contrast, muscle tenderness in myositis and muscle spasm can be generalized over the whole muscle. Myofascial TrPs are very common and may be active or latent. Active TrPs are hypersensitive and display continuous pain in the zone of reference that can be altered with specific palpation. Latent TrPs display only hypersensitivity with no continuous pain. This localized tenderness has been found to be a reliable indicator of the presence and severity of MFP with both manual palpation and pressure algometers.[8-10] However, the presence of taut bands appears to be a characteristic of skeletal muscles

in all subjects regardless of the presence of MFP. Palpating the active TrP with sustained deep single finger pressure on the taut band will elicit an alteration of the pain (intensification or reduction) in the zone of reference (area of pain complaint) or cause radiation of the pain toward the zone of reference. This can occur immediately or be delayed a few seconds. The pattern of referral is both reproducible and consistent with patterns of other patients with similar TrPs (Figure 45-1). This enables a clinician to use the zone of reference as a guide to locate the TrP for purposes of treatment.

Limited Range of Motion

Diminished mandibular opening may result from structural disorders of the TMJ system such as ankylosis, internal derangements, coronoid hypertrophy, or gross osteoarthritis, all of which must be ruled out by clinical examination and joint imaging. In MFP, limitation in range of motion may be slight (10% to 20%) and unrelated to joint restriction, whereas in muscle spasm, myositis, and contracture it may be gross (50% or more). A study of jaw range of motion in patients with MFP and no joint abnormalities demonstrated a slightly diminished range of motion of 35 to 45 mm (approximately 10% compared with unaffected individuals) and pain in the full range of motion. This is considerably less limitation than was found with joint locking due to a TMJ internal derangement (20 to 35 mm).[11] This restriction may perpetuate the TrP and develop other TrPs in the same muscle and in other agonist muscles. This can cause multiple TrPs with overlapping areas of pain referral, with subsequent changes in pain patterns over time as TrPs are inactivated.

Other Symptoms

Other associated signs and symptoms that may occur include increased fatigability, stiffness, subjective weakness, pain in movement, otologic symptoms including dizziness, tinnitus, and plugged ears, paresthesias including numb feelings, decreased sensation and tingling, and dermatographia including increased redness of the skin on palpation or rolling. The affected muscles may also display an increased fatigability, stiffness, subjective weakness, pain in movement, and slight restricted range of motion that is unrelated to joint restriction.[1,4-7] The muscles are painful when stretched, causing the patient to protect the muscle through poor posture and sustained contraction.[12] There are no neurologic deficits associated with muscle pain disorders unless a nerve entrapment syndrome with weakness and diminished sensation coincides with the muscle tightness. Although routine clinical electromyography (EMG) shows no significant abnormalities associated with TrPs, some specialized EMG studies reveal differences.[13-16] The consistency of soft tissues over the TrPs has been found to be denser than over adjacent muscle.[17,18] Skin overlying the TrPs in the masseter muscle appears to be warmer as measured by infrared emission.[19,20] Routine clinical utility of these measurements remains controversial, however.

Comorbid Conditions and Complicating Factors

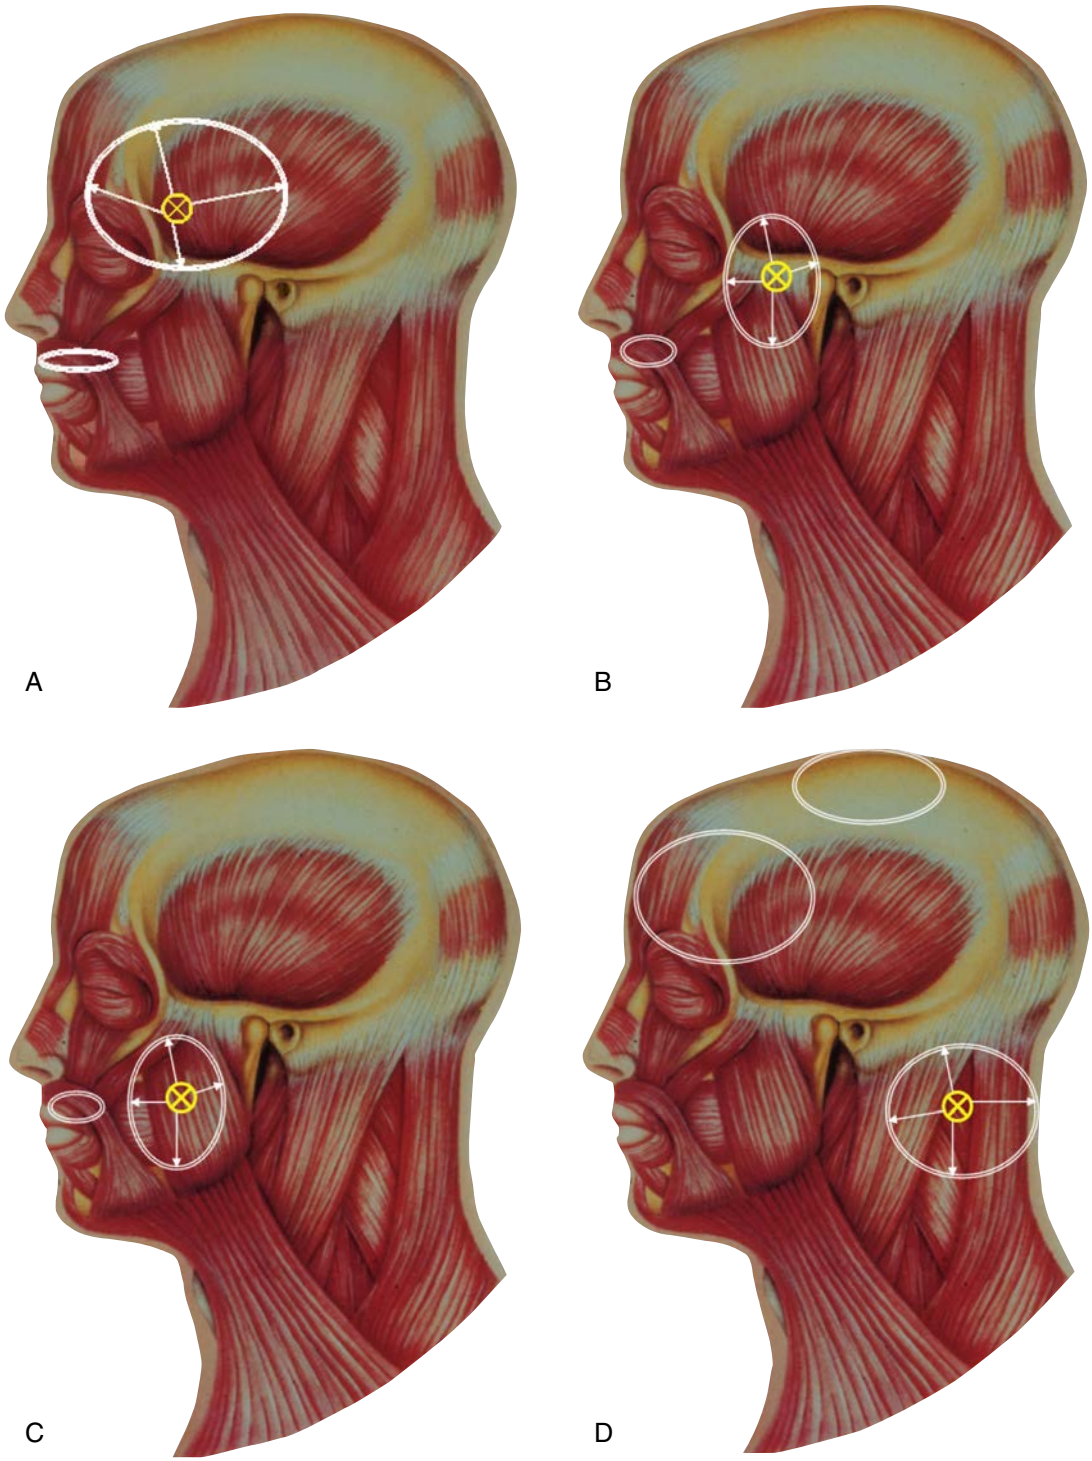
There are many comorbid conditions with myogenous TMD pain that reflect both common causative factors and mechanisms of pain. In most recent classifications, the regional pain found with MFP is distinguished from the widespread muscular pain associated with fibromyalgia (FM). These two disorders have many similar characteristics and may represent two ends of a continuous spectrum. For example, as Simons[21] points out, 16 of the 18 tender point sites in FM lie at well-known TrP sites. Many of the clinical characteristics of FM such as fatigue, morning stiffness, and sleep disorders can also accompany MFP. Bennett[22] compares these two disorders and concludes that they are two distinct disorders but may have similar underlying pathophysiology. The clinical significance of distinguishing between them lies in the more common centrally generated contributing factors in FM (sleep disorders, depression, and stress) versus the more common regional contributing factors in MFP (trauma, posture, and muscle tension habits) as well as the better prognosis in treatment of MFP as compared with FM.

Other comorbid conditions that have often been cited to accompany myogenous disorders include joint disc displacement and osteoarthritis, malocclusion and functional occlusal dysfunction, connective tissue diseases, neuropathic pain disorders, migraine and tension type headaches, gastrointestinal disorders, and hypothyroidism. It is not clear what mechanism underlies the coexistence of these conditions. Common central and peripheral pain mechanisms and causes may play a role.

Furthermore, many associated behavioral and psychosocial factors can accompany the chronic pain associated with myogenous disorders, including behavioral factors such as muscle tension, oral parafunctional, and maladaptive postural habits; psychologic factors such as frustration, anxiety, and depression; secondary gain from pain behaviors such as pain verbalization and avoidance of activities; medication dependencies; and sleep disturbance.

Diagnostic Tests

Diagnoses of masticatory myalgia are typically determined through the clinical diagnostic criteria that are listed in Box 45-1. However, some diagnostic strategies can be helpful. In MFP, injections of local anesthetic into the active TrP will reduce or eliminate the referred pain and the tenderness. Imaging studies often used to evaluate for dental or TMJ disease, including radiographs and magnetic resonance imaging, are generally normal. Routine clinical EMG studies are abnormal in muscle spasm only. Some specialized EMG studies (twitch response) reveal differences in cases of MFP but have limited applicability in routine clinical



• **Figure 45-1** Trigger points in myofascial pain with associated patterns of referral in the jaw, head, and neck. **A,** The pain source is the anterior temporalis trigger point. Pain occurs as temple, frontal, and retro-orbital headaches and pain in the maxillary anterior teeth. These muscles are activated by clenching, bruxism, and other oral parafunctional habits. **B,** The pain source is the deep masseter trigger point. Pain occurs as preauricular pain, earaches, and pain in the maxillary posterior teeth. These muscles are also activated by clenching, bruxism, and other oral parafunctional habits. **C,** The pain source is the middle masseter trigger point. Pain occurs as temple, frontal, and retro-orbital headaches and as pain in the maxillary anterior teeth. These muscles are also activated by clenching, bruxism, and other oral parafunctional habits. **D,** The pain source is the splenius capitus trigger point in the posterior cervical area. Pain occurs as posterior cervical pain, vertex headache, and frontal headache. These muscles are also activated by clenching and forward head pressure.

• BOX 45-1 Diagnostic Criteria for Masticatory Myalgia Disorders

Myofascial Pain—Repetitive Strain

- Dull aching pain in the jaw, face, ear, temples, or forehead
- Localized tenderness (trigger points) in specific taut muscle bands with tenderness on the same side as the pain; see Figure 45-1 for sites and referral patterns
- Duplication of the pain with palpation of the tender trigger points

Muscle Spasm—Acute Overuse

- Acute onset of pain in the jaw, face, ear, or temples at rest and in function
- Moderate to severe acute limited range of motion due to continuous muscle contraction; in lateral pterygoid spasm, the jaw has a shift to one side with subsequent acute malocclusion that is reversible
- Generalized tenderness of the muscle

Myositis—Injury or Infection

- Pain, usually continuous, in a localized muscle area after injury or infection; pain is increased with mandibular movement
- Diffuse tenderness over the entire muscle area involved
- Moderate to severe limited range of motion
- Swelling over muscle area involved

Muscle Contracture—Muscle Fibrosis

- Gross limited range of mandibular motion
- Unyielding firmness on passive stretch (hard end feel)
- Little or no pain unless the involved muscle is forced to lengthen
- Remote history of trauma, infection, or long period of disuse and limited range of motion

practice. Blood and urine studies are generally normal unless caused by a concomitant disorder. Pain questionnaires such as the Chronic Pain Battery and TMJ Scale may identify contributing factors including emotional issues, somatization, secondary gain, and disability.

Treatment

Simple to Complex

Treatment of myogenous pain can range from simple cases with transient single muscle syndromes to complex cases involving multiple muscles and many interrelating contributing factors. Many authors have found success in treatment of myogenous pain using a wide variety of techniques such as exercise, TrP injections, vapocoolant spray and stretch, transcutaneous electrical nerve stimulation (TENS), biofeedback, posture correction, tricyclic antidepressants, muscle relaxants and other medications, and addressing of perpetuating factors.[13,23-25] However, the management challenge lies in the critical need to match the level of complexity of the management program with the complexity of the patient. Failure to address the entire problem, including all involved muscles, concomitant diagnoses, and contributing factors, may lead to failure to resolve the pain or, worse, perpetuation of the pain.

• BOX 45-2 Criteria for Complex Cases

Fulfilling any one of these criteria suggests that this patient's case is complex and may require the use of team treatment to address the contributing factors and improve the prognosis.

- Persistent pain (daily or regular) longer than 6 months in duration
- Significant lifestyle disturbances such as loss of work, social activities, or home activities
- High use of past health care including medications for problem or related problems
- Emotional difficulties related to problem including depression, anxiety, or anger
- Daily oral habits such as clenching or grinding of the teeth
- Significant stressful life events such as pacing problems, divorce, or recent death in family

Although there are no prospective studies examining progression of chronic pain syndromes, results from clinical studies reveal that many patients with muscle pain have seen many clinicians and received numerous medications and multiple other singular treatments for years without receiving more than temporary improvement. In one study of 164 muscle pain patients, the mean duration of pain was 5.8 years for males and 6.9 years for females, with a mean of 4.5 past clinicians seen for the study.[2] In another study of 102 consecutive TMJ and craniofacial pain patients including 59.8% muscle pain patients, the mean duration of pain was 6.0 years, with 28.8 previous treatment sessions, 5.1 previous doctors, and 6.4 previous medications.[26] These and other studies of chronic pain suggest that regardless of the pathogenesis of muscular pain, a major characteristic of many of these cases is the failure of traditional approaches to resolve the problem. Therefore each clinician confronted with a patient with muscle pain needs to recognize and address the whole problem to maximize the potential for a successful outcome.

Treating only those patients whose complexity matches the treatment strategy available to the clinician can improve success. Simple cases with minimal behavioral and psychosocial involvement can typically be managed by a single clinician. Complex cases (Box 45-2) should be managed within an interdisciplinary pain clinic setting that uses a team of clinicians to address different aspects of the problem in a concerted fashion. Box 45-3 presents a hierarchy of treatment strategies depending on whether the condition is acute, simple, or complex.

Treatment Goals

The short-term goal is to restore the muscle to normal length and posture and allow full joint range of motion through exercises and TrP therapy. This is followed long term with a regular muscle stretching, postural, and strengthening exercise program, as well as control of contributing factors.

• BOX 45-3 Protocol Checklist for Managing Masticatory and Cervical Myalgia Pain

I. Evaluation
  A. Identify masticatory and cervical muscles involved
  B. Identify each area of pain
    - Frequency
    - Duration
    - Intensity
  C. Identify contributing factors
    - Direct macrotrauma (e.g., blow to jaw)
    - Indirect macrotrauma (e.g., whiplash injuries)
    - Repetitive postural strain (e.g., phone bracing)
    - Oral parafunctional habits (e.g., clenching and grinding of teeth)
    - Dietary factors (e.g., caffeine)
    - Sleep disturbance
    - Psychosocial stressors
    - Anxiety and depression
  D. Determine simple versus complex
    - Simple: single clinician evaluation and treatment
    - Complex: team evaluation including dentist, physical therapist or chiropractor, psychologist

II. Management
  A. Acute
    - Palliative self-care
  B. Simple case management with single clinician
    - Self-care
    - Splint
    - Jaw exercises
    - Vapocoolant spray or other modality with stretching
    - Oral habit instruction
  C. Complex case management
    - Self-care
    - Splint
    - Trigger point or muscle injections
    - Medications (muscle relaxants and anti-inflammatories as needed)
    - Exercises with physical therapist
    - Cognitive-behavioral therapy
    - Counseling as needed

Long-term control of pain depends on patient education, self-responsibility, and development of long-term doctor-patient relationships. This often requires shifting the paradigms implicit in patient care as listed in Table 45-1. The difficulty in long-term management often lies not in treating the TrPs, but rather in the complex task of changing the identified contributing factors because they can be integrally related to the patient's attitudes, lifestyles, and social and physical environment. Interdisciplinary teams integrate various health professionals in a supportive environment to accomplish both long-term treatment of illness and modification of these contributing factors. Many approaches, such as habit reversal techniques, biofeedback, and stress management, have been used to achieve this result within a team approach.

Management follows goals including self-care, muscle exercises, muscle therapy, and reducing all contributing factors and is directed at rehabilitating the muscle to improving tenderness and range of motion, reducing tenderness, and reducing or eliminating contributing factors. Muscle rehabilitation is focused on exercise to improve range of motion, relaxation, and strength of the muscle. Reduction of contributing factors includes reducing biomechanical strain to the muscles from oral parafunctional habits such as clenching, gum chewing, and other repetitive strain activities. In addition, improved posture of the head, neck, and tongue will reduce sustained muscle activity and encourages healing. Reducing tenderness can be accomplished by inhibiting peripheral neural input through various treatment modalities such as cold, heat, analgesic medications, massage, muscle injections, and TENS. Reducing central modulating factors requires the patient to manage contributing factors such as improving stress, sleep, anxiety, and depression.

TABLE 45-1 Shifting Paradigms in Patient Care

Shifting the doctor-patient paradigms involves each member of the team following the same concepts by conveying the same messages implicit in the dialogue with the patient.

Concept	Statement
Self-responsibility	You have more influence on your problem than we do.
Self-care	You will need to make daily changes in order to improve your condition.
Education	We can teach you how to make the changes.
Long-term change	It will take at least 6 months for the changes to have an effect.
Doctor-patient relationship	We will support you as you make the changes.
Patient motivation	Do you want to make the changes?

Control of Contributing Factors

One of the common causes of failure in managing masticatory myalgia is failure to recognize and subsequently control contributing factors that may perpetuate muscle restriction and tension. As noted earlier, postural contributing factors, whether behavioral or biologic, perpetuate muscle pain if not corrected. In general, a muscle is more predisposed to developing problems if it is held in sustained contraction in the normal position and especially if it is in an abnormally shortened position. Such a situation exists with structural problems such as loss of posterior teeth, an excessive lordosis of the cervical spine, a unilateral short leg, or a small hemipelvis.[11] An occlusal imbalance can be corrected with an occlusal stabilization splint, also termed a *flat plane* or *full-coverage splint*. Other postural factors that can be corrected include a foot lift for a unilateral leg length discrepancy, a pelvic lift for a small hemipelvis, and proper height of arm rests in chairs for short upper arms.

• BOX 45-4 Palliative Self-Care Program for Acute Episodes of Masticatory Myalgia

- Eat a soft diet and avoid caffeine.
- Keep your tongue up and gently resting on the palate. Keep teeth apart as the rest position of the jaw.
- Chew on both sides at the same time or alternate sides to minimize strain to muscles.
- Avoid oral parafunctional habits such as clenching and grinding the teeth, jaw tensing, or gum chewing.
- Avoid excessive or prolonged opening of mouth.
- Avoid sleeping on your stomach to minimize strain to the jaw during sleep.
- Use over-the-counter analgesics or nonsteroidal anti-inflammatories as directed for pain.
- Use heat or ice over the tender muscles.

Behavioral factors causing sustained muscle tension can also occur with habits such as a receptionist cradling a phone between the head and shoulder for hours each day, a laborer lifting with lumbar strain, a student studying with the head forward for hours at a time, or bruxism, clenching, gum chewing, or other oral parafunctional habits. Correcting poor habits through education and long-term reinforcement is essential to preventing a reduced TrP from returning. Biofeedback, meditation, hypnosis, stress-management counseling, psychotherapy, antianxiety medications, antidepressants, and even placebos have been reported to be effective in treating masticatory myalgia.[26-30] Many of these treatments are directed toward reducing muscle tension that produces habits such as bruxism or bracing of muscles. Teaching control of habits is a difficult process because of the relationship that muscle tension may have to psychosocial factors. Simply telling a patient to stop the habits may be helpful with some, but with others it may result in noncompliance, failure, and frustration. An integrated approach involving education, increased awareness, and other treatments, such as behavior modification, biofeedback, hypnosis, or drug therapy, may prove to be more successful.

Simple Management

Self-Care

Most acute recent symptoms are self-limited and resolve with minimal intervention. Initial treatment should be a self-care program (Box 45-4) to reduce repetitive strain of the masticatory system and encourage relaxation and healing of the muscles.

This strategy includes jaw range of motion exercises, oral habit change, and protective gentle use of the jaw. Most patients respond well to self-care in 4 to 6 weeks; if not, further assessment and treatment are indicated.

Orthopedic Intraoral Splints

Orthopedic intraoral splints can encourage relaxation of the muscles, alter muscular recruitment patterns, and reduce oral habits. Stabilization splints allow passive protection of the jaw and reduction of oral habits owing to the flat passive occlusal surface on mandibular or maxillary teeth. Mandibular splints can be smaller and result in higher patient satisfaction in some cases. Splints should be adjusted to achieve mutually protected occlusion with bilateral balanced contact on all posterior teeth with the condyles in their most seated positions, with anterior guidance (lateral and protrusive) provided by the canines and/or incisors.

Anterior repositioning splints can be efficacious for concomitant joint problems with intermittent jaw locking with limited range of motion, especially on awakening, and are recommended for short-term, part-time use, primarily during sleep. Long-term or continuous use must be avoided because they can cause occlusal changes.

Partial coverage splints may cause occlusal changes in some patients. Splints should cover all of the mandibular or maxillary teeth to prevent movement of uncovered teeth resulting in iatrogenic malocclusion.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) approaches can help change maladaptive habits and behaviors that contribute to myalgia such as jaw tensing, teeth clenching, and teeth grinding. Although many simple habits are easily abandoned when the patient becomes aware of them, changing persistent habits requires a structured program that is facilitated by a clinician trained in behavioral strategies. Habits do not change themselves, and patients are responsible for initiating and maintaining behavior changes.

Habit reversal can be accomplished by becoming more aware of the habit, knowing how to correct it (e.g., what to do with the teeth and tongue), and knowing why to correct it. Correcting a habit during the day will also help reduce it at night. These educational points from the clinician must be combined with the patient's commitment to conscientious self-monitoring and focus on the goal.

Muscle Exercises

The most useful exercise techniques for muscle rehabilitation include muscle stretching, posture, and strengthening exercises.[13,24,25,31] In patients with muscle pain, a home program of active and passive muscle stretching exercises will reduce the activity of muscle pain, and postural exercises will reduce susceptibility to reactivation of pain by physical strain (Figure 45-2). Strengthening and cardiovascular fitness exercises will improve circulation, strength, and durability of the muscles.

Pharmacotherapy

Pharmacotherapy is a useful adjunct to initial treatment of muscle pain. The most commonly used medications for pain are classified as nonnarcotic analgesics (nonsteroidal anti-inflammatory agents [NSAIDs]), narcotic analgesics, muscle relaxants, tranquilizers (ataractics), sedatives, and antidepressants. Analgesics are used to allay pain; muscle

• **Figure 45-2** Jaw exercises. These jaw stretching exercises can be used for initial postural correction and range of motion restoration for masticatory myofascial pain. They can restore normal joint function and mobility and result in a more comfortable and normal jaw position. They are performed gradually and gently six times daily for about 1 minute each. The jaw should be progressively stretched slightly beyond the point of tightness and pain. Caution should be taken to avoid overstretching with acutely strained jaws or capsulitis of the temporomandibular joint. Place one finger between the teeth for 1 minute. Rest and repeat. Then place two fingers between the teeth for 1 minute. Rest and repeat. In some cases without significant joint restriction, using three fingers to stretch may be needed.

relaxants and tranquilizers for anxiety, fear, and muscle tension; sedatives for enhancing sleep; and antidepressants for pain, depression, and enhancing sleep.[23]

Randomized clinical trials on NSAIDs such as ibuprofen and piroxicam suggest that for myalgia, short-term use of these medications for analgesic and/or anti-inflammatory effects certainly can be considered as a supplement to overall management. Chronic, long-term use is undertaken with caution owing to the long-term systemic and gastrointestinal effects. If some therapeutic result is not apparent after 7 to 10 days or if the patient develops any side effects, especially gastrointestinal symptoms, the medication should be discontinued.

For muscle pain, especially with stress and sleep disturbance, benzodiazepines, including diazepam and clonazepam, have been shown to be effective. Experience suggests that these are best used before bedtime to minimize sedation while awake. Cyclobenzaprine (Flexeril) has also been shown in clinical trials of myalgia to be efficacious in reducing pain and improving sleep[32,33] and can be considered when a benzodiazepine is too sedating. These medications, with or without NSAIDs, can also be considered for a 2- to 4-week trial with minimal habituation potential. However, long-term use has not been adequately tested.

Advanced Management

Cognitive-Behavioral Therapy

When necessary, basic habit reversal may be supplemented with additional behavioral strategies such as biofeedback, meditation, stress management, or relaxation techniques. It may also be important to address poor pacing or hurrying related to a day overloaded with commitments, depression, anxiety, sleep disorders, or emotional problems. This may require behavioral and psychologic therapy and/or medications and is best managed by a competent psychologist or psychiatrist.

Muscle Exercises

Passive and active stretching of the muscles will increase the opening to the normal range as well as decrease the pain. Passive stretching of the masticatory muscles during counter stimulation of the tender muscle can be accomplished through placing a properly trimmed and sterile cork, tongue blades, or other object between the incisors while the spray and stretch technique is accomplished. It must be emphasized to avoid rapid, jerky stretching or overstretching of the muscle to reduce potential injury to the muscle.

Postural exercises are designed to teach the patient mental reminders to hold the body in a balanced relax position and use the body with positions that afford the best mechanical advantage. In improving posture, specific skeletal conditions such as structural asymmetry or weakness of certain muscles need to be considered. For the masticatory system the patient should be instructed to place the tongue gently on the roof of the mouth and keep the teeth slightly apart. For the cervical spine, a forward or lateral head posture must be corrected by guiding the chin in and the head vertex up. The shoulders will naturally fall back if the thorax is positioned up and back with proper lumbar support. Patients need to be instructed in proper posture for each position—sitting, standing, and lying down—as well as in movements that are done repetitively throughout the day such as lifting or turning the head to the side. Sleeping posture on the side or back is particularly important for patients who wake up with soreness.

Improved posture is also facilitated by regular physical conditioning. Patients need to be placed on a conditioning program to facilitate increased aerobic capacity and strength. Aerobic programs, such as becoming involved in an exercise class, regular running, walking, biking, or swimming, will improve comfort, endurance, and functional status of patients with muscle pain.[11]

Muscle Therapy

There are many methods suggested for providing repetitive stimulation to tender muscles. Massage, acupressure, and ultrasound provide noninvasive mechanical disruption to

reduce tenderness. Moist heat applications, ice packs, fluoromethane, and diathermy provide skin and muscle temperature change as a form of counter stimulation. TENS, electroacupuncture, and direct current stimulation provide electric currents to stimulate the muscles and TrPs. Acupuncture and TrP injections of local anesthetic, corticosteroids, or saline cause direct mechanical or chemical alteration of TrPs. However, the two most common techniques for treating muscle pain include spray and stretch technique and TrP injections.

With the spray and stretch technique, an application of a vapocoolant spray such as fluoromethane over the muscle with simultaneous passive stretching can provide immediate reduction of pain, although lasting relief requires a full management program.[8] The technique involves directing a fine stream of fluoromethane spray from the finely calibrated nozzle toward the skin directly overlying the muscle with the TrP. A few sweeps of the spray are first passed over the TrP and zone of reference before the addition of sufficient manual stretch to the muscle to elicit pain and discomfort. The muscle is put on a progressively increasing passive stretch while the jet stream of spray is directed at an acute angle from 30 to 50 cm (1 to 1½ feet) away. It is applied in one direction from the TrP toward its reference zone in slow even sweeps over adjacent parallel areas at a rate of about 10 cm/sec. This sequence can be repeated up to four times if the clinician warms the muscle with his or her hand or uses warm moist packs to prevent overcooling after each sequence. Frosting the skin and excessive sweeps should be avoided because they may lower the underlying skeletal muscle temperature, which tends to aggravate TrPs. The range of passive and active motion can be tested before and after spraying as an indication of responsiveness to therapy. Failure to reduce TrPs with spray and stretch may be due to inability to secure full muscle length because of bone or joint abnormalities, muscle contracture, or the patient avoiding voluntary relaxation; incorrect spray technique; or failure to reduce perpetuating factors. If spray and stretch fails with repeated trials, direct needling with TrP injections may be effective.

TrP muscle injections have also been shown to reduce pain, increase range of motion, increase exercise tolerance, and increase circulation of muscles.[9,10,14] The pain relief may last from the duration of the anesthetic to many months, depending on the chronicity and severity of TrPs and the degree of reduction in perpetuating factors. Because the critical factor in relief appears to be the mechanical disruption of the TrP by the needle, precision in needling of the exact TrP and the intensity of pain during needling appear to be the major factors in TrP inactivation.[15] TrP injections with local anesthetic are generally more effective and comfortable than dry needling or injecting other substances, such as saline, although acupuncture may be helpful for patients with chronic TrPs in multiple muscles. The effect of needling can be complemented with the use of local anesthetics in concentrations less than those required for a nerve conduction block. This can markedly lengthen the relative refractory period of peripheral nerves and limit the maximum frequency of impulse conduction. Local anesthetics can be chosen for their duration, safety, and versatility. Three percent chloroprocaine (short acting) and 5% procaine (medium acting) without vasoconstrictors are suggested.

Pharmacotherapy

Research on medications for FM, especially with sleep disturbances, indicates that tricyclic antidepressants such as amitriptyline (Elavil) have a significant impact on sleep disturbances, anxiety, and pain in FM patients. Therefore these medications can be used in appropriate cases long term.[34] However, the side effects with amitriptyline can be significant, and nortriptyline (Pamelor) can be considered an analogous medication with fewer side effects. Typically the dose for either of these medications in patients without depression is in the 25- to 75-mg range, taken at bedtime. The use of selective serotonin reuptake inhibitors (SSRIs) has been suggested for depression and pain but may also have the common side effect of increasing muscle tension and aggravating the pain.

For chronic pain conditions that are resistant to interventions, use of opioids can be considered. Tramadol has been shown to be effective in FM. However, there are no randomized clinical trials evaluating the appropriateness of opioids in the long-term treatment of chronic pain. At this time, chronic opioid use is mainly indicated for patients with chronic intractable severe pain conditions that are refractory to all other reasonable treatments because of their side effects, including constipation, sedation, potential for dose escalation, and unknown effects with long-term use.

Despite the advantages of medications for pain disorders, there exists an opportunity for problems to occur owing to their misuse. The problems that can occur from use of medications include chemical dependency, behavioral reinforcement of continuing pain, inhibition of endogenous pain relief mechanisms, side effects, and adverse effects from the use of polypharmaceuticals. For this reason the use of medication should proceed with caution.

Pain Clinic Team Management

Although each clinician may have limited success in managing the "whole" patient alone, the assumption behind a team approach is that it is vital to address different aspects of the problem with different specialists in order to enhance the overall potential for success.[17-19] Although these programs provide a broader framework for treating the complex patient, they have added another dimension to the skills needed by the clinician: working as part of a coordinated team. Failure to adequately integrate care may result in poor communication, fragmented care, distrustful relationships, and eventually confusion and failure in management.

However, team coordination can be facilitated by a well-defined evaluation and management system that clearly integrates team members.

A prerequisite to a team approach is an inclusive medical model and conceptual framework that places the physical, behavioral, and psychosocial aspects of illness on an equal and integrated basis.[20,35] With an inclusive theory of human systems and their relationship to illness, a patient can be assessed as a whole person by different clinicians from diverse backgrounds. Although each clinician understands a different part of the patient's problem, she or he can integrate understanding with other clinicians' perspectives and see how each part is interrelated in the whole patient. For example, a physician or dentist will evaluate the physical diagnosis, a physical therapist will evaluate poor postural habits, and a psychologist will evaluate behavioral problems or social stressors. Each factor will become part of the problem list to be addressed in the treatment plan. In the process, the synergism of each factor in the cause of the disorder can become apparent to clinicians. For example, social stressors can lead to anxiety, anxiety can lead to poor posture and muscle tension, the poor posture and muscle tension can lead to MFP syndrome, the pain contributes to more anxiety, and a cycle continues. Likewise, a reduction of each factor will work synergistically to improve the whole problem. Treatment of only one factor may improve the problem, but relief may be partial or temporary. Treatment of all factors simultaneously can have a cumulative effect that is greater than the effects of treating each factor individually.

The problem list for a patient with a specific chronic illness includes both a physical diagnosis and a list of contributing factors. In establishing the problem list the clinician needs to determine if the patient's case is complex and requires a team approach. Recommended criteria for determining complexity include any one of the following: multiple diagnoses, persistent pain longer than 6 months in duration, significant emotional problems (depression, anxiety), frequent use of health care services or medication, daily oral parafunctional habits, and significant lifestyle disturbances. The use of a screening instrument such as IMPATH, the McGill Pain Questionnaire, or the Multidimensional Inventory can readily elicit the degree of complexity of a case at initial evaluation.[1,36-38] The more complex the case is, the greater the need for a team approach. The decision to use a team must be made at the time of evaluation and not partway through a failing singular treatment plan. If a team is needed, the broad understanding of the patient is then used to design a long-term management program that both treats the physical diagnosis and helps reduce these contributing factors.

The primary goals of the program include reducing the symptoms and their negative effects and helping the patient return to normal function without need for future health care. The patient first participates in an educational session with each clinician to learn about the diagnoses and contributing factors, why it is necessary to change these factors, and how to do it. The dentist or physician is responsible for establishing the physical diagnosis, providing short-term medical or dental care, and monitoring medication and patient progress. The health psychologist is responsible for providing instruction about contributing factors; diagnosing, managing, or referring for primary psychologic disturbances; and establishing a program to support the patient and family in making changes. The physical therapist is responsible for providing support, instruction, and a management program for specifically assigned and common contributing factors, such as an exercise and posture program. Depending on the therapist's background and the patient's needs, this person may also provide special care such as physical therapy modalities or occupational therapy. Each clinician is also responsible for establishing a trusting, supportive relationship with the patient while reaffirming the self-care philosophy of the program, reinforcing change, and ensuring compliance. The patient is viewed as responsible for making the changes. The team meets weekly to review current patient progress and discuss new patients.

Summary

Goals of treatment of masticatory myalgia include reducing or eliminating pain, restoring normal jaw function, reducing the need for future health care, and restoring normal lifestyle functioning. The short-term strategy is to restore the muscle to normal length, posture, and full joint range of motion with exercises. The long-term strategy includes reducing the symptoms through muscle rehabilitation while helping the patient reduce contributing factors and return to normal function without the need for future health care.

Recent onset cases can often be managed with palliative self-care strategies designed to protect the muscles and encourage healing. Simple cases with minimal behavioral and psychosocial involvement can be managed by a single clinician (monodisciplinary fashion) with self-care, exercises, and a stabilization splint. Complex cases can be most effectively managed within an interdisciplinary pain clinic setting that uses a team of clinicians to address different aspects of the problem in a concerted fashion. Behavioral and psychosocial evaluation should be conducted on all patients with persistent pain to determine complexity and contributing factors. To improve outcomes, it is important to match the level of complexity of the management program with the complexity of the cases and use a pain clinic team approach to facilitate success in complex cases. Employing clinical paradigms of self-care, education, and self-responsibility in care will enhance long-term outcomes and maintain positive relationships between the patient and clinician.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To Chester, Lady, Cheerio, Moxie, Domino, Sasha, Tuxedo, Chairman Meow, Zoey, Apollo, Ayla, Annabelle, and Atticus for enriching our lives.

Raymond J. Fonseca

To my wife, Martha, and my children, Samantha, Amanda, Blake, and Mackenzie, for their patience and understanding.

Timothy A. Turvey

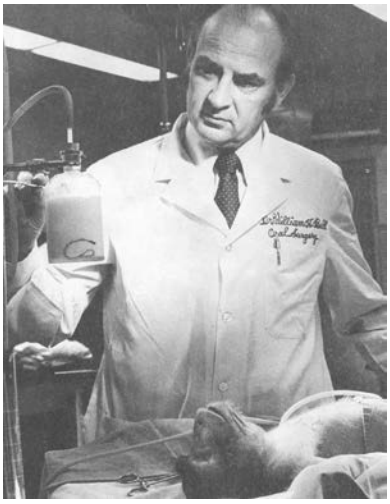
To my family, Jackie, Mia, and Michael, who inspire me every day. To my parents, for giving me every opportunity. To my mentors, including Drs. Thomas W. Braun, Jeffrey Posnick, Raymond Fonseca, and Peter Quinn, for the opportunity to experience their uncommon knowledge, skill, and compassion. To my colleagues and students, for the ever-present scholarly challenge.

Bernard J. Costello

To Drs. Peter D. Waite, Timothy A. Turvey, Jeffrey C. Posnick, and the late Victor J. Matukas, for teaching me by example. To my parents, Ramon R. and Aurora M. Ruiz, for teaching me about the beauty of intellectual pursuit. To my beautiful daughters, Julia, Maia, and Josephine, for their love and joy. To my wife, Laura, whose unconditional love, beauty, sweet intellect, and strength constantly inspire me.

Ramon L. Ruiz

In Memoriam



William H. Bell, DDS

We respectfully dedicate this edition of *Oral and Maxillofacial Surgery* to the memory of Dr. William "Bill" Harrison Bell. Matchless among his peers, Dr. Bell was an inimitable leader in surgery and medicine throughout his career.

In the early 1970s, Dr. Bell revolutionized oral and maxillofacial surgery through his landmark research on the biologic basis and clinical rationale for the Le Fort I osteotomy. In subsequent decades, he guided the hands of generations of surgeons, whether in academic medical centers across the world or through his meticulously detailed textbooks. It is a testament to Dr. Bell's always-passionate and always-persistent pursuit of excellence that his textbooks still remain contemporary decades after their publication.

While Dr. Bell was a revolutionary in our field, it is not simply in this spirit that we dedicate this book. Dr. Bell also served as an inspiration and mentor to us throughout our careers and lives, showing us always a readiness to inspire and a passion to change lives however he could. We are, quite simply, not alone in this feeling. It was this passion that compelled him to devote his life to improving patient care. It was this passion that affected so many others in our field. And it was this passion that also characterized so many areas of his vibrant and rich life—a life very well-lived.

It was an honor to learn from and know Bill. He was unwavering and uncompromising, and his love was unconditional. We know that the passion that burned in him to help others will continue to ignite the spirits of generations of surgeons to come. It will guide our hands and our actions as well.

Chapter 37: Nonsyndromic Craniosynostosis: Diagnosis and Contemporary Surgical Management

Lewis C. Jones, DMD, MD
Assistant Professor
Oral and Maxillofacial Surgery
University of Louisville
Louisville, Kentucky
Chapter 16: Perioperative Management of the Orthognathic Patient

Paul Kloostra, DDS, MD
Faculty and Co-Director FACES
Oral and Maxillofacial Surgery
Charleston Area Medical Center
Charleston, West Virginia
Chapter 30: Cleft Palate Repair

James Koehler, MD, DDS
Private Practice
Cosmetic Surgery
Eastern Shore Cosmetic Surgery
Fairhope, Alabama
Chapter 20: Basic Rhinoplasty

Caitlin B.L. Magraw, DDS, MD
Resident Surgeon
Department of Oral and Maxillofacial Surgery
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina
Chapter 11: Combined Maxillary and Mandibular Osteotomies

Andrei Marechek, DDS
Oral and Maxillofacial Surgery
Case Western Reserve University
Cleveland, Ohio
Chapter 24: Botulinum Toxin and Facial Chemical Peels for Skin Enhancement

Nicholas A. Medel, DDS, MD
Oral Surgeon
Private Practice
Athens Oral and Facial Surgery
Athens, Texas
Chapter 5: Common Mandibular Ramus Osteotomies: Sagittal Split Ramus Osteotomy and Intraoral Vertical Ramus Osteotomy

Gabriele A. Millesi, MD, DMD
Vice President Elect of the IAOMS
Assistant Professor
Medical University of Vienna
Vienna, Austria
Chapter 43: Complications: Maxilla

Mark P. Mooney, PhD
Professor and Chair
Department of Oral Biology
Professor, Departments of Anthropology, Plastic Surgery, Orthodontics, and Communication Science and Disorders
School of Dental Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 36: Craniomaxillofacial Surgery in the Pediatric Patient: Growth and Development Considerations

Elena Victoria Mujica, DDS
Resident
Department of Oral and Maxillofacial Surgery
Central University of Venezuela
Caracas, Venezuela
Chapter 12: Intraoral Distraction Osteogenesis

Sumit K. Nijhawan, DDS, MD
Chief Resident
Department of Oral and Maxillofacial Surgery
Case Western Reserve University, University Hospitals
Cleveland, Ohio
Chapter 26: Facial Implants in Cosmetic Surgery

Esther S. Oh, DDS, MD
Clinical Assistant Professor
Oral and Maxillofacial Surgery
University of Florida
Gainesville, Florida
Chapter 4: Orthognathic Model Surgery

Neil Oishi, DDS, MD
Oral and Maxillofacial Surgery
University of Florida College of Dentistry
Gainesville, Florida
Chapter 4: Orthognathic Model Surgery

Robert A. Ord, MD, DDs, MS
Professor and Chairman
Oral and Maxillofacial Surgery
University of Maryland
Baltimore, Maryland
Chapter 41: The Management of Pediatric Craniomaxillofacial Pathology

Todd G. Owsley, DDS, MD
Private Practice
Oral, Maxillofacial, Facial Cosmetic and Reconstructive Surgery

Chapter 32: Evaluation and Management of Speech Disorders for the Patient with Cleft Palate

Preface

We are excited to present the third edition of *Oral and Maxillofacial Surgery*. This three-volume text is the result of the collaboration of multiple contributors. The first edition, published in 2000, and the second edition, published in 2009, were very well-received. However, with all the advances in our profession, we felt it was time for a new edition. The section editors have done an excellent job recruiting the most knowledgeable individuals in their specific areas of expertise. The authors have submitted chapters that reflect the state of the art in their areas of responsibility.

This text is a comprehensive resource on oral and maxillofacial surgery. Every area in our specialty has been addressed. It defines the scope of the specialty. Every surgical procedure performed by an oral surgeon is covered in this text. This multi-volume text provides coverage of a wide range of issues related to surgical care, such as anesthesia, diagnostic imaging treatment planning, rehabilitation, physical therapy, and psychological considerations.

After an analysis of the changing field of oral and maxillofacial surgery, we strove to present a comprehensive, current book that covers the complete scope of our specialty. We hope that the reader appreciates and agrees with our efforts. We stated in the preface of the first edition that we hoped that our future attempts will present an even broader scope of oral and maxillofacial surgery. The fact that this edition has succeeded in that regard is a testament to the individuals who are constantly expanding the envelope.

Acknowledgments

The third edition of *Oral and Maxillofacial Surgery* is a team approach. The section editors—Timothy A. Turvey, Bernard J. Costello, and Ramon L. Ruiz—were invaluable contributors to the success of this effort. They diligently pestered authors so that deadlines were almost met. This edition, like the last two, attempts to define the scope of oral and maxillofacial surgery and could not have come to fruition without these contributors.

Residents are the lifeblood of our specialty. Many have helped to contribute portions of chapters in this book. They have also provided us with friendship, dedication, intellectual stimulation and humility, without which this book would not have been written.

Last, I would like to thank all the staff who helped to prepare these manuscripts and the editorial staff at Elsevier, who were so patient with our procrastination, and meticulous in their development and editing of this book. Additionally, I would like to thank my staff—Laynee Adams, Sally Brown, Heather Early, Patty Martin, Sarah Merrill, Josie Ray, and Ashley Wood—who collectively and individually make my life so enjoyable.

Raymond J. Fonseca, DMD

The History of Orthognathic Surgery

TIMOTHY A. TURVEY

Introduction

This historical account is authored by a North American whose principal language is English. Although there are many foreign references and some written in English that I have not included or have overlooked, my apologies in advance. There is no slight intended.

The author proposes to touch on the major events that shaped the development of orthognathic surgery over 170 years. I would appreciate hearing of any corrections, deletions, and additions from readers. It is only with your comments that an accurate account of orthognathic surgery will pass on to other generations.

The Pioneering Era

Little did Simon Hullihen realize that his 1849 publication would serve as the ignition switch for the development of the subspecialty of orthognathic surgery. His publication is the first known record of an operation performed to address jaw deformity and malocclusion.[1] The significance of this publication is the undertaking of a novel operation to reposition the dentoalveolus of the mandible. Also of significance is that the operation occurred prior to the development of antibiotics or general anesthetics. Another monumental milestone recorded in this manuscript is the recognition that soft tissue scarring which contributed to the patient's skeletal deformity had to be released to improve success. This bold maneuver was not accomplished in a major teaching center with observation theaters; it took place in the rural mining community of Wheeling, West Virginia. Hullihen is the first surgeon in the United States known to limit his practice to the face and neck and is considered the father of oral and maxillofacial surgery in this country.

Mandibular Osteotomies

Not much occurred in the development of mandibular osteotomies until near the end of the 19th century when several French surgeons, Jaboulay, Berard and Berger, published on subcondylar osteotomies for correction of prognathism.[2,3] In the United States, Whipple and Angle, both orthodontists, reported cases of prognathism correction in 1898.[4,5] The surgeons involved were Harvey Mudd and Vilray Blair. Blair was a general surgeon by training but his interest in mandibular corrective surgery led to the publication of several textbooks on this topic. Blair recognized the importance of orthodontic involvement in jaw surgery and relied on the expertise of Angle—who is considered the father of orthodontics—and others in the dental profession for guidance and advice. Blair and Angle seemed to have mutual respect and collaborated but never published together. Both were prolific writers and documented their experiences well.[6-9] Angle published seven editions of a textbook, *Treatment of Malocclusion of the Teeth and Fractures of the Mandible,*[10] and documented several orthognathic surgical cases. Blair's book on *Surgery of the Mouth and Jaws* (Mosby) was also published in several editions and he also documented multiple osteotomy case. It appears that they were the first surgeon/orthodontist team whose work paved the way for the future. They recognized the importance of surgical and orthodontic collaboration and discussed pre- and postsurgical orthodontic treatment, timing and sequencing of surgery, and growth considerations. Most of Blair's early surgical experience was in the body of the mandible, which he approached through neck incisions. By 1915 he altered his approach to the vertical ramus of the mandible.

Kostecka, a Czech surgeon, led the mandibular surgery pioneering efforts in Eastern Europe and performed ramus osteotomies with a closed, Gigli saw approach while the French continued to favor subcondular osteotomies.[11] Although Kostecka's procedure could be done as an open or closed technique, there were many complications with both approaches including nonunion, relapse, nerve injury, scarring, and parotid fistulas.

By 1932 American surgeon Kazanjian reported a 2-stage mandibular body osteotomy technique, which was conducted through premolar extraction sites. He experienced infection when he attempted a single-stage (intraoral and

neck approaches) operation and reported better results when staging the procedure.[12,13] Dingman, another American, published on mandibular body osteotomies as well. He advocated preservation of the inferior alveolar nerve.[14,15]

In 1945 Sanford Moose, a U.S. surgeon, introduced an intraoral approach to the ramus of the mandible for correction of prognathism. Another American, Sloan, described a similar approach in 1951, and Moose published refinements of the technique in 1964.[16-18] By 1956 Robinson published on correction of prognathism via an extraoral vertical ramus osteotomy.[19,20] Thoma published on a similar procedure shortly after.[21] In 1954 Caldwell and Letterman proposed a vertical ramus osteotomy done through a neck incision and they reported good results.[22] They advocated decortication of the bone segments to promote wound healing. This maneuver was studied extensively by Boyne using tetracycline staining in a monkey model. Boyne's findings suggested that the maneuver was unnecessary for bone healing.[23] Caldwell, Haywood, and Lister published on the inverted L osteotomy primarily for mandibular advancement in 1968.[24]

Genioplasty

A German surgeon, Hofer, first described a genioplasty conducted on a cadaver in 1942.[25] It wasn't until 1957 that Trauner and Obwegesser published the intraoral horizontal osteotomy of the inferior border leaving the free segment pedicled to the lingual musculature.[26,27] Stability and outcome of this procedure was far superior to the free grafts suggested by Converse in 1950, who placed the bone grafts intraorally to help project the chin further forward.[28] Since then many modifications have been described to enhance the results of this procedure but the basic principle of a pedicled bone graft remains. Those who have published on this include Schendel, Triacca, Precious, and others.[29-31]

Segmental Maxillary and Mandibular Osteotomies

In 1959 an Austrian surgeon, Köle, published in the American literature on maxillary and mandibular subapical osteotomies.[32] These procedures were performed more commonly in Europe at the time while they were relatively unheard of in the United States. Cohn-Stock from Berlin initiated enthusiasm for segmental maxillary osteotomies, which he published in 1921.[33] Some consider him to be the father of maxillary osteotomy techniques.[34] Later reports by Wassmund, Axhausen, Immenkamp, Wunderer, Cupar, and others documented extensive experience with these and other osteotomies of both jaws by the Germans and Austrians.[33-40] A textbook co-authored by Reichenbach and Köle and published in 1964 served as the resource for many surgeons wanting to learn these techniques.[41] Although multiple authors described different soft tissue incisions, they all stressed the need for maintaining well-perfused vascular pedicles to the mobilized dento-osseous segments. There were concerns expressed about bone healing, soft tissue healing, and tooth survival but little non-human experimentation was evident at this time.

Sagittal Osteotomy

In 1953 Obwegeser performed the first sagittal osteotomy of the mandible and he reported this in 1955.[42] This operation was inspired by Schlossman, described by Perthes and Schuchardt, but completely described, performed, and published by Trauner and Obwegeser.[43-46] By 1959 Obwegesser had moved from Graz to Zurich and had accumulated considerable experience with the procedure. Although modifications of the procedure have been published by Obwegeser himself, multiple other surgeons have modified the procedure to fit their own needs, including Dalpont, Hunsuck, Epker, Bell, and others.[47-50] The major advantages of this operation were the lack of scar, because it was conducted transorally, and the wide surface area of cancellous bone, which helped promote healing and obviate the need for bone grafting.[51] The advantages of a transorally conducted ramus osteotomy were recognized by Obwegeser and the earlier pioneer Moose.[16]

Total Mandibular Subapical Osteotomies

Macintosh, an American who spent 2 years at Obwegeser's clinic in Zurich in the late 1960s, described a unique operation that mobilized and repositioned the entire mandibular dentoalveolar. This was published in 1973 and again in 1975 with Carlotti to demonstrate the procedure's efficacy for treating anterior open bite.[52,53] As with all operations, modifications were made by multiple other surgeons, including Booth and Buckley.[54,55]

Maxillary Osteotomies

The introduction of maxillary osteotomies lagged behind mandibular osteotomies. Von Langenback, a German surgeon of remarkable talents, originally published a technique for infracturing the maxilla unilaterally for tumor access in 1849.[56] Billroth was another early pioneer of maxillary mobilization for surgery access. He was a very popular Viennese surgeon whose image appeared on Austrian coins and stamps in honor of his surgical talents. There remains a beautifully restored meeting hall in Vienna bearing his name as a tribute to his surgical legacy. Cheever, an American, published what appears to be a down fracture of the entire maxilla in 1867.[57-59] This procedure too was done for tumor access. Other surgeons who published on maxillary osteotomies early on commented about the blood loss and difficulty with the operation.

In 1927 Wassmund from Berlin (a student of Cohnstock) published on complete maxillary osteotomy to correct post-traumatic malocclusion. During the operation he never released the posterior attachments of the maxilla to the pterygoid plates and relied on postsurgical traction to achieve the desired movement.[35,36]

Auxhausen, another Berlin surgeon, described osteotomy of the maxilla in 1934.[37] This is the first recording of complete osteotomy of the maxilla with the release of the pterygoid plates and repositioning. Most surgeons around the world would not undertake this type of surgery for fear of blood loss, necrosis, and difficulty performing the procedure. The early pioneers who performed this surgery used multiple vertical incisions on the buccal, or transfacial incisions to maintain blood supply. Some used palatal incisions as well and others staged the procedure.[56-64]

When the great wars occurred, there was tremendous need for facial reconstruction of the wounded and the disfigured survivors. Ganzer, Pichler, Gilles, Rowe, Killey, Kazanjian, Schuchardt, Schmidt, and many other surgeons on both sides of the Atlantic developed extensive experience caring for the facially disfigured as a result of these catastrophic events. The major beneficiaries of these horrific events were not the war injured but the patients with dentofacial and craniofacial anomalies who eventually benefited from the learning experiences created by the victims of war injuries. These war-related experiences further encouraged the development of facial osteotomies and orthognathic surgery for congenital and developmental problems.

It is not surprising that the decades from 1950 through 1970 were very productive times for many surgeons worldwide who recognized the functional and esthetic benefits of jaw repositioning surgery not just for the war injured or post-trauma patients but also for those with birth or developmental defects. This seemed to have occurred more in Europe than in the United States.

By 1959 Obwegeser recognized the importance of separating the pterygoid plates and completely mobilizing the maxilla for success with maxillary surgery. He encouraged the use of bone grafts in the defects to help with healing.[43] By 1969 he had gained enough experience with complete mobilization and repositioning of the maxilla as well as utilizing a circumvestibular incision, that he published the technique in English.[65] It is notable that several of the cases required segmentation of the maxilla in 2 pieces. Converse and Shapiro and Dingman and Harding described performing LeFort I osteotomies in 1951 and 1952.[15,60] Gilles and Rowe also published on total maxillary segmental osteotomy in 1954 but they relied on postsurgical elastic forces to reposition the maxilla.[61] Karl Hogeman from Malmo was another early pioneer of LeFort I osteotomy, and most of his early experience was with cleft lip and palate patients.[66] He accumulated enough experience by 1973 that he and Willmar published a report on more than 100 patients undergoing the procedure.[67] Most others shied away from maxillary osteotomies in the United States. The diagrams of Converse's operation leave doubts about the survivability of the maxilla with both palatal and buccal flaps being elevated as extensively as is illustrated. Converse mentions in his article incomplete bone coverage at the completion of surgery and problems with bone sequestration following surgery; however, he did not indicate loss of teeth or substantial amounts of bone following this operation. He did not publish the postoperative photographs but provided only a short description of the postoperative course.[60] Dingman's approach to LeFort I osteotomy was confined to a vestibular incision, bone cuts and then impression trays, cement, and brute force as well as external traction to complete the repositioning effort. Dingman offered postoperative photographs with external traction in place approximately 3 weeks following surgery.[15] These two pioneering efforts set the stage for Obwegeser's later visit to the United States.

Posterior Maxillary Osteotomies

Schuchardt, a student of Wassmund's who relocated to Hamburg, introduced a two-stage posterior maxillary osteotomy technique for closure of anterior open bite in 1955.[62] Schuchardt was obviously aware of the esthetic issues of trying to close open bite with anterior maxillary osteotomies only and proposed that moving the posterior maxilla superiorly would facilitate closure of the bite while maintaining good upper lip to incisor relationships. During the first stage of Schuchardt's posterior maxillary osteotomy a palatal flap and bone cuts were made. The palate was sutured and three weeks later the buccal osteotomies were performed as well as pterygoid maxillary separation. A mallet and soft wooden wedge were then used to drive the posterior maxilla superiorly into the sinus. When the procedure was done with local anesthesia, the patient was asked to bite forcefully to help with the mobilization. By 1960, Josef Kufner from Prague published a single-stage posterior maxillary osteotomy for open bite closure. This was written in his native Czech language and not many people were aware of the contribution until he published and presented it in English in 1968 at the 3rd International Congress on Oral Surgery.[68,69] The approach was all buccal with transantral access to the palate. The virtues of a transantral approach to maxillary osteotomies was later described in detail by Perko.[70] The usefulness and stability of this procedure was further elaborated by West and Epker and Stoker and Epker.[71,72]

Complete Maxillary Osteotomy in Multiple Segments

Mobilization of the entire maxilla at LeFort I level and then segmenting it had been described by multiple pioneer surgeons including Auxhausen, Gilles, Rowe, and Obwegeser as well as many others. Most of the early reports involved cleft palate or trauma victims. During the evolution of orthognathic surgery, advancement, widening, leveling, and space closure in the maxillary arch were recognized issues that were addressed and the details of the procedure were later described and illustrated thoroughly by Epker, Wolford, Bell, and others.[73-75]

Simultaneous Mobilization of the Entire Maxilla and Mandible

Hogeman and Obwegeser were early pioneers of simultaneous mobilization of the entire maxilla and mandible.[66,76]

Obwegeser indicates that his first experience took place in 1965.[76] Köle was a champion of simultaneous maxillary and mandibular osteotomies but his experience did not involve complete mobilization of both jaws.[32] Mohnac, an American surgeon, published his experience with simultaneous mobilization of the maxilla and mandible in 1965. Like Köle, his cases did not involve complete mobilization of the entire maxilla and mandible conducted simultaneously.[77]

In 1975 two Americans, Gross and James, reported their experiences with simultaneous mobilization of the entire maxilla and mandible.[78] Lindorf and Steinhauser from Ehrlagen reported their experiences in 1978.[79] By the early 1980s the timing and sequencing of simultaneous complete mobilization of the maxilla and mandible had been described in detail and many Americans adopted the procedures, recognizing the benefits.[80-83]

Higher Level Mid-face Osteotomy

The development of higher level mid-facial osteotomies was much slower in comparison to the lower level procedures. Gilles and Harrison are credited with publishing the first attempt of a LeFort III osteotomy accomplished in 1950.[84] Although Gilles performed several of these procedures on post-trauma and congenital malformation patients, he indicated that the complexity and difficulty of the procedure should carefully be considered before it is attempted.[61,84] There were several others who pioneered high level mid-facial osteotomies, including Burien who was assisted by Kufner. They attempted LeFort III osteotomy in 1958 in Prague.[85] In 1967, Paul Tessier stunned the world when he presented very impressive results of LeFort III osteotomy for patients with Crouzon and Apert syndrome as well as malunited mid-facial fractures. At the same time he also introduced the transcranial approach to orbital hypertelorism correction.[86-88] The enthusiasm created by his and Obwegesser's accomplishments inaugurated the development of craniofacial surgery.

In the decade between 1970 and 1980 multiple surgeons described a variety of high level mid-facial osteotomies, including Murray, Converse, Edgerton, Epker, Wolford, Psilakis, Henderson, and Jackson.[89-97] Sailer from Zurich described combining LeFort I with LeFort III mid-facial osteotomies to address anterior open bite simultaneously with mid-face advancement.[98]

The Discovery Phase

The pioneering phase of orthognathic surgery demonstrated that surgery for repositioning the facial skeleton was possible. During the discovery phase, surgeons learned the indications and contraindications of these interventions, the biologic and physiologic basis of these procedures were delineated, and instrumentation was developed, manufactured, and sold to facilitate the performance of surgery. Treatment outcomes were studied extensively and safe anesthetic techniques were also developed. Refinements of the basic techniques described by the pioneers were numerous.

Nothing was more seminal to the development of orthognathic surgery worldwide than Obwegeser's visit to the Walter Reed Army Hospital in Washington, D.C. This occurred in June of 1966 when Robert Shira invited Obwegeser to lecture about the techniques of orthognathic surgery and other maxillofacial surgical procedures that he pioneered. Shira was then a U.S. Army General and oral and maxillofacial surgeon who was impressed with Obwegeser's work. He invited more than 500 U.S. oral surgeons to the lectures and the event breathed new life into a fledging specialty in the United States. At that time oral and maxillofacial surgery was under siege by a group of postwar influential and disgruntled competitors who tried desperately to discredit the specialty and bar its practioners from hospitals through their influence with hospitals and with hospital accreditation groups. The stimulation of Obwegeser's presentations empowered the specialty with new meaning and relevance to health care. With levelheaded leadership and perseverance by people like Fred Henny, R.V. Walker, Scott McCallum, Elmer Bear, and Daniel Laskin this specialty resurrected itself in health care and gained increased relevance within hospital communities.

During Obwegeser's visit he demonstrated his famous sagittal split osteotomy for both advancement and setback of the mandible. He also demonstrated segmental maxillary and mandibular surgery as well as LeFort I level maxillary osteotomy. These lectures also included many cleft and preprosthetic surgical applications.

After Obwegeser's presentation in 1966, it didn't take Americans long to accumulate experience with the procedures demonstrated. Walker, Bell, Costich, White, Hinds, and many others quickly adopted Obwegeser's techniques in their practices. Just as important, they began to publish their experiences.

Within two years of Obwegeser's lecture, White published on his experience with sagittal osteotomy in 17 patients followed for more than a year and Bell published on anterior maxillary osteotomy in a similar time frame.[99,100] Kent and Hinds also published on anterior maxillary and mandibular osteotomies.[101] Friehofer and others began to examine the results of patients treated in Zurich.[102,103]

After Obwegeser's visit, an American tradition had a breakthrough. Although Vilray Blair and Edward Angle both published in the early 20th century and indicated the importance of interdisciplinary collaboration, they never published together. Prior to Obwegeser's visit, Converse and Shapiro and later Converse and Horowitz published together.[60,91] After Obwegeser's visit, a cascade of teams of surgeons and orthodontists began publishing in the United States. These included R.V. Walker and Phelps Murphy, William Bell and Tom Creekmore, William Ware and Don Poultan, Bruce Epker and Chuck Fish, Raymond White and William Proffit, Larry Wolford and Frank Hilliard, Roger West and Bill McNeil. By publishing in tandem, these discoverers were able to establish the credibility of orthognathic surgery to both the surgical and orthodontic communities. From these early reports, techniques were modified, safety

of treatment improved, problems were identified, instruments were developed, anesthetic protocols were defined, and studies ensued to determine and improve outcomes.

The benefits of orthognathic surgery were recognized and extended to the preprosthetic populations early on. Kazanjian published on the correction of mandibular prognathism to assist denture construction in 1932.[12] West and Burk published on using maxillary osteotomy techniques and applying it to the preprosthetic population.[104] This was followed later by publications involving the posterior maxilla.[105] Eventually, Sailer and others published on using orthognathic surgery in conjunction with bone grafting and implant rehabilitation simultaneously to improve the outcomes of preprosthetic patients.[106]

Pivotal to the worldwide acceptance of orthognathic surgery as a legitimate treatment option for dentofacial and craniofacial abnormalities were the works of William Bell, whose revascularization studies provided a biologic basis for many of the commonly performed surgical procedures. Mohnac's communication to Bell in the late 1960s about the vascularity of the maxilla stimulated Bell to pursue investigations of flap design applicable to LeFort I osteotomy. Using the microangiography techniques of Rhinlander, Bell and many of his students and colleagues studied wound healing following facial osteotomies.[107-111] Without Bell's works and investigations, skeptics' doubts and questions about the soundness of orthognathic surgery would still be looming.

Orthodontist William Proffit studied and published extensively on the physiologic adaptations that occur with orthognathic surgery and the stability of the changes. Bite force changes, lip and tongue pressure changes, airway and breathing pattern changes, neurosensory changes, speech and velopharyngeal function changes, and psychosocial changes were studied extensively.[112] In addition to Proffit, there were multiple other investigators who pursued these same studies. Proffit was awarded an NIH grant to study the long-term stability of orthognathic surgery in 1979 and this grant remained funded for more than 35 years. Throughout the lifetime of this grant, there were more than 300 manuscripts and a similar number of abstracts published on the subject. Proffit teamed with biostatistician and clinical researcher Ceib Phillips, as well as a cadre of others, and learned and shared more about the stability of orthognathic surgery than is even known about conventional orthodontics.[113,114] The data bank built as a result of this effort includes the records of more than 8,000 patients at the University of North Carolina.

Another monumental step toward the acceptance of orthognathic surgery was the publication of major textbooks dedicated to the subject. Liberally and beautifully illustrated, these classic texts made it easier for other surgeons to follow the steps of orthognathic surgery and avoid the pitfalls of the early pioneers. The three-volume text by Bell, Proffit, and White and the textbook by Epker and Wolford are highly relevant to the development of orthognathic surgery.[73,74] Prior to 1980 there were two textbooks published on orthognathic surgery. Steinhauser cites the textbook of Reichenbach, Köle, and Schuchart as the authoritative reference for European maxillofacial surgeons.[41,115] In 1972 Hines and Kent from Houston published the first textbook on orthognathic surgery that was written in English.[116] Bridging the gap from 1980 until recently were four additional texts by Proffit and White and by Epker and Fish that documented advances in treatment and research.[117-120] Today there are multiple texts published in a variety of languages on orthognathic surgery, including a recent comprehensive treatise by Posnick.[121]

Throughout the 1970s and 1980s, there were multiple modifications to surgeries described, surgical and orthodontic protocols were developed, and instruments were designed and manufactured. Although the Europeans pioneered the development of orthognathic surgery, Americans and Europeans took it to the next level primarily by promoting surgical and orthodontic interaction and in developing reliable and well-designed instruments and power equipment to conduct these operations.[122,123]

Another seminal step in the acceptance of orthognathic surgery was the continuing education efforts via seminars, lectures, and mini residencies conducted by Bruce Epker, Larry Wolford, William Bell, Raymond White, Raymond Fonseca, and these surgeons included their orthodontic collaborators Charles Fish, Frank Hilliard, William Proffit, Harry Legin, David Hall, John Casko, and Robert Vanarsdale in the education of surgeons and orthodontists. In no other area of interest in oral and maxillofacial surgery has there ever been as much continuing education offered.

Bruce Epker is a prolific writer and speaker whose works helped to demystify orthognathic surgery. He confronted the issues of importance with surgical techniques, instrumentation, stability, and adaptation with the methodical approach of a scientist as well as a clinician. Analysis of results with data and statistical review were critical parts of his works.

Larry Wolford, a very talented surgeon with gifted dexterity, often combined TMJ surgery with orthognathic surgery and introduced total alloplastic joint replacement with orthognathic surgery.

The charismatic Robert V. Walker was responsible for recruiting William Bell and Bruce Epker to the faculty at the University of Texas Southwestern Health Science Center in Dallas, and to the oral and maxillofacial surgery faculty of Parkland Memorial Hospital and John Peter Smith Hospital. He provided a pathway and atmosphere for these very talented orthognathic surgeons to grow and develop professionally. His efforts as well as those of Bell and Epker, lead to the training of an entire generation of orthognathic surgical leaders including Roger West, Raymond Fonseca, Douglas Sinn, Timothy Turvey, Ghali Ghali, Stephen Schendell, Richard Finn, Caesar Guerrero, Scott Boyd, and many others.

The material to be published about orthognathic surgery during the decades between 1980 and 2000 was so voluminous that traditional scientific journals could not absorb it all. Orthodontist Robert Vanarsdale and surgeon Raymond White initiated a special journal, published by

Quintessence, *Adult Orthodontics and Orthognathic Surgery,* which encouraged publication and dissemination of the most current findings of orthognathic surgery.

Americans were hungry to learn orthognathic surgical techniques and many flocked to Europe to observe surgery performed by Obwegeser. However, there were multiple sites other than Zurich that were open and receptive to having visitors come to learn, including the unit in Nymejgen headed by Paul Stöelinga and Henk Tiedeman. For many years they hosted visitors from around the world to observe and participate in orthognathic surgery. Jaque Dautrey, a Frenchman from Straussburg, was a gracious host to many visitors. He was a clever innovator who not only was a gifted surgeon but also was highly instrumental in promoting orthognathic surgery in France and Europe. His colleague Maxine Champy was another maxillofacial surgeon/innovator who developed small plating systems for the facial bones and promoted their use in orthognathic surgery. Jean Delaire from Nante possessed a keen intellect and developed many facial analysis methods. He was a very talented cleft surgeon and also developed treatment algorithms for patients with facial bone abnormalities.[124,125] He commonly hosted visitors as well. Rudy Fries from Lientz, Frans Harlë from Kiel, Wilifred Schilli from Freiberg, Derek Henderson and Kersheed Moose from Cannesburn, Norman Rowe from Roehampton, and Rolf Ewers from Vienna were also frequent hosts for surgeons wanting to learn orthognathic surgery and other maxillofacial surgical techniques. Paul Tessier from Paris, the father of craniofacial surgery, was also a gracious host to many visiting surgeons wishing to learn his techniques including craniofacial and orthognathic surgery.

The origin of the term "orthognathic surgery" can be traced to Harold Hargis. Hargis was a U.S. Army oral and maxillofacial surgeon who was fortunate to be assigned to duty in Obwegeser's clinic in Zurich in the late 1960s. While there, Hargis shared many activities with Emile Steinhauser, Obwegeser's first trainee, and Bruce MacIntosh, another American who was sent to Obwegeser's unit by Fred Heney, the chairman of oral and maxillofacial surgery at Henry Ford Hospital in Detroit. After participating in many of the exciting jaw surgeries conducted in Zurich, Hargis coined the term "orthognathic surgery" (ortho-straight, gnathic-jaw). Although he frequently used the term (as did many clinicians), it never appeared in the literature until the late 1970s. Hargis returned from Zurich, completed his army career, and became the chairman of oral and maxillofacial surgery at the University of California-Los Angeles.

Walter Lorenz was a German-born American citizen who began a surgical instrument company in New York City. Initially he traveled from office to office, selling and servicing his products. His outstanding support for the oral and maxillofacial surgical community allowed him to parlay his entrepreneurial skills into becoming one of the leading oral and maxillofacial surgery instrument distributors in the world. From his modest early setup he developed a multinational corporation which prided itself in manufacturing high quality instruments with ergonomic designs that permitted orthognathic and craniofacial surgery to be conducted. He employed instrument designers who worked with surgeons to improve the conduct of orthognathic and craniofacial surgery. Obwegeser's original instruments were sold exclusively by the Walter Lorenz company in the United States. Now the only true Obwegeser equipment sold in the United States is by the KLS Corporation of Jacksonville, FL, which specializes exclusively in craniomaxillofacial surgical instruments.

Although there were early references to soft tissue surgery being a useful adjunct to orthognathic surgery, its popularity became apparent in the late 1980s and 1990s.[126,127] This was an era when many U.S. oral and maxillofacial surgeons were introduced to the benefits of esthetic soft tissue procedures and rhinoplasty. Although there was stimulation to learn and develop soft tissue surgery from within the OMFS community, external stimulation came from the American Academy of Cosmetic Surgery and the American Academy of Facial Plastic Surgery. Both groups sponsored educational opportunities that allowed oral and maxillofacial surgeons to learn the techniques and adapt them to their patients. Many surgeons popularized simultaneous orthognathic surgery and soft tissue surgery efforts. Among them were Bruce Epker, Peter Waite, Joe Niamtu, John Griffin, Kevin McBride, Douglas Sinn, Ghali Ghali, and orthodontist David Sarver. [126-133] These surgeons explored the benefits and pitfalls of simultaneous rhinoplasty and other soft tissue procedures performed with orthognathic surgery. Blepharoplasty, lip surgery, face-lift, forehead lift, and submental lipectomy with platysma tightening were all cited as procedures that could be done concomitantly with orthognathic surgery without wound healing issues and with major benefit of reducing the time of recovery.

Approaching the turn of the 21st century, most surgeons recognized the importance of esthetics and function in the diagnosis and treatment planning for orthognathic surgery. Johan Reyneke, from Johannesburg, and now Cape Town, published a book dedicated to the basics of diagnosis and treatment planning, emphasizing the importance of the most esthetically pleasing placement of the maxillary incisors relative to the lip. The book is beautifully illustrated by the author, emphasizing the importance of soft and hard tissue relationships and the benefits of occlusal plane rotation.[134]

Computers and technology have impacted every facet of life and orthognathic surgery is no exception. Beginning with Geoffrey Walker's introduction to the benefits of digitizing cephalometric radiographs, cephalometry's use in orthognathic surgery planning and analysis of results has advanced substantially.[135] Conventional radiographs have given way to digital radiographs, and now cone beam CT imaging is improving diagnostic capabilities. Blending three-dimensional radiographic images and magnetic resonance scans with three-dimensional photography is a quickly evolving field of interest that will have an impact on orthognathic surgery in the future. By 1980, Eisenfeld and Mishelevich were demonstrating the use of computers for

data analysis with orthognathic surgery patients.[136,137] Corporate America has contributed to the commercialization of computer software products to facilitate cephalometric data organization and planning of treatment. Dolphin Imaging, SAS Institute, and Quintiles are examples of U.S. companies that have contributed to the advancement of orthognathic surgery treatment planning, data storage, and analysis of results.

Gatano and Xia from Houston and Swennan from Belgium independently developed systems utilizing three-dimensional imaging to assist virtual planning for orthognathic surgery. [138-140] Andy Christiansen, who founded Medical Modeling Corporation in Golden, CO, quickly embraced the technology and made virtual treatment planning available to all U.S. surgeons. Using 3D CT scans of the face and teeth and 3D photographic images, the latest technology permits planning without plaster study modes or hand-fabricated acrylic splints. Cutting guides and customized plates and screws are other examples of how this technology is revolutionizing orthognathic surgery.[141] Christiansen also made available the production of accurate stereolithic skull models from 3D CT scans. This technology employs 3D printers, computer technicians, and simulations that allow surgeons to plan treatment in all dimensions. Although it is time-saving and is less messy than conventional treatment planning, the expense and need for technological support is substantial. The accuracy has been tested in a limited capacity and it seems favorable for the conduct of accurately planned orthognathic and craniofacial surgery.

Intraoperative navigation is another technologic advance that is impacting surgery with the hopes of improving accuracy. Its efficacy has been realized in tumor surgery and trauma and is being tested in orthognathic surgery.[142-144] Endoscopically assisted surgery is an additional technology impacting the conduct of orthognathic surgery.[145]

Orthodontist Lucia Cevidanes must be cited for her ingenious work of calculating size, shape, and volumetric changes as well as positional and remodeling changes of soft and hard tissues following orthognathic surgery. Utilizing 3D cone beam CT scans, she has developed methods of analysis that will provide invaluable understanding to adaptive changes associated with orthognathic surgery.[146] Nooreyazdan and Trotman, who are also orthodontists, are using 3D photography to further delineate soft tissue esthetic changes associated with orthognathic surgery.[147] These are more examples of how technology is improving the predictability of orthognathic surgery.

As with every other aspect of craniomaxillofacial surgery, bone plates and screw technology has had a significant impact on the conduct of orthognathic surgery and patient care. Without the need for intermaxillary fixation, orthognathic surgery has become a more attractive treatment option for patients and families. Prior to Luhr's introduction of compression bone plates and screws, primitive bone plates and screws existed (Collison, Robinson, Sampson) for maxillofacial surgery but were seldom used for anything other than trauma. As Luhr's work progressed, compression plates and screws were developed for facial use.[148-150] Michelet, Lodde, and Champy are credited with the development of miniature stainless steel bone plates and screws for maxillofacial fracture use.[151,152] In 1974 Spiessel published on use of screw fixation for stabilizing sagittal ostetomies.[153] Spiessel's technique included transfacial placement of the screws, but later others described transoral placement with good results.[154] In 1982 Steinhauser discussed the use of bone plates and screws for orthognathic surgery and by 1986 he had developed an all-titanium system for orthognathic surgery use.[155,156] Many surgeons are credited for their efforts in developing the rationale, instrumentation, and usage of this exciting breakthrough, including Van Sickles, Jeters, Härle, Terry, and Tucker.[157-160]

In some countries it is customary to remove all metallic devices at the completion of wound healing. The Finns developed biodegradable bone plating and screw systems to permit orthognathic surgery to be accomplished without the need for a secondary operation to remove the hardware. Surronen and Linquvist are credited for their works with the development of polylactate bone plates and screws for application during orthognathic surgery.[161,162] The efficacy of using bioresorbable materials for stabilizing facial osteotomies has been studied by many and found to be equally successful when compared to titanium.[163-166] Cost, difficulty with insertion, and instrumentation are issues impeding the advancement of this technology.

The facial application of distraction osteogenesis, which was resurrected by Illizaroth as a viable orthopedic method of limb lengthening, was initially introduced by Snyder in 1973.[167-170] Almost two decades later, McCarthy, Bell and Guerrero, and many others began promoting this concept as an alternative to orthognathic surgery.[171,172] Tairov from Tajikistan was an early pioneer of midfacial distraction osteogenesis who dates his introduction to 1977.[173] The promoted benefits of these techniques were: less invasive surgery, no need for bone grafting, and less morbidity. McCarthy and Guerrero and Bell published textbooks documenting the biologic and physiologic basis of this approach and demonstrated many successfully treated cases.[171,172] The level of sophistication of results demonstrated by Guerrero in his text are unsurpassed, and clearly he has mastered the technique better than most. Careful planning, intensive postoperative monitoring, and attention to the details of esthetics and occlusal function are the requirements for success with these techniques. Numerous contributions by many talented surgeons including Walker, Smith, Cohen, Polly, Rachmiel, Wangerin, Hoffmeister, MacCormick, Chin, and many others are testimony to the popularity and efficacy of the technique.[174-182] Its exact place in routine orthognathic surgical applications remains under investigation. When initially introduced, the distraction devices were bulky and awkward and were transfacially placed, leaving obvious scarring. Today, most devices are sleek (in comparison) and are transorally placed or placed in the hair-bearing area of the scalp. Molina's claim that the technique signals

a farewell to major facial skeletal surgery is yet to be realized.[183] Most agree that the cleft- and syndrome-involved populations are the major beneficiaries of distraction osteogenesis techniques.

The application of orthognathic surgery to improve disease processes is yet another recent recognition of the versatility of orthognathic surgery. Powell and Riley, both otolaryngologists who were disciples of William Ware and Roger West, were early advocates of orthognathic surgical techniques to improve the symptoms of obstructive sleep apnea. They published that these techniques could be applied to patients with airway issues, with favorable changes.[184] Waite reported similar findings.[185] The obstructive sleep apnea population can be substantially improved with orthognathic surgery. More recently, Boyd and Bundell have assembled convincing data that demonstrates that bimaxillary advancement has the best cure rate for obstructive sleep apnea over other treatment modalities.[186,187]

The psychosocial aspect of orthognathic surgery is a fascinating subject that has been studied by many, including Kiyak, Broder, and Phillips.[188-194] Most agree that if patients perceive the changes of treatment to be positive, self-concept and self-image changes are also positive. Orthognathic surgery seems to have a positive impact on quality of life and helps people attain their potential.

Conclusion

Orthognathic surgery is a vibrant part of the health care system offering patients an opportunity to improve their situation. As the functional, esthetic, and psychosocial benefits of surgery have been realized, its popularity has increased. The length of time in treatment is substantial and the expense is considerable. Moving forward, surgeons must develop protocols for reducing treatment time, improving accuracy and predictability, and keeping expense under control. Constant reinforcement to government officials and commercial health insurance carriers is critical to keep this treatment available to those in need.

Treatment Planning in Orthognathic Surgery

JEFFREY C. POSNICK

Importance of Proportions and Symmetry to Establish Ideal Facial Esthetics

Fundamental Concepts

We use the word *proportion* to describe the comparative relationship between parts of things in an attempt to describe harmonious and disharmonious relationships between different parts of a whole.[1] The first clear, and still unsurpassed, definition of what has become known as the *Golden Ratio* was given by Euclid of Alexandria around 300 BC.[2] Euclid is best known as the founder of geometry, a branch of mathematics that uses deductive reasoning.[1] Euclid defined a harmonious proportion derived from the simple division (sectioning) of a line into what he called its "extreme and mean ratio." In Euclid's own words: "A straight line is said to have been cut in extreme and mean ratio when, as the whole line is to the greater segment, so is the greater to the lesser." [2] Stated in another way, if the ratio of the length of a line (AC) to that of the greater segment of the line (CB) is the same as the ratio of the segments AB to CB, then the line "has been cut or sectioned" into "extreme and mean ratio" (Figure 2-1), which Euclid named the golden ratio. Interestingly, this ratio represents a never-ending (irrational) number 1.6180339887… . The common symbol for the golden ratio is the Greek letter thau (τ) the meaning of which is "the cut" or "the section." It was later renamed phi (ψ) after the Greek sculptor Phidias who was said to have employed it.[3]

Webster's Unabridged Dictionary defines beauty as "the quality which makes an object seem pleasing or satisfying in a certain way." The golden ratio is said to be an important feature found in many of the classically beautiful works of art, architecture, objects designed for human use, the music of the great composers, and most of what is found in nature (Figures 2-2 and 2-3).[4] Objects of "classic" beauty and "attractive" forms found in nature consistently reveal the golden ratio.[5,6] An important question, however, is: Does form and function really follow? Richard Buckminster Fuller, a great American architect and writer (1895-1983), once stated, "When I am working on a problem, I never think about beauty. I think only of how to solve the problem. But when I finish, if the solution is not beautiful, I know it is wrong."[5]

In their simplest form, attractive facial images, whether in drawings, photographs, or in reality seem to incorporate a consistent symmetry of proportion. It has been stated that most people have a common appreciation of what is attractive when they visualize it even if they cannot quite explain why. This has been demonstrated across cultures and throughout the ages, and has been relatively consistent in art.[7] A strict mathematic formula may not be required to define classic attractiveness, but the question remains: Can the golden ratio (a mathematic formula) be found in these commonly agreed upon beautiful images (Figure 2-4)?

Current Philosophy

From Pythagoras, Polykleitos, Plato, Aristotle, Euclid, Vitruvian, Galen, Fibonacci, Piero, da Vinci, and Pacioli, to the more recent Le Corbusier and all of their disciples for over two millennia, we have learned that the proportions of the parts to the whole affect the observers' impression of beauty and attractiveness.[8,9] From the premier artists, architects, and designers throughout the centuries, we know that mirror image symmetry and the harmony of proportions matter when judging facial esthetics. Studies in each of these fields have also shown that the precise (to the millimeter) achievement of an exacting mathematic ratio is not sufficient or even preferred for the creation of the most important end products, but an approximation of the golden ratio is.

In the realm of facial esthetic and reconstructive surgery, clinicians from all involved fields have from time to time attempted to match facial esthetics to a strict mathematic model (ex normative cephalometric measurements) without always considering individual biologic variations

and esthetic nuances (Figure 2-5).[7,10-15] When doing so, they have often fallen short of the objective. In 1984 Ricketts reported on a significant number of golden proportions when analyzing the facial skeleton and overlying soft tissues.[16-18] He was a strong advocate of the use of these "divine proportions" as a guide for planning the correction of dentofacial deformities (orthognathic surgery) (Figure 2-6). The validity of Ricketts' approach to facial analysis for the correction of jaw deformities has been questioned by some while supported by most.[16-18] For the clinician who is asked to correct a congenital or developmental craniofacial or maxillofacial deformity, attention is directed to both form and function. As Buckminster Fuller stated, "rarely are the two objectives divergent." In the achievement of a harmonious face, attention is directed toward the practical objectives of improving the upper airway and occlusion, which will effect speech, swallowing, chewing, and breathing. Facial esthetic perfection is not a specific millimeter distance or degree of angulation but a visual impression at conversational distance in three-dimensional life.[19-24] At the same time, neither "divine proportions" nor biologic realities or the patient's personal preferences can be ignored in the process. Rediscovery of the importance of achieving an approximation of Euclidean proportions and mirror image symmetry as a treatment objective in the correction of dentofacial deformities remains an essential step in the education of all students of the human face.[25-32]

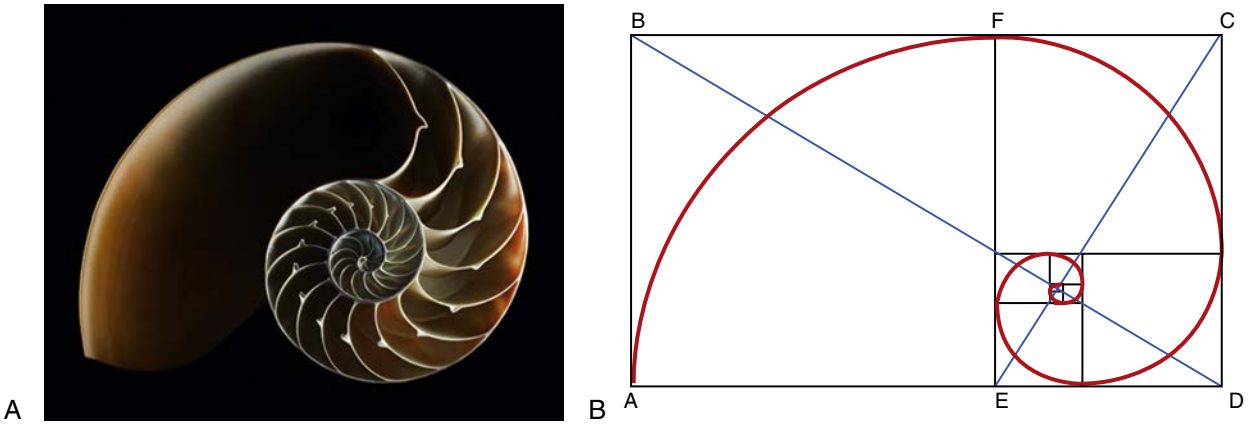
Clinical Evaluation of the Dentofacial Deformity Patient

Background

For the correction of a dentofacial deformity, the clinician's esthetic sense and knowledge of patient-specific biologic and psychosocial factors must be condensed into precise millimeter measurements and angular changes that are then accomplished on the surgically sectioned (osteotomized) maxilla, mandible, and chin with a goal of establishing Euclidean facial proportions and improved functions.[25, 33-40] Although there is no singular normative table of numbers or a formula that can be relied on to direct the surgeon to the golden ratio, a methodical approach is nevertheless required. The clinician's vision is based on: fundamental



• **Figure 2-3** **A,** Photograph of the chambered nautilus, demonstrating structural anatomy. **B,** The golden ratio as found in nautilus spiral structural anatomy. esthetic principles; biologic realities of the tissues; patient specific dysfunctions (i.e., chewing, swallowing, speech articulation, breathing, lip closure/posture); and treatment preferences (i.e., timing, techniques, and extent of intervention).[25] It is expected that a degree of uneasiness about the end result will be felt by both the operating surgeon and patient/family in this process. With clinician experience, this creative tension for the surgeon and patient/family uncertainty is reduced but can never be fully alleviated prior to surgery.

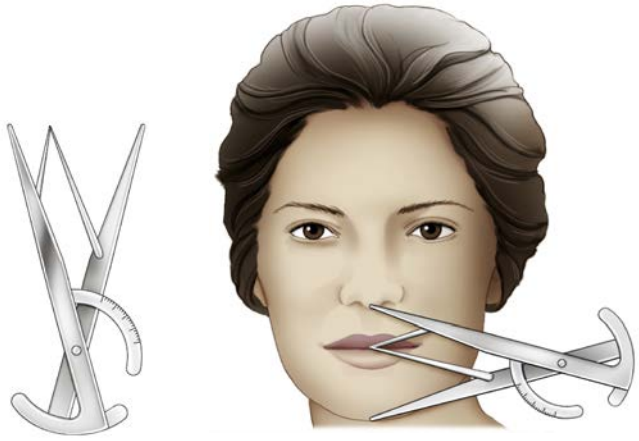
By the time of the preoperative direct face-to-face planning patient examination by the operating surgeon, several evaluations will have already been carried out. Review of relevant medical data, combined with facial photographic, radiographic, and dental analysis should be fresh in mind. The patient's facial structures are examined while he/she is upright and sitting in the natural head position (NHP). This is considered the most rational, physiologic, and anatomic orientation of the head and neck for evaluating the face, jaws, and teeth.[33,41-44] This is generally not the head and neck position that the patient with a dentofacial deformity naturally relaxes into; the surgeon must place the patient in the NHP. The teeth are also placed in centric relation (CR) or with a normal freeway space and the lips are relaxed (not pursed together). The surgeon then observes the patient three-dimensionally at different angles in both repose and with dynamic facial expression. It is from this position (NHP) that the surgeon makes crucial decisions of what facial features are abnormal and will require surgical reorientation.

Global head and neck assessment includes evaluation of the following aspects:

1. **Quality of the overlying soft tissue envelope** of the head and neck. The surgeon must recognize distortions of the soft tissue envelope that will self correct once the skeleton is reconstructed versus intrinsic soft tissue malformations/deformities that will not (i.e., hypoplasia, hyperplasia, effects of trauma and aging).
2. **Symmetry and harmony of the upper facial skeleton** (i.e., cranial vault, orbits, nasofrontal process, and zygomatic arches). Although most individuals with a dentofacial deformity have a relatively normal upper facial skeleton, some do not (i.e., hemifacial microsomia, Treacher Collin syndrome).
3. **Morphology of unique esthetic units of the face** (i.e., external nose, external ears, periorbital soft tissues)
4. **History of temporomandibular joint disorder** (TMD) symptoms and signs and documentation of any current limitations in mandibular range of motion



• **Figure 2-6** Human face with use of the Rickett's divider confirming the golden ratio. (Reprinted from Posnick JC: *Orthognathic surgery treatment planning. Orthognathic surgery: Principles and practice*, St Louis, 2014, Elsevier.)

5. **History of cervical spine symptoms and signs** and documentation of current safe neck range of motion
6. **Symmetry and harmony of the lower facial skeleton** (i.e., maxilla, mandible, chin region). The dentofacial deformity patient will have significant variations from normal in this region of the craniofacial skeleton
7. **Dental rehabilitative needs** (i.e., restorative and periodontal) as well as orthodontic aspects

Evaluation of the Overlying Soft Tissue Envelope

An individual with a routine developmental jaw disproportion will generally have a normal overlying soft tissue envelope, which is simply distorted by the underlying skeletal disharmony. On the other hand, normal variations in thickness and quality of the skin, density of sweat glands, fat distribution, and degree of pigmentation are to be expected. An example of soft tissue distortion (not deformity) is seen in maxillomandibular deficiency (i.e., short face growth pattern). The impression of "chubby cheeks" and excess fat in the neck is typical. With maxillomandibular (skeletal) advancement and vertical lengthening the normal facial contours/curvatures will be restored. There are exceptions where the soft tissue envelope is directly affected due to a malformation (e.g., Treacher Collins syndrome, hemifacial microsomia, cleft lip, hemifacial hypertrophy), previous trauma (burns, lacerations), or scarring after infection. When a jaw deformity is associated with a syndrome, clefting, or a soft tissue traumatic deformity, facial esthetics and head and neck functions are further negatively impacted and the soft tissue envelope may require special consideration.

Evaluation of the Upper Facial Skeleton

In most individuals presenting with a dentofacial deformity, the upper facial skeleton (i.e., cranial vault, orbits, and zygomas) will be reasonably symmetric and proportionate. There are exceptions due to congenital anomalies (craniofacial microsomia, Treacher Collins syndrome, Apert syndrome, Crouzon syndrome), traumatic events (molding in infancy, torticollis, previous facial bone fractures with malunion), and/or tumors (fibrous dysplasia, neurofibromatosis). In routine dentofacial deformities, minor upper face skeletal variations from normal are expected and may include differences in convexity of the forehead (anterior cranial vault) and/or prominence of the supraorbital ridge (anterior frontal sinus wall bulging). Minor mirror image asymmetries in the upper face are also common (external ear position, eyebrow height, CN VII dysfunction). When present, facial variations and asymmetries should be documented through medical quality photographs and then discussed with the patient/family from the outset.

In the presence of a dentofacial deformity the cheeks/cheekbones may appear "bigger or smaller" than they actually are. Correction of the jaw deformity toward Euclidian proportions is likely to change the observer's impression. This phenomenon is typically seen in a maxillary deficiency (i.e., relative mandibular excess) jaw growth pattern (Figure 2-7). Once the maxilla is advanced and rotated clockwise in conjunction with mandibular ramus osteotomies (clockwise rotation), the apparent flat cheekbones, deficient infra-orbital rims, and enlarged nose typically disappear.

Evaluation of Unique (Discrete) Facial Esthetic Units

There are discrete esthetic units of the face that stand out and should be independently considered, including the periorbital (eyelid) regions, external ears, and the nose. The periorbital (adnexal) tissues may be of special concern as a result of congenital hypoplasia (Treacher Collins syndrome, hemifacial microsomia, upper eyelid ptosis), previous trauma (medial or lateral canthal injury, nasolacrimal apparatus injury, upper or lower eyelid injury), or the normal aging process (descent, deflation, ptosis). The individual's eyelid appearance may either add a sparkle to or be a distracting focal point of the face. The external ears display considerable variation in size, shape, extent of protuberance, and asymmetry. The external nose will display a wide range of esthetic variation due to unique bony, cartilaginous, and soft tissue anatomy. In the presence of a dentofacial deformity, the middle third of the face (nose) may appear "bigger" or "smaller" than its actual size (see Figure 2-7). Correction of the presenting jaw discrepancy toward Euclidean proportions will improve harmony between the upper, middle, and lower thirds of the face. Once this is accomplished, a more accurate assessment of the actual nasal esthetic unit can be made. Disproportion of the nose as a stand-alone esthetic unit may nevertheless exist and benefit from alteration. Dysfunction of the nose characterized by chronic obstructive nasal breathing and inadequate sinus drainage should also be recognized and dealt with at the appropriate time. Clarification of these issues with the patient/family at the first consultation visit, and rediscussion at the time of orthognathic planning and again after surgical healing is essential to achieve patient satisfaction.

Assessment for TMD and Current Mandibular Range of Motion

An accurate history of any past and current TMD symptoms and signs should be documented, including any previous therapy, subjective complaints, joint noise, mandibular range of motion, any centric relation to centric occlusion discrepancy, masticatory muscle tenderness to palpation, and current radiographic findings. Active TMD will require treatment to diminish symptoms and achieve adequate range of motion before orthodontic treatment is initiated.

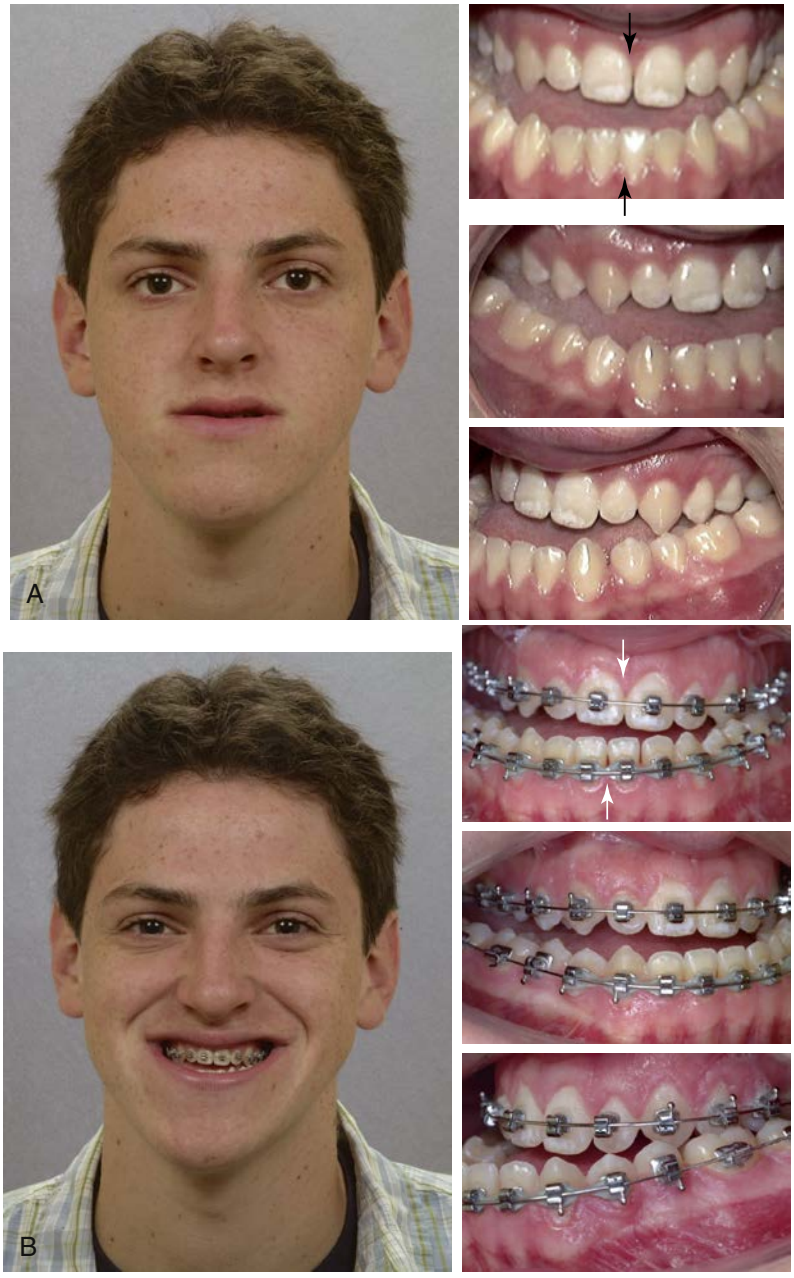
Assessment of the Cervical Spine and Current Neck Range of Motion

An accurate history of past and current cervical spine symptoms and signs should be documented. Individuals with a dentofacial deformity are at higher than average risk for cervical spine anomalies. If suspicion of cervical spine dysfunction exists, consultation with an appropriate specialist (i.e., neurologist, orthopedic surgeon, neurosurgeon) and

focused imaging studies (i.e., MRI, CT scan, plain cervical spine radiographs) should be carried out. Confirming the safe range of motion of the neck (while awake) in the office setting and understanding any limitations is important for safe orthognathic surgery and recovery.

Evaluation of the Lower Facial Skeleton

Confirmation that the upper facial skeleton and the overlying soft tissue envelope of the face do not require surgical alteration and that the neck and mandible can be put through an adequate range of motion without significant limitations



• **Figure 2-7** A 17-year-old with the diagnosis of left hemimandibular elongation (HE). The dentofacial deformity affects chewing, swallowing, speech articulation, lip closure/position, and breathing. He has normal cervical spine function and neck range of motion. He is without TMD and has a full range of mandibular motion. The upper facial skeleton (i.e., cranial vault, orbits, zygomas) is symmetric and with normal proportions. The facial soft tissue envelope is distorted by the maxillomandibular deformity but without malformation. In the early teenage years, he underwent an initial phase of orthodontics without success. He was referred for surgical evaluation and then underwent a combined orthodontic and surgical approach. With relief of dental compensation, surgery included: maxillary Le Fort I osteotomy (horizontal advancement, cant correction, vertical change, arch expansion, clockwise rotation); bilateral sagittal split ramus osteotomies (cant correction, mandibular straightening); osseous genioplasty (straightening and minimal advancement) and septoplasty/inferior turbinate reduction. **A,** Frontal facial view in repose prior to treatment. Occlusal views prior to orthodontic retreatment are also shown. **B,** Frontal view with smile prior to surgery. Occlusal views with orthodontic (dental) decompensation in progress.

is essential prior to focusing on detailed maxillomandibular surgical planning. Qualitative decisions concerning which components of the maxillomandibular skeleton are asymmetric and/or disproportionate and require surgical repositioning will have already been discussed with the patient/family and other treating clinicians prior to initiating treatment. These details should be reconfirmed by the surgeon at the immediate preoperative planning visit.

Assuming that both the maxilla and mandible are part of the dentofacial deformity that requires reconstruction, quantitative (to the millimeter) decisions of the preferred esthetic and best functional repositioning of the upper jaw (at the time of Le Fort I osteotomy) must first be made.[25,27,36,37] When thinking through the details of maxillary (surgical) repositioning, it is understood that the "new" upper jaw position (in two-jaw surgery) will serve as the platform on which the mandible is to be placed. Where the lower jaw "ends up" is equally important and will be entirely dependent on the "new" (surgical) position of the maxilla and the orthodontic alignment of the teeth.[45]

Evaluation of Overall Dental Rehabilitation Needs

Recognizing when a patient seeking orthognathic surgery has additional dental needs beyond standard orthodontics is essential to achieving a favorable outcome. The need for a periodontal evaluation and treatment as well as the need for complex dental restorative work should be considered in every patient prior to initiating a coordinated orthodontic and jaw surgical approach. This is especially true for the adult who has suffered dental and periodontal sequelae from a long-standing uncorrected dentofacial deformity and who may have undergone camouflage treatment in attempts to neutralize the malocclusion (e.g., orthodontics, occlusal equilibration, restorative dentistry).

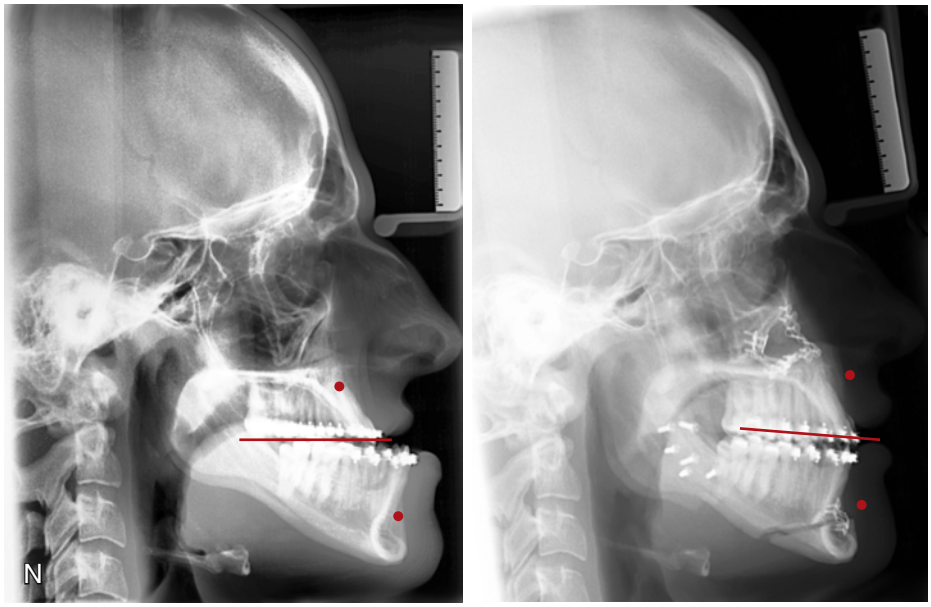
Detailed Maxillomandibular Surgical Planning: Eight Critical Quantitative-to-the-Millimeter Decisions

1. Assess current and preferred position of the maxillary dental midline with reference to the upper face (yaw orientation). Anticipate any potential yaw effect of the new (surgical) maxillary orientation on the mandible and mid-face (cheeks) (see Figure 2-7).
2. Assess for presence of any maxillary cant (role orientation) with reference to the upper face. Decide the preferred upper jaw repositioning for cant correction (see Figure 2-7).
3. Assess current and preferred vertical position of the maxillary incisor crown with reference to the upper face. Consideration is given to the upper lip to incisor relationship in both repose and smile (see Figure 2-7).
4. Assess current and preferred horizontal position of the maxillary incisor crown with reference to the upper face (see Figure 2-7).
5. Assess current and preferred A-point to B-point relationship of the jaws (pitch orientation) when the face is viewed in profile (NHP). Consider the need to differentially alter the vertical maxillary height at the first molars and/or at the incisors (maxillary plane change) to achieve objectives (see Figure 2-7).
6. Assess the baseline pyriform rim/floor of nose/anterior nasal spine morphology. Anticipate the location of each after maxillary reorientation including any planned maxillary plane change. Consider advantages of skeletal recontouring of the pyriform rims/floor of nose/ANS to achieve airway and esthetic objectives (see Figure 2-7).

Prior to retreatment

Presurgery

4 years after treatment



• **Figure 2-7, cont'd** **M,** Occlusal views prior to retreatment, with orthodontic decompensation in progress, and 4 years after treatment. **N,** Lateral cephalometric radiographs before and after surgery. (From Posnick JC: *Orthognathic surgery treatment planning. Orthognathic surgery: Principles and practice*, St Louis, 2014, Elsevier.)

7. Assess the baseline chin morphology. Anticipate location of pogonion after jaw reorientation that may also include mandibular plane change. Consider advantages of chin reshaping (osseous genioplasty) to achieve preferred horizontal and vertical esthetics and shape of the chin (see Figure 2-7).
8. Reconfirm advantage of (need for) segmentation of the maxilla to achieve preferred arch form and occlusion with the mandible (see Figure 2-7).

Assess Position of the Maxillary Dental Midline with Reference to the Upper Face (Yaw Orientation)

Once the decision has been made to surgically reposition the maxilla and mandible (two-jaw surgery), no additional risk is encountered in making a change in the maxillary dental midline position. In fact, the surgeon must make a conscious decision to either leave the midline as it is or to adjust it. At the immediate preoperative direct (face-to-face) examination, the operating surgeon should consider the preferred location of the maxillary dental midline. This is a clinical observation when viewing the patient at conversational distance and closer up. It is measured in millimeters of variation of the maxillary dental midline (point between the incisors at the incisal edge) in comparison to the baseline upper facial midline. Ideally, the midline of the maxillary central incisor should coincide within 2 mm with the facial midline. When the upper face has satisfactory basic symmetry the decision of where to position the maxillary dental midline is generally straightforward (see Figure 2-7). In the presence of upper face asymmetry, especially when combined with canting of the maxilla, and asymmetry/disproportion of the mandible, the decision of where to reposition the maxillary midline becomes more complex.

When the surgeon decides on the new preferred location of the maxillary (incisor) midline (at the time of surgery) the "yaw effect" (of the midline change) must also be taken into account (see Figure 2-7). For example, the maxilla may be either bodily moved to one side (to correct the incisor midline) or the maxillary dental midline may be corrected while leaving the buttress regions (side to side) essentially unchanged. This would require a rotation (twisting) of the maxilla (rather than a bodily movement) so that the posterior maxilla moves slightly anterior on one side while the other side moves slightly posterior. This is a similar movement to the twisting open of a lid on a jar. As stated, a twisting movement of the maxilla around the vertical axis of rotation (yaw orientation) will result from a simultaneous anterior incisor midline shift and a posterior shift at the molars. When "twisting" the maxilla, the resulting posterior shift will cause a relative ipsilateral class III and a contralateral class II molar relationship change. On the other hand, a lateral (side to side) shift of the maxilla would cause a different yaw orientation change (see Figure 2-7).

Establishing the correct maxillary dental midline position and yaw orientation is especially of concern in cases that present with moderate to severe 3D facial asymmetry of multiple bones (i.e., hemifacial microsomia). A 3D CT scan (top of the skull through bottom of the chin) can be helpful to appreciate where specific mirror image dysmorphology exists and how best to manage it. At surgery, the introduction of unwanted yaw effects are often visualized as asymmetries in:

- The maxillary incisor midline compared to the facial midline
- The cheek region (side to side) with fullness on one side and deficiency on the other
- The angle of mandible region (side to side) with fullness on one side and deficiency on the other

Assess for any Maxillary Cant with Reference to the Upper Face (Roll Orientation)

Once the decision has been made to surgically reposition both the maxilla and mandible (two-jaw surgery), no additional risk is encountered when making a change (correction) of any observed cant (roll orientation) of the maxilla. The operating surgeon is forced to make a conscious decision to either leave the roll orientation (cant) as is or to alter it and, if so, by how much. Studies confirm that a three-degree occlusal cant is perceived as a noticeable asymmetry by 50% of both professionals and lay people while a four-degree cant is noticeable by 90% of professionals and lay people.[46] At the preoperative direct planning examination, the clinician should make an observation when viewing the patient face to face that the maxilla is vertically "even" (side to side) or, if not, how much of a deviation (cant) is present. What is generally called a maxillary cant (vertical height discrepancies of the maxilla side to side) may also be viewed from the perspective of the esthetic line of the dentition or at the functional line of the occlusion (see Figure 2-7). Maxillary cant considerations are in comparison to the upper face (structures above the maxilla). When the upper face is basically symmetric, the interpupillary line may be used as an accurate baseline reference (see Figure 2-7).

The presurgical planning visit is a good opportunity for the surgeon to clarify and discuss directly with the patient/family both major and minor presenting facial asymmetries. This can be done by viewing a medical quality frontal facial photograph or while the patient is looking into a handheld mirror. Typical minor asymmetries include differences in height (position) and shape between the external ears, eyebrows, lateral canthi, as well as asymmetries in cheek/lip (soft tissue) elevation during smiling. Quantifying any presenting maxillary cant and the extent of correction planned (to the mm) may be complicated by upper facial skeletal asymmetries, other directional abnormalities of the maxilla (transverse, horizontal, or dental midline to facial midline), and any asymmetry/disproportion of the mandible. When present, these compounding factors make it difficult to correctly predict the most esthetically pleasing outcome.

Thought is simultaneously given to the yaw orientation (rotation around the Y-axis) of the presenting maxillary deformity and the yaw effect at the level of the mandibular angles and the mid-face (cheek) regions anticipated from the (planned) maxillary change (see Figure 2-7). In complex facial asymmetry cases, the clinician's ability to simultaneously analyze the presenting yaw and roll orientations and the subsequent esthetic changes of the planned correction can be augmented with use of craniofacial 3D CT scan imaging.

The clinicians' assessment of the extent of maxillary cant and the desired correction may be facilitated by:

1. **Use of a Fox Plane during the direct visual examination:** Placement of a Fox Plane directly over the occlusal surfaces of the maxillary dentition is helpful to judge the presence and extent of maxillary cant compared to the upper face (interpupillary reference line). Soft wax can be added to the deficient side (wax placed between the Fox Plane and occlusal surfaces of teeth) until the cant is corrected (in comparison to upper face). The mm amount of wax built up (for example at the first molar, mesiobuccal cusp) is a measure of the cant. When using a Fox Plane, the clinician must consider the patient's maxillary arch form. Often, two separate dento-alveolar planes (steep curve of Spee) have been accentuated by the orthodontic mechanics and will be managed with segmental osteotomies. How the Fox Plane is seated to the patient maxillary occlusal plane is important when assessing for a cant.
2. **Comparison measurements from posterior-anterior (PA) cephalometric radiograph (left to right sides):**
   - Incisal edge to nasofrontal suture (mm distance left and right sides)
   - Canine edge to nasofrontal suture (mm distance left and right sides)
   - First molar edge to fronto-zygomatic suture (mm distance left and right sides)
3. **Comparison measurements from a 3D craniofacial CT scan (left to right sides)**
   - Incisal edge to nasofrontal suture (mm distance left and right sides)
   - Canine edge to nasofrontal suture (mm distance left and right sides)
   - First molar edge to fronto-zygomatic suture (mm distance left and right sides)
4. **Comparison measurements taken directly from the anthropometric (facial) surface (left to right sides)**
   - Incisal edge to medial canthus (mm distance left and right sides)
   - Canine edge to medial canthus (mm distance left and right sides)
   - First molar edge to lateral canthus (mm distance left and right sides)

Assess Preferred Vertical Position of the Maxillary Incisor Crown with Reference to the Upper Face

The upper lip to maxillary incisor relationship represents a key facial esthetic landmark.[47] Ideally, with the upper lip at rest, several millimeters (1-3 mm) of the lower aspect to the maxillary incisor crowns should be seen in frontal view. With a broad smile, the upper lip elevates and, ideally, the entire maxillary incisor crown and a few millimeters (1-2 mm) of the gingiva will be seen. This will vary when evaluating a posed (as for a photograph) versus a dynamic (as seen when laughing) smile. The so-called *esthetic line of the dentition* follows the surfaces of the maxillary anterior and posterior teeth. The *functional line of occlusion* takes into account arch form, arch width, and symmetry. In the presence of malocclusion due to distortions in arch width, curve of Spee, and overall arch form, the functional line of occlusion may not be even (on a single plane) (see Figure 2-7). In many of the typical developmental jaw deformities the lip-to-tooth relationship (i.e., esthetic line and functional line) will find variation from ideal. Effected individuals will benefit from differential surgical repositioning of the anterior and posterior maxilla (i.e., intrusion or lengthening) as part of the surgical correction not only to positively influence the occlusion itself but also the esthetic line of the dentition and the functional line of occlusion.

Through a Le Fort I osteotomy with vertical intrusion, less gingiva with smile and incisor crown height in repose will be seen. With surgical (vertical) lengthening of the upper jaw (at Le Fort I osteotomy), more dental show and gingival exposure is to be expected (see Figure 2-7). Unfortunately, even with a pure vertical vector change of the maxilla, the upper lip soft tissue response is generally less than a one-to-one relationship and not entirely predictable. Soft tissue predictions become even less accurate with: combined upper jaw vector changes (vertical, horizontal, and transverse); in the presence of maxillary asymmetries (cant and dental midline shifts); when other procedures are simultaneously carried out (mandible and chin osteotomies and pyriform rim/nasal floor/anterior nasal spine recontouring); and in the presence of a hypotonic upper lip (long-standing skeletal class III) or an immobile scarred upper lip (fibrosis after cleft lip repair). Nevertheless, with thoughtful planning, a favorable esthetic outcome of the incisor vertical position to upper lip relationship should be achieved for the vast majority of orthognathic patients (see Figure 2-7). As a general rule, it is best to prevent too little maxillary incisor and gingival show in relationship to the upper lip (i.e., edentulous/aged/sad look). Also, remember that with age the upper lip lengthens (i.e., loss of muscle tone). As long as excess lip separation at rest and mentalis strain with closure is avoided, erring on the side of more rather than less incisor show is generally a preferred esthetic objective.

Note: I prefer to make final decisions concerning the exact esthetic vertical position of the maxillary incisors at operation once the maxilla is secured to the mandible through the intermediate splint. At this point, with the condyles seated in the terminal hinge position, all other vector changes for the maxilla are predetermined. The maxillomandibular complex is rotated, the vertical height is measured (i.e., medial canthus to incisor height), and the final incisor (vertical) position is decided.

Assess Preferred Horizontal Position of the Maxillary Incisor Crown with Reference to the Upper Face

The "ideal" esthetic horizontal position of the maxilla is not a specific millimeter or angular number but represents a limited range of what will be considered proportionate within the overall face. For each specific developmental jaw growth pattern (i.e., long face, short face, maxillary deficiency with relative mandibular excess, cleft maxilla), the needed directional horizontal surgical change of the maxilla should be

clear at the initial consultation. This will be reconfirmed at the preoperative planning examination by the operating surgeon. An exact preferred horizontal (millimeter) change at the maxillary incisors can be gauged through a combination of analysis including:

1. **Cephalometric Analysis. Evaluation of the Lateral Cephalogram:** Taken in the adjusted natural head position, lips relaxed, centric relation.
2. **Andrew's Profile Analysis. Evaluation of the Lateral Facial Photograph:** Taken in the adjusted natural head position, in centric relation, with broad smile (exposing the maxillary incisors) and with exposure of forehead skin (i.e., hair pulled back).
3. **Anthropometric Surface Analysis. Visual Examination of the Face:** When viewing the patient on direct examination in the adjusted natural head position from varied perspectives in both repose and with smile.

Comment: Normative cephalometric measurements such as the SNA angle generally underestimate but may also overestimate the preferred horizontal esthetic projection of the maxilla and therefore cannot be relied on. On the other hand, Andrew's Profile analysis of how much to advance the maxilla in the horizontal plane can be useful to the clinician when evaluating a patient with a dentofacial deformity. Spending time with an experienced orthognathic surgeon is a valuable way for a clinician in training to gain the knowledge required to make consistent favorable esthetic judgments of the preferred 3D reorientation of the maxilla at operation.

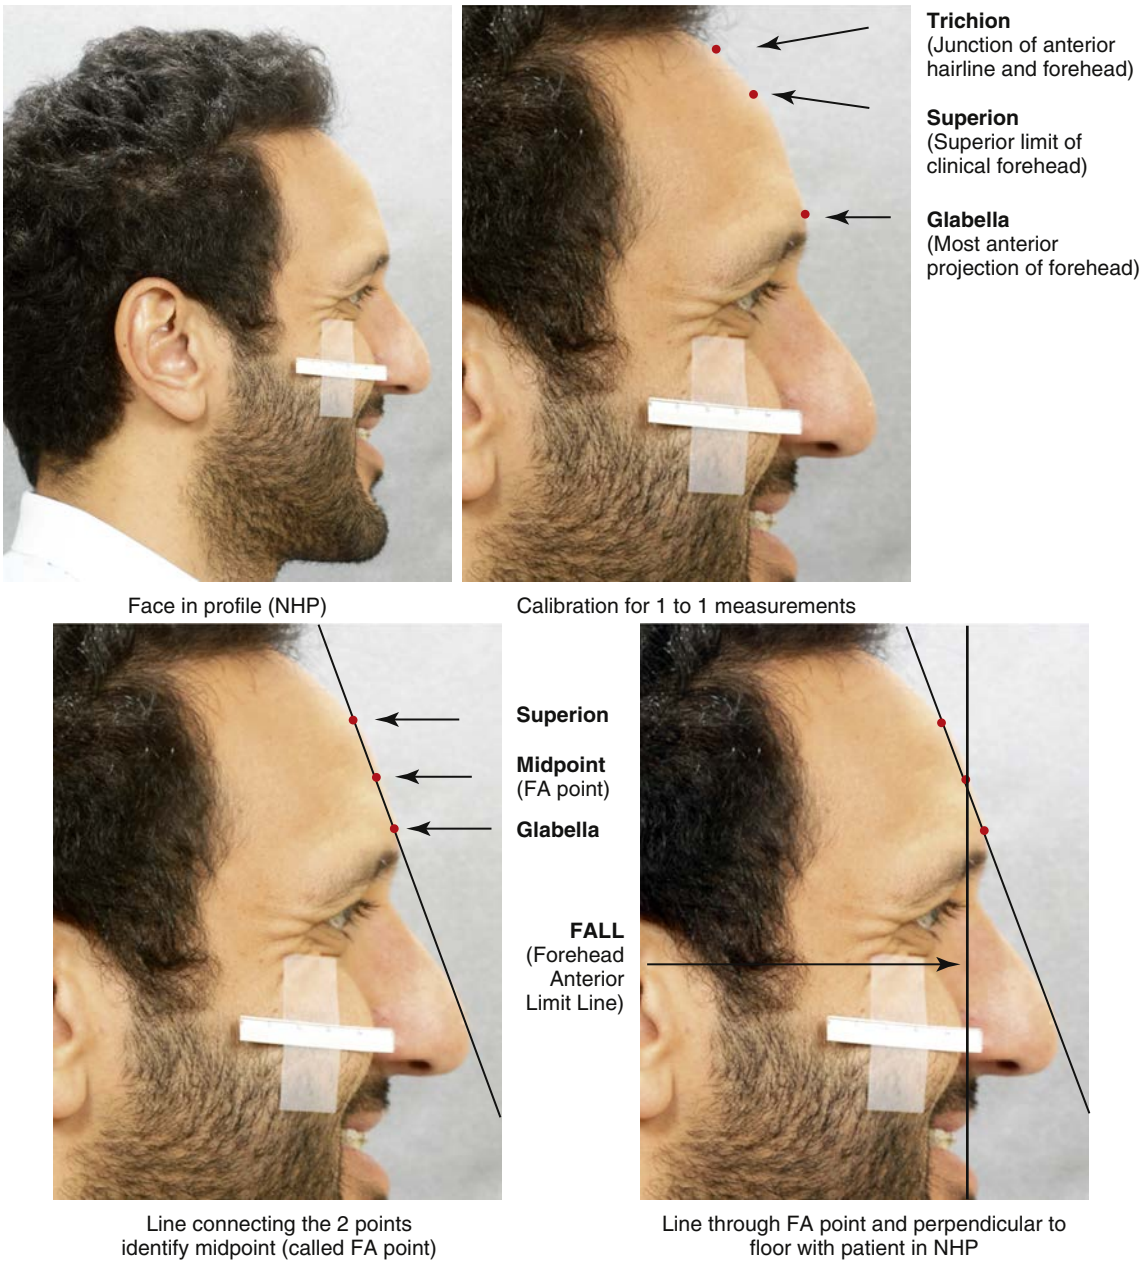
Andrew's Profile analysis can be an extremely useful tool to assess the preferred horizontal projection of the maxilla in the dentofacial deformity patient.[33] This author's application of Andrew's "Element II of Orofacial Harmony" is described in Figure 2-8. A step-by-step outline of how to do so follows:

- Photograph the face (head and neck) in profile. This is with the patient in the natural head position (NHP) and with a broad smile (i.e., so that the labial surfaces of the maxillary incisors are fully visualized). The forehead skin up to the hairline must also be exposed (i.e., hair pulled back). The dentition should be in centric relation or with a normal freeway space. There should be a calibration scale confirming 1:1 life-size measurements included on the facial photograph.
- Identify *trichion* (junction of forehead skin and anterior hairline and is the most superior aspect of the forehead when the forehead is relatively flat).
- Identify *superion* (i.e., the most superior aspect of the forehead, when the forehead is either rounded or angular in contour).
- Identify *glabella* (most anterior projection of the lower forehead).
- Draw a line connecting superion and glabella.
- Identify the midpoint between trichion and glabella (i.e., for foreheads with rounded or angular contour). This is called the *forehead anterior (FA) point.*
- Locate and drop a vertical line through the FA point. The line should be perpendicular to the floor with the patient in the NHP. This is called the *forehead anterior limit line* (FALL).
- Measure the angle at the superior forehead between these two lines. This angle is a measure of the forehead inclination.
- Locate and drop a second vertical line parallel to the FALL. The location of this line is measured in millimeters anterior to the FALL according to the formula (forehead inclination angle – 7) × 0.6. This is called the *goal anterior limit line* (GALL). Note: The GALL is parallel and anterior to the FALL.
- Locate and drop a third vertical line that is parallel to both the FALL and GALL. This line runs through the anterior surface of maxillary central incisors. This is assuming that element I is correct (i.e., the maxillary incisor inclination is correct). This is called the *dental anterior limit line* (DALL). The difference between GALL and DALL is the "recommending" distance in millimeters that the maxilla should be horizontally (sagittally) advanced to improve mid-face esthetics in the maxillary deficient mid-face.

Suggested adjustments to Andrew's Profile standard analysis are as follows:

- I have found that a strict interpretation of Andrew's analysis for the preferred horizontal position of the maxillary incisors is best suited for the Caucasian rather than Asian or African morphology. Facial variation according to race has much to do with forehead, nasal, and mid-face morphology.
- I have found that variations in thickness of the facial soft tissue envelope have an effect on preferred esthetic horizontal position of the maxilla. This is an additional factor that should be taken into account when reorienting the maxilla in conjunction with Le Fort I osteotomy. For example, the individual with a "thick" soft tissue envelope (i.e., obstructive sleep apnea patient with elevated body mass index) will typically estetically require (handle) greater horizontal advancement than Andrew's analysis indicates. The opposite may be true for the individual with a "thin" skin facial soft tissue envelope.
- Andrew's points out that mid-face esthetics in profile is highly dependent on the proper positioning of the maxillary teeth within the arch (element I). For example, in the maxillary deficient/relative mandibular excess growth pattern, if the decision is to avoid maxillary bicuspid extractions to fully retract the incisors toward a normal inclination, then mid-face esthetics may be negatively impacted. In this case, the maxillary incisal edge may be positioned correctly in the horizontal plane, but due to procumbency of the anterior teeth the basal bone of the maxilla remains retrusive. As a consequence of incisor procumbency, the nasolabial angle in repose and with elevation of the upper lip during smile may be esthetically compromised.

Achieving a favorable smile is influenced by several factors, including but not limited to: (1) the quality of the perioral soft tissues; (2) the vertical position of the maxilla; (3) the horizontal position of the maxilla; (4) the maxillary arch width; and (5) the inclination of the anterior teeth within the arch (see Figure 2-7). The *smile arc* is analyzed in frontal view by evaluating parallel lines representing the lower lip and upper dentition. The ideal smile arc or *consonant smile line* is characterized by the curvature of the lower lip line paralleling the curvature of the maxillary incisal edges. A consonant smile line is felt to project a happy and youthful appearance. The *buccal corridor* is the space created between the buccal surfaces of the posterior teeth and the inner aspect of the oral commissure when the individual is smiling. Those with excessive buccal corridors *(negative space)* are generally rated as less attractive than those with smaller buccal corridors. When a maxilla is narrow and horizontally retrusive, the visual appearance of *dark buccal corridors* reduces smile attractiveness. Smile esthetics are also enhanced when the *display zone* is filled with the maxillary teeth. This concept is best appreciated when viewing the before-and-after orthognathic surgery smile in an individual with maxillary deficiency (relative mandibular excess) who presents with a class III negative overjet malocclusion (see Figure 2-7). Improvement of smile esthetics in the maxillary deficient patient is often accomplished through



• **Figure 2-8** Patient viewed in profile in the natural head position (NHP). He is shown as a case example to demonstrate application of Andrew's "Element II of Orofacial Harmony" (see text). • **Figure 2-8, cont'd**

a combination of maxillary arch expansion, horizontal advancement, and adjustment of the vertical height. Decisions concerning where to position the maxillary incisors (vertical and horizontal) at the time of Le Fort I osteotomy will greatly affect smile esthetics.

Assess Preferred A-Point to B-Point Relationship of the Jaws When Viewed in Profile (Pitch Orientation)

The facial esthetic advantage of achieving an ideal A-point, B-point relationship has been discussed by contemporary orthodontists and orthognathic surgeons.[25,26,34-36,48-50] This may require clockwise or counterclockwise rotation of the maxillary and/or mandibular planes, but rarely requires a true lengthening or shortening of the posterior facial height. When using sagittal split ramus osteotomies, the unchanged proximal segment of the mandible establishes the posterior facial height, while any plane change carried out occurs in the distal segment. The height of the proximal segment (i.e., posterior facial height) does not change with either clockwise or counterclockwise rotation of the distal segment in conjunction with a sagittally split ramus osteotomy. When establishing the preferred A-point to B-point relationship and achieving full mid-face projection and vertical height through orthognathic technique, the upper airway will also improve.

Assessment of profile esthetics should be in the adjusted NHP, with the teeth in centric relation and then relaxed to allow the normal freeway space, but without anterior mandibular posturing through a "dual" bite. The lips are first relaxed (i.e., not pursed together) and then also assessed with full smile (see Figure 2-8). Individuals who present with a jaw discrepancy frequently have an altered mode of respiration and tend to rest their head in a position that an experienced evaluator will consider either neck extended or flexed or with a head tilt. Adjustment of the individual's head position (by the clinician) to the NHP is required to accurately assess the profile. Often, the patient's lateral facial photograph and/or lateral cephalometric radiograph are also not taken in the NHP. If the profile photograph, 3D CT, and/or lateral cephalometric radiograph are to be used in facial esthetic analysis, then the image should first be rotated to establish natural head position. A perpendicular (vertical) line can then be dropped from which to consider the patient's current A-point to B-point relationship and what surgical corrections will be helpful to achieve the desired facial esthetic and upper airway results (see Figure 2-8).

Achieving the preferred A-point and B-point relationship will influence the relative position of the skeletal structures above (i.e., anterior wall of the maxilla, pyriform rims, anterior nasal spine) and below (i.e., pogonion) as well as the dentoalveolar components of each jaw (i.e., incisor inclination) (see Figure 2-7). The position of these superior and inferior skeletal structures will then be reflected through the overlying facial soft tissue envelope. This includes the soft tissues of the lower eyelids (i.e., improvement in tear trough/negative vector), cheeks (i.e., improvement in nasolabial folds), nose (i.e., improvement in depressed nasal sills/plunging tip), lips (i.e., improvement in turned down oral commissures/marionette lines), chin (i.e., prevention of ptosis), and neck (i.e., improvement in obtuse neck angle/double chin).

Surgical repositioning of the jaws to improve the A-point and B-point relationship is also carried out with consideration of its effects on the relative inclination of the maxillary and mandibular incisors (see Figure 2-7). Rotation of the maxillary plane can improve the relationship of the maxillary smile arc, making it consonant with the lower lip. With respect to incisor inclination, when the maxillary plane is surgically rotated clockwise, the relative incisor inclination decreases. When the maxillary plane is surgically rotated counterclockwise, the incisors become more procumbent. When the mandibular plane is rotated clockwise, the incisors become more proclined. When the mandibular plane is rotated counterclockwise, the incisors become more retroclined. These effects must be considered during the presurgical orthodontic phase and again at the time of detailed preoperative planning.

Assess the Baseline Pyriform Rim/Floor of Nose/Anterior Nasal Spine Morphology: Anticipate the Location of Each After Maxillary Repositioning

Surgical positioning of the A-point and B-point to a corrected pattern will generally result in more pleasing esthetics at the pyriform aperture (paranasal) regions (see Figure 2-7).[25,34-36,48-51] However, at the time of Le Fort I osteotomy recontouring of the pyriform rims, the anterior floor of the nose, and the anterior nasal spine region to correct baseline skeletal deformities may also be beneficial. The advantage of these recontouring procedures to the upper lip/tooth relationship and base of the nose esthetics should always be considered in the preoperative planning.

Riola's textbook of cephalometric measurements confirms that the normal mean vertical height of the anterior nasal spine down to the maxillary incisal edge is 30 mm (±3 mm) for females, and 33 mm (±3 mm) for males.[52] At the time of Le Fort I osteotomy, the patient's specific measurement can be confirmed with a caliper. This is useful information to guide nasal recontouring. For example, in the long face growth pattern, a patient undergoing Le Fort I osteotomy with vertical intrusion to reduce a "gummy" smile will frequently have an average height of between 40 to 45 mm. After down-fracture, recontouring and lowering the floor of the nose and anterior nasal spine toward 30 mm is useful to normalize anatomy. In so doing, the nasal airway and nasal esthetic unit will be favorably enhanced.

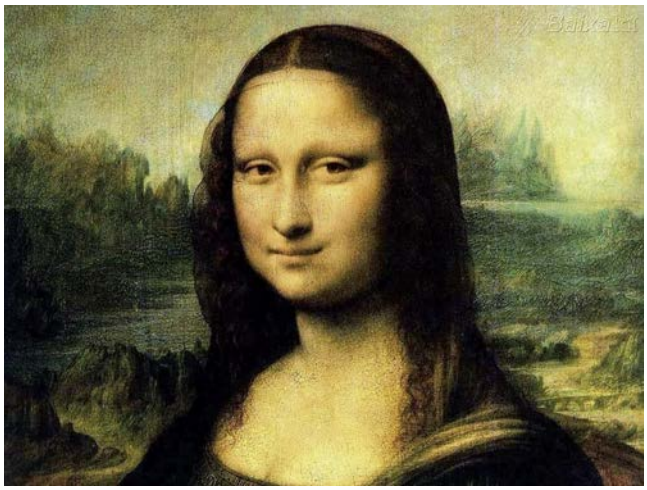
Assess the Baseline Chin Morphology: Anticipate the Position of Pogonion After Jaw Repositioning and the Potential Benefits of an Osseous Genioplasty

An individual's lateral cephalometric radiograph is useful to assess the anterior facial heights, any baseline bony chin dysmorphology, maxillary and mandibular incisor inclination, and A-point to B-point relationships (see Figure 2-7). Riola's table of normative mandibular cephalometric values confirms that the mean vertical height of a chin (mandibular incisal edge to menton) is approximately 42 mm (±2.7 mm) for females and 49.4 mm (±2.9 mm) for males. These measurements can be a useful benchmark from which to judge preferred vertical height of the chin.

Effective alteration of the A-point to B-point relationship at the time of orthognathic surgery will generally have a positive effect on pogonion position.[25,34-36,48-51] Additional direct surgical alteration of the chin (i.e., osseous genioplasty) is also frequently beneficial to achieve enhanced facial esthetics (i.e., vertical lengthening or shortening, midline shifts, horizontal advancement or recontouring of the chin surface anatomy). This should be considered at the immediate preoperative (face-to-face) examination and discussed with the patient/family. A plan for chin region management is agreed to and then executed at the time of orthognathic surgery with a goal to further improve esthetics, lip function, and possibly breathing (i.e., genioglossal advancement in the individual with OSA).

Reconfirm Advantage of (Need for) Segmentation of the Maxilla

The advantage of segmentation of the maxilla will have been considered prior to initiating orthodontic treatment. Maxillary segmentation is often a necessary procedure to achieve favorable long-term occlusal stability and periodontal



• **Figure 2-9** *Mona Lisa* by Leonardo da Vinci. (From Posnick JC: *Orthognathic surgery treatment planning. Orthognathic surgery: Principles and practice*, St Louis, 2014, Elsevier.)

health. It may be required to achieve an ideal curve of Spee, arch width, and incisor inclination, and successful closure of dental gaps. Segmentation is generally performed as either a two-segment LeFort I with osteotomies between the incisors and then parasagittally through the hard palate, or as a three-segment Le Fort I with osteotomies between the lateral incisor and canine (on each side) and then down the parasagittal midline on one or both sides. Segmentation of the upper jaw is not an excuse for poor orthodontic preparation. It does provide an opportunity to correct skeletal anomalies through the basal bone rather than through orthodontic (dental) compensation that would otherwise position the teeth outside (or on the edge of) the alveolar process. An orthodontic compensation (i.e., dental camouflage) approach would be unstable for the occlusion and periodontium in the long run. Plans for maxillary segmentation should be agreed on prior to commencing orthodontic treatment, reconfirmed at the time of immediate presurgical planning, demonstrated on the articulated dental models, registered on the prefabricated acrylic splints, and then executed during surgery (see Figure 2-7).

Conclusions

From a patient/family perspective, facial esthetic aspects are of significant importance in the correction of a dentofacial deformity. The most attractive faces will always incorporate a consistent symmetry of proportions in which the golden ratio can be found. An in-depth visual facial analysis, use of radiographic and photographic imaging, meticulous model planning, and experienced surgical execution remain the important components to achieving success in orthognathic surgery. There is much to be said for both the scientific and artistic aspects and a methodical approach to accomplish facial esthetic objectives, restoration of dental health and improved head and neck function (i.e., breathing, swallowing, chewing, speech) in the reconstruction of a dentofacial deformity. Accomplishing Euclidian facial proportions through orthognathic surgery by attempting to reach the *Kanon of Beauty,* as described by Polyclitus and visualized in the nautilus found in nature, is the ultimate objective.

In current clinical practice, we can take some solace in knowing that even Leonardo da Vinci was not entirely able to articulate the link between theory and practice in the establishment of ideal facial esthetics. When analyzing the Mona Lisa, academicians still disagree about Leonardo's intent and the meaning of his work vis-à-vis the golden ratio (Figure 2-9). Nevertheless, with a working knowledge of the golden ratio and its fascinating impact on the arts, architecture, and nature, the clinician's esthetic sense of harmony and symmetry is enhanced for the benefit of patients.

Virtual Treatment Planning for Orthognathic Surgery

JAMES J. XIA, JAIME GATENO, JOHN F. TEICHGRAEBER, DAVID M. ALFI, PENG YUAN

Introduction

The success of orthognathic (CMF) surgery depends not only on surgical techniques, but also on an accurate surgical plan. The adoption of computer-aided surgical simulation (CASS) is creating a paradigm shift in surgical planning for patients with CMF deformities, including maxillofacial surgery,[1-5] craniofacial surgery,[6] and trauma and distraction osteogenesis.[6-8] Our Surgical Planning Laboratory has developed a CASS protocol that is specifically designed for orthognathic surgery.[5] In this protocol, a three-dimensional (3D) composite skull model of a patient is generated to accurately represent the CMF skeleton, the dentition, and the facial soft tissue.[9-12] In addition, an anatomic reference frame is created for the 3D composite skull model.[13-15] Virtual osteotomies are then performed and orthognathic surgery is simulated.[1,5,10,16,17] Finally, surgical splints and templates are designed in the computer, fabricated by a rapid prototyping machine, and used during surgery to accurately position the bony segments.[18,19] The protocol has been proven to be more accurate and efficient than the traditional planning methods.[5,9,15,18,20-23]

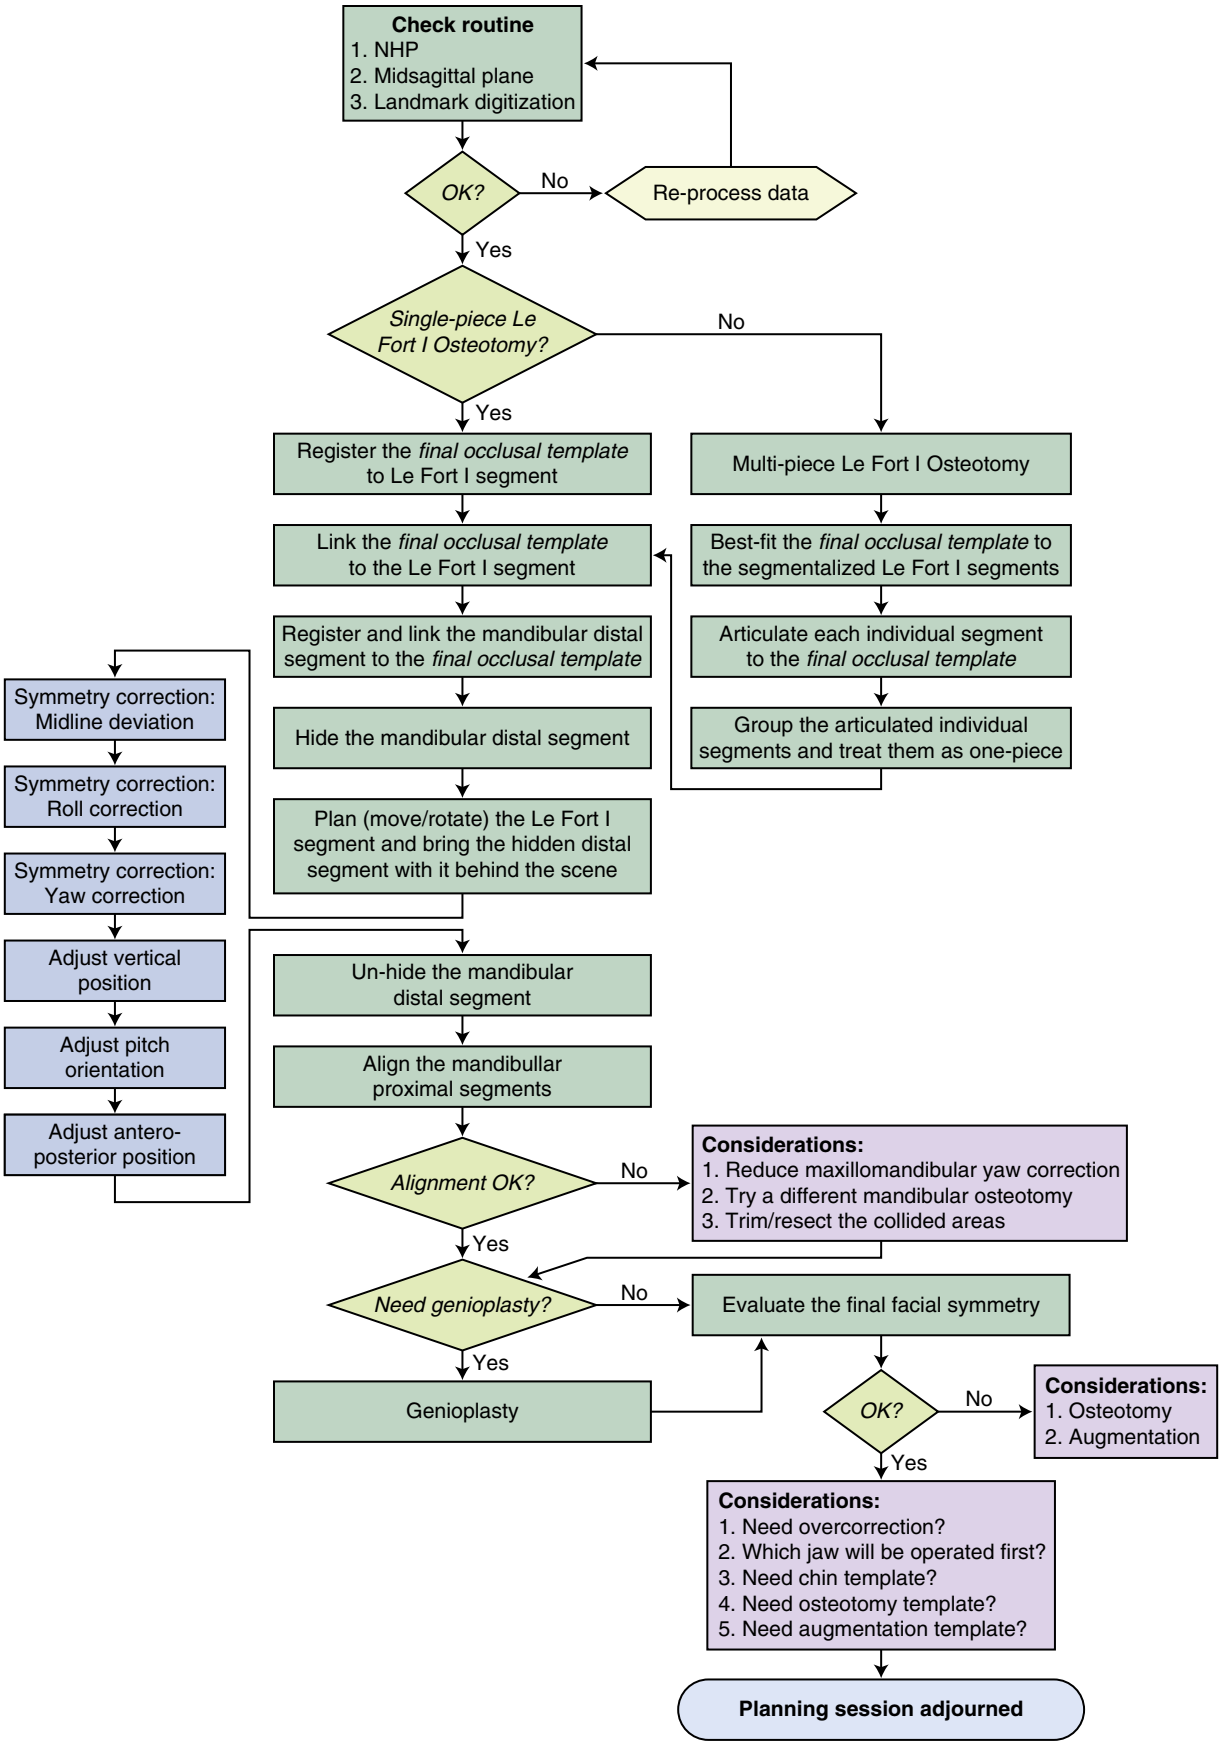
Planning an orthognathic surgery using CASS differs fundamentally from planning the same surgery using traditional methods.[24,25] Over the years, we have developed and significantly improved a new planning protocol using CASS to plan orthognathic surgeries (Figure 3-1). The purpose of this chapter is to present this streamlined CASS protocol.

The Streamlined CASS Protocol

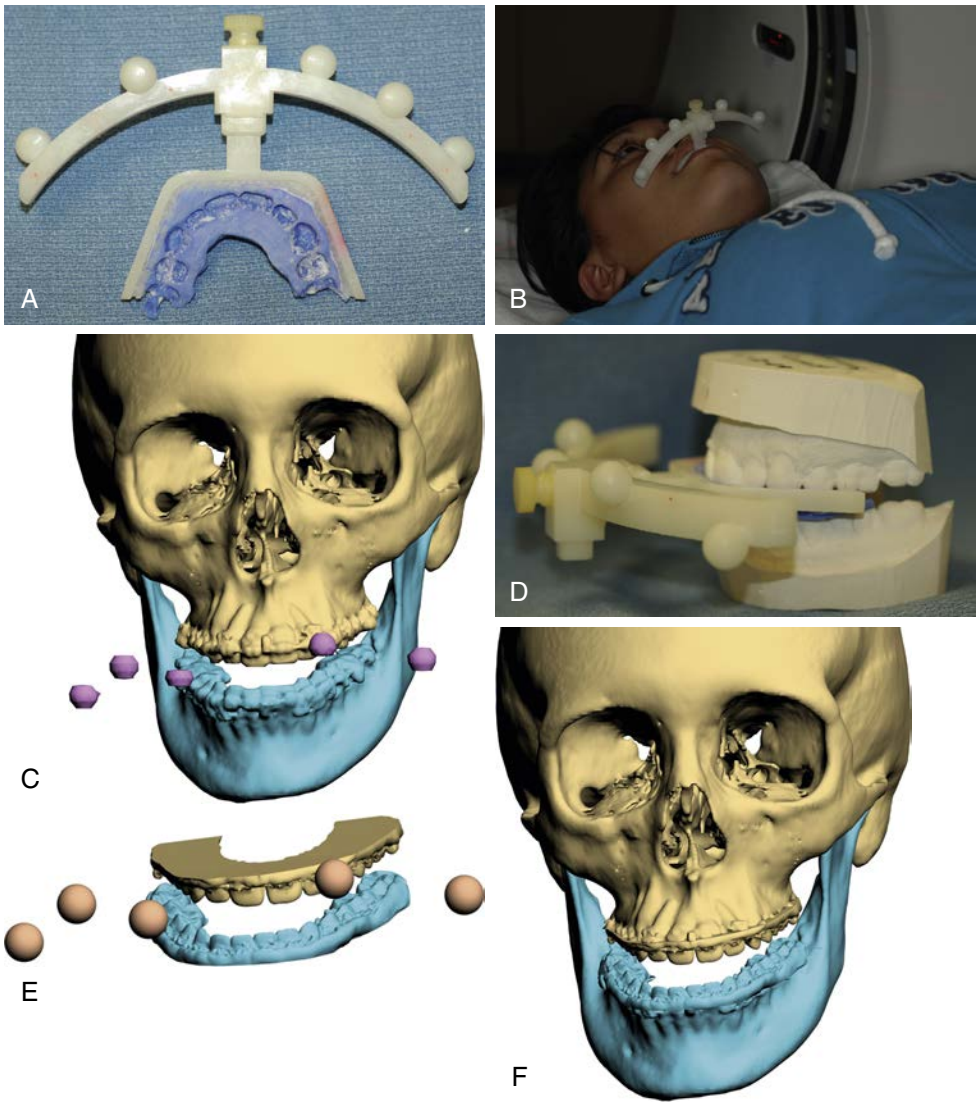
Before employing the CASS protocol, a clinician must confirm that the patient is ready for surgery. The desired occlusion should be achievable and the patient's growth and medical condition should be optimal for the surgery. To assess the occlusion, progress dental models may be hand-articulated into Class I occlusion, confirming that the patient is ready for surgery. Because our CASS protocol is mainly designed for a traditional orthodontics-first approach, this step is required because a computed tomography (CT) or cone-beam CT (CBCT) scan is needed for CASS, and patients should not be exposed to ionizing radiation if they are not going to have the surgery. However, this protocol can also be adapted to a surgery-first approach with minor alterations. In this chapter we use the term *CT* to refer to both CT and CBCT, unless otherwise specified.

Our CASS protocol accomplishes the tasks of modeling, planning, and preparing for plan execution. The task of the modeling is to construct a virtual model of the head (cranium and face). This model should have three distinct characteristics: (1) it renders the patient's bones, teeth, and soft tissues with accuracy; (2) its mandible is in centric relation, an important reference position in orthognathic surgery; (3) it has an anatomic reference frame.

CT scans can be used to create 3D models of the facial skeleton, teeth, and soft tissues. However, the teeth of these 3D CT models are not sufficiently accurate for surgical planning. Our CASS protocol solves this problem by replacing the inaccurate teeth of the CT with accurate digital dental models that are created by scanning stone dental models.[9] This facial model created by aligning and merging digital dental models into a maxillofacial CT is called a *composite model*. This aligning and merging process is called *registration*. The registration is done by aligning corresponding features (fiducial markers) that are presented in both images. The fiducial markers can be part of the anatomic structures being imaged, or easy to identify parts that are added in, on, or around the objects (or subjects)



• **Figure 3-1** Algorithm for planning a double-jaw orthognathic surgery using the CASS protocol.



• **Figure 3-2** Creation of the composite model. **A,** A facebow with fiducial markers is attached to the bite-jig. **B,** The patient bites on the bite-jig and facebow during the CT scan. **C,** Four separate but correlated computer models are reconstructed: a mid-face model, a mandibular model, a fiducial marker model, and a soft tissue model (not shown). **D,** The bite-jig and facebow is placed between the upper and lower plaster dental models during the scanning process. **E,** Three separate but correlated digital dental models are also reconstructed: a maxillary dental model, a mandibular dental model, and a fiducial marker model. **F,** By aligning the fiducial markers, the digital dental models are incorporated into the 3D-CT skull model. The computerized composite skull model is thus created. It simultaneously displays an accurate rendition of both the bony structures and the teeth.

before the image acquisition. Our method utilizes a two-component device that consists of a bite-jig and a fiducial facebow (Figure 3-2, *A*). The bite-jig serves two purposes: it anchors the fiducial facebow to the patient for accurate registration, and keeps the mandible in unique centric relation during the CT acquisition and the stone dental model scanning.[9,21,22]

The composite model used for planning must have an accurate anatomic frame of reference. This is a *Cartesian* frame that includes a mid-sagittal plane, an axial plane, and a coronal plane. The reference reframe is the basis for most diagnostic and treatment decisions. Incorrectly defining the reference frame may cause postoperative deformity. The reference frame for a composite model is usually established using the neutral head posture (NHP) method, because traditional anatomic landmark method is problematic.[26]

The principle behind using NHP is that a reference frame for the head can be derived from the patient's head posture. When a patient stands upright looking straight forward, the cardinal directions of the face are orthogonal to gravity. The axial plane is perpendicular to the gravitational pull and the mid-sagittal and coronal planes are aligned with it. Thus, when the head is in the NHP, it is simple to construct a reference frame for the face. The axial plane is the horizontal plane that passes through both porions. The mid-sagittal

plane is a vertical plane that best divides the face into right and left halves. The coronal plane is the vertical plane that is perpendicular to the other planes and is aligned with the coronal suture.

The remaining tasks in the CASS protocol are surgical planning and preparing for plan execution. Surgical planning uses a Visualized Treatment Objective (VTO) approach, simulating the operation until the desired outcome is attained and visualized. Preparing for plan execution is getting ready for surgery. To complete this task, a clinician collects clinical measurements and fabricates physical appliances such as occlusal splints, templates, and drill guides. These appliances are designed in the computer and fabricated using a rapid prototyping machine.

Clinical Implementation of CASS Protocol

CASS is implemented clinically in four major steps: preoperative record collection, data processing, surgical planning and simulation, and preparation for plan execution. The first and the third steps are completed by a clinician, whereas the other two can be outsourced, either to a planning specialist within one's clinic or institution or to an independent service provider.

Collection of Preoperative Records

In this step, preoperative data is gathered in an hour-long appointment. This appointment is scheduled 2 to 4 weeks prior to the surgery. The surgeon and an assistant accrue the records. They include: dental impressions and their stone models, a bite-jig, clinical measurements, photographs, an NHP recording, a CT scan, and a bite registration of the final occlusion. This appointment has eight steps: (1) taking and pouring dental impressions; (2) fabricating a bite-jig; (3) taking clinical measurements; (4) clinical photographing of the patient; (5) recording the patient's NHP; 6) testing the fit of the bite-jig on the stone dental models; (7) acquiring a CT scan; and (8) establishing final occlusion.

The *preoperative record appointment* begins by taking and pouring upper and lower dental impressions. We recommend utilizing wax to block and eliminate the undercuts caused by orthodontic braces and wires. This is to prevent impression distortion or separation between the dental impression material (e.g., alginate) and impression tray. Once the impressions are taken, they should be immediately poured by an assistant. The impressions should be taken and poured at the beginning of the appointment to shorten its length, because the fitting of the stone dental models on the bite-jig must be confirmed before the patient is CT scanned and this check cannot be done until the stone models are set. Since it takes about 45 minutes for the stone to set, postponing the models will delay the CT. Thus pouring the impressions early allows the models to be ready on time. In addition, the number of impressions needed for planning depends on the type of surgery. Obviously, a clinician needs to take at least one upper and one lower impression. But, when one is planning to segmentalize a dental arch into two or more pieces, the clinician should take two impressions of the arch needing segmentalization.

In the second step of the preoperative appointment, a patient-specific bite-jig is constructed by customizing a stock jig frame (see Figure 3-2, *A*). The surgeon customizes the frame by adding a self-curing, dimensional-stable and rigid bite-registration material (e.g., LuxaBite, DMG America, Englewood, NJ) to the frame. The jig is then placed between the patient's teeth until the material is cured. This bite registration should be taken in centric relation.

In the third step of the preoperative appointment, key clinical measurements needed for planning are recorded. They include: (1) incisal show at rest and smile dentogingival show to determine the vertical position of the maxilla; and (2) dental midpoint (midline) deviations to determine transverse jaw position.

In the fourth step, the clinical photographs are taken of the patient. The photographs should image both the face and the teeth. The facial photographs should be taken with the patient in the NHP. In addition, a plumb line should be shown on the background, so the correct orientation of the face can be determined later. These photographs will be used to verify that the *virtual head model* is correctly oriented for planning.

In the fifth step of the preoperative appointment the NHP is recorded. This measurement is needed to create an anatomic reference frame (mid-sagittal, axial, and coronal planes) for the virtual facial model. To record the NHP, the authors use an electronic orientation sensor (3DM, MicroStrain Inc, Williston, VA).[13-15] The sensor is first attached to the previously fabricated bite-jig (see Figure 3-2, *A* and *B*), and then the jig is placed between the patient's teeth. The patient is asked to stand upright with her head in NHP. Finally, in this posture, the pitch, roll, and yaw of the sensor are recorded. The NHP can be attained by asking patients to self-balance into this stance, or by manipulating their heads into this posture. The authors begin with a self-balance position but feel free to manipulate it if the patient posture is incorrect.

In the sixth step, a clinician or an assistant tests the fit of the stone dental models on the bite-jig. This test is done to confirm that the models and the bite-jig are correct. If the models do not fit the bite registration, one can assume that either the dental models or the bite-jig are distorted. Common reasons for the lack of fit are air bubbles on the occlusal surfaces of the dental impressions, deep indentations in the bite registration, and slight separation between the dental impression material (e.g., alginate) and impression tray. Air bubbles in an impression are filled with stone during pouring, resulting in spherical bumps that arise from the surfaces of teeth. They prevent the model from seating into the bite registration. However, they can be easily spotted and removed with a sharp instrument to improve the fitting. Deep indentations in the bite registration, especially those that extend above the height of contour of the teeth, also prevent the models from fully seating on the bite

registration. This lack of seating occurs because the material used for bite registration is rigid. This problem can be solved by grinding the bite registration to reduce the indentations.

If the dental models and bite-jig still don't fit after the above maneuvers, the bite-jig should be retested on the patient's teeth. If the bite-jig fits the patient well, it must be assumed that the stone models are distorted. The dental impressions should be repeated. If the bite-jig does not fit well, the jig should be relined, and the NHP recording should be repeated, because relining of the bite-jig can affect the alignment of the orientation sensor.

In the seventh step of the preoperative appointment, a CT scan is obtained. Before scanning, the fiducial registration facebow is attached to the bite-jig, and the jig is affixed to the patient (see Figure 3-2, *B*). The patient is instructed to keep his/her facial soft tissues relaxed during scanning. The scan can be completed using either a spiral multislice CT scanner (using the standard scanning algorithm, matrix of 512 × 512 at 0.625- to 1.25-mm slice thickness, 25 cm or lesser field-of-view, and 0° gantry tilt) or a CBCT scanner (with 0.4-mm isotropic voxel).

In the last step (eighth) of the preoperative appointment, a clinician establishes the final occlusion. This is usually done after the patient leaves the clinic. Currently, we establish the final occlusion on stone dental models because there is no reliable method to establish final occlusion in the computer, especially when one of the jaws is segmentalized. When dental arch segmentalization is not required, the maxillary and the mandibular stone dental models are mounted on a Galetti articulator and articulated into final occlusion. Final occlusion is then captured with a bite-registration taken with a stable material like silicone or polyvinyl siloxane. When arch segmentalization is required (e.g., a three-piece Le Fort I osteotomy), a clinician cuts the extra stone dental model into the require number of segments. The clinician then hand articulates each segment into final occlusion and makes a new plaster base for the segmentalized model. Finally, he articulates the upper and lower models into final occlusion (in a Galetti articulator), capturing the occlusion with a bite registration. Currently our Surgical Planning Laboratory is working on digital establishment of final occlusion for both one- and three-piece Le Fort I osteotomies.[27-30] We expect that in the future, the need of the stone dental models will be eliminated and this step will be done within our software.[a]

Data Processing

The second major step of CASS is data processing. This takes place after all the preoperative records have been gathered. It can be done by the surgeon, or it can be outsourced to an independent service provider, or to a person familiar with CASS planning within the surgeon's clinic or institution. Data processing entails the creation of a composite head model, the creation of an anatomic reference frame for the head model, the digitization of cephalometric landmarks, the creation of the virtual osteotomies, and the establishment of final occlusion.

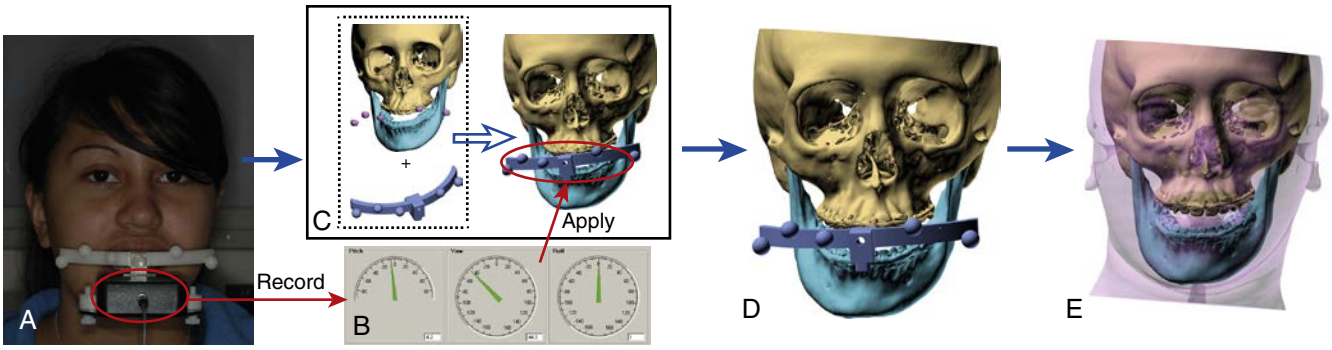
The first step in data processing is to create a virtual model that displays an accurate rendition of the skeleton, the soft tissues and the teeth. Four separate but correlated 3D CT models are generated: a mid-face model, a mandibular model, a soft tissue model, and a fiducial marker model (see Figure 3-2, *C*). This task is completed using specialized planning software. Digital dental models (see Figure 3-2, *E*) are then generated by scanning the stone dental models with the fiducial registration frame in place (see Figure 3-2, *D*), either with a high-resolution laser scanner, or with a CBCT scanner (at a high resolution setting of 0.125-mm to 0.2-mm isotropic voxel). Next, the digital dental models are incorporated into the 3D CT models by registering the fiducial markers of the digital dental models to the markers of the 3D CT (see Figure 3-2, *F*).

The second step in data processing is to establish an anatomic reference frame for the head model. An accurate anatomic reference frame is critical for planning. The recorded NHP (the pitch, roll, and yaw of the head) is used to orient the computer head model to the NHP. Using the fiducial facebow as reference, the NHP of the computer model is established by applying the recorded pitch, roll, and yaw to the facebow frame (Figure 3-3, *C* and *E*).[15] Once the virtual head model is in the NHP, the construction of a reference frame is straightforward. The mid-sagittal plane is the vertical plane that best divides the head into right and left halves. The axial plane is the horizontal plane that is perpendicular to the mid-sagittal plane, passing closest to the right and left porion. The coronal plane is the vertical plane that is perpendicular to the other planes, aligned with the coronal suture.

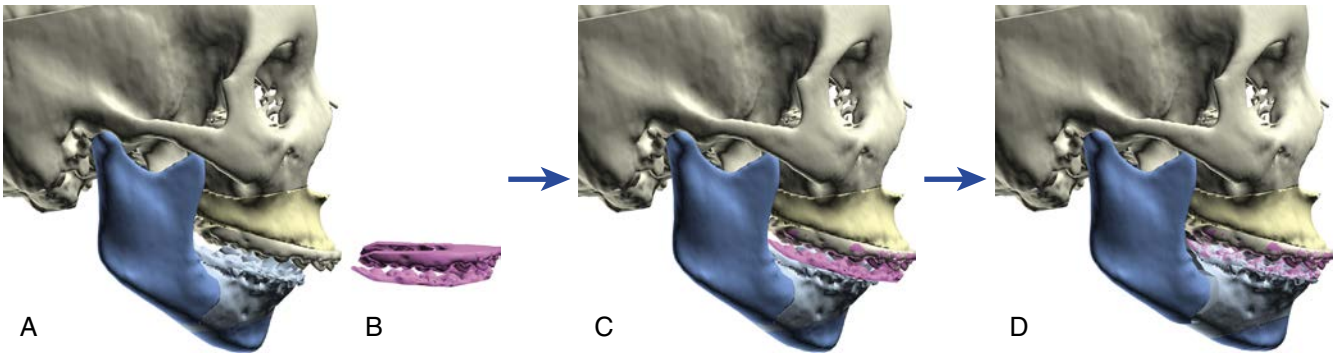
The third data processing step is to digitize all the cephalometric landmarks and to perform a cephalometric analysis. The surgeon may request any cephalometric analysis but he/she should take into consideration that 3D cephalometry is significantly more complex than its 2D counterpart. Simply adapting 2D cephalometric measurements to 3D space may cause diagnostic errors.[31-33] If necessary, landmark digitization can be altered later in the planning phase.

The fourth data processing step is to perform virtual osteotomies (e.g., a Le Fort I osteotomy, mandibular ramus osteotomies, and a genioplasty) (Figure 3-4, *A*). If necessary,

[a] Any commercial computer graphic software that is capable of handling and manipulating 3D models may be used for CASS planning (e.g., SimplantOMS [Materialise Dental Inc, Glen Burnie, MD], ProPlan CMF [Materialise NV, Leuven, Belgium], 3D Studio Max [Autodesk Inc, San Rafael, CA], or Dolphin 3D [Dolphin Imaging & Management Solution, Chatsworth, CA]). In addition, the authors are developing a CASS planning software package, *AnatomicAligner*. It is designed specifically for orthognathic surgery. The software will be available freely to broader clinical and research communities in the future (www.AnatomicAligner.com). This project is partially sponsored by National Institutes of Health/National Institute of Dental and Craniofacial Research (NIH/NIDCR).



• **Figure 3-3** Orientation of the composite skull model to the neutral head posture (NHP) using the digital orientation sensor method. **A,** A digital orientation sensor is attached to the bite-jig and facebow. **B,** The pitch, roll, and yaw of the sensor are recorded. **C,** In the computer, a digital replica (CAD model) of the fiducial facebow is registered and attached to the composite skull model via the fiducial markers. **D,** The recorded pitch, roll, and yaw are applied to the facebow frame, reorienting the composite skull model to the NHP. **E,** After the composite skull is orientated to the NHP, the CAD model of the fiducial facebow is marked hidden.



• **Figure 3-4** Incorporating the final occlusal template and placement of the mandibular distal segment into final occlusion in a single-piece Le Fort I osteotomy. **A,** In this example, virtual osteotomies, including a single-piece Le Fort I osteotomy and bilateral sagittal split osteotomy, are completed. Each bony segment is located in its original location. **B,** The digital final occlusal template is generated by scanning the hand-articulated stone models using a high-resolution scanner. **C,** The upper part (maxillary teeth) of the final occlusal template is first registered to the maxillary teeth in the composite model. **D,** The mandible is set into the final occlusion by registering the distal mandibular teeth to the lower part (mandibular teeth) of the template.

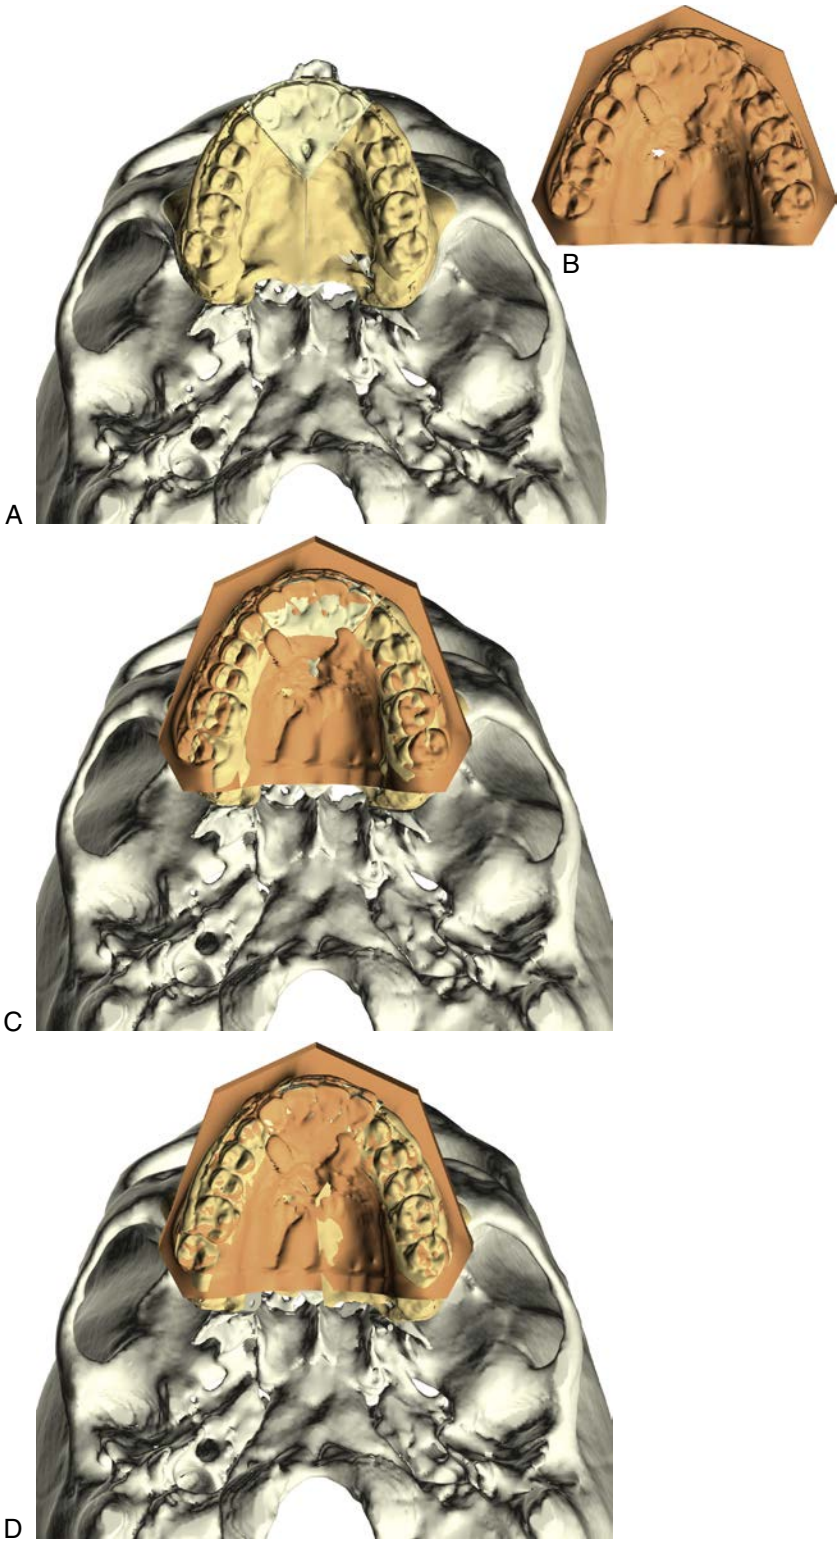
these osteotomies can be revised or redone during the planning phase. At this stage, all the osteotomized segments remain in their original position. Their movements are completed later in the planning phase.

The last step of data processing step is to establish virtual final occlusion (see Figure 3-4). This is done by copying the final occlusion which was established by the surgeon on the stone dental models. First, the upper and lower stone models are articulated into final occlusion using the bite registration provided by the surgeon. Next, the models are scanned together, using a high-resolution optical surface scanner, or a CBCT scanner. Finally, the scan is segmented to create a 3D image of the upper and lower teeth in final occlusion (see Figure 3-4, *B*). This image, the *final occlusal template*, is imported into the planning software and is used as a guide to articulate the jaws in final occlusion.

The virtual final occlusion is established in the following manner: First, the upper teeth of the final occlusion template are aligned to the upper teeth of the Le Fort I segment (see Figure 3-4, *C*). Then, the distal mandibular segment is moved until its lower teeth are aligned to the lower teeth of the template (see Figure 3-4, *D*). Because the upper and lower teeth of the template are in final occlusion, aligning the template to one jaw and then aligning the other jaw to the template, automatically places both jaws into final occlusion.

After the distal mandible is set in final occlusion, it is linked to the Le Fort I segment. As a result, future movements of the Le Fort segment will be automatically transferred to the mandibular segment. This guarantees that the final occlusion is maintained during the planning process. Maintaining the final occlusal relationship during the maxillary movements simplifies mandibular planning,

In a double-jaw surgery with a single-piece Le Fort I osteotomy, it is simple to align the upper teeth of the final occlusion template to the upper teeth of the Le Fort I segment, since they are identical (Figure 3-5). This is not true in a multi-piece Le Fort I. In this case, the shapes of the upper dental arches of the virtual head model and the final occlusal



• **Figure 3-5** Incorporating the final occlusal template in a multiple-piece Le Fort I osteotomy. **A,** In this example, a three-piece Le Fort I osteotomy is completed. All bony segments *(yellow)* are located in their original locations. **B,** The upper part (maxillary teeth) of the digital final occlusal template. The template is also generated by scanning the hand-articulated stone models, in which the upper stone model is first cut into three pieces, then hand-articulated to the final occlusion without using an articulator. Note that the posterior Le Fort I segments in the composite model are medial. **C,** The upper part of the final occlusal template is registered to the maxillary teeth at the central dental midline, best fitting the posterior parts of the teeth. **D,** All Le Fort I segments are then perfectly registered to the corresponding segment in the final occlusal template, resulting in a new intra-arch relationship among the Le Fort I segments.

template are different. This is because the template depicts the upper jaw segments in their final alignment, while virtual head model depicts the upper teeth in their original condition (see Figure 3-5). In this situation the alignment is completed in two steps.

First, the final occlusal template is best fit to the maxillary arch of the composite models, and then each Le Fort I segment is individually moved until their teeth are aligned with the template. This creates a new intra-arch relationship for the Le Fort I segments (see Figure 3-5, *D*). Afterwards, the individual Le Fort segments are grouped together forming one piece. From then on, the Le Fort I unit is treated as one piece, as in a one-piece Le Fort I osteotomy.

Surgical Planning

The third major step of the CASS protocol is surgical planning. It is done in the computer using CASS software. It is important to note that planning an orthognathic surgery using CASS is conceptually different from planning the same operation using traditional planning methods (e.g., stone dental models). In stone dental model surgery, one intuitively executes all transformations, including rotations, as linear translations of particular points. It is different in CASS. It has six degrees of freedom, enabling the measurements of inclinations (pitch, roll, and yaw) in degrees and positions (anteroposterior, vertical, and transverse) in millimeters, independently of each other. Another difference between the CASS and the traditional planning methods is the sequence of the planning process. In traditional double-jaw stone dental model surgery, the position of the upper jaw is established first and the lower jaw is then placed in the final occlusion for the final alignment. In CASS, the final occlusion is established first and then both jaws are moved together into the final alignment while they are occluded in final occlusion.

The CASS planning process may be completed by a surgeon working alone, or by a surgeon working together with a planning specialist who is familiar with the software. In the case where an outside service center is utilized, the planning specialist from the service center communicates with the surgeon, and any other parties (e.g., orthodontist) via web meeting. In this meeting, all parties view the same images, even if the people involved are located in different countries. Guided by clinical measurements and real-time 3D cephalometric measurements, a surgeon plans orthognathic surgery by simulating surgical procedures and visualizing their outcomes. This VTO process is iterated until the desired results are obtained.

The planning process begins with a checklist to ensure that the data processing is correct. The checklist includes the following items: (1) Is the anatomic reference frame correctly defined? (2) Are all the cephalometric landmarks correctly digitized? (3) Are all virtual osteotomies correct? and, (4) Is the final occlusion accurate?

Orthognathic surgery may involve one jaw or both jaws. Planning a single-jaw surgery is simpler than planning a double-jaw operation. In order to best describe how to plan an orthognathic surgery using CASS, we will use a double-jaw surgery as an example (see Figure 3-1). Once the planning algorithm for a double-jaw surgery is understood, it is easy to adopt it to a single-jaw procedure.

CASS planning for any double-jaw surgery should always begin with the maxilla (see Figure 3-1) even when mandibular surgery is desired to be performed first. The reason is that the surgeon is more certain of where the maxilla should go than the mandible. The maxilla should not be canted (zero roll) and should have zero yaw. The upper dental midline (incisal midpoint) should be on the mid-sagittal plane. And, vertically, the incisor show should be normal at rest and smiling.

Correction of Maxillary Deformities

Planning begins by hiding the mandible and moving the maxilla into the ideal alignment. A series of transformations (translations and rotations) are needed to reach this alignment. Rotational transformations are best done on a single point, following a specific sequence. Empirically, we have determined that the best point at which all transformations should be performed is the incisal midpoint, the point at the intersection of the dental midline and the arc defined by the incisal edges. This point represents the middle of the dental arch. Selecting it avoids iterations. For the same purpose, we have also established the following planning sequence:

1. Symmetric alignment
   a. Normalization of transverse position
   b. Normalization of roll
   c. Normalization of yaw
2. Normalization of vertical position
3. Normalization of pitch
4. Normalization of anteroposterior position

In the first step, the maxilla is symmetrically aligned to the mid-sagittal plane. Symmetric alignment involves three transformations: transverse translation, roll rotation, and yaw rotation. Transverse translation places the maxillary incisal midpoint on the mid-sagittal plane. Roll rotation pivots the maxilla around the incisal midpoint until the right and left teeth are vertically leveled. Finally, yaw rotation pivots the maxilla around the incisal midpoint. This makes sure that the posterior teeth are as equidistant as possible to the mid-sagittal and coronal planes.

In the second step, the vertical position of the maxilla is normalized. The planner translates the maxilla up or down, placing its incisal midpoint in an ideal position in relation to the upper lip stomion.

In the third step, one normalizes the maxillary pitch. The planner pivots the maxilla around the incisal midpoint until its pitch is optimized. Maxillary pitch rotation affects the inclination of the maxillary central incisors, the inclination of the maxillary occlusal plane, the airway size, the projection of the anterior nasal spine, and chin projection. It is necessary to consider all these items when deciding on the ideal maxillary pitch for a given patient. The first three items

relate to function, the last two to esthetics. Frequently, the planner needs to make compromises among the items based on the priorities of an individual case.

The final adjustment aligns the maxilla in an anteroposterior position. This adjustment is left for the last because previous transformations can alter one's decision as to how much to advance the maxilla. For example, decreasing the maxillary pitch or changing its yaw can produce a collision between the maxillary tuberosities and the pterygoid plates. These collisions can be easily avoided by advancing the upper jaw.

Correction of Mandibular Deformities

After the maxilla is set into an ideal alignment, the mandible is rendered. The distal segment of the mandible will automatically be in the final alignment because it had been previously linked to the maxilla into final occlusion. Each of the transformations applied to the maxilla was transferred to the distal mandible.

In the next step, the proximal segments of the mandible are aligned. Each proximal segment is rotated around the center of its condyle until the segment is well aligned with the distal mandible. Ideally, there should be no overlap between the proximal and distal segments, because overlap corresponds to areas of bony collision. When present, segment overlap can be avoided by readjusting the yaw of the maxilla and distal mandible, by planning the resection (ostectomy) of the areas of overlap, or by planning a different ramus osteotomy.

Readjustment of the yaw of the maxilla and distal mandible by one or two degrees may avoid proximal segment collision without altering esthetics. Adjustments larger than two degrees should be avoided because they can produce buccal corridor asymmetry—the right to left difference in the amount of posterior teeth displayed while smiling. To prevent displacement of the previous corrections, all yaw readjustment must be made around the upper incisal midpoint. Small areas of bone overlap are amenable to ostectomy. However, large areas of collision that remain after maxillary yaw adjustment can be avoided only by selecting a different operation (e.g., by selecting an inverted L osteotomy over a sagittal split).

Correction of Chin Deformities

In the next step, the planner reexamines the chin. This assessment is necessary because the movement of the mandibular distal segment alters chin position. If the chin is normal, the planner proceeds to the final step. If it is abnormal, the planner should simulate a genioplasty, moving the chin segment until satisfied with the outcome.

Examination of the Residual Final Symmetry

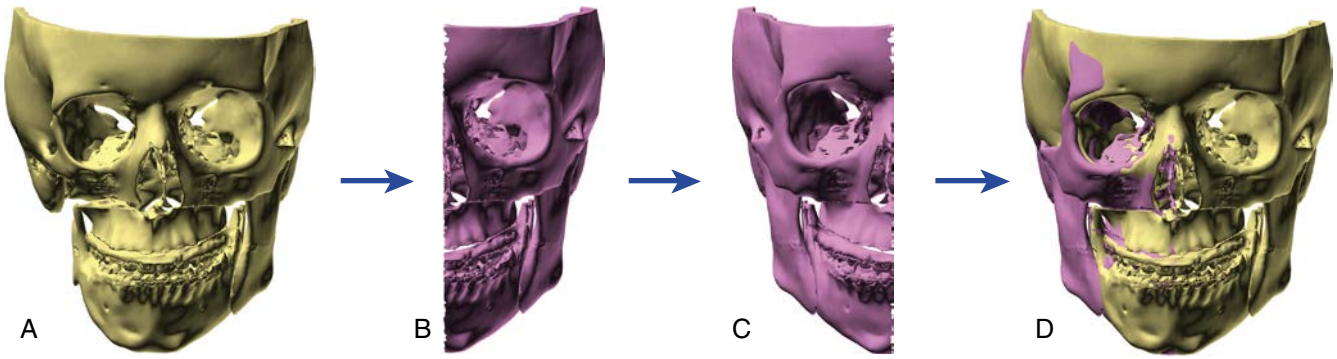
In the last step, the planner assesses final symmetry. When the mandible is abnormal but symmetric, placing the distal mandible in final occlusion maintains symmetry. But when the patient has intrinsic mandibular asymmetry, placing the distal mandible into final occlusion may not correct the asymmetry. Because mild to moderate degrees of intrinsic asymmetry may be imperceptible to the eye, it is important to complete a final symmetry assessment on all patients.

The final assessment of symmetry is done using a mirror image routine (Figure 3-6). In this routine, the composite model is cut in half across the median plane. One side is then copied and reflected (flipped) across the median plane, superimposing it over the contralateral half. The right-left differences are calculated using a Boolean subtraction—a mathematic operation that shows differences between objects. If the symmetry is good, the plan is complete. However, if there is residual asymmetry, the surgeon should consider an osteoplasty, which may entail augmentation or reduction.

Preparing for Plan Execution

A computerized plan is of no clinical value if it cannot be executed at the time of surgery. The final step of the CASS protocol is to prepare the tools necessary for transferring the computerized surgical plan to the patient at the time of the surgery. This is usually outsourced to an independent service provider.

The tables and images that display the planned movements, including mapped areas collision, are generated



• **Figure 3-6** Mirror image routine. **A,** The planned outcome after all bony segments are moved to their desired positions. **B,** One side of the face is first copied. **C,** The copy is flipped horizontally. **D,** The flipped copy is superimposed on the contralateral side; finally, side-to-side differences are calculated.

and displayed at surgery to guide the operation. Moreover, surgical splints are designed in the computer and fabricated using a rapid prototyping machine.[5,10,16,18,21] Genioplasty and other bone templates (e.g., graft or ostectomy) and cutting and drilling guides can also be fabricated as needed.[5,10,16,21] Surgical plates can be either prebent on a physical model[10,16,34] or custom-fabricated.[35] If necessary, a roadmap can also be created for the navigational surgery to guide the surgeon performing osteotomies and drilling screw holes.[10,34,36]

Outcome Evaluations

An old engineering adage holds that a new technology should provide at least one of the following advantages to be considered a significant advance in a routine practice: better outcome, better accuracy, or better cost-effectiveness. The same is true of our CASS protocol, and the authors have evaluated outcomes of our protocol in those three aspects.

Surgical Outcome Evaluation

The authors have completed a study to evaluate whether the surgical outcomes achieved with CASS are better than those achieved with traditional methods.[20] In this study, a total of 12 consecutive patients with CMF deformities were enrolled. Following the CASS clinical protocol,[5] a 3D computer composite skull model for each patient was generated and reoriented to the NHP. These models underwent two virtual surgeries: one was based on CASS (experimental group) and the other was based on traditional methods (control group). Once both virtual surgeries were completed, two experienced CMF surgeons at two different settings evaluated both surgical outcomes. They were blinded to the planning method used on the virtual models and to each other's evaluation results. The primary outcome was overall CMF skeletal harmony. The secondary outcomes were individual maxillary, mandibular, and chin harmonies.

Finally, statistical analyses were performed. The results showed that the overall CMF skeletal harmony achieved with CASS was statistically better than that achieved with traditional methods. In addition, the maxillary and mandibular surgical outcomes achieved with the CASS method were also statistically better. Furthermore, although not included in the statistical model, the chin symmetry achieved by CASS tended to be better. Finally, the study discovered that the most critical step in achieving better overall CMF skeletal harmony was to restore mandibular symmetry.[20]

Accuracy Evaluation

The authors evaluated the accuracy of CASS in the treatment of patients who had dentofacial deformities requiring double-jaw orthognathic surgery.[21] In this study, the accuracy of the CASS protocol was assessed by comparing the planned and postoperative outcomes of 65 consecutive patients. Computer-generated occlusal splints were used for all patients. For the genioplasty, one center utilized computer-generated chin templates to reposition the chin segment of patients with asymmetry. For the remaining patients, standard intraoperative measurements were utilized. The primary outcome measurements were positional and orientation differences for the maxilla, mandible, and chin; planned and postoperative models were registered at the cranium. Secondary outcome measurements were: maxillary dental midline difference between the planned and postoperative positions; and positional and orientational differences of the chin segment between the groups with and without the use of the template. The latter was measured when the planned and postoperative models were registered at the mandibular body. Statistical analyses were performed, and the accuracy was reported using root mean square deviation (RMSD) and Bland and Altman's method for assessing measurement agreement.[37]

In the primary outcome measurements there was no statistically significant difference amongst the three centers for the maxilla and mandible. The largest RMSD was 1.0 mm and 1.5 degrees for the maxilla, and 1.1 mm and 1.8 degrees for the mandible. For the chin, there was a statistically significant difference between the groups with and without the use of the chin template. The chin template group showed excellent accuracy with the largest positional RMSD of 1.0 mm and the largest orientational RSMD of 2.2 degrees. However, larger variances were observed in the group not using the chin template (3.5 mm in positional difference and 5.8 degrees for orientation). Positional differences were significant in the anteroposterior and superoinferior directions. Orientation differences were significant in pitch and yaw. The results of Bland and Altman's method for assessing measurement agreement are presented in Table 3-1.

In the secondary outcome measurements, the RMSD of maxillary dental midline position was 0.9 mm, with a Bland and Altman's limit of –1.3 mm and 1.1 mm. When registered at the body of the mandible, the positional and orientational differences of the chin segment between the groups with and without the use of the chin template were consistent with the results found in the primary outcome measurements (1.1 mm versus 2.0 mm in positional difference, and 1.6 degrees versus 5.0 degrees in orientational difference, respectively). The results of Bland and Altman's method for assessing measurement agreement are presented in Table 3-2.

Finally, a recent published systematic review of 9 studies (out of 375) also evaluated the accuracy and benefit of virtual planning for orthognathic surgery.[38] The accuracy of translation was <1.2 mm in the maxilla (vertical) and <1.1 mm in the mandible (sagittal), and for rotation was <1.5 degrees in the maxilla (pitch) and <1.8 degrees in the mandible (pitch). The results indicated that computer-aided planning was considered accurate. The authors also concluded that high quality randomized clinical trials are

TABLE 3-1 Accuracy (Bland and Altman Upper and Lower Limits) of Positional and Orientational Differences Between Planned and Postoperative Outcomes (Models Registered at the Cranium)

			Positional Difference (95% CI)			Orientational Difference (95% CI)	
			Lower Limit	Upper Limit		Lower Limit	Upper Limit
Maxilla		Mediolateral	–1.7 mm (–2.0 to –1.4)	1.4 mm (1.0 to 1.7)	Pitch	–2.3° (–2.9 to –1.7)	3.4° (2.8 to 4.0)
		Anteroposterior	–0.7 mm (–0.9 to –0.4)	1.6 mm (1.4 to 1.9)	Roll	–1.8° (–3.2 to –1.4)	1.8° (1.4 to 2.1)
		Superoinferior	–0.8 mm (–1.0 to –0.6)	0.9 mm (0.7 to 1.0)	Yaw	–2.7° (–3.2 to –2.1)	2.3° (1.7 to 2.8)
Mandible		Mediolateral	–1.4 mm (–1.5 to –1.0)	1.0 mm (0.8 to 1.3)	Pitch	–3.7° (–4.5 to –2.9)	3.6° (2.8 to 4.3)
		Anteroposterior	–0.9 mm (–1.1 to –0.6)	1.5 mm (1.3 to 1.8)	Roll	–2.0° (–2.4 to –1.6)	1.8° (1.4 to 2.2)
		Superoinferior	–0.8 mm (–1.0 to –0.6)	0.7 mm (0.6 to 0.9)	Yaw	–3.3° (–4.0 to –2.6)	3.3° (2.6 to 4.0)
Chin	Intraoperative linear Measurements	Mediolateral	–2.9 mm (–4.9 to –0.1)	3.9 mm (2.0 to 5.8)	Pitch	–9.4° (–15.6 to –3.2)	12.9° (6.6 to 19.1)
		Anteroposterior	–6.2 mm (–10.1 to –2.2)	7.8 mm (3.8 to 11.7)	Roll	–5.8° (–9.3 to –2.4)	6.3° (2.9 to 9.7)
		Superoinferior	–5.3 mm (–8.2 to –2.5)	4.6 mm (1.8 to 7.4)	Yaw	–7.1° (–11.5 to –2.8)	8.4° (4.1 to 12.8)
	Template	Mediolateral	–1.7 mm (–2.6 to –0.7)	1.8 mm (0.8 to 2.8)	Pitch	–4.1° (–6.5 to –1.7)	4.9° (2.5 to 7.3)
		Anteroposterior	–2.1 mm (–3.3 to –1.0)	2.0 mm (0.8 to 3.2)	Roll	–4.0° (–6.1 to –2.0)	3.7° (1.6 to 5.7)
		Superoinferior	–1.4 mm (–2.1 to –0.8)	1.0 mm (0.3 to 1.6)	Yaw	–4.0° (–6.2 to –1.9)	4.1° (1.9 to 6.2)

TABLE 3-2 Accuracy (Bland and Altman Upper and Lower Limits) of Chin Position and Orientation for Genioplasties Done with Intraoperative Measurements versus Those Done with Chin Templates (Models Registered at Body of Mandible)

			Positional Difference (95% CI)			Orientational Difference (95% CI)	
			Lower Limit	Upper Limit		Lower Limit	Upper Limit
Chin	Intraoperative Measurements	Mediolateral	–2.9 mm (–4.5 to –1.2)	2.9 mm (1.3 to 4.6)	Pitch	–9.7° (–12.8 to –4.9)	10.4° (1.2 to 9.1)
		Anteroposterior	–4.1 mm (–6.4 to –1.8)	4.0 mm (1.7 to 6.2)	Roll	–5.5° (–7.2 to –3.1)	5.0° (0.2 to 4.3)
		Superoinferior	–3.4 mm (–5.1 to –1.7)	2.7 mm (1.0 to 4.4)	Yaw	–4.3° (–4.9 to –0.9)	6.6° (2.2 to 6.2)
	Template	Mediolateral	–1.2 mm (–2.0 to –0.5)	1.4 mm (0.7 to 2.1)	Pitch	–1.7° (–2.9 to –0.6)	2.6° (1.4 to 3.7)
		Anteroposterior	–2.1 mm (–3.4 to –0.8)	2.4 mm (1.1 to 3.7)	Roll	–3.5° (–5.3 to –1.7)	3.3° (1.5 to 5.2)
		Superoinferior	–1.1 mm (–1.7 to –0.6)	0.9 mm (0.4 to 1.5)	Yaw	–3.5° (–5.2 to –1.7)	3.1° (1.3 to 4.8)

needed to definitively compare the accuracies of computer-aided and conventional planning methods.

Cost-Effectiveness Evaluation

Recent reports also demonstrated the cost-effectiveness of using CASS planning compared with the conventional planning method for routine orthognathic surgery.[5,23] The initial CASS records appointment (dental impressions, bite-jig fabrication, clinical examination, anthropometric measurements, recording neutral head posture) takes about 60 minutes.[5,23] It takes another 5 to 10 minutes to set the final occlusions on the stone dental models. After the patient's CT scan is completed, the preparation of the computer data, including dental model scanning, segmentation of CT images, 3D model reconstruction, composite skull model creation, landmark digitization and virtual osteotomies, is completed by a planning specialist or an outsourced service provider. Once the computer data is prepared, it is electronically transmitted to the clinician. The clinician only spends time on examining the cephalometric analysis results, formulating a surgical plan, and testing the plan with the virtual surgical movements. Although there is a learning curve in this process, after the process is mastered it usually takes 10 to 20 minutes to plan a routine case and up to an hour for a complex one. After the plan is finalized, based on the clinician's request (which jaw is operated first), the service facility designs the surgical splints and templates and fabricates them using a rapid prototyping machine. CASS may further save clinicians time during the surgery. This is because the 3D nature of computer planning allows the clinician to anticipate potential complications and pitfalls, which may not be readily apparent during conventional stone model surgery. Currently, at the service center, the entire process takes around 4 hours and costs up to $1000.[39] This is slightly above the amount that is now reimbursed by insurance companies for the fabrication of an oral surgical splint (CPT code 21085). Ultimately, in this entire CASS planning process, the total surgeon's time is reduced to 70 to 100 minutes per case in comparison to 9.75 hours[40] in the conventional planning process.

Orthognathic Model Surgery

ESTHER S. OH, NEIL OISHI

Introduction

Orthognathic surgery involves complex three-dimensional movements of the maxilla and mandible. A plan of precise surgical moves is formulated to achieve a desired functional and esthetic outcome based on many factors, including: facial symmetry and balance, occlusion, incisor tooth show at rest and full smile, soft tissue drape, and co-morbidities such as obstructive sleep apnea. These surgical moves can be described as translations or rotations (roll, pitch, and yaw) along the anterior-posterior, transverse, and vertical axes, respectively (Figure 4-1).

Presurgical model surgery allows the surgeon to carry out the planned osteotomies and movements ex vivo. This exercise enables the surgeon to plan and preview the exact surgical movements and outcome prior to entering the operating room. Additionally, model surgery allows for fabrication of rigid interdental splints to replicate the planned surgical movements intraoperatively. These splints relate the teeth and corresponding skeletal segments in their planned positions during application of rigid internal fixation.

Prior to the advent of model surgery, the earliest form of orthognathic surgery was described in 1849 when Hullihen published an article describing a case of "elongation of the underjaw," where a prognathic patient from burn contractures was successfully treated.[1] In 1898, Edward Angle, Jr. published an article in *The Dental Cosmos* suggesting the use of presurgical model surgery for "double resection of the lower maxilla."[2] In his article, he recommended the use of plaster models to replicate the intended osteotomies, and then fabrication of a vulcanite or metal splint to be used during surgery to achieve more accurate results. Since that time, the use of model surgery and surgical splints for orthognathic surgery have become the gold standard. Model surgery has increased the precision of surgery, decreased intraoperative time, and resulted in predicable and repeatable surgical results. There are various ways and styles to perform model surgery, but we present one of these ways with our usual and customary technique.

Data Collection

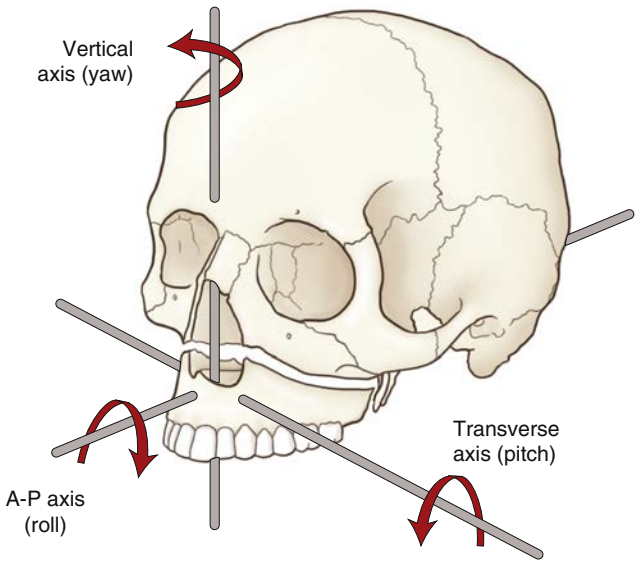
Model surgery begins with data collection at a workup appointment. Immediate presurgical records are obtained for model surgery which may include the following items.

Intraoral and Extraoral Photographs

High quality standardized photos should be taken for documentation, treatment planning, and medico-legal purposes. These photos can assist in verifying accuracy of mounting the casts as well. Obtaining photographs prior to impressions is recommended because residual alginate may get lodged between orthodontic brackets and wires, which can lead to suboptimal pictures (Figure 4-2). Suggested intraoral and extraoral photograph views are listed in the following paragraphs.

Full Head/Extraoral Views

These include frontal views at rest and at full smile, left and right lateral views, and left and right ¾ views. All



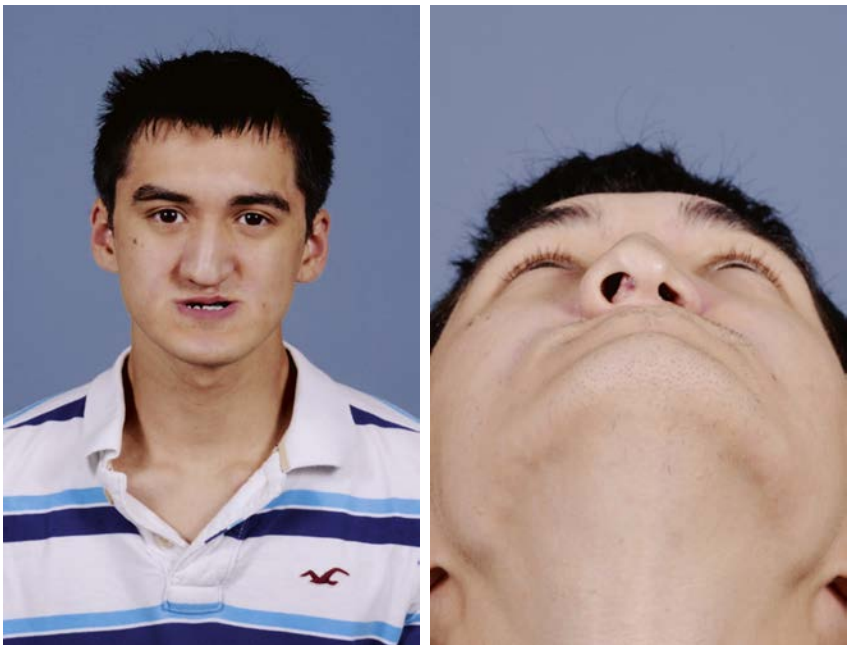
• **Figure 4-1** Roll, pitch, and yaw.

• **Figure 4-2** Poor quality photos.

photos should be taken straight on with the Frankfort horizontal plane parallel to the floor for consistency. With the exception of the full smile view, patients should have their lips relaxed in all the views to document any lip incompetency and to increase accuracy for the lateral cephalometric tracing and soft tissue predictions. Additional views such as bird's eye or worm's eye views may be indicated in select patients such as a person with a cleft lip and palate to document his or her alar collapse (Figure 4-3).

• **Figure 4-3** Clinical extraoral photos. (Courtesy Timothy Turvey.)

Continued



• **Figure 4-3, cont'd.**

Intraoral Views

These include maxillary and mandibular occlusal arch views, global and close-up frontal views, and left and right posterior lateral views to demonstrate canine and molar Angle's classification. Additional left and right anterior lateral views may be taken to demonstrate overbite and overjet (Figure 4-4).

Clinical Measurements

A worksheet is useful during the workup appointment to ensure that all key landmarks and measurements are recorded (Figure 4-5).

Impressions and Models

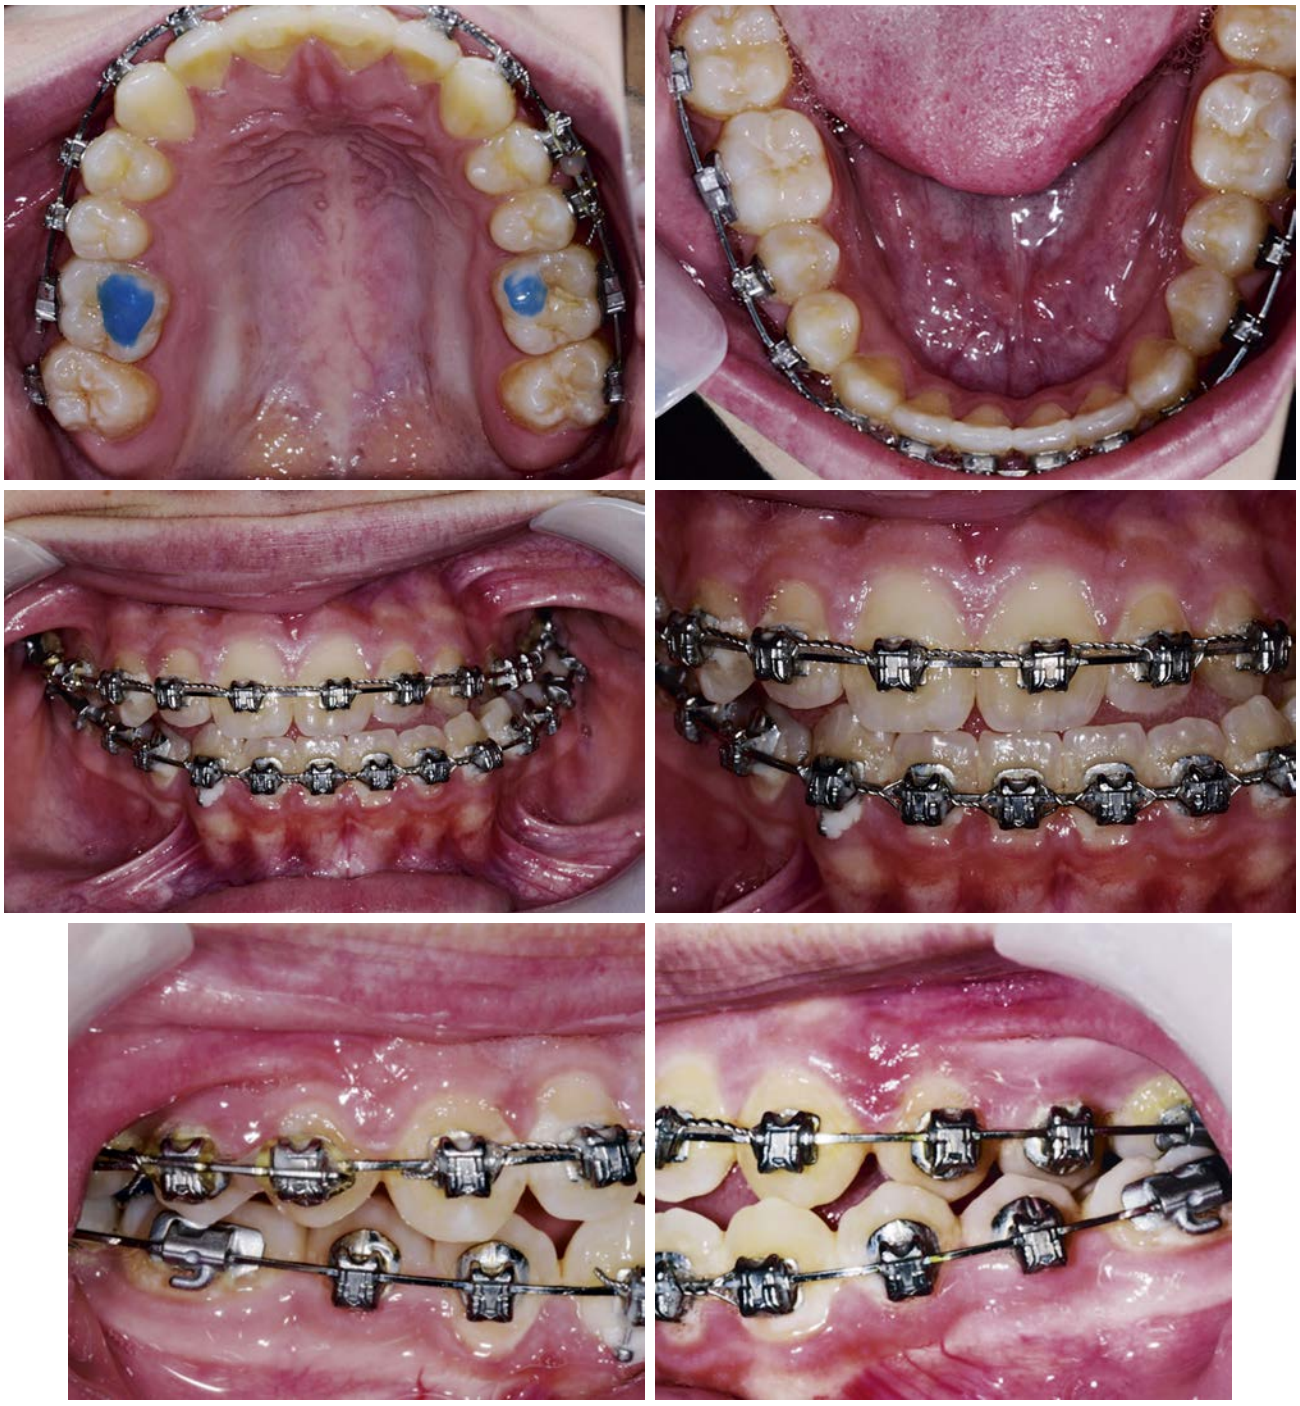
If single jaw surgery is planned, only one set of impressions for the maxilla and mandible is necessary. If a double jaw surgery is planned, two sets of impressions are necessary: one set for the final occlusion and one set for the model surgery. If a multi-piece Le Fort is planned, one extra impression of the maxilla is required. With the required number of impressions in mind, one extra set of impressions is suggested as a "spare" set. Once the models are poured, the most accurate (i.e., without air bubbles on the occlusal surface, chips, etc.) set of impressions should be used for the final occlusion, and the second best set should be used to perform the model surgery to set the intermediate occlusion. The remaining "spare" set can be set aside and used only if there is a chip or break in the other casts. Duplicating the casts instead of taking multiple impressions on the patient is another option, but is not ideal because duplication can decrease the accuracy and detail of the casts (Figure 4-6).

Bite Registration Record

The bite registration should be recorded in centric relation (CR), with the condyles in the most posterior superior position in the glenoid fossa, to create a repeatable position in the operating room. Leaning the patient back in the chair may help to relax the patient's jaw with gravity. Multiple materials can be used for this record, including wax, compound, or polyvinylsiloxane (PVS) products (i.e., BluMousse). Practicing with the patient prior to taking the actual record will allow the patient to feel his or her jaw relaxed and then guided into centric relation. At least two bite registration records should be taken and compared to ensure that the patient's jaw position is repeatable and accurately captured.

Facebow Record

The facebow that corresponds to the surgeon's particular semiadjustable articulator should be used in the usual fashion. Accurate capture of the maxillary relationship to the skull base is critical for mounting the maxillary cast with precision. From the frontal view, the facebow is adjusted to be parallel with the pupils at the level of the infraorbital rims. In many cases, mounting the maxilla while using the facebow can facilitate identification of midline, cant, or yaw discrepancies, and further highlight asymmetric faces, ears, or pupils.



• **Figure 4-4** Clinical intraoral photos. (Courtesy Timothy Turvey.)

Continued

Patients with a grossly asymmetric face may pose a particular challenge. Key points for these asymmetric patients include the following:

- If the patient's orbits are asymmetric (i.e., hemifacial microsomia), Posnick suggests using a plane parallel to the floor in the natural head position as the reference plane instead of the interpupillary line.[3]
- If the ear canals are asymmetric, the ear prong on the side of the malpositioned ear should be placed at the appropriate position to approximate the contralateral "normally positioned" ear.

Once the facebow is recorded, it is used to mount the maxillary cast on the semiadjustable articulator. The mandibular cast is then related to the maxillary cast via the bite registration and then mounted on the articulator with the vertical pin set at zero.

Radiographs

Each patient requires either a cone beam CT (CBCT) reconstruction or three plain films: panorex, PA cephalometric (PA ceph), and lateral cephalometric (lateral ceph) radiographs.

• **Figure 4-4, cont'd.**

Orthognathic Measurements

Name: Jane Dough DOB: 1/1/97 Sex: F

Chart #: 1234-1234 Date: 1/1/15

Examiner: EO

Occlusal plane: 2mm cant R / L canine 2 mm below R / (L) canine

Upper CI exposed at rest: 6 mm CI length: 10

Upper CI exposed at full smile: 10 mm + 1 mm of gingiva

Maxillary dental midline 0 mm to R / (L) of facial skeletal midline

Mandibular dental midline 6 mm to R / (L) of maxillary dental midline

Mandibular dental midline 6 mm to R / L of mandibular skeletal midline

Overjet: 0 mm (end-to-end) Overbite/openbite: 0 mm

Lip incompetence: 8-10 mm

MIO: 55 mm Protrusive: 6 mm R lat: 7 mm L lat: 7 mm

Facial symmetry: (L) orbital dystopia (~ 1-2 mm inferior)

Facial width: 130 mm (137 mm) Facial height: 110 mm (114 mm)

Facial height/width ratio: 83 %

Naso-labial angle: 95 deg Mand incisor to chin length: 40 mm

Other comments:

PLAN: 1) Ext teeth # 1, 16, 17, 32
2) Cranial BG harvest → maxilla
3) LFI (keep maxillary midline, move R maxilla ↑)
4) BSSO, mandible BG harvest → maxilla
5) Genteplasty

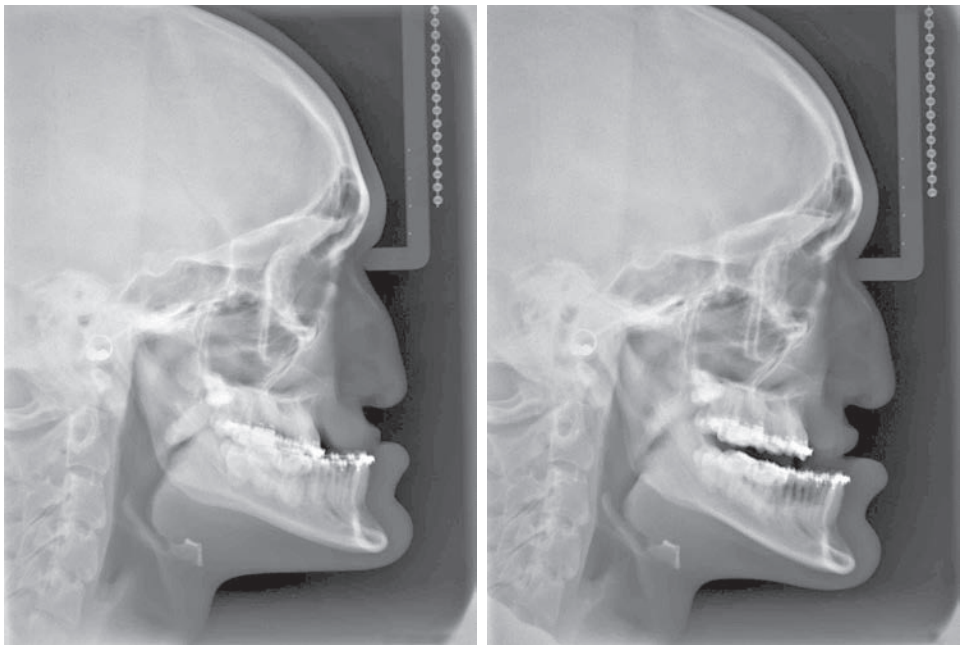
• **Figure 4-5** Worksheet of clinical facial measurements. (Courtesy University of North Carolina Oral Maxillofacial Surgery residency program.)

• **Figure 4-6** Poor quality casts due to air bubbles on the occlusal surface. (Courtesy Carrie Baldwin.)

The panorex will give a general overview of the patient's dentition and anatomy, and will reveal any pathology or impacted teeth. The PA ceph will reveal any skeletal asymmetries, and the lateral ceph will show a general view of the posterior airway space and will be necessary for the cephalometric tracing.

The patient should be instructed to keep his or her teeth together and lips relaxed during the radiographs for a repeatable position. If the patient has trouble relaxing their lips, have the patient lick his or her lips and/or hold the lips still after saying "Mississippi" prior to taking the radiograph. This small but key detail is especially important during the lateral ceph for the best accuracy during both the hard and soft tissue cephalometric tracings.

If the patient is overclosed, two lateral ceph radiographs are recommended: one in relaxed mandibular position and one in maximal intercuspation. The difference in distance can be measured to assess how much the mandible is overclosed. The cephalometric tracing and surgical planning should strive to not exceed the vertical limit of the relaxed mandible (Figure 4-7).



• **Figure 4-7** Lateral ceph (over-closed and relaxed). (Courtesy Timothy Turvey.)

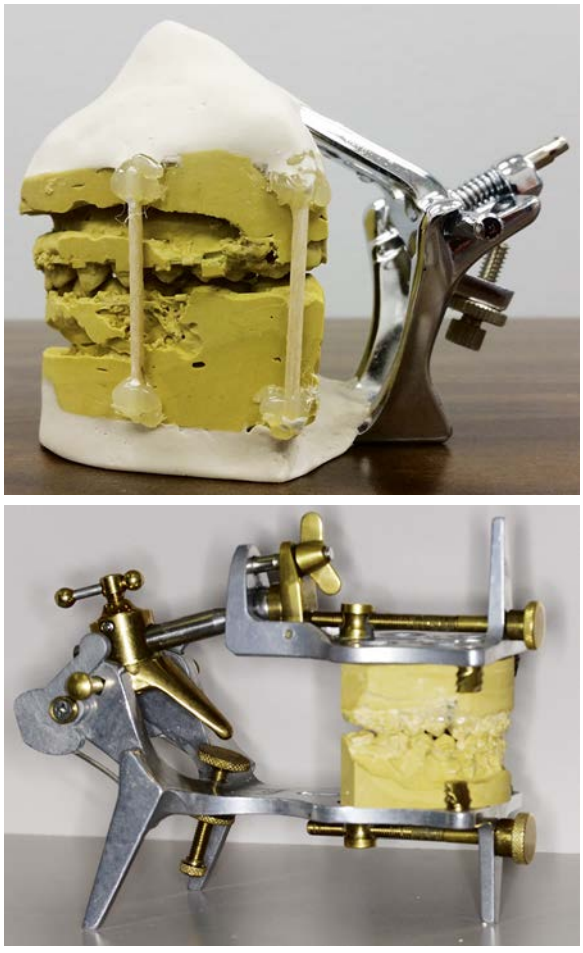
If a multi-piece Le Fort is planned, periapical radiographs should be taken at the planned interdental osteotomy sites to assess for adequate bony space and root flaring. We recommend a minimum of 3 mm of space between roots to decrease the risk of dental trauma during the osteotomies.

Setting the Final Occlusion

Prior to setting the occlusion, casts may be treated with die hardener to prevent abrasion of stone or chipping of teeth, but care should be taken not to use an excess amount, which can create interferences. The dental casts are mounted in a simple hinge or Galetti articulator in their proposed final occlusal relationship for fabrication of the final splint. If using the hinge articulator, wooden sticks from a cotton tip applicator may be spanned and fixated between the maxillary and mandibular cast bases with hot glue or sticky wax. These sticks act as struts prior to mounting the casts on the upper and lower segments of the simple hinge articulator with dental plaster or stone (Figure 4-8).

When possible, the final occlusion should be determined with the orthodontist's preferences and the following criteria in mind:

1. Achieve ideal overbite and overjet (1-3 mm each).
2. Place the canines and first molars in Angle's class I occlusion. A class II molar relationship may be acceptable to the orthodontist, but a class III molar relationship is less desirable because mandibular first molars will function against the maxillary second premolars.[4]
3. Correct transverse discrepancies.
4. Align maxillary and mandibular dental midlines. Although coincidental midlines of the face, maxilla, and mandible are ideal, a study by Profitt and colleagues found that patients may be able to tolerate up to 3 mm of



• **Figure 4-8** Simple hinge and Galetti articulators with the casts in final occlusion.

midline discrepancy before becoming noticeable by the general public and significantly affecting facial esthetics.[5]

5. Close open bites. Although the occlusion should come as close as possible to the final position intended for the orthodontist, extrusion of posterior molars is one of the most straightforward movements for the orthodontist to perform post-operatively.

With ideal presurgical orthodontic preparation, all of the aforementioned criteria may be met. However, presurgical orthodontic results often are less than ideal due to patient or orthodontic factors. In such cases, the compromises and surgical objectives should be discussed with the orthodontist.

Fabricating the Final Splint

For single jaw surgery (maxilla only or mandible only), the final occlusal relationship is the only cast mount needed, which can be mounted on a hinge or Galetti articulator. A final splint is fabricated from the mounted final occlusion. The maxillary and mandibular casts are coated with a thin layer of petroleum jelly to prevent the acrylic from sticking to the cast. For the log roll technique the acrylic resin powder and polymer liquid are mixed to a workable doughy consistency and flattened to a log roll or a sheet approximately 5 mm thick (thicker if there is a larger open bite in the final occlusion). The acrylic is flattened between two tongue blades that have been lubricated with petroleum jelly and the excess is trimmed with Dean scissors. This trimmed strip is placed between the maxillary and mandibular occlusal teeth surfaces and the articulator is closed. Dean scissors are used to trim the gross excess acrylic around the entire buccal and palatal surfaces. Removal of excess acrylic at this stage will significantly reduce the time it takes to trim the splint in later stages.

The articulator is continuously opened and closed until the acrylic hardens to prevent the acrylic from locking into under-cuts around the teeth. After the acrylic starts to feel hot, the articulator is closed and a rubber band may be tied around the articulator to prevent separation of the teeth during the minor expansion that occurs during the self-curing process. A pressure pot may be utilized to increase the strength of the splint. After the splint cools and hardens, easy opening and closing of the articulator should be ensured, and the posterior molar area may be ramped to remove any interferences or excess acrylic with an acrylic bur. The splint should be made as thin as possible to minimize interferences and error, as well as maximize patient comfort. Afterwards, the splint should be polished with coarse and fine pumice for a smooth, glass-like finish for patient comfort and cleanliness.

If the surgeon plans to leave the final splint in place after surgery, the splint is replaced between the maxillary and mandibular casts. Using a pencil or thin permanent marker, marks are made in the buccal embrasures where the surgeon would like holes for circumdental wires to secure the splint intraoperatively. Some surgeons prefer to place a hole in every embrasure to increase options intraoperatively, whereas others may prefer to place select holes in the midline and one or two bilaterally. Minimizing the number of holes helps to maximize the strength of the splint, and drilling these holes after the polishing process helps minimize the risk of breaking the splint. A 701 burr is used to drill these wiring holes, ensuring that the flutes of the bur are cleared after every 1-2 holes. If the flutes are not cleared, acrylic sticks to the burr and progressively increases the diameter of each subsequent hole drilled. Afterwards, each hole should be cleared with a burr or wire to ensure that residual acrylic does not occlude the hole and prevent passing of the wire intraoperatively (Figure 4-9).

Double Jaw Surgery

Mounting the Casts

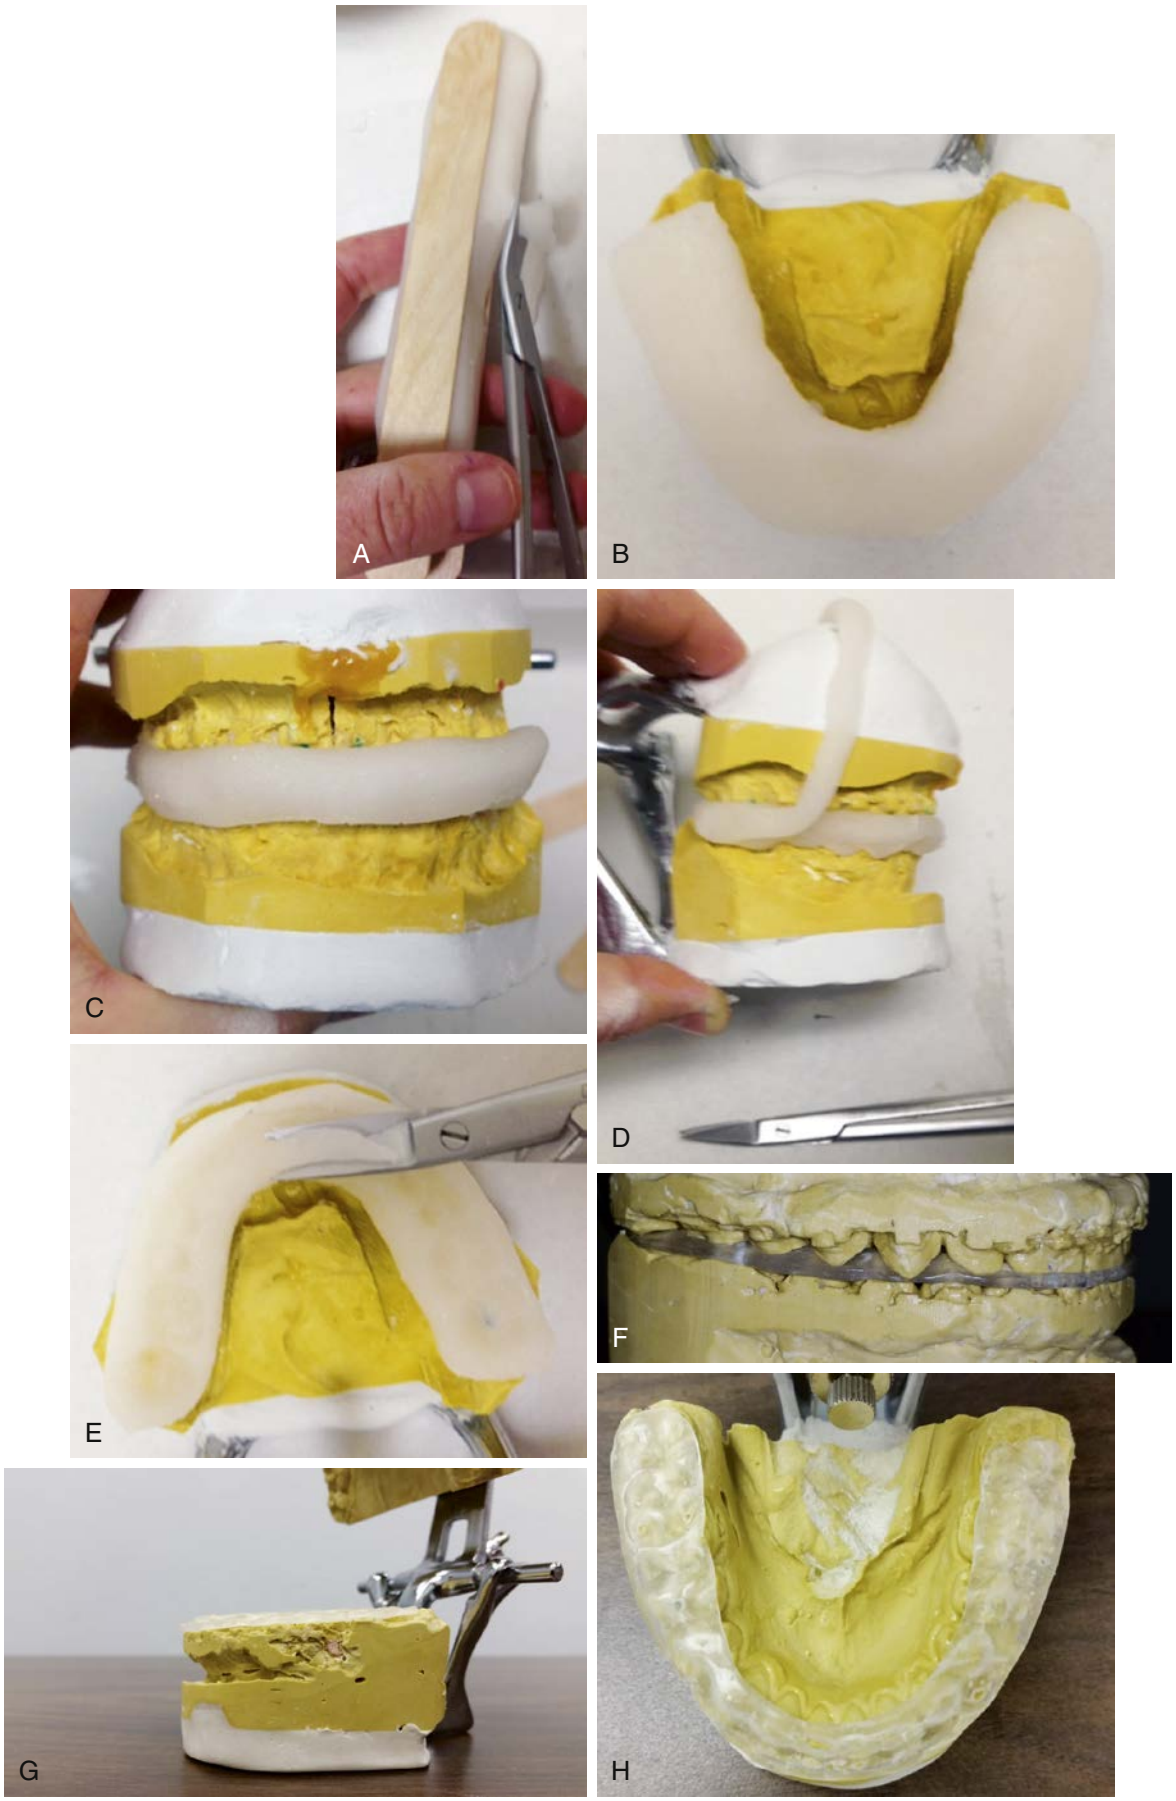
For double jaw surgery or other complex cases, mounting the casts on a semiadjustable articulator is indicated. The articulator needs to replicate the relationship of the maxilla and mandible to the condylar hinge axis as accurately as possible using a facebow transfer for the maxilla and a bite registration record in CR for the mandible. The accuracy of these reference points is critical because the uncut jaw serves as a reference point for the cut jaw during the intermediate move.

Reference Lines and Marking the Casts

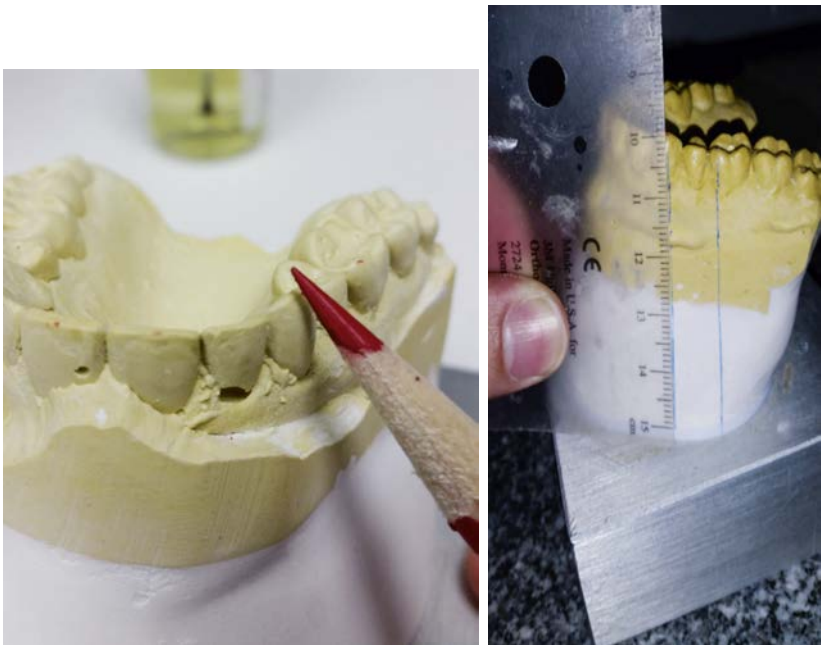
There are various methods for marking casts to simulate the planned surgical moves. We prefer to create horizontal markings that are parallel to the baseplate, and therefore, the Frankfort horizontal plane. A ruler may be used to measure and mark three parallel lines: one indicating the proposed osteotomy line, and two lines about 5 mm on either side of the osteotomy line to be used as reference lines.

A pencil or thin permanent marker can be used to dot several key points on the maxillary dentition: the middle of the incisive edge of the bilateral central incisors, cusp tips of the bilateral canines, and the mesiobuccal cusp tips of the bilateral first molars. These markings serve as measuring reference points to confirm predicted movements during model surgery. Therefore, these dots should be as small as possible to ensure precision of measurements. These dots may be coated with a thin layer of die hardener to prevent abrasion or accidental erasing or these points.

Vertical reference lines are then placed perpendicular to the baseplate from each of these marked dots to the base plate. Another vertical line drawn at the maxillary midline (or mandibular midline if it aligns better with the facial midline) is helpful in visualizing midline shifts. In addition, a vertical line is marked on the posterior side of the cast behind the bilateral maxillary tuberosities to monitor against unintentional yaw shifts during the proposed movements. These horizontal and vertical reference lines are used for evaluation of movements and midline changes of the model surgery (Figure 4-10).



• **Figure 4-9** Fabricating the final splint. (**A-E,** courtesy Carolyn Dicus.)



• **Figure 4-10** Marking reference lines.

Measurements

Now that the patient's maxillofacial and occlusal relationships are accurately replicated on the semi-adjustable articulator, the previously marked occlusal surfaces on the maxillary teeth are recorded on a worksheet as starting reference points in the AP, vertical, and transverse dimensions. Additional reference points such as the anterior nasal spine (ANS), point A, or posterior maxilla also may be recorded as adjuncts. If a multi-piece Le Fort surgery is planned, measurements between both the first molar to first molar at the mesiolingual cusps and the canine to canine should be recorded before and after the model surgery to help assess the amount of planned transverse expansion (Figure 4-11).

The Erickson Model Table (Great Lakes Orthodontics, Tonawanda, NY) is a measuring instrument with a flat granite base and an electronic caliper positioned at 90 degrees which provides a simple, repeatable method for accurately recording these measurements on the dental casts. The caliper is capable of metric measurements to an accuracy of 0.01 mm. The device comes with a model block that secures the mounted maxillary cast via a mounting screw that attaches to the baseplate. The model block is rectangular with precise 90 degree angles and acts as a fixed plane of reference for orientation and measurements in the AP, vertical, and transverse dimensions (Figure 4-12).

These presurgical measurements can be correlated to the clinical facial assessments and photos to check accuracy. For example, if the patient's maxillary midline is coincident with the midsagittal plane clinically, the maxillary midline should line up with the middle of the Erickson mounting block along the transverse axis. Likewise, if the patient clinically has a cant about 2 mm down on the right at the canines, one would expect the vertical Erickson table measurements to be about 2 mm greater for the right canine as compared to the left canine. These simple checks are useful in verifying accuracy of the initial mounting (Figure 4-13).

Once these values are obtained and recorded, the planned surgical movements should be added or subtracted from

• **Figure 4-12** Erickson Model Table.

these values as indicated to obtain the desired final measurements. For example, if planning a 4 mm maxillary advancement, 4 mm should be added to each AP value to determine the planned final value. These planned final values are also recorded on the worksheet.

Repositioning the Maxilla

Double jaw surgery may be performed by starting with either the maxilla or the mandible. Regardless of the sequence of osteotomies, the primary role for model surgery is to replicate correct maxillary repositioning as determined during the initial clinical and cephalometric evaluation. The position of the mandible is dictated by the maxillary position and previously determined final occlusion. Now that the

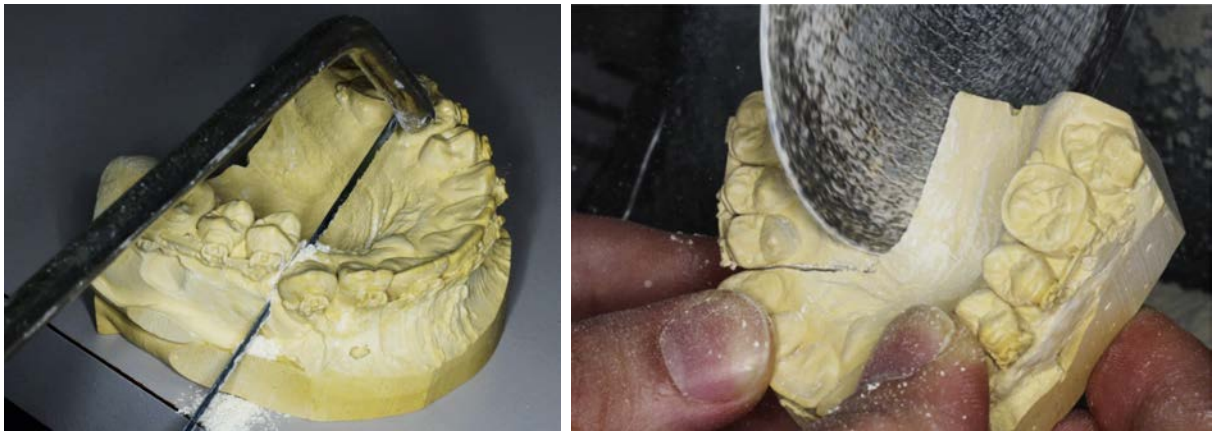
• **Figure 4-14** Measuring the cut cast with the Erickson Model Table after repositioning with modeling clay.



• **Figure 4-15** Sectioning the cast for a multi-piece Le Fort.

casts are mounted, marked, and measured, model surgery usually is performed on the maxillary cast first.

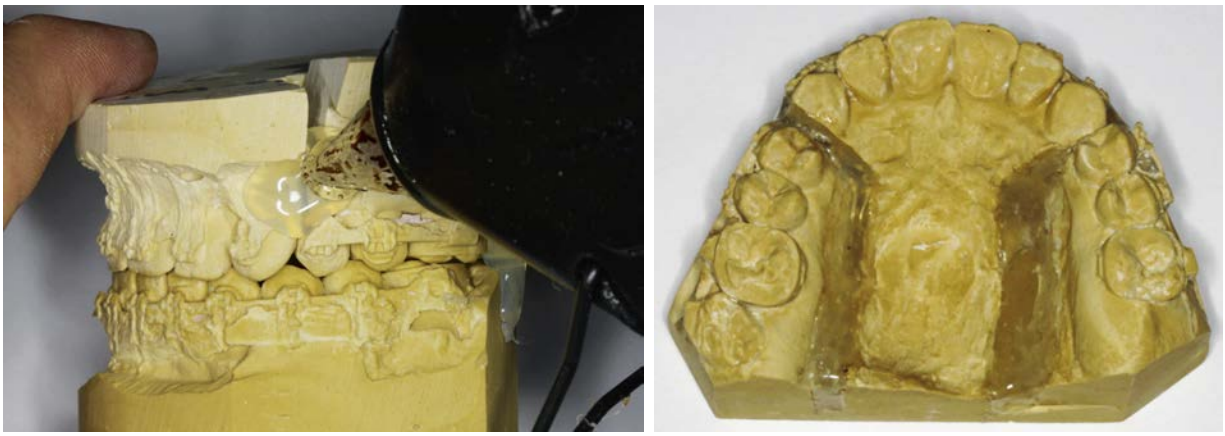
Single-Piece Le Fort I Osteotomy

The mounting plaster of the maxillary cast is cut with a lathe along the previously drawn middle horizontal line to separate the maxillary cast from the baseplate. This cut roughly should simulate the height of the maxillary osteotomy. At this point, the cast and baseplate segments should be trimmed to allow room to freely position the maxillary cast in the proposed final position without interference. In impaction cases, larger amounts of mounting plaster should be removed to allow adequate space for manipulation of the cast.

The baseplate segment is placed on the mounting block of the Erickson Model Table, and a thin layer of modeling clay such as Play-Doh is placed on the baseplate segment. The maxillary cast segment is then seated on the modeling clay to approximate the final position. The maxillary cast is then manipulated on the modeling clay until the calculated final AP, transverse, and vertical measurements are achieved to within 0.02 mm. Once the desired position of the maxilla is achieved, the cast segment is secured in position to the baseplate segment with a hot glue gun or sticky wax. The final measurements of the maxillary occlusal reference points are recorded in the AP, vertical, and transverse dimensions on the worksheet to verify the accuracy of the movement (Figure 4-14).

Multi-piece Le Fort I Osteotomy

In cases planned for a multi-piece Le Fort I osteotomy, the maxilla is sectioned with either a die saw, lathe, and/or a 701 fissure burr along the bony cut, and then a chisel and mallet may be used to guide the break through the contact point between the teeth at the proposed osteotomy sites. If abrasion of the interproximal areas of the adjacent teeth during the interdental osteotomies is unavoidable, one must keep that detail in mind during the actual surgery. One alternative to this scenario to prevent intraoperative interproximal reductions that are not reproducible is to set a gap the width of the saw blade between the maxillary segments. This gap can be closed easily post-operatively with orthodontics.[6] Every effort should be made to avoid or at least minimize step defects in the bony portion of the models because this setup will create periodontal issues for the patient post-operatively (Figure 4-15).



• **Figure 4-16** Multi-piece segments secured and rebased.

The sectioned maxillary pieces are then related to the mandibular cast in accordance with the aforementioned criteria for the final occlusion, and then the maxillary pieces are stabilized to each other with modeling clay and a hot glue gun or sticky wax. The maxillary model then may be rebased with stone to further stabilize the glued maxillary cast. Some surgeons prefer duplicating the reconstituted cast and utilizing this duplicated maxillary model for intermediate and final splints. But the first method of rebasing the cast in stone mimics the steps followed intraoperatively, and therefore, more likely provides greater accuracy than does using duplicate casts. After the reconstituted maxillary cast and the mandibular cast are secured into the final occlusal relationship in the simple hinge or Galetti articulator, a final splint is fabricated.

For the intermediate move, the baseplate segment is mounted on the mounting block of the Erickson Model Table, and modeling clay is placed on the baseplate segment. The reconstituted maxillary cast is then placed on the modeling clay by using the final splint as a guide, and then manipulated to achieve the desired final AP, transverse, and vertical measurements as described for the single-piece Le Fort I osteotomy. Once the desired position of the maxilla is achieved, the reconstituted cast segment is secured in position to the baseplate segment with a hot glue gun or sticky wax. The final measurements of the AP, vertical, and transverse dimensions of the maxillary occlusal reference points are recorded on the worksheet (Figure 4-16).

Fabricating the Intermediate Splint

The intermediate splint is imperative for intraoperative use during double jaw surgery. After the osteotomy of the first jaw (whether maxilla or mandible), this splint helps position the cut jaw in relation to the uncut jaw. Once this position is established intraoperatively, the cut jaw is secured with internal fixation.

Maxilla-first Surgery

After the maxillary segment is oriented and secured on the baseplate in its final position, it is mounted back on the semi-adjustable articulator. The intermediate setup is achieved by mounting the unmoved mandibular cast against the repositioned maxillary cast, mimicking the setup that will be achieved during surgery after the first osteotomy. The fabrication of the intermediate splint is dependent on whether the surgery is for a single-piece or multi-piece maxillary surgery.

• **Figure 4-17** Intermediate splint. (Courtesy Michael Huang.)

Single-piece Maxillary Surgery

In single-piece maxillary surgery, the splint is made directly between the repositioned maxillary cast and unmoved mandibular cast on the semi-adjustable articulator. The articulator pin should be set at zero to minimize inaccuracies, and then the splint is fabricated in a similar fashion to the final splint. Some authors recommend using colored monomer powder to help differentiate between the intermediate and final splints during the operation. We recommend the log roll technique rather than the sheet technique to fabricate the intermediate splint, because large inter-occlusal gaps in the intermediate occlusion usually require a larger amount of acrylic compared to the final splint.

The intermediate splint also should be trimmed as thin as possible with an acrylic burr to minimize interferences and error. Because the intermediate splint is not retained following surgery, wiring holes are not necessary. Particular attention should be directed towards eliminating occlusal bracket interferences and achieving a low buccal profile to minimize interferences intraoperatively when wiring the patient into maxillomandibular fixation. The splint is then polished with coarse and fine pumice for a smooth finish (Figure 4-17).

• **Figure 4-18** Foil technique.

Multi-piece Maxillary Surgery

In multi-piece maxillary surgery a "splint-within-a-splint" technique is recommended. The final splint is wired to the maxillary segments intraoperatively to orient the segments in their proposed final relationship. Because this final splint usually is retained postoperatively to stabilize the segments for healing, the intermediate splint is fabricated around the final splint.

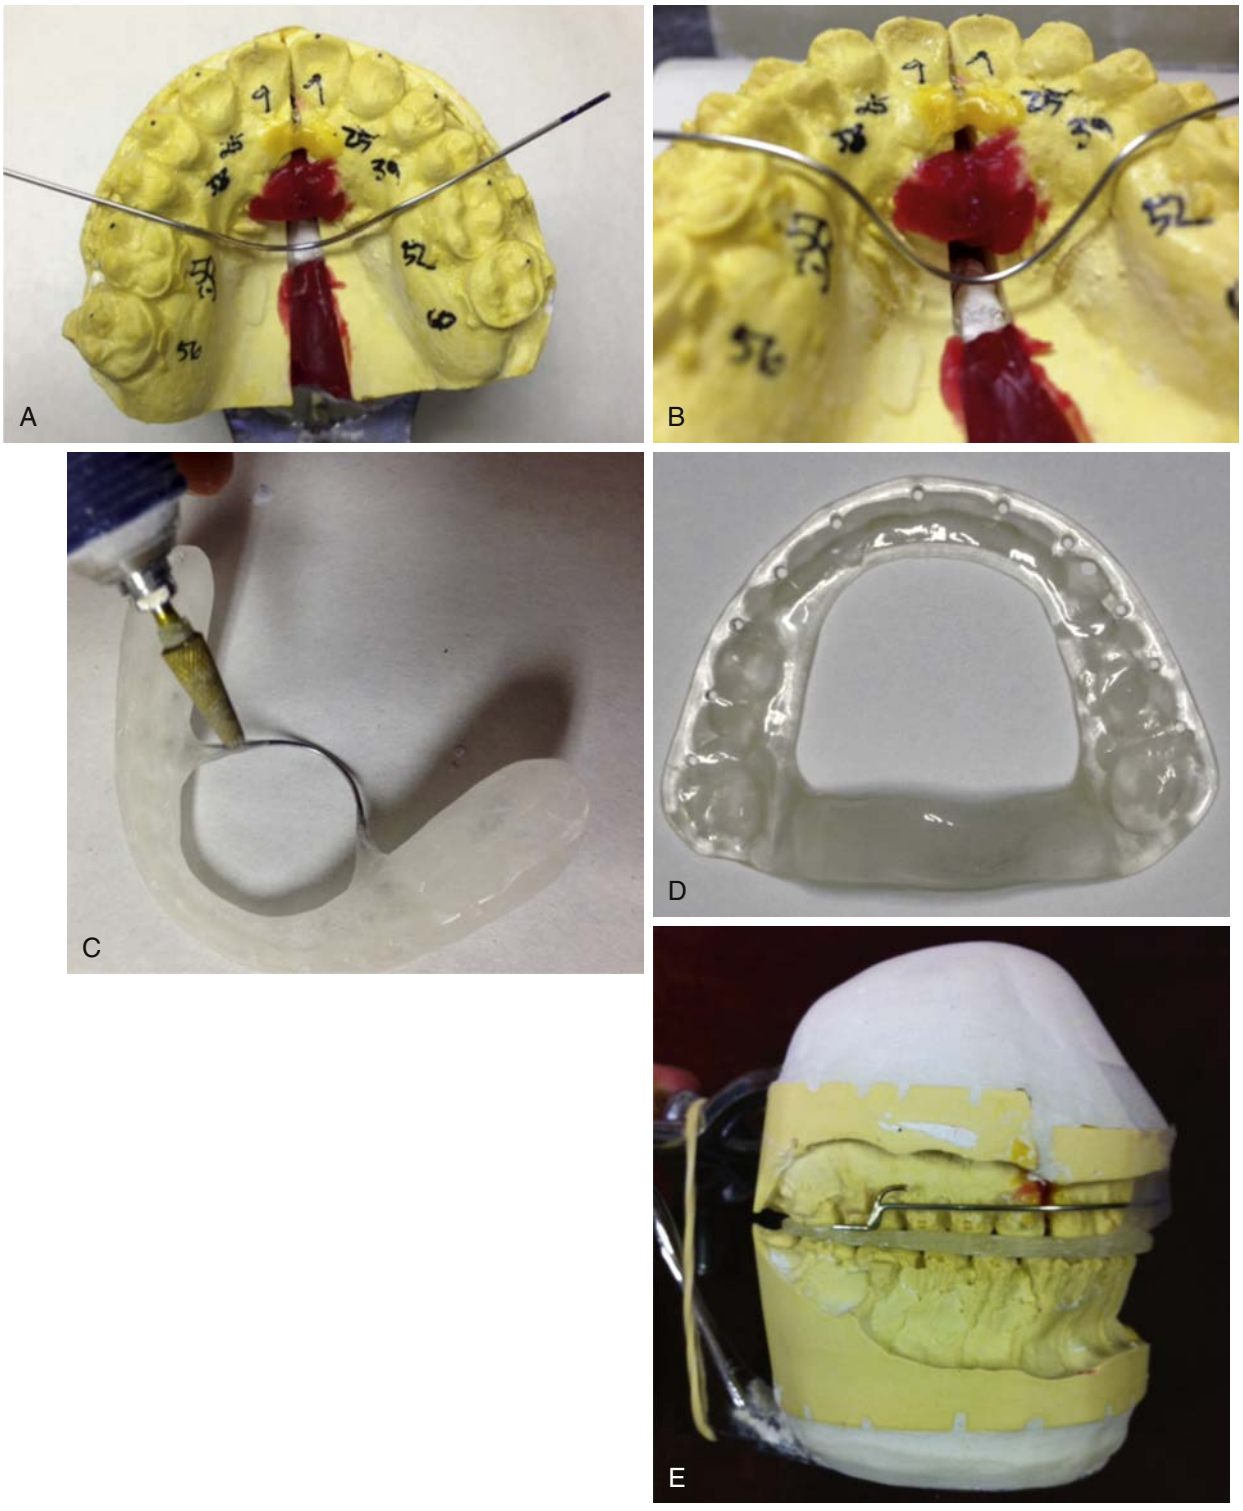
To fabricate the "splint-within-a-splint," the final splint is luted onto the moved maxilla with a hot glue gun or sticky wax. The unmoved mandible is mounted in the semi-adjustable articulator, and the articulator pin is set to zero. The final splint and the mandibular cast occlusal surfaces are coated with a generous but thin layer of petroleum jelly. One alternative to ensure that the intermediate and final splints do not lock together is to adapt aluminum foil around the mandibular teeth using a pencil eraser. The outer surface of the foil and the mandibular casts then are coated with petroleum jelly (Figure 4-18).

The intermediate splint is fabricated between the maxillary final splint and mandibular cast with the log roll technique as described previously, paying special attention to adapt the acrylic along the full extent of the buccal and lingual aspects of the final splint. Encasing the final splint along the buccal and lingual aspects of the intermediate splint prevents rotation and inaccurate seating of the intermediate splint intraoperatively. Once the intermediate splint polymerizes and hardens, the inner surface of the intermediate splint should be flat, and the outer surface should outline the final splint's perimeter.

• **Figure 4-19** Fabrication of a "splint-within-a-splint." (**A-C,** courtesy Carrie Baldwin. **D-E,** courtesy Carolyn Dicus Brookes, MD, DMD.)

Once again, the intermediate splint is trimmed as thin as possible with an acrylic burr to minimize interferences and error. This intermediate splint should have a low buccal profile to match the height of the final splint for easy verification of complete seating of the splint intraoperatively. Although wiring holes are not necessary, the "splint-within-a-splint" naturally will have more buccal prominence and, therefore, some surgeons prefer placing buccal grooves in the intermediate splint where the wires will be passed buccally. The splint is then polished with coarse and fine pumice in the usual fashion (Figure 4-19).

Other adjuncts to increase stability of the multi-piece maxillary segments include incorporation of a palatal strap, either as a continuation of the acrylic used for the final splint, or adding a 0.036 mm orthodontic wire onto the final splint. One must pay close attention to the palatal area by adding wax to the palate of the cast to ensure that the palatal strap is not impinging on the palatal tissues intraoperatively. Another option is to have the orthodontist fabricate a buccal strap by adapting a 0.036 mm wire across the buccal surfaces of the maxillary teeth on the cast in final occlusion. For this option, the orthodontist will need to place maxillary molar headgear tubes preoperatively so that this buccal wire can be secured into these headgear tubes intraoperatively (Figure 4-20). In addition, the headgear tubes can be utilized intraoperatively to widen the maxilla by placing a temporary 22-gauge wire as a "handle". After placing the wire in each headgear tube on either both the right and left molars, one can pull them independently and



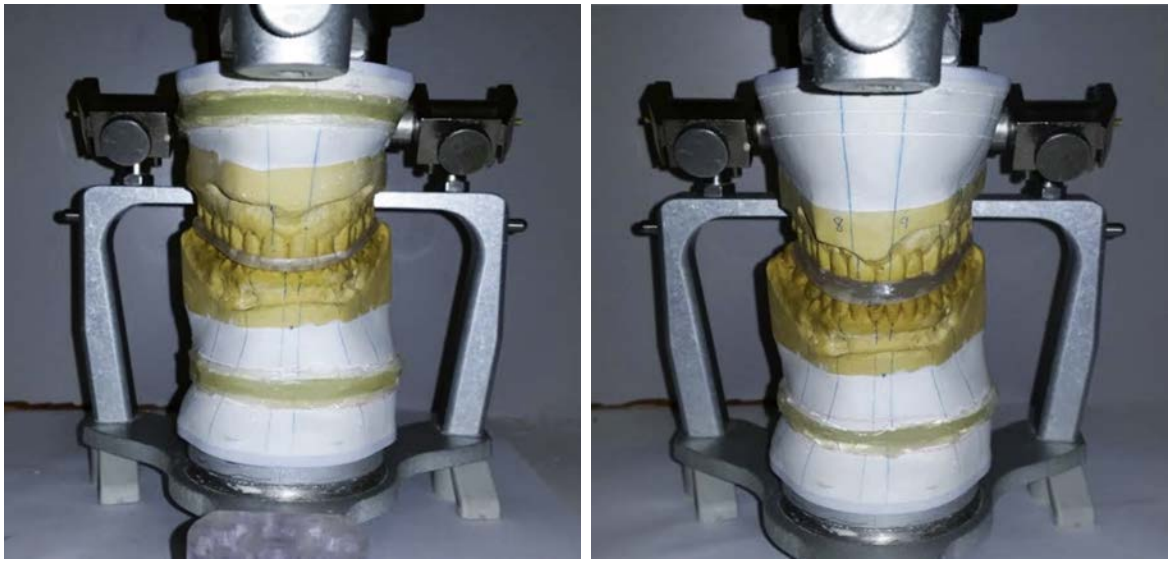
• **Figure 4-20** Adjuncts for multi-piece maxillary surgery. (**A-C,** courtesy Carolyn Dicus Brookes, MD, DMD. **D-E,** courtesy Carrie Baldwin.)

away from each other to place them into the final splint with more control in all three dimensions.

Mandible-first Surgery

Cottrell and Wolford published an article in 1994 suggesting that mandible-first orthognathic surgery may improve surgical accuracy.[7] They argued that when repositioning the maxilla first, the thin bony walls of the maxilla and/or large mandibular advancements may cause maxillary shifting when maxillo-mandibular fixation is applied. Such shifting may decrease surgical accuracy and cause compromised surgical results. Although most surgeons typically do maxilla-first surgery, occasionally mandible-first surgery may be indicated for the following: large mandibular advancements for the reasons mentioned by Cottrell and Wolford, major interferences and

• **Figure 4-21** Indication for mandible-first surgery.



• **Figure 4-22** Intermediate splint for mandible-first surgery.

subsequent inaccuracies with a bulky intermediate splint, and potential instability of maxillo-mandibular fixation with the intermediate splint (Figure 4-21).

In the case of mandible-first surgery, two maxillary casts and one mandibular cast need to be mounted on a semi-adjustable articulator. Both maxillary casts should be marked and measured in the aforementioned fashion and then the measurements compared to assess the precision of the mountings. Even though mandible-first surgery is planned, model surgery is still carried out on the maxillary cast, and the final splint is secured against the repositioned maxillary cast with either a hot glue gun or sticky wax.

The mandibular cast is separated from the baseplate as previously described, and the mounting plaster is trimmed to allow free movement of the mandibular cast without interference. The mandibular cast is seated into the final splint opposing the moved maxilla and secured with a hot glue gun or sticky wax. The mandibular cast is remounted onto a baseplate in its final position with the semi-adjustable articular pin set to zero. The glue or sticky wax is then removed from the final splint, leaving the maxillary and mandibular casts in their proposed final position. Finally, the repositioned maxillary cast is replaced by the second unmoved maxillary cast to achieve the intermediate setup. The pin is set to zero and an intermediate splint is fabricated in this position. Unlike maxilla-first surgery, a "splint-within-a splint" technique is not required for mandible-first surgery for a planned multi-piece maxilla, because the intermediate splint will relate the mandible to an uncut maxilla intraoperatively (Figure 4-22).

Special Considerations

Edentulous Ridges

When a patient is partially or fully edentulous, maxillo-mandibular fixation can be a particular challenge, and the role of the assistant surgeon intraoperatively is especially critical. For fully edentulous patients, one solution is to fabricate Gunning splints with an Erich archbar incorporated into the buccal surface of the acrylic. The splints can be fixated to the jaws using skeletal wiring or screws. But intraoperative error can be introduced by over-compression of the soft tissues during application of the maxillo-mandibular fixation. These small errors can result in unintentional asymmetries, over-, or under-rotation of the occlusal plane, and inaccurate AP movements. Therefore, internal skeletal reference marks, "eye-balling" the final jaw position, and the surgeon's background knowledge of where the edentulous ridge should be in relation to the remaining skeleton, all can help the surgeon get "in the ballpark." Ultimately, dentures and possibly dental implants likely will dictate the patient's final occlusion and vertical dimension.[6]

Splints for partially edentulous patients also deserve careful consideration, especially when only the patient's anterior teeth are present. The acrylic of the splint should fully engage the lingual and occlusal/incisal aspects of the remaining teeth in the arch, where lingual holes can be utilized to secure the splint with circumdental wires. Erich archbars should be incorporated into the buccal portion of the edentulous areas of the acrylic splint to allow for adequate maxillo-mandibular fixation. The circumdental wires will help prevent movement of the splints and jaws during the application of the rigid fixation. Although an acceptable occlusion may be achieved, inattention to these critical details may result in inaccurate positioning with a poor skeletal relationship.[6]

Genioplasty

When a genioplasty move is not straightforward (i.e., asymmetric jaw), model surgery can be used to assess the effects of the maxillary and mandibular movements on the chin point. The distance between the patient's lower incisal edge (L1) to soft tissue menton should be measured clinically at the time of data collection. A repositioned maxillary cast is mounted against an unmoved mandibular cast on a semi-adjustable articulator. A vertical reference line through the maxillary dental midline should then be marked on the maxillary and mandibular casts. An approximated soft tissue menton point is then marked on the mandibular cast along this vertical line using the previously measured L1 to soft tissue menton distance. A horizontal line is then drawn on the cast at the level of the approximated soft tissue menton point, and the base is cut along this mark. The mandibular cast is then placed into final occlusion using the final splint. With the vertical pin of the articulator set to zero, the mandibular cast is then resecured to the baseplate with a hot glue gun or sticky wax. The vertical reference line from the baseplate is then continued onto the mandibular cast. The distance between the original vertical reference line to the new vertical reference line estimates the effects of the maxillary and mandibular movements on the soft tissue menton. This distance can assist in planning the genioplasty move (Figure 4-23).

• **Figure 4-24** Virtual model surgery. The maxilla has more detail due to the iTero scanning of the teeth directly, whereas the mandible shows less detail from scanning the casts of the teeth. (2017 © Materialise, All Rights Reserved.)

Summary

Presurgical model surgery allows for precise surgical planning of complex three-dimensional movements of the maxilla and mandible for orthognathic surgery. Since Edward Angle II suggested the use of plaster models and fabrication of vulcanite or metal splints in 1898, model surgery has gradually evolved with advances in technology and dental materials. The advent of the semi-adjustable articulator, facebow, Erickson Model Table, acrylic, PVS, and various dental stones, all have led to improvements in accuracy and precision of model surgery.

Perhaps the greatest advancement in recent years has been the introduction of virtual surgical planning. Both popularization of CBCT and improvements in computer technology and 3D printing have made the role of virtual surgical planning increasingly apparent. Anatomic data from a CBCT in combination with digital dental impressions or data from scanned dental casts can be used to create virtual 3D models. This digital process minimizes possible error that may be introduced with traditional facebow transfer and mounting, which especially may be instrumental in asymmetric patients. With the assistance of a computer engineer, model surgery can be performed virtually and surgical guides can be computer manufactured. Visualization of the movements on the screen allows the surgeon to better anticipate and prevent adverse sequelae, such as revealing the need for infracturing the proximal segment when over-torquing the condyle. Virtual surgical planning may increase the efficiency and accuracy of the presurgical workup, and eventually may replace traditional model surgery as we know it (Figure 4-24).

Common Mandibular Ramus Osteotomies: Sagittal Split Ramus Osteotomy and Intraoral Vertical Ramus Osteotomy

NICHOLAS A. MEDEL, DOUGLAS P. SINN

Historical Background

The earliest performed mandibular ramus osteotomies[1,2] at the turn of the last century seemed to be modifications of Simon Hullihen's original reports of mandibular setback with various body osteotomies.[3] Although landmark in nature, these operations had their shortcomings; they were approached extraorally, and addressed mandibular prognathism only via setting the mandible back. Nearly 50 years later in Austria, Hugo Obwegeser pioneered the first mandibular ramus osteotomy that was not only approached intraorally, but also could shorten and lengthen the mandible.[4]

Obwegeser had observed sagittal traumatic fractures of the mandible, and then performed sagittal splitting of the mandibular ramus on cadavers. While training with Professor Richard Trauner, at the department of surgery, at the Medical University of Graz, Austria in 1953, Obwegeser executed the first sagittal split ramus osteotomy. Obwegeser did so on one side of a patient whose contralateral mandibular ramus was cut by Dr. Trauner via a combined intra-orally and extra-orally approached L-shaped osteotomy. The sagittal split ramus osteotomy was subsequently published internationally by Obwegeser in 1957 (Figure 5-1, *A*).[5] Today, the bilateral sagittal split ramus osteotomy (SSRO) is one of the most frequently utilized osteotomies to correct mandibular prognathism, retrognathia, and asymmetries.

Two modifications to the sagittal split ramus osteotomy were eventually implemented. Giorgio Dal Pont, while visiting Obwegeser in Zurich, experimentally designed a modification in an effort to create more osseous contacting surface area of the split segments to enhance bony union and allow for increased advancement of the distal segment (see Figure 5-1, *B*). He altered the horizontal orientation of the lateral corticotomy of the ascending ramus to a vertically oriented lateral corticotomy of the mandibular body.[6] Obwegeser found this modification possible and indeed likely beneficial after performing it on a patient. Dal Pont returned to his home in Italy in 1958 to independently publish his results on jaw models and cadavers, omitting a description of the clinical execution of the modification by Dr. Obwegeser.[7-9]

A second modification of Obwegeser's osteotomy later evolved.[10,11] Hunsuck and Epker found that an incomplete lingual osteotomy extending just beyond the neurovascular bundle simplified splitting of the medial ramus compared with the original full-length lingual osteotomy carried to the posterior border, which was at times difficult and could propagate unfavorable splits. The Hunsuck modification employs an incomplete extension of the lingual cut (see Figure 5-1, *C*), resulting in a favorable incomplete fracture along the medial ramus. Splitting the ramus in this fashion left more muscular attachment on the proximal segment, freeing up the distal segment for positioning. Despite less bony contact with an incomplete fracture of the medial ramus, the sagittal split ramus osteotomy (SSRO) in combination with the compensating Dal Pont modification remains the workhorse ramus osteotomy of today.

For the next couple of decades after the birth of the SSRO, fixation was achieved with a combination of

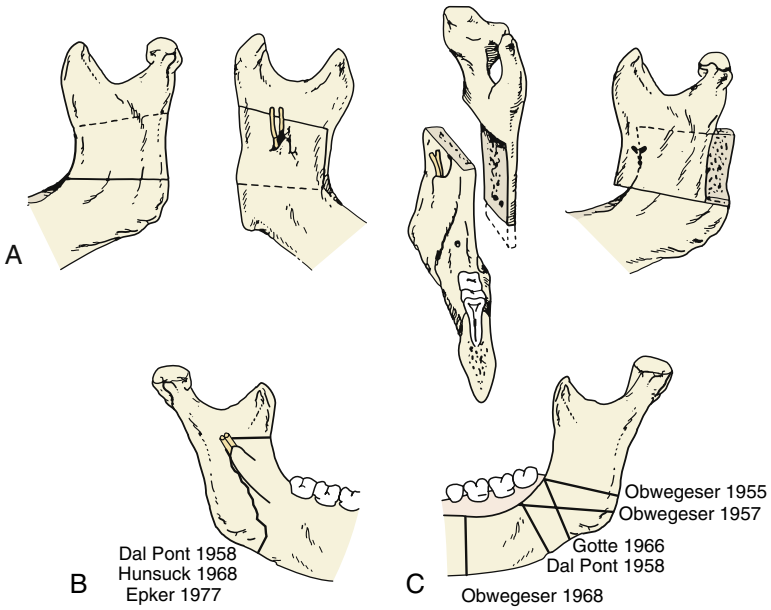
intermaxillary fixation (IMF) for a considerable amount of time and wire stabilization of bony segments. Although wire osteosynthesis of segments was occurring, surgeons sought greater stability, improved bony union, and avoidance of long periods of IMF. Stable compression osteosynthesis with steel bone screws for the SSRO, introduced in 1974 by B. Spiessl from Switzerland,[12] brought about a major breakthrough and began to replace osteosynthesis by wire fixation and/or intermaxillary fixation. Immediate postoperative stability improved, and for many, obviated the need for IMF. Spiessl's steel screws utilized a lag screw technique, and many surgeons realized the technique's inherent technical challenge to prevent condylar dislocation and resultant malocclusion from torsion occurring at SSRO lag sites.

Soon thereafter, some surgeons began utilizing a "bicortical" (non-lag screw) fixation technique to eliminate torqueing of the proximal segment of the SSRO. Lindorf and Niederdellmann and colleagues described this technique, now known as "positional screws."[13,14]

Around the same time, other major developments were taking place. Hans Luhr, often credited as the first to apply maxillofacial compression osteosynthesis in humans with his Vitallium fixation set,[15] set forth miniplate applications in maxillofacial trauma,[16] Le Fort I osteotomies and the SSRO. Maxime Champy was utilizing steel miniplates for mandible fractures and Le Fort I osteotomies.[17,18] Francois Michelet's report in 1971 out of France documents using miniplate fixation of Obwegeser's sagittal split osteotomy.[19]

Throughout the 1980s, fixation hardware continued to improve and took hold throughout the world. Titanium replaced other metal alloys and steel with its far superior biologic compatibility. Plates and screw size profiles decreased, enabling easier anatomic contouring. Although still widely used today in orthognathic surgery, titanium fixation components and their permanent nature can at times illustrate some inherent material imperfections. The risk of infection or rejection of titanium is low, but sometimes requires retrieval from the human body. There are other proposed drawbacks to titanium such as growth restriction, palpability, scatter formation with future imaging, and interference in radiation therapy.

The quest for an ideal fixation material has expanded into the realm of bioresorbable materials. Poly-alpha-hydroxy acids (copolymers of polylactide and polyglycolide), first proposed for the repair of bone fractures in the late 1960s,[20] are now available in the form of small plates and screws and manufacturers claim sufficient stability until hydrolytic resorption at 12 weeks. Researchers began reporting use of bioresorbables in orthognathic surgery around the turn of the twentieth century.[21-23] Turvey and colleagues subsequently published their findings in 2006 with bioresorbable screw fixation: similar stability



• **Figure 5-1** **A,** Obwegeser's technique of intraoral sagittal split osteotomy. The cut at the outer cortex ends at the gonial angle, which allows rotation, but not large advancements. **B,** The Dal Pont technique sets the cut at the horizontal ramus farther forward, which allows advancements up to 15 mm. **C,** Hunsuck showed a technique whereby the cut at the inner cortex of the ascending ramus ends immediately behind the entrance to the neurovascular bundle. Muscles of mastication stay attached to the proximal segment. Positioning of the condyle into the fossa during fixation is easier. (**A,** From Obwegeser HL: *Mandibular growth anomalies,* Berlin, 2001, Springer, Fig 80c, p 360; **B,** from Obwegeser HL: *Mandibular growth anomalies*, Berlin, 2001, Springer, Fig 85d, p 372; **C,** from Obwegeser HL: *Mandibular growth anomalies*, Berlin, 2001, Springer, Fig 85b, p 372.)

at one year compared to traditional titanium screw fixation for mandibular advancement via bilateral sagittal split ramus osteotomies.[24] Currently, titanium hardware remains the most widely used fixation method in orthognathic surgery.

Another intraoral mandibular ramus osteotomy, later to be known as the intraoral vertical ramus osteotomy or IVRO, was described by Moose in 1964.[25] This particular ramus osteotomy seemed to originate from Limberg's original extraoral subcondylar osteotomy,[26] and was used to set the mandible back in cases of mandibular prognathism. Moose's technique differed from the subcondylar osteotomy in using an intraoral approach from the medial side of the mandible and incorporated a vertical rather than a more horizontal/oblique ramus cut. The osteotomy coursed from the sigmoid notch, just behind the mandibular foramen, to the inferior border of the mandible. Winstanley modified the IVRO with his lateral approach in 1968,[27] and in 1970 Herbert and colleagues introduced the currently employed method of cutting the mandible from the lateral side with an oscillating saw. In comparison with the SSRO, surgeons predictably achieved osteosynthesis after the IVRO with the use of IMF. Initially, efforts were made to fixate both segments of the IVRO with wires or screws, and researchers advocated favorable bony union with rigid fixation.[28-30] Surgeons, however, began to notice successful bony union occurring through cortical overlapping of the segments, without intersegment fixation, but with early allowance of mandibular movement after a 2-week period of IMF,[31,32] and a replicated study on adult dogs found the same.[33]

Description and Indications for Bilateral Sagittal Split Ramus Osteotomy

Since its introduction in 1956, the bilateral sagittal split ramus osteotomy has become the most widely used ramus osteotomy for correction of mandibular growth discrepancies. It has been modified in many ways to optimize its numerous benefits and advantages (Box 5-1), which have been well demonstrated over the last 50 years. Obwegeser's original osteotomy design in combination with the various modifications now commonly incorporated make the sagittal split ramus osteotomy especially effective for surgical correction of nearly all mandibular deformities.

The versatility of the procedure stems from its wide application in either mandibular advancement, setback, and asymmetry correction. Compared to dental movements achieved through orthodontic treatment alone, it tremendously increases the range of possible movements as demonstrated by Proffit's envelope of discrepancy.[34] Furthermore, the broad surface area of bony overlap created along the sagittal osteotomy allows not only advancement or setback of the distal tooth-baring mandible, but also rotations. Large anterior and posterior movements still result in excellent healing secondary to the broad bony interfaces. The pterygomandibular sling stays attached to the proximal segment at the gonial angle. With rigid fixation from an intraoral approach, little detachment of the musculature is necessary. This technique results in very little muscle traction, offering protection against long-term relapse. Because these muscles of mastication stay attached to bone, it is easier to position the condyle during fixation of the segments. Correct positioning of the condyle is required to prevent postoperative arthropathy and possible malocclusion as the condyle returns to a more centric position in the fossa. Over the years, its repeated application has made the surgical procedure itself quite standardized, helping to minimize the risk of complications and shorten operating time (Case Study 5-1 to 5-4).

• BOX 5-1 Characteristics and Advantages of BSSO

Great three-dimensional flexibility in repositioning the distal fragments
which allows accurate intraoperative positioning of the fragments
Broad bony overlap of osteotomized segments
which results in excellent healing
Minimal alteration of the natural position of muscles of mastication
which prevents relapse from muscular traction
Minimal alteration of the original position of the temporomandibular joint
which minimizes the risk of postoperative athropathy
Short operating time and low complication rate

Limitations of the Sagittal Split Ramus Osteotomy

Without question, the SSRO is the most commonly selected ramus osteotomy for a vast list of mandibular growth discrepancies, mainly because there are very few limitations to the surgical procedure itself. Large mandibular setbacks of the mandible can produce amounts of bony interference removal found to be cumbersome by some surgeons, especially in cases where the mandibular rami are significantly laterally flared, producing a triangular or "V-shaped" mandible. With the aid of virtual surgical planning, one can know preoperatively the exact dimensions and location of the bony interference to be removed, decreasing intraoperative time spent doing so. A concern with large setbacks approaching a centimeter is the risk of iatrogenically induced obstructive sleep apnea in certain patients such as overweight males. In some cases of severe mandibular hypoplasia (i.e., when the ramus is rendered so thin that little marrow space is left for sagittal splitting) surgeons have opted for other ramus osteotomies. The extremes of mandibular advancement, especially with concurrent counterclockwise rotation, can significantly

CASE STUDY 5-1

Mandibular Deficiency With Normal Face Height

R.J. was referred for orthodontic treatment at age 12. She presented with class II malocclusion and severe crowding in the lower arch. She wanted her teeth fixed and hadn't liked her teeth for as long as she could remember (Figures 5-2, 5-3, 5-4).

Oral health was good, and some bone loss was evident at the right medial lower incisor. R.J. had some clicking in the right joint and occasional pain.

On clinical examination of her face, AP mandibular deficiency was noted. Combined orthodontic-surgical treatment was suggested. Her parents believed she was too young for surgery at this point. Because of the joint pain, splint therapy was suggested. Orthodontic treatment was started when R.J. was 15 years old. Cephalometric analysis confirmed AP mandibular deficiency. At that time, bone loss at both of the medial lower incisors had worsened.

The treatment plan was as follows: To align the crowded lower arch, the left lower medial incisor had to be extracted; because some bone loss was apparent and all other teeth were in good health without caries, bilateral sagittal split osteotomy (BSSO) to advance the mandible was recommended.

• **Figure 5-2** The patient at age 12. Facial view shows her lower lip everted. At rest, she shows 4-mm lip incompetence. The lower dental arch is severely crowded.

Continued

Mandibular Deficiency With Normal Face Height

• **Figure 5-3** **A-C,** The patient at age 16 after orthodontic stabilization of the dental arches. Facial view shows the lower lip everted with a deep sublabial fold. The profile is convex. **D** and **E,** The teeth are well aligned, overjet is 9 mm and overbite 4 mm. The patient shows 3 mm of upper incisor at rest. The lower arch has only three incisors after extraction of the left medial incisor and the remaining right incisor with some bone loss. **F,** Lateral cephalometric radiograph confirms the anterior-posterior (AP) mandibular deficiency.

Mandibular Deficiency With Normal Face Height

• **Figure 5-4** At 3-year recall, the patient presents with good balance of the facial thirds and relaxed lips. She is very satisfied with the outcome. She thinks that her quality of life has improved; she likes her teeth and her profile and has no difficulty eating all kinds of food. Both the temporomandibular joint (TMJ) clicking and the pain that she experienced prior to treatment have disappeared.

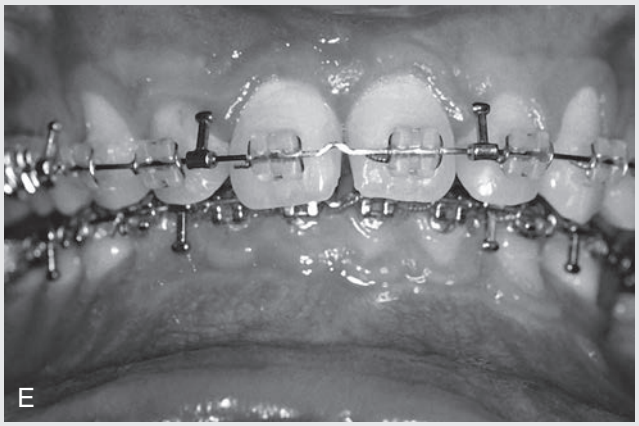
CASE STUDY 5-2

Mandibular Deficiency With Short Face

This 25-year-old patient was seeking orthodontic treatment because of a deep bite that caused inflammation lingual to the maxillary teeth (Figures 5-5 and 5-6). He had some facial esthetic concern because of the strong chin button, but this was not his main reason for seeking orthodontic treatment.

The patient had difficulty with chewing and pain because of the inflammation, which had increased in intensity and duration over previous months.

On clinical examination, the periodontal condition was good except for severe inflammation lingual to the maxillary incisors.



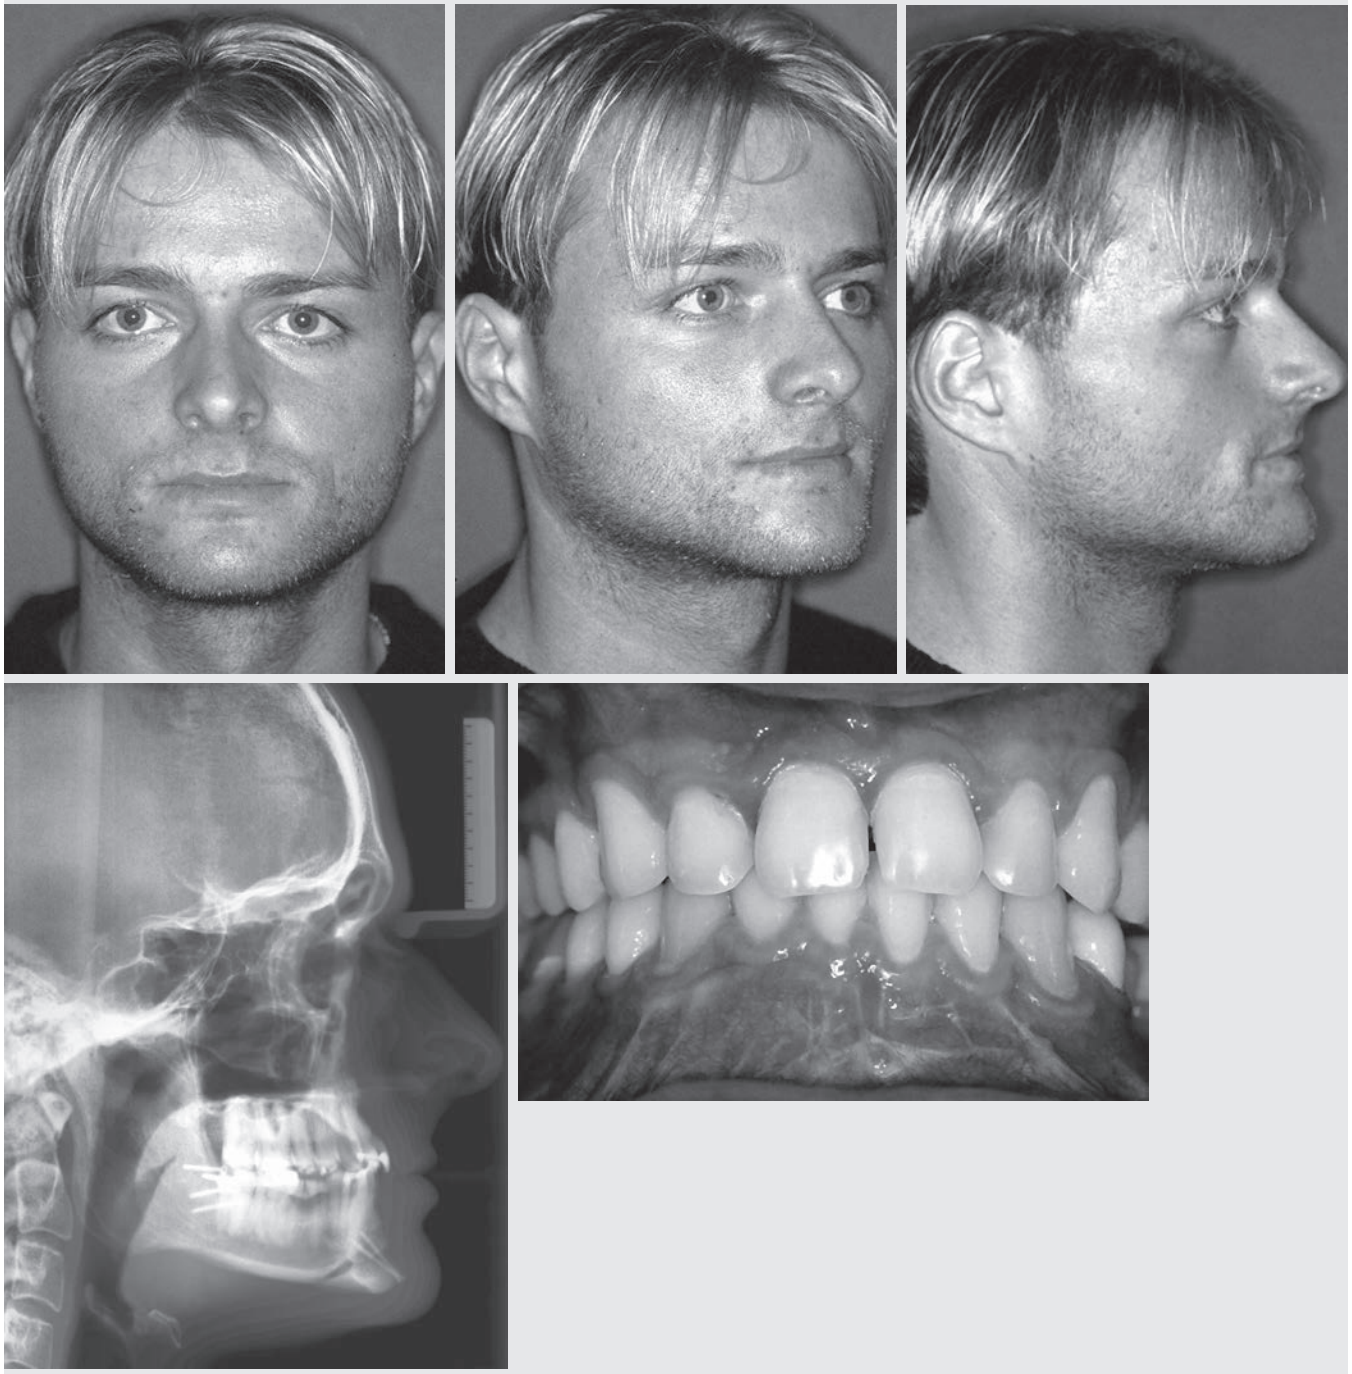
• **Figure 5-5** **A-C,** Facial examination shows reduced lower face height and anterior-posterior (AP) mandibular deficiency with a prominent chin button and a deep labiomental fold. **D,** Cephalometric radiograph confirms the AP deficiency of the mandible and the skeletal deep bite. The mandibular forward and upward rotation is obvious; the chin button seems higher than the gonial angle. **E,** The severe overbite "hides" the lower incisors.

CASE STUDY 5-2—cont'd

Mandibular Deficiency With Short Face

He had 10 mm overjet and 7 mm overbite. He had lost his left lower first molar because of caries, but oral health was good. Lower face height was short with a strong chin button, a retrusive lower lip, and an exaggerated labiomental fold. Cephalometric analysis showed AP mandibular deficiency and skeletal deep bite with the mandible rotated upward and forward.

The treatment plan was as follows: BSSO should be performed to advance the mandible and rotate the distal segment to increase the mandibular plane angle and correct the deep bite, followed by inferior border osteotomy to further increase lower face height.

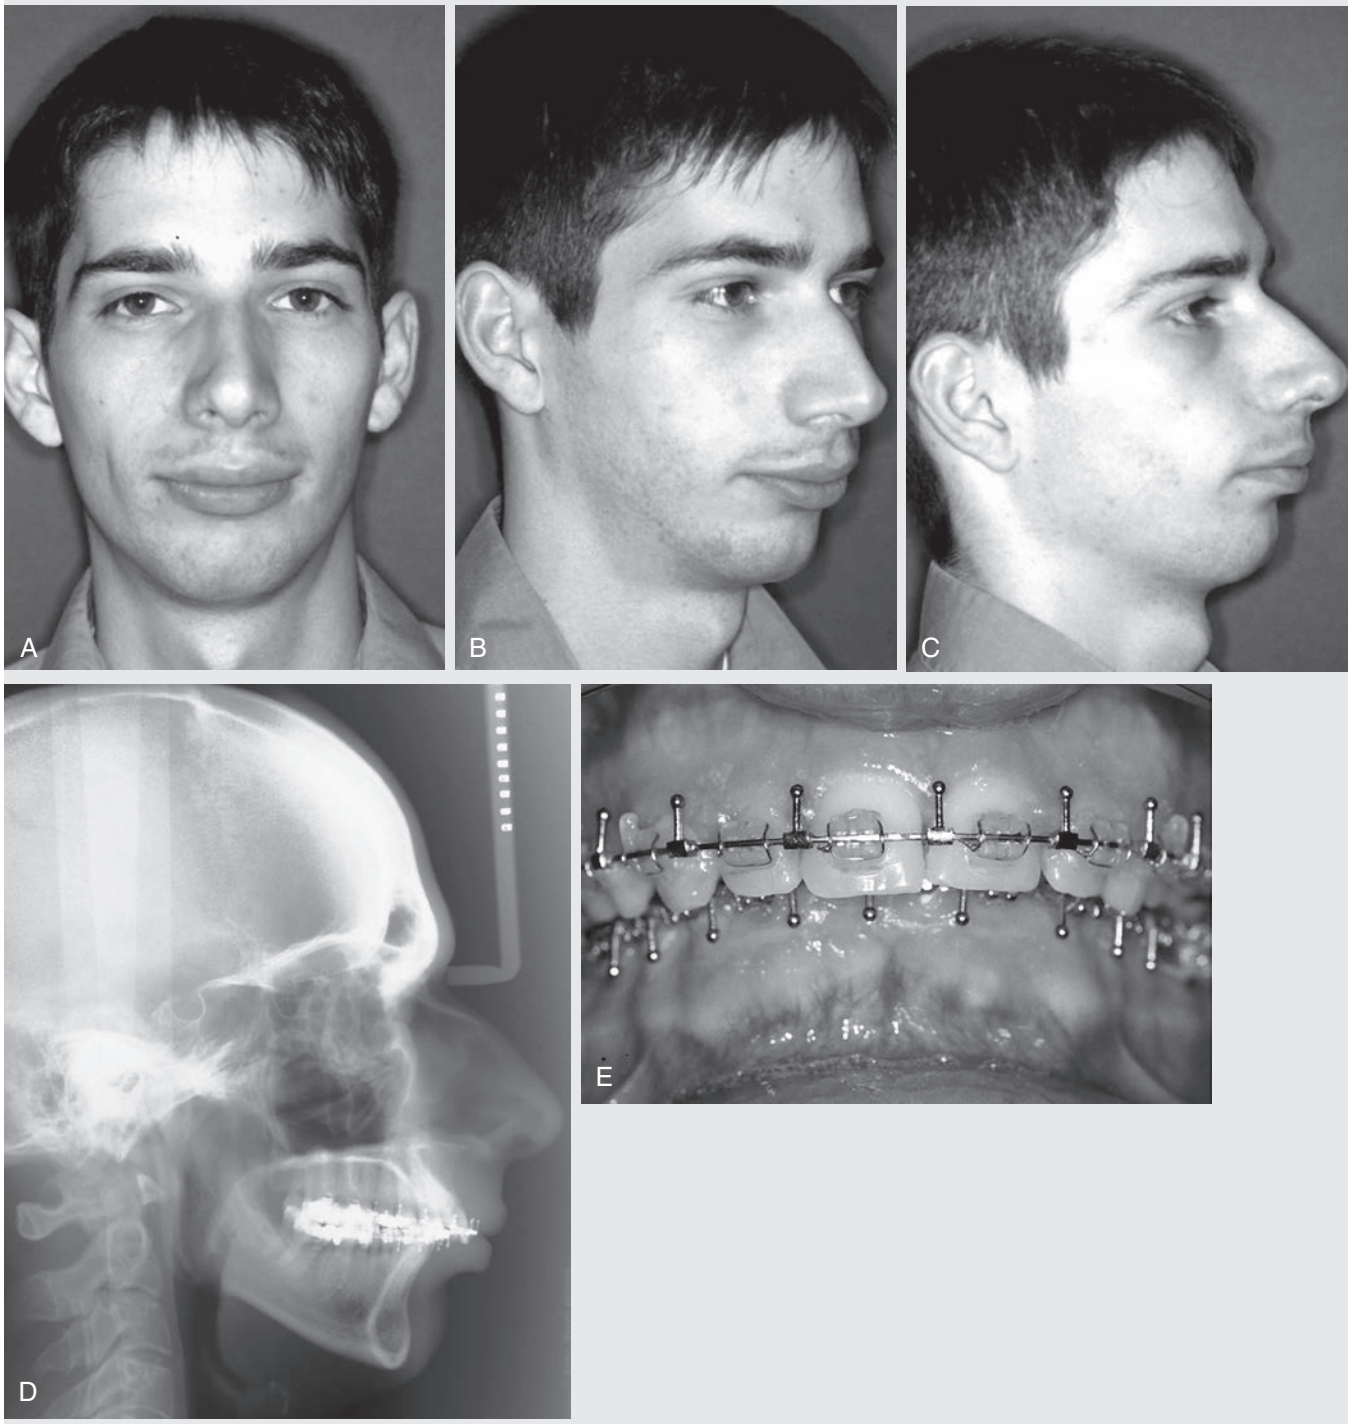


• **Figure 5-6** On 2-year recall, facial proportions and occlusal relationship had been maintained. Overbite and overjet remained ideal. The patient was very pleased with the outcome of the surgical treatment. Because facial esthetics was not an important aspect, advancement and downward rotation of the maxilla were not suggested.

CASE STUDY 5-3

Mandibular Deficiency With Long Face

This 24-year-old student was referred for combined surgical-orthodontic treatment. The patient's chief concerns were his deep bite and the fact that his teeth did not fit together properly. He found that his chin was a little deficient and that he had a "protrusive maxilla." He underwent orthodontic treatment when he was a child for about 3 years. He felt very uncomfortable with his profile, and chewing was difficult. Clinical examination showed a good nasolabial angle. The long face deformity was due to excessive length of the chin. Clicking was noted in both joints as was 9 mm overjet and 8 mm overbite; the dental midline was slightly off to the right side (Figures 5-7 and 5-8).

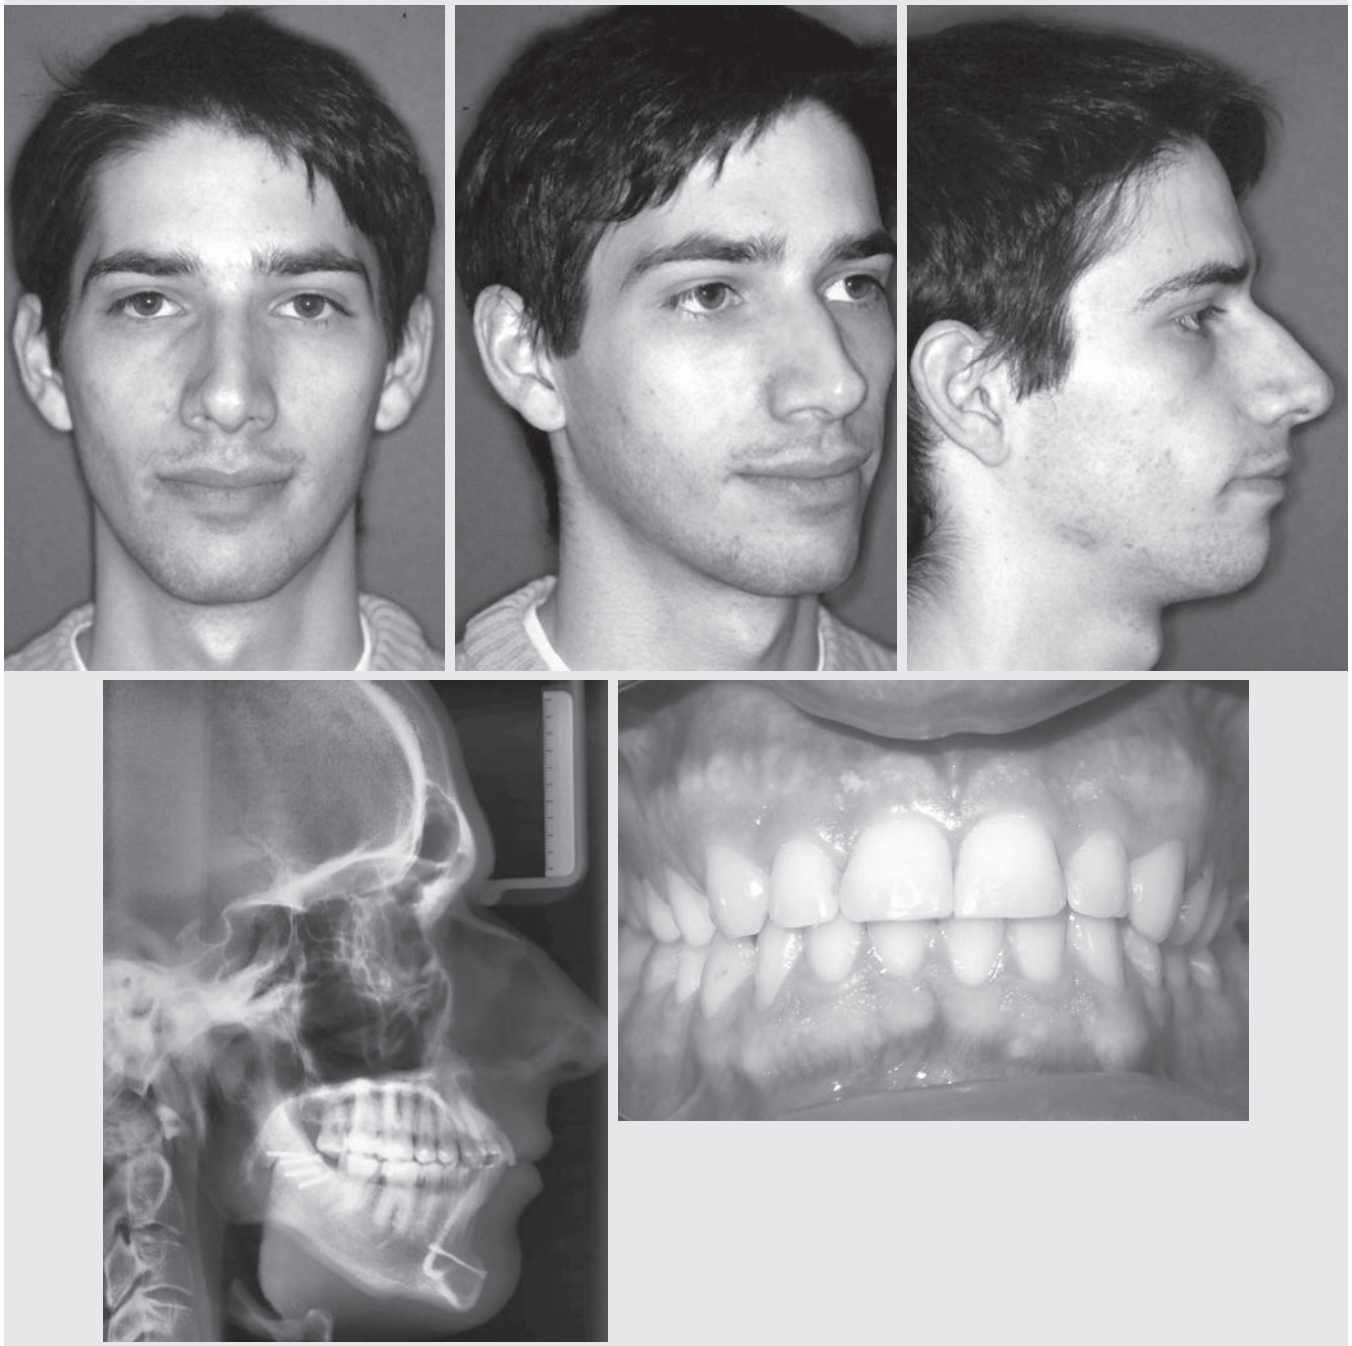


• **Figure 5-7** **A-C,** On frontal view, the lower face height appears long despite the deep bite. The lower lip is curled and fuller compared with the upper lip. On profile, the anterior-posterior (AP) mandibular deficiency is obvious. The nasolabial angle is good, and no maxillary protrusion is evident. The profile is convex, and the tip of the nose, lips, chin, and Adam's apple are on a straight line. Chin projection is markedly deficient. **D,** Cephalometric radiograph shows an exaggerated curve of Spee, a skeletal deep bite, retrogenia, and mandibular deficiency. **E,** Severely deep bite; teeth are well aligned after orthodontic treatment.

CASE STUDY 5-3—cont'd

Mandibular Deficiency With Long Face

The treatment plan for this patient included BSSO to correct the mandibular deficiency and rotation at the gonial angle to correct the deep bite. For correction of the retrogenia and reduction of increased anterior face height, an inferior border osteotomy was planned.



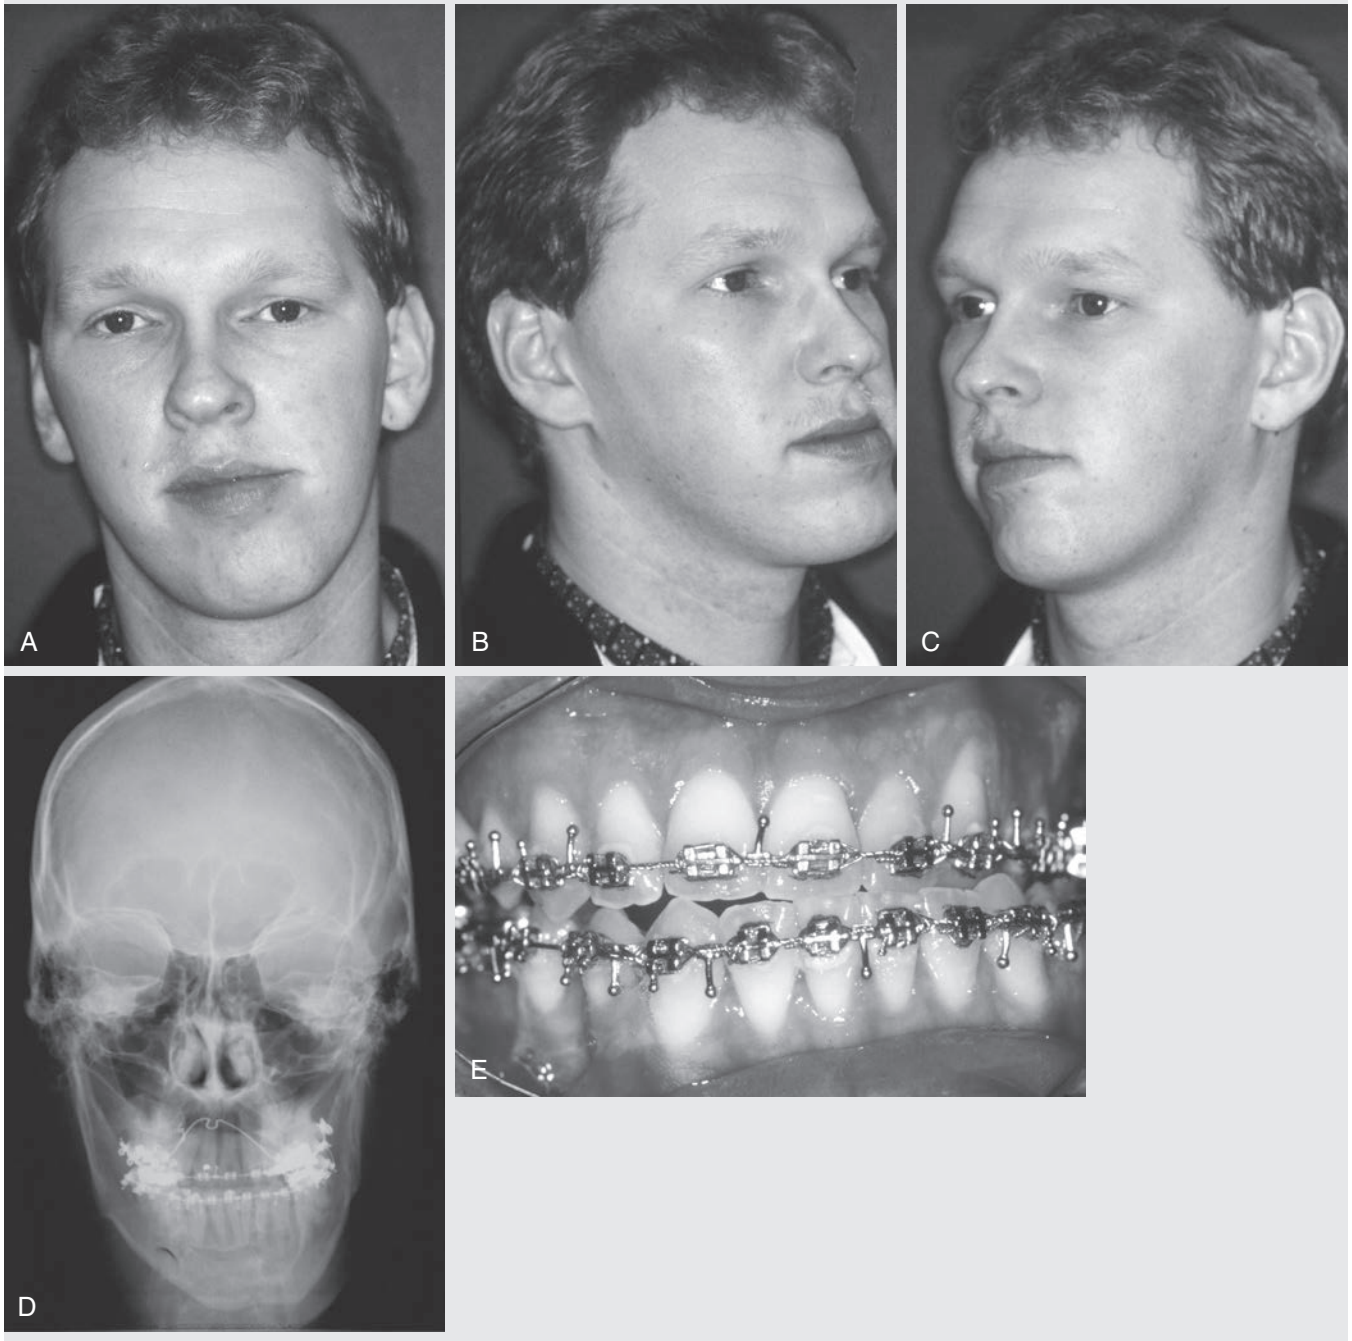
• **Figure 5-8** Two-year follow-up shows well-balanced facial proportions. Upper and lower lips are relaxed and have equal width. On profile, the anterior-posterior (AP) relationship has remained stable. The patient has a nice throat-chin relationship. His temporomandibular joints (TMJs) still click occasionally on maximum mouth opening, and he has slight deviation on maximum mouth opening to the right side. He is very pleased with esthetics and function.

CASE STUDY 5-4

Mandibular Asymmetry

G.G., age 27, was seeking surgical orthodontic treatment because of facial asymmetry. Clinical examination revealed deviation of the lower jaw to the left side (Figures 5-9 and 5-10). The chin was deviated 12 mm to the left, nonaffected side. The dental midline was deviated one and a half incisors to the left side. The patient said that this had started 2 years ago and had become worse since that time. He was very uncomfortable, and chewing was difficult; clicking of both TMJs had become worse. A control 99Tc scan performed prior to surgery showed no activity.

Treatment plan for this patient included BSSO to shift the mandible to the right side and a lower border osteotomy to reposition the chin.



• **Figure 5-9** Hemimandibular elongation of the right mandible. **A-C,** Facial view shows severe deviation of the mandible to the left side. The chin is 12 mm to the left side. Half-profiles look completely different. **D,** Posterior-anterior (PA) cephalometric radiographs show severe asymmetry. **E,** Dental midline is shifted to the left side. The lower right canine is in contact with the upper right medial incisor.

CASE STUDY 5-4—cont'd

Mandibular Asymmetry

• **Figure 5-10** The patient 5 years following surgery. Facial proportions are well balanced. The right side of the face seems slightly more prominent, but the patient is very pleased with the functional and esthetic result. Occlusion remains stable, and dental midline is on.

reduce the amount of bone to bone contact for healing. In terms of postoperative incidence of neurosensory disturbance to the inferior alveolar nerve, the SSRO is thought to cause more than the IVRO,[35-40] although many surgeons find the impact on quality of life over the long term to be negligible.

Sagittal Split Ramus Osteotomy: Surgical Sequence

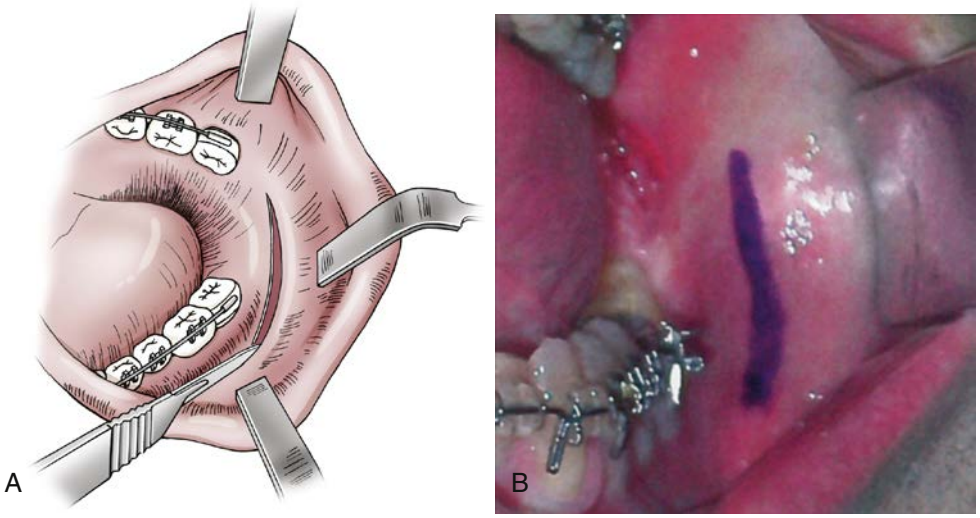
Soft Tissue Access

The soft tissue of the cheek is retracted with two Langenbeck hooks or Obwegeser toe-ins and a broad Austin retractor. At the level of the occlusal plane and 1 cm lateral, the incision begins at the anterior aspect of the ramus (Figure 5-11). The incision should be 2 cm long and course down the lateral crest of the external oblique ridge, ending in the buccal vestibule at approximately the first molar region. An incision extending too far superiorly, or failing to keep the soft tissues retracted laterally will expose buccal fat. After sharp dissection through mucosa, the buccinator muscle is positioned over the medial aspect of the ramus before incising through, to keep as much soft tissue as possible laterally. The incision is then completed through the periosteum down to bone.

Periosteal reflection is initiated laterally over the body of the mandible, extending to the inferior border just below the second molar, creating space for a channel retractor. It continues posteriorly over the anterior aspect of the ramus and then superiorly. Remaining in the subperiosteal plane with limited freeing of the temporalis muscle attachment over the ramus prevents bleeding and protects critical blood supply to the ramus. Dissection is carried up the ramus to a point where the temporalis fibers are visualized attaching into the coronoid process. At this level, the curved Kocher retractor is inserted deep enough to engage the coronoid process with the tips in the sigmoid notch. The lingula and mandibular foramen are then identified, usually at the same level with the greatest concavity of the anterior border of the ascending ramus. Next, when elevating the periosteum lingually it is essential to stay beneath the periosteum but above the mandibular foramen and the neurovascular bundle. Doing so will prevent bleeding and minimize damage to the neurovascular bundle. Once the periosteum has been reflected just beyond the lingual, the created tunnel should provide space for instrumentation to perform the medial cut without tension on the neurovascular bundle. The subperiosteal envelope created prior to initiating the osteotomy should allow sufficient visualization, but overzealous exposure of the mandible compromises blood supply and increases postoperative edema. A Hannihan retractor is placed medially to stretch the soft tissues to allow visualization of the lingula and the inferior alveolar nerve as it enters the mandible. In the event that you cannot visualize the lingula and the nerve, an abruptly curved freer elevator may assist in visualizing the nerve. The tip of a suction apparatus retracts soft tissue cranially. This allows protection of soft tissue during osteotomy while providing access and visualization (Figure 5-10).

Osteotomy

A horizontal bone cut through the medial cortex of the ascending ramus starts the osteotomy. The level of this cut should be at a point about 2 to 3 mm superior to the lingula. The cut extends from the anterior border of the ascending ramus to a point just posterosuperior to the lingula, staying parallel to the occlusal plane. In other words, the cut extends about 4 to 5 mm posterior to the lingula or two thirds of the anterior posterior dimension of the medial ramus. The depth of this cut at the anterior border of the ramus penetrates the medial cortex or about half way



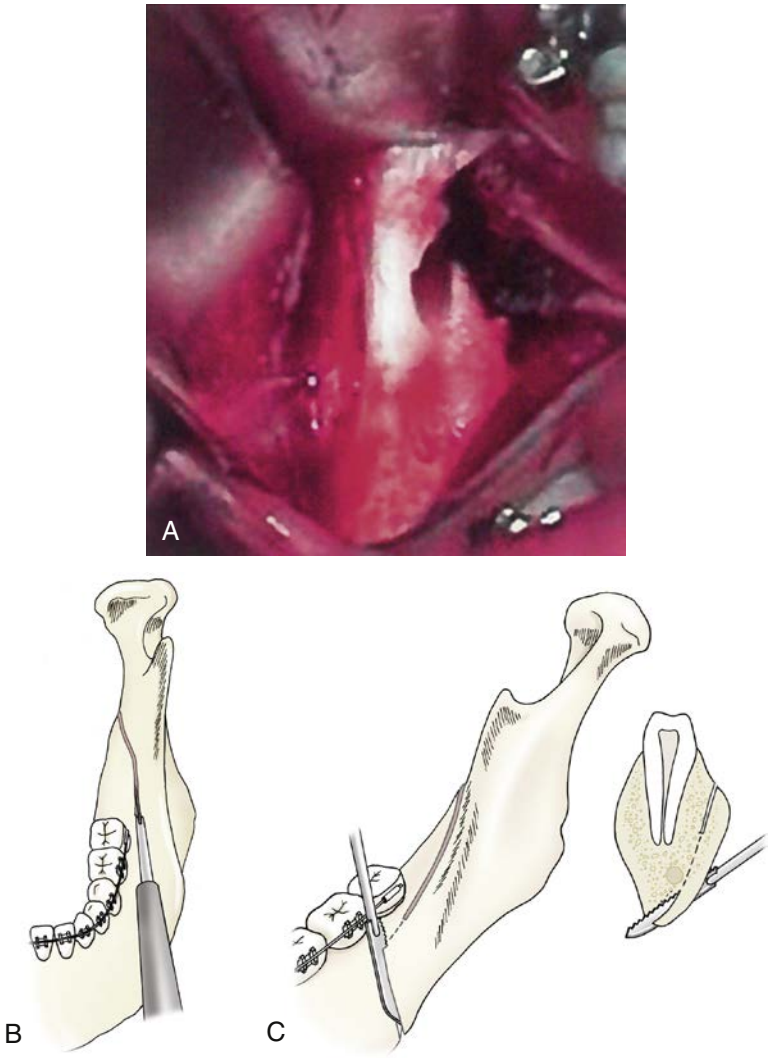
• **Figure 5-11** **A,** Soft tissue dissection for sagittal split osteotomy. **B,** Surgical status. (From Proffit WR, White RP Jr, Sarver DM: *Contemporary treatment of dentofacial deformity*, St Louis, 2003, Mosby.)

through the ramus if no cancellous space can be identified, which sometimes occurs. The depth is tapered shallower posteriorly as the saw blade or burr enters the concavity above and behind the lingula.

The anterior border of the ascending ramus may sometimes display a prominent bony shelf medially. This sometimes necessitates bone reduction with the use of a rotary instrument on the medial anterior ramus and the temporal crest to gain access to the medial ascending ramus before the cut is made, remaining only slightly into medullary bone (Figure 5-12, *A*). A longer rotating burr (Lindemann burr) or a 703 burr can suffice for this step. Many surgeons then prefer switching to a reciprocating saw to deepen the cut at the inner cortex of the ascending ramus to confirm slight penetration into the medullary bone and begin transition to the sagittal portion of the osteotomy (see Figure 5-12, *B* and *C*).

The sagittal portion of the osteotomy then proceeds down the ascending ramus, staying just inside the external oblique ridge, once again maintaining a depth of a single cortex to avoid trauma to the neurovasculature. This cut is carried inferiorly to the mesial area of the second molar where the vertical cut will be initiated. There is usually a prominence of cortical bone, sometimes referred to as a lateral bulge, adjacent to the second molars, offering protection from the underlying inferior alveolar nerve.

A channel retractor is placed at the inferior border and the vertical cut is extended superiorly from the inferior border through the buccal cortex connecting the aforementioned cuts. The inferior alveolar nerve is especially vulnerable at this point, requiring strict adherence to monocortical depth. This vertical cut should run perpendicular from the inferior border. The reciprocating saw can be held at a 45- to 60- degree angle (rather than at a right angle) to the surface of the bone to further minimize risk of damage to the inferior alveolar nerve and providing a channel for upcoming osteotome placement.



• **Figure 5-12** Osteotomy at the inner cortex of the ascending ramus. **A,** Soft tissue is protected by suction tip and freer elevator. Surgical status. **B,** The cut with a long rotating burr through the medial cortical bone of the ramus. **C,** The osteotomy is extended into medullary bone with a reciprocating saw. (From Proffit WR, White RP Jr, Sarver DM: *Contemporary treatment of dentofacial deformity*, St Louis, 2003, Mosby.)

• **Figure 5-13** Large handle osteotome seen propagating the sagittal split along the inferior border while the Smith spreader is used for superior access.

To further define the osteotomy, a fine 6-mm spatula or Epker osteotome is used starting at the medial cut of the inner cortex of the ascending ramus to begin the splitting of the buccal from the lingual cortex. The osteotome is then worked down the anterior border of the ramus and follows the osteotomy cut along the body of the ramus to the inferior border of the mandible. The osteotome should penetrate just beneath the cortical plate in a meticulous fashion to avoid damage to the inferior alveolar nerve. Next, some surgeons prefer to further define the osteotomy with an Epker osteotome prior to finalizing the split. A large-handled, flat cutting osteotome is then used to propagate the inferior split along the inferior border of the mandible. This can easily be done while holding a Smith sagittal spreader at the superior access of the split (Figure 5-13). Next, opening pressure is applied to stabilize the superior aspect while advancing the osteotome through the inferior border.

As the mandible splits, an eye is kept on the inferior alveolar nerve and along the ramus looking for any splintering buccal or lingual plate fractures. Ideally, the inferior alveolar neurovascular bundle should separate from the proximal segment and be allowed to fall medially. A freer elevator can be used to assist in gently teasing the bundle from the proximal segment. Occasionally, the bony nerve canal remains within the proximal segment. In this case, a small 4 mm straight or curved chisel can be used to separate it from the proximal segment. Once the neurovascular bundle has been freed from the proximal segment, the osteotome can be used in a more vigorous manner to guide the separation posterosuperiorly along the ramus on the desired course of the osteotomy. To ensure split completion, a Kocher is placed on the distal segment just anterior to the vertical cut and mobilized while holding the proximal segment seated in the fossa with a wire director. At this point it is helpful to mobilize the proximal segment posteriorly to stretch the muscular sling. This is especially important in large advancements. The medial pterygoid muscle is then stripped from the inferior border of the distal segment to reduce the relapse and allow the mandible to passively move forward. In large posterior movements the medial pterygoid should also be stripped from the proximal segment to prevent movement posteriorly.

Any sharp projections along the course of the inferior alveolar nerve are smoothed prior to fixation. For a planned setback or asymmetry case, bone along the anterior aspect of the vertical cut of the proximal segment is reduced to allow passive segment approximation during fixation (Box 5-2).

• BOX 5-2 Osteotomy Precautions

Identification of course of neurovascular bundle prior to separation with fiber handle osetotome
Removal of all bony interferences before osteosynthesis

Osteosynthesis

Upon completion of splitting the mandible bilaterally, IMF is secured using a prefabricated interocclusal acrylic wafer splint. Good condylar position is established by gently positioning the proximal segment into the fossa with the use of a ramus pusher, a wire director, or a periosteal elevator. Once this is done, the proximal and distal segments should align passively and with little to no step at the inferior border. At this point, a modified Allis clamp can be applied to the ramus engaging both segments of bone to hold them while applying rigid fixation (Figure 5-14). If bony interferences exist along the osteotomy (usually along the vertical portion), a burr of choice can be used to recontour the proximal segment.

Historically, osteosynthesis was achieved with either upper border wire, lower border wire, or circum-ramus body wire. This is currently hard to justify for use on a routine basis owing to its requirement for MMF for weeks following surgery. Bicortical position, lag screws, plates with monocortical screws, as well as resorbable screws are used to fixate the two segments.

Osteosynthesis With Screws

Screw fixation with either a lag or position screw technique can be accomplished either intraorally or very simply from an extraoral approach with a trocar. Stabilization usually is achieved with three bicortical screws. The screw pattern is usually either three screws at the superior border or two screws at the superior border and one at the inferior border (inverted L pattern). Screws may be placed as position (bicortical) or lag screws. Lag screws may be indicated only

• **Figure 5-14** Modified Allis clamp which can be used to stabilize both the proximal and distal segments during fixation.

when passive bone contact without any tension exists as they have been known to torque the condyle laterally upon tightening.

For placement of a commonly used 2.0-mm screw, a 1.5-mm drill hole is passed through the proximal and distal segments. This is often done using a standard trocar technique. The two segments must remain aligned and are held together as the first hole is drilled with a 1.5-mm wire-passing burr. Good retraction of the lingual tissues is necessary at this point to visualize the proximal and distal segments lined up as you pass the burr through them. Next, a 2-mm self-tapping screw engages both segments of cortical bone. It is essential that the pilot screw is placed at a point of overlapping bone contact between segments, avoiding the inferior alveolar nerve and roots of the second molar, and keeping the condyle in a passively seated position within the fossa. Figure 5-15 illustrates this positioning between the distal and proximal segments. Stability can be confirmed by gently attempting to pry apart the two bony segments with a periosteal elevator.

Proponents of the lag-screw technique like the excellent bone-to-bone contact it provides. Placing screws in a lag fashion, such that screw threads engage the lingual cortex only while the screw head alone compresses the buccal cortex, can easily precipitate lateral displacement of the condyle if the bony fragments are not in absolute passive contact. Lag screws are available in different sizes (2 mm, 2.3 mm, 2.4 mm). To place a 2-mm diameter lag screw, a 2-mm wire-passing burr is used to make an initial hole into the proximal condylar segment, followed by passing a 1.5-mm wire-passing burr through the distal segment. A depth gauge is then used to measure the length drilled and the hole with a smaller diameter has to be tapped with a special tapping device. The lag screw can then be placed. It is possible to use a combination of lag and positional screws in certain scenarios.

Osteosynthesis with Miniplates

Fixation may be achieved by bridging the osteotomy gap with a bone plate. A 4-hole bone plate with two screws on each side of the cut is sufficient for stable fixation and is often employed. Nonlocking monocortical screws provide adequate stability. An added benefit of plate fixation is its ability to be secured without extraoral trocar access. We prefer a single 2.0-mm semi-rigid 4-hole plate at the mid-body region as shown in Figure 5-16 and have found it to provide adequate stability. A single low-profile malleable plate with 1.8-mm diameter does not bear enough load for function. Therefore, when using nonrigid plates for fixation, we recommend a second plate or position screws to provide additional stability.

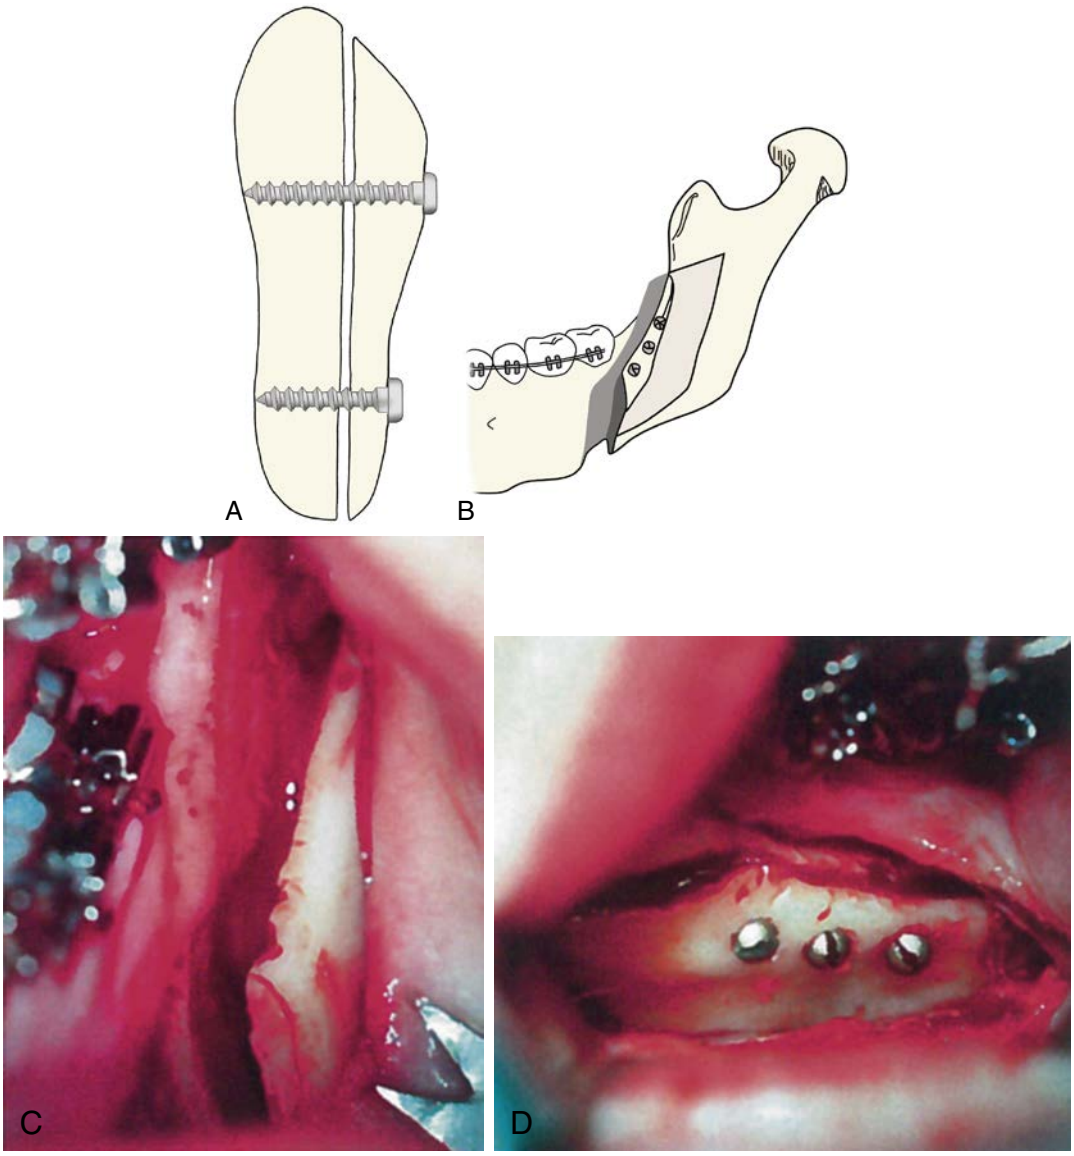
Osteosynthesis With Resorbable Fixation Screws

The use of biologically inert resorbable screws eliminates the possible need for a second operation to remove fixation material. Although the incidence of infection of titanium implants overall is very low, there are still times when titanium hardware must be removed due to infection, biofilm formation, hardware loosening, and, rarely, palpability.

To accomplish stabilization with resorbable screws, proponents of the technique have recommended using four screws per osteotomy site. If bony contact on the superior border is sufficient for placement of three screws, the fourth screw is inserted at the inferior border. The two screws at the inferior border of the mandible then are placed through a transoral technique, as described earlier. Typically, an appropriate trocar that can accommodate a long-shank drill is placed through an extraoral approach. The length of the required screw is measured with a depth gauge; a screw tap and a screwdriver are used to set the screw through the trocar.

Resorbable materials such as polyglycolic acid, polylactic acid, and polyester polyparadioxanon are organic macromolecular compounds that are degraded and absorbed by the body. These compounds do possess enough rigidity, tensile strength, and flex strength for use as internal fixation devices in orthognathic surgery. Manufacturers claim that about 70% of the material in resorbable implants remains in situ for about 3 months prior to degradation, affording the aforementioned properties to provide stability.

The rate of degradation appears to be dependent on several factors: molecular weight, crystallinity, and the thermal history and geometry of the resorbable implant. This



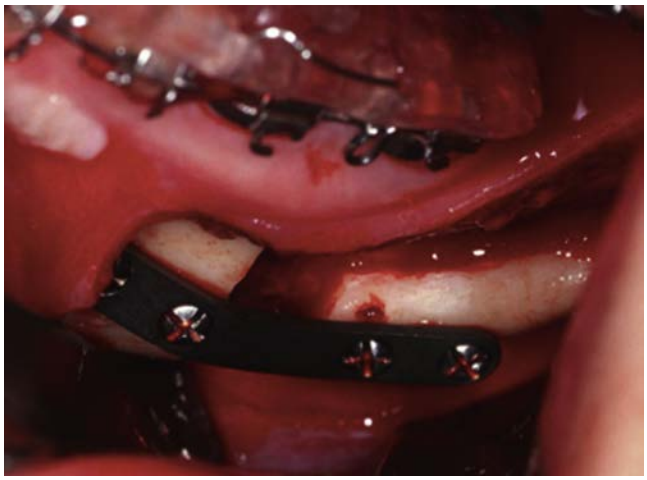
• **Figure 5-15** **A,** Position screw technique allows proper position of the proximal segment, without torque of the condyle; interbony gap is maintained. **B,** Osteosynthesis with screws. **C,** The cut is completed. **D,** Three position screws in place. (**A,** From Proffit WR, White RP Jr, Sarver DM: *Contemporary treatment of dentofacial deformity*, St Louis, 2003, Mosby.)

means that the bulk of a resorbable screw donates prolonged degradation in contrast to a thin porous sheet that dissolves much more rapidly. Degradation occurs mainly as a result of hydrolytic activity and, to a lesser extent, via nonspecific enzymatic reactions. It has been shown that these polymers are completely absorbable within bony tissue, and that new bone is deposited on and within the implants as degradation proceeds.[41] The principal route of elimination after degradation is respiration, in the form of CO_2 and H_20. Excretion through the urine and feces plays a minor role.

Inflammatory foreign body reactions have been cited as one of the few major potential problems with resorbable screws. Recurring episodes of soft tissue swelling around implantation sites and, in rare cases, draining fistulas have been observed.[42] Clinical reports speculate that these problems may secondary to the delayed resorption rate of the polymer.[43]

Commercially available materials include pure polyglycolic acid (PGA) in the form of screws and pins, pure poly-L-lactic acid (PLLA), and a co-polymer of PLLA and PGA. The latter has been found to be most appropriate for stabilization in orthognathic surgery, as it represents a combination of the best physical and chemical properties of PLLA and PGA. It is likely that these co-polymers maintain most of their strength for 8 weeks, and that they will be completely resorbed within 12-15 months. Few complications have been reported so far when these co-polymers were used.

Prior to closure of the osteotomy site, the surgeon must confirm desired occlusion. Although some surgeons prefer to keep the patient in MMF for a 2-3 week period in cases incorporating large movements and/or



• **Figure 5-16** The author's preference for fixation of the sagittal split ramus osteotomy as seen here; 2.0-mm semi-rigid 4-hole plate at the mid-body region.

highly unstable movements, MMF is routinely released and the occlusion is examined. Mouth opening, left and right excursive movements, and protrusive movements are then evaluated. Doing so also helps confirm appropriate condyle position within the fossa. Any resistance to full range of motion, clicks, or occlusal discrepancies require removal of the fixation, repositioning, and revision of fixation.

The wounds are then irrigated copiously with saline, and hemostasis is confirmed. For wound closure, we recommend closing mucosa primarily with a 3-0 resorbable chromic gut suture in a running locking horizontal mattress suture technique. The mucosa and submucosal tissue are closed to reapproximate and evert some of the deeper tissue to reduce the possibility of wound dehiscence (Box 5-3).

SSRO Complications

Despite the routine nature of the SSRO for most oral and maxillofacial surgeons, a wide range of complications exists. Their overall frequency and severity are rather low, with death being very rare and inferior alveolar neurosensory disturbance being the most common.[44-46] Most complications, such as unanticipated bony splits, can be corrected sufficiently intraoperatively. Others, such as neurosensory disturbances, may be immediately repaired or may necessitate postoperative therapeutic interventions. Maintaining an engaging attitude at the preoperative consultation to educate patients thoroughly regarding the perioperative risks thus becomes imperative.

Edema

Although postoperative edema is expected, it can rarely become life threatening and thus complicating. Unlike maxillary surgery where intraoperative hemorrhage is the most common severe complication, the most common severe complication (although still rare) as a result of SSRO is life-threatening airway compromise secondary to edema.[44] Postoperative compressive dressings are contraindicated because they may cause increased medial edema compromising the airway.

No matter the length of surgery, edema can be expected to occur in a moderate to severe amount. In most cases, it is only discomforting for the patient and not hazardous, but corticosteroids, ice packs, and nonsteroidal anti-inflammatory agents help reduce edema.

• BOX 5-3 Advantages and Features of Resorbable Implants

Tensile and flex strengths are comparable with titanium plating systems
Wide selection of implant sizes and shapes available
Convenient hex-drive breakaway delivery system simplifies screw placement
Resorbs completely, which may eliminate the need for second operation
Does not induce late-stage inflammatory reaction

Nerve Injury

Neurosensory impairment after SSRO most often involves the inferior alveolar nerve, but can involve the lingual nerve, and, very rarely, the facial nerve. Facial nerve impairment, if encountered, will likely be transient and is thought to arise from compression during retraction. Numbness of the lower lip and chin is the most commonly reported complication after SSRO. Patients may experience varying degrees of inferior alveolar nerve sensory deficit for 6 months or longer. The prevalence of immediate postoperative trigeminal impairment ranges from 12% to 100%. Long-term follow-up has shown nerve dysfunction to persist 40% of the time 1 to 2 years after bilateral SSRO,[47] although many surgeons feel the incidence of permanent paresthesia after bilateral SSRO performed by experienced hands to be closer to 10% to 20%. Increasing age and the use of concurrent genioplasty are two main risk factors.[48,49] An inherent flaw to any study reporting neurosensory outcomes after SSRO is the wide variance of methods used to test the neurosensory disturbance seen throughout the literature. Fortunately, patients seem to adapt to mild sensory deficits and report sensory function as normal despite slightly altered sensation objectively. The majority of patients experience a return to baseline sensation a year after SSRO. Over the last decade, there has been more attention dedicated to performing SSRO with piezoelectric surgery to decrease neurosensory deficits. Reports have been contradictory on whether piezoelectric surgery positively affects the incidence of neurosensory deficit after SSRO.[50,51]

Nerve injuries may be caused by direct trauma in the form of compression, tear, or cut with a rotary instrument.

• BOX 5-4 Mechanisms of Injury to the Inferior Alveolar Nerve (IAN)

Application of local anesthesia
Stretching of the nerve from the medial protecting retractors
Deep osteotomy with reciprocating saw or chisel during splitting
Abnormal anatomic position of the IAN canal
Presence of an impacted third molar

They may also develop by indirect trauma such as compression from postoperative edema. Patient's should receive counseling regarding the possibility of significant sensory deficits such as numbness, pain, burning, tingling, or hyposensitivity that can affect the lips or chin in the event of an injury to the inferior alveolar nerve (IAN). Sequelae of such an injury such as lip biting during mastication and difficulty with eating, tooth brushing, speaking, shaving, or kissing are distressing experiences for the patient.

Facial nerve injury is a rare but devastating possible complication of SSRO. The incidence of facial nerve impairment has been reported as less than 1% in bilateral SSRO, and has only been reported in setback procedures. Prognosis was found to be good with mild impairment of function but poor with complete loss of function.[52]

Injury to the Inferior Alveolar Nerve (IAN)

Postoperative neurosensory deficits are generally considered to be caused by direct damage to the IAN. Any laceration, compression, or significant stretching of the sensory fibers of the IAN results in a postoperative neurosensory disturbance of the lower lip and chin. Even in cases in which the IAN is not visibly traumatized during surgery, postoperative neurosensory deficit can occur. This can be referred to as a closed injury and may result from edema, hematoma, protruding bone fragments within the osteotomy, or from penetrating screws during fixation.

A prolonged neurosensory disturbance is strongly related to age and the degree of manipulation of the IAN during surgery. At all times during the SSRO instrumentation is in close proximity to the IAN and many factors can lead to damage of the nerve (Box 5-4). Maneuvers to free the IAN when stuck within the proximal segment after splitting and overcutting the inferior border osteotomy both place the nerve at higher risk, for example.

The long-term incidence of paresthesia from IAN injury ranges from 0% to 20%,[39,53] and has been found to be greater when performed concurrently with inferior border osteotomy.[54]

Unintentional, witnessed transection of the IAN may occur while performing the SSRO. Immediate primary repair with 8 or 9-0 prolene suturing of the epineurium under loupe or microscope vision provides the optimum chance for recovery. If circumstances prevent such repair, establishing care with a microsurgeon early in the postoperative course is important.

• BOX 5-5 Keys to Prevent Injury to the IAN During BSSRO

Remaining subperiosteal along the medial side of the ascending ramus
Judicious use of the medial protecting retractors
Osteotomes and saws should penetrate just to a single cortical depth
Suction tip should be placed at the superior border of the split for safe visualization while splitting
Removal of impacted third molars at least 6-12 months before surgery

Furthermore, anatomic variation of the course of the nerve within the mandible predisposes to injury. One study found the distance between the mandibular canal and the buccal cortex was less than 1.2 mm in 91% of sides associated with a severe grade of neurosensory disturbance persisting 3 months after bilateral SSRO.[55] Severely prognathic mandibles are known to be associated with a more cephalad entrance of the IAN into the mandible. Occasionally, the course of the IAN runs very close to the inferior border of the mandible near the molar region. Close examination of the panoramic radiograph affords the surgeon valuable insight to such nuances (Box 5-5).

Injury to the Lingual Nerve

Although less frequent than IAN injury, a temporary disturbance of the lingual nerve can occur. The incidence varies from 1% to 19%,[56] and is usually transient. Long-lasting anesthesia of the lingual nerve seems to be exceedingly rare after SSRO, but has been reported.[57] Disturbances in lingual nerve function likely occur from one of two causes: bicortical screw placement with over-extended or prepared superior positioning screws, or through pressure neuropathy secondary to development of a lingual hematoma. Bicortical superior positioning screws in the region of the third molar should not extend beyond the medial cortex of the mandible because they may damage the lingual nerve in this region. Painful sensations when moving the tongue postoperatively may be reported if such an error occurs. This can require revision of fixation. Typically, it is safe to use screws up to 15 mm long. In cases where longer screws are required, measurement of the depth of the drilled hole is important.

Hematoma ensuing after hemorrhage along the medial side of the mandible exerts pressure on the lingual nerve. This can lead to temporary paresthesia of the tongue that is characterized by loss of sensation and taste on the affected side. If screw placement is acceptable and the hematoma mild, acute interventions are usually not necessary and spontaneous recovery can be expected. Extensive hematoma formation should be drained to allow quick recovery (Box 5-6).

• BOX 5-6 Keys to Prevent Lingual Nerve Injury During BSSO

Subperiosteal dissection
Use of a depth gauge to ensure proper screw length for superior positioning screws
Recognition and drainage of hematomas to allow quick recovery from pressure on lingual nerve

Arthropathy of the Temporomandibular Joint

Dysfunction of the Temporomandibular Joint

TMJ dysfunction, most commonly exhibited by joint noises (clicking, popping) or pain, is a relatively common occurrence in the "normal" population. The prevalence of TMJ dysfunction in patients with dentofacial deformities seems to be the same and is estimated to range from 20% to 25%, although reports have shown an incidence of TMJ dysfunction prior to surgery of up to 41%.[58]

The exact position of the condyle is almost always changed during mandibular surgery. After IVRO, the condylar sag that occurs postoperatively leads to an equilibrated condyle-disc relationship improving TMJ noises and pain. With the SSRO, it is likely that some rotation around and across the condylar axis occurs. Despite knowing this, no conclusive evidence exists suggesting that the osteotomy and associated condylar changes influence the development of post-surgical TMJ problems. All patients experience some degree of limited mouth opening after surgery as a result of muscle stripping and soft tissue edema. In addition, there is likely a short period of condylar remodeling post-surgically that also contributes to functional impairment. After resolution of swelling, muscle reattachment and rehabilitation, and condylar remodeling, patients usually regain their presurgical level of function several months after surgery is performed.

Displacement of the Condyle and Condylar Resorption

Displacement of the condyle can occur in an anterior-posterior or vertical plane of rotation as a result of surgery. Resultant condylar torque may induce a clinically apparent midline shift and sometimes pain.[59] Severe hypomobility can be another sign of condylar malposition, particularly of lateral or medial condylar displacement.

During the SSRO, efforts should be directed to keeping the condyle in a passive position near centric relation during fixation. Malpositioning of the condyle can cause early occlusal changes postoperatively from immediate skeletal relapse. Such failure to seat the proximal segments properly into the fossa during surgery and resultant condylar displacement is thought to be the main reason for TMJ symptoms after bilateral SSRO in those who were without symptoms prior to surgery. Resorption of the condyle has been described as a consequence of this malpositioning.[59-61] This phenomenon reportedly occurs in between 1% to 31% of patients.[62] Other predisposing factors include high mandibular plane angle, condyle with posterior inclination, and a low posterior-to-anterior face/height ratio.[63] Contributing surgical factors include counterclockwise rotation of the proximal segment, preoperative TMJ disorder, and possible avascular necrosis of the condyle secondary to overstripping of the proximal segment.[64]

Preoperative management of existing TMJ disorder remains controversial. Some authors have suggested that TMJ derangements should be corrected prior to orthognathic surgery because symptoms may deteriorate or even lead to condylar resorption.[65] Others have found that orthognathic surgery alone establishes skeletal and occlusal harmony and leads to resolution of TMJ symptoms without the need for isolated TMJ surgery.[66,67] We tend to agree that the majority of patients with preoperative popping or clicking and pain experience improvement or resolution after surgical correction of dentofacial deformities and associated malocclusions. It seems prudent, however, to control any acute exacerbations of TMD with at minimum conservative management prior to performing orthognathic surgery. Patients with documented disc displacement (confirmed by MRI) and limited opening should receive intervention with disc repositioning either prior to or simultaneously with orthognathic surgery.

Unfavorable Bony Split

A particularly complicating but not very common problem associated with the SSRO is an unfavorable bony split. Its occurrence ranges from 2% to 20% throughout the literature.[59] An unfavorable split may occur on the distal tooth-bearing segment or along the proximal segment.

A poor split of the distal segment most often affects the lingual cortical bone posterior to the third molar region. Left unstabilized, this may result in sequestration of the fragment, delayed union, malunion of the osteotomy site, or even infection. Stabilization of the unfavorable fracture can be quite challenging but helps prevent post-surgical instability and healing issues. A positional screw placed from the proximal segment into and through the fractured lingual segment will serve to stabilize this segment, reducing the incidence of these problems.

Unanticipated splits of the proximal segment may occur before or after splitting of the mandible and are best prevented by recognizing its development before the fracture is complete. Often, bone is used as a fulcrum against an incomplete osteotomy where bridges of cortical bone are left intact. Some believe that the most common reason for an unfavorable split is incomplete cortical bone removal along the inferior border. Prior to splitting, careful inspection to ensure the osteotomy is completely through the outer cortex and inferior border

• BOX 5-7 Keys to Prevent Unfavorable Split During BSSRO

Careful technique with complete cortical cuts
Careful inspection of the inferior border and ascending ramus during separation
Removal of third molars at least 6-12 months prior to BSSRO

is paramount. It is important to initiate the inferior border separation with an osteotome directed from the vertical cut posteriorly splitting the inferior border from the distal segment.

There are known predisposing factors that increase the risk of an unfavorable split. These include difficult anatomic variants, poor osteotomy design, and the presence of impacted third molars.

Wide anatomic variations from the norm in terms of width and thickness of the ascending ramus and the relationship between canal location exist.[68] Lack of cancellous bone between the two cortices makes the split more difficult, as does a high mandibular foramen (Box 5-7).

Complete cuts through cortical bone with the use of a reciprocating saw or a burr are essential for avoiding a bad split. This is especially true for the medial ramus cut and the inferior border prior to application of the chisel to the osteotomy.[69]

The presence of impacted third molars has been associated with an increased risk of unanticipated fracture during bilateral SSRO.[70] They have been postulated to compromise the anatomic structure of the mandible, causing adverse proximal and distal segment splits. Most authors recommend removal of impacted lower third molars at least 6 to 12 months prior to orthognathic surgery; others found no reduction in fracture incidence when impacted third molars were removed at the time of surgery. Fracture of the lingual or buccal plate can occur when non-erupted third molars are present during SSRO. The buccal cortex of the mandible is thinner posterior to the second molar. The presence of a lower third molar can further complicate splitting of the mandible as medullary bone between the cortices is lacking where the third molar is. Fractures often start at the lingual cortex during removal of the tooth or at the outer cortex during splitting. Horizontal fracture of the ramus and even subcondylar fractures make reduction and fixation of remaining segments difficult.[71] Stabilization is more challenging than in non-fractured splits, often requiring more hardware material. Plates, bicortical screws, or a combination of these can be used to stabilize fractured bony segments. If circumstances call for concurrent third molar removal during orthognathic surgery, we recommend extending the buccal cortical osteotomy no differently other than extending the cut deeper along the third molar itself to section it. When appropriately managed, unanticipated bony splits shouldn't influence stability or the long-term success of the sagittal split.

• BOX 5-8 Preventive Measures

Allow sufficient time for vasoconstriction after local anesthesia
Subperiosteal dissection
Good soft tissue retraction and visualization when using rotary instruments and chisels
Placement of the suction tip into the bottom of the split

• BOX 5-9 Preventive Measures

Duration of operation
High dosage and short perioperative course of antibiotics
Good oral hygiene and wound cleanliness

Hemorrhage

Uncontrolled hemorrhage is exceedingly rare in mandibular surgery. When encountered, it likely results as a consequence of clumsy or inexperienced use of rotating instruments or chisels. The retromandibular vein, inferior alveolar vessels, and, rarely, facial vessels can be traumatized inadvertently. Mandibular hemorrhage, of life-threatening severity, is very rare and found to be usually an intraoperative problem, unlike delayed bleeds that can occur after maxillary orthognathic surgery.[72] Transfusion of blood products occurs only on rare occasions in BSSRO.[59] Most bleeding episodes are minor and can be controlled by administering local anesthetics and gauze packs. Bleeding from laceration of the facial artery requires suture or clip ligation. Even minor oozing can impede visualization and effective surgical execution, thus making its avoidance important (Box 5-8).

Infection

Wound dehiscence and/or infection is a rare complication[73] and most often thought to be related to poor oral hygiene. Tobacco smoking seems to be an additional risk factor. Contributing factors include lengthy duration of the operation, the patient's age, the presence of foreign bodies, sequestrum formation after bone fracture, and hematoma. Although not common, sometimes loose hardware and associated infections require wound re-exploration. Care to preserve vascularity of segments will aid in prevention of infection. The use of a single preoperative dose of antibiotics and two days of postoperative antibiotics has been found to substantially reduce the risk of postoperative infection[2] (Box 5-9).

Relapse

Stability and predictability of orthognathic surgical procedures have improved as a result of constantly evolving surgical techniques and instrumentation. Relapse rates range throughout the literature and seem to be highly dependent on the presurgical diagnosis. Relapse is a multifactorial problem that is hard to attribute to a single etiology. Proper

• BOX 5-10 Preventive Measures to Minimize Relapse

Proximal segment control including proper condyle positioning, and avoidance of condyle rotation
Caution with counterclockwise rotation of the distal segment with high mandibular angle cases
Careful evaluation of TMJ prior to surgery
Care by orthodontist to avoid building in dental compensations of skeletal discrepancies

diagnosis, adequate treatment planning, and well-executed surgical technique are essential contributions of the surgeon. The soft tissue envelope, muscle tension, and orofacial habits may influence postoperative stability. Other factors that have an effect on relapse include fixation choices, magnitude and vector of mandibular movement,[74,75] position of the proximal segment, and disc displacement. Long-term relapse in mandibular deficiency appears greatest with large mandibular advancement (>6 mm) in non-growing patients.[76] Some authors have noted a correlation between relapse and counterclockwise rotation[77] (Box 5-10).

Although some have reported similar stability after orthognathic surgery with wire fixation in comparison to more rigid plates and/or screws,[78] we recommend the use of plates and/or position screw fixation. Modern hardware is user friendly and places less reliance on IMF. Reports have shown improved stability with the use of more rigid internal fixation.[74,79,80] Resorbable screws have been shown to provide equal stability to titanium hardware.[24,22]

Immediate relapse, hours to days after surgery, may occur with mandibular advancement in patients with TMJ functional problems caused by internal derangements not correctly repositioned prior to surgery. When this is the case, it becomes difficult to place the condyle correctly into the fossa intra-operatively. Shortly after surgery, the anteriorly displaced disk can slip back into the fossa as the result of complete relaxation of the muscles and the absence of chewing. Condylar displacement from being positioned too far posteriorly in the fossa during surgery is another cause of immediate relapse. Postoperatively, the condyle settles back into a passive position within the glenoid fossa, which may result in unsatisfactory occlusal changes.[59] Confirming complete and passive mobilization of the distal segment and removal of all obstructive bone fragments are crucial for proper positioning of the condyle after SSRO.

Description and Indications for Intraoral Vertical Ramus Osteotomy

The IVRO is a simple and quick surgical procedure to set back the prognathic mandible. It can also be used to address mandibular asymmetry to rotate one side of the mandible. The IVRO finds its main application in cases of mandibular excess with concomitant widely flared rami, often referred to as "V-shaped" mandibles. Sometimes, executing the SSRO on such cases of mandibular anatomy can result in lateral flaring of the condyle/proximal segment when a significant amount of bony interference is encountered with large setbacks or asymmetry corrections. Unfavorable condylar displacement that can occur during fixation of the SSRO has been repeatedly documented,[81-84] and many surgeons attribute this problem to bony interferences on large setbacks or asymmetry corrections that are no doubt magnified in cases with "V-shaped" mandibles.

The condylar head undergoes immediate anterior sagging, but ultimately returns upright after the IVRO is performed.[85,86] For this reason, intersegmental fixation is not mandatorily used with the IVRO because it can precipitate postoperative open bites as the condylar head repositions. The passively positioned condyle after IVRO renders the procedure helpful often in cases of concomitant temporomandibular disorder. IMF is required to facilitate intersegmental union, and most surgeons prefer a 2-week period with early return to physiotherapy. Despite absence of fixation, long-term results on maintenance of the mandibular position and occlusion show excellent postoperative stability after the IVRO procedure[87] (Case Study 5-5 and 5-6).

Limitations of the Inraoral Vertical Ramus Osteotomy

The principal limitation of the IVRO is the need for IMF[88,89] and the required patient cooperation with physiotherapy. After release of IMF, close follow-up is required to guide return to normal function.

The morphology of the mandibular ramus, specifically the thickness, or in cases of large setbacks, can impede passive overlapping of the two segments requiring reduction of the medial volume of the proximal segment. Such limitations can be easily overcome by reducing the medial volume of the proximal segment. The segmental overlapping can alter bigonial width which can be problematic, although in some cases has seen to result in favorable esthetic changes.[90,91]

Another limitation is the mechanical interference between the coronoid process and the skull base, or with the TMJ capsule when significant posterior impaction of the maxilla or significant setback of the mandible occurs simultaneously. In these cases, coronoidectomy can relieve the interference, however, removal of the coronoid process can further impose difficulties in physiotherapy.

Introral Vertical Ramus Osteotomy: Surgical Sequence

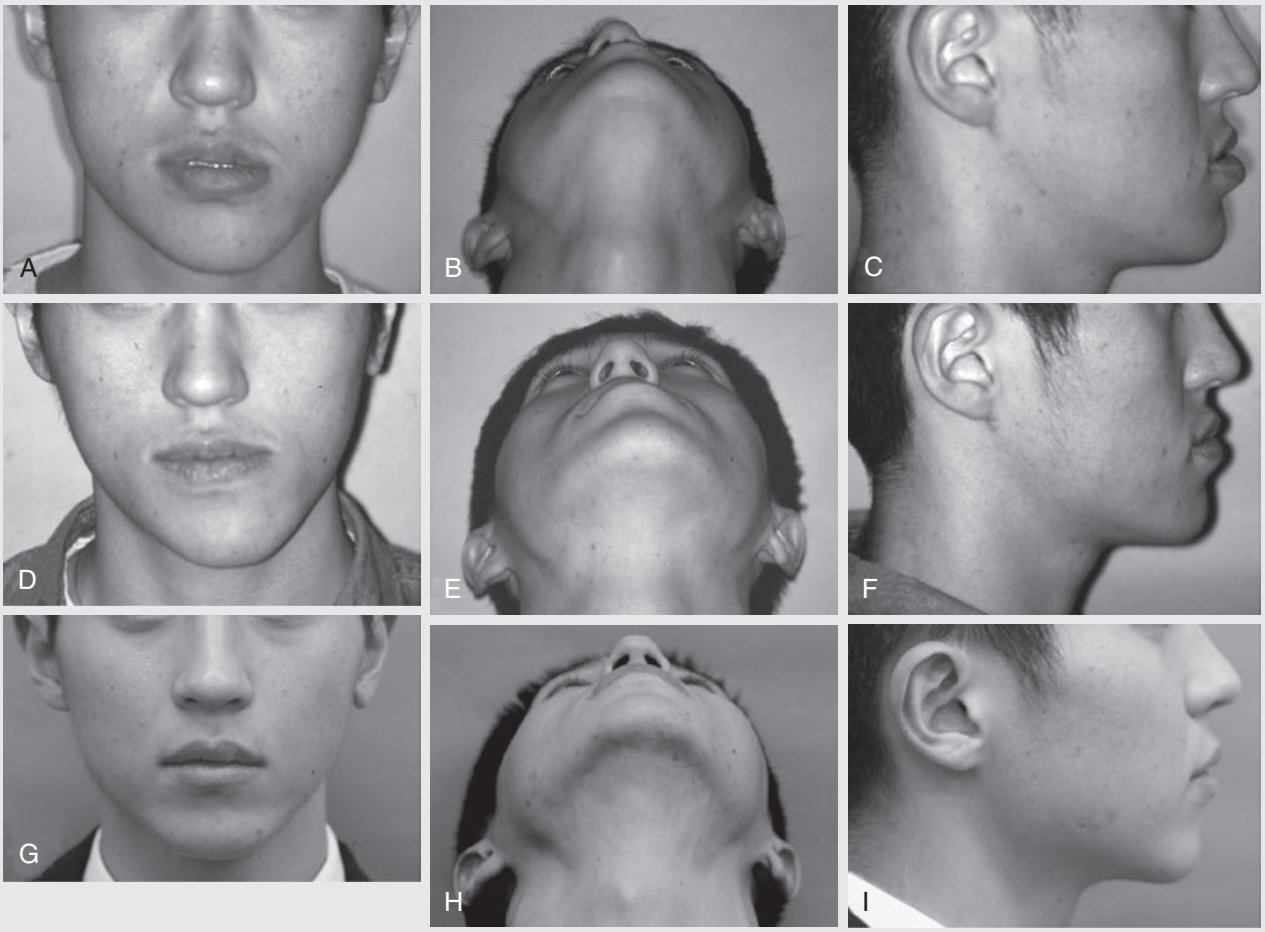
Soft Tissue Access

For convenience of sequencing, many prefer to secure the surgical splint to the maxillary dentition prior to incision. The incision design and location for the IVRO is modified slightly compared to the SSRO. It is extended approximately one centimeter longer to allow for instrumentation of both the superior and inferior portion of the lateral ramus.

CASE STUDY 5-5

Mandibular Prognathism and Maxillary Retrognathism With Severe Facial Asymmetry

A 21-year-old young man visited our clinic with a chief complaint of facial asymmetry, prognathic mandible, and chewing difficulties (Figure 5-17, *A* through *C*, *J*, *K*). On the basis of initial dentofacial deformity (DFD) analysis, mandibular prognathism and maxillary retrognathism with severe asymmetry and mild open bite were diagnosed. For treatment, preoperative orthodontic treatment for dental decompensation was planned first. Then, according to surgical treatment objectives (STO), as illustrated in Figures 5-17, *P* and *Q*, we planned orthognathic surgery for advancement (2.0 mm), posterior impaction (3.0 mm), and canting correction of the maxilla and TOVRO setback of the mandible, thereby establishing a proper upper and lower dental midline that coincided with the facial midline. In keeping with the treatment plan, the patient first received preoperative orthodontic treatment for about 1.5 years (see Figure 5-17, *J* and *K*); then he received two-jaw orthognathic surgery according to the STO plan. Postoperative physiotherapy was enforced for 2 weeks after our routine protocol without interference. After routine 2-year follow-up, we were fortunate to evaluate his status 45 months after the surgery. He had an excellent symmetric face (see Figure 5-17, *G* and *H*), a normal profile (see Figure 5-17, *I*), and excellent occlusion without an open-bite tendency (see Figure 5-17, *N* and *O*).



• **Figure 5-17** Facial appearance of a 21-year-old man with mandibular prognathism, maxillary retrognathism, and severe asymmetry. **A-C,** Facial appearance at first examination. **D-F,** Facial appearance before orthognathic surgery since completion of preoperative orthodontic treatment shows no remarkable change. **G-I**, Facial appearance at 45 months after two-jaw surgery, including transoral vertical ramus osteotomy (TOVRO), shows an excellent symmetric face and normal profile.

CASE STUDY 5-6

Mandibular Prognathism, Maxillary Retrognathism, and Severe Open Bite

A 22-year-old man was given the diagnosis of mandibular prognathism and maxillary retrognathism, accompanied by severe open bite and mild asymmetry (Figure 5-18, *A* through *C*, *J*, *K*). After DFD analysis, it was decided that the upper right and left first bicuspid should be extracted, and preoperative orthodontic treatment proceeded for 2 years (see Figure 5-18, *L*, *M*). Once preoperative orthodontic treatment had been completed, two-jaw orthognathic surgery was performed; it included Le Fort I osteotomy for maxillary advancement (3.0 mm) with posterior impaction (4.0 mm) and TOVRO setback of the mandible, which were performed according to the preoperative STO (see Figure 5-18, *S* and *T*). Routine physiotherapy was enforced for 2 weeks. Once stable occlusion had been confirmed, the patient was sent to the orthodontist for detailed dental alignment. At 36-month follow-up, the patient showed excellent facial esthetics (see Figure 5-18, *G* through *I*), excellent bony remodeling on radiography (see Figure 5-18, *P* through *R*), and proper occlusion that was maintained as stable without an open-bite tendency (see Figure 5-18, *N* and *O*).

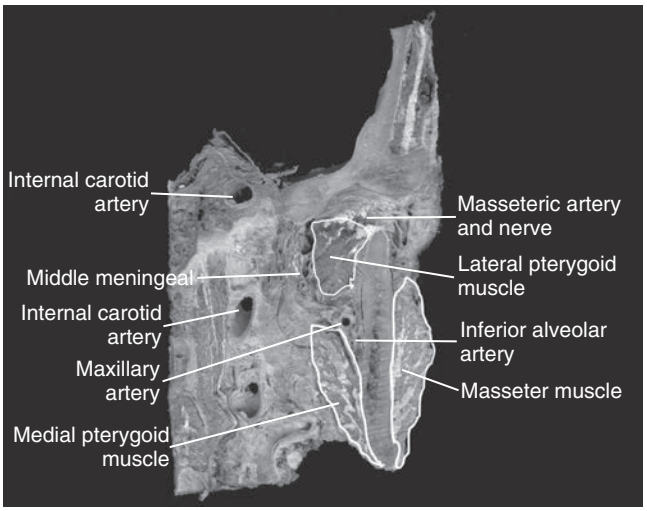
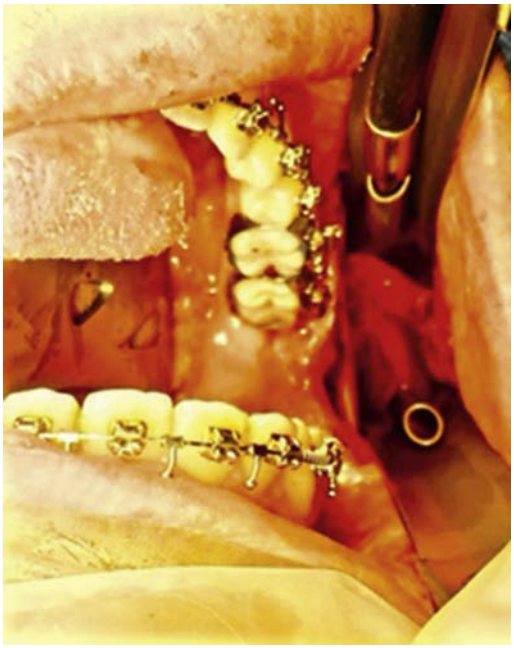
• **Figure 5-19 A,** Bauer retractor. **B,** A round oscillating saw blade (Stryker's).



• **Figure 5-20** Vertical sectional view of important anatomic structures around the osteotomy line of a transoral vertical ramus osteotomy (TOVRO) in human cadaver.

Following incision down through the submucosal layer, the periosteum is incised along the anterior border of the ramus with a fine tipped bovie. A full thickness mucoperiosteal flap including muscle attachments along the lateral surface of the ramus is reflected broadly from the sigmoid notch to the antegonial notch, although some of the pterygomandibular sling attachments should be left attached at the posterior border of the mandible and angle. Clean and subperiosteal stripping of the soft tissue attachment around the sigmoid notch is important for safe insertion of a wing of a Bauer retractor (Figure 5-19), to avoid damage to the masseteric branch of the maxillary artery located near the notch during osteotomy (Figure 5-20). Each wing of two Bauer retractors is inserted into the sigmoid notch and the antegonial notch simultaneously (Figure 5-21), and the lateral surface of the ramus is wiped with a gauze sponge and important landmarks on the bone surface can be marked with a sterile #2 pencil if desired. We recommend using the antilingular eminence, located on the lateral surface of the ramus as is shown in Figure 5-22, *A* as a general guideline only for the lateral correspondence of the mandibular foramen. The antilingular prominence is a small protuberance

located at the posterior one third from the posterior border in the horizontal aspect of the ramus and about 10 mm above the occlusal plane of the lower molars in the vertical aspect. Hall[92] recommended that the cut should begin 6 to 7 mm from the posterior border of the ramus and, like Hogan and Ellis,[93] described that it is less reliable to use the antilingula eminence as a landmark for the mandibular foramen. A recent cadaveric study found that at a measurement of 5 mm posterior to the antilingula (at the level of the antilingula), there was no risk of damaging the neurovascular bundle.[94] We advise marking the osteotomy location about 7 mm anterior to the posterior border near the level of the mandibular foramen to avoid injury to its contents.



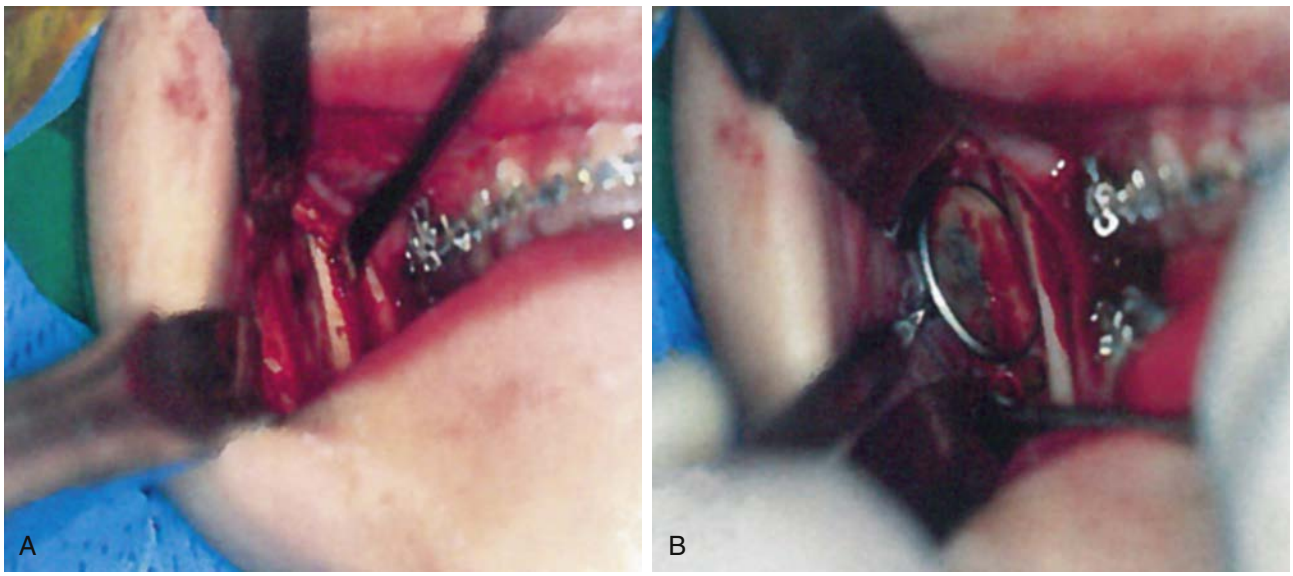
• **Figure 5-21** Presentation of the ramus with two Bauer retractors inserted just prior to performing the intraoral vertical ramus osteotomy.

Osteotomy

Figure 5-23 illustrates a vertical guide line for osteotomy that should be drawn from the sigmoid notch to the inferior border staying 7 mm anterior to the posterior border and keeping parallel to the posterior border of the ramus. This line can be confirmed with the use of a mouth mirror as is shown in Figure 5-22, *B* or with insertion of a curved freer elevator with markings at 7 mm. The osteotomy is started to completion through both the medial and lateral cortices with an oscillating saw under copious irrigation. Once the saw blade is confirmed to have passed through the medial cortex, a downward cutting movement of the saw is carried out to the antegonial notch without resultant injury to the inferior alveolar neurovascular bundle inside of the ramus; which runs anterior to the guide line (Figure 5-24). If positioned correctly, this osteotomy carries little risk to any major vessels.

After completion of the inferiorly directed osteotomy, the saw blade is directed cephalad to the anterior half of the sigmoid notch (see Figure 5-23, *A*). Notice that the osteotomy courses in an oblique direction from the posterior border of the ramus and that the mandible becomes thinner, requiring careful adaptation of the depth of the saw blade.

Figure 5-25 demonstrates the increased risk of damage to branches of the maxillary artery that are located medially near the mandibular foramen. The oscillating saw blade should not be inserted deeply when the level of the mandibular foramen is passed during the cephalad portion of the osteotomy. Furthermore, this anatomy highlights the importance of securing the wing of a Bauer retractor at the sigmoid notch to the end for protecting the masseteric branches of the maxillary artery.



• **Figure 5-22** Marking of the antilingular eminence **(A)** and drawing with a black pencil of a lower guide line for osteotomy on the lateral surface of the mandible. • **Figure 5-24** Photograph shows lateral overlapping of the proximal and distal segments after successful completion of transoral vertical ramus osteotomy (TOVRO).

When the IVRO is performed to completion, the proximal segment usually becomes mobile and its lateromedial cut surface can be seen partially. A periosteal elevator can then be introduced to aid in lateral mobilization and overlap of the proximal segment. The same procedure is performed on the opposite side.

After copious irrigation of the wounds with normal saline, an orogastric tube is passed to suction gastric contents reducing postoperative nausea and vomiting. The final planned occlusion is obtained with or without the use of a surgical splint, and MMF is achieved with loop wires. At this point, careful inspection is given to confirm passive overlapping of the lateral proximal segments and a periosteal elevator can be used between the proximal and distal segments to facilitate. If any interference is visualized during setback of the distal segment, or if large divergence of the proximal segment is noted, the medial portion of the proximal segment should be reduced. This can be achieved with rotary instrumentation. Finally, the level of the inferior border of the proximal segment should be evaluated. If it is at any portion overextended over the inferior border of the distal segment, it should also be reduced to prevent abnormal irritation of soft tissue and an excessively prominent gonial angle. The incisions are closed primarily with a running chromic gut suture. After 14 to 21 days, MMF is removed and active physiotherapy is begun (Box 5-11).

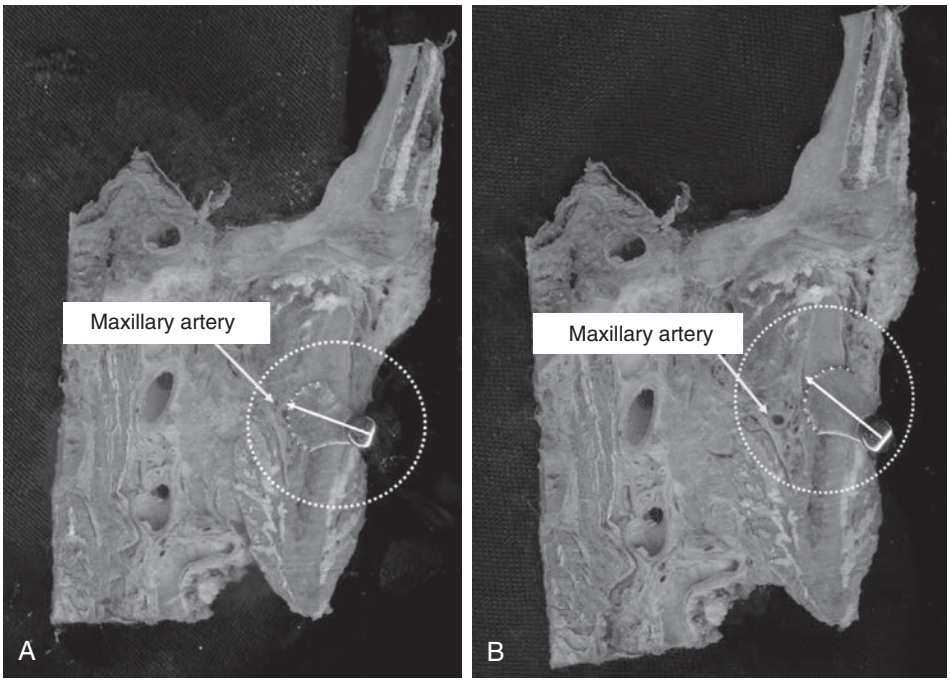
During this phase, the use of elastics enables adjustments in postoperative occlusion, thereby promising prolonged stability, and offering a curable effect on preoperative TMD as muscle activation realigns the sagging condyle. As patients begin active physiotherapy while in elastics, any developing anterior open bite must be closely supervised by the surgeon. Self-exercise to maximize hinge opening, protrusion, and lateral excursion should be guided as illustrated in Figure 5-26. If the occlusion remains stable after three to four weeks, guiding elastics can be transitioned to night-time only during sleep and the surgical splint can be removed. By the sixth week, if the occlusion is stable and full range of mandibular motion established, the patient is referred to the orthodontist for retentive and maintenance orthodontics. Until the sixth week, patients are kept on a non-chew diet.

Any open-bite tendency should be evaluated carefully every day or on alternate days during the first week of physiotherapy after removal of MMF. If an open bite greater than 2 mm of interincisal distance develops within the first week of the physiotherapy period, MMF should be again instituted for 3-5 days. The same protocol of physiotherapy should be then repeated.

IVRO Complications

Stability

Controversy remains on the stability of the IVRO. This could be related to movements that create changes that are beyond the limits of this procedure. Using the IVRO for



• **Figure 5-25** Important anatomic location of the maxillary artery in association with penetrating direction and depth of a round oscillating saw blade along transoral vertical ramus osteotomy (TOVRO). High risk of injury to the maxillary artery in perpendicular direction of the saw blade **(A)** and safe modification of its direction **(B).**

• BOX 5-11 Postoperative Physiotherapy Requirements

Active physiotherapy initiated by patient after 14-21 days/wire MMF released
Frequent office visits to monitor open bite development
Re-application of wire MMF or heavy elastics for 3-5 days if open bite develops
Aim to achieve normal mandibular range of movement by 6 weeks

large movements, closure of open bites, or in cases with high mandibular plane angles is contraindicated. Literature does not support horizontal overcorrection as a method to prevent skeletal or dental relapse.

Nerve Damage
