While the term disability is commonly thought to relate to long-term physical, mental, intellectual or sensory impairments (United Nations 2006), Patston (2007) presents a wider view. In describing nine types of human functioning, namely biological, aesthetic, motor, sensory, cognitive, social, emotional, creative and spiritual, he suggests nine areas for potential dysfunction (i.e. disability). In so doing he sheds light on the 'doing' and 'being' aspects of personhood, while at the same time recognising that 'doing' is commonly more highly valued than 'being'.

• CRITICAL REFLECTION POINT

Think about your own family members. Identify those with disabilities and the nature of those disabilities. How many of your family members have disabilities? Is it more or less than 50%?

The extent of disability in Australia and New Zealand

Disability is a 'complex multidimensional experience' (WHO 2011:21) which causes challenges in its measurement. The WHO (2011) estimates the global disability prevalence rate among the adult population to be between 15.6% (2002–04 *World Health Survey*) and 19.4% (2000–04 *Global Burden of Disease Study*). Based on 2010 worldwide population estimates, 785 to 975 million persons aged 15 years or older are living with a disability (WHO 2011).

In Australia, the *2012 Survey of Disability, Ageing and Carers* estimated that just under 1 in 5 people or 18.5% of the population (4.2 million Australians) have a disability; this is a 1.5% reduction in the prevalence of disability since 2003 (ABS 2012).The rate of people with a profound or severe core activity limitation (6.1% in 2012) has remained stable over this period. In New Zealand, the *2013 Disability Survey* identified 24% of the population (1.1 million New Zealanders) as disabled; an increase of 20% since 2001 (Statistics New Zealand 2014). This increase is attributed to an increase in the proportion of the population over 65 years of age.

In Australia and New Zealand, more than 50% of older adults (> 65 years) report having a disability of some kind (ABS 2012, Statistics New Zealand 2014). In both countries, a higher rate of disability occurs in females; however, this is likely to be the result of females being over-represented in the older adult age group. In child populations (5–14 years), a higher proportion of people with disability were males (11.2% compared to 6.2% for females in Australia); however, the overall prevalence of disability is lower for children < 15 years (7%) compared with adults 25–65 years (17%) (Australian Institute of Health and Welfare (AIHW) 2013a).

Government data collections can only provide a snapshot of the nature and scope of disability in Australia and New Zealand. In reality, disability is more widespread and more diverse. Looking at the mechanisms of disability can help us understand this.

Mechanisms of disability

There are many and varied ways of understanding the mechanisms by which disability occurs. The four mechanisms discussed here present just one way of thinking about this.

Physiological mechanisms of disability

Physiological mechanisms of disability can be classified under four broad causes: congenital disorders, trauma, chronic disease and ageing.

Congenital disorders

Congenital disorders occur prenatally or during birth and include structural deformities in a developing fetus. Congenital defects can occur in response to environmental and/or genetic (or chromosomal) abnormality. Exposure to certain medications and substances during pregnancy can lead to congenital defects. Examples of teratogenic medications and substances include certain anticonvulsant drugs, warfarin, retinoic acid, cigarette smoking and alcohol (see Chapter 16). However, not all congenital defects are identifiable at birth. Many familial or genetic defects may lead to degenerative conditions that become evident later in life.

Trauma

Trauma is a leading cause of disability. For example, in Australia, motor vehicle-related trauma is the major

cause of spinal (AIHW 2010) and brain injury (AIHW 2007). Sport, work and violence are also major causes of trauma that can lead to disabilities. A person's occupation can place them at risk of visual, hearing and peripheral nerve alterations (Box 19-2), in addition to the risk of accidental injury such as falls. Individuals who are exposed to loud noises at work or who have occupations involving exposure to chemicals or flying objects should be screened for hearing and visual problems. People who use their hands in a repetitive fashion, causing trauma to the median nerve, can develop carpal tunnel syndrome, the most common peripheral nerve disorder. Occupations that involve strenuous movement or long periods of extension and flexion of the wrist may cause a person to develop inflammation, which creates pressure on the nerve as it passes between the carpal bones and the transverse carpal ligament in the wrist and may cause numbness, tingling, pain and weakness in the hand while performing fine movements (Scanlon & Maffei 2009).

BOX 19-2 Occupations and leisure activities that pose risk of sensory alterations

Hearing
- Factory worker
- Airport worker
- Rock musician
- Construction worker with power tools

Vision
- Exposure to irritating gases
- Welder
- Exposure to high-speed machinery
- Squash or fencing
- Motorcycle riding
- Power-tool use

Peripheral nerve injury
- Computer operator
- Manual labour requiring repetitive motion
- Trauma

Chronic diseases

Disability can be directly or indirectly caused by the physiological disruption related to specific chronic diseases. For example, multiple sclerosis, myasthenia gravis and Guillain-Barré syndrome are neuromuscular disorders where the immune system attacks the nervous system, blocking nerve impulses and causing muscle weakness and alterations in sensation – therefore, disability. Conversely, poorly controlled diabetes mellitus is an example of an indirect cause of disability associated with an increase in eye disease (e.g. diabetic retinopathy, cataract and glaucoma), which can lead to loss of sight; and nerve damage and poor circulation in the lower limbs, which can lead to altered sensation in the limb and restrictions in physical activity (AIHW 2013b). Atherosclerosis is the disease process of fatty plaque formation in arteries, and depending on the location of the artery, is the cause of stroke, heart attack and peripheral vascular disease. All of these conditions, depending on the severity of the damage, may restrict a person's physical activity and could impair activities of daily living and create a self-care deficit.

Ageing

The normal physiological changes of ageing also make older adults more vulnerable to common clinical conditions. The physiological changes that occur in ageing are discussed in detail in Chapter 18; however, some of the common physiological changes that may lead to sensory impairment are included in Table 19-1. In addition to these sensory impairments, older adults experience physiological changes to all body systems; for example, older adults experience a reduction in cardiac output and an increased systolic blood pressure, a loss of balance, uncoordinated motor response and a reduction in muscle mass and strength, all of which can restrict physical activity. While there are some normal neurological changes that occur in older adults, this does not mean that ageing inevitably leads to cognitive impairment. However, there are a number of disorders in older adulthood that can cause cognitive impairment, such as Alzheimer's disease.

Focusing on sensory impairments, Table 19-1 provides examples of physiological mechanisms of disability. These examples include mechanisms of disability across the life span, as well as mechanisms of acquired disability such as from injury.

Psychological mechanisms of disability

The definition of what is and what is not a psychological mechanism of disability is less clear than for physiological mechanisms. However, this does not in any way reduce the significance of these types of disability. Primary psychological disability involves changes in thinking, emotions and/or behaviours. While everyone experiences disequilibrium in their thoughts and feelings from time to time, it is only when these changes cause restrictions in everyday life that they become a mechanism of disability.

TABLE 19-1 Sensory impairments and associated physiological mechanisms

Sensory impairment	Congenital	Trauma	Chronic disease	Ageing
Sight	Hyperopia Astigmatism	Corneal abrasions Foreign objects and penetrating injuries Chemical burns Subconjunctival hemorrhage Traumatic iritis	Diabetic retinopathy Glaucoma	Cataracts Senile macular degeneration Presbyopia
Hearing	Sensory neural loss	Ruptured tympanic membrane Fractured middle ear bones	Labrynthitis Acoustic neuroma	Otosclerosis Presbycusis
Touch	Autism Congenital insensitivity to pain with anhidrosis (CIPA) Neurofibromatosis	SCI	Peripheral neuropathy Multiple sclerosis	Reduced ability to detect vibration, touch, pressure and temperature and reduced sensitivity to pain
Taste **Ageusia** – absence of the sense of taste **Hypogeusia** – decreased sense of taste **Dysgeusia** – an unpleasant sense of taste		Head injury Fractures of the temporal bones or the mandible can lead to damage to the facial nerve	Oral infections Periodontal disease Metabolic and endocrine disorders	Hypogeusia due to changes in taste cell membranes
Smell **Anosmia** – lack of ability to smell	Congenital anosmia	Anosmia from brain injury	Neurodegenerative illnesses (such as epilepsy, Alzheimer's disease, Parkinson's disease) and schizophrenia can cause anosmia	Sensory cell loss in the olfactory mucosa

In Australia, the *2012 Survey of Disability, Ageing and Carers* referred to psychological disability as:

- a nervous or emotional condition which causes restrictions in everyday activities that has lasted, or is expected to last for six months or more, or
- a mental illness for which help or supervision is required that has lasted, or is expected to last for 6 months or more, or
- a brain injury, including stroke, which results in a mental illness or nervous and emotional condition which causes restrictions in everyday activities (ABS 2015).

The results of this survey shed light on how common psychological disability actually is. Of all people with any type of disability, 18.5% had a psychological disability. Further, 3.4% of Australians (770,500 people) reported having a psychological disability, with similar rates for men and women. This was an increase from 2.8% (606,000 people) in 2009. Of those with a psychological disability, just over four in ten reported profound levels of core activity limitation, and a further two in ten reported severe core activity limitations. The majority of people who reported a psychological disability reported having one or more other disabling conditions (ABS 2015).

Like physiological disabilities, psychological disability impacts on everyday functioning. Ninety-six per cent of people with psychological disability reported needing assistance or experiencing difficulty in at least one of the broad activity areas of everyday life. Only 1.8% of people with psychological disability who reported needing assistance did not have their need met at all. This survey also revealed lower participation in education and employment for people with psychological disability, compared with those with no disability (ABS 2015).

Social mechanisms of disability

Social mechanisms of disability operate within the context of interactions between persons with disability and others (individually and collectively). More specifically, social mechanisms include spoken language, body language,

social interaction, values and beliefs, power relationships and culture.

The **International Classification of Functioning, Disability and Health** (ICF) (WHO 2001) identifies social mechanisms as environmental factors, which can act either as enablers of or barriers to human functioning. The inclusion of two specific lists of factors (support and relationships, and attitudes) relating to social mechanisms in ICF indicates their importance.

In talking about support and relationships, ICF refers to 'people and animals that provide practical, physical or emotional support, nurturing, protection, assistance and relationships to persons, in their home, place of work, school or at play or in other aspects of their daily life' (WHO 2001:187). Our inclusion within the following groups draws attention to how we each contribute to the social mechanisms of disability: immediate and extended family; friends; acquaintances, peers, colleagues, neighbours and community; people in positions of authority; people in subordinate positions; personal care providers and personal assistants; strangers; health professionals; and other professionals.

It is important to recognise that attitudes underpin all social mechanisms of disability. In the ICF (WHO 2001:190), attitudes relate to customs, practices, ideologies, values, norms, factual and religious beliefs. Attitudes influence the way 'individuals behave at all levels, including interpersonal relationships, socially, and in community associations, as well as influencing political, economic and legal structures' (WHO 2001:190). This means that the personal attitudes and beliefs of every nurse, as well as every other health worker, will influence the social mechanisms of disability. As nurses, we have a responsibility to ensure that this influence is positive, and acts as an enabler of human functioning, not as a barrier to it.

Biopsychosocial mechanisms of disability

Physiological, psychological and social mechanisms, when thought of in isolation, provide a fragmented understanding of how disability really comes about. Bringing the three mechanisms together to adopt a biopsychosocial approach, the ICF (WHO 2001) portrays disability and functioning as outcomes of complex interactive processes (see Figure 19-1).

The inclusion of two types of contextual factors (environmental and personal) in the model in Figure 19-1 is a particular strength. In addition to the two specific subsets of environmental factors discussed above (support and relationships, and attitudes), environmental factors also include: the natural environment and human-made

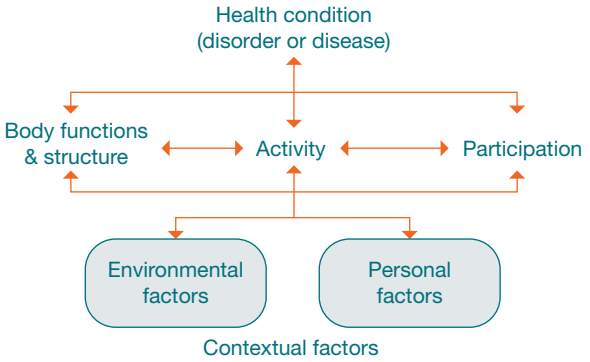

Figure 19-1 Interactions between components of the International Classification of Functioning, Disability and Health (ICF).

WHO 2013 How to use the ICF: A practical manual for using the International Classification of Functioning, Disability and Health (ICF). Exposure draft for comment. WHO, Geneva.

changes to the environment; products and technology; and services, systems and policies. For example, steep hills may be problematic for some people with mobility limitations, but so too might be the period of time a lift door remains open, or the placement of everyday items, such as milk and bread, a long way from the supermarket checkout counter.

Attitudes can be very powerful enablers of or barriers to functioning and disability. The first National Disability Survey in Ireland, conducted in 2006, included two questions about attitudes in an effort to determine the extent of their influence as environmental factors (Kostanjsek et al 2013). Fifteen per cent of people with disability reported frequently or always avoiding doing something they could otherwise do because of the attitudes of other people. The impact was particularly negative for younger men with disabilities (aged 35–44 years) and for people with mental health problems. The attitudes of employers and some service providers towards disability were also more problematic for younger people (and for young men in particular).

In recognising the role of personal factors, ICF does not provide extensive lists of individually mediated factors as it does for environmental factors. Instead, it simply notes that:

> **Personal factors are the particular background of an individual's life and living, and comprise features of the individual that are not part of a health condition or health states. These factors may include gender, race, age, other health conditions, fitness, lifestyle, habits, upbringing, coping styles, social background, education, profession, past and current experiences (past life events and concurrent events), overall behaviour pattern and character style, individual psychological assets and other characteristics (WHO 2001:17).**

Geyh et al (2011) conducted a systematic review of literature and found a further 238 examples of personal

RESEARCH HIGHLIGHT

The first year following acute stroke is difficult for individuals in many ways, but re-engagement with friends and community is reported as a significant source of dissatisfaction.

Using a qualitative systematic review method, the authors synthesised the results of 18 studies to explore individual experiences of reintegration into community in the first year after stroke.

Four themes emerged from the qualitative synthesis as barriers and facilitators of community reintegration:

1. The primary effects of the stroke
2. Personal factors
3. Social factors
4. Relationships with professionals

Survivors of stroke reported that emotional and physical rehabilitation conducted in familiar environments and in real-life situations is a facilitator of individual perseverance and adaptability post stroke and was an enabler of community reintegration. Real-life rehabilitation activity, facilitated and supported by family, friends and the broader community (such as driving to and from work), enabled the stroke survivor to develop a more meaningful reintegration with their community.

Walsh ME, Galvin R, Loughnane C et al 2015 Factors associated with community reintegration in the first year after stroke: a qualitative meta-synthesis. Disability and Rehabilitation 37(18):1599–608.

factors not named in the ICF definition. Work is underway to more fully understand the scope of personal factors in disability, with subsequent research suggesting that personal factors may fall into 12 broad areas: socio-demographic factors, behavioural and lifestyle factors, cognitive psychological factors, social relationships, experiences and biography, coping, emotional factors, satisfaction, other health conditions, biological/physiological factors, personality, motives/motivation (Muller & Geyh 2014:430).

While it could be argued that focusing on factors within the person contributes to blaming the person for being disabled, in fact the opposite is true. Understanding personal factors encourages a strengths-based approach to thinking about people with disability. This involves looking for characteristics of the person and their life circumstance which are positive enablers of functioning. When positive enablers are purposefully sought and found, personal strengths will also be easier to find. This is illustrated in a study by Walsh et al (2015), where an individual's perseverance and adaptability post stroke were found to be enablers of community reintegration (see *Research highlight*).

Person-centred care for the person with disability

While this chapter is about seeing a person's abilities, understanding the nature of disability and the range of causation mechanisms helps nurses provide the care that best fits the person's individual needs.

Many people with disability live lives that flow on a daily basis similar to our own; waking, washing, dressing and grooming in the morning, engaging in personally meaningful activities, as well as some of the more mundane activities, and seeking out those whose company we enjoy. And like all of us from time to time, people with disability need health care. This means nurses working everywhere across the continuum of health care, regardless of age, diagnosis or setting, will encounter people with disabilities.

Therefore, it is not only nurses working in disability-specific services who need to be competent in the care of people with disability; it is all nurses. Earlier in the chapter, we introduced Angus (see *Critical reflection point*), a man in his early 50s with chest pain. While the treatment plan for a person presenting to the emergency department with chest pain may be routine, meeting Angus's specific needs to enable his optimal level of functioning within the context of the treatment regimen requires **person-centred care**. The central tenet of person-centred care is respect for and integration of individual differences when delivering patient care (Lauver et al 2002:248), with the critical characteristics being:

- understanding the patient as a unique person presenting with individual characteristics, needs, values, beliefs and preferences
- responding flexibly to patients' individual needs and preferences by selecting and delivering interventions that are mindful of, and responsive to, the patients' needs and preferences (Souraya et al 2006:118).

Similarly, Diane (see *Critical reflection point*) will have very specific care regimens already in place to maintain her skin integrity and manage her urinary and faecal elimination that are central to her health and wellbeing. She is the expert in relation to this care and her expertise needs to inform the nursing care she receives. Molly, on the other hand, can probably indicate what she likes and

doesn't like, but decisions about her health care need to involve members of her family or others who are legally appointed to make these decisions on her behalf.

Communication

Communication is central to a nurse's ability to provide person-centred care. Enabling patients to communicate their needs and preferences is a priority for every nurse–patient interaction. For example, interactions with Angus will be enabled by nurses possessing a positive attitude towards people with intellectual disability, showing respect for his concerns and priorities, and in the immediate absence of a sign language interpreter, establishing a communication system that enables two-way communication with Angus that satisfies the needs of both parties. Respect for Diane's expertise in her own care needs, along with support to address her immediate concern about after-school pick-up, will be central to the effectiveness of nurse interactions with Diane. Gaining Molly's trust may be central to her immediate safety; this may require one particular person to engage with Molly in preference to a number of different people.

There are a variety of conditions that can lead to changes in a person's ability to communicate. Communication can be broken down into the ability to express thoughts or ideas and the ability to understand what someone else is communicating. Both of these areas can be affected as the result of disability. A person may experience difficulty expressing themselves as a result of various impairments. For example, they may not be able to produce the words clearly (secondary to **dysarthria**, **apraxia** of speech or impairments affecting their voice) or may have difficulty using the correct words (secondary to **aphasia** or changes to their cognition). This may include difficulties with writing (**agraphia**). Problems understanding what has been said may arise from difficulty understanding words, or a person may be able to understand words but may have difficulty paying attention or remembering what has been said. This can also affect reading. Some people may have difficulty with both expressing themselves, as well as understanding what is being said or read.

People with communication difficulties have been found to have fewer opportunities to communicate, leading to social exclusion (Parr 2007). When being cared for in healthcare settings, they are at risk of not being able to communicate effectively, which may compromise their health care (O'Halloran et al 2008). The single most valuable way of addressing this is to provide these patients with the same opportunities to communicate as you would a patient who does not have communication difficulties.

Every nurse–patient interaction has the potential to be positive or negative for a person living with disability. Professional nursing competence required to maximise positive nurse interactions with individuals with disability is dependent upon specific knowledge, skills and attitudes. A nurse's attitudes towards people with disability and beliefs about their value, their place in society and their right to access health care can be positive or negative. How nurse attitudes can act as enablers or barriers to patient functioning has been highlighted earlier in this chapter.

Context

The experience of disability is often associated with higher usage rates of health services. This is reflected in Australian data from the *2007–08 National Health Survey* and the *2007 National Survey of Mental Health and Wellbeing* conducted by the ABS (AIHW 2011). These surveys found that when compared with people without disability, people with severe or profound disability in the 15–64-year age group were 10 times more likely to have check-ups with general practitioners (GPs) at least once a month (29% versus 3%); 3.5 times more likely to consult specialist doctors in the 12 months before the survey period 2007–08 (56% versus 16%); and 5 times more likely to consult both specialist doctors and other health professionals in the 12 months before the survey period 2007–08 (41% versus 8%) (AIHW 2011:2).

A subsequent Australian report (AIHW 2015a) highlights the complexity of care needed by some people with disability and some of the problems encountered in accessing that care. Up to one-third (32%) of people with disability saw three or more different health professionals for the same health condition, and while 22% received assistance, 16% had difficulties caused by lack of communication or coordination of care among different health professionals. Further, the report identified that approximately 13% of people with disability who reported a need for ongoing help or supervision with healthcare activities (such as taking medications, manipulating or exercising muscles or limbs) had no such source of assistance (AIHW 2015a:1).

Nurses play a central role in not only the provision of such care, but also the coordination of care using a person-centred approach. Three types of knowledge are central to person-centred care for persons with disability: knowledge about normal and abnormal body functioning, knowledge about the lived experience of disability and knowledge of assistive technologies.

Normal and abnormal body functioning

Abnormal body functioning is understood as a deviation from normal functioning. For this reason knowledge

about normal body function is central to understanding the pathophysiology of disabling conditions causing abnormal function (congenital, trauma, chronic diseases and ageing) and the provision of person-centred care for a person with disability. Because sensory stimuli give meaning to a person and an order to events in their environment, normal and abnormal sensory functioning are discussed in this section as one aspect of nursing knowledge.

Stimulation comes from many sources in and outside the body, particularly through the sight (visual), hearing (auditory), touch (tactile), smell (olfactory) and taste (gustatory) senses. The body also has a kinaesthetic sense (**proprioception**) that enables a person to be aware of the position and movement of body parts without seeing them. **Stereognosis** is a sense that allows a person to recognise an object's size, shape and texture. The ability to speak is not considered a sense, but it is similar in that a person without speech may lose the ability to interact meaningfully with other people. Meaningful stimuli allow a person to learn about their environment and are necessary for healthy functioning and normal development. When sensory function is altered, a person's ability to relate to and function within the environment changes drastically.

Normal sensation

Normally, the nervous system continually receives thousands of signals from sensory nerve organs, relays the information through appropriate channels and integrates the information into a meaningful response. Sensory stimuli reach the sensory organs and can elicit an immediate reaction or present information to the brain to be stored for future use. The nervous system must be intact for sensory stimuli to reach appropriate brain centres and for the individual to perceive the sensation. After interpreting the significance of a sensation, the person can then react to the stimulus. Table 19-2 summarises normal hearing and vision.

Reception, perception and reaction are the three components of any sensory experience. **Reception** begins with stimulation of a nerve cell called a receptor, which usually responds to only one type of stimulus, such as light or sound. The receptor is composed of specific sensory fibres which are sensitive to that particular stimulus (Hickey 2008). Simply put, when a nerve impulse is created, it travels along pathways to the spinal cord or directly to the brain. For example, sound waves stimulate hair-cell receptors within the Organ of Corti, which causes impulses to travel along the eighth cranial nerve to the acoustic area of the temporal lobe. Sensory nerve

TABLE 19-2 Normal hearing and vision

Function	Anatomy and physiology
The ear	
Transmits to the brain an accurate pattern of all sounds received from the environment, the relative intensity of these sounds and the direction from which they originate	Two ears provide stereophonic hearing to judge sound direction The external ear canal shelters the eardrum and maintains relatively constant temperature and humidity to maintain elasticity The middle ear is an air-containing space between the eardrum and oval window. It contains three small bones (ossicles) The eardrum and ossicles transfer sound to the fluid-filled inner ear Movement of the stapes in the oval window create vibrations in the fluid that bathes the membranous labyrinth, which contains the end organs of hearing and balance The union of the vestibular (balance) and cochlear (hearing) portions of the labyrinth explains the combination of hearing and balance symptoms of inner ear disorders Vibration of the eardrum is transmitted through the bony ossicles. Vibrations at the oval window are transmitted in the perilymph within the inner ear to stimulate hair cells that send impulses along the eighth cranial nerve to the brain
The eye	
Transmits to the brain an accurate pattern of light reflected from solid objects in the environment and transformed into colour and hue	Light rays enter the convex cornea and begin to converge Fine adjustment of light rays occurs as they pass through the pupil and through the lens Change in the shape of the lens focuses light on the retina The retina has a pigmented layer of cells to enhance visual acuity The sensory retina contains the rods and cones – photoreceptor cells sensitive to stimulation from light Photoreceptor cells send electrical potentials by way of the optic nerve to the brain

pathways usually cross over to send stimuli to opposite sides of the brain. The actual perception or awareness of unique sensations depends on the receiving region of the cerebral cortex, where specialised brain cells interpret the quality and nature of sensory stimuli. When the person becomes conscious of the stimuli and receives the information, perception takes place. **Perception** includes integration and interpretation of the stimuli based on the person's experiences. A person's level of consciousness influences how well stimuli are perceived and interpreted. Any factors lowering consciousness impair sensory perception. If sensation is incomplete, as with blurred vision, or if past experience is inadequate for understanding stimuli such as pain, the person may react inappropriately to the sensory stimulus.

It is impossible to react to all of the multiple stimuli entering the nervous system. The brain prevents sensory bombardment by discarding or storing sensory information. A person will usually react to stimuli that are most meaningful or significant at the time. After continued reception of the same stimulus, however, a person stops responding and the sensory experience goes unnoticed. For example, a person concentrating on reading a good book may not be aware of music in the background. This adaptability phenomenon occurs with most sensory stimuli except those of pain.

The balance between sensory stimuli entering the brain and those actually reaching a person's conscious awareness maintains a person's wellbeing. If a person attempts to react to every stimulus in the environment, or if there is insufficient variety and quality of stimuli, sensory alterations will occur.

Sensory alterations

Many factors change a person's capacity to receive or perceive sensations (Box 19-3), thereby causing sensory alterations. The types of sensory alterations commonly

BOX 19-3 Factors that influence sensory function

Age

Infants are unable to discriminate sensory stimuli.

- Nerve pathways are immature.
- Visual changes during adulthood include presbyopia (inability to focus on near objects) and the need for glasses for reading (usually occurring between ages 40 and 50 years).
- Hearing changes, which begin at age 30 years, include decreased hearing acuity, speech intelligibility, pitch discrimination and hearing threshold. Tinnitus often accompanies a hearing loss as a side effect of drugs. Older adults hear low-pitched sounds the best but have difficulty hearing conversation over background noise.
- Older adults have reduced visual fields, increased glare sensitivity, impaired night vision, reduced accommodation and depth perception and reduced colour discrimination.
- Older adults have difficulty discriminating the sounds f, s, th and ch. Speech sounds are garbled, and there is a delayed reception and reaction to speech.
- Gustatory and olfactory changes include a decrease in the number of taste buds in later years and reduction of olfactory nerve fibres by age 50. Reduced taste discrimination and reduced sensitivity to odours are common.
- Proprioceptive changes after age 60 years include increased difficulty with balance, spatial orientation and coordination.
- Older adults experience tactile changes, including declining sensitivity to pain, pressure and temperature.

Medications

Some antibiotics (e.g. streptomycin, gentamicin) are ototoxic and can permanently damage the auditory nerve; chloramphenicol can irritate the optic nerve. Narcotic analgesics, sedatives and antidepressant medications can alter the perception of stimuli.

Environment

Excessive environmental stimuli (e.g. equipment noise and staff conversation in an intensive care unit) can result in sensory overload, marked by confusion, disorientation and the inability to make decisions. Restricted environmental stimulation (e.g. with protective isolation) can lead to sensory deprivation. Poor-quality environmental stimuli (e.g. reduced lighting, narrow walkways, background noise) can worsen sensory impairment.

Comfort level

Pain and fatigue can alter the way a person perceives and reacts to stimuli.

Pre-existing illness

Peripheral vascular disease can cause reduced sensation in the extremities and impaired cognition. Chronic diabetes mellitus can lead to reduced vision, blindness or peripheral neuropathy. Stroke often produces loss of speech. Some neurological conditions result in altered sensory function.

Noise levels

Constant exposure to high noise levels (e.g. on a construction site) can cause hearing loss.

Endotracheal intubation

Temporary loss of speech results from insertion of an endotracheal tube through the mouth or nose into the trachea or from surgery to the neck, which may also interfere with the recurrent laryngeal nerve.

seen by health professionals are sensory deficits, sensory deprivation and sensory overload. When a client suffers from more than one sensory alteration, the ability to function and relate effectively within the environment is seriously impaired.

Sensory deficits

A deficit in the normal function of sensory reception and perception is a **sensory deficit**. A person may not be able to receive certain stimuli (e.g. a person who is blind or deaf), or stimuli may become distorted (e.g. a person with blurred vision from cataracts). A sudden sensory loss can cause negative emotions and feelings of helplessness. When senses are impaired, the sense of self is impaired. Initially a person may withdraw by avoiding communication or socialisation with others, in an attempt to cope with the sensory loss. It becomes difficult for the person to interact safely with the environment until new skills relying on existing functions are learned. When a deficit develops gradually or when considerable time has passed since the onset of an acute sensory loss, the person learns to rely more on their unaffected senses. Some senses may even become more acute to compensate for an alteration. For example, a blind person often develops an acute sense of hearing.

People with sensory deficits may change behaviour in adaptive or maladaptive ways. For example, one person with a hearing impairment may turn the unaffected ear towards the speaker to hear better, whereas another may shun the company of other people to avoid the embarrassment of not being able to understand their speech. Box 19-4 summarises common sensory deficits and possible influences on those affected.

BOX 19-4 Common sensory deficits

Visual deficits

Diabetic retinopathy: pathological changes occur in the blood vessels of the retina, resulting in decreased vision or vision loss.

Cataract: cloudy or opaque areas in part or all of the lens that interfere with passage of light through the lens. Cataracts usually develop gradually, without pain, redness or watering eyes.

Dry eyes: result when tear glands produce too few tears. Common in older adults and results in itching, burning or even reduced vision.

Open-angle glaucoma: an increase in intraocular pressure caused by an obstruction to the normal flow of aqueous humour through Schlemm's canal. Causes progressive pressure against the optic nerve, resulting in visual field loss, decreased visual acuity, and a halo effect around the eyes if untreated.

Presbyopia: a gradual decline in the ability of the lens to accommodate or to focus on close objects. Individual is unable to see nearby objects clearly.

Senile macular degeneration: a condition in which the macula (specialised portion of the retina responsible for central vision) loses its ability to function efficiently. First signs may include blurring of reading matter, distortion or loss of central vision and distortion of vertical lines.

Hearing deficits

Cerumen accumulation: build-up of ear wax in the external auditory canal. Cerumen, which is normally absorbed in a younger person's ear, becomes hard and collects in the canal, causing a conduction deafness.

Presbycusis: a common progressive hearing disorder in older adults.

Balance deficit

Dizziness and disequilibrium: common condition in older adulthood, usually resulting from vestibular dysfunction. Frequently an episode of vertigo or disequilibrium is precipitated by a change in position of the head.

Taste deficit

Xerostomia: decrease in salivary production that leads to thicker mucous and a dry mouth. Can interfere with the ability to eat and leads to appetite and nutritional problems.

Neurological deficits

Peripheral neuropathy: disorder of the peripheral nervous system. This can occur in older adults, endocrine disorders, entrapment syndromes and connective tissue disorders, and can be associated with potential life-threatening causes such as inflammatory demyelinating polyneuropathy, genetic disorders, toxins, medications, renal and liver disease, infectious diseases, vitamin B (B6 and B12) deficiency and neoplasms (Azhary et al 2010). Symptoms include numbness and tingling of the affected area and stumbling gait.

Stroke: cerebrovascular accident caused by clot, haemorrhage or emboli affecting a blood vessel leading to or within the brain (Scanlon & Kevin 2008). Creates altered proprioception with marked lack of coordination and imbalance. Loss of sensation and motor function in extremities controlled by the affected area of the brain also occurs.

Azhary H, Farooq MU, Bhanushali M et al 2010 Peripheral neuropathy: differential diagnosis and management. Am Fam Physician 81(7):887–92; Scanlon A, Kevin J 2008 Stroke (cerebrovascular accident). In Chang E, Johnson A (eds), Chronic illness and disability: principles for nursing practice. Churchill Livingstone, Sydney, pp. 236–50.

Sensory deprivation

The reticular activating system mediates all sensory stimuli to the cerebral cortex, so that even in deep sleep people are able to receive stimuli. Clients in intensive care units (ICUs) are often exposed to physical touch, but this is usually associated with technical intervention rather than personal, comforting touch (Price 2004). When a person experiences an inadequate quality or quantity of stimulation, such as monotonous or meaningless stimuli, **sensory deprivation** occurs.

Three types of sensory deprivation are:

- reduced sensory input (sensory deficit from visual or hearing loss)
- elimination of order or meaning from input (e.g. exposure to strange environments)
- restriction of the environment (e.g. bed rest or reduced environmental variation) that produces monotony and boredom (Ebersole et al 2008).

Commonly, people at risk of sensory deprivation are thought to be those living in a confined environment such as in residential aged care. Although most good-quality nursing homes offer meaningful stimulation through group activities, environmental design and mealtime gatherings, there are exceptions. The older adult who is confined to a wheelchair, suffers from poor hearing and/or vision, has decreased energy and avoids contact with others is at significant risk of sensory deprivation. If the organisational environment creates monotony, the resident has a reduced capacity to learn and to think.

More generally, persons with deformities or disfigurements, and those displaying atypical behaviours (such as drooling, moaning or uncontrolled limb movements) may be at higher risk of sensory deprivation because people with these characteristics are frequently marginalised by society (Kristeva 1982). Furthermore, much of the care required by extremely disabled or disfigured persons is considered 'dirty or unclean' (Lawler 1991). This means that although severely disabled people may be daily recipients of compensatory nursing care for extended periods (sometimes for all of their life), this care may be so routine as not to be humanised, and as such, lacks the authenticity required to prevent sensory deprivation.

There are many effects of sensory deprivation, some of which are contained in Box 19-5. The symptoms of sensory deprivation can easily cause nurses and doctors to believe that a client is psychologically ill and confused, is suffering from severe electrolyte imbalance or is under the influence of psychotropic drugs. Therefore, the nurse must always be aware of the client's existing sensory function and the quality of stimuli within their usual environment.

BOX 19-5 Effects of sensory deprivation

Cognitive

- Reduced capacity to learn
- Inability to think or solve problems
- Poor task performance
- Disorientation
- Bizarre thinking
- Regression
- Increased need for socialisation, altered mechanisms of attention

Affective

- Boredom
- Restlessness
- Increased anxiety
- Emotional lability
- Panic
- Increased need for physical stimulation

Perceptual

- Visual/motor coordination
- Colour perception
- Apparent movement
- Tactile accuracy
- Ability to perceive size and shape
- Spatial and time judgement

Modified from Ebersole P, Hess P, Schmidt Luggen A et al 2008 Ebersole & Hess' Toward healthy ageing: human needs and nursing response. Elsevier Health Sciences, St Louis.

Sensory overload

When a person receives multiple sensory stimuli and cannot perceptually disregard or selectively ignore some stimuli, **sensory overload** occurs. Excessive sensory stimulation prevents the brain from appropriately responding to or ignoring certain stimuli. Because of the multitude of stimuli leading to overload, the person no longer perceives the environment in a way that makes sense. Overload prevents meaningful response by the brain; the person's thoughts race, attention moves in many directions and anxiety and restlessness occur. As a result, overload causes a state similar to that produced by sensory deprivation. However, in contrast to deprivation, overload is individualised. The amount of stimuli needed for healthy function varies with each individual. People may be subject to more environmental overload at one time than at another. A person's tolerance to sensory overload may vary by level of fatigue, attitude and emotional and physical wellbeing.

The behavioural changes associated with sensory overload can easily be confused with mood swings or

simple disorientation. The nurse should look for symptoms such as racing or disordered thoughts, scattered attention, restlessness and anxiety. Clients in intensive care units sometimes resort to constantly touching tubes and dressings. It is important, therefore, to constantly reorient and control excessive stimuli as part of the client's care (Price 2004).

The lived experience of disability

We conduct daily business in our world in and through our bodies; therefore, the function of our body is highly significant to daily life (Draper 2014:2237). Disability can interrupt both expectation and experience of life, lifestyles and livelihoods, as well as cause disruption to self-identity and body image (see Chapter 20). Many studies have now been published about the experience of people living with both congenital and acquired disability.

For example, an Australian study by Kearney and Griffin (2001) has challenged the prevailing belief that having a child with a significant congenital disability is always a tragedy. In addition to experiencing anguish and sorrow, parents in this study also spoke of 'hope, love, strength and joy' (p. 582). Their lived experience included living with tensions between the confusing and conflicting emotions of joy and sorrow, at the same time as having hope and no hope, defiance and despair (p. 587).

The literature in relation to acquired disability is rich, incorporating studies of the experience of individuals across diagnostic groups, across the life span, and from around the world. Two consistent themes emerge from these studies: firstly, that negotiating life immediately following acquired disability involves work; and secondly, that the outcome of that work may be a reconstructed self. Three qualitative studies of the lived experience of persons with disability are shown in Table 19-3. Qualitative research methods allow nurses and other health professionals to access a more accurate and personalised version of the patient experience and journey.

• CRITICAL REFLECTION POINT

Look in your local library for the lived experience of disability stories, such as those listed in Box 19-6 or similar. Read a couple and note your emotional responses to the person's situation. Think about how you could facilitate the person's optimal level of functioning if you were providing them nursing care.

Rehabilitation

Rehabilitation is commonly associated with the period immediately following acquired disability. Rehabilitation is fundamentally about a person regaining control over their body and their life (Ozer 1999), and for some people this entails 'the holistic reconstruction of the "self"' (Siegert et al 2007:1609). The important point to remember is that each patient's rehabilitation journey is unique as it is informed by the significance they assign to their situation (Donnelly et al 2005). Acquiring information and learning through doing are key aspects of regaining control (Bourke et al 2015). The timing and amount of information sought can vary between individuals, so it is important to determine what information patients want, in what format, how detailed and when.

While the construction and reconstruction of self is ongoing for all of us, the process is less challenging when it is self-directed. The reconstruction of self journey following acquired disability can be slow to start as return to the usual self is commonly the preferred destination (Nanninga et al 2015). It can also take considerable time for the person to realise that life can be lived with an altered body (see Chapter 20). Once the new normal is established, however, life is not static. Like everyone, transition points are experienced.

TABLE 19-3 Examples of key aspects of the lived experience of acquired disability

Stroke	Spinal cord injury	Traumatic brain injury
Bodily recovery and functional improvement	Looking for understanding to a life that is unknown	Mind/body disconnect
Recreating and restructuring daily life	Stumbling along an unlit path	Disconnect with pre-injury identity
Biographical adjustment and transformation	Viewing self through a stained glass window	Social disconnect
	Challenging the bonds of love	Reconstruction of identity
	Being chained to the injury	Reconstruction of a place in the world
	Moving forward in a new way of life	Reconstruction of personhood
	Reaching a new normalcy	
Kirkevold (2010)	DeSanto-Madeya (2006)	Levack et al (2010)

BOX 19-6 Examples of stories of the lived experience of disability

A long season in hell: The battle to save my son by G Graham (1996, Macmillan)

Ghost boy by M Pistorius with M L Davies (2011, Simon & Schuster, London)

I hear more than you see by J Daisley (2005, Landers Publishing, Dural, NSW)

Just a head: Stories in a body by D Fassett & M R Gallagher (1998, Allen & Unwin, St Leonards, NSW)

Monster in the bedroom: The life of Jo Ann Dolan by Janine Hosking (1992, Allen & Unwin, North Sydney, NSW)

Waterlemon: husband in a coma and other setbacks by R Ritche (2006, Macmillan, Sydney)

A good example of this is a study of the transition to motherhood for women with disability (Lawler et al 2015). In addition to describing a three-phase reconstruction process, this study details interventions to facilitate each phase of that transition. The three phases are presented in Table 19-4 and while specifically related to mothers with a disability, are also applicable to the nursing care of many people with disability.

Assistive technologies

Persons with disability have one or more specific functional losses that impair, limit or restrict their normal activity to varying degrees. This functional loss can range from a situation where some individuals remain independent by using simple aids, to a situation where some are completely dependent on others for all activities. A New Zealand mixed methods study identified inaccessible environments, negative attitudes, unreliable transportation and poor access to information as the key barriers experienced by disabled people in their everyday living. However, lack of adequate and appropriate resources to overcome these barriers was the main obstacle to participation in society (Wilkinson-Meyers et al 2014:1540). The type of supportive aids an individual requires will depend on the nature of their disability and the complexity of the task or action being undertaken. Supportive aids could be considered to assist within the areas of mobility, feeding, communication, vision and hearing.

Mobility

There are many conditions that can lead to an alteration in a person's ability to mobilise. For example, people with musculoskeletal disorders and lower limb amputation, neurovascular, spinal and neuromuscular degenerative disorders, stroke and brain injury may all have varying difficulties with mobility. This can include changing and maintaining body position, carrying, moving and handling objects, walking and moving, and moving around using transport (WHO 2001). The mobility assistance device required is dependent on functional ability, the desired activity and choice of the individual.

Mobility assistance equipment comes in many forms, shapes and sizes. There is a range of assistive devices that can be used in the bedroom to help with changing and

TABLE 19-4 Interventions to facilitate the transition to motherhood of women with disability

Phase 1: Having a sense of self	Phase 2: Making meaning of self as a mother	Phase 3: Reforming the self as a mother
Disability awareness and training provided for all caregivers	Provision of appropriate information in appropriate format for women with disability	Access formal and informal supports for women with disability
Structural adaptations to improve accessibility to maternity units	Development of a mechanism of referral to formal supports relevant to women with disability	Develop a peer support network for women with disability
Conduct an assessment of needs early on	Establish peer support groups for women with disability	Develop a website specific to parents with a disability
Consider community-based models of care	Liaise with voluntary disability agencies	Devise a directory of services and resources available for women with disability
Appoint disability midwife advisor		Develop and adopt family-friendly policies in the workplace
Development of policies and guidelines for the provision of care for women with disability		Link women with disability to appropriate forums and discussion boards
Continuity of carer		Devise a range of information leaflets on parenting for parents with a disability

Lawler D, Begley C, Lalor J 2015 Re-constructing myself: the process of transition to motherhood for women with a disability. Journal of Advanced Nursing 71(7):1672–83.

maintaining body position, for example, bed ladders (used to assist the user to sit up in bed by sequentially pulling on the rungs of the ladder), bed sticks (used as an anchor point to be grabbed when turning), monkey poles, leg lifters and electric beds. Lifters and hoists may be used if the person is unable to weight-bear. Bathroom modifications, such as bath hoists, grab rails and non-slip flooring, should be considered, along with the use of aids such as raised toilet seats, shower chairs and commodes.

Many will require an assistive device for ambulation such as crutches, walking stick, forearm, wheeled or pickup walking frame, or may be dependent on a wheelchair (manual or powered) or scooter. The type of chair required is dependent on the degree of disability; for example, persons with poor upper body control will require a powered chair. People with severe sight loss may need to use a walking cane or guide dog to assist them with mobilisation.

While public transport systems are increasingly being transformed to accommodate people with disabilities, many people with disabilities still find public transport largely unreliable and inaccessible. Wilkinson-Meyers et al (2014) suggest that currently only public transport limited to place (dictated by route) and time (timetable) will be likely to assist people with disabilities and many may need to use specially customised forms of transport, such as wheelchair lift taxis or modified private vehicles.

Eating

There is a range of conditions that can impact on a person's ability to prepare meals (planning, organising, cooking and serving simple and complex meals and drinks) and coordinate the task of eating and drinking (see Chapter 31). There are now many simple assistive devices that can be used to help a person prepare their own meals or drinks. Devices such as specialist kitchen utensils with built-up handles and angled knives allow a stronger grip and put less stress on joints. Using electric appliances such as blenders, food processors and electric can openers and knives can also assist with food preparation. Specialist devices such as jug or kettle tippers, bowl tippers, clamps to stabilise jars and bottles for one-handed use can also promote independence.

Other devices that can be used to promote independence in eating are, for example, the use of weighted shaft cutlery, angled shaft cutlery and rocker knives, plate guards and non-slip matting or suction cap plates, to hold and secure the plate in place. There is also a range of adapted cups, such as two-handed cups, weighted cups and cups with lips, all designed to assist the person with decreased hand fine motor function.

Communication devices

As discussed earlier, communication may be altered in varying ways including: comprehending spoken, non-verbal and written messages; speaking, producing non-verbal and written messages; and an inability to start, sustain and end a conversation (WHO 2001). There are numerous strategies that nurses can use to provide patients with altered communication an opportunity to communicate. Some patients will use aided or unaided modes of communication. Examples of unaided communication include signing, gestures and facial expressions. Aided forms of communication include electronic devices (such as type-to-talk devices, voice synthesisers and amplifiers), communication boards and specialised communication computer software. These are known as alternative and augmentative communication (Finke et al 2008).

Some patients may simply require other more common devices to aid their communication, such as hearing aids or glasses. For those patients with more subtle communication difficulties, other strategies may be useful. Table 19-5 gives examples of strategies that could be used for communication with patients experiencing a range of communication difficulties.

Vision

As a result of the normal changes of ageing, the pupil's ability to adjust to light is diminished and older adults can be very sensitive to glare. The nurse can suggest ways to minimise glare, for example, using satin and non-gloss finishes for walls and countertops in the home and choosing sheer curtains, tinted windows or adjustable shades to reduce outdoor light. Wearing sunglasses outside can obviously reduce the glare of direct sunlight.

The ability to read is important to everyone. Patients should be facilitated to use their glasses whenever possible (e.g. during procedures and client instruction) as this will help patients remain oriented, maintain some control and retain their dignity (Larsen et al 1997). People with reduced visual acuity may need more than corrective lenses. A pocket magnifier can help a person read most printed material and mobile apps are now available for this. Telescopic lens glasses are smaller, easier to focus and have a greater range. There are also books and other publications available in large print. If patients have legal or other important documents they wish to read, most photocopiers have enlarging capabilities. People with severe sight loss may use newer technological assistive devices such as voice recognition software and screen-reading software in addition to Braille.

With ageing, a person also experiences a change in colour perception. Perception of the colours blue, violet and green usually declines. Brighter colours such as red, orange and yellow are easier to see. The nurse can suggest ways to decorate a room and paint hallways or stairwells so that differentiations can be made between surfaces, edges and objects in a room.

Hearing

One simple way to help an older adult with a hearing loss is to ensure that the problem is not related to impacted cerumen. With ageing, cerumen thickens and builds up in the ear canal. Excessive cerumen occluding the ear canal can cause a conductive hearing loss. Softening agents can be used to loosen the cerumen prior to irrigation of the canal with tepid water in a 60 mL syringe. Removal of cerumen can significantly improve the person's hearing ability; however, extreme caution is required when undertaking this procedure.

To maximise residual hearing function, the nurse can suggest ways to modify the environment. Telephones and televisions can be amplified. Alarm clocks that shake the bed or activate a flashing light are useful. An innovative way to enrich the lives of the hearing-impaired is recorded music. Music recorded in the low-frequency sound cycles can be heard by patients with severe hearing loss.

Individuals with moderate to severe hearing loss commonly use hearing aids. There are many styles of hearing aids available, and the choice of device is dependent on the cause and severity of hearing loss. Hearing aids do not restore normal hearing, but they do make sounds louder. A small microphone collects sounds from the environment, and a microchip converts the sound into digital code, which is then analysed. The aid then alters the sound wave delivered to the ear, amplifying the sounds according to the individual's needs. People who are profoundly deaf or severely hard-of-hearing may have a cochlear implant. Unlike hearing aids, which amplify sounds, the cochlear implant works by bypassing the damaged parts of the ear and directly stimulating the auditory nerve. More information about assistive devices can be found at the Independent Living Centres Australia website (see *Online resources*).

While being generally aware of the types and range of adaptive device is important, knowledge about the specific requirements of an individual needs to come directly from the individual or their immediate carer.

Key skills for person-centred care for persons with disability

A wide range of skills is required for the care of persons with disability, many of which are covered elsewhere in this text. The person with disability is first and foremost a person, so all other sections of this text are relevant. While individuals may have very specific care requirements, all will benefit from individualised and person-centred approaches to their care.

TABLE 19-5 Examples of communication strategies

Impairment	Strategy that may assist
Difficulty communicating with you	Ask the patient to try and describe using a different word
	Ask the patient simple questions, e.g. Are you hungry? Do you want to go to the bathroom? to try and determine what they need
	If the patient cannot speak, try a different option, write some words down for them to choose from, show them pictures or objects to choose from
	Ask them to try and say it again, write it down for you or draw a picture
Difficulty understanding what you are saying	Reduce your speech rate
	Use fewer words
	Use less complex words
	Write down what you have said
	Show the patient what you are talking about, e.g. if you are asking if they want to use the bathroom, point to the bathroom when you are talking about it
	Check that the patient has understood, by asking them to tell you what they have understood

Sweidel GB 1991 Management strategies in the communication of speaking persons and persons with a speech disability. Research on Language and Social Interaction 25(1-4): 195–214.

Autonomy-supportive interventions

Enablement of self-determination is a core skill for the person-centred care of persons with disability. This can be achieved through the use of **autonomy-supportive interventions** (Kayser et al 2014), which are based on understanding that the fundamental needs for psychological growth and wellbeing are autonomy, relatedness and competence (Deci & Ryan 2012). It is important to note that autonomy is more about choice than independence, and that the opposite of being autonomous is being controlled.

The core components of autonomy-supportive interventions are: providing choice, communicating a meaningful rationale, showing empathy, collaboration, and using strengths-based interactions (Kayser et al 2014). Nurses need to possess attitudes in harmony with these components and skills in strengths-based interactions.

Values-based goal setting is an asset in autonomy-supportive interventions. Values-based goals provide a foundation for a plan of care that is in harmony with what and who is important to the person. Values may relate to life domains such as work, relationships, personal growth/health and leisure. The interpersonal nursing skills required include rapid rapport building, developing trust, providing emotional support, instilling confidence, motivational interactions and providing feedback (Pryor 2014:308).

Conservation and restoration of function

Central to person-centred care in disability is the conservation and restoration of function. Conservation of function focuses on maintaining or improving existing function, and the prevention of functional decline. As such, the aim is to prevent further deconditioning and functional decline, otherwise known as disability. Deconditioning and functional decline are serious problems for the hospitalised older or disabled person. **Deconditioning** can be acute or chronic, with acute deconditioning happening within days to a few weeks of a sudden decrease in activity (Siebens et al 2000). **Functional decline** is a consequence of deconditioning. It is described as a resulting inability to perform the activities that would normally ensure a person's independence (Graf 2006:60). While chronic deconditioning is a feature of a sedentary lifestyle, acute deconditioning and functional decline have been linked to patient inactivity in acute hospitals.

The prevention of functional decline is complex, requiring care in relation to the following domains: cognition and emotional health; mobility, vigour and self-care; continence; nutrition; skin integrity; and medication management (Tropea et al 2011). More broadly, the prevention of functional decline requires nurses to see the whole person, who is the patient, within their context. This means looking beyond the presenting or immediate health problem to see the person's 'bigger picture' (Pryor 2014). **Function-promoting nursing practice** is when care includes an 'awareness of the patient's tomorrow, and the relationship between what does and does not happen today and the tomorrow that follows' (Plaisted 1978:726).

This whole-person awareness needs to achieve more than just recognise that a person has the potential or ability to undertake self-care and participate in everyday life. To make a difference, awareness needs to be enacted in strategies that facilitate **functional performance**. This refers to what an individual can do in their societal context and includes 'all aspects of their physical, social and attitudinal world' (WHO 2001:15). Person-level function is another term for this (Pryor 2014). Enriching the person's environment is emerging as a positive strategy for many aspects of nursing care.

Enriched environments

As identified in the ICF (WHO 2001), a person's environment comprises a multitude of factors that can act as enablers or barriers to human functioning. While each person's environment is unique, environmental factors generally fall into three groups: naturally occurring factors (e.g. the weather); human-made structures and processes; and interpersonal interactions.

As nurses, we can positively influence a person's functional performance. Nurses' attitudes towards persons with disability have been stressed throughout the chapter as key elements of care, but it is also important to ensure that collectively, nurses as individuals working in a particular setting, and nursing as a professional group, are mindful of this. Individually and collectively, nurses and nursing can positively influence functional performance by enriching the patient environment.

Within the context of health, enriching the environment refers to enabling the functional performance of the person who is the patient through the purposeful use of strategies that maximise the potential of the physical, social and attitudinal aspects of their inpatient environment as environmental enablers. Also known as milieu therapy (Dotterman & Bulechek 2004) and ward atmosphere (Moos 1989), this is not new thinking. Interest in ward atmosphere in inpatient mental health facilities began decades ago (e.g. Echternacht 2001, Moos 1974, 1989, Milne 1986, Smith et al 1996) with the overall purpose being to create conditions that support positive change in patients (Geanellos 2000) and a particular interest in developing patients' relationships with other

RESEARCH HIGHLIGHT

In some conditions the onset of disability is sudden, but in others the onset is much slower. The sudden onset of disability is commonly confusing and confronting. One condition commonly associated with sudden onset acquired disability that has gained a lot of attention in recent years is stroke. Understanding the experiences of persons who suffer stroke is central to best-practice person-centred care.

The findings of a recent Dutch study of 33 stroke survivors helps us to understand the experiences and needs of stroke survivors. The findings make explicit the need for personal coherence; stroke survivors' bodies and selves change, but spatially and socially their home does not. Engagement with the world outside home can be exceedingly complex and lead stroke survivors to turn inwards.

The findings of this qualitative study are presented in three phases (the clinical phase, the post-discharge phase and the reintegration phase). Central to each phase is a longing for bodily recovery and domestic places followed by a longing for pre-stroke activities and role, then a longing for recognition and a new sense of belonging.

patients and staff; the personal growth of patients; and organisational factors such as program clarity.

Nurses have been able to enrich environments in inpatient rehabilitation through the use of interventions known as rehabilitative milieu therapy. Before the ICF (WHO 2001), Pryor (2000) proposed that nursing could and should positively influence physical, social and cultural aspects of the inpatient rehabilitation environment. In a subsequent Australian study (Pryor 2010:124), nurses were found to enrich inpatient rehabilitation environments by allowing time for patients to do for themselves, keeping patients' spirits up, protecting patients from embarrassment, and making hospitalisation more homelike than typically experienced in acute care. In another Australian setting, the implementation of the rehabilitative milieu nursing intervention comprised patient education about the roles of nurses and patients in rehabilitation, and lunchtime dining-room activities (Pryor & Buzio 2010). These initiatives were found to both authorise and enable rehabilitation by positively influencing both patients and nurses.

In a New Zealand study, Tyrrell et al (2012:2466) found that the environment of rehabilitation inpatients was enriched by a 'best fit' nurse. These best fit nurses were identified by patients based on their 'nature', 'being available' and 'being attuned' to the patient's individual needs. If a 'connection' was formed, then the best fit relationship maximised the older person's motivation to participate in his or her rehabilitation therapy.

Recent developments in our understanding of the role of **enriched environments** in relation to neuroplasticity underline the significance of these findings. **Neuroplasticity** is described by Doidge (2015:xv) as a property of the brain that enables it to change its own structure and functioning in response to mental activity and mental experience. Through purposeful and directed enrichment of patient environments, nurses and other health professionals have a clear potential to make a significant contribution in this area (see *Research highlight*).

Key concepts

- We will all experience disability at some time in our life.
- The biopsychosocial model adopted in the International Classification of Functioning, Disability and Health is a valuable tool for understanding the multiple factors that contribute to disability.
- Personhood is a status bestowed upon a human being by others.
- Communication is a basic human right.
- Your attitudes and behaviours towards persons with or without disability can act as either an enabler or a barrier to that person's functional performance.
- Every nursing interaction with a person with or without disability can positively influence that person's functioning, wellbeing and quality of life.

Spiritual distress, p. 456
Spirituality, p. 445

Learning outcomes

Mastery of content will enable you to:

- explain the five components of self: identity, body image, self-esteem, roles and spirituality
- define the components of what constitutes a healthy self as related to psychosocial and cognitive stages of development
- discuss the relationship of spirituality to an individual's conception of self
- describe the relationship between faith, hope, trust and spiritual wellbeing
- identify most commonly recognised spiritual needs
- describe stressors that can affect a person's perception of self
- describe behaviours indicating identity confusion, disturbed body image, low self-esteem, role conflict and spiritual distress
- identify and discuss ways in which nursing activities can affect the client's perception of self
- discuss nursing interventions designed to promote spiritual healing and spiritual health
- identify important aspects of culture that affect nursing care in support of clients' conception of self
- distinguish factors that promote a healthy self.

Relationship with oneself is the most intimate of relationships and one of the most important aspects of life experience, yet it is one of the most difficult to define. What we think and feel about ourselves affects the way in which we care for ourselves and others physically, psychologically, emotionally and spiritually. People with a poor conception of self often do not feel a sense of personal worth, which influences whether they seek physical, emotional and spiritual help as the need arises.

Dimensions of the self

The ways in which a person comes to know and understand themselves as a unique individual is primarily determined by two key elements: self-concept and a person's spirituality. **Self-concept** is an individual's awareness about the self (e.g. 'I am good at maths') (Stein-Parbury 2013), while a person's **spirituality** is concerned with a search for meaning, purpose and interconnectedness with self, others/nature and possibly an ultimate other.

A person's conception of self as a unique individual has its origins in the psychic representation of an individual, the central core of 'I' around which all perceptions and experiences are organised. Conception of self is developed through a range of processes involving five key elements – identity, body image, self-esteem, role performance and spirituality. The development of a person's conception of self is a dynamic combination formulated over years and based on the following:

- reactions of others to one's body
- ongoing perceptions of the reactions of others to the self
- relationships with self and others
- personality structure
- perceptions of stimuli that have an impact on the self
- prior and new experiences
- present feelings about the physical, emotional, social and spiritual self
- expectations about the self
- spiritual identity.

A positive conception of self offers a sense of continuity, wholeness and consistency to a person. A healthy conception of self has a high degree of stability, despite the person experiencing either positive or negative feelings towards the self. Being 'oneself' is the crux of a healthy self in all its dimensions (Edward et al 2014).

The five dimensions that constitute self – identity, body image, self-esteem, role performance and the spiritual self or a person's spirituality – form the basis of an individual's overall sense of who they are as a human being (see Figure 20-1).

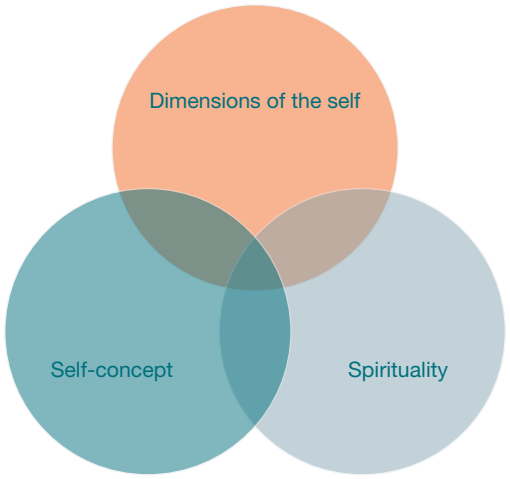

Figure 20-1 Dimensions of the self.

Identity

Identity involves a person's sense of individuality, wholeness and consistency in various life circumstances over time. The concept of identity therefore includes constancy and continuity. Identity implies being distinct and separate from others – being able to view oneself as a unique individual.

Identity develops over time. A child learns culturally accepted values, behaviours and roles through **identification**. The child first identifies with parenting figures and later with teachers, peers and heroes (see Chapter 16). To form an identity, the child must be able to bring together learned behaviours and expectations into a coherent, consistent and unique whole (Erikson 1963).

The achievement of identity is necessary for intimate relationships because one's identity is expressed in relationships with others. Sexuality is a part of one's identity. Sexual identity is a person's image of the self as male or female, and the meaning of this image. This image and its meaning are influenced by sociocultural values that are learned through socialisation (see Chapter 21).

Body image

Body image is an individual's mental picture of their physical appearance. It includes a person's feelings and attitudes towards the body. These images are not necessarily consistent with the actual body structure or appearance. Body image may change within a few hours, days, weeks or months, depending on the impact of external stimuli on the body and actual changes in appearance, structure or function. Body image is also influenced by personal views of physical characteristics and abilities and by the perceptions of others. For example, a controlling, violent husband might tell his wife that she is ugly and that no

one else would want her. Over the years of marriage, she believes this image of herself and incorporates it into her self-concept.

Body image is affected by cognitive development and physical growth. Normal developmental changes such as physical growth and ageing have a more apparent effect on body image than on other aspects of self-concept (Saucier 2004). Hormonal changes during adolescence and menopause influence body image, and changes associated with ageing (e.g. wrinkles, greying hair and decrease in visual acuity, hearing and mobility) may also affect body image.

Body image is also influenced by cultural and societal attitudes and values (Cafri et al 2005, Shilling 2012) (see *Working with diversity*). In Australia and New Zealand, youth, beauty and wholeness are emphasised and valued by society – a fact apparent in television programs, movies and advertisements. Western cultures have been socialised to accept the normal ageing process as a part of life, whereas in Eastern cultures, ageing is viewed very positively and the older adult is highly respected.

WORKING WITH DIVERSITY

Focus on cultural care

Culture influences what people tend to value in their lives. How people think about themselves, what motivates them and how they behave are all related to the culture within which people are socialised. In order to provide culturally safe care, healthcare professionals need to be aware of the significance of culture to a person's health and wellbeing. This involves becoming culturally aware and responding to the cultural needs of individuals and their families. It is important to remember that a person's cultural needs and spiritual needs are intertwined. This means that in providing culturally safe care, the spiritual needs of the person must be considered.

Body image is influenced by the person's attitude to their body, which changes over time. For some people, inevitable physical changes may or may not be incorporated into their body image (Landa & Bybee 2007). For example, people who have experienced significant weight loss may not perceive themselves as thin. Older adults often report that they do not feel different despite such changes as wrinkled skin or greying hair. However, for others, attitudes towards body image may mean that a change in one's body may have a significant impact on the way they view themselves (Cash & Smolak 2012).

Self-esteem

Self-esteem relates to an individual's sense of self-worth and is influenced both by self-evaluation and the responses of others. According to Erikson (1963), young children begin to develop a sense of usefulness or industry by learning to act on their own initiative. A child's self-esteem is related to the child's evaluation of their effectiveness at school or work and play, within the family and in other social settings. The evaluation of others is also likely to have a profound influence on the child's self-esteem. A person's family and society in general set the standards by which individuals evaluate themselves. A child who excels in school and who is liked by peers is likely to have high self-esteem, whereas a child who has difficulty in school and is not liked by peers is more likely to develop low self-esteem.

Understanding of self-esteem can be enhanced by considering the relationship between a person's self-concept and the ideal self. The **ideal self** consists of the aspirations, goals, values and standards of behaviour that a person considers ideal and strives to attain. The ideal self originates in the preschool years and develops throughout life. It is influenced by societal norms and the expectations and demands of parents and significant others. In general, a person whose self-concept comes close to matching the ideal self has high self-esteem, whereas a person whose self-concept varies widely from the ideal self has low self-esteem.

A person's perception of self is based on gender, age, perceived health status, background, family roles, occupation, social roles and external interests. Basic feelings about the self tend to be constant, even though there is normal fluctuation, with perceived good and bad days. An individual's self-perception does not necessarily match the perceptions of others. Self-evaluation is an ongoing mental process. A positive sense of self-worth, or self-esteem, is a basic human need, according to Maslow's hierarchy of needs (Maslow 1954). People's self-esteem affects their self-concept and how they function in the world.

A person's ability to contribute in a meaningful way to society often affects their self-concept and self-esteem. Individuals who are unwell may find it difficult to be actively involved with others and may feel a sense of low self-esteem, including feelings of worthlessness (Christensen et al 2014). The recognition and acceptance of a client as an individual of worth and with dignity can be vital in maintaining and improving the client's self-esteem.

Role performance

Role performance is concerned with the roles individuals assume or follow in given situations and involves expectations or standards of behaviour that they have developed over time. An individual develops role behaviour based on patterns established through their socialisation.

Socialisation begins just after birth, when an infant reacts to the responses made by parents or other adults, who in turn are responding to the infant's behaviours. The patterns of behaviour established in early life change only minimally during childhood and adulthood.

A child learns behaviours that are approved by society through the following processes (Parsons 2012):

- *Reinforcement–extinction*: certain behaviours become common or are avoided, depending on whether they are approved and reinforced or discouraged and punished.
- *Inhibition*: a child learns to refrain from behaviours, even when tempted to engage in them.
- *Substitution*: a child replaces one behaviour with another, which provides the same personal gratification.
- *Imitation*: a child acquires knowledge, skills or behaviours from members of the social or cultural group.
- *Identification*: a child internalises the beliefs, behaviour and values of role models into a personal, unique expression of self.

Through the process of socialisation, a child generally develops the skills necessary for functioning in many different roles. Unsuccessful socialisation is an inability to function according to the general norms and values of the society in which the individual lives.

Ideal societal role behaviours are often hard to realise in the context of everyday life, where individuals have multiple roles and individual needs. Successful adults learn to distinguish between ideal role expectations and realistic possibilities. To function effectively in roles, people must know the expected behaviour and values, must want to conform to them and must be able to meet the role requirements. Most individuals have more than one role. Common roles include mother or father, partner, wife or husband, daughter or son, employee or employer, sister or brother, and friend. Each role involves meeting certain expectations. Fulfilment of these expectations leads to rewards. Difficulty or failure in meeting role expectations often contributes to decreased self-esteem.

Role performance is the way people perceive their competency in carrying out significant roles (Sargent 2003). An individual's perception of competency may or may not match the evaluation of others who relate to the person.

Spirituality

The word *spirituality* derives from the Latin word *spiritus*, which refers to breath or wind. The spirit gives life to, or animates, a person. It signifies whatever is at the centre of all aspects of a person's life, including their sense of self (Elder et al 2009). The human spirit is a powerful force that defines our existence, offers a source of hope and helps us to achieve inner harmony (Edward et al 2014).

Spirituality is a concept that is unique to each individual. People's definitions of their own spirituality are influenced by their culture, development, life experiences, beliefs and ideas. A person's spirituality enables the person to love, have faith and hope, seek meaning in life and nurture relationships with others. Spirituality offers a sense of connectedness: intrapersonally (connected within oneself); interpersonally (connected with others and the environment); and transpersonally (connected with what a person may perceive as a higher power).

Elements of spirituality discussed in the literature include spiritual health, spiritual needs and spiritual awareness. Berman et al (2010) describe spiritual wellbeing as a force that provides meaning and purpose in life and a sense of harmony between self, others/nature and an 'Ultimate Other', which exists throughout and beyond time and space. There are two important characteristics of spirituality about which most authors agree: it is a unifying theme in people's lives, and it is a state of being.

There are people who either do not believe in the existence of a god (**atheist**) or who do not believe in any ultimate meaning for the way things are (**agnostic**). However, this does not mean that spirituality is not an important concept for the atheist or agnostic. Atheists often search for meaning in life through their work and their relationships with other people. They also tend to believe in a joint responsibility for others. In acting for themselves, they feel they should also act for all humankind. In the case of agnostics, it is important to discover or find meaning in what they do or how they live. Spirituality can be viewed from other perspectives, including faith, religion and hope.

Faith

The concept of **faith** has two definitions in the literature. In the first, faith is defined as a *cultural* or *institutional religion*, such as Judaism, Buddhism, Islamism or Christianity (faith as religion is described in the next section). The second deals with *faith as a relationship with a divinity, higher power, authority or spirit* that incorporates a reasoning and a trusting faith (Doucet 2008). A *reasoning faith* deals with a person's belief and confidence in something for which there is no proof. It is an acceptance of what reasoning cannot reach. However, faith is also manifest in the manner in which a person chooses to live life. Faith in this sense enables action. For

example, a person might believe that having a positive outlook on life is the best way to achieve life's goals. The belief that comes with faith involves transcendence, or an awareness of that which one cannot see or know in ordinary physical ways. Faith gives purpose and meaning to life. A *trusting faith* deals with the inner resources that allow a person to act. For example, clients with cancer who have faith in a positive outlook on life might search out more knowledge about their disease and continue to pursue daily exercise and activities rather than resign themselves to the symptoms of the disease.

Religion

Religion is a term used to describe the formal practice of a set of spiritual beliefs held by a group of people or community. Religion is a means by which individuals express a personal set of values and beliefs which are often referred to as a person's spirituality, their core or central values (Gollnick 2005). Many people hold a faith or belief in the doctrines and expressions of a specific religion or sect, such as the Anglican church within Christianity or the Orthodox Jewish faith. Religion serves different purposes in people's lives. For some, religion is a set of rules and rituals used to worship a supreme being. For others, religion is a way of living life, providing nourishment and connectedness to all life. In this latter context, religion is more directly associated with spiritual wellbeing.

Religion as a system may form the basis of and nurture spirituality. Many people are spiritual without being religious, and some people are religious without being

WORKING WITH DIVERSITY

Focus on cultural care

Spirituality is not limited to the concepts of faith, religion and hope from a religious perspective, but is also present within the context of culture. There are numerous cultural groups throughout the world whose sense of the spiritual is not aligned with religion but with their cultural heritage, identity, connection to the land and language group. Evidence of cultural alignment to a person's sense of spirituality can be found in such cultural groups as the Native Americans, Māori, and Aboriginal and Torres Strait Islander peoples. Each of these cultural groups has a rich repository of spiritual beliefs that play a significant role in daily life, illness, health and healing. Premonitions, apparitions and visitations are points of connection with the spirit world – both past and present (Eckermann et al 2006).

From the perspective of Māori culture, which embodies both a belief in a deity and a spiritual bonding with the earth, spirituality overarches both of these notions. A priest or qualified person of the community can facilitate connection with a deity and speak to the spirit of a particular god through the use of a godstick. In relation to connecting with the land, many of New Zealand's geographical features have spiritual meaning and are important anchors in defining self. Underpinning Māori culture is the belief that each human being has a spiritual essence which is connected to the person, nature, land, and objects made by humans.

RESEARCH HIGHLIGHT

Research focus

During the last few decades a large and growing body of research has emerged examining the relationship between spirituality and health. Williams and Sternthal (2007) provide a review of the empirical evidence linking measures of spirituality or religious involvement to health, with an emphasis on recent Australian research.

Research findings

- Levels of spirituality and religious beliefs and behaviour are relatively high in Australia, although lower than those in the United States.
- There is mounting scientific evidence of a positive association between religious involvement and multiple indicators of health.
- The strongest evidence exists for the association between religious attendance and mortality, with higher levels of attendance predictive of a strong, consistent and often graded reduction in mortality risk.
- Negative effects of religion on health have also been documented for some aspects of religious beliefs and behaviour and under certain conditions.
- Health practices and social ties are important pathways by which religion can affect health. Other potential pathways include the provision of systems of meaning and feelings of strength to cope with stress and adversity.

overtly spiritual. The writings and lives of leaders such as Mahatma Gandhi (known for such quotes as 'Be the change you wish to see in the world' and 'The best way to find yourself is to lose yourself in the service of others') are rich in spiritual material that may be influential for others in their spiritual quest. In the literature, spirituality and religiosity are often referred to as being synonymous, but for an accurate assessment of clients' spiritual needs it is important for nurses to realise that they are not the same (Baldacchino & Draper 2001).

Hope

Spirituality is often identified as a key element in hope. When a person has the attitude of something to live for and look forward to, hope is present. Miller and Powers (1988) describe hope as a multidimensional concept consisting of anticipation of a continued good, an improvement or the lessening of something unpleasant. **Hope** is energising, giving people a motivation to achieve and the resources to use towards that achievement. Hope is an invaluable personal resource when people are faced with a loss (see Chapter 22) or a challenge that seems difficult to achieve. Hope has purpose and direction and gives reason for being (Berman et al 2010). Loss of hope can give way to spiritual distress in which the person feels abandoned and left without direction or sense of purpose.

Development of self-concept

The development of self-concept is a lifelong process. As we have seen in the previous chapters (16–18), each stage of development has specific tasks. The successful negotiation and completion of these tasks promotes a positive self-concept (Box 20-1). Influential theorists who have considered components of human development include Erikson (1963), Gilligan (1982), Kohlberg (1969) and Piaget (1963). We will briefly revisit the stages of human development from the perspective of developing self-identity. For additional information, consult the chapter indicated with each section.

BOX 20-1 Self-concept: developmental tasks

0–1 year
- Begins to trust
- Distinguishes self from environment

1–3 years
- Has control of some language
- Begins to be autonomous in thoughts and actions
- Likes body
- Likes self

3–6 years
- Takes initiative
- Identifies with a gender
- Increases self-awareness
- Increases language skills

6–12 years
- Is industrious
- Interacts with peers
- Increases self-esteem with new skill mastery
- Is aware of strengths and limits

12–20 years
- Accepts changed body
- Explores goals for future
- Feels positive about self
- Interacts with those whom they find sexually attractive

Mid-20s to mid-40s
- Has intimate relationships with family and significant others
- Has stable, positive feelings about self

Mid-40s to mid-60s
- Can accept changes in appearance and endurance
- Reassesses life goals
- Shows contentment with ageing

Late 60s on
- Feels positive about their life and its meaning
- Is interested in providing a legacy for the next generation

Stages of development

Infant

Infants need to establish relationships with consistent primary caregivers in order to develop a concept of self and identity. This nurturing role can be filled by a mother, a father or other responsible carers (e.g. foster parents, grandparents). When the infant has pleasant, nurturing interactions with caregivers, these are remembered and internalised into the infant's psyche. If the interactions are unsatisfying, painful or frustrating, this can result in difficulties in establishing a positive self-concept. When an infant's needs are met with reasonable consistency, the infant develops a sense of trust in the world (see Chapter 16). During this phase of development, the infant begins to differentiate between self and others.

Toddler

Toddlers (1–3 years of age) are more mobile than infants, and therefore more able to interact with others. A toddler's

major psychosocial task is the development of autonomy (see Chapter 16). Toddlers move from total dependence to a greater sense of independence and separateness of themselves from others. They also tend to view others and themselves in terms of 'all good' or 'all bad'. They gain skills in feeding themselves and in performing basic hygiene tasks. Toddlers learn to coordinate movements and imitate others. They begin to learn control of their bodies through locomotion, toilet training, speech and socialisation skills.

Preschooler

Preschoolers develop a sense of body boundaries, and a sense of self and gender due to their developing sexual curiosity and increasing awareness of differences between those of same and opposite gender. Learning about the body – where it begins and ends, what it looks like and what it can do – is basic to self-concept and body image formation.

Growing self-awareness includes the discovery of feelings. For example, preschoolers learn names for their feelings. They begin to learn how their behaviours and emotions affect others, and how others respond to them. They also learn the rudiments of control over feelings and behaviour. The concept of body is reflected in the way children talk, move, draw pictures and play. Children begin to test roles and imitate people as they identify with the same-sex parent or a family member (see Chapter 16). Appraisal by a family member becomes self-appraisal. If the family is critical of the child's budding self-concept, this negative input creates a decreased self-esteem, which the person will have to work to overcome as an adult.

School-age child

Until children attend school, their self-concept and body image are based mainly on parental attitudes. At school, a range of others begin to contribute to the child's development of self-concept. This can have a counterbalancing effect for children whose families have been extremely critical, or it can be negative if the child experiences a negative educational environment.

As the child enters the school years, growth is steady, and more motor, social and intellectual skills are acquired. The child's body changes and their sexual identity strengthens. The child's attention span increases, and reading allows expansion of the child's self-concept, through imagination, into other roles, behaviours and places. The child begins to reason in a more systematic way and is able to apply previous learning to current situations (Piaget 1963). Through games, children interact with peers, develop additional motor and intellectual skills, and thereby expand their self-concept and body image (Figure 20-2). Children express feelings through games, literature, drawing and music. The nurse can therefore use these activities to gain clues to a child's self-concept. With increased problem-solving abilities, a greater self-awareness of personal strengths and limitations develops. Because the child is changing physically, emotionally, mentally and socially, self-concept and body image can also change at this time.

Figure 20-2 A child learns to define self partly through interactions with peers.

iStockphoto/Christopher Futcher.

Adolescent

Adolescence brings rapid physical, emotional and social changes. Throughout adolescence, sexual maturation, new feelings, roles and values are being integrated into the self. Rapid growth, noticed by the adolescent and others, is an important factor in the development of body image and acceptance of transformation (see Chapter 16). Physical changes in size and appearance prompt changes in self-perception and use of the body such that adolescents are required to continuously alter their mental pictures of themselves. Adolescents may spend a great deal of time in front of the mirror for hygiene, grooming and dressing, as they seek to accept and improve their appearance. Great distress can arise from perceived body imperfections.

Development of self-concept and body image is closely related to identity formation (Erikson 1963). The ways in which adolescents consider moral situations also demonstrate differences. In Chapter 16 we introduced the work of Lawrence Kohlberg (1969), whose research involved following boys over time to observe their moral development. Kohlberg found that girls were more likely to give caring responses to moral problems whereas adolescent males appeared to have more highly developed moral reasoning concerning equality and reciprocity, and

gave more justice-oriented responses. Being aware of possible gender differences in identity and self-concept when interacting with young people may help the nurse to understand an individual's perceptions of what is important and valued.

Young adult

Although physical growth has slowed or ceased by the early 20s, cognitive, social and behavioural changes continue throughout the rest of life. Young adulthood (late teens to mid-to-late 30s) is a period of choice – a period for settling into responsibility, gaining stability in employment, and beginning intimate relationships. Self-concept and body image become relatively stable at this time, but can be challenged by pregnancy and childbirth occurring within this developmental period (see Chapter 17). Self-concept and body image are social creations with approval and acceptance given for what is regarded as normal appearance and appropriate behaviour according to societal standards. Self-concept constantly evolves and can be identified in the values, attitudes and feelings about the self.

Middle-aged adult

Between the mid-to-late 30s and the mid-60s, physical changes such as additional fat deposits, baldness, grey hair, wrinkles and varicosities confront the body image and self-concept of the middle-aged adult. People begin to realise that they look older, and they may feel older as well. Work may become stressful if middle-aged adults feel a decline in stamina, endurance and vigour to cope with the tasks at hand. This reduced energy level is often a result of lower basal metabolism and reduced muscle tone.

Illness or the death of loved ones can create concern about personal health and impending mortality. The middle-aged adult may begin to feel inferior, as their previous youthful self-image of a strong and healthy body with boundless energy is replaced with a self-image reflecting the biological, psychological and physical changes of ageing. Difficulties in accepting the loss of youth are accelerated by the effects of menopause, folklore about diminished sexual function and sexuality, and social and advertising pressures consistently extolling the virtues of youth.

Middle adulthood is often a time of self-reflection and re-evaluation (see Chapter 17). Individuals are likely to re-examine their past, considering whether they are satisfied with what they have accomplished and thinking about how they want to live the rest of their lives (Sheehy 1995). This self-reflection may be difficult for some, as they consider what has, or has not, been fulfilled in their lives. Even though this self-reflection may be difficult, it can foster growth and the development of a more integrated self-concept moving into older adulthood. This reassessment of life experiences and redefinition of the self in life roles and values is sometimes called the 'midlife crisis' and might also include a re-evaluation of career or marriage choices. Successful resolution of this developmental stage involves the integration of new qualities into the self-concept. Most people gradually adjust to their slowly changing bodies and accept these changes as part of normal maturation. Emotionally mature people realise that they cannot return to youth and acknowledge that their own pasts and experiences are valid and valuable. Acceptance of ageing and choosing to age positively is consistent with a healthy self-concept.

Older adult

The physical changes of older adulthood can be seen as gradual reductions of structure and function (see Chapter 18). Loss of muscle strength and tone occurs. Osteoporosis, which is a loss of bone density and mass, may increase the risk of fractures and create changes to physical appearance (e.g. a dowager's hump).

Loss of sensory acuity is a significant factor influencing older adults' interaction with the environment. The normal process of ageing causes decreased visual acuity and loss of hearing. Hearing loss can impact negatively on personality, such as creating suspiciousness, irritability, impatience or withdrawal as older people realise that they are less aware of what is happening around them. Many older adults view the wearing of a hearing aid as a further threat to body image and will delay hearing tests, or devise strategies to hide their hearing difficulties. However, greater discretion in the design of hearing devices is taking place with continuing advances in technology. To many older adults, glasses are more socially acceptable because they are worn by all age groups and have almost gained the status of fashion accessory whereas hearing aids are still perceived as direct evidence of old age.

Loss of skin tone with accompanying wrinkles may also affect self-esteem and cause older people to feel unattractive in a society that values youth and beauty. Western culture generally discriminates more severely against the appearance of ageing in women, portraying men as becoming more distinguished with age.

Self-concept during older adulthood is highly influenced by experiences that occur throughout life and is also influenced by people's present perceived health status. Many older adults continue to reflect on their lives – reviewing successes and disappointments and thereby creating a unified sense of meaning about themselves and

WORKING WITH DIVERSITY

Focus on older adults

Reminiscence has been found to support a positive self-concept in older adults. Suggestions for reminiscence include the following:

- Spend time reviewing old photographs and have the older adult tell their stories that relate to the pictures.
- Plan sessions where the older adult and a friend can talk about past shared experiences.
- Encourage the person to write about a positive past event.*
- Ask a person to tell you about a memorable event and record their story (asking permission before you begin), then play the recording back for the person, either at that time or at another time.*
- Encourage the person to write letters to old friends.*

the world (see *Working with diversity*). Helping/mentoring the younger generation often helps the older adult to develop a sense of fulfilment and offers the opportunity to share experiences and gain meaning from their life by leaving a legacy (see generativity, Chapter 17).

Stressors affecting self-concept

It has long been recognised that stressors challenge a person's adaptive capacities. In 1956, Selye defined stress as the normal wear-and-tear of life, and not the specific result of any one action or typical response to any one thing. The normal human processes of maturation and development are stressors. The inevitable changes that occur in physical, spiritual, emotional, sexual, familial and sociocultural health are also stressful. A stressor to self-concept can be any real or perceived change that threatens identity, body image, self-esteem and role behaviour (Figure 20-3).

Different people react to similar situations with varying degrees of stress. Personal perceptions also influence how people respond and learn patterns of behaviour as a way of coping with or adapting to stressors. These same patterns are often repeated when a person encounters a new stressor and some of these patterns are more adaptive than others. Being able to adapt to stressors is more likely to lead to a positive sense of self, whereas failure to adapt

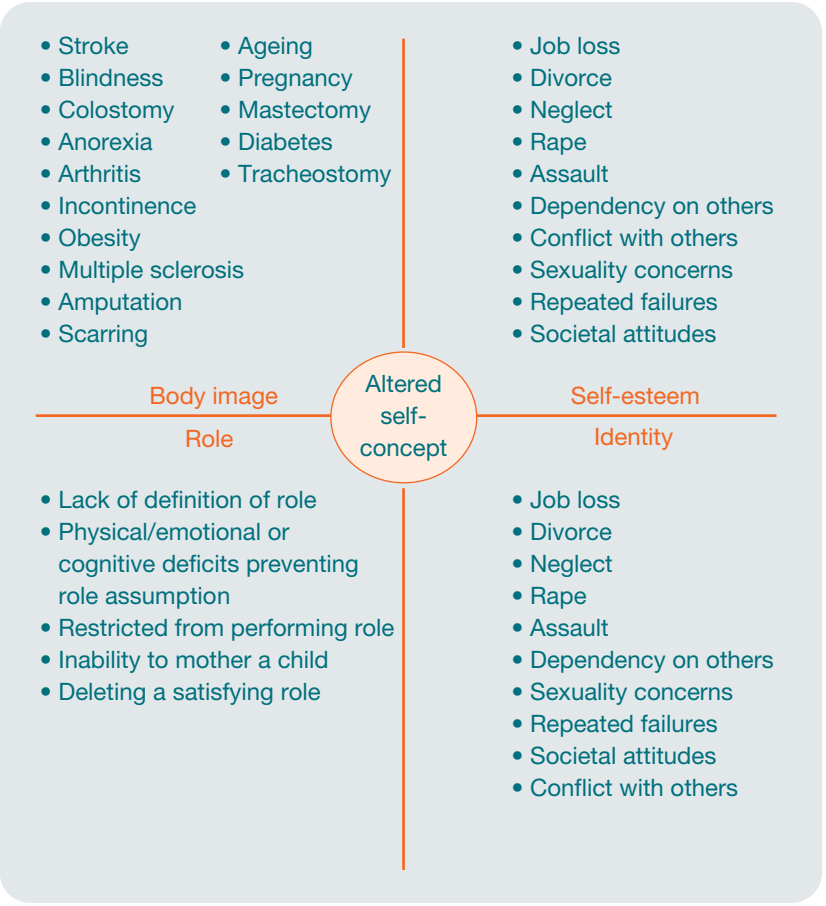

Figure 20-3 **Common stressors that can influence self-concept.**

often leads to a negative sense of self (Berge & Ranney 2005). A person's ability to adapt is related to numerous factors, including the number of stressors, duration of the stressor, and their health status.

Any change in health status can be a stressor that affects a person's self-concept. A physical change in the body can lead to an altered body image, affecting identity and self-esteem. Chronic illnesses often alter role performance, which in turn may alter one's identity and self-esteem. The *Clinical example* below illustrates the interrelationship between components of self-concept.

CLINICAL EXAMPLE

Paul, a 48-year-old man, suffers a stroke. The stroke is unexpected and sudden; he was not even aware that he had hypertension, because he had not been having annual check-ups. Paul wakes up in a hospital bed to find that he cannot even move his hand. He cannot care for himself. He cannot even turn himself for days. Finally, he is able to pull himself out of bed and into a chair with the nurse's help. He wonders what lies in store for him. Paul's body image has dramatically changed from that of a man of strength and endurance to that of a helpless individual. Paul worries about his family and what will happen. His daughter, the oldest child, is away at university, and his son is still at secondary school. Paul and his wife, Meredith, are terrified. Although Meredith works, they have not saved enough money to be able to educate their children without Paul's wages. Paul's role as chief financial provider for the family may be drastically changed if his condition does not change.

Paul's self-esteem wanes as his recovery and rehabilitation move slowly. His self-concept changes from that of a strong labourer, one who did his own plumbing and car repairs, to a man who has to tell his son what to do because he does not have the strength to do these tasks. Although he is now at home in the rehabilitation process, Paul is not able to perform tasks for the family and must wait until his wife and son get home to help him with things that require strength. Paul's adaptation capabilities are stretched to the maximum, although his neurologist tells him that he is very fortunate to be alive. His life is now changed – for how long he does not know. Paul's identity is not clear to him any more; he has no clear role within the family, his body image has been drastically altered and his self-esteem is spiralling lower and lower.

Paul continues in outpatient physical therapy. It takes much time and hard work even on simple tasks, but he begins to gain some strength. Paul continues to make gains. He is able to return to work. He has some diminished mental quickness and some muscle weakening, but he is able to perform his job. His self-esteem recovers, and his body image is enhanced. Although he still feels somewhat altered, his capabilities closely resemble his capabilities before the stroke.

A crisis situation occurs when a person fails to overcome obstacles with their usual methods of problem-solving and coping, so that any crisis has the potential to threaten the person's self-concept and uncertain self-esteem (Luxton et al 2006). Some crises, such as described in the *Clinical example*, directly affect all four components of self-concept. As with any crises, supportive resources can be invaluable in helping a person learn new ways of coping with and responding to events or situations to maintain a positive self-concept.

Identity stressors

A person's identity is challenged by stressors throughout their life. Adolescence is one example of a time of significant adjustment to the physical, emotional and mental changes of maturity. Insecurity and anxiety may arise as a result of changes in any of these areas, or as a result of conflicts among them.

An adult generally has a more stable identity and, therefore, a more firmly developed self-concept. As a result, cultural and social stressors may have more of an impact on an adult's identity than personal stressors. Developmental markers, such as the initiation of menses, puberty, pregnancy, menopause, retirement, and decreasing physical abilities associated with ageing may all affect self-identity and, like body image, identity is closely related to appearance and abilities (Figure 20-4). Retirement may mean the loss of an important measure of personal achievement and continued success (see Chapter 18). On reaching retirement age, people may begin to question their identity and past accomplishments. The loss of a significant other around this time can also lead the surviving person to re-explore aspects of their identity. **Identity confusion** results when people do not maintain a clear, consistent and continuous consciousness of who they are as a person. Identity confusion may occur at any stage of life if a person is unable to adapt to identity stressors. Under extreme stress an individual may experience *depersonalisation*, a state in which internal and external realities or the differences between the self and others cannot be determined.

Body image stressors

Any change in the appearance, structure or function of a body part requires a person to alter their body image. Changes to the appearance of the body, such as amputation, disfigurement or scarring, are obvious stressors affecting body image. Mastectomy, colostomy and ileostomy are surgical procedures that significantly alter the appearance and function of the body. While these changes may not be apparent to others when people are clothed, there is still a significant effect on the individual. Chronic illnesses

Figure 20-4 An individual's appearance influences self-concept.

iStockphoto/LifesizeImages.

such as cardiac and renal disease, and treatments such as radiotherapy or chemotherapy, impact on how the body functions and how it looks. Even body changes resulting from normal developmental processes such as pregnancy and ageing can affect body image, as can significant weight gain or loss.

An individual's perception of body changes may be affected by how the changes came about. For example, paralysis caused by war injuries may be considered more acceptable to the individual because government resources are available for rehabilitation and a veteran is praised for bravery by society as a result of injuries sustained during service. However, people who sustain significant injuries from car accidents while under the influence of alcohol or drugs may receive a very different response from society. Further, the significance of a loss of function or a change in appearance is dependent on the individual's perception of the alteration. Body image consists of ideal and real elements. For example, if a woman incorporates breasts as part of their ideal body image, the loss of a breast by mastectomy may cause a very significant alteration. The greater the importance of the body or a specific body part, the greater the threat felt by a change in body image.

Many people associate success with a specific body part or function. For example, athletes may consider their bodies, their athletic achievements and physical attributes as the focus of their personal success. If an athlete can never again participate in physical activities because of an accident, their adaptation and rehabilitation is affected by this association. To regain a positive self-concept, and to maintain good health, the athlete will need to face the challenge of revising long-standing assumptions and learn to adapt to stressors affecting their body image.

There is a trend towards positive social change with regard to perceptions of illness and altered body image. The media now frequently presents positive stories about people with serious disabilities or who have experienced major body-altering insults or surgery. These stories offer positive evidence of people regaining identity following life stressors, and model ways that families, friends and society as a whole can adjust their perceptions.

Self-esteem stressors

Positive or high self-esteem involves seeing oneself as being a good person, worthy of respect and love. A person with low self-esteem tends to feel unloved and may experience depression and/or anxiety as a consequence. The level of self-esteem may fluctuate depending on surrounding conditions, although a basic core of positive or negative self-esteem generally remains constant even with changing circumstances. Most people experience 'bad days', when they feel less worthy and competent, but these feelings pass relatively quickly for someone with a basic core of positive self-esteem.

Stressors to self-esteem occur at many different stages of the developmental life cycle. For example, a child's inability to meet parental expectations, constant harsh criticism, inconsistent punishment, sibling rivalry and repeated defeats may reduce the child's level of self-worth. In an adult, different stressors such as failure in work or relationships affect self-esteem. Illness, surgery or accidents that change life patterns and relationships may also impact on a person's feelings of self-worth (Fung et al 2006). Chronic illnesses such as diabetes, arthritis and cardiac disease require sustained changes to long-assumed and accepted behavioural patterns. The more the chronic illness interferes with the ability of the person to engage in activities contributing to feelings of worth or success, the more it affects the individual's self-esteem.

Role stressors

People undergo numerous role changes throughout life. Normal changes associated with growth and maturation result in *developmental transitions*. *Situational transitions* occur when parents, partners, spouses or close friends die or people move, marry, divorce or change employment. A *health–illness transition* is a movement from a state of health or wellbeing to one of disability, illness or vice versa. Any of these transitions may lead to role conflict, role ambiguity, role strain or role overload (role stressors). It is important to recognise that a shift along the continuum from illness to wellness can be just as stressful as the shift from wellness to illness.

Role conflict results when a person is required to simultaneously assume two or more roles that are inconsistent, contradictory or mutually exclusive. For example, when a middle-aged woman with teenage children assumes responsibility for the care of her older parents, conflicts may arise in relation to being both a parent to her own children and being the child of her parents. Negotiating the balance of time and energy spent between her children and her parents may create a role conflict. The perceived or actual importance of the role will influence the degree to which conflict is experienced.

Role ambiguity involves unclear role expectations. When there are unclear expectations, people are unsure about what to do, how to do it, or both. Such a situation is often stressful and confusing. Role ambiguity is common during the adolescent years. Adolescents are pressured by parents, peers and others to assume adult-like roles, such as dedicating time to study, yet remain in the role of a dependent child. Role ambiguity can also be present in some employment situations. In complex, rapidly changing or highly specialised organisations, employees often become unsure about what role they play and what is expected of them.

Role strain can occur as a result of role conflict and role ambiguity. Role strain may be expressed as a feeling of frustration when a person feels inadequate or unsuited to a role. Role strain is often associated with gender role stereotypes (Levant 2011). Women in positions typically held by men may be perceived by others as less competent, less objective or less knowledgeable than their male counterparts. This creates a situation where women may feel that they must work harder and be more competitive in the workplace. Men in typically female roles, such as men in nursing, also encounter gender bias.

Role overload occurs when a person has more roles or responsibilities within a role than is manageable. It is relatively common that those experiencing illness, or their significant others, find themselves in role overload.

The **sick role** is deeply entrenched in the expectations of society regarding how one should behave when sick. Role conflict may occur when general societal expectations (such as go home and take care of yourself and you'll get better) and the expectations of co-workers (such as who is going to do the work if you are not there) collide. The conflict between taking care of one's physical and emotional self, while still getting everything done, can be a major challenge for contemporary workers and families. The sick role may also involve role ambiguity. People are expected to be dependent while sick, but simultaneously actively participate so that they can leave the sick role quickly when well. While the sick role is supposed to be temporary, people with chronic illness must comply with therapies and role stressors that may persist for the remainder of their life.

The family and self-concept development

The family plays a key role in creating and maintaining the self-concepts of its members. Children develop a basic sense of who they are and how they are expected to behave from their parents, siblings and friends. Parents who are harsh, inconsistent or have low self-esteem themselves may behave in ways that foster negative self-concept in their children. Even competent, well-meaning parents are capable of cultivating negative self-concept in their children. To reverse negative self-concept in a child, it is important to assess the whole family's style of relating (see Chapter 15).

The role of the nurse

The non-judgemental acceptance of a client with an altered self-concept is a first step to promoting positive change. When a client's physical appearance has been abruptly altered due to injury or surgical intervention, it is likely that a nurse or doctor will be the first person to see this change. Both the client and family will look to nurses, observing their responses and reactions to the changed appearance. Therefore, nurses and other health professionals can have a significant impact on clients with an altered self-concept – enhancing or defeating their motivations for acceptance of changed body image and self-concept. It is therefore important for nurses to reflect on how their own thoughts, feelings and actions may impact on clients and their families and how they portray themselves to others in:

- feelings about health and illness
- reactions to stress
- non-verbal communication and actions
- personal values and expectations
- non-judgemental attitude and acceptance of diversity.

This does not mean that nurses should deny that they have feelings, ideas, values and expectations for their patients, or pretend that they do not make personal judgements. Self-awareness is critical in initially understanding and accepting others and nurses must understand themselves before they can understand their effects on others (Jack & Smith 2007). All people make decisions about themselves, the environment and other people on the basis of personal frames of reference. As professionals, nurses must be prepared to work with people who will have different frames of reference from themselves. Adults who are

secure in their own identities are more readily accepting and therefore more supportive and reinforcing of their clients' chosen identities.

Nurses can also have a significant impact on how others perceive their own body. For example, a nurse's initial reaction to a mastectomy scar can positively influence the developing body image of a woman who has had a mastectomy. On the other hand, a shocked or disgusted facial expression will likely contribute to the woman developing a negative body image. Clients closely watch the reactions of others to their wounds and scars. Statements such as 'This wound is healing nicely' or 'This scar looks good' can be very affirming for the body image of the client.

Inadvertently frowning or grimacing when performing procedures, or obviously avoiding contact, can have profound effects on the client. The nurse's non-verbal behaviours help to convey their level of care and concern (Figure 20-5). For example, the self-concept of incontinent clients can be threatened by the perception that caregivers find the situation unpleasant. Nurses can anticipate these reactions, acknowledge them and focus on the client instead of the task or situation. Putting oneself in the client's position is a productive way of finding measures to ease embarrassment, frustration, anger and denial.

Figure 20-5 **Nurses can use touch and eye contact to increase a patient's self-esteem.**

• CRITICAL REFLECTION POINT

You are caring for a 23-year-old male who was in a car accident and sustained multiple fractures to his face and a fractured femur (which was fixated through surgery on admission 4 days ago). Prior to his accident he was in full-time employment and lives with his girlfriend and their 7-month-old daughter. You have been with him for most of the morning and found that he is in moderate pain, which has been treated with morphine. The morphine has decreased his pain rating from a 6 to a 3 (out of 10), but has left him somewhat drowsy. During the morning he voiced some of his concerns about when he will be able to return to work. You are in the room when the surgeon tells him about his upcoming surgery – a temporary tracheostomy is planned because of the extensive work needed in the nasal and throat area. After the surgeon leaves, the client tells you that he does not want the tracheostomy. He indicates that he is unclear about what it actually entails, even though the surgeon explained it in fairly simple terms. He says, 'I just want to get back to my normal self.'

How would you tackle his comment about 'getting back to normal' and his lack of understanding regarding the tracheostomy?

Altered self-concept

We have established that self-concept can be altered by stressors affecting identity, body image, self-esteem or roles. These same stressors can also affect health. If people are unable to adapt to such stressors, their health may be at risk. If the resulting identity confusion, disturbed body image, low self-esteem, role conflict, role strain, role ambiguity and family effects are not relieved, illness may result. The impact of stressors on a person is not limited to their self-concept, but extends also to the spiritual domain.

Stressors and spirituality

When illness, loss, grief or a major life change affects a person's self-concept, spiritual resources may help move the person towards recovery. **Spiritual distress** is a state in which an individual experiences a disturbance in the belief or value system that provides strength, hope and meaning to their life (Carpenito-Moyet 2010). A catastrophic illness, for example, can upset a person's spiritual wellbeing sufficiently to cause doubt and loss of faith. Spiritual distress may cause the person to feel alone or even abandoned by resources which at one time were very nurturing. People may question their spiritual values, raising further questions about their whole way of life, purpose for living and source of meaning (Gorman & Sultan 2008). Spiritual distress can also occur when there is a conflict between a person's beliefs and prescribed health regimens, the inability to practise usual rituals, or during the onset and progression of illness, leaving

the person with feelings of isolation, fragmentation and despair (Cressey & Winbolt-Lewis 2000).

Acute illness

A sudden unexpected illness that poses both an immediate and a long-term threat to a client's life, health and/or wellbeing can create significant spiritual distress. For example, the 50-year-old woman who has a myocardial infarction and the 20-year-old victim of a car accident both face crises that may threaten their spiritual health. The illness or injury creates an unanticipated scramble to integrate and cope with new realities (e.g. disability), prompting people to look for ways to remain faithful to their beliefs and value systems. They may pray, meditate, attend religious services more often or spend time reflecting on the positive aspects of their lives. Often, conflicts can develop in relation to a person's beliefs and the meaning of life. Anger is not uncommon, and clients may express anger against their god, their families, themselves or the nurse. The strength of a client's spiritual resource influences how they cope with sudden or unexpected illness, including how quickly the move to recovery is established.

Chronic illness

People with chronic illness often suffer relentless and debilitating symptoms that challenge their ability to continue their pre-illness lifestyles. A symptom is more than just a signal of a persistent health problem, or a road map for diagnosing a disease. Symptoms are meaningful to the individual, and that meaning is shaped by the person's history and the current context of their illness.

Chronic illness threatens independence, causing fear, anxiety and an overall dispiritedness. Dependence on others for routine self-care can create a feeling of powerlessness and of being a burden on others. A chronically ill person may feel the loss of a sense of purpose in their life, affecting the inner strength needed to deal with alterations in functioning. A person's spirituality can be a significant determinant of how well they adapt to changes resulting from chronic illness. Successful adaptation can strengthen a person's spirituality and lead to a re-evaluation of life and self-concept.

Ageing

Ageing is a relative state which all people experience. With advancing age there are many losses and associated grief experiences. There is often a decline in the number of social and physical resources, increasing the potential to isolate the older person physically, mentally and spiritually. With ageing there is sometimes a related fear of the process of dying, more so than the fear of death itself.

Ageing is not an illness – it is a state involving a personal journey; however, with advancing age there is an increased incidence of age-related disorders. Myths relating to those who are ageing include assumptions about the older person's loss of memory and ability to learn new things, loss of sexuality, the ability to work, and their role in society. Older people are generally not targeted for health promotion and maintenance – creating a society in which the older person seems not to belong or is given up on. This situation encourages older people to retreat from an active and healthy lifestyle, which not only reinforces stereotypes but also affects their image of themselves, and their self-esteem and confidence.

Older people, especially those who are unwell, often require spiritual care and spiritual healing in addition to their physical care. The relative incidence of suicide among older people in Australia and New Zealand has declined steadily since 1997. In New Zealand in 2012, the 65+ years age group recorded its lowest suicide rate since 1948, at 9.3 per 100,000 (Ministry of Health 2015). This is in comparison to rates of 32.3 per 100,000 for females and 13.8 per 100,000 for males in the 15–24 years age groups (Ministry of Health 2015). In Australia in 2013, males in the 85+ years age group had the highest rate of suicide (38.3 per 100,000), while young males aged 15–19 years had the lowest (14.3 per 100,000). For females in the 65+ years age group, the rate of suicide was 4.0 per 100,000, while for young women aged 15–19 years, suicide rates were 5.0 per 100,000 (Australian Bureau of Statistics 2013).

In many cultures, people define themselves through their work and their contribution to society (Price 2000). When people retire, they may experience loss of meaning and purpose in their life, as the lifestyle they have followed for many years finishes quite abruptly. Retirement can be a period of considerable stress and self-reflection, as the older person strives to establish a new role within a new social context (see Chapter 18). The movement of a person into the early stages of what is recognised as old age may be a period of extreme crisis or vulnerability. Gerontologists recognise that planning for old age is a critical component in determining happiness and fulfilment in the later years of life. It cannot be assumed that older people are beyond spiritual growth just because they are old. Spiritual growth continues throughout life and ageing needs to be recognised as part of that spiritual journey.

Advanced illness

Advanced illness is commonly associated with fear of pain, isolation, death, the unknown, and threats to integrity. Advanced illness creates an uncertainty about what

death means and can make clients susceptible to spiritual distress. There are also clients who have a spiritual sense of peace that enables them to face death without fear and view death as moving towards self-actualisation (Williams 2006).

People experiencing advanced illness will often find themselves reviewing their life and questioning its meaning. Common questions might include 'Why is this happening to me?' or 'What have I done?' Family and friends can be equally affected, with important questions about short- and long-term outcomes and how this illness will affect their relationship with the client; many questions arising from the experience are unanswerable.

Near-death experience

Nurses may encounter clients who have had a near-death experience (NDE). An NDE has been identified as a psychological phenomenon in people who have been either close to clinical death, or have recovered after being declared dead. A review of the literature by Cant et al in 2011 found that NDEs are reported in 4–9% of general community members and in up to 23% of critically ill patients, although NDEs can also occur in healthy individuals who may think they are in peril. People who experience an NDE after cardiopulmonary arrest, for example, often tell the same story of feeling themselves rising above their bodies and watching caregivers initiate lifesaving measures. Most people describe passing through a tunnel into a bright light, encountering people who have preceded them in death and feeling an inner tranquillity and peace. One explanation is that paranormal visions (seeing bright lights, a tunnel and having feelings of peace) may in fact be a stage of enlightenment as death approaches. Other explanations point to neurochemical changes in a stressed or dying brain for nearly all the elements of NDE.

Clients who have an NDE are often reluctant to discuss it, thinking family or caregivers will not understand. Isolation and depression can occur as a result. People who can discuss an NDE with family or caregivers, however, generally report positive after-effects, including a positive attitude and spiritual development (Cant et al 2011). After a client has survived cardiopulmonary arrest, it is important to give them a chance to explain and explore what happened. Effective communication and listening skills (Cant et al 2011) support the patient and their family in comprehending this experiential event.

Chronic illness and spiritual healing

Healing is commonly understood within the context of injury or damage, and is seen as a defined process in which cells and tissues are repaired and ultimately normal function is restored to the injured part. Just as the body can be injured, so can the self (what some may call the soul). Injury arising from spiritual problems leads to spiritual distress. *Spiritual healing* brings an equilibrium in which the person recovers from the pain and anguish of spiritual distress. Spiritual healing is a complex phenomenon, a journey in itself, which restores wholeness to the person.

Spiritual healing is more than remedy and cure. This special form of healing requires making sense out of the experience, finding meaning and placing the experience within one's belief system and life (Berman et al 2010). The nurse involved in spiritual healing will be connected to the client at a very basic and deep human level, which involves trust, compassion and respect for both the person and that person's dignity.

Three challenging examples of people in need of spiritual healing are people who suffer chronic pain, people who have an advanced illness and are in need of palliative care, and older people who have dementia. For these three examples, the concept of physical healing is remote. The nature of these conditions isolates people and challenges their very being. Caring for people with these conditions offers the greatest challenge to a nurse in connecting with them and their sense of the meaning of their condition. For the person with dementia there are additional and compounding losses – loss of memory, loss of cognition, loss of the ability to relate to and interpret the environment and, most importantly, loss of the ability to communicate needs and wants, and the ability to practise coping behaviours. Older people who are confused need nurses and carers who are prepared to spend the time to communicate and try to understand them. The use of prayer, ritual and symbols may help in spiritual caring, as does trying to capture moments of clarity in which the perceptive and caring nurse can communicate effectively with their client.

CLINICAL REASONING PROCESS

Critical thinking requires the synthesis of knowledge, experience and information gathered from clients and families, evidence from research and the maintenance of intellectual, professional and ethical standards. Clinical judgement requires the nurse to anticipate, gather and analyse the information necessary for making informed decisions; to set priorities and establish goals with the client; and to constantly evaluate the impacts and outcomes of the actions taken.

The dimensions of self (self-concept and spirituality) are complex and multifaceted. The integrated knowledge of all health disciplines contributes to the planning and delivery of care – including self-concept theory, spirituality theory, communication principles (see Chapter 12), and a consideration of cultural and developmental factors (see Chapter 14).

Experience in caring for clients with self-concept alterations and associated spiritual wellbeing/distress takes time to develop, but maintaining critical thinking attitudes such as integrity ensure that the client receives professional and respectful care. Nursing professional and ethical standards support the client's autonomy and right to choose. The way in which people view themselves and their relationships to others and the world profoundly influences a person's response to illness. A critical thinking approach that respects each client's uniqueness is essential to best quality care.

GATHERING RELEVANT INFORMATION AND DATA

In assessing the various dimensions of the self, the nurse should focus on each component of self (identity, body image, self-esteem, role performance and spirituality), behaviours suggestive of alterations to self-concept (Box 20-2), actual and potential stressors (see Figure 20-3), and individual coping patterns. Gathering relevant information and data requires a critical synthesis of information from multiple sources and application of clinical reasoning. Much of the data regarding self-concept and spiritual needs are effectively gathered through observation of the client's non-verbal behaviours and by paying attention to the content of the client's conversation, rather than through direct questioning. Taking note of the manner in which clients talk about the people in their lives can offer clues to both stressful and supportive relationships, and to key roles.

Using knowledge of normal human development to determine what is likely to be most important to the client at their current developmental stage is a useful frame within which to inquire about the person's life. For example, the nurse might ask a 65-year-old client about their life and, looking back, what they see as most important. We know from Chapter 18 that this is the stage in life during which people re-examine their lives and consider the impact they have had in the world. The person's response is then more likely to provide relevant and individual information relating to their role performance, identity, self-esteem, stressors and coping patterns. At times, specific questions or prompts may also be useful (Table 20-1) to explore their dimensions of self.

Coping strategies

The gathering of information should also include consideration of the client's previous coping behaviours; the nature, number and intensity of stressors; and the client's internal and external resources. Knowledge of how a client has dealt with stressors in the past can provide insight into the client's style of coping. Not all issues are faced in the same way by clients, but often one uses a familiar coping pattern for newly encountered stressors. As the nurse identifies previous coping patterns, it is useful to determine whether these patterns have contributed to healthy functioning or created further problems. For example, the use of drugs or alcohol during times of stress often creates additional stressors.

Exploring the client's resources and strengths, such as support from significant others or previous use of community resources, is also important in formulating a realistic and effective plan. Also pertinent to this assessment is determining how the client views the situation. What is perceived as a crisis by one client may be seen as less significant by another. For example, one client might express great fear and distress over needing to have a colonoscopy and biopsy, whereas another client may see the need for the diagnostic testing simply as a consequence of growing older, and take the attitude that if there is something to be concerned about, they will know about it soon enough.

Significant others

Valuable data may also evolve out of conversations with family and significant others. Significant others may have insights into the person's way of dealing with stressors and what strategies are most supportive to them. The way in which significant others talk about the client, and their non-verbal behaviours, can offer additional information about what kind of support is currently being offered or is available.

Client expectations

Individual expectations vary; therefore, asking the client how they believe interventions will make a difference to their situation can provide useful information regarding their expectations, and provides an opportunity for the client to lead their own goal-setting. For example, a nurse working with a client who is experiencing anxiety related to an upcoming diagnostic study might ask the client about their expectations of the relaxation exercise that they have been practising together. The client's response will give the nurse valuable information about the client's beliefs and attitudes regarding the efficacy of the interventions.

BOX 20-2 Behaviours suggestive of altered self-concept

Avoidance of eye contact
Overly apologetic
Hesitant speech
Overly critical
Excessive anger
Frequent or inappropriate crying
Puts self down
Excessively dependent
Hesitant to express views or opinions
Lack of interest in what is happening
Passive attitude
Difficulty in making choices
Slumped posture
Unkempt appearance
Self-harming
Disordered eating

• CRITICAL REFLECTION POINT

A 51-year-old man has been transferred to the rehabilitation unit following 2 weeks of hospitalisation resulting from an industrial accident in which his pelvis was crushed by a hydraulic press. His pelvis was stabilised with external fixation. Initially he was paralysed from T12 down.

TABLE 20-1 Assessing self-concept

Assessment questions*	Responses reflecting difficulties with self-concept
Identity	
'How would you describe yourself?'	Derogatory answers (e.g. 'I don't know; there's not much that is very exciting about me' or 'I'm not good at much of anything') should raise concern
Body image	
'What aspects of your appearance do you like?' 'Are there any aspects of your appearance that you would like to change? If yes, describe the changes you would make.'	Most people can identify something about their appearance that they like (e.g. 'People have always told me I have nice eyes'). If a person cannot identify any appreciated characteristic, this is suggestive of a negative body image and self-esteem. Most people have one or two areas that they would like to change (e.g. 'My nose is too big' or 'My hips are too big'), but a long list of problem areas should lead the nurse to consider difficulties with self-concept
Self-esteem	
'Tell me about the things you do well.'	Statements about not having any strengths or not being able to do anything well should raise concern
Role performance	
'What are your primary roles (e.g. partner, parent, friend, sister, professional role)? How do you see yourself carrying out each of these roles?'	The nurse should listen for the number of primary roles identified. A large number of primary roles will put the client at risk of role conflicts and role overload As with the questions above, if the client indicates that they do not feel that these roles are adequately covered, the person may be experiencing alterations in self-concept. Although in Western cultures most people carry out many roles and often feel as though some of them are not adequately covered, listen for the person's perception about their overall role competency

* In addition to the verbal content of the client's answer, the nurse should note the client's non-verbal behaviours. Hesitant speech, poor eye contact and hunched posture suggest alterations in self-concept.

During the 2 weeks since the accident, feeling and movement have begun to return to his lower extremities.

With the return of function, there have also been spasms that occur with movement and increase in severity if movement is continued. With the gradual return of functioning, medical staff have been hesitant to give the client a prognosis and have told him that watching and waiting will reveal his returning functioning. The client seems satisfied with this explanation at this point. His main focus is on directing his personal care to minimise risk of infection and to ensure that whoever is caring for him understands the importance of waiting for a muscle spasm to subside before continuing with care.

You are a student nurse assigned to care for the client during a 4-week rotation. How might you establish trust and assess the client's concerns about the future?

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Appropriate judgements and decisions are driven by relevant and accurate data. Analysis of data from a range of sources assists in the identification of a client's actual or potential priority problems. The nurse uses their knowledge and experience to apply appropriate standards and attitudes and look for clusters of defining characteristics in order to make an evidence-informed clinical judgement (Box 20-3).

Making appropriate judgements and decisions in the realm of self-concept and spirituality is complex and cannot be done without partnering with the client in their care. Data may also identify the characteristics of more than one presenting problem or condition (Box 20-4). For example, a client might express feelings of regret and inadequacy. These are defining characteristics for anxiety, spiritual distress and situational low self-esteem. To make the most appropriate decisions in this situation, the nurse must be open to seeing the possibilities of different yet interrelated care plans. In fact, awareness that the client is demonstrating the defining characteristics of more than one problem can guide the nurse in gathering more specific data to validate and differentiate the underlying condition. To further assess the possibility (for instance) of anxiety as a diagnosis in the person feeling regret or inadequacy, the nurse might consider whether the person has any of the following defining characteristics: increased muscle tension, shakiness or restlessness – symptoms that suggest anxiety may be the underlying diagnosis.

Defining characteristics reflecting patterns of dispiritedness may indicate that a person is in a spiritual crisis. For example, expressing concern with the meaning of life and belief systems, anger towards a god, verbalising conflicts about personal beliefs or asking for spiritual assistance are consistent with spiritual distress. Examples of presentations where clinical judgement may indicate the need for spiritual support are given in Box 20-5.

On the other hand, if the person expresses a predominantly negative self-appraisal, including an inability to handle situations or events, and difficulty making decisions, these characteristics would suggest that the more likely problem might be situational low self-esteem. To further differentiate

BOX 20-3 Identifying priority problems

Disturbed self-concept

Assessment activities	Defining characteristics	Priority problem
Observe client's behaviour during conversation.	Client demonstrates restlessness, glancing about, facial tension, increased perspiration and focus on self.	Anxiety related to accidental injury, pain, uncertainty of outcome of upcoming surgery.
Ask client, 'How are you going?' or 'How do you feel about tomorrow's procedure?'	Client replies, 'I'm feeling really scared. You know there is a possibility they may amputate my leg tomorrow. I just don't know how I will manage if it comes to that. I just couldn't sleep last night. There was the pain, and I just kept thinking about all that is happening.'	

BOX 20-4 Example of priority problems associated with alterations in self-concept

Adjustment, impaired
Anxiety
Body image disturbance
Caregiver role strain
Coping, ineffective individual
Denial, ineffective
Fear
Hopelessness
Loneliness, risk of
Parental role conflict
Parenting, altered
Personal identity disturbance
Powerlessness
Rape-trauma syndrome
Role performance, altered
Self-esteem, chronic low
Self-esteem, situational low
Self-esteem disturbance
Self-mutilation, risk of
Spiritual distress (distress of the human spirit)
Violence, risk of: self-directed

BOX 20-5 Examples of priority problems requiring spiritual support

Spiritual wellbeing, potential for enhancement
Spiritual distress
Coping, ineffective individual
Coping, ineffective family; compromised
Coping, family; potential for growth
Family processes, altered
Dysfunctional grieving
Anxiety
Fear
Hopelessness
Powerlessness
Self-esteem disturbance

between the three diagnoses presented above (anxiety, spiritual crisis, situational low self-esteem), information regarding recent events in the person's life and how the person has viewed themselves and their life circumstances in the past would provide useful insight. Sometimes these three problems are closely related, but at other times several independent problems will be present. The client may demonstrate several defining characteristics from different diagnoses; but as additional relevant data are gathered, diagnosis of the priority problem(s) usually becomes evident and judgements and decisions about care can be made.

It is also important to have sufficient data to correctly identify the factors that have contributed to the diagnosis of the priority problem. If the information gathered is neither accurate nor relevant, diagnostic errors are likely. For example, a nurse is caring for a 62-year-old woman who was admitted because of chronic back pain. The client demonstrated signs of anxiety (inattentiveness, frequent starting, self-report of poor sleep, diminished appetite and increased muscle tension). The nurse knows that the client had undergone diagnostic testing to rule out cancer as the cause of pain. The nurse proposes that anxiety, related to the possibility of a cancer diagnosis, may be the cause. The nurse later learns that the woman was anxious because her grandson had been in a serious motor vehicle accident and was in intensive care.

The above example illustrates the danger in making a decision without sufficient data – in this case, information that could have been gained by simply engaging in conversation with the client. In order to avoid a similar situation when making a diagnosis of, for example, spiritual distress, critical thinking requires a review of more concrete data (e.g. religious rituals and sources of fellowship), as well as an assessment of previous client experiences, and appraisal of the client's spiritual wellbeing. The nurse's own spiritual wellbeing and perceptions are important to

spiritual care, and nurses should avoid imposing their personal beliefs on the client or their significant others.

It is vital to make judgements and decisions about planning care in partnership with the client and their family. Before involving the family, however, the nurse needs to consider the client's wishes for their involvement, and social and cultural norms regarding who most often makes decisions in the family. Sharing observations during conversation and asking the client to verify the nurse's perceptions is one way of validating clinical judgements. This approach often results in the client providing additional data, which further clarifies the situation. In the example above, the nurse might say to the client, 'I notice you haven't eaten much of your breakfast or lunch and that you jumped when I came up behind you. Are you feeling uneasy today?' This could allow the client to verify whether she is, in fact, anxious and to tell the nurse about her concerns. In summary, defining characteristics must be validated and clarified with the client (and their family) to establish priorities and goals that are meaningful to them before a purposeful and goal-directed plan of care is possible.

• CRITICAL REFLECTION POINT

A client with a progressive neurological disease tells you he is afraid he will soon be unable to walk. His affect is blunted and he often looks away into the distance. His wife tells you that difficulty walking and getting to the toilet in time prevent him from going out much, such as going to church. At one point both of them were very active in church activities.

What might you want to learn about the client during your assessment?

SETTING PRIORITIES AND ESTABLISHING GOALS

During goal-setting, the nurse continues to use critical thinking skills to synthesise knowledge and experience with professional standards of care. Critical thinking ensures that the plan of care integrates all that the nurse knows about the individual, their condition and the context of care. Professional standards for nursing practice are especially important to consider when developing a plan of care (Australian College of Mental Health Nurses 2010, Australian Nursing and Midwifery Accreditation Council 2015). These standards propose a professional and ethical framework for establishing the evidence base for effective nursing interventions.

Individualised plans of care are developed according to priorities and goals established through the shared decision-making process (see the following *Sample student nursing care plan* for an example). Goals should be targeted and realistic, with measurable outcomes. Consultation with significant others, mental health teams, social workers and community resources (Box 20-6) can result in a more comprehensive and workable plan. Once a goal has been formulated, it is important to consider how resolution of the problem could be measured as outcome data. For example, a client is diagnosed with situational low self-esteem related to a recent job loss. The defining characteristics that she demonstrates are complaints of 'not being able to do anything right lately' and expression of shame about losing her job. How does the client and nurse know whether the problem is reducing or, indeed, if it has been successfully managed? The nurse and client formulate a goal to achieve an improvement in the client's self-esteem within a realistic period of time. Appropriate and realistic goals to achieve the expected outcome might be that over the next week the client will find opportunities to discuss a minimum of three areas of her life where she is functioning well and voice the recognition that losing her job is not reflective of her worth as a person.

The first care plan presents an example of the goals, expected outcomes and interventions for a client with an alteration in self-concept. Interventions focus on helping the client adapt to the stressors that led to the self-concept disturbance and on supporting and reinforcing the development of coping methods. Often, a client perceives a situation as overwhelming and may feel hopeless about returning to the level of previous functioning. The client may need time to adapt to physical changes. Looking for strengths in both the individual and the family, offering community resources, client teaching and encouraging engagement with online education resources can assist with developing understanding of why certain events have happened (e.g. nature of a chronic disease, change in relationships, effect of a loss). Increasing understanding is often beneficial to reducing the sense of hopelessness and helplessness. Alterations in self-concept are not simple problems to resolve. Referral to mental health professionals and community resources may help support the client to work through and resolve complex problems over the longer term (see Box 20-6).

As is the case in developing any plan of care, a spiritual care plan must include realistic and individualised goals and individually relevant outcomes. It is important for both nurse and client to collaborate closely in setting goals and choosing related interventions. Setting realistic goals requires the nurse and client to establish respectful communication and work together. In cases where spiritual care requires helping clients

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data*

Mr Johnson is a 45-year-old man who was involved in a car accident in which he sustained a crushing blow to his femur. On admission, an open reduction and internal fixation (ORIF) of the femur was carried out. Since then, he has developed an infection, and the most current X-ray film shows misalignment of the bone fragments. The chart reveals that Mr Johnson was in essentially good health up until the time of the accident.

When Ian, the student nurse, first goes in to meet Mr Johnson, he finds that although Mr Johnson makes eye contact and answers questions, his **answers are brief** and to the point without elaboration. As Ian spends more time with Mr Johnson, his eye contact increases, but his answers to questions remain brief. He is **restless** and **shifts frequently in the bed**.

Mr Johnson tells Ian that before the accident he had a nearly ideal life. He describes his family as a source of pleasure and satisfaction. He tells him briefly about a recent trip the family took and the adventures of his two teenagers. He describes his work as okay. He states, 'I have been at the factory for 25 years. I know my job. Sometimes it gets boring, but it pays the bills, and I will be able to retire with good benefits if I can just work a few more years.'

In gathering the nursing history, Ian learns that Mr Johnson has had trouble sleeping since admission. He says that in addition to the pain, there is just **so much to think about**. Specifically, he says, 'You know, they may not be able to save my leg.'

In reviewing the progress notes since admission, Ian notes that Mr Johnson's **appetite has been recorded as poor and he usually eats only a quarter to a half of his meals**.

Priority problem(s)

Anxiety related to accidental injury, pain and uncertainty of outcome of upcoming surgery and treatment.

** Important data to cluster in setting priorities in bold.*

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Reduce Mr Johnson's anxiety	Mr Johnson will state that his anxiety/worry is less Mr Johnson will discuss his concerns openly with a staff person Mr Johnson will perform progressive relaxation exercises Mr Johnson's restlessness will decrease
Regain normal sleeping patterns or achieve restorative sleep	Mr Johnson will report restorative sleep
Maintain stable weight	Mr Johnson will report an increased appetite and eat at least three-quarters of his meals

Preparing for and taking actions†	Rationale
Coping enhancement	
• Help Mr Johnson to define his level of anxiety (use terminology Mr Johnson is comfortable with, e.g. worry, nervous).	Anxiety is highly individualised, and different clients manifest anxiety to varying degrees.
• Empathise with Mr Johnson that worry is a normal response to what has happened.	Anxiety is a normal response to an actual or perceived danger.
• Explore coping skills that Mr Johnson has used in the past. Encourage and support adaptive coping skills used in the past.	Most clients have developed effective coping skills during their lives. Supporting these coping skills in currently stressful situations can aid adaptation.
• Encourage Mr Johnson to express concerns verbally.	Verbalising a concern can allow the client to be more objective about what is happening.

Preparing for and taking actions†	Rationale
Calming techniques	
• Decrease the number of new stressors (e.g. answer client's call bell promptly, explain procedures, decrease unnecessary noise).	The number of stressors affects the stress experience.
Pain management	
• Treat pain before it becomes moderate to severe.	Pain is a stressor that can increase anxiety.
• Teach Mr Johnson the importance of seeking pain relief before the pain reaches a rating of 5.	Increasing the client's ability to control his experiences and environment will help to decrease anxiety.
Alterations in self-concept	
• Pain management	
– Teach Mr Johnson progressive relaxation techniques.	Relaxation is psychophysiologically in opposition to anxiety.
– Progressive muscle relaxation	Relaxation is energy conserving and nurturing.

† Intervention classification labels from McCloskey JC, Bulechek GM 2000 Nursing interventions classification (NIC), 3rd edn. Mosby, St Louis.

Evaluating impacts and outcomes

1. Explore with Mr Johnson what his current level of anxiety is.
2. Ask Mr Johnson how he slept the night before.
3. Inquire regarding Mr Johnson's appetite and monitor the amount of food eaten from meal trays.
4. Weigh Mr Johnson weekly.
5. Explore with Mr Johnson his concerns and note areas he discusses.
6. Observe non-verbal clues regarding eye contact and degree of restlessness during discussion.

to adjust to loss or stressful life situations, goals may be long term (see *Sample student nursing care plan* below). Short-term outcomes can also be established so that, progressively, the client reaches a more spiritually healthy situation.

PREPARING FOR AND TAKING ACTION

Once priorities, goals and outcome criteria have been developed, the interventions that help move the client towards their goals are agreed on. To develop effective interventions for care, the nurse and client can collectively consider the broad, evidence-based interventions relating to their diagnosis, and begin to tailor these to the individual client.

Promoting a healthy self-concept

Interventions are designed to promote a client's health and sense of wellbeing. Strategies are designed to help clients regain or restore the elements that contribute to a strong and secure sense of self and purpose in life. The approaches that are chosen will vary according to the level of care that clients require. Nurses often have the opportunity to work with clients to help them develop healthy lifestyle habits that contribute to a healthy self-concept and spiritual wellbeing. Measures that support adaptation to stress, such as balanced nutrition, regular exercise within the client's capabilities, measures that facilitate adequate sleep and rest (see Chapter 30), and stress-reducing practices, all contribute to a healthy self-concept.

Spiritual care should be a central theme in promoting an individual's overall wellbeing. Spirituality is one personal resource that affects the balance between health and illness. In settings where health-promoting activities occur, clients can be offered information, counselling and guidance to make appropriate lifestyle choices to remain physically and mentally healthy. Food and nutrition are important aspects of care, with food and patterns of eating being important components of some religious observances (Table 20-2). As with many aspects of diversity, culture or religion, food and the rituals surrounding the preparation and serving of food are important to a person's spirituality and should therefore be part of nursing knowledge and respectful care.

Nurses are often in a unique position to identify lifestyle practices that put a person's self-concept at risk or that suggest altered self-concepts. For example, a young teacher visits a clinic with complaints of being unable to sleep and having difficulty with anxiety attacks. In gathering relevant information and data, the nurse learns that the young woman has a large number of life changes occurring simultaneously, is getting too little rest and is using alcohol to relieve stress. These defining characteristics are suggestive of either self-concept disturbances or spiritual distress. Talking with the client to determine how she views the various elements of her life, to discuss how her lifestyle choices may be triggering anxiety, and making appropriate referrals or providing appropriate online or other resources are important strategies to encourage self-care (Box 20-7).

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data

James is a 24-year-old who has recently been diagnosed with HIV. The clinic registered nurse (RN) has been talking to James during his last three visits. During that time James expresses a fear of dying and anger with God: 'How can God do this to me? This just can't be happening!' The RN attempts to learn more about James's faith and sources of spiritual support. James begins to cry and admits that he feels very alone. 'I just don't know what to believe in any more; this has happened so suddenly. It is as though God and everyone else has abandoned me. I am so afraid. Life isn't making sense.' In further discussion, James says he has been unable to sleep, has little desire for food and is having difficulty finding ways to talk to his friends.

Priority problem(s)

Spiritual distress related to fear and uncertainty of advanced illness.

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
James will express a sense of purpose.	Client will discuss how the experience of having AIDS may have a positive influence in life.
James regains a sense of hope.	Client expresses a sense of confidence in treatments available for AIDS. Client begins to talk of the future.

Preparing for and taking action	Rationale
Instilling hope	
• Plan a session to discuss typical course of HIV, emphasising the typical pattern of remissions with drug therapy. Review therapies available for treatment.	Knowledge about disease will help client think as a person living with HIV rather than dying with HIV. Reality of disease course will help instil hope.
Spiritual support	
• Encourage James' expression of loneliness through establishing a caring presence.	Presence reflects being in tune with the client and displays caring. It is an effective technique that makes a topic of discussion more approachable.
• Listen to James' feelings and concerns.	
• Have James discuss his ability to cope with HIV and the meaning it has spiritually. Use spiritual resources.	People question and become open to discovering their unique spiritual meaning after a crisis that threatens health. Provide client with a resource from his community of faith to share concerns.

Evaluating impacts and outcomes

1. Ask James to discuss what meaning he has gained from experiencing HIV.
2. Have James discuss how he plans to adjust to the disease in the future (including continuing work, social activities, and so on).

Reference

Hall B 1998 Patterns of spirituality in persons with advanced HIV disease. Res Nurs Health 21: 143.

Acute care

In the acute care setting, the nurse is likely to encounter clients who are experiencing threats to their self-concept and/or spirituality because of the nature of diagnostic procedures and treatment. Threats to a person's sense of self, and the meaning attached to the experience, can result in anxiety and/or fear. Numerous stressors, including the diagnosis, fear of the unknown, the need to make changes in lifestyle, and change in functioning, may be present and need to be recognised and reduced where possible. There is often more than one stressor in the acute care setting, thereby increasing the overall stress level for the client and their family.

Clients receiving care for acute problems are often also faced with the need to adapt to an altered body image as a result

TABLE 20-2 Religious dietary practices

Religion	Dietary practices
Hinduism	Some sects are vegetarian. The belief is not to kill any living creature
Buddhism	Some are vegetarians, and many will not use alcohol or tobacco and may hesitate to use drugs Many will fast on holy days
Islam	Eating pork and consuming alcohol are prohibited Fasting occurs during the month of Ramadan
Judaism	Some observe the kosher dietary restrictions of avoiding pork and shellfish and not preparing and eating milk and meat at the same time
Christianity	Some faiths discourage the use of alcohol, caffeine and tobacco Some Roman Catholics may fast during Lent, Ash Wednesday, Good Friday and one hour before receiving Communion
Jehovah's Witnesses	Members may avoid food prepared with or containing blood
Mormonism	Members abstain from alcohol, caffeine and tobacco
Baha'i	Members abstain from alcohol, caffeine and tobacco
Russian Orthodox Church	Followers must observe fast days as well as a 'no meat' rule on Wednesdays and Fridays. During Lent all animal products, including dairy products and butter, are forbidden

BOX 20-7 Strategies for reducing anxiety

Objectives

- Client will identify physical sensations associated with anxiety.
- Client will describe the location, size and shape of physical sensations associated with uncomfortable emotional feelings.
- Client will, while maintaining awareness of the size and shape of physical sensations associated with uncomfortable emotional feelings, verbalise whether the size and shape remain constant or change in some way.
- Client's voice will become soft and slower in pacing as the experience unfolds.
- Client will voice feeling more relaxed.
- Client will explain how they could use the technique by themselves when experiencing anxiety.

Strategies

- Explain to the client that often our habitual way of coping with emotional discomfort/anxiety is to ignore it or try to get away from it in some way (e.g. eating, use of substances). Suggest other ways of working with anxiety, paying attention to physical sensations and allowing them to move and change. This way of being with physical manifestations of anxiety can allow one to experience anxiety in a more accepting way. This acceptance can allow one to notice that all experience is constantly changing and that in fact what one sees as unbearable has periods of time when it is intense but also periods when the sensations are less intense.
- To guide the client in using this technique, have the client find a comfortable position. This could be lying in bed with arms at the sides and legs uncrossed or sitting with good body alignment.
- Ask the client to take in several deep breaths and let them go, relaxing onto the chair or bed.
- Ask the client to make contact with the physical sensation experienced in touching the chair or bed.
- Ask the client to describe the location, size and shape of the sensation. Ask them to stay with the physical sensation and every 5 or 10 seconds voice whether the sensation is the same, saying 'same' or, if changing, 'changing'. If the client is quiet for 30–60 seconds, you can say 'And now?' to remind the client to stay with their sensations. If the client notes the sensation changing, ask if it is getting larger or smaller. If larger, have the client note 'expanding'; if smaller, note 'contracting'; if no change, note 'same'.
- Continue in this way for 20–60 minutes. At the end of this time, ask the person to take in a deep breath, let it go and then gently open their eyes.
- At the completion of this experience, if a person has been able to focus on their sensations, they are likely to experience a sense of relaxation and a sense of peacefulness.
- Review the steps of the process as outlined above.

continued

Evaluation

- Ask the client to describe their physical sensations at the beginning of the experience.
- Ask the client to describe the location, size and shape of a physical sensation.
- Ask the client to voice the ongoing characteristic of the physical sensation as either changing or remaining the same. If changing, describe whether it is expanding or contracting.
- Note whether the client's voice quality and speed of speaking change as the experience unfolds.
- Ask the client how they are feeling and note their response.
- Ask the client if they could use this technique when anxiety arises.
- If you have continuing contact with the client, inquire if they have used the technique since practising it with you, and how it went.

of surgery or other physical change. Receiving a visit from someone who has experienced similar changes and adapted to them (e.g. someone who has had a laryngectomy or an amputation) may be helpful. The timing of such a visit is important, being sensitive to the client's level of acceptance of the change. Forcing confrontation with the change before the client is ready could delay the person's acceptance. Signs that a person may be receptive to such a visit include the client asking questions about how to manage a particular aspect of their personal care at home, or looking at the changed or injured area. As the client expresses readiness to integrate their new body change into their self-concept as part of making life-change adjustments, the nurse can either let the client know about support groups or ask the client whether they would like the nurse to make contact for them. Another way to facilitate adjustment to a change in physical appearance and the associated psychospiritual alterations is through the nurse's response to the change. As the nurse responds with acceptance, this models acceptance for both the client and the family.

• CRITICAL REFLECTION POINT

Mrs Stills has been hospitalised with cancer of the ovaries. Her disease has progressed but she expresses a satisfaction with her life and a faith that God will guide and protect her. She asks you about meditation exercises. In the acute care environment, how might you arrange a teaching session on meditation?

Restorative care

Nurses in long-term nurse–client relationships such as in home health, community and primary healthcare or restorative-care environments, have greater opportunity to work with clients to reach their identified health goals over time. Interventions designed to help a client reach the goal of adapting to life changes are based on the premise that the client first develops insight or self-awareness concerning problems and stressors and then acts to solve the problems and associated stressors. The approach (Table 20-3), outlined by Stuart and Laraia (2001), involves the following levels of intervention: expanded self-awareness, self-exploration, self-evaluation, planning of realistic goals and commitment to action.

Increasing the client's self-awareness is achieved through establishing a trusting relationship that allows the client to openly explore feelings. Open exploration can make the situation less threatening for the client and encourages behaviours that expand a person's awareness of self. Encouraging the client's *self-exploration* is achieved by respecting the client's feelings and thoughts, by helping the client to clarify interactions with others and by being empathetic. The nurse encourages self-expression and stresses the client's self-responsibility. Helping the client to *evaluate themselves* involves working with the client to define problems clearly and to identify positive and negative coping mechanisms. The nurse works closely with the client in analysing adaptive and maladaptive responses, exploring different alternatives and discussing outcomes.

Supporting the client to establish *realistic goals* (Table 20-3) involves encouraging the client to identify appropriate alternative solutions and develop realistic goals. This facilitates real change and encourages further goal-setting behaviours. The nurse designs opportunities and plans with the client to achieve success, reinforcing the client's skills and strengths and helping the client to actively seek the assistance they need. Helping the client become *committed to decisions and actions* to achieve goals involves working with the client to support their move away from ineffective coping mechanisms and develop successful coping strategies. Supporting adaptive, flexible, health-promoting activities in addressing threats to or alterations in self-concept and a person's spirituality is critical for health and healing.

Clients who experience threats to or alterations in self-concept and spirituality often benefit from collaboration with mental health and community health resources to promote increased awareness. Knowledge of available community resources, such as counselling, allows the nurse to make appropriate referrals. Establishing a therapeutic environment and relationship (see Chapter 12) and increasing self-awareness are important to successfully intervene with clients, whether care is focused on health promotion or dealing with an acute process or restorative care.

EVALUATING IMPACTS AND OUTCOMES

Client care

Evaluating success in meeting each client's personal goals and their established expected outcomes requires critical thinking. Frequent evaluation of client progress is recommended so that changes can be instituted if necessary. Knowledge of behaviours and characteristics representative of a healthy self-concept and spiritual wellbeing are crucial to reviewing the actual behaviours clients display. Establishing measures and timelines for meeting goals also helps to determine whether outcomes have been met.

Expected positive outcomes for a client with a self-concept disturbance or alterations to spirituality might include

TABLE 20-3 Levels of nursing interventions for self-concept disturbance

Principle	Rationale	Actions
Goal: Expand client's self-awareness		
Work with resources client possesses	Some resources, such as self-control and self-perception, are needed as foundations for later nursing care	Confirm identity Provide support measures to reduce anxiety Approach client in an undemanding way Accept and attempt to clarify any verbal or non-verbal communication Prevent client isolation Help establish simple routine Help set limits on inappropriate behaviour Orient client to reality Reinforce appropriate behaviour Gradually increase activities and tasks that provide positive experiences Help with personal hygiene and grooming Encourage client to care for self
Maximise client's participation in therapeutic relationship	Mutuality is necessary for client to assume ultimate responsibility for behaviour and coping responses	Gradually increase client's participation in decisions that affect care Convey that client is a responsible individual
Goal: Encourage client's self-exploration		
Show interest in and accept client's feelings and thoughts	When nurse shows interest in and accepts client's feelings and thoughts, the nurse helps client to do so also	Attend to and encourage client's expression of emotions, beliefs, behaviour and thoughts – verbally, non-verbally, symbolically or directly Use therapeutic communication skills and empathetic responses Note use of logical and illogical thinking and reported and observed emotional responses
Help client clarify self-concept and relationships to others through self-disclosure	Self-disclosure and understanding self-perceptions are prerequisites to bringing about future change; this may in itself reduce anxiety	Elicit client's perceptions of strengths and weaknesses Help describe ideal self Identify self-criticisms Help describe how client perceives relationships to other people and events Be open to your own feelings
Be aware and have control of your own feelings	Self-awareness allows nurse to model authentic behaviour	Accept your positive and negative feelings Practise therapeutic use of self: share your feelings with client, describe how another might have felt and mirror your perception of client's feelings
Respond empathetically, not sympathetically, emphasising that power to change lies with client	Sympathy can reinforce client's self-pity; rather, nurse should communicate that client's life situation is subject to one's own control	Use empathetic responses and monitor yourself for feelings of sympathy or pity Reaffirm that client is not helpless or powerless when dealing with problems Convey verbally and behaviourally that client is responsible for behaviour, including choice of maladaptive or adaptive coping responses Discuss with client scope of choices, areas of strength and coping resources available
Goal: Assist client in self-evaluation		
Help client to clearly define problem	Only after problem is accurately defined can alternative choices be proposed	Identify relevant stressors with client and ask for appraisal of them Clarify that client's beliefs influence feelings and behaviours Mutually identify faulty beliefs, misperceptions, distortions, delusions and unrealistic goals Mutually identify areas of strength

continued

TABLE 20-3 ***continued***

Principle	Rationale	Actions
Explore client's adaptive and maladaptive coping responses to problem	Examination of client's choices made during coping will help define successful and unsuccessful responses	Place concepts of success and failure in proper perspective Explore use of coping resources Describe how coping responses are chosen and have positive and negative consequences Contrast adaptive and maladaptive responses Mutually identify disadvantages of client's maladaptive coping responses Mutually identify advantages or 'payoffs' of client's maladaptive coping responses
Goal: Assist client in forming realistic goals		
Help client identify alternative solutions	Only when all possible alternatives have been evaluated can change be effected	Help client understand that one can change only oneself, not others If client holds inconsistent perceptions, show that the following can change: beliefs or ideals to bring them closer to reality, and environment to make it consistent with beliefs. If self-concept is not consistent with behaviour, client can change the following: behaviour to conform to self-concept, beliefs underlying self-concept to include behaviour and ideal self Mutually review use of coping resources
Help client conceptualise realistic goals	Goal-setting that includes clear definition of expected change is necessary	Encourage client to form personal (not nurse's) goals Mutually discuss emotional and practical consequences of each goal Help client define concrete change to be made Encourage client to enter new experiences for growth potential Use role-modelling and role-playing when appropriate
Goal: Assist client in becoming committed to decision and in achieving goals		
Help client take necessary action to change maladaptive coping responses and maintain adaptive ones	Ultimate objective in promoting client's insight is to replace maladaptive coping responses with more adaptive ones	Provide opportunity for success Reinforce strengths, skills and healthy aspects of client's personality Help client gain assistance (e.g. vocational, financial, social services) Use family and groups to enhance client's self-esteem Allow client sufficient time to change Provide support and positive reinforcement to maintain progress
Goal: Assist client in acknowledging goals achieved and evaluating those not achieved		
Help client to purposefully review achievements and explore reasons for any problems or setbacks	Reinforcement of gains made in strengthening self-concept will motivate continued change	Mutually review progress made Affirm achievements with client and family or significant others Evaluate what contributed most to success Help client discuss feelings regarding goals not achieved
Goal: Assist client to re-form plan for achieving goals		
Support client in reviewing goals Identify alternatives not tried previously	Insight gained from attempts to change will support further progress Different approaches may be necessary to achieve desired outcomes	Review with client the need for further self-evaluation Encourage client to continue those experiences that were successful Explore how new coping resources can be applied to continued change Redefine changes in adaptive behaviours to be made Continue to reinforce strengths and successes

Modified from: Stuart GW, Laraia MT 2005 Principles and practice of psychiatric nursing, 8th edn. Mosby, St Louis.

observations of non-verbal behaviours indicating a positive sense of self, statements of self-acceptance, acceptance of change in appearance or function, and a reconfiguration and acceptance of their life purpose and meaning.

Non-verbal behaviours are key indicators of a client's self-concept. For example, a client who has had difficulty making eye contact may demonstrate a more positive self-concept by making more frequent eye contact during conversation. Social interaction, adequate self-care, acceptance of the use of prosthetic devices, and statements indicating understanding of client education, all indicate progress at both self-concept and spiritual levels. A positive attitude towards rehabilitation and increased movement towards independence facilitates a return to pre-existing roles at work or at home.

The priorities and goals of care may become inappropriate as the client's condition changes or their self-concept improves. Reflecting on successful experiences is a positive way to revise the plan. Client adaptation to major changes may take a year or longer, but the fact that this period is long does not signify maladaptation. Life changes, whether these are to self-concept or spirituality, take time. A person's sense of self, and their meaning and purpose in life, is a dynamic process formed over years – it should not be discouraging that changes in the way a person views themselves and changes their adaptive behaviours also require time.

Client expectations

If the nurse and client have developed a good rapport, they may well be able to share how things are going from their own perspective. This sharing may be facilitated by initiating a review of what has happened over time, offering an opportunity to share perceptions of outcomes, and encouraging a dialogue for clients to consider and voice their own experience.

Key concepts

- The development of a sense of self is an integrated set of conscious and unconscious feelings, attitudes and perceptions and beliefs about the self.
- Self-concept is influenced by health, family experiences, social and occupational roles and intellectual and leisure activities.
- The dimensions of self are identity, body image, self-esteem, role performance and spirituality.
- Each developmental stage involves factors that are important to the development of a healthy, positive self-concept, sense of wellbeing and meaning/purpose in life.
- Identity is particularly vulnerable during adolescence.
- Body image is the mental picture of one's body and is not necessarily consistent with a person's actual body structure or appearance.
- Body image also includes attitudes, emotions and reactions of the person towards their body.
- Body image is influenced by growth and development, cultural and societal values and attitudes and individual perceptions of the body.
- Body image stressors include changes in physical appearance, structure or functioning caused by normal developmental changes or illness.
- Self-esteem depends on a person's perception of the ideal self as it compares with the real self.
- Self-esteem stressors include developmental and relationship changes, illness (particularly chronic illness involving changes in what were normal activities), surgery, accidents and the responses of other individuals to changes resulting from these events.
- Roles are learned through socialisation, from one's family and from one's culture.
- Role stressors, including role conflict, role ambiguity and role strain, may originate in unclear or conflicting role expectations and may be aggravated by the effects of illness.
- Nursing actions can have an effect on a client's self-concept.
- Spirituality is the sense of a presence or meaning that is intrinsic to human nature and can be a deep resource for healing.
- Spiritual forms of expression can and do have effects on an individual's physical wellbeing.
- The concept of spirituality as a unifying theme in our lives demonstrates the importance of the spiritual dimension influencing a person's physical, psychological, social and developmental health.
- The spiritual needs most commonly recognised are the search for meaning and purpose in life, a sense of forgiveness, the need for love, the need for hope and the need for belief and faith in self, in others and in a god or higher being/order.
- Faith in a higher power or in one's choice of how to live life can enable a person to take action.
- Hope is a multidimensional concept that energises, is future-oriented and gives people a motivation to achieve and to face difficulties.
- Spiritual health is a balance between people's life values and goals and their relationship with themselves and others that can be threatened by illness or loss.
- Spiritual healing brings with it an equilibrium in which the person recovers from the pain and anguish of spiritual distress. Spiritual healing is a complex phenomenon, a journey in itself, which restores wholeness to the person.
- The nurse involved in spiritual healing will be connected to the client at a very basic human level, which involves trust, compassion and respect for both the person and their dignity.
- Planning and implementing nursing interventions for self-concept disturbance and/or spiritual distress involve expanding the client's self-awareness, encouraging self-exploration, aiding in self-evaluation,

helping formulate goals in regard to adaptation and helping the client achieve those goals.

CHAPTER

21

Understanding sexuality and sexual health

Donna Tilley and Joanne Perks

Learning outcomes

Mastery of content will enable you to:

- reflect on personal values, attitudes and beliefs about sexuality and sexual health
- discuss communication strategies for use in the sexual health context
- describe the elements of a sexual health risk assessment
- describe the impact of specific health conditions on sexuality and sexual health
- identify appropriate sexually transmissible infection and blood-borne virus screening for different population groups
- identify appropriate contraceptive options for men and women across the life span
- discuss issues impacting on pregnancy and fertility options
- reflect on the role of the nurse in promoting sexual health
- identify sexual and reproductive health referrals and resources
- use critical thinking skills to help clients address sexual health needs and concerns.

KEY TERMS

Abortion, p. 485
Bisexual, p. 474
Condom, p. 481
Emergency contraception, p. 486

Lesbian, p. 474
Men who have sex with men (MSM), p. 474
Menopause, p. 485
Same-sex attracted, p. 474
Sexual health, p. 473
Sexual health history, p. 477
Sexual orientation, p. 473
Sexually transmitted infections, p. 476
Transgender, p. 474

Introduction

A person's sexuality is unique and is central to their expression of identity and wellbeing. The expression of sexuality is impacted by social mores, cultural expectations and psychological and physical health. Definitions within legislation also have an impact. Given the importance of sexuality, it is essential that nurses have an understanding of how patients or clients are experiencing and expressing their sexuality, and any barriers that may arise. Discussion of sexuality and **sexual health** should be incorporated into all interactions with young people, patients who have a chronic illness, and people presenting for sexual or other health screening.

There are several models that can be used to help frame sexuality and guide nurses' interactions with patients. Nurses and other health professionals need to feel comfortable discussing sexuality, and to have sufficient knowledge and skills to feel confident in gaining experience in these discussions. Essential skills for providing health care relating to sexuality include having a non-judgemental attitude, being willing to discuss alternative lifestyles, providing a private space, active listening using appropriate body language, open questioning and reflection skills, willingness to discuss drug use and sexual behaviour in detail, and being open to learning from patients, who are the experts in their own unique experiences (McNulty et al 2014). Not all facets of sexuality and sexual health are able to be addressed in this chapter and further reading is recommended.

Sexuality

The expression of sexuality is as unique as each individual. The World Health Organization (2015) provides a working definition of sexuality which seeks to encompass all of the expressions and influences on an individual's sexuality:

> **… a central aspect of being human throughout life encompasses sex, gender identities and roles, sexual orientation, eroticism, pleasure, intimacy and reproduction. Sexuality is experienced and expressed in thoughts, fantasies, desires, beliefs, attitudes, values, behaviours, practices, roles and relationships. While sexuality can include all of these dimensions, not all of them are always experienced or expressed. Sexuality is influenced by the interaction of biological, psychological, social, economic, political, cultural, legal, historical, religious and spiritual factors.**

Sexuality as discussed is how we feel about ourselves. In times of crisis, particularly with disease states, we are all challenged by the impact on our sexuality. Nurses often feel that sexuality is a personal issue and not one to be discussed openly, yet patients often want to talk about their sexual health concerns and to receive advice and education in this area (Tsai et al 2013). Knowledge of sexual health concerns, and a willingness to address these issues, is an important aspect of the nursing role (Julien et al 2010). The importance of learning to feel comfortable talking to patients or clients about sex and sexuality cannot be understated.

Definitions of terms

There are many terms that are used when describing and discussing sexual health and sexuality (see Table 21-1). Although these terms are useful, it is equally important to be aware that many individuals do not want to be labelled by their sexual identity, sexual behaviour or **sexual orientation**.

Our individual expressions of sexuality are shaped by so many factors that it can be useful to look at models relating to different aspects of sexuality. The purpose of these models is to guide our thinking and deepen our understanding. As we develop our understanding we can develop greater empathy and appropriateness in responding to the wide variety of people and situations we encounter in our personal and professional lives.

The sexual trichotomy model

Sexuality is much more than what people 'do' sexually and with whom. Sexuality affects the way we think about ourselves, the choices we make and the behaviours we use to express ourselves. One model developed by researchers at the Australian Research Centre in Sex, Health and Society at La Trobe University (Ollis & Mitchell 2001) divides sexuality into three parts: sexual orientation, sexual behaviour and sexual identity (Figure 21-1). This model seeks to identify and help us understand aspects of variation and diversity in human sexuality.

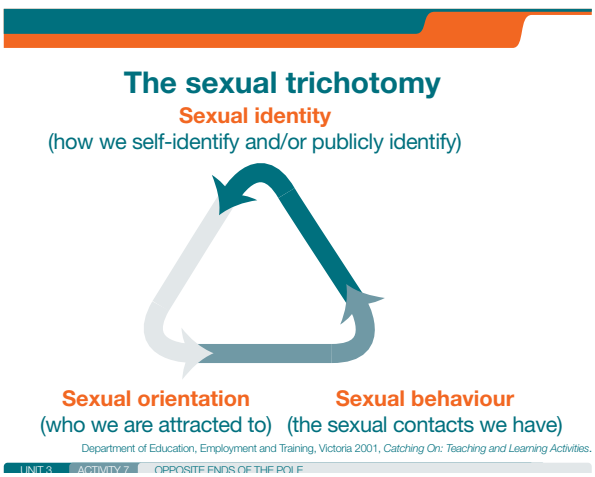

Figure 21-1 Sexual tricotomy diagram.

Catching On, Teaching & Learning Activities, 2004 © State of Victoria (Department of Education and Training).

TABLE 21-1 Definitions of sexuality

Term	Definition
Sex	Sex is the biological characteristics that define us as male or female. There are people who have both male and female sex characteristics (WHO 2015b). Sex is sometimes used to describe identity based on sex characteristics; however, some people do not have a sex identity that is exclusively male or female (Chan 2011). Sex is often used to describe 'sexual activity'.
Gender	'Gender is a cultural expression of sex identity (often but not always based on stereotypes of masculinity and femininity). Gender can be understood as a person looking, dressing or acting as male or female. Some people do not have a gender identity that is either exclusively male or female. Some people's gender identity is not linked to their sex' (Australian Human Rights Commission 2013).
Sexual activity	Sexual activity most commonly refers to sexual intercourse, which may be vaginal, oral or anal (Chan 2011). It can also include solo sexual behaviours such as masturbation.
Same-sex attracted	Refers to people who experience sexual attraction to others of their own sex.
Men who have sex with men (MSM)	This includes any **men who have sex with men**.
Women who have sex with women (WSW)	This includes any women who have sex with women who may identify as lesbian, bisexual, or heterosexual or other.
Gay	An individual whose primary emotional and sexual attraction is towards the opposite sex (see homosexual and lesbian). This term is most commonly applied to men, although some women describe themselves as gay.
Lesbian	A woman whose primary emotional and sexual attraction is towards other women may identify as **lesbian**. Some women who have sex with other women may not call themselves lesbians.
LGBTI	Refers collectively to people who are lesbian, gay, bisexual, transgender and/or intersex (National LGBTI Health Alliance 2015).
Heteronormative	A belief that heterosexuality is 'natural' and becomes the norm by which gendered relationships are framed and sexuality diversity is judged as unnatural and deviant (Robinson et al 2014).
Homophobia and Transphobia	**Homophobia** and transphobia refer to the discrimination, bullying and harassment of people who identify as gender variant and sexuality diverse (Robinson et al 2014).

TABLE 21-1 *continued*

Term	Definition
Queer	Refers to people who identify as gender and sexuality diverse (Robinson et al 2014).
Transgender	An umbrella term for people who do not conform to typically accepted gender roles for the sex they were assigned at birth. People who are **transgender** may undertake hormonal therapy and/or undergo sexual reassignment surgery (The Gender Centre 2015).
Intersex	An **intersex** person is born with sexual anatomy, reproductive organs, and/or chromosome patterns that do not fit the typical definition of male or female. This may be apparent at birth or become so later in life. An intersex person may identify as male or female or as neither. Intersex status is not about sexual orientation or gender identity: intersex people experience the same range of sexual orientations and gender identities as non-intersex people (Organisation Intersex International Australia 2013).

Sexual orientation

Sexual orientation refers to the sex of the people we are attracted to. This attraction may be to members of the opposite sex (heterosexual), members of the same sex (homosexual) or members of both sexes (**bisexual**). Sexual orientation may be fixed or it may change throughout a person's life.

Sexual behaviour

Sexual behaviour refers to the sexual contacts we have, or who we have 'sexual activity' with. The behaviour may match a person's sexual orientation, but in many cases it does not.

Sexual identity

Sexual identity refers to how people see themselves and how they present themselves to others. Sometimes a person's sexual identity can be different to their sexual orientation and sexual behaviour, which can cause a high level of personal stress. An example of this may be a man who has an identity as a heterosexual man in a married relationship; however, he is attracted to other men and may have sexual contact with other men.

The sexual response model

Models of sexuality and the sexual response have changed over the years. In the 1950s, the Kinsey report and the Masters and Johnson traditional linear model

(of excitement, plateau, orgasm and resolution) proposed models based on physical responses to sex. While these models were considered very innovative at the time, it has been suggested that this approach may have ultimately led to the myriad of sexual function disorders diagnosed today, particularly those affecting women (Wylie & Mimoun 2009).

A more recent model of sexual response proposed by Basson (2003) is based on psychosocial theory. This model recognises and incorporates emotional intimacy, sexual stimuli and relationship satisfaction. For example, female sexual functioning is thought to proceed in a more complex and circuitous manner than male sexual functioning. Female sexual function is often dramatically and significantly affected by numerous psychosocial issues including satisfaction with the relationship, self-image and previous negative sexual experiences (Basson 2003). The male sexual response, however, has traditionally been seen as a physical process of arousal (erection) and ejaculation (Russell 2011). In men, heart disease, hypertension, prostate cancer and other chronic conditions can impact on their physical ability to achieve the sexual response. This focus on physical ability to perform, rather than focusing on emotional intimacy (as suggested in Basson's model), is likely to produce a more stressful and less satisfactory response for both men and women.

• CRITICAL REFLECTION POINT

Clarification of values

Values and attitudes towards many life issues are often formed during childhood and early adolescence. Values and attitudes can be related to family or religious beliefs, or result from ignorance or lack of awareness about some of the lifestyle choices that people in our care might make. It is often through life experience that we learn to value and respect the belief systems of others.

Take some time to consider the scenarios below. How do you feel about them and what considerations would you need to make if you were nursing someone in that situation?

- **Caring for a client who has been diagnosed with a sexually transmitted infection (STI).**
- **Caring for a same-sex couple who have recently had a baby.**
- **A client tells you he has been on a sex tour of Thailand when you are taking a sexual history.**
- **Caring for a woman who has experienced female circumcision.**
- **A woman requesting information on termination of pregnancy.**
- **An HIV positive man or woman requiring long-term care for chronic disease.**
- **A man who is wanting advice on gender reassignment.**
- **A gay couple seeking advice about surrogacy.**

CLINICAL EXAMPLE: CODY

You are a registered nurse working with Cody, a 15-year-old male on your adolescent mental health unit. Cody was recently admitted after attempting suicide and has a history of deliberate self-harm. During your assessment, Cody reveals to you that the reason he attempted suicide is that he feels he might be gay. He is confused about his sexuality and feels isolated from his peer group at a private boys-only school. He is also concerned about how his family might feel about his sexual orientation. Cody says that he has not told anyone else and is uncertain whether he should tell his parents.

1. What was your reaction when Cody said he might be gay?
2. In your family of origin or cultural background, what are the values and beliefs surrounding same-sex attraction?
3. What can you do to make Cody feel comfortable about his disclosure to you?
4. What community supports might assist Cody and his family on discharge?

In the *Clinical example*, this young man has revealed information that indicates he trusts you. The first and subsequent responses and actions of the nurse are critical to how this young person might feel about telling his parents and other important people in his life. It would be appropriate to thank Cody for placing his trust in you, and affirm his decision to discuss this with you. The nurse might then suggest that perhaps the reason Cody feels this way is that he is afraid that his parents may not be supportive and encouraging of his decision to 'come out', or that he may not yet be emotionally strong enough to cope with a possible negative reaction from them. Identifying someone close to Cody who could be supportive in this situation may be helpful. Similarly, it is important to reinforce to him that he can ask for confidentiality from anyone he comes out to, and that he does not need to discuss his sexuality with anyone until he is ready. With increased population understanding of diversity, a range of age-appropriate services and excellent information sources have been developed which may also assist him (see *Research highlight*, *Online resources*).

Communication and sexual health history-taking

Health professionals recognise that sexuality is an important part of wellbeing but can often feel uncomfortable discussing sexuality and sexual health with patients (Ayaz 2013, Steinke 2013, Bates 2011). Barriers to talking about sexual health can include embarrassment, lack of

RESEARCH HIGHLIGHT

Research focus

Society's attitudes towards sexuality and sexual health are important because they influence laws and affect provision of sexual health and other health services. Key components within models of behaviour change and health promotion address attitudes. These models inform evidence-based interventions aimed at improving the health of populations and individual patients. *The Second Australian Study of Health and Relationships* was conducted to provide accurate data about current aspects of sexual health of the general Australian population; and to analyse changes in beliefs, behaviours and experiences in the decade since the first study was undertaken. The findings are presented in a special edition of the journal *Sexual Health*.

Research abstract

The purpose of the analysis of attitudes towards sex and relationships, as one aspect of the main study, was to describe attitudes towards sex, identify correlates of sexual liberalism and identify changes in attitudes since the first study conducted in 2002. A representative sample (20,094 men and women aged 16–69 years) of the Australian population was contacted by landline and mobile phone via random digit dialling. A computer assisted telephone interview was completed. Respondents were asked to express their agreement with 11 attitude statements. There was general agreement that sex was important for wellbeing (83%), premarital sex was acceptable (87%) and having an affair when in a committed relationship was unacceptable (83%). Only 17% agreed that termination of pregnancy was always wrong, only 20% believed sex between two adult men was always wrong and 15% believed sex between two adult women was always wrong. Only 24% believed sexual health education increased the likelihood of early sexual activity. More liberal attitudes were associated with being female, speaking English at home, homosexual or bisexual identity, not being religious, greater education, higher incomes and more diverse patterns of sexual experience. Since 2002 there has been a shift to less tolerance of sex outside a committed relationship, but greater acceptance of homosexual behaviour.

Evidence-based practice

- Attitudes towards sex and relationships have implications for government policy and sex education
- Locally based studies of sub-populations are often essential for developing culturally appropriate health promotion strategies and the data from a large population-based study provides a useful baseline for comparison
- The awareness of the diversity and importance of the sex lives of Australians can increase the capacity of nurses to appropriately address expressing sexuality as an activity of daily living.

knowledge, fear of causing offence, lack of time and not regarding sexuality as a health priority (Bates 2011). Patients and clients may pick up on the reluctance of health professionals to discuss sexuality, or may be waiting for the health professional to ask first. If neither nurse nor patient initiates the discussion, opportunities for addressing concerns, providing health and preventive information or making appropriate referrals, can be missed.

It is often appropriate to begin any health assessment with more general questions and then move to more specific questions. Building rapport, trust and creating a safe and confidential environment for the person to discuss sexual health concerns may take time. Effective communication includes using active listening, asking open-ended questions, demonstrating empathy and displaying a non-judgemental attitude. Open questions invite patients to think before responding and provide the nurse with more information than a closed question (Miller & Rollnick 2013). It is also important to take note of the non-verbal cues offered by the patient (McNulty et al 2014).

Safe sex

Safe sex is defined as any sexual activity where the partners involved are protected from **sexually transmitted infections** and unintended pregnancy. Safe sex (also called safer sex) is where there is no exchange of blood or body fluids, such as semen and vaginal fluids. Safe sex can include abstinence, non-sexual contact like massage or hugging, mutual masturbation, kissing, rubbing against one another, fantasy, fingering and using a condom and lube every time sex happens (State Government of Victoria 2014). Safe sex also encompasses consenting to sexual activity and feeling emotionally safe. Consider the term 'safe sex'. What does safe sex mean to you?

Sexual risk-taking, or not practising safer sex, may happen for a wide variety of reasons. It may be a one-off episode or may be more frequent. Common themes in discussions about risk-taking include addressing knowledge deficits, exploring how safer sex is negotiated with sexual partners, exploring the impact of drug and alcohol use on decision-making and whether other factors

such as mental health, physical health or interpersonal violence might impact the ability to practise safe sex. Conversations about safe sex need to be non-judgemental and aimed at exploring knowledge, feelings and barriers. Also consider the impact of a person's beliefs and cultural norms on their decision-making, such as, 'contraception is a woman's responsibility' or 'he looked healthy so he couldn't have HIV'. It is important that the person does not feel judged or lectured about their behaviour, but rather, is provided with an opportunity to explore choices to increase safety (McNulty 2014).

Nurses are ideally placed to share preventive health messages for safer sex with all clients in their care, including those with diverse orientation, identity and behaviour. Offering written information can also support discussions and provide an opportunity for reflection after the clinical encounter. Most sexual health services have web-based fact sheets on safe sex topics.

The sexual health history

The PLISSIT model developed by Annon (Box 21-1) (Ayaz 2013, Bates 2011) is an example of a patient/provider collaboration framework that can be used to initiate a dialogue about sexuality in any setting. All beginning nurses will be able to utilise the first two or three levels of the model; however, more specific training is needed to provide intensive therapy (Ayaz 2013).

The level of detail contained within the **sexual health history** must be discussed and agreed with the patient or client. Appropriate questioning and recording will vary between services; for example, a person presenting with the signs and symptoms of a sexually transmitted disease requires a different approach to sexual history-taking than a person presenting for an annual influenza vaccination. However, a sexual health history should always include elements of the following (Brook et al 2013):

- An assessment of symptoms to guide examination and tests offered.
- History of exposures (sexual contact, sharing of injecting drug equipment) to identify sites for testing and STIs the patient may be at risk for.
- An assessment of contraception use and risk of pregnancy.
- Assessment of other sexual health concerns, allowing for a discussion of sexual function and psychosocial issues.
- Assessing risk for blood-borne viruses to guide testing and prevention.
- Assessment of risk behaviour and prevention activities (condom use, drug use, frequency of testing, previous infections, vaccination history).
- Assessment of gender-based or interpersonal violence, which can impact on sexuality, sexual health and access to care.

The *Clinical example* illustrates what type of questions may be useful to ask in a follow-up visit. Note that permission is obtained from the patient, open questions are used,

BOX 21-1 PLISSIT Model of patient–provider engagement

P – permission	The first step is to seek permission to talk about sexuality and sexual health Use open questions to start the conversation about sexual health and assessing patient needs. Be clear that you are asking the patient whether they would like to talk about their sexuality and relationships and if they have any concerns, e.g. 'Sex is an important part of life and can be affected by our health status. Would you feel comfortable to talk with me about how the operation has affected the sexual part of your life?'
LI – limited information	This is where nurses can give general information directly related to the patient's health issue The aim is to increase the patient's knowledge and provide an opportunity to correct any inaccurate information. The nurse might explain what is normal or how some medical conditions, medication or surgery affect sexual function. Written information or websites can be useful at this stage.
SS – specific suggestions	Provide specific suggestions Needs to directly relate to the issues described by patient, e.g. 'Can you tell me more about how the timing of your pain medication impacts on your sexual activity?' A thorough history will identify unique issues. It is important to check in with the patient that suggestions you offer are suitable to their individual needs and lifestyle.
IT – intensive therapy	Involves referring the patient to a relevant specialist to address any ongoing needs or for a more detailed consultation. Referrals could be to a psychologist, sexual health counsellor or sex therapist. Referrals should be made in consultation with the multidisciplinary team.

Ayaz S 2013 Sexuality and nursing process: a literature review. Sexuality and disability 31:3–12; Bates J 2011 Broaching sexual health issues with patients. Nursing Times 107(48):20–2.

CLINICAL EXAMPLE

Communicating about sexual health

All men who have sex with men are recommended to have a sexual health screen every 3–12 months (STIs in Gay Men Action Group 2013). Before undertaking the sexual health screen, I need to know a bit more about the reason the patient attended the clinic and if there might be any additional tests I need to order. My first patient for the day is a 25-year-old man; below is an example of the discussion:

Nurse: Hi Matt, can you tell me what has brought you into the clinic today? (*Open question*)

Patient: I got a reminder that I was due for my check-up.

Nurse: So there is nothing that is worrying you today and you just want to have a check-up. (*Reflection/ summarising*)

Patient: Yes.

Nurse: Is it okay if I ask you some specific questions about symptoms of sexual infections, and some detail about your recent sexual history? This will help me decide what tests to offer you today. (*Asking permission*)

Patient: That's fine.

Nurse: Have you got any symptoms at the moment, such as pain when you pee, discharge from the penis, pain in your testes, lumps or sores, or any rectal pain or bleeding? (*Closed question to elicit a specific response*)

Patient: No, nothing like that.

Nurse: In the last 3 months how many different sexual partners have you had? (*Non-judgemental approach*)

Patient: Four.

Nurse: Were they men, women or both? (*No assumptions made about gender of sexual partners*)

Patient: All of them were men.

Nurse: What percentage of the time did you use condoms in the past 3 months? (*Non-judgemental approach*)

Patient: All of the time. I am really cautious about protecting myself from infections.

Nurse: So you are aware the rates of some infections are high among men who have sex with men and you always use condoms to protect yourself. (*Reflection/ summarising*)

Patient: That's right.

Nurse: Great. Before I explain the tests for the routine sexual health check, were there any questions you wanted to ask or anything else concerning you today? (*Open question*)

language is neutral, assumptions are not made about the gender of sexual partners, and frequent opportunities are provided for the patient to add additional information.

• CRITICAL REFLECTION POINT

Reflect on the last six patients you have cared for or been involved with during clinical placements, or in your work as a nurse. Were there, or could there have been, issues related to their sexuality and sexual health that you could have explored with them? Ask an experienced registered nurse how they broach the topic to give you some strategies for your future practice.

Impact of health conditions on sexuality and sexual health

It is beyond the scope of this chapter to discuss all of the possible altered states of health that may affect sexuality; however, a few specific examples are given below. Nurses need to remain aware of the possible impacts of specific health conditions on sexual function and expression that may significantly influence the results and outcomes of treatment in clients of all ages. Altered states of health, including a range of chronic medical and surgical conditions; major trauma; disability; mental health conditions; and the medications that are part of their treatment (see Box 21-2) may temporarily or permanently affect sexual function. These considerations are an important part of the initial nursing assessment, planning for chronic disease or disability management, and also as part of ongoing discharge and community health education.

Chronic diseases

The sexuality of people living with chronic disease such as diabetes or heart disease is often neglected in

BOX 21-2 Conditions that may affect sexuality

Medical conditions

Multiple sclerosis, arthritis, cardiac disease, lung disease, diabetes, renal disease, incontinence and obesity, chronic pain

Surgical conditions

Mastectomy, hysterectomy, prostatectomy, colon surgery (from cancer, Crohn's disease or ulcerative colitis), cardiac surgery, orthopaedic surgery – particularly on the knees and hips

Mental illness

Depression, anxiety, obsessive compulsive disorder, schizophrenia, post-traumatic stress syndrome, substance abuse

Intellectual disability

Down syndrome, autism spectrum disorders, developmental disability

Trauma

Brain injury, spinal cord injury, burns

discussions of long-term care with nurses and other health professionals. While developing plans for chronic disease management in primary healthcare has become part of routine care, sexuality is rarely incorporated (Verschuren 2010). Consider also any person with a disability. Sexual wellbeing is equally important for maintaining quality of life for patients living with chronic disease or disability. The impact of chronic or long-term conditions on self-esteem; societal attitudes towards people living with disease or disability; cultural and other values of family and friends (see *Working with diversity*); the possible effects of depression or drug and alcohol use – all may intervene and all may impact on individual expressions of sexuality. There are also gender differences to consider when developing care plans; for example, a large amount of research has been dedicated to the treatment of erectile dysfunction in males, but there is limited evidence to inform strategies to address female sexual dysfunction (Verschuren 2010).

Mental health and wellbeing

Clients with a mental health problem often have both their physical health and sexual health concerns overlooked. Sexuality is not seen as an important priority in many interactions with mental health clients, yet many of the medications prescribed to the person receiving treatment for a mental illness negatively impact on sexuality and the sexual response. Sexuality is a basic human right and all people, including those with a mental illness, have the right to appropriate information, and appropriate referral and access to sexual health care (Quinn & Heppell 2011).

WORKING WITH DIVERSITY

Using interpreters

Sexuality and heart disease: planning for discharge

Sexuality issues are sensitive for many people. Men and women from diverse cultural backgrounds may find it difficult to talk about sexuality issues that are often seen as taboo topics; however, diversity exists within all cultures, and a particular patient may differ from the norms and other members of his or her culture.

In addition, people from culturally and linguistically diverse backgrounds can face barriers to accessing appropriate services. For patients who do not speak English as a first language an interpreter may be needed to ensure effective communication between the healthcare provider and the patient. The values and attitudes of an interpreter towards sensitive issues may also need to be clarified prior to the consultation going ahead.

Mr B is a 62-year-old Arabic-speaking man. Mr B has recently had a pacemaker inserted for atrial fibrillation. Mr B is about to be discharged from your ward and your role is to offer information about how he might manage his health over the next couple of months. Mr B does not have English as a first language and you are concerned that you may not be able to provide high-quality information without the use of an interpreter. Some issues to consider when you are preparing for the discussion are: What is best practice around talking to a client where English is not the first language? and, what will you do if the interpreter refuses to talk about sexuality?

Mrs B is with her husband during the discharge planning session and asks about when the couple can resume having sex as it is a vital part of their relationship together. How would you answer this question, and what other issues might you discuss before the couple go home? Answers might include: sex is fine as long as you are feeling better; avoid positions that place pressure on the arms and chest for the first 4 weeks; talk to each other about your fears; there are other ways of sexual intimacy besides penetrative sex; the risk of subsequent heart attack during sex is low (NHS Choices 2013).

Implications for practice

- The best practice around talking to a client where English is not the first language is to use an accredited interpreter who must adhere to a code of ethics that includes respecting a client's confidentiality and privacy.
- Use trained interpreters only, not relatives.
- Consider the gender of the interpreter when making the booking and what would be the most appropriate for the patient.
- An interpreter's role is to convey the words used by the healthcare provider and the patient.
- The interpreter should not decide what should or should not be conveyed.
- During the consultation speak to the patient not the interpreter.
- Consider confidentiality issues as some groups may be wary about use of interpreters due to issues such as potentially knowing the interpreter.
- Some languages may not have equivalent terms for discussing sexual identity or practices.
- Ask the interpreter if they are comfortable discussing sexuality issues and if not arrange for another interpreter (Centre for Culture, Ethnicity and Health 2011).

For various reasons, those suffering mental illness, mental disability, or periods of extreme stress, may need to live in mixed accommodation settings. Sexual safety is a common area of concern in such settings and has been raised as an issue by both men and women. Nurses often find it difficult to discuss and address the sexual concerns of their clients, and of particular concern are issues that may be raised in regard to safe sex and sexual assault.

Sexual violence and risk for both unplanned pregnancy and sexually transmitted infections (STIs) are also important issues to consider when working with those who are vulnerable, those who may have experienced short or longer periods within institutional-type care, or those experiencing family violence and abuse. Inappropriate personal boundary setting and risk-taking behaviours – particularly if associated with concurrent drug and alcohol use – place many people (young and old), and those with intellectual or cognitive disabilities or mental health problems, at greater risk for sexual assault and STIs. For gay, lesbian, bisexual, transgender and intersex clients coping with discrimination in its many forms, the invisibility of sexuality and diversity in the general community may further impact on self-esteem, self-worth and sense of security. These factors in turn may impact on mental health, such as causing depression and anxiety, as well as other disorders (Barker 2009).

Table 21-2 takes you through a clinical reasoning process for gathering relevant information and data to identify STI risk and to make appropriate decisions to plan actions to reduce this risk. This is another way you can frame your approach to planning nursing care.

Cancer

While surgical and pharmacological treatments for cancer have become increasingly more sophisticated and successful, cancer treatments and living as a survivor of cancer have known impacts on a patient's sexual identity and sexual confidence. These impacts may include feelings (such as fear, anxiety, sadness, anger and joy), the body's production of the hormones needed for sexual response, physical ability to give and receive sexual pleasure, body image and self-esteem issues, and roles and relationships affected by loss or grief (Cancer Council Australia 2013b). Talking about a cancer diagnosis and the effects of

TABLE 21-2 Clinical reasoning process: sexually transmitted infection (STI) risk in a client with a mental health issue

Patient priority problem(s)	Ivy is a 56-year-old woman with schizophrenia who lives in a boarding house in the inner city
Gather relevant information and data	Build rapport with Ivy during the consultation by active listening and displaying a non-judgemental attitude Ivy has never had a Pap test and during the course of a consultation, tells you that she has a strange smell 'down there' You ask further questions about the smell and any other symptoms she may be experiencing such as vulovaginal itch, discharge, dysuria or post-coital bleeding
Make appropriate judgements and decisions	Based on the history of symptoms given to you by Ivy you offer testing for sexually transmitted infections, despite Ivy being outside the high-risk age group for STIs You do the Pap test, take a swab for the STIs chlamydia and gonorrhoea, and do a high vaginal swab for common vaginal conditions candidiasis and bacterial vaginosis
Identify patient problem(s)	The swab result returns positive for chlamydia If untreated, chlamydia can be transmitted to sexual partners and lead to pelvic inflammatory disease in women
Set priorities and establish goals	Ivy needs treatment and management of chlamydia infection
Prepare for and take action	Ivy is treated for chlamydia infection with Azithromycin 1g po stat. She is provided with information about chlamydia and its management, including avoiding sex for one week after treatment and contact tracing recent sexual partners over the past 6 months Through the community outreach worker you arrange safe sex information, sexual health screening and advocacy work with the Boarding House Mental Health Team for Ivy's housemates, while maintaining confidentiality about Ivy's care
Evaluate impacts and outcomes	Phone Ivy in one week to see if she avoided sexual contact and if she was able to contact current and past sexual partners Offer any ongoing support required
Reflect on and process new learning	Next time would you do anything differently?

Centre for Culture, Ethnicity and Health 2011 CALD communities, sexually transmissible infections and viral hepatitis: a resource manual for health and community services. Multicultural Health and Support Service.

associated treatments like chemotherapy and radiotherapy seems to be an easier and more frequently performed task than talking about the significant emotional, physical and sexual impacts of cancer and its treatments. A cancer diagnosis and the subsequent management and long-term effects on cancer survivors will also impact on the patient's carer or significant other. Grief and loss around sexuality are part of the holistic effects of a cancer diagnosis and its management. Readily available and confidently shared information about the short- and long-term effects of cancer treatment on sexuality are infrequently and often inadequately addressed in cancer care.

Sexual health

Sexually transmitted infections and blood-borne viruses

STIs are bacterial, viral or parasitic infections that are passed from one person to another through sexual activity, including oral, vaginal and/or anal sex. Blood-borne viruses (BBVs) such as HIV and hepatitis B are included in the definition of an STI as they are also transmitted via sexual activity. STIs have different modes of transmission such as body fluid contact, blood-to-blood contact, skin-to-skin contact or vertical transmission via mother to baby. One of the key features of STIs is that they are often asymptomatic. Due to patients not having any symptoms, they will not necessarily present to a doctor or clinic for sexual health screening. Offering screening for STIs and BBVs in high-risk populations is therefore an essential public health activity. If patients do have symptoms, these can vary in severity, duration and presentation, depending on the type of infection. In some situations, diagnosis of an STI is made on the basis of a syndromic presentation; for example, pelvic inflammatory disease (PID) is characterised by mild to severe pelvic pain in women, or proctitis, characterised by anal discharge and pain in men who have sex with men (Australasian Sexual Health Alliance n.d). In these cases, STI testing is performed on the basis of presenting symptoms; however, the specific pathogen is not always found.

Table 21-3 provides a summary of clinical presentations and transmission of the most common STIs and BBVs. The table is adapted from the Australian STI Management Guidelines for use in Primary Care (Australasian Sexual Health Alliance nd) and the New Zealand Sexual Health Society Best Practice Guidelines (The New Zealand Sexual Health Society 2015). Detailed information about the treatment and management of STIs is located in both of these up-to-date, evidence-based online resources (see *Online resources*).

Prevalence of STIs

In Australia, data on the rates of STIs that are of public health significance are notifiable to public health authorities in each state or territory. In Australia, The Kirby Institute publishes annual surveillance reports about HIV, viral hepatitis and STIs (The Kirby Institute 2015). In New Zealand, STIs (with the exception of HIV) are not notifiable and data is derived from sexual health clinics, family planning clinics and laboratories; therefore, the quality and quantity of data is variable (Institute of Environmental Science and Research 2015). In addition to public health surveillance, research on STIs and HIV continually adds to new information on prevalence, testing and behaviours in specific population groups.

Chlamydia is the most common notifiable STI. Rates of chlamydia infection have been increasing over the past decade, particularly among people under 29 years of age, and in 2013, more than 82,000 Australians were notified with chlamydia infection (The Kirby Institute 2015).

Gonorrhoea, *syphilis* and *human immunodeficiency virus* (HIV) predominantly affect men who have sex with men in Australia and New Zealand.

Several common STIs (herpes simplex virus, human papilloma virus, trichomonas vaginalis, molluscum contagiosum virus) are not notifiable and contact tracing is not recommended due to limited public health benefit.

Populations mostly affected by chronic hepatitis B are those who have migrated from countries of high prevalence (Australasian Society for HIV Medicine 2014). Universal infant vaccination programs for hepatitis B, and vaccination for at-risk groups contribute to low rates of newly acquired infections (The Kirby Institute 2015, Australasian Society for HIV Medicine 2014); however, Indigenous peoples are at risk of poorer health outcomes, including in relation to STIs. This is due in part to barriers to accessing health care and additional programs that may be needed to appropriately support STI and BBV prevention, testing and treatment efforts.

Testing for STIs and BBVs

Screening and testing recommendations for STIs and BBVs are based on population prevalence data and the health impact of the infection. The NSW Sexually Transmissible Infections Programs Unit in Australia (2015) has developed an STI testing tool (see Figure 21-2) to be used as a guide for identifying which populations to test, which tests to perform and how often, normalising sexual health screening and contact tracing.

STI and BBV prevention

In addition to safer sex and the use of a **condom** to prevent blood and body fluid transmission there are some

TABLE 21-3 Clinical presentation of common STIs and BBVs

STI/BBV	Transmission	Clinical presentation
Chlamydia trachomatis	Bacteria transmitted by body fluids	**Women**: 50% have no symptoms Symptoms when present may include vaginal discharge, dysuria, pelvic pain, intermenstrual bleeding, post-coital bleeding **Men**: 75% have no symptoms Symptoms when present may include dysuria, urethral discharge, testicular pain, ano-rectal symptoms
Neisseria gonorrhoea	Bacteria transmitted by body fluids	May be asymptomatic **Women**: Vaginal discharge, dyspareunia, irregular bleeding **Men**: Urethral discharge, dysuria Ano-rectal symptoms: discharge, irritation, painful defecation, disturbed bowel function
Treponema pallidum (Syphilis)	Bacteria transmitted by skin-to-skin contact or vertical transmission	Clinically the disease has three stages; however, about 50% of people will have no symptoms **Primary syphilis**: painless genital ulcer or chancre(s) with well-defined indurated base often occurring at transmission site, enlarged inguinal lymph nodes. Spontaneously resolves within a few weeks **Secondary syphilis**: rash typically on palms, soles and trunk; constitutional symptoms such as fever, malaise, headache and lymphadenopathy; alopecia, condlylomata lata. If untreated, symptoms resolve in a few weeks, but may recur **Latent and tertiary**: reactive serology but no clinical symptoms **Tertiary**: symptoms including skin lesions (gummas), cardiovascular or neurological disease, may develop months or years later if not treated
Human papilloma virus (HPV)	Virus transmitted by skin-to-skin contact	More than 40 types of HPV virus. Warty growths, commonly caused by types 6 and 11, in and around ano-genital skin with minimal discomfort. Sometimes itchy. Psychological distress may be present **Women**: Sub-clinical cervical infection
Herpes simplex virus (HSV)	Virus transmitted by skin-to-skin contact	Recurrent ano-genital ulcers or blisters with itching/tingling and erythema Initial episodes may be severe with extensive ulceration and systemic features Significant psychological distress may be present
Hepatitis B virus (HBV)	Virus transmitted by blood and body fluid contact; and vertical transmission	Commonly asymptomatic **Acute hepatitis**: lethargy, nausea, fever, anorexia for a few days then jaundice, pale stools and dark urine Chronic hepatitis defines as infection lasting over 6 months, can be lifelong Complications of chronic infection include cirrhosis and hepatocellular carcinoma
Human immunodeficiency virus (HIV)	Virus transmitted by blood and body fluid contact; and vertical transmission	May experience seroconversion illness approximately 2 weeks after exposure, fever, rash, lymphadenopathy, pharyngitis, myalgia, diarrhoea, then usually asymptomatic for several years Treatment with antiretroviral medication will delay or prevent onset of symptoms of immune deficiency: oral thrush, diarrhoea, weight loss, skin infections, herpes zoster Infection with HIV causes chronic immune deficiency, which, if untreated, leads to acquired immunodeficiency syndrome (AIDS) after a variable period, although on average 10 years after infection.

STI Testing Tool

Who? is the patient?	Why? would you do an STI test?	Which? STI	How? WHAT specimen do you need?	How? WHAT test do you order?
A sexually active young person under 29 years	This population is at higher risk for Chlamydia	Chlamydia	First pass urine **OR** Self-collected vaginal swab **OR** Endocervical swab	NAAT
		HBV	**Consider vaccination for HBV & HPV**	
A sexually active Aboriginal young person under 29 years	This population is at higher risk for Chlamydia * Can also be conducted as part of the Aboriginal health check - Medicare item 715	Chlamydia Gonorrhoea	First pass urine **OR** Self-collected vaginal swab **OR** Endocervical swab	NAAT
		HBV	Blood **Consider vaccination for HBV & HPV**	HBcAb
An (asymptomatic) person of any age requesting "a STI checkup"	The patient has requested it, so may be at risk. Ideally, take a sexual history to ascertain: a) if they fall into one of the groups below b) help you decide on sites for specimen collection	Chlamydia	First pass urine **OR** Self-collected vaginal swab **OR** Endocervical swab	NAAT
		HIV Syphilis HBV	Blood **Consider vaccination for HBV**	HIV Ab Syphilis EIA HBcAb
A man who has sex with men (MSM)	This population group is at higher risk for Chlamydia, Gonorrhoea, Syphilis, HIV, HAV, HBV	Chlamydia	First pass urine & anal swab	NAAT
		Gonorrhoea	Throat swab Anal swab	Gonorrhoea culture NAAT
		HIV Syphilis HAV HBV	Blood **Vaccinate for HAV & HBV**	HIV Ab Syphilis EIA HAV Ab (total) HBcAb
A sex worker	This population group is at higher risk for Chlamydia, Gonorrhoea, Syphilis, HIV, HBV See above for MSM sex workers	Chlamydia Gonorrhoea	First pass urine **OR** Self-collected vaginal swab **OR** Endocervical swab	NAAT
		HIV Syphilis HBV	Blood **Vaccinate for HBV**	HIV Ab Syphilis EIA HBcAb
A person who injects drugs	This population group is at higher risk for Chlamydia, Gonorrhoea, Syphilis, HIV, HBV and HCV* * HCV is not an STI but is included due to risks associated with injecting drugs	Chlamydia Gonorrhoea	First pass urine **OR** Self-collected vaginal swab **OR** Endocervical swab	NAAT
		HIV Syphilis HBV HCV	Blood **Vaccinate for HBV**	HIV Ab Syphilis EIA HBcAb HCVAb

HAV = Hepatitis A
HBV = Hepatitis B
HCV = Hepatitis C

HPV = Human Papilloma Virus

NAAT= Nucleic Acid Amplification Test (eg: PCR)

Produced March 2012

Getting started with an STI discussion

Bringing the subject up opportunistically

"We are offering Chlamydia testing to all sexually active people under the age of 25, would you like to have a test while you're here or find out more about Chlamydia?"

Using a 'hook'

"Have you heard about HBV or HPV vaccination? They protect against infections that can be sexually transmitted, perhaps we could discuss these while you're here?"

As part of a reproductive health consultation

" Since you're here today for a pap smear/to discuss about contraception could we also talk about some other aspects of sexual health, such as an STI check up?"

Because the patient requests a "checkup" for STIs

"I'd like to ask you some questions about your sexual activity so that we can decide what tests to do, is that OK?"(See Brief Sexual History ☑)

Brief Sexual History ☑

"I'd like to ask you some questions about your sexual activity so we can decide what tests to do, is that OK?"

- ☐ Are you currently in a relationship?
- ☐ In the last 3 months, how many sexual partners have you had? How many partners have you had in the past 12 months?
- ☐ Were these casual or regular partners?
- ☐ Were your sexual partners male, female or both?
- ☐ When was the last time you had vaginal sex/oral sex/anal sex without a condom?
- ☐ In the past year were you ever paid for sex?
- ☐ Have you previously been diagnosed with an STI?
- ☐ Is there anything else that is concerning you?

Other risk behaviours

"I'd now like to ask about some other activities that could increase a person's risk of certain infections, is that OK?"

- ☐ Have you had any tattoos? If yes, was that here in Australia or overseas?
- ☐ Have you ever injected drugs?
- ☐ Have you ever shared needles or injecting equipment?
- ☐ Have you ever been in gaol?

Consent

"I suggest that we test for..." eg: Chlamydia

- ☐ This will involve a urine test. Can you tell me what you understand about Chlamydia?
- ☐ If the result is positive, we can also talk about recent partners you've had being tested as well."

Contact tracing

Contact tracing aims to reduce the transmission of infections through early detection and treatment of STIs. It is the diagnosing clinicans responsibility to initiate a discussion about contact tracing.

From what you have told me today there are a few people who need to be informed. Would you like some tips about how to do this?

Explain different methods and offer choice: Different methods might be needed for each partner. (in person, phone, SMS, email or letter)

Theses sites can support your patients to tell their partners:

other key prevention activities for STIs and BBVs. These include testing, treatment, and contact tracing/partner notification.

As most STIs and BBVs can be asymptomatic, testing can detect infection in people who otherwise might not be aware and could potentially pass on the infection to others. Treatment shortens the duration of an infection, reducing the amount of time a person is infectious. This is particularly relevant for bacterial infections that can be cured with antibiotics.

Contact tracing, also known as partner notification, is an important part of the management of people diagnosed with an STI or BBV. The aims of contact tracing are to interrupt the ongoing transmission of infection, identify people who may benefit from treatment, and prevent reinfection (Australasian Society for HIV Medicine 2010). In practice, this means working with the patient or client who has been diagnosed with an infection to identify contacts, and developing a plan about how to inform the contacts of the infection. The timing of discussing and instigating contact tracing depends on several factors, including the patient's emotional state and the risk to the public. The role of the nurse in contact tracing is to provide clear information about the course of the infection and how far back to trace, explore concerns with the patient/client and discuss options about how to contact trace. Clients can be reluctant to trace contacts due to concerns about loss of confidentiality or negative repercussions and may need additional support, including using anonymous contact tracing websites or provider-assisted contact tracing.

A combination of strategies (behavioural, bio-medical, pharmacological and structural/socio-legal) is needed to prevent STIs and BBVs. Pharmacological prevention is particularly relevant to HIV. Treatment with antiretroviral medication can reduce a person's viral load and reduce the risk of HIV transmission by up to 96% (AVERT 2015). Non-occupational post-exposure prophylaxis (nPEP) is a 28-day course of HIV antiretroviral medication taken within 72 hours of a potential exposure and reduces the risk of transmission by approximately 80% (Australasian Society for HIV Medicine 2013). Pre-exposure prophylaxis (PrEP) is a way for people who do not have HIV to help prevent HIV by taking antiretroviral medication every day. PrEP has been shown to reduce the risk of getting HIV by up to 92% (Wilton et al 2015) for people who take the medication consistently. HIV prevention is rapidly changing and PrEP is currently available in Australia through demonstration trials, with trials planned for New Zealand in the near future.

CLINICAL EXAMPLE

STI screening

As a sexual health nurse working in a primary healthcare clinic I see a mix of patients each day. Once a week we run a travel vaccination clinic. Many of the patients I see are young people about to go on a 'gap year' overseas. We know that young people are at highest risk of chlamydia, but we weren't sure how to bring it up with our young patients and what they would think.

At a team meeting we talked through how we could implement screening and decided that we would offer chlamydia testing to all young people under 30 years old. Initially the nurses and doctors were uncomfortable with how to introduce and discuss testing within their conversation, and so we developed a script to use.

We now say to all young people: 'As part of a comprehensive travel consultation, I would also like to do a sexual health check-up with you before you go overseas, is that okay with you?' When they say 'Okay', we then tell them how easy it is to do a urine test and how if the test result comes back positive, chlamydia can be treated with a single dose tablet. It has made it much easier to test for chlamydia now that it is integrated into our usual practice. It also gives me an opportunity to find out what these young adults already know about STIs and how to prevent them. We have had some positive results and it is great to know these patients have been treated and managed before they travel overseas.

• CRITICAL REFLECTION POINT

Populations most at risk of sexually transmitted infections and blood-borne viruses (men who have sex with men, sex industry workers, injecting drug users) are often marginalised and stigmatised within the community.

1. **What were the prevailing attitudes you grew up with in relation to people with sexually transmitted infections?**
2. **Have your attitudes changed through your nursing studies, and, if so, what knowledge or experiences have influenced that change?**

Female reproductive health

Reproductive health implies that people are able to have a responsible, satisfying and safe sex life and that they have the capability to reproduce and the freedom to decide if, when and how often to do so. People have the right to be informed of and have access to safe, effective, affordable and acceptable (WHO 2015a) methods of birth control and access to health care throughout pregnancy and childbirth.

Reproductive health and sexual health care are closely linked and are often provided by the same healthcare service such as family planning clinics. A woman

attending a family planning clinic may have a Pap test, a chlamydia test, a pregnancy test and a discussion about contraceptive needs all in the same consultation. However, there are still significant challenges to providing effective reproductive and sexual health care in many countries and settings, especially in developing countries. There is also much variability in levels of knowledge related to reproductive and sexual health and limited recognition that reproductive health needs are very different at different stages throughout life (see Chapters 17 and 18).

Pregnancy

A full-term pregnancy is approximately 40 weeks in length and is divided into three trimesters: weeks 1–12, weeks 13–27, and weeks 28–40 (see Chapters 16 and 17). The period of pregnancy before birth is known as the antenatal period and the period of 6 weeks after the birth is known as the postnatal period. The birth itself includes labour, during which the cervix dilates up to 10 cm and uterine contractions facilitate the passage of the infant, placenta and membranes through the birth canal. Babies are also born by caesarean section for various reasons, including malposition and fetal distress. In Australia and New Zealand, registered midwives care for women throughout their pregnancy and in the postpartum period.

Choices for birthing might include hospital midwifery care, team midwifery, shared care models with a GP or care by an obstetrician. There are also women who choose to give birth at their home with a suitably qualified midwife. Many same-sex couples have chosen to become parents and, as described in Chapter 15, a non-judgemental approach to our clients or patients is paramount as loving families of many different types are formed and welcome children.

Termination of pregnancy

It is estimated that approximately 1 in 5 women will have an **abortion** in their lifetime (Sexual Health and Family Planning Australia 2012). There are two methods used to terminate a pregnancy and these are partly determined by the stage of the pregnancy. Medical abortion, for early pregnancies, involves the use of prescribed drugs to induce a termination. Surgical abortion involves a minor surgical procedure in which the fetus is removed from a woman's uterus. In Australia, there is no federal legislation concerning termination of a pregnancy and therefore, access to healthcare services may be different in each state and territory. Abortion is legal in New Zealand (New Zealand Family Planning 2015).

As outlined in a review by Sexual Health and Family Planning Australia in 2012 (Sexual Health and Family Planning Australia 2012), there is still considerable stigma attached to abortion despite the fact that most Australians support women's choice to undertake a safe and legal abortion. It is commonly expressed that women who terminate a pregnancy will experience guilt, grief and shame. Despite this, international studies consistently show that the vast majority of women feel that they have made the right decision and do not appear to suffer any subsequent psychological or emotional problems. It is important for nurses to be aware that women may choose to have an abortion for a wide variety of reasons. It is the role of the healthcare professional to support a woman's decision and to provide safe clinical and compassionate care, or refer the woman to an appropriate provider who can do so.

Menopause

Menopause is often defined as a woman's final menstrual period, but more specifically refers to when a woman has not had a menstrual period for more than 1 year. Female menopause usually occurs between the ages of 45–55 years, with an average onset age of 51 years. Changes in reproductive hormones cause the woman's ovaries to cease releasing eggs (see Chapter 18).

Perimenopause is the stage before the menopause when the menstrual cycle changes to being up to 3–12 months apart, and is often the time when women begin to experience the symptoms of menopause. In some cases menopause occurs earlier in life due to ovarian insufficiency, induced through surgery or treatment for cancer (Jean Hailes 2014).

Common symptoms of menopause include:

- hot flushes
- night sweats
- muscle and joint pain
- anxiety
- sleep disturbance
- vaginal dryness and painful intercourse
- fatigue
- crawling sensations on the skin
- low libido.

The management and treatment of menopausal symptoms depends very much on the individual. Most women presenting with symptoms have already identified the impact of menopause on their wellbeing and simply require evidence-based information about menopause and treatment options (both natural and pharmacological). While many women will not require treatment, those experiencing symptoms that significantly impact on their daily life may consider hormone replacement

therapy (HRT). Similarly, those who have experienced an early menopause would also be recommended to commence HRT with a view to reducing bone loss and cardiovascular disease risk. HRT would also be recommended to women under the age of 60 years who have osteoporosis, to reduce further bone loss. HRT is a combination of oestrogen and progesterone which can be taken daily (or oestrogen only if the woman has had a hysterectomy and does not need progesterone to protect the endometrium).

In addition to a medical history, questions to ask a patient who reports menopausal symptoms include:

- What are the symptoms and when did they start?
- When do symptoms occur?
- When and how often do symptoms occur?
- Do symptoms impair your sleep or quality of life?
- Are you experiencing any genito-urinary symptoms such as incontinence, vaginal dryness, dyspareunia or painful sex? (Patients may not volunteer these symptoms but will tell you about them if asked.)

Female genital mutilation

Female genital mutilation (FGM) involves all procedures where there is removal of part or all of the external female genitalia for non-medical reasons. The WHO states that FGM is 'recognized internationally as a violation of the human rights of girls and women. It reflects deep-rooted inequality between the sexes, and constitutes an extreme form of discrimination against women' (WHO 2014).

In Australia and New Zealand, the performance of any type of FGM is illegal and is also prohibited by the Royal Australian College of Obstetricians and Gynaecologists (Mathews 2011). FMG can result in immediate complications of severe pain, shock, haemorrhage, tetanus, sepsis, urinary retention, open wounds and injury to adjacent genital tissue. In addition to the impact on sexual pleasure, there are also long-term complications including recurrent bladder and urinary tract infections, the development of cysts, infertility, and an increased risk of complications during childbirth – often requiring additional surgery to cut open and re-suture the vaginal orifice for sexual intercourse and childbirth.

Female contraception

Contraceptive advice is most commonly provided by general practitioners, nurse practitioners or other health professionals with specialised education and training. A comprehensive assessment that takes into account the woman's general health, financial circumstances, lifestyle, cultural and spiritual health and previous experiences with contraceptive methods is integral to the selection of the most appropriate contraceptive method for her. In the tertiary or acute care setting, asking questions about contraceptive use as part of the nursing assessment is very relevant to the patient presentation. For example, a woman presenting with chest pain might have a thromboembolism due to use of the combined oral contraceptive pill.

The Australian Primary Health Care Nurses Association (APNA) recently developed a Decision Support Tool to assist health professionals in making decisions with women about their contraceptive choices. Shown in Figure 21-3, the APNA Family Planning Decision Support Tool provides an introduction to the methods of contraception available in Australia. There are some minor differences in methods available in New Zealand; however, the local family planning services in each country are a good starting point for information and fact sheets. There is no one perfect method of contraception and contraceptive needs change throughout the life span. Contraceptive effectiveness also depends on user compliance, which may be improved by sharing information, educational resources and counselling.

Some medical conditions can affect the suitability of a particular method of contraception. Table 21-4 gives a summary of contraceptive methods for women with existing health problems (Department of Reproductive Health 2010). Choice of contraception method is also important for women living with HIV and their male partners, whether HIV-positive or HIV-negative. If a woman's male partner is HIV-negative, prevention needs to include information about HIV transmission and prevention adherence to antiretroviral therapy and consistent condom use. If the woman is on treatment and has an undetectable viral load, however, the couple may choose not to use condoms. Women with HIV can use all hormonal contraceptive methods without restriction (Department of Reproductive Health 2010).

Emergency contraception

Emergency contraception is an important and underused method of contraception that can be used for contraceptive failure (e.g. ruptured or slipped condom, missed pill(s), dislodged diaphragm, non-use of contraception, and sexual assault). Emergency contraception should be introduced and included in discussions or counselling for methods of contraception, as well as be made more widely known about in the community (Calebretto 2009). Hormonal emergency contraception (EC) is the most common method (although the copper **intrauterine device** (IUD) can also be used). The principal mechanism

Contraceptive methods available in Australia

This decision support tool provides an overview of contraception, with the aim of improving accurate information on contraceptive methods, to women and men seeking contraceptive advice. A comprehensive medical assessment is required by a trained health professional prior to initiation of a contraceptive method.

apna Supporting nurses in primary health care

APNA Family Planning Decision Support Tool

	Name	Action	Efficacy	Advantages	Disadvantages
Long Acting Reversible Contraception (LARC)					
Levonorgestrel IUD 	**Levonorgestrel IUD (LNG-IUD)** – progesterone only (Mirena®)	Thickens mucous at the cervix, thins the lining of the uterus, inhibits sperm migration	99%	Effective for 5 years, reduces menstrual bleeding, inexpensive, alternative to sterilisation and an option for women who have contraindications to oestrogen, easily reversible.	Requires procedure for insertion and removal by trained health professional, risk of infection or perforation, may experience discomfort/pain during procedure, may experience irregular bleeding, offers no protection against STIs.
Contraceptive implant 	**Etonogestrel implant** – progesterone only (Implanon NXT®)	Prevents ovulation and thickens mucous at cervix	>99.9%	Effective for 3 years, inexpensive, option for women who have contraindications or side effects to oestrogen, minimal action required on the part of the user, easily reversible.	Requires procedure for insertion and removal by trained health professional, may cause bruising and bleeding, may cause a small scar at site of insertion, may experience irregular bleeding, provides no protection against STIs.
Copper IUD 	**Copper IUD**	Inhibits sperm migration, ovum transport and prevents implantation	99%	Effective for 5 to 10 years depending on the type used, for use when hormonal methods are contraindicated, can be used as emergency contraceptive inserted within 120 hours (5 days) after potential pregnancy risk.	Menstruation may become heavier, requires procedure for insertion with risk of infection or perforation, requires insertion by trained health professional, may experience discomfort/pain during procedure. Further disadvantages may be cost; both the initial purchase price of the device and insertion charges. Also requires removal by a trained health professional and offers no protection against STIs.
Contraceptive injection 	**Contraceptive injection** – depot medroxyprogesterone (DMPA) (Depo Provera® and Depo Ralovera®)	Prevents ovulation, thickens cervical mucous	Perfect use 97%, typical use 97%	Highly effective, lasts for 12 weeks, reduces heavy menstrual bleeding.	Injection can not be reversed once administered, requires attendance for injection every 12 weeks, may delay resumption of fertility, can cause irregular bleeding, offers no protection against STIs.
Other hormonal methods					
Combined oral contraceptive pill 	**Combined oral contraceptive pill** – contains oestrogen and progestogen	Prevents ovulation, thickens cervical mucous	Perfect use 99.7%, typical use 92%	Can predict or stop monthly bleeding, can reduce menstrual bleeding, can improve period pain, can improve acne.	Requires a pill to be taken each day, some pills can be expensive, efficacy may be affected by some medical conditions and medications, does not protect against STIs.
Progestogen-only pill 	**Progestogen-only pill (mini pill)**	Thickens mucous at the cervix to prevent sperm entering the uterus	Perfect use 99.7%, typical use 92%	Small dose of one hormone (progestogen) suitable for women who have contraindications or side effects from oestrogen and breastfeeding women.	Requires a pill to be taken each day with small margin for error, menstrual bleeding may be irregular, does not protect against STIs.
Vaginal ring 	**Vaginal ring** – plastic ring placed in the vagina, containing oestrogen and protestogen (NuvaRing®)	Prevents ovulation, thickens cervical mucous	Perfect use 99%, typical use 92%	Lower dose of hormones, remains in vagina for 3 weeks, highly effective, better cycle control than combined pill.	Expensive, requires user to remove ring after 3 weeks and reinsert after 7 day break, does not protect against STIs.
Emergency contraception 	**Emergency contraception** – Levonorgestrel (LNG), available as a single tablet containing 1.5mg LNG or 2 doses of 750mcg LNG (depending on the brand used)	Mainly works by preventing or delaying ovulation	**Key messages:** • Take as soon as possible after unprotected sexual intercourse (most effective when taken within 24 hours after intercourse, but can be taken up to 120 hours after intercourse) • Can be purchased over the counter at a pharmacy following a consultation with a pharmacist, or on prescription • A repeat dose should be taken if unprotected intercourse occurs any time more than 12 hours after emergency contraception was taken • Follow up with health professionals to discuss ongoing contraception and STI check if appropriate • Commonly but incorrectly referred to as the 'morning after pill'		

Contraceptive methods available in Australia

APNA Family Planning Decision Support Tool

	Name	Action	Efficacy	Advantages	Disadvantages
Barrier methods					
Male condom 	**Male condom** – use once only, made of latex or polyurethane (for latex sensitivity)	Collects semen containing sperm	Perfect use 98%, typical use 85%	Decreases the risk of STIs, back-up to other methods e.g. missed pill/s, inexpensive, usually easily available.	Needs high degree of motivation by user and partner, less effective than hormonal methods.
Female condom 	**Female condom** – use once only, made of polyurethane and inserted into the vagina before sexual contact	Acts as a barrier to sperm entering the cervix and uterus	Perfect use 95%, typical use 79%	Provides protection against STIs, suitable for people with latex allergy.	Needs high degree of motivation by user and partner, more expensive than male condoms.
Diaphragm 	**Diaphragm** – made of silicone	Covers the cervix and prevents sperm travelling into the uterus	Perfect use 94%, typical use 84%	No hormones, suitable for use when there are medical conditions or contraindications to other methods, back-up to other methods, can be used with the male or female condom for added protection against pregnancy and STIs.	Less effective than hormonal methods, needs high degree of motivation.
Sterilisation					
Female 	**Female**	Surgical procedure, performed to block the fallopian tubes preventing sperm fertilisation of an egg (ovum). The most common procedure is done under anaesthetic using a laparoscope. A clip or ring is place on the fallopian tube. A newer procedure is called Essure®. A micro-insert is placed inside the fallopian tube. This procedure can be performed under local anaesthetic with no incisions required.	>99%	Permanent method, does not alter sexual function or the menstrual cycle.	Requires a procedure, difficult to reverse, Essure® procedure is not effective for 3 months.
Male 	**Male**	Vasectomy is a surgical procedure which prevents sperm from entering the seminal fluid. A small incision is made in the scrotum and the tubes which carry sperm (vas deferens) are cut and blocked.	>98%	Permanent method, does not affect sexual function, procedure can be undertaken in a surgery and takes around 30 minutes, no stitches required.	Requires trained health practitioner, may be some swelling, bruising and pain immediately after the procedure lasting a few days.
Fertility awareness-based methods (FABMs) / Natural Family Planning					

Key messages:
- Based on an awareness of the menstrual cycle in order to identify the fertile phase of the cycle
- Can include observation of cervical mucous, cervical changes, basal body temperature and lactational amenorrhea
- Can be used to achieve or prevent a pregnancy
- Requires high motivation by user and her partner
- Cost effective, women gain knowledge about their menstrual cycle
- Not suitable for women with an irregular cycle
- May require long periods of abstinence
- Refer to trained health professional for education and instruction

TABLE 21-4 Contraceptive methods for women with existing health problems

Condition	Unsuitable methods	Suitable methods
Venous thromboembolism	COCs contraindicated No sterilisation until condition treated and resolved	Progestogen-only methods, IUDs
Ischaemic heart disease or stroke	COCs contraindicated	Progestogen-only methods when other methods are not available or acceptable
Hypertension	Moderate and severe hypertension complicated with vascular disease are contraindications for COCs Sterilisation for women increases GA risk, therefore vasectomy could be considered instead	Low-dose COCs for mild hypertension and no additional risk factors (i.e. smoking, diabetes, obesity or age > 35 years) when other methods unsuitable or unavailable POPs, IUDs, implants good choices; DMPA good second choice
Diabetes	Copper IUD with screening and treatment of pre-existing infection prior to insertion, strict asepsis Prophylactic antibiotics considered	COCs normally contraindicated except where there is no vascular disease POI (injectables), but only if other methods are not available or acceptable to the client Hormonal contraception may be used if there are no vascular complications (nephropathy, neuropathy or retinopathy) POP or Implanon can be used when there are vascular complications
Convulsive disorders	DMPA and copper or LNG IUD EC – in the absence of scientific data on how drug interaction affects efficacy, the standard regimen should be used	All methods are suitable but use of anticonvulsants – phenytoin, carbamazepine, ethosuximide, phenobarbitone and primidone – may reduce the efficacy of COCs, POPs, Implanon
Migraine	COCs contraindicated in focal migraine Onset or exacerbation of migraine with a new pattern which is recurrent, persistent or severe requires discontinuation of the COC and evaluation of the cause	For focal migraine, POPs, Implanon or non-hormonal methods POIs is last choice in the absence of hypertension Low-dose COCs for women who have simple migraine without aura
Liver disease	COCs contraindicated in active liver disease, severe cirrhosis, or liver tumour	Non-hormonal method should be first choice Progestogen-only contraceptives may be used if other methods not acceptable or not available Women who carry hepatitis viruses can use any method of contraception. Mild cirrhosis can generally use progestogen-only contraception
Breast cancer	COCs, POI contraindicated POPs and LNG IUSs should not be initiated	Copper IUD is a good choice
Anaemia	Copper IUCDs not suitable as they can increase blood flow	COCs. Progestogen-releasing IUD, POI can reduce blood loss through menstruation
Sickle-cell disease		Pregnancy can be life-threatening for women with sickle-cell anaemia, therefore effective method is needed. Long-acting progestogen-only contraceptives should be first choice COCs and copper IUDs are good second choices
Tuberculosis		Efficacy of COCs, POPs and Implanon is reduced, therefore the woman should be advised to employ a back-up method while taking rifampicin and two weeks after cessation of therapy
Psychiatric disorders	Sterilisation is not recommended for women or men with a psychiatric illness such as depression that may impair informed decision-making	Methods that do not require strict compliance are more suitable for women with an acute or severe psychiatric disorder for whom making contraceptive choices may be difficult

COC = combined oral contraceptive; DMPA = depot medroxyprogesterone acetate; EC = emergency contraception; GA = general anaesthetic; HIV = human immunodeficiency virus; IUD = intrauterine device; IUS = intrauterine system; LNG = levonorgestrel; POI = progestogen-only injectables; POP = progestogen-only pill.

Based on World Health Organization (WHO) 2015 Medical eligibility criteria for contraceptive use. Geneva, WHO. Online. Available: www.who.int/reproductivehealth/publications/family_planning/MEC-5/en/

of action of ED is to inhibit or delay ovulation, with no demonstrated effect of an implanted ovum. Efficacy is greatest the sooner a single or stat dose can be taken after unprotected sex, and is demonstrated up to 120 hours after unprotected sex (Family Planning NSW 2013). Hormonal emergency contraception is available over the counter from pharmacies, and can be obtained without cost from some sexual health and family planning clinics.

Reproductive cancer screening and prevention

Prevention or early detection of some reproductive cancers may be assisted by routine screening, human papilloma virus (HPV) vaccination and effective promotion of individual health behaviours. Primary healthcare nurses remain at the forefront of population health promotion and health education. In homes and clinics around the globe, nurses who have undertaken appropriate training conduct assessments and self-care education with people of all ages to prevent reproductive cancers such as cervical, ovarian, breast, uterine and testicular.

Breast cancer

Breast cancer is the most common invasive cancer in Australian women after non-melanoma skin cancer, and is the most common cancer in New Zealand women. Women are advised to be physically familiar with their breasts, check regularly for any non-hormonal changes and seek advice if they notice any non-normal changes. In Australia, mammograms are recommended 2-yearly for women aged 50–74 years and are available to women over 40 years (BreastScreen Australia 2015). In New Zealand, mammograms are recommended 2-yearly for women aged 45–69 years (National Screening Unit 2015a). It is important to discuss both the risks and benefits of population-based screening and to assist and encourage women to make informed treatment decisions. In some situations, the best decision may be to simply watch and wait, as screening has been linked with the over-diagnosis of some conditions. Any woman with a new breast symptom needs to be investigated regardless of their age. This may include mammography, breast ultrasound and biopsy.

Cervical cancer

Cervical cancer is the third most common gynaecological cancer (Family Planning NSW 2013). The rates of morbidity and mortality from cervical cancer have decreased dramatically over the past few decades due to organised approaches to national cervical screening using the Papanicolaou smear test, more commonly known as a 'Pap' test (National Health and Medical Research Council 2005). The Pap test involves collecting cells from the

RESEARCH HIGHLIGHT

Research focus

Intimate partner violence (IPV) is the most common form of gender-based violence and an important global health problem. In Australia, it is estimated that one in six women have experienced sexual or physical violence from a current or former partner (Australia's National Research Organisation for Women's Safety n.d.). Reproductive coercion is one form of IPV and is associated with poor reproductive health outcomes, including rapid repeat pregnancy (pregnancy within 24 months of a previous pregnancy), unintended pregnancy, pregnancy termination and incident HIV infection.

Research abstract

There is a growing literature on the associations between IPV and the reproductive health of women. This systematic review and meta-analysis synthesised evidence to estimate the impact of IPV on women's use of contraception. The reviewers searched 11 electronic databases from 1980–2013 for studies that examined longitudinal measures of either IPV or women's use of contraception. Of the articles identified in the search 179 were included in the full text review and 12 studies matched the inclusion criteria.

Evidence-based practice

- IPV is associated with a reduction in women's use of contraception
- Women who experience IPV are less likely to report using condoms with their male partners
- Family planning and HIV prevention programs should consider women's experiences of IPV
- Understanding how IPV modifies women's ability to adopt or to continue to use contraception is central to informing evidence-based FP and HIV prevention interventions

transformation zone of the cervix, located at the neck of the uterus. The cells are 'smeared' onto a glass slide and sent to the laboratory to be checked for precancerous cell changes. If abnormal changes are found at screening, the woman will be referred to specialist colposcopy for further testing and diagnosis.

In Australia, women are recommended to have Pap tests every 2 years from the age of 18 years up to the age of 70 years. Women with a history of cervical screening abnormalities may be recommended to have more frequent screening and women with HIV are recommended to have annual screening. For women who have had a hysterectomy for cancer of the cervix, vaginal vault screening is recommended. In New Zealand, the National Screening Unit advises that all women who have ever had sex should be offered a Pap test every 3 years from the age 20 to 69 years. For the first Pap test, or if it has been more than 5 years since the previous test, a follow-up test is recommended one year after the first test, then 3-yearly smears thereafter (National Screening Unit 2015b).

Cervical cell changes are almost always caused by the human papilloma virus (HPV) 'high risk' types. Cervical cell changes can be treated to prevent cervical cancer from developing. A vaccine has been developed that prevents the HPV types (deVisser et al 2014, Steinke 2013) that are most commonly linked to cervical cancer. National immunisation programs provide free vaccination to school-age females in Australia and New Zealand (Immunise Australia Program 2015, Ministry of Health 2011), and to males in Australia. Since the introduction of the HPV vaccine in 2007 there has been a dramatic decline in genital wart presentations reported in young women aged under 21 years at Australian sexual health clinics and a decrease in the detection of high grade histological abnormalities detected on the cervix of young women undergoing cervical screening (The Kirby Institute 2015).The Australian cervical cancer screening program is being revised and from 2017 will screen for HPV every 5 years in women aged 25–74 years in both vaccinated and non-vaccinated women (National Cervical Screening Program 2015).

Ovarian cancer

Ovarian cancer is the eighth most common cancer and the sixth most common cause of cancer death affecting women in Australia. There are no effective screening tests for ovarian cancer and as symptoms are relatively vague, patients will often present when the cancer is well-advanced or has spread to other organs. Symptoms may include abdominal bloating, difficulty eating or feeling full quickly, back, abdominal or pelvic pain, change in bowel habit and abnormal vaginal bleeding. If any of these symptoms are present, women should have a medical review and further investigations, which can include vaginal ultrasound and CA125 blood test (Cancer Council Australia 2015a). Women with a genetic risk for ovarian cancer (an abnormality with the breast cancer genes BRCA1 and BRCA2) require specialist health advice from early adulthood.

Prostate cancer

Prostate cancer is the most common male specific cancer. While tests are available for prostate cancer screening, these are not yet suitable (sufficiently sensitive or specific) for whole of population screening. Therefore, the acceptance of screening for prostate cancer is a matter of individual choice (Cancer Council Australia 2015b). One of the more common screening tests is measurement of the serum prostate-specific antigen (PSA). Men considering a screening test should discuss the benefits and risks of testing and treatment with their healthcare provider (Cancer Council Australia 2010).

Testicular cancer

Testicular cancer is one of the more rare forms of cancer. There is no routine screening test for testicular cancer and, therefore, population-based screening is not recommended (Cancer Council Australia 2013a). What is recommended is that men become familiar with the usual shape, size and feeling of their testicles, such that any deviation from their own 'normal' such as a lump, or swelling on the surface of the testicles, any heaviness, aching or other changes becomes an indicator to seek medical advice (Cancer Council Australia 2013a). Males with a family history (in father or brother) of testicular cancer, or a personal history of undescended testes should discuss the increased risk of testicular cancer with their healthcare provider.

Sexuality and sexual health are key activities of daily living throughout the life span. Being aware of our own values and beliefs ensures that a non-judgemental attitude underpins all professional conversations about sexuality and sexual health. Expressions of sexuality and factors that impact on sexual health are extremely diverse. The role of the nurse includes discussing safe sex and risk-taking behaviour, testing for sexually transmitted infections, advising about contraceptive options, providing education about the impact of health conditions on sexuality and sexual functioning, undertaking preventive screening and vaccination and providing opportunities for patients to raise issues of concern to them. There are many excellent evidence-based resources to further develop knowledge

CLINICAL EXAMPLE

Sexuality and illness

Prior to surgery for bowel cancer, which will result in a permanent colostomy, a patient may not be thinking about the impact of the surgery on future sexuality; however, it is essential to discuss sexuality prior to surgery. Sexuality issues also need to be addressed after surgery, prior to discharge. Below is an example of some conversation starters to initiate discussion about their sexual concerns.

- 'Hello … when I admitted you last Monday, you mentioned to me that you have a partner. Can you tell me if you are sexually active?'
- 'Now that you are recovering from your surgery, I was wondering how you are feeling about your colostomy and cancer treatment and how this might affect your relationship with your partner?'
- 'It is common to have concerns about sexual intimacy, and how your partner might react to being sexually intimate with you after surgery.'
- 'The stomal therapy nurse will be coming today to discuss the management of your stoma when you get home. Would you like your partner to be involved as well?'

In reading the clinical example, did you consider the possibility that the client could be gay? If he normally engages in anal sex and has had his rectum removed, his current form of sexual behaviour will no longer be possible; and in addition to his further treatment for cancer, this could have a significant impact on his sexuality and quality of life. Nurses must always be aware that by not discussing particular issues they give a message that the issue is not important. Nurses are conscientious about providing information about medication management, wound management and dietary advice. Sexuality should be given the same consideration.

that will support the development of skills and confidence to address sexuality and sexual health.

Key concepts

- Sexuality is a unique experience for each person and is influenced by many factors.
- The nurse's role includes addressing sexuality and sexual functioning as part of holistic nursing care.
- Awareness of the diversity and importance of the sex lives of Australians and New Zealanders can increase the capacity of nurses to appropriately promote the expression of sexuality as an activity of daily living.
- Addressing sexuality and sexual health within the nursing assessment requires the nurse to develop skills in active listening and reflection and have a willingness to learn about different lifestyles.
- Nurses can provide confidential sexual health screening and non-judgemental care for sexually transmitted infections.
- Reproductive health choices and contraceptive needs vary across the life span.
- Nursing interventions include providing information about screening, prevention, immunisation, and impacts of health conditions on sexuality and sexual health that are targeted and relevant to the patient.
- Referral to appropriate services is an integral component of sexual and reproductive health care.

Online resources

Sexual health, HIV and family planning organisations have a wide range of information and resources for health professionals and many also offer clinical services for patients.

Learning outcomes

Mastery of content will enable you to:

- explain the physiological, social and psychological aspects of dying
- describe key approaches to care and support for the dying person
- discuss the care of the body following death
- define loss, grief, bereavement and mourning
- discuss the categories of loss
- describe normal grief patterns for adults
- describe normal grief patterns for children
- identify the ways nurses can address self-care in providing end-of-life care.

From the hour you're born you begin to die. But between birth and death, there's life.

Simone de Beauvoir (1908–1986)

Birth, living, dying and death – this is the inevitable cycle of the human condition. Life brings with it the unavoidable experiences of change, with gain and loss in a dynamic relationship with each other. Some losses are seemingly innocuous – a change of school, the loss of visual acuity with age, the gradual distancing of friends over time; while others, such as the unexpected loss of employment, the destruction of a home in a natural disaster or the death of a family member, are clear, tangible and sometimes traumatic events. Yet each loss, regardless of its apparent magnitude, brings with it a constellation of reactions that are both normal and laden with risk for those experiencing it.

Understanding the language and nature of loss and grief is an essential foundation to working with death and grief. Providing therapeutic benefits to those receiving nursing care requires us to confront the concept and reality of human mortality – that each of us will die. This can enable us to appropriately support those in our care who are nearing the end of their lives. It is not just the remit of palliative care services or aged care facilities to care for dying people; it is difficult to identify an area of practice where nurses will not have to provide care for people near the end of their lives. Learning and practising excellence in the clinical care of those dying and grieving can produce optimal outcomes for the most vulnerable in our communities.

Acknowledging our own reactions to the losses we observe in others during the course of our nursing practice can empower us to ensure our **self-care** is effective. Compassionate and skilful nursing practice when working with dying, death and grief provides an opportunity to promote the living to be done between birth and death and this is the focus of this chapter.

The physiological, psychological, existential and social aspects of dying

Palliative care services and aged care facilities are not the only settings of care where dying people are supported. Whether practising in midwifery, neonatal care, paediatrics, acute medical or surgical care, mental health, intensive care or accident and emergency, nurses will encounter dying people. The knowledge and skills required, therefore, are wide-ranging.

To understand the holistic nature of **dying**, it is essential to remember:

> **The experiences of serious illness, dying, caregiving, grieving and death cannot be completely understood within a medical framework alone. These events are personal, but also fundamentally communal. Medical care and health services constitute essential components of a community's response, but not its entirety (Byock 2001:760).**

In other words, your work as a nurse with a dying person and their family represents just one component of the whole experience of dying taking place. There are many changes that occur leading up to death. Sudnow (1967) made the influential suggestion that a dying person might move through four types of **death**: social, psychological, biological and physiological death (Box 22-1). This suggestion has endured and continues to underpin observations of withdrawal (Kellehear 2007). Of course, these components are artificially separated for the sake of learning about them – in reality, all are experienced to varying degrees at the same time.

The physiological changes experienced as a person nears death depend largely on the disease processes taking place. Historically, palliative care services emerged from cancer care; however, in the past decade

BOX 22-1 Four types of death

- Social death refers to gradual social withdrawal and represents the symbolic death of the person in relation to the world they have known. Both the individual and those who know them gradually drift away from one another.
- Psychological death refers to the death of aspects of the dying person's personality. Regression and varying degrees of dependency may occur as the illness progresses. Grief over losses, both physical and symbolic, leads to psychological death. Medications and illness bring on biochemical changes within the body, sometimes leading to a personality change, changes in relationships, isolation and invalidation. Rando (1984) suggests that 'In essence, the individual, as others know that person, dies.'
- Biological death is determined by medical criteria and refers to death in which the organism as a human entity no longer exists.
- Physiological death is the complete cessation of all functioning in the vital organs. Death is recognised when respiration and cardiac action cease. The pupils of the eyes become fixed and dilated and the skin on the face and extremities becomes cool to the touch. The time of death should be noted and documented and the attending doctor or medical officer informed. However, physiological death is not clear-cut; it is debated whether a person is actually dead when, for example, they are on a life-support system with biological function but are considered 'brain dead'.

Sudnow D 1967 Passing on: the social organization of dying. Englewood Cliffs, NJ, Prentice Hall.

or so, an acknowledgement of the application of palliative care principles and practices to end-of-life care for people without malignancy has become more evident (Addington-Hall & Higginson 2001). For example, if you consider the most recently compiled primary causes of death in Australia, you will see that most people do not die of cancer. The Australian Bureau of Statistics (2012) reported that, in 2010, the leading causes of death in Australia were cardiovascular and cerebrovascular disease (see Table 22-1). It is clear from this information that many of the leading causes of death were preventable, but it is important to note that a large proportion of Australian deaths are also predictable. That is to say, many of the people who died in 2010 were known to have had a disease or diseases that would inevitably lead to their death: cancer, chronic heart, lung, kidney or liver disease, dementia, and even stroke can have a trajectory where the death of the person can be predicted.

Key approaches to care and support for the dying person

Palliative care

The area of health care and nursing practice that specialises in the care and support of dying people and their families is called **palliative care**. The language and definitions of palliative care are continually evolving according to the cultural and social influences of the time – for example, there is reluctance in some settings to use the term 'dying'; to this end, you might read terms like 'people with life-limiting illness' instead. Nevertheless, there are some core definitions and themes of palliative care that have endured since the emergence of the modern hospice movement in the 1960s. The central goal of palliative care is to promote quality of life, even when cure is unlikely or impossible.

TABLE 22-1 Leading causes of death in Australia 2010

Cause of death	Number of deaths	Rank
Ischaemic heart diseases	21 708	1
Cerebrovascular disease	11 204	2
Dementia and Alzheimer's disease	9 003	3
Trachea and lung cancer	8 099	4
Chronic lower respiratory diseases	6 122	5
Colon and rectal cancer	4 056	6
Diabetes	3 945	7
Blood and lymph cancer (including leukaemia)	3 933	8
Heart failure	3 468	9
Diseases of the kidney and urinary system	3 315	10
Prostate cancer	3 235	11
Breast cancer	2 864	12
Pancreatic cancer	2 434	13
Influenza and pneumonia	2 364	14
Suicide	2 359	15
Skin cancers	1 897	16
Hypertensive diseases	1 734	17
Accidental falls	1 648	18
Cirrhosis and other diseases of liver	1 592	19
Cardiac arrhythmias	1 535	20

Data from Australian Bureau of Statistics (ABS) 2012 Causes of death, Australia 2010. Cat. no. 3303.0. Melbourne, ABS. Online. Available at www.abs.gov.au/ausstats/abs@.nsf/mf/3303.0; accessed 14 May 2016.

This is now a global message, articulated by the World Health Organization (WHO 2011) in this way:

> **Palliative care is an approach that improves quality of life of clients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychological and spiritual.**

The World Health Organization (2011) also states that palliative care:

- provides relief from pain and other distressing symptoms
- affirms life and regards dying as a normal process
- intends neither to hasten nor to postpone death
- integrates psychological and spiritual aspects of client care
- offers a support system to help clients live as actively as possible until death
- offers a support system to help the family cope during the client's illness and in bereavement
- uses a team approach to address the needs of clients and their families, including bereavement counselling if indicated
- will enhance quality of life, and may also positively influence the course of illness, and
- is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications.

Palliative approach

In some settings where end-of-life care is provided by non-specialists, this care is referred to as the 'palliative approach'. A **palliative approach** aims to improve the quality of life for individuals with a life-limiting illness and their families, by reducing their suffering through early identification, assessment and treatment of pain, physical, cultural, psychological, social and spiritual needs (Kristjanson et al 2003). This can take place in a number of settings of care, including residential aged care (McVey et al 2014) and in the community (Holloway et al 2015).

In Australia, Palliative Care Australia is the peak national organisation representing the interests and aspirations of all who share the ideal of high-quality care at the end of life for all. The equivalent organisation in New Zealand is Hospice New Zealand (see *Online resources* for details of both organisations). Hospice New Zealand (2015:5) states its core values as follows:

- Clients come first: every decision we make is based on this belief.
- Caring: we genuinely care about our people, clients and their families' needs.
- Respect: we demonstrate respect in all our dealings with clients and families, recognising diversity.
- Professional: in all instances we will act professionally and with compassion.
- Determination: we are driven to work in partnership with our members and communities as guardians of the hospice philosophy.

These peak bodies inform the health services and communities of their respective nations about dying, death and grief and the role of palliative care. In Australia, Palliative Care Australia has developed *National Standards for providing quality palliative care for all Australians* and Hospice New Zealand has developed a similar set of standards, available on their website (see *Online resources*).

What does 'quality of life' mean?

Whatever the approach or setting of care, the goal during palliative and end-of-life care is to improve the quality of life for clients, their families and carers by providing care that addresses their many needs, including physical (including treatment of pain and other symptoms), psychological, social and spiritual care. The aim is to help the person live as well as possible, even in the presence of advanced illness and expected death. Support is also offered to help family and carers manage during the client's illness and in bereavement. What 'quality' means in this context is typically defined by the client and their family or carers.

Settings of care

In the same way that nurses will care for dying people in all sorts of specialties and fields, so too will dying people be found in many settings of care. The majority of people in Australia and New Zealand die in hospital. For many, this is an expected death in the course of treatment of chronic and progressive disease. For others, death is the outcome of severe trauma or another lethal health event. In some hospital settings, non-palliative care clinicians are able to competently provide end-of-life care; however, many larger hospitals include a consultative specialist palliative care service or even a sub-acute palliative care unit, both of which provide specialist-level knowledge and care to hospital clients at the end of life.

A longstanding feature of modern palliative care is the presence of the **hospice** as a setting of care. Encapsulating

the philosophy of palliative care, a hospice is not simply a building but a program of support that may include medical and nursing care, respite care and end-of-life care for those unable to be supported at home to die (Palliative Care Australia 2008). Hospices are an alternative approach to traditional care. They are places where specially trained healthcare personnel care for people who are dying (Phillips et al 2014). The main reason for developing hospice-based services is a philosophy of care for the dying person that emphasises spiritual care, pain relief and control, and open communication between the dying person and carers. Physical, psychological, social and spiritual support underlies the philosophy. Although the guidelines may vary between jurisdictions, it is generally accepted that a hospice will accept clients with a life expectancy of less than 6 months.

Home is, of course, a place of care for people nearing the end of life and is a preferred place of death for most (Gomes et al 2013). In fact, most people in the final year of their lives will spend most of their time at home, not in hospital (Murray et al 2013). Community-based palliative care services, or the provision of a palliative approach (by primary care providers such as general community nurses and general practitioners), is a key strategy in supporting dying people and their families at home. It is clear that appropriate and effective home-based palliative care substantially increases the likelihood of a home death (Gomes et al 2014). Nurses can play a vital role in helping the dying person and their family assess their situation, arrange supportive infrastructure, and determine the adequacy of coping resources (Box 22-2). Deteriorating health, anxiety and uncertainty about the future pose difficulties for the client and family, and they will benefit from support in the form of domiciliary nursing services, or a home care/outreach program or respite care. **Respite care** is a form of care that provides time-out for the family while the client is cared for by a temporary caregiver. When the client dies, workers from the hospice team often visit the family. This is important for the survivor/s in grief work and eventually in making the transition to life without the deceased.

Home care can be a challenging practice setting for nurses, who need to be able to work largely autonomously and comprehend the social nature of health and illness in a multidisciplinary team, without the immediacy of the hospital infrastructure. Entering the home of another person, regardless of the intention to provide palliative care, places the nurse on another's 'turf'; the nurse is, in many ways, a visitor (Rosenberg 2011). How visitors to the home are viewed is also subject to cultural variations; some ethnic groups in Australia and New Zealand have strong cultural practices regarding welcoming visitors, while others may consider privacy to be paramount. Of course, these differences can occur between households and are not solely cultural in nature. Remember that the home is not always a place of loving kindness, supportive families and skilled family caregivers. Longstanding family conflicts, domestic violence, illicit drug use and other social problems can all be encountered by nurses practising in the home setting. Moreover, a small proportion of people dying at home have no family caregiver, or have an aged, perhaps frail spouse unable to cope with the physical demands of the caregiving role.

BOX 22-2 Suggestions for involving family in the care of a dying client

- Help plan a visit schedule for family members to prevent the client and family from becoming tired.
- Allow young children to visit a dying parent when the client is able to communicate.
- Be willing to listen to family complaints about the client's care and feelings about the client.
- Help family members learn to interact with the dying person (e.g. using attentive listening, avoiding false assurances, conducting conversations about normal family activities or problems).
- Allow family members to help with simple care measures such as feeding, bathing and straightening bed linen. Recognise that family members are often more successful than nursing staff in persuading the client to eat.
- When the family becomes tired with care activities, relieve them from their duties so that they can get needed rest and support. Refer them to resources for meals and lodging.
- Support the mutual act of grieving by the client and family. Provide privacy when preferred. Do not discourage open expression of grief by the family and client.
- Provide information daily with regard to the client's condition. Prepare the family for sudden changes in the client's appearance and behaviour.
- Communicate news of impending death when the family is together, if possible. Remember that members can provide support for one another. Convey the news in a private area and be willing to stay with the family.
- As death nears, help the family stay in communication with the dying person through short visits, caring silence, touch, and telling the client of their love.
- After death, help the family with decision-making, such as selection of an undertaker, transport of family members and collection of the client's belongings.

An increasing number of older persons spend the end of their lives in residential aged care facilities, or nursing homes. The Australian Department of Health and Ageing has provided *Guidelines for a palliative approach in residential aged care* (Department of Health and Ageing 2006). These guidelines provide comprehensive information regarding the application of a palliative approach to support the dying older person in a residential aged care facility, incorporating:

- dignity and quality of life
- advance care planning
- advanced dementia support
- physical symptom assessment and management
- psychological support
- family support
- social support, intimacy and sexuality
- Aboriginal and Torres Strait Islander issues
- other cultural issues
- spiritual support
- volunteer support
- end-of-life (terminal) support
- bereavement support.

It is important to remember that not everyone who is dying lives in these various care settings. People also do their dying in prisons, in shelters and public spaces, and in boarding houses and hotel rooms.

Advance care directives

As the person receiving care, the client is the most important partner in planning their care and managing their condition. Family and carers also have an important role in this area. When people are well informed, participate in treatment decisions and communicate openly with their doctors and other healthcare professionals, they help make their care as effective as possible. Care planning is an important process in ensuring the client's wishes in relation to care are met. Clients can anticipate their changing needs and specify their wishes for end-of-life care through **advance care planning**. This can be defined as a collaborative process between patients, families and healthcare providers during which preferences for future care are decided upon for when the patient is no longer able to articulate such wishes (see *Online resources*).

Advance care planning provides a mechanism to improve the quality of end-of-life care for people. It enables the coordination of their desired access to resources and services, to match their anticipated care needs. An *advance care directive* is the formal written documentation of this process. As with all aspects of palliative care, such approaches need to be tailored to the needs of the individual patient (Lovell & Yates 2014). Discussions about appointing a substitute decision-maker may also be important. This proxy decision-maker can be legally appointed with *power of attorney* for health matters if the patient is no longer considered legally competent.

Nursing priorities and goals for care

Assessment

Impeccable assessment is a fundamental component of nursing practice in the care of dying people and there are many ways in which the clinical assessment of palliative care clients can be documented. Regardless of what is in use in each setting of care, a good-quality palliative care assessment tool will address the physiological, psychological, social and spiritual complexities being experienced.

One example of such an assessment tool is the 10-page palliative care client information form from Queensland Health (Figure 22-1) (see *Online resources*). This is a standardised electronic and hard-copy document that represents consensus best practice regarding admission data required for palliative clients managed across inpatient and community settings by public, non-government and private service providers.

The form has been developed with the aims of:

- decreasing the need for unnecessary client reassessment
- decreasing duplication of clinician effort
- facilitating seamless transition of care
- improving communication between organisations
- supporting appropriate and timely referral patterns.

The palliative care client information form is used to record and confirm client information on admission to a palliative care service. The form can also be used to transfer information during discharge and referral to other service providers as a means of facilitating the admission process for those services, and for the provision of feedback to service providers. This enhances communication regarding a client across the care continuum.

The likely benefits of utilising such a form include:

- smooth and timely transitions of client care across and within services
- standardisation of information collection and presentation across and within services
- improved clinical time efficiency
- its contribution to a basis for palliative care data collection.

Figure 22-1 ***continued***

This form makes it obvious that the complex needs of many palliative care clients require sound nursing interventions. These are the subject of detailed discussion throughout this textbook and specialised palliative care nursing textbooks. A brief summary of the main points is given in Table 22-2.

Care of the body following death

Nurses have a unique role in the care of the body following death, and that is to maintain the dignity and respect of the person who has died (Martin & Bristowe 2015). A number of procedures are carried out within physiological, legal or cultural parameters. In many cultures, deaths are acknowledged by viewing the body. When this is carried out formally, it is psychologically important for the next-of-kin that the deceased appears clean and comfortable. This lessens anxiety and distress and epitomises respect for the dead (Howarth 2007, Mooney 2003). Once circulation of the blood stops, the body begins to cool. As the skin cools it loses its elasticity, and therefore tapes, dressings and medical appliances are removed with caution to prevent tearing of the skin or bruising occurring.

TABLE 22-2 Promoting comfort in the seriously ill client

Characteristics or causes	Nursing implications	Special considerations
Pain		
Pain can be acute or chronic (with acute exacerbations)	Administer narcotic and adjuvant analgesics on a regular schedule (see Chapter 36) Administer prn medications as indicated	Not every person with advanced disease experiences pain Impeccable pain assessment is essential to high-quality nursing practice
Pain from advanced disease is often chronic	Use combinations of analgesics or other therapies as client's needs change Use relaxation, guided imagery, distraction and peripheral nerve stimulators to provide relief Administer narcotics as ordered (oral route for narcotics is preferred, but other routes including transdermal patches and continuous intravenous infusions are available)	A person with advanced disease may have more than one kind of pain, requiring multiple strategies to obtain relief Refer to the World Health Organization's three-step pain ladder (WHO 2016)
Any source of physical irritation may worsen pain	Minimise irritants through skin care, including daily baths, lubrication of skin, frequent repositioning and dry, clean bed linen	If pressure area care causes pain, consider use of breakthrough analgesic prior to procedure Unattended skin lesions can be a source of preventable pain
As client approaches death, mouth remains open, tongue and lips become dry and cracked	Provide frequent oral care every 2–4 hours. Use soft toothbrushes or foam swabs for frequent mouth care. Use plain water sprays or atomisers as desired. Artificial saliva products can be used. Apply light film of petroleum jelly to lips (see Chapter 29)	Mouth swabs containing lemon and glycerine exacerbate oral dehydration and are not recommended for use
Blinking reflexes diminish near death, causing drying of cornea	Remove crusts from eyelid margins and provide eye care. Reduce corneal drying with artificial tears	
Fatigue		
Metabolic demands of advanced disease cause weakness and fatigue	Set mutual goals with client after identifying valued or desired tasks, and conserve client's energy for only those tasks Time and pace nursing activities to conserve client's energy Provide frequent rest periods in quiet environment	Fatigue is one of the most common symptoms in people with advanced disease, including cancer and neurodegenerative disorders such as motor neuron disease and multiple sclerosis

continued

TABLE 22-2 ***continued***

Characteristics or causes	Nursing implications	Special considerations
Ineffective breathing patterns		
Causes include disease progression involving lung tissue capacity, pneumonia, pulmonary oedema or anaemia	Position client upright to improve breathing capacity Administer supplemental oxygen as ordered Administer bronchodilator as ordered Administer narcotics as ordered to suppress cough and ease breathing and apprehension Administer anticholinergic agents as ordered	Where dyspnoea is reversible, there can be a strong case for intervention given the degree of distress caused Suctioning can cause distress and is generally avoided; oral suction may be tolerated Anticholinergic agents (such as hyoscine) can dry oral secretions
Dehydration		
As disease progresses, client is less willing or able to maintain oral fluid intake	Provide relief of thirst by using ice chips, sips of fluids or moist cloth to lips	
Inadequate nutrition		
Nausea and vomiting can decrease appetite	Suggest that smaller portions and bland foods may be more palatable Suggest home-cooked meals, which may be preferred by client and gives family chance to participate	Meals often have strong symbolic value in family – loss of appetite can cause distress as it represents the person's inevitable deterioration
Nausea and vomiting		
Nausea and vomiting may result from disease process (e.g. gastric cancer), complications (e.g. bowel obstruction) or treatment, including medications	Confer with doctor about changing medications when possible Administer antiemetic before meals Consider providing relief from obstruction with bowel decompression with insertion of nasogastric tube Provide mouth care and promptly clean up emesis	Nausea and vomiting are common side effects of narcotic analgesics
Constipation		
Narcotic medications and immobility slow peristalsis Lack of bulk in diet or reduced fluid intake may occur with appetite changes	Provide preventive care, including increasing fluid intake (e.g. bran, whole-grain products and fresh vegetables in diet) and encouraging exercise Assess and monitor bowel function closely	Impeccable assessment of bowel function underpins improved outcomes for patients: a complete bowel history, with auscultation, palpation and digital rectal examination, are essential components of nursing assessment
Diarrhoea		
Diarrhoea may result from disease process (e.g. colon cancer) and complications of treatment or medications	Assess for faecal impaction with overflow Confer with doctor to change medication if indicated Provide low-residue diet Assist with personal hygiene as required	Compromised mobility may exacerbate anal excoriation from diarrhoea
Urinary incontinence		
Urinary incontinence may result from advanced disease (e.g. involvement of spinal cord or reduced level of consciousness)	Protect skin from irritation or breakdown using absorbent pads and clean linen Prepare for possible use of indwelling urinary or condom catheter	

prn = 'as needed' (Latin: pro re nata*).*

World Health Organization (WHO) 2016 WHO's pain ladder. WHO, Geneva. Online. Available: www.who.int/cancer/palliative/painladder/en/; accessed 11 Feb 2016.

If the deceased is not the subject of a coronial inquiry, care of the body involves the nurse removing indwelling catheters and other medical appliances from the body. Jewellery or other personal adornments are also removed if requested by the next-of-kin. At the time of death, the muscles relax and the contents of the stomach, bladder and bowel may be released; this necessitates washing the body. This is a sensitive area of nursing practice as the next-of-kin may complain if the body, when it is viewed, looks or smells as if it has been neglected during the last moments of life. If the body is to be viewed by family or others, the body must be positioned before rigor mortis begins.

The procedure recommended by Docherty (2000) is that the eyes are closed and gentle pressure is applied to the eyelids for about 30 seconds. Wounds, open sores or pressure areas are covered by simple dressings. McNamara (2001) has noted that although bodily orifices are sometimes packed with cotton wool or gauze ribbon to prevent leakage of fluids, this is not the case in all organisations. The teeth or dentures are cleaned and the dentures replaced in the mouth to retain the shape of the face. The hair is groomed, fingernails are cleaned and men are shaved. The lower jaw may be supported with a bandage that wraps around the head to keep the mouth closed. Limbs are positioned, tied in place and identification tags are attached. The body is swathed in a shroud, placed in a body bag and delivered to the mortuary (Quested & Rudge 2001).

Washing, laying out and dressing the body for burial has always been recognised as the final service the living can perform for the dead before burial or cremation. This procedure is considered a mark of respect to the deceased, and it is important to remember that modesty and privacy must be maintained throughout the procedure. Religious and/or cultural preferences may demand specific steps in the care of the body after death. Sometimes this involves specific people caring for the body after death, or parents or families may wish to dress the deceased in special clothes, or may wish special toys to accompany the body of a child. It is, therefore, vital to discuss these requirements with family members, preferably before the death if possible (Mooney 2003).

Loss, grief, bereavement and mourning

No one is immune to the effects of loss at some time during the course of a lifetime. When nurses care for those who are experiencing reactions to loss, they will find wide-ranging behaviours and, perhaps, confronting encounters with people in distress. For many nurses these reactions are the source of concern, either through empathy for the suffering of others, or from a sense of inadequacy in dealing appropriately with the situation. For nurses who are new to their practice, it can be tempting to rely on standard problem-solving techniques and responses learned by rote, but these may not always be possible or desirable in times of crisis. Frequent encounters with death have been found to be the most challenging and intensely personal experiences of those working in the healthcare environment (Currow 2004, Kearney et al 2009).

Clearly, it is important for nurses to have an accurate understanding of the key terms in this field: *loss*, *grief*, *bereavement* and *mourning*. Sometimes these terms are colloquially used interchangeably, and certainly can be used in varying cultures and communities in different ways. However, the foundations for understanding rest in these definitions.

Loss refers to that state that exists when something to which one has an attachment is now gone. While commonly used to describe the experiences of people following the death of another person to whom they are emotionally or socially attached, it also applies to any loss experienced following detachment: for example, burglary with theft of personal possessions; miscarriage; divorce; the loss of functional independence with chronic illness or injury; the loss of dignity, privacy and confidence that may accompany relocation into a residential care facility. Types of losses are explored in more detail below.

RESEARCH HIGHLIGHT

Research focus

Constipation is a frequent and distressing symptom for people with advanced and incurable disease. As it is a highly subjective experience, constipation requires diligent nursing assessment and individualised intervention. The application of best available evidence and expert opinion to the clinical practice of nursing for the management of constipation can reduce discomfort and distress in palliative care patients.

Research abstract

Constipation is best defined in two ways. First, defecation at a frequency of less than three times a week can be diagnostically significant (Heidrich 2007, Larkin

continued

et al 2008). In the same way, the characteristics of stool (such as consistency) can also be measured (e.g. using the Bristol Stool Form Chart; see Chapter 32). However, this definition cannot be applied to all people, as there are such wide variations in what can be considered 'normal' patterns of bowel function. Second, defining constipation requires an individualised assessment of frequency, consistency and effort required. A more helpful definition of constipation is 'the passage of small, hard faeces infrequently and with difficulty. Individuals vary in the weight they give to the different components of this definition when assessing their own constipation and may introduce other factors, such as pain and discomfort when defecating, flatulence, bloating or a sensation of incomplete evacuation' (Larkin et al 2008:798).

A principle-based approach to symptom management in palliative care is recommended (Connor & Muir 2007, Larkin et al 2008, Palliative Care Expert Group 2010). This offers an effective approach to nursing assessment and intervention for the constipated patient:

- A detailed history of the patient's bowel patterns to identify possible causative factors should be taken (Joanna Briggs Institute 2008, Larkin et al 2008).
- A physical, clinical examination of the patient is essential, examining the oral cavity; observing, palpating and auscultating the abdomen; examining the anus and performing a digital rectal examination (Terelinck 2005).
- Preventive strategies should be introduced in this at-risk group as early as possible (Larkin et al 2008); certainly as soon as narcotic analgesics are introduced. Close monitoring of bowel patterns and early intervention in constipation is optimal. Increasing dietary fibre and oral hydration can be difficult in palliative care patients, as a reduction in fluid and fibre intake is commonplace; intravenous rehydration alone is typically not enough to resolve constipation without the use of laxatives (Larkin et al 2008, Sykes 2006). Similarly, even gentle exercise to manage constipation may be problematic for palliative care patients as mobility decreases. The patient can be encouraged to mobilise within their limits of safety and tolerance; range-of-motion exercises may be beneficial to the immobile patient (Heidrich 2007).
- Oral laxatives are divided into four groups – stool softeners, peristaltic stimulants, osmotic agents and bulking agents. While the clinical evidence is not strong, a combination of laxatives is most effective in palliative care (Joanna Briggs Institute 2008, Palliative Care Expert Group 2010); there appears to be no apparent relationship between opioid dose and laxative regimen (Droney et al 2008), which again underscores the importance of individualised assessment.
- Rectal treatments – it is again important to link the treatment to the information obtained at assessment. A microenema, or simple lubricating suppositories (such as glycerol) or those containing stimulants to effect rectal peristalsis (such as bisacodyl suppositories or microlax enemas), may be effective. Regardless of the type of rectal treatment, adequate lubrication, caution in insertion, and ensuring fluid is at body temperature are essential considerations; similarly, the acceptability of rectal treatments may vary from person to person (Larkin et al 2008). Where rectal disease is present, high enemas should not be used as they pose the risk of perforation of the bowel.

Evidence-based practice

- Constipation is a highly individualised experience, best defined by the patient describing the variation from their normal patterns of bowel function.
- Comprehensive nursing assessment is essential to effective intervention.
- Nursing management of constipation must be linked to assessment findings; while preventive measures may have some effect, oral laxatives such as those that combine a stool softener and peristaltic stimulant are often an appropriate intervention. Rectal treatments are invasive and uncomfortable and should only be implemented when other interventions are ineffective.

The multifaceted assortment of reactions to the experience of loss is called **grief**. Grief reactions are complex, and experienced with interrelated physical, emotional, behavioural and cognitive aspects. Raphael (1999:22) once described grief as 'an inevitable consequence of the intensity of human attachments'. Grief has been described as the price we pay for love and investing ourselves in others. Grief has the power to upset the body's stability, which is vital to our sense of self (Freeman 2005) and may manifest itself in ways that are disruptive and disturbing to the person experiencing it. Grief is both unique to each person and a highly complex sociological phenomenon. Grief varies enormously from one person to another and sometimes between men and women, and may be hindered or helped by the support offered.

Bereavement is a term referring to the objective state of having lost attachment to something of value and is *situational* and *tangible*. In Australia and New Zealand, the word bereavement is largely used to apply specifically to a person who has a relative or friend who has died, although this usage varies. Therefore, it is possible to refer to someone as 'bereaved' – such as a widow or widower – who may not be actually 'grieving' if their adjustment to their changed circumstances has resolved.

The cultural and social practices around the expression of grief and bereavement are collectively known as **mourning**. These are influenced by culture, religious affiliation, family expectations, personality and other factors. Mourning typically possesses a ritualistic quality. Martin and Doka (2000:151) indicate that ritual is best defined as 'special acts that offer sacred meaning to events'. Funerals are rituals; they provide visual confrontation of the death, social support, a safe haven for the bereaved, rites of passage for the deceased and a way of disposing of the body. For thousands of years people have relied on some form of ritual to mark human death and fulfil the vital psychological, spiritual and social needs of the bereaved. Ceremonies have formed part of mourning and burial rituals for tens of thousands of years of human history (Howarth 2007, Kellehear 2007).

In recent decades traditional forms of mourning have become less prevalent, with more informal and secular practices increasing in popularity. For example, in Australia and New Zealand, fewer people are opting for traditional funerals in churches. Instead, secular events facilitated by a civil funeral celebrant in non-consecrated settings are seen more often. While predominantly secular in nature, these ceremonies can still have ritual power. Recent incidents of mass death of younger persons, such as in the 2003 Bali bombings, saw secular mourning rituals played out on football fields and in 'surf circles' (Figure 22-2) throughout the region (Rosenberg 2009).

Categories of loss

It can be helpful to think about different categories of loss. Loss may take many forms and does not simply describe the loss of a person through their death. Understanding the categories of loss (below) enables the nurse to anticipate the likely lived experience of the client. This in turn can enable the nurse to respond appropriately and sensitively to the client's reaction to their loss.

- *Actual loss* describes the change to a person's situation that follows when something to which one has an attachment is now gone. For example, bereavement is usually a description of the actual loss of a person through death, such as a spouse, partner, family member or friend.
- *Perceived loss* is more difficult to identify, as it is less obvious to the observer. The loss of dignity, modesty, freedom, confidence, prestige or self-esteem are all examples of perceived losses. It is easy to see how a client in an unfamiliar hospital setting might react to these perceived losses and their subsequent vulnerability.
- *Maturational loss* occurs as a result of normal life transitions; for instance, when a child goes to school for the first time or leaves the family home. The sense of loss may be profound for both child and parents. The loss experienced upon retirement may weigh heavily on the person whose sense of identity has rested on their role as primary wage earner.
- *Situational loss* occurs in response to sudden, unpredicted and specific events that have the capacity to threaten and immobilise a person's physiological, psychological and social equilibrium. Some frequently documented and commonly encountered situational losses include divorce, separation from the family, childbirth, life-threatening or chronic illness, and death. Situational loss also includes the multiple losses caused by man-made or natural disasters – such as terrorism, flooding and fire – where survivors must

deal with losses that are enough to overwhelm them and render them, their families and communities helpless.

Normal grief patterns for adults

People's reactions to loss are varied and highly individual; however, a number of patterns can be identified that are considered 'normal'. Sadness, anger, fear, anxiety and denial are common reactions to loss and can sometimes represent adaptive responses to stress. It is, however, important to note that the grieving person does not necessarily experience all of them. Freeman (2005) and Corr et al (2003) suggest that responses from physical, behavioural, cognitive, emotional and spiritual domains may be manifested during the grief experience (Box 22-3).

Theories of grief and loss

There have been some ground-breaking grief theories that have helped us gain better insights into people's experiences of loss. The early work of Sigmund Freud (1856–1939) introduced three significant concepts that influenced 20th-century thinking about grief:

- a *developmental perspective* – that as children develop, they change in their reactions to loss
- the idea of *grief work* – the process of withdrawing emotional attachment to the object of loss, and
- that grief and depression are *distinct phenomena*.

Freud's work was influential in subsequent attempts to describe the experience of grief. An important contribution was made by John Bowlby (1907–1990), who proposed that a person's reaction to loss is underpinned by a sense of violation of their attachment to the lost object. Bowlby went on to describe four phases experienced following loss: *numbing*, *yearning*, *disorganisation* and *reorganisation*. Importantly, Bowlby noted that these phases do not happen in a set order, and this is an important concept to grasp in understanding grief (Cobb 2008). Similarly, Colin Murray Parkes (b.1928) explored grief as a transition between a world that is assumed to be known and stable, and one in which control is lost as the bereaved person adjusts to a new reality. Parkes also described phases, using the terms numbness, pining, depression and recovery, to describe normal patterns of grieving. Again, Parkes notes that these phases do not necessarily occur as a linear process (Cobb 2008).

Perhaps one of the best-known grief theories has emerged from the work of Elisabeth Kübler-Ross (1926–2004), a Swiss-American psychiatrist who interviewed dying people to better understand their experiences as their lives came to an end (Kübler-Ross 1969). In its application to bereavement, Kübler-Ross's theory proposes that people move through stages of grief not unlike the phases suggested by Bowlby. This theory has gained tremendous traction both with healthcare professionals and with the general public, and is often assumed to be the most accurate description of 'normal grieving'. However, all theories are subject to criticism and this bereavement theory has been strongly criticised for assuming that stages of grief take place sequentially. Payne et al (1999) have provided a comprehensive critique of this model.

In his pioneering work in the area of grief and loss, William Worden (b.1932) proposed that the grieving person faces four 'tasks of mourning' that contribute to their adjustment to their loss:

1. To face the reality of the loss.
2. To experience the pain of grief.
3. To adjust to a world without the deceased.
4. To emotionally relocate the deceased and move on with life in a new reality (Worden 2009).

Over time, Worden has amended this fourth task to reflect the important and ongoing nature of remembrance,

BOX 22-3 Manifestations of the grieving experience

Physical

Hollowness in the pit of the stomach, tightness in the chest or throat, muscular weakness, lack of energy, dry mouth, insomnia, depression, generalised anxiety, loss of appetite, anhedonia (absence of pleasurable experience), sense of depersonalisation ('Nothing seems to be real, including me').

Behavioural

Withdrawal from others, dreams of the deceased, searching and calling out, sighing, loss of interest in normal events, increased consumption of tobacco and alcoholic beverages, startled reactions, crying and difficulties sleeping, a wish for isolation, suspiciousness.

Cognitive

Preoccupation with the deceased, intrusive thoughts, disbelief, calculation difficulties, confusion, images about death, nightmares, decreased attention span, sense of presence and hallucinations, or decreased interest, motivation, initiative or direction.

Emotional

Anger, guilt, depression, anxiety, loss of confidence, sadness, fear, numbness, remorse, loneliness, relief, frustration, fear of going crazy, self-reproach, panic.

Spiritual

Search for meaning, doubt about the importance of anything, hostility towards God or experiencing a crisis in faith.

recognising that 'moving on' or 'getting over it' is no longer the goal of mourning, but rather that the adjustment to changed reality is an ongoing process. Worden's fourth task of mourning has been rephrased as 'to reinvest energy in life, loosen ties to the deceased and forge a new type of relationship with them based on memory, spirit and love'. It is essential to remember that there is no 'magic' period of recovery from loss and most people will experience an enduring relationship with the deceased.

• CRITICAL REFLECTION POINT

Think about an experience of bereavement in your life, and consider Worden's 'tasks of mourning'. Ask yourself the following questions; you may like to write down your answers for your own reflection.

To accept the reality of the loss:

1. **How do you remind yourself that the loss you have experienced is real?**
2. **What reminders are there in daily life that your loss is real?**

To experience the pain of grief:

3. **What feelings, thoughts and sensations have you experienced since your loss?**
4. **How have they affected your ability to go about your life?**

To adjust to the new environment where the deceased is missing:

5. **In what ways has your life changed since the loss?**
6. **Will these changes be temporary or permanent?**

To reinvest energy in life, loosen ties to the deceased and forge a new type of relationship with them based on memory, spirit and love:

7. **What would you say to the person you have lost if you were writing them a letter?**
8. **How did you (or could you) honour their memory?**

Each of these attempts to describe the nature of grieving may be helpful, but should be embraced with caution by nurses and others. Indeed, some argue that applying standardised models of bereavement can be the source of depersonalised care that devalues the experience of the griever (Cobb 2008). Grieving is a highly individual phenomenon, influenced by personality, culture, family and other contextual issues, and any model must not be considered prescriptive of the process. Models are useful to provide frameworks for understanding the experiences of loss and grief, but are never a checklist or 'recipe' for caring for people who are bereaved.

Grief and gender

Some discussion has taken place regarding gendered differences in grieving patterns (Doka & Martin 2010, Millan 2010, Rosenberg 2009). Most cultures provide social sanctions for the expression of emotions such as sorrow and anger, which often differ between men and women. Emotions expressed by people of one culture may not necessarily be sanctioned in another; for example, in many Western cultures men have been socialised not to cry and society discourages men from the public expression of tears (Golden 1996). A notable exception to these gendered expectations in Australia and New Zealand can be found in the sanctioned grieving and memorialisation on ANZAC Day, where fallen soldiers are commemorated and returned soldiers honoured. In this setting, the public expression of emotion by men in the context of grieving is considered acceptable (Rosenberg 2009), although we often still hear men apologise for their displays of sadness. In Australia and New Zealand, then, certain assumptions about gender are popular. We have a stereotypical picture, for example, of the stoic, controlled man whose grieving is intensely private. We have an impression, perhaps, of the grieving woman who shares her feelings readily and finds great solace in the connections she makes in a grief support group. Are there ways of grieving that are more 'masculine' or more 'feminine'? Are gendered boundaries of grieving changing? Consider the assumptions listed in the *Critical reflection point* below.

• CRITICAL REFLECTION POINT

In your experience, do these assumptions about gender and grieving hold true?

Women talk readily about feelings.	**Men are stoic and appear to lack feelings.**
Women tell and retell their stories to make sense of it.	**Men know the story is etched in their mind; no need to be reminded.**
Women seem to *feel* their way through grief – emotions are the pilot.	**Men tend to *think* their way through grief – intellect is the guide.**
Feminine language is often described as intuitive, earthy, fluid.	**Masculine language is thought to be orderly, concise, controlled and goal-orientated.**
Women focus on connection, intimacy and interdependence.	**Men focus on independence, self-reliance, less self-disclosing, less expressiveness.**
Women seek companionship, including groups.	**Men appreciate time alone to think it through.**
Women are more amenable to demonstrative expression of feelings in group work.	**Men are more likely to benefit from being left alone to work through their grief.**

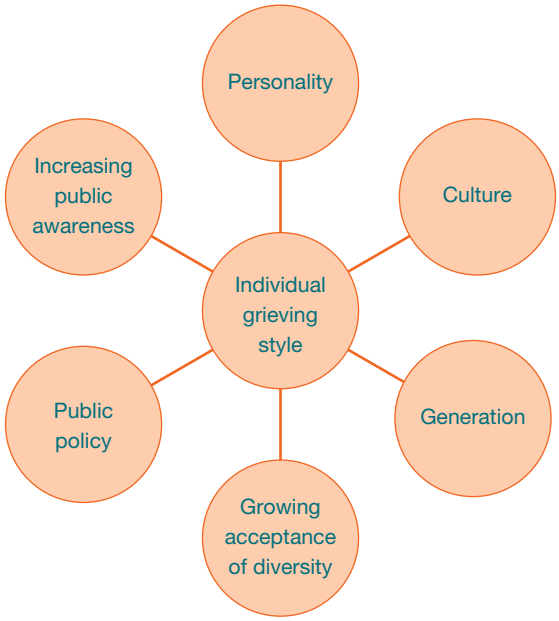

Figure 22-3 **Factors in gender and grieving.**

In reflecting on these assumptions, it would be fairly easy to identify a number of people for whom they simply do not apply, for example, a woman who is intensely private in her grieving, or a man who is demonstrative and open about his feelings of sadness. Most grieving people will sit, and sometimes move, between these two extremes and it can be helpful to conceptualise grief patterns and gender along a continuum, rather than as two mutually exclusive boxes.

Yet this continuum is not 'female ↔ male' or even 'feminine ↔ masculine'. Grieving is not really about gender, but about individual styles, and is in a constant state of change. Figure 22-3 illustrates a number of factors that influence how an individual might grieve. Importantly, these factors themselves are dynamic and changing; for example, cultural norms for mourning behaviour in a second-generation Australian may have been modified by assimilation.

Individual grieving styles

Another way of understanding individual grieving styles comes from considering differing styles on a continuum 'intuitive ↔ instrumental' (Figure 22-4) (Doka & Martin 2010). The characteristics of each end of this continuum are described below.

The intuitive griever

An intuitive griever's adaptation to loss is shown through their lived experience of grief and their expression of feelings. Individuals typically benefit from connection with others, sometimes in groups. As many of these characteristics have been assumed to be 'feminine', some male intuitive grievers may seek validation that their grief reaction is 'normal for a man'. The *intuitive griever*:

- experiences intense feelings of loss
- will talk to process feelings
- demonstrates outward expressions such as crying and lamenting, which mirror their inner experience ('wear your heart on your sleeve')
- may experience prolonged periods of confusion, inability to concentrate, disorganisation and disorientation
- often feels physically exhausted and/or highly anxious.

Intuitive grievers are at risk of slowing their own progress towards adjustment, as their empathy for others can distract them from their own needs. Moreover, as intuitive grievers rely on relationships and interconnection to navigate their grief, they can focus fully on this process at the cost of their health and usual activities.

Figure 22-4 **The continuum of gendered grieving.**

The instrumental griever

At the other end of the continuum is the *instrumental griever*. Instrumental grievers typically use problem-solving as a strategy to enable mastery of their feelings and control of the environment in creating their 'new normal'. Not always isolated, their connections with others can be made by 'doing with' rather than 'sharing with'. Female instrumental grievers can be judged as 'cold' or 'uncaring' because their grieving doesn't necessarily include crying. The *instrumental griever*:

- experiences feelings, but these are less intense and less obvious
- tends not to cry, although may feel pressure to do so
- considers mastery of their feelings and recovery as important; controlling their behaviour is valued
- talks to process issues, not feelings
- commonly experiences brief periods of cognitive dysfunction – confusion, forgetfulness, obsessiveness
- often has enhanced energy levels; 'doing stuff' is an outlet.

The risk for instrumental grievers is that because their grieving style is less obvious, they can in fact be leaving their grief unattended to, and poor health outcomes can eventuate as a result. Significantly, both intuitive and instrumental grievers can experience prolonged periods of confusion, inability to concentrate, disorganisation and disorientation as a normal reaction to grief. It is important to remember that while people will usually

demonstrate predominantly one or the other tendency on this continuum, most sit somewhere in between, in a 'blended' mix of the two.

Normal grief patterns for children

Understanding of death and responses to loss and death vary according to age. Like adults, children are not immune from grief reactions to loss and bereavement. Understanding the psychological and emotional development of a child is essential to the provision of support that is appropriate to each child's developmental stage (see Chapters 16 and 17). Children experience age-related constraints on their ability to comprehend and deal with loss (Piaget 1970). All children move through cognitive developmental stages in a set sequence; however, the rate of cognitive development varies among children. Although children may not totally comprehend the concept of death at an early age, it has been argued that they do experience separation anxiety and a perception of what it is to lose something or someone. As the child grows, an understanding of what it means to die develops (Table 22-3), and this conceptual understanding continues through middle to old age where the loss effect is diminished.

There are certain patterns in the sequence of stages in children's responses to death:

- children do not advance from one stage to another simply because it is their birthday
- children advance through each stage in the prescribed order
- children never skip a stage
- children may exhibit cognitive aspects of both stages as they exit one stage and enter another
- adolescent children (and, on odd occasions, adults) may rely on lower levels of thinking, even though they are capable of advanced reasoning
- the stages are universal, irrespective of culture.

Personal experience is also an important component of human development. It is crucial to shaping an individual's attitudes and behaviours, and this is particularly relevant in terms of each person's experience with death, dying, grief and bereavement. Coming to terms with loss entails a personal quest by the survivor to make sense and meaning of the loss experience – consider Worden's tasks of mourning discussed above. It is also a time for putting the loss experience into perspective, re-evaluating previously held knowledge, beliefs and attitudes, and moving on. This is largely influenced by

TABLE 22-3 Children's responses to death

Birth to 2 years	2–5 years	5–8 years	8–12 years
Lacks a conceptualisation of death.	Has a basic understanding of 'dead'.	The child's notion of causality has developed and evolved.	The child's understanding of death has become equivalent to that of the adult.
Loss and grief may be evident in the form of separation anxiety.	Denies death as a normal process.	The child begins to understand that death is final and irreversible.	Understands that death is universal, irreversible and inevitable.
Infants between the ages of 6 months and 2 years demonstrate the beginnings of grief and mourning.	The child has difficulty in grasping the permanency of death.	The child understands that death is a natural process and that it happens to everyone.	Fears and defences towards death are developed.
	There is a matter-of-fact curiosity about death.	There is a development of the child's sense of guilt at having in some way caused the death.	Difficulty accepting their own future death.
	Magical thinking about death predominates.	The child uses words or drawings to communicate their understanding of death.	Reverts to egocentric and magical thinking during the stress of the crisis.
	Displaced anger and angry protests may be observed following the death.	The child may resort to denial as a defence when experiencing the trauma of loss.	Becomes aware of the implications that loss will have in the future.
	Sees death as reversible.	May take on a 'caregiving role' and become more 'self-reliant'.	May invent a fantasy relationship to help deal with the trauma of the loss.
	May respond in a similar manner to that of the parents.	The child feels the vulnerability that accompanies death.	May resort to telling stories and jokes about death to hide fear and anxiety.
			Grief and mourning are often disenfranchised, causing a change in behaviour.

how people perceive their social world and their place in it. During bereavement, four factors which develop throughout childhood, adolescence and young adulthood help condition emotional responses: personality, social roles, personal values and perception of the importance of the deceased.

Personality

Put simply, behaviour is the way one conducts oneself. The personalities of individual human beings are often consistent, and reveal qualities in their behaviour, which in many respects can be predicted. For example, some people will shy away in some circumstances while others will, perhaps, be aggressive, warm or outgoing. People have learned to count on certain behaviours in those they know, for example, family members and close friends.

By assuming that a person will react in a certain way, the implication is that we have certain knowledge about that person's personality. A working definition of personality is proposed by Clarke (1995) as 'a dynamic compilation of instinctual emotional predispositions and psychological factors which, when combined, determine our unique adjustment to the environment'. Personality is unique to the person, yet relatively stable across a lifetime. It is a concept referring to the person as a unified whole and not just a part of the person (Peterson 2004). If a person has consistently run away during crises over the course of their lifetime, then it is highly likely that person will behave in the same manner during a time of grief. Alternatively, a person with high self-esteem and self-concept and a positive approach is well placed for a healthy resolution in a grieving situation.

Social roles

Everyone has social roles they fulfil. In a family, everyone has interdependent roles, and members depend on one another for support, nurturance, guidance and social interaction (see Chapter 15). Following the death of a family member, losses resulting from the unoccupied role become apparent and are grieved for. Adaptation to the loss may become increasingly difficult as new roles are assigned and extra demands and new responsibilities are absorbed. Death of any close friend or relative is a time for struggling with loss, and it is seldom clear at the time exactly what is lost. This can be particularly apparent if a person has lost a parent.

Personal values

A person's value system represents personal beliefs and attitudes about the worth of different experiences and possible outcomes. Values are shared ideas about what is good, right and desirable, and are learnt in a number of ways. For example, moralising (a direct but subtle way of inculcating preferred values in someone else); *laissez faire* (values are determined on an individual basis); modelling (the actions of someone else are copied); and value clarification (learners are taught the process of valuing). Everyday life situations that call for opinions, thought, decision-making and action challenge each person. Each time a decision is called for, a choice has to be made based on the values that are held. A person's values will have an enormous impact on that person's experience of the death of another, as well as on their own death. Children will often mimic the apparent values of their parents, although as they move into adolescence they are more likely to adhere to peer-group values.

Perception of the deceased person's importance

A further factor in the grief response is the importance of the deceased person, or the place the deceased person held in the survivor's life. For adults, the loss of a spouse or partner (for example) may or may not mean the loss of a best friend, sexual partner, companion, accountant, gardener, baby-minder, audience, breadwinner, and so on, depending on the particular roles normally performed by this partner. In addition, relationships as complex as marriages vary in terms of the levels of loving or caring shared between the partners. For children, however, the loss of a parent can violate the child's sense of safety, or remove a source of affection and direction; equally, the loss of a peer can confront a child's sense of their own mortality and expedite their movement through elements of the developmental stages. Generally speaking, the closer the perceived relationship, the stronger the grief response.

Complicated or high-risk grief

There is some expectation in society that those who are grieving will eventually 'get over it' and return to their previous state of functioning. Some people who are grieving become distressed when they don't 'feel better' 12 months after the loss. However, rather than framing the outcome of grieving as 'resolution', it can be helpful to understand it, in the terms put forward by Worden, as *the process of readjustment to a changed reality*. For many people, however, this readjustment can be compromised by a number of factors that place them at high risk of ongoing emotional instability or withdrawal from usual tasks or activities that were once viewed as meaningful.

It has been proposed (Payne 2008) that the risk factors for complicated grief are influenced by a range of factors that are considered below:

- the circumstances of the death
- the meaning of the relationship with the deceased
- the internal resources of the bereaved, and
- the quality of social support and other external resources.

Many people in our society expect to live a long life with a peaceful death at its conclusion and the *circumstances of the death* may indeed follow this pattern. While this is the experience of some, a number of people find themselves expecting the death of a family member or friend. In this case, anticipated death can provide opportunities to begin to adjust to the impending loss. Such deaths maximise the chances of uncomplicated grieving on the part of the survivors, although other factors interact with the nature of the death and this may not always be the case. For example, the nature of the relationship between the deceased person and the survivor may place a person at risk of complicated grieving.

The *relationship between deceased and survivor* can represent a risk factor for complicated grief. As noted above, the closer the perceived relationship, the stronger the grief response. The death of a spouse/partner disrupts all aspects of the survivor's life – from the moment of rising to going to sleep in an empty bed. Habits of action (setting the table for two) and thoughts ('I must ask my wife about that') are confronted, sometimes daily. Grief following death is aggravated if the person lost is the person to whom one would turn in times of trouble. A bereaved person may find themselves repeatedly turning towards a person who is not there or feel isolated and alone in their grief. There is a feeling of being dismembered, of being acutely aware of the scope and dimension of the loss and that everything has changed. Further, there is painful self-examination and the tendency for physical and psychological health decline.

The death of a child is particularly difficult, as it ends plans, hopes and dreams for the child's life. The death is regarded as being out of sequence and against the natural order of things. The death of a child, irrespective of age, gives rise to intense emotional and physical reactions and is identified in the literature as a 'high-grief' death. On the other hand, the death of a parent represents the loss of a potential or actual long-term relationship. During the developmental years, children receive nurturing, support, care and protection, security, regulation of behaviour and socialisation from their parents. The loss of a parent signals a critical point in the life of the surviving children. It is a time for reflecting on the developing years and for reviewing the importance of relationships. It is also a time when grown children may become acutely aware of how old they are and that they are indeed adults. Perceptions about life and what it means may drastically change.

Disenfranchised grief occurs when people experience a loss that, for whatever reason, is not or cannot be socially sanctioned, publicly mourned or openly acknowledged (Corr 1999). Such a concept recognises the notion of *social control*. All societies have systems of social control, whereby behaviours are socially and culturally defined. Mourning 'rules' exist in societies to ensure that their members generally behave in appropriate, expected and approved ways (DeSpelder & Strickland 2005). There are four reasons the grief of survivors may be disenfranchised. Also consider the examples in Box 22-4:

- the relationship is not recognised
- the loss is not recognised
- the griever is not recognised, and
- the death is clearly affected by specific social values and attitudes (Bruce 2000, Corr 1999, Doka 1989).

When *multiple losses* occur, intense grief is experienced. Multiple deaths may be associated with the loss of two or more members of the same family at the same time in the same event, such as a multiple-fatality car accident, plane crash or bombing attack. Alternatively, intense grief may be associated with many deaths occurring within a relatively short period of time, such as the Black Saturday bushfires and the Lockyer Valley flood disaster in Australia or the Christchurch earthquakes in New Zealand. Multiple deaths cause multiple losses and have an immense impact, not only on the survivors, but also on family and the wider community.

Sudden and unnatural death

In stark contrast to an anticipated death at the end of a 'normal' life span is *sudden and unnatural death*. Unexpected death by suicide, homicide, accident, injury or disaster is difficult to accept and has been found to be a precursor to poor psychological adjustment (Updegraff & Taylor 2000). Surviving a disaster in which others have gone missing, are injured, or have died, presents unique grief responses for people. They survive not only the overwhelming, frightening and often sudden experience of the disaster and its aftermath, but also the death of others. 'Survivor guilt' is a term sometimes used in this situation to describe the feelings of those who, in all probability, would have also been victims.

Suicide, or the taking of one's own life, remains a confronting experience in our communities. It is typically unexpected and seldom makes sense to those left behind. Suicide poses many difficult problems when it comes to healthy grieving by the victim's significant others. Difficulty

BOX 22-4 Disenfranchised grief – examples

- When others see the relationship between the bereaved and the deceased as relatively superficial or undeveloped, e.g. relationships between friends, a stillborn infant, colleagues, ex-spouses and caregivers, or non-traditional relationships such as same-sex partnerships and those involved in extramarital affairs. Fathers of stillborn infants have been identified as a particularly disenfranchised group (Bonnette & Broom 2011).
- When the loss is one that falls outside everyday notions of loss, e.g. loss of a body part, the death of a pet, an elective abortion, or a miscarriage.
- When 'psychological death' occurs, e.g. if an individual's personality drastically changes as a result of a chronic, debilitating mental illness such as Alzheimer's disease.
- When, as Doka (1993) notes, those 'individuals to whom the socially recognised status of griever is not attached' experience loss, e.g. very young children, the elderly, people with intellectual disability or professionals who care for dying and distressed clients.
- When the death itself falls within areas of societal sexual taboos, e.g. death through human immunodeficiency virus (HIV) or acquired immunodeficiency syndrome (AIDS). The grief associated with this is complicated in many ways, both for the person infected by the disease and for significant others. First, every society carefully regulates the sexual behaviour of its members, and Benton (1999) makes it clear that HIV/AIDS has forced us to examine those aspects of life that are often taboo: sex, sexuality, blood, drugs and other lifestyles and behaviours viewed by many as non-conforming. People whose relationships do not conform to society's expectations, who live with and love those infected with the disease or who deviate from expected lifestyles and behaviours are forced to endure disenfranchisement, discrimination and stigma imposed by communities (Klein 1999). Stigmatisation in itself creates multiple problems when it deprives the survivor of the opportunity to grieve the loss, and of support and religious rituals required for healthy confirmation of the death and subsequent mourning (Mooney 1998).
- When the death comes about through suicide. Suicide is considered one of the most difficult deaths that a mourner must contend with, and is considered traumatic by its survivors. Suicide poses many difficulties in relation to grief resolution by significant others, as a sense of moral repugnance on the part of others may lead to the withdrawal of support for survivors (Noonan 1999). Some proposed reasons for this reaction are the fear of death, fear of mental illness and fear of contamination by suicide. The survivors in turn may withdraw into themselves and become further isolated and choked by guilt (Corr et al 2003).

Benton K 1999 Grief and HIV/AIDS: an Australian story. Grief Matters 2:3; Bonnette S, Broom A 2011 On grief, fathering and the male role in men's accounts of stillbirth. Journal of Sociology; Corr CA et al 2003 Death and dying; life and living, 4th edn. Grief Matters 2:47.

in coming to terms with the sudden death is considered by many researchers as the trigger for extreme difficulties with the bereavement experience and a disturbed kind of mourning by those left behind (Corr et al 2003). This places survivors at high risk of physical and psychological health problems.

Following a death by suicide, significant others are often left feeling like victims themselves. Anger, shame, guilt, rejection and abandonment serve to strengthen negative grief responses (Mooney 1998). Survivors are often left with a numbing feeling and ask themselves questions like 'Why did he do this to me?' Such questions and personal torment increase the impact of emotions. Suicide is often described as the ultimate affront, the final insult – one that, because questions cannot be answered, compounds the survivor's frustration and anger (DeSpelder & Strickland 2005).

Currier and colleagues (2015) suggest that following a homicide the survivors are at a high risk of complicated mourning and developing post-traumatic stress disorder. Not only is the death unexpected, senseless and random, but it is also brutal. Body mutilation and difficulties associated with retrieving the body following death tragically alter and further complicate mourning processes (Corr et al 2003). For the survivor, anger and fear seem to predominate and can be exacerbated during a coronial inquiry into the death. Not only is the death difficult to comprehend, but also the grief is re-stimulated and compounded by events such as facing and identifying the accused, recollecting the event, court hearings, appeals, coronial proceedings and the intrusion of media into the event, as well as anniversaries and other significant events pertaining to family life. This can be particularly problematic following intrafamilial homicide, such as the murder of eight children in Cairns, Australia, in 2014.

How can we know when grief has moved from 'normal' to 'complicated'? The Australian Centre for Grief and Bereavement (2012) describes some of the possible features of complicated grieving. They suggest that further help may be required if the grieving person:

- does not have people who can listen to them and care for them
- finds it difficult to manage the tasks of daily life, such as going to work or childcare
- finds their personal relationships are being seriously affected
- has persistent thoughts of self-harm or harming others
- persistently over-uses alcohol or other drugs
- experiences panic attacks or other serious anxiety or depression
- remains preoccupied and acutely distressed by grief over time
- feels that, for whatever reason, they need help to get through this experience.

Nursing practice and grief

We have shown above that everyone grieves in their own way. Imposing inflexible or unfounded expectations on people experiencing grief can be inappropriate at best, and harmful at worst. Most importantly, imposing time limits on the resolution of grief is unhelpful and, as Anstey and Lewis (2001) remind us, cannot be considered as a valid outcome measure in determining successful adjustment. Mourning is a way of coping. Mourning is considered labour-intensive and unique, and is regarded as a private and personal journey that no two people experience in the same way. Nurses have a responsibility to assess each grief and mourning situation as it arises, taking into account the many factors described above that lead a person to respond to loss in a particular manner. Nurses who understand the importance of grief and bereavement are better placed to facilitate grief work and help their clients and family survivors cope with their loss.

Supporting the grieving person

Most people's grief reactions, while possibly uncomfortable to witness, can usually be considered a normal reaction to loss. Clearly, not every nurse is going to be trained in grief and bereavement support; however, there are some fundamental attitudes and skills that promote optimal practice in the support of the grieving person.

Understand the therapeutic relationship

The primacy of the therapeutic relationship in palliative care nursing was identified by Canning et al (2007). While nursing practice is a set of activities requiring scientific knowledge and expert clinical skills, it is fundamentally also an interpersonal engagement with a therapeutic intent. Whether a death is sudden or anticipated, takes place in the home or the hospital, involves a baby, a child, an adolescent, youth or a middle-aged or elderly person, it is nearly always the nurse who provides the final care along with the family and supports those most deeply affected by the loss. Empathy, compassion and involvement have long been recognised as essential attributes of nursing care. A truly compassionate approach involves willingness to learn from others, viewing each situation as unique, responding to situations in an honest, sensitive and caring manner and taking the time to intervene sensitively and appropriately when caring for those who have experienced a loss.

Avoid judgement

Clearly, each person has their own approach to dealing with loss. The interpretation of loss is diverse and, as noted above, depends on such factors as cultural and ethnic heritage, socioeconomic status, gender, and religious and racial perspectives. The concept of culture encapsulates those complex learned behavioural patterns that enable the individual or group to adopt specific habits based on a prescribed set of norms related to their daily conduct (see Chapter 14). In the Western world, grieving is often viewed as a very personal and private process. In many other parts of the world, such as India and the Middle East, public expression of grief is commonplace. The values and beliefs evident within a culture shape and direct an individual's pathway through life, including religious, social and cultural sympathies. Although values and beliefs are not easily assessed, it is essential for nurses to understand the ways in which they are manifested through behaviour.

Maintain open communication

It is not uncommon for anger to be expressed as an immediate response to grief. Remember that the witnessing of grief behaviours does not mean they are personally directed at the witness. Approaching each situation in a non-judgemental way and being open and sensitive in communication with families, the skilled nurse conveys acceptance and represents commitment to the grieving person at a time when their sense of control may be compromised.

Stay informed of resources and support

It is not within the scope of practice of every nurse to be an expert bereavement counsellor. But staying informed of the resources and other forms of support available within the workplace and in the wider community is a reasonable expectation. The nurse should be able to facilitate access to hard-copy materials or online resources that may assist

the griever. A list of local psychologists or counsellors who are skilled in bereavement support can be an invaluable resource, as can an after-hours telephone support number or liaison persons in the griever's community.

CLINICAL REASONING PROCESS

Grieving is a natural response to a loss and is considered to be a beneficial coping process. It is also a reactive process and has therapeutic value. Grieving is healthy and enables the bereaved to reflect on and accept the reality of the loss. The nurse must feel confident to assess the situation critically and make an initial needs analysis. The overall goal of nursing assessment is to gather relevant information and data in order to gain a total view of the client's health and psychosocial status. By carefully exploring information gained from interaction and collating the data in a precise and methodical way, appropriate judgements and decisions can be made to work with the client in their grieving process. Assessment provides an opportunity for the nurse to explore with the client information relating to perceived and actual priority problems (mental and physical).

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Verbal and non-verbal communication techniques can encourage free flow of information and provide meaningful data for evaluation (see Chapter 12). These include listening, reflecting, clarifying, using non-verbal cues, appropriate use of silence, sharing perceptions, confronting contradictions and reviewing the discussions.

Culture and developmental considerations are two factors that influence communication. Culture has a profound effect on the way people communicate and behave. It is therefore important to keep in mind that cultural differences may influence how verbal and non-verbal messages are interpreted. For example, in many South-East Asian cultures – of which there are significant immigrant populations in both Australia and New Zealand – many women avoid eye contact with men. Conversely, many Western women look directly at the person to whom they are talking. *Age or developmental level* can also affect the way the assessment is handled, especially if the client is very young or very old. In the young, communication depends on the child's cognitive maturity, as noted above. In the elderly, consideration must be given to the extent to which the memory and sensory function may be affected by the ageing process. There are times when both the young and the elderly, in particular, are hesitant to share personal information, and developing communication skills that maximise the possibility of open communication is a priority for student nurses.

During periods of loss or anticipated loss, a client's emotions and behaviours may be in a state of flux. This makes assessment all the more challenging. Nurses should not assume they know how a client or family members will react. Continual assessment is essential if support and/or interventions are to be compatible with their current needs. Assessment of the client and family begins by exploring the meaning of the loss to the people involved. Examples of topics to be explored include the survivor's model of the world, personal characteristics such as personality, values, the nature of family relationships, support systems, nature of loss, cultural and spiritual beliefs, loss of personal life goals, hope, phase of grief, risks and nursing role perceptions.

When interviewing the client and family, it is important that an honest and empathetic approach is taken. Be mindful of setting the tone and direction of the interview, and of establishing a mutual understanding of the purpose of the exchange. In the initial phase it is important to establish rapport, ensure a comfortable and non-threatening setting and clarify the expectations or goals of the interview.

Establishing rapport

Establishing trust and rapport is a challenging process, particularly given the cultural diversity of Australian and New Zealand populations. A clear demonstration of respect for the client and an acceptance of the client's uniqueness as a person facilitate rapport. Greet the client by name and introduce yourself. It is usual practice not to use the client's first name unless invited to do so. In Australasian society, offering to shake hands is one way to demonstrate sincerity and acceptance.

Non-verbal behaviours

Non-verbal behaviours should match the verbal messages. Appropriate and sensitive eye contact and non-intimidating positioning should be used. Sincere and open eye contact (except in certain cultures/circumstances) is often vital with a vulnerable person, as normal contact with others may be disrupted by the emotions generated from circumstances surrounding the death. Position yourself so that you are facing the client. If the client is seated, sit at a slight angle opposite but facing, with an appropriate distance between. Avoid non-verbal behaviours such as frowning or yawning, or expressions of impatience or boredom, which imply a lack of interest. When beginning the interview, it may be appropriate to start with a brief but casual conversation that helps the client relax. Client-focused casual conversation may help alleviate any awkwardness the client may feel in talking to a stranger in the healthcare setting. Casual conversation can also be a source of valuable information.

Ensuring comfort

Ensure that the exchange of information takes place in a private setting free from interruptions and distractions. It is important to clarify that the client is feeling up to the interview before starting. Verbal therapeutic communication techniques involve open-ended questions that give the client a sense of control over the process – for example, 'Tell me about your family', 'How are you feeling now?' or 'What can you tell me about your relationship with X?'

Defining expectations

At the beginning of any interaction it is important to clarify what both the nurse and the client expect from the exchange. Make it clear that any information exchanged will be treated with sensitivity and respect. This is especially important in Australian Indigenous culture where the abuses of the past continue to have impacts on establishing trust in services (see Chapter 14).

During the assessment phase, it is important to focus on how the client is reacting, not on how you believe they should be reacting. Give special attention to grief-related behaviours displayed by the client, and pay careful attention to the client's experience and the tasks of grief that may be left incomplete, which may threaten the client's psychological or physical

health. When people are in crisis they expect the nurse to meet them on an equal footing, so be honest, non-judgemental, open, compassionate and willing to listen. Dignity in the face of death and grief is also expected, and the nurse should accept emotional responses and personal disclosures in a non-threatening and accepting manner.

Clients' responses to grief will vary, and depend on many factors. Remember that the bereavement models described above are only guides to help nurses and others understand the grieving pathway. For example, there may be times when a client becomes angry, does not seem happy with anything that is offered and takes their anger out on everyone, including the nurse who just walked in the door. In this situation, it would be reasonable to assume that the client is not really directing their anger towards the nurse but towards their situation. Of course, there could be any number of complex and interrelated factors contributing to the client's anger. Rather than responding in a defensive or aggressive manner, the nurse should acknowledge the client's feelings: 'You're obviously upset. I'm here to talk when you're ready.' It is important that the nurse remains available to clients, and that clients eventually understand that their outburst has not isolated them from support they may require later.

It is clearly within the scope of all nursing practice to have a grasp of the issues that influence grieving. The information above can be distilled into a guide to support therapeutic conversations with clients and families (Table 22-4).

Grief work is unique to the griever and it may take months or even years to adjust. Consideration by the nurse of the factors that influence grief reactions is necessary for planning

TABLE 22-4 Assessment factors for grieving clients

Factors	Areas/suggested questions to explore
Personal characteristics	Age, sex role, education, socioeconomic status Examples: What is a child's response to the loss? What is an older adult's life satisfaction? What spiritual beliefs do you relate to death? Does the age of the deceased make a difference? How do you expect your life to change with the loss of your leg? arm? breast? child? How does the gender of the client affect the response to death as described by society? What resources do clients have to cope with a loss (e.g. medical insurance, costs for schooling)?
Nature of relationships	Functions of family, community, society Examples: How long have you known the deceased? What role did the deceased play in your family? What is your relationship? Will it change? What contributions have been made by the deceased? How do you interpret the potential loss? How will family relationships change as a result of the loss?
Social support system	Availability of health workers, timing, family needs Examples: Who is present? absent? supportive? non-supportive? Are they always actually available or do they just say 'Call me if you need me'? Are they helpful, or do they avoid the issues offered for discussion by the grieving client? Do they use a listening ear approach rather than a judgemental approach? Is the grieving client's self-esteem built up and supported? What support do the grieving significant others have? Are these people available when needed?
Nature of loss	Death issues: personal, family or community; private or group; actual versus perceived; high risk; disenfranchised Examples: What is your belief about death? How do you define death? Define the loss in your own terms. What factors will help you grieve? What factors will interfere with grieving? What past experiences have you had? Outcomes? What has helped you cope in the past? What has not? Can you identify coping behaviours?

continued

TABLE 22-4 ***continued***

Factors	Areas/suggested questions to explore
Cultural and spiritual beliefs	Values, practices, customs, attitudes, clergy, spirituality Examples: How is the deceased valued, based on spiritual and cultural expectations? How does the loss of a limb change this valuing? How does the grieving client perceive physical death? the meaning of life? How should the body (or part) be treated when removed? What traditions are required to show value of all life? Can religious practices interfere with medical treatment? Who has the right to say 'yes' or 'no'? legally? ethically? Can the court intervene?
Loss of personal life goals	Actual or perceived individual losses affecting future decisions and options Examples: What is your goal in life? How was this changed with this loss? diagnosis? surgery? How have things changed since the accident (e.g. a car accident causing permanent quadriplegia)? How will your role change your personal goals? What planning has occurred for your own life?
Hope	Goals, worth, adaptations to future changes Examples: What do you expect now? How do you feel about yourself? Tell me what you will do now. What do you expect to help you through this?
Phases of grief	Relate to a theorist Examples: Use assessment to classify behavioural theory. Contrast the stage of the client to the stage of the significant other. Validate feelings expressed in emotions: 'You seem angry; tell me more about …', 'You seem sad; tell me…', 'What are your feelings about …?'
Family's grief for the deceased	Relationships, involvement with dying process Examples: Observation of client and family's level of grieving, patterns, rank of leadership and power person. What has helped you deal with problems in the past? What has not helped? What do you perceive as your strength? Weaknesses?
Risk factors in survivors	High risk, such as sudden death, violent death, length of processes or loss of a child Examples: Prior and subsequent variables: ambivalence, dependence, marked emotions, unresolved issues, mental health problems, mourners' perception of the lack of social support. Describe your feelings; your grieving processes. Who has helped you the most? What are your feelings? Could you really have prevented this? Are you feeling guilty because …? What did you use for early interventions with this problem, and were they helpful?
General health issues	General health check-up Nutritional evaluation Assessment of changes

and practising appropriate approaches to care. Grieving is an individual process and does not depend on a set time or sequence schedule, or follow a particular set of guidelines. It is important for clients and their families to share their concerns and talk about their experience with significant others. Continual evaluation of the impacts and outcomes of care provided to clients and families by nurses is necessary for maintaining quality of life and facilitating a forum conducive to healthy grieving.

Self-care for nurses providing end-of-life care

Nurses may care for dying clients for months before their death, and they are often present at the time of death. Nurses also deal with the emotional instability of the grieving clients and their families. As the person's body fails, nurses take on the sometimes confronting tasks associated with providing comfort and hygiene. It is usually the same nurses who cared for the client before death who will perform post-mortem care. Just how do nurses deal with such situations?

Strategies and practices that encourage nurses to evaluate their capacity and understand their personal limitations have long been recognised as fundamental to developing effective coping skills and empowerment (Martin & Bristowe 2015). Moreover, the fostering of these skills encourages the development of the therapeutic relationship as a helpful, facilitative partnership (Canning et al 2007). The reflective process and the formal and informal mechanisms of clinical debriefing help nurses, as individuals and as members of a group that share similar experiences, to gain control over issues and circumstances that shape personal dispositions and abilities to cope within the ever-changing environment of health care.

Coping strategies

Defence-oriented behaviour consists of using a set of coping strategies that are considered rational ways of reducing the impact of anxiety and other emotional responses. Various coping patterns are unconscious ways of protecting the psyche by enabling people to ignore, deny or distort stressful events by decreasing awareness and reducing emotional involvement. Conflict and trauma are reframed in a way that makes the stressor less disturbing. Denial, rationalisation, reaction–formation, humour and identification are just some of the more common defence mechanisms. Such defences are considered normal and healthy and are instrumental in helping the individual survive stressful situations. In general, the 'normal' use of defence mechanisms is appropriate and does not threaten health. Unfortunately, when people face conflict or trauma in their lives and feel unable to cope, or depend on ineffective means of coping, there is a tendency to succumb to physical and psychological distress.

Avoiding intense involvement in relationships with dying clients may be one of the most common defence mechanisms practised by nurses. Resolving the repetitive grief reactions associated with the sequential loss of close relationships with clients is extraordinarily challenging. The spectrum of defence mechanisms – denial, repression, avoidance and isolation – is available to nurses as a means of coping with the stress of working with dying clients (DeSpelder & Strickland 2005).

The nature of death also varies. Death may be sudden or anticipated, take place in the home or the hospital and involve a baby, a child, an adolescent or an adult or aged person. One thing seldom changes, however, and that is the fact that nurses are nearly always the people who provide the final care to the client and support those most deeply affected by the loss. Many nurses experience grief at the death of clients, and if this grief is not dealt with appropriately, bereavement 'overload' may develop (Kastenbaum 1967). Effective and timely support must be provided as a matter of course for the wellbeing of all those who work with death and the dying.

The experience of post-mortem care can be distressing for many nurses. Mooney (2003) found that although post-mortem care elicits a mix of emotions, sadness was the dominant emotion reported by nurses, followed in importance by fear and anxiety. The importance of death in Western culture, in which nurses in Mooney's (2003) study were socialised, presumably accounted for much of this fear and brought into sharp focus the nurses' own thoughts on mortality. The results of the study confirm that beginning nurses resort to using predominantly emotion-focused coping strategies, such as positive reappraisal, when faced with post-mortem care. However, given the multifaceted nature of grief, a multifaceted response is optimal.

Reflective practice

Beginning practitioners are well placed to take advantage of new technology, current knowledge and new insights into grief and bereavement in health care. It is important, however, not to lose track of the important role nurses play in the quest to help others face personal crises such as dying and death and the mourning that follows. To do this, nurses must look after themselves both physically and psychologically if they are to care for others. How do nurses do this? One helpful and practical strategy designed to facilitate coping is **reflective practice**. This is

an essential component of self-evaluation. Exploration of personal feelings is crucial to professional development and self-awareness.

Reflection is a process of reliving experiences and emotions in order to judge and evaluate what has occurred and why, and to learn from the experience. Therefore, reflection and reflecting on practice prompts the framing of new questions, strategies and objectives that combine to facilitate personal growth and professional development. This happens when the nurse returns to the experience to be reflected on, deals with the feelings that are associated with the experience and then assimilates these feelings and knowledge to form new understanding. Nurses should critically analyse their approach to clinical practice. Reflective practice accesses the wealth of information and knowledge available in the clinical setting, enabling choices to be made about the ways one practises and the personal costs and capacities invoked in order to do so.

The use of reflection by nurses begins with the recognition and appreciation of the individual's experience and the belief that people learn from personal experiences. Nurses learn from their experiences and continue to do so in an environment of increasing complexity and rapid and continual change. Unfortunately, not all nurses step back and take time to reflect on and seek meaning in the nature of their practice.

Reflection requires nurses to possess particular knowledge and skills and to be committed to the process. It is also necessary for the work environment to permit and encourage the process, for example, giving time off the ward or unit to attend clinical supervision or reflective debriefing. Peers and colleagues should be able to help one another recognise patterns in their practice and self-reflection, and talk about the knowledge arising from this process. The process and products of reflection involve some form of verbal expression. There must, therefore, be a climate of trust in which the confidentiality of reflective statements is guaranteed, and participants in the reflective process must not use information acquired from these exchanges when evaluating performance.

• CRITICAL REFLECTION POINT

1. **What are the three most difficult aspects of your work with the dying and the bereaved?**
2. **What are you doing (or what will you do) to help yourself cope with these? (see Box 22-5)**
3. **How do (or will) you debrief after the death or relocation of a client with whom you have had either a long-term or an emotional involvement? Does this afford you sufficient release and closure? If not, what can you do to achieve more of this?**

BOX 22-5 Self-care strategies

- Take the first crucial step by involving yourself in subjects that lend themselves to informing you about the many facets of loss and grief.
- Get in touch with yourself. Knowing who you are is just the beginning for you as a nurse. Taking care of others requires you to respect and care for yourself. Physical and psychological health and attending to personal and professional stress are crucial to preserving your personal integration and wellbeing.
- Consider your personal values. Your own perceptions of death and dying, grief and loss are shaped by your personal values and beliefs, which have been formed in part by your personal history. Consider these questions:
  - Who/what have been the major influences in your life?
  - What are the characteristics of the culture in which you grew up?
  - What values underpin this culture?
  - What is regarded as a 'normal' life for people in your own culture? How do death and dying, grief and loss fit into these perceptions of 'normal'?
- Reduce stress and burnout. First identify the stresses in your professional and personal life. The next step is to develop coping mechanisms to either eliminate or deal with the stresses effectively. The mechanisms you choose depend on your particular lifestyle and outlook on life.
  - Explore various solutions
  - Choose adaptive coping mechanisms
  - Keep trying
  - Don't be afraid to change direction
  - Proceed slowly
  - Reward yourself
- In your professional life:
  - Maintain realistic expectations of yourself and the relationships on the job
  - Set realistic job goals
  - Ask for help from management
  - Continue your education
  - Learn to say no
  - Look for new challenges
  - Cultivate a supportive friendship or join a support group
  - Establish a decompression routine
  - Take a holiday or leave of absence
  - Change your job.
- In your personal life:
  - Eat well
  - Exercise regularly
  - Relax
  - Play
  - Practise structured reflection.

4. **In your work setting, do you have access to appropriate psychological counselling? If so, do you consider it important to take advantage of this support system?**
5. **Do you have a personal action plan in place following the process of reflection?**

Reflection is difficult because it may result in altered beliefs or behaviours that challenge the status quo or long-established practices. Reflection requires nurses to recall what they did and identify the consequences. It is also a personal and private way of ridding oneself of the excess baggage that tends to accumulate when working in highly charged environments, including care of dying people and support of the bereaved.

Key concepts

- Birth, living, dying and death are all part of the inevitable cycle of the human condition.
- The experience of illness, caregiving, dying, grieving and death are individual and cannot be understood within a medical/scientific framework alone.
- It has been suggested that a dying person moves through four types of death, which may occur simultaneously: social, psychological, biological and physiological.
- Palliative care is the area of health care that specialises in the care and support of dying people and their families.
- The goal during palliative and end-of-life care is to address the physical as well as the psychological, social and spiritual needs of clients, their families and carers, regardless of the setting.
- Advance care planning is a collaborative process during which preferences for future care are decided upon for when the dying person is no longer able to articulate their own wishes.
- All people will experience loss, grief, bereavement and mourning during their lifetime.
- Complex grief reactions, such as guilt or post-traumatic stress disorder, may occur following the sudden or unnatural death of a loved one by suicide, homicide, accident, injury or disaster.
- Grieving is a natural response to loss and is considered part of a beneficial coping process.
- Nurses have a unique role in caring for the body following death, and in supporting the grieving and bereaved family or significant others.
- The development of therapeutic relationships, effective coping skills and formal or informal mechanisms for clinical debrief offer support to nurses dealing frequently with the emotions of grieving clients and their families.
- Reflective practice is a process of reliving experiences and emotions in order to evaluate what has occurred and why.
- The exploration of personal feelings and examining your response through reflective practice develops self-awareness and specialist knowledge for professional nursing practice.

Monitoring vital signs: using a primary survey approach for patient assessment

Anthony Schoenwald and Clint Douglas

Learning outcomes

Mastery of content will enable you to:

- apply the primary survey (ABCDE approach) as the foundation of any patient assessment
- describe normal parameters for vital signs based on the physiology of respiratory and cardiovascular systems and body temperature regulation
- measure and document vital signs accurately using appropriate equipment
- begin to make clinical judgements and decisions about the meaning of assessment data, including the need to escalate care appropriately.

KEY TERMS

Airway, p. 535
Blood pressure, p. 555
Body temperature, p. 566
Breathing, p. 535

Heart rate, p. 547
Level of consciousness, p. 565
Oxygen saturation, p. 542
Primary survey (ABCDE approach), p. 533
Pulse, p. 547
Respirations, p. 539
Vital signs, p. 533

Introduction

Assessment of airway, breathing, circulation and disability (neurological state) is the crucial first element of clinical assessment in every patient encounter (Considine & Currey 2015). A structured and systematic **primary survey (ABCDE approach)** provides essential information about patient status in the order of clinical importance, allowing you to identify and correct threats to patient safety before moving on to a focused assessment (discussed in the next chapter). This chapter is organised around the primary survey relevant to general acute care settings (Box 23-1), focusing on basic airway assessment, respirations, oxygen saturation, pulse, blood pressure, level of consciousness, and body temperature (Adam et al 2010, Clarke & Ketchell 2011, Price et al 2016). Collectively, these parameters are known as the **vital signs**, the ongoing monitoring of which is a primary nursing responsibility.

The importance of nursing assessment for patient safety

Sudden or gradual changes in vital signs can indicate life-threatening clinical states requiring urgent intervention and escalation of care (Cardona-Morrell et al 2015). Although more research is needed on the effectiveness of routine vital signs for early recognition of adverse events in general ward patients (Zeitz & McCutcheon 2006, Storm-Versloot et al 2014), the importance of vital signs to confirm serious illness and predict poor patient outcomes during hospitalisation is well established (Cardona-Morrell et al 2015).

Bleyer and colleagues' (2011) study of over 1 million vital signs collected from patients over the course of their hospitalisation is one of the largest studies available. You can see in Figure 23-1 the line graphs that show the prevalence of vital signs recorded, which peak around the normal adult ranges as expected. What is interesting here are the bar graphs, which show the proportion (%) of patients who died during hospitalisation with a vital sign recorded in that range. For example, you can see that a normal adult respiratory rate (< 20/min) was associated with a very low mortality. However, as respiratory rates increased outside of the normal range, patient mortality increased in a linear way: 10% of patients died with a respiratory rate of 28 to < 32 breaths/min, 16% with 32 to < 36 breaths/min, 20% with 36 to < 40 breaths/min, and 25% with 40 to < 44 breaths/min (Bleyer et al 2011). Respiratory rate is one of the most neglected vital signs, yet one of the earliest indicators that patients are at risk of clinical deterioration (Cretikos et al 2008).

Having two or more critically abnormal vital signs is also strongly associated with death. Bleyer and colleagues (2011:1387) used the same data set to examine patient outcomes with multiple critical vital signs defined as 'a systolic blood pressure < 85 mmHg, heart rate > 120 bpm, temperature < 35°C or > 38.9°C, oxygen saturation < 91%, respiratory rate ≤ 12 or ≥ 24, and level of consciousness recorded as anything but alert'. You can see in Table 23-1 that increased simultaneous presence of abnormal vital signs, together with increased age, was strongly associated with higher mortality. Almost 1 in 4 patients died (23.6%) with a trio of critically abnormal vital signs.

The importance of nursing assessment for patient safety cannot be overstated. The bedside RN carries the highest level of responsibility for the accurate measurement and interpretation of clinical data (Considine & Currey 2015). Using the primary survey framework discussed in this chapter can help you organise and communicate clinical findings to others. To improve the recognition of patients at risk of clinical deterioration, most acute care settings in Australia and New Zealand have adopted standardised charts for vital sign monitoring that follow

BOX 23-1 ABCDE approach to patient assessment in general wards

Airway	Assess airway patency
Breathing	Measure respiratory rate
	Evaluate work of breathing
	Measure oxygen saturation
Circulation	Palpate pulse rate and rhythm
	Measure manual blood pressure
	Assess urine output
Disability	Assess level of consciousness
	Evaluate speech
	Assess for pain
Exposure	Measure body temperature
	Inspect skin integrity
	Inspect and palpate skin for signs of pressure injury
	Observe any wounds, dressings or drains, invasive lines
	Observe ability to transfer and mobilise
	Assess bowel movements

TABLE 23-1 In-hospital mortality (%) associated with the simultaneous occurrence of critical vital signs

Number of simultaneous critical vital signs	All ages	Age > 60 years	Age > 70 years	Age > 80 years
0	0.24 (44)	0.40 (32)	0.62 (26)	0.92 (15)
1	0.92 (174)	1.47 (134)	1.96 (100)	2.09 (44)
2	6.95 (295)	9.84 (213)	11.5 (148)	13.0 (80)
3	23.6 (186)	33.1 (128)	42.0 (99)	42.9 (48)
4 or more	42.4 (61)	57.7 (41)	63.0 (29)	52.4 (11)

The number of patients who expired is noted in parentheses.

Bleyer AJ, Vidya S, Russell GB et al 2011 Longitudinal analysis of one million vital signs in patients in an academic medical center. Resuscitation 82(11):1390.

an ABCDE approach (Figure 23-2). The primary survey is also aligned with rapid response systems, which vary across organisations, but also follow an ABCDE approach (Figure 23-3). Rapid response teams are called when ward staff identify patients at risk of clinical deterioration to provide timely assessment and management. However, activation of rapid response systems and rescue of deteriorating patients are primarily dependent on the patient assessment and escalation of care decisions made by ward nurses (Considine & Currey 2015).

Airway

Anatomy and physiology

The primary survey begins with a priority airway assessment. The **airway** supports free exchange of air between the external environment and the lungs. Essentially, the structures involved are the oral cavity, nasal passages, pharynx, larynx, trachea and the left and right main bronchi. Any type of obstruction to one or more of these structures will reduce the diameter of the airway leading to decreased flow of air. Examples include pathological (asthma, infection, abnormal lesions, immunological responses) and/or mechanical obstruction (secretions, airway trauma, foreign objects, aspiration of gastric contents, obstructive sleep apnoea). You may observe coughing and increased respiratory rate and effort. Inadequate compensation will lead to decreased oxygen delivery to tissues (hypoxia) and/or inadequate elimination of carbon dioxide.

Basic airway assessment

Basic airway assessment must be a priority before any other assessment because an ineffective airway can be life-threatening within minutes and should be treated immediately (Adam et al 2010). Look at your patient and observe for chest movement. If the patient can talk normally and is conscious and alert, the airway is patent (Adam et al 2010). If an oxygen mask is already in place, it is possible to observe humidification of the plastic mask by the patient's expirations. Listen closely for air entry and feel respirations with your hand.

Any noisy respirations, such as obstruction from secretions, will need immediate intervention, such as suctioning. Assess the patient's ability to cough. If warranted, look in the mouth for obvious foreign bodies that could be removed (Figure 23-4). Partial obstruction may be present if you detect snoring (occlusion of the pharynx by the tongue or palate), stridor (obstruction above the level of the larynx), wheezing (obstruction of the lower airway), gurgling sounds (liquid or semi-solid material) or a hoarse voice (Adam et al 2010, Price et al 2016). The patient with a compromised airway may be very anxious, sitting up and drooling. Look, listen and feel for signs of respiratory distress in adults and children (Figures 23-5 and 23-6). Remember, the patient will appear distressed unless a complete obstruction leads to unconsciousness and respiratory arrest (Price et al 2016).

Breathing

Physiology and regulation

Knowledge of the structure and function of the respiratory system facilitates accurate assessment of **breathing**. Human survival depends on the ability of oxygen (O_2) to reach body cells and for carbon dioxide (CO_2) to be removed from the cells. Respiration is the mechanism the body uses to exchange gases between the atmosphere and the blood and between the blood and the cells. Effective respiration requires *ventilation* (the movement of gases into and out of the lungs), *diffusion* (the movement of oxygen and carbon dioxide between the alveoli and the red blood cells) and *perfusion* (the distribution of red blood cells to and from the pulmonary capillaries).

REFER TO YOUR LOCAL CLINICAL EMERGENCY RESPONSE SYSTEM (CERS) PROTOCOL FOR INSTRUCTIONS ON HOW TO MAKE A CALL TO ESCALATE CARE FOR YOUR PATIENT

CHECK THE HEALTH CARE RECORD FOR AN END OF LIFE CARE PLAN WHICH MAY ALTER THE MANAGEMENT OF YOUR PATIENT

Yellow Zone Response

IF YOUR PATIENT HAS ANY YELLOW ZONE OBSERVATIONS OR ADDITIONAL CRITERIA* YOU MUST

1. Initiate appropriate clinical care
2. Repeat and increase the frequency of observations, as indicated by your patient's condition
3. Consult promptly with the **NURSE IN CHARGE** to decide whether a **CLINICAL REVIEW** (or other CERS) call should be made

Consider the following:

- What is usual for your patient and are there documented 'ALTERATIONS TO CALLING CRITERIA'?
- Does the trend in observations suggest deterioration?
- Is there more than one Yellow Zone observation or additional criterion?
- Are you concerned about your patient?

IF A CLINICAL REVIEW IS CALLED:

1. Reassess your patient and escalate according to your local CERS if the call is not attended within 30 minutes or you are becoming more concerned
2. Document an A-G assessment, reason for escalation, treatment and outcome in your patient's health care record
3. Inform the Attending Medical Officer that a call was made as soon as it is practicable

***Additional YELLOW ZONE Criteria**

- Increasing oxygen requirement
- Poor peripheral circulation
- Excess or increasing blood loss
- Decrease in Level of Consciousness or new onset of confusion
- Low urine output persistent for 4 hours (< 100mLs over 4 hours or < 0.5mL/kg/hr via an IDC)
- Polyuria, in the absence of diuretics (urine output > 200mL/hr for 2 hours)
- Greater than expected fluid loss from a drain
- New, increasing or uncontrolled pain (including chest pain)
- Blood Glucose Level < 4mmol/L or > 20mmol/L with no decrease in Level of Consciousness
- Ketonaemia > 1.5mmol/L or Ketonuria 2 + or more
- **Concern by patient or family member**
- **Concern by you or any staff member**

CONSIDER IF YOUR PATIENT'S DETERIORATION COULD BE DUE TO SEPSIS, A NEW ARRHYTHMIA, HYPOVOLAEMIA/HAEMORRHAGE, PULMONARY EMBOLUS/DVT, PNEUMONIA/ATELECTASIS, AN AMI, STROKE, OR AN OVERDOSE/OVER SEDATION

Red Zone Response

IF YOUR PATIENT HAS ANY RED ZONE OBSERVATIONS OR ADDITIONAL CRITERIA# YOU MUST CALL FOR A RAPID RESPONSE (as per local CERS) AND

1. Initiate appropriate clinical care
2. Inform the **NURSE IN CHARGE** that you have called for a **RAPID RESPONSE**
3. Repeat and increase the frequency of observations, as indicated by your patient's condition
4. Document an A-G assessment, reason for escalation, treatment and outcome in your patient's health care record
5. Inform the Attending Medical Officer that a call was made as soon as it is practicable

#Additional RED ZONE Criteria

- **Cardiac or respiratory arrest**
- **Airway obstruction or stridor**
- **Patient unresponsive**
- Deterioration not reversed within 1 hour of Clinical Review
- Increasing oxygen requirements to maintain oxygen saturation > 90%
- Arterial Blood Gas: PaO_2 < 60 or $PaCO_2$ > 60 or pH < 7.2 or BE < -5
- Venous Blood Gas: $PvCO_2$ > 65 or pH < 7.2
- Only responds to Pain (P) on the AVPU scale
- Sudden decrease in Level of Consciousness (a drop of 2 or more points on the GCS)
- Seizures
- Low urine output persistent for 8 hours (< 200mLs over 8 hours or < 0.5mL/kg/hr via an IDC)
- Blood Glucose Level < 4mmol/L or > 20mmol/L with a decreased Level of Consciousness
- Lactate ≥ 4mmol/L
- **Serious concern by any patient or family member**
- **Serious concern by you or any staff member**

Figure 23-4 **Look inside the mouth for any obvious upper airway obstruction.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

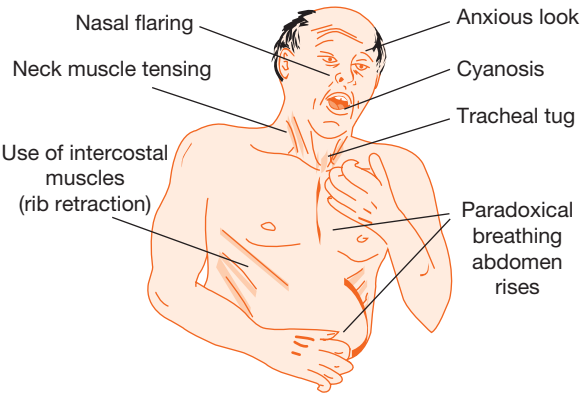

Figure 23-5 **Signs of acute respiratory distress in adult.**

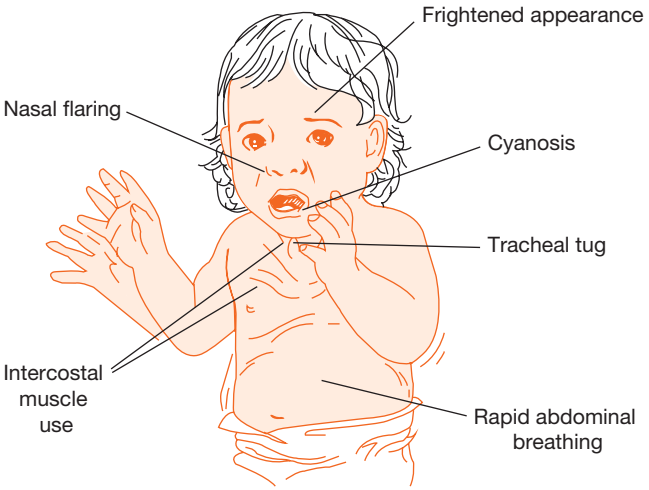

Figure 23-6 **Signs of acute respiratory distress in children.**

The respiratory centre in the brainstem regulates the involuntary control of respirations. Adults normally breathe in a smooth, uninterrupted pattern 12–20 times per minute. The respiratory drive is regulated by carbon dioxide, oxygen and hydrogen ions (pH) in the arterial blood. The most important factor in the control of ventilation is the level of CO_2 in arterial blood. An elevation in the CO_2 level (hypercapnoea) or hypoxia causes the respiratory control system in the brain to increase the rate and depth of breathing, which removes excess CO_2 by increasing exhalation. Some patients with chronic lung disease have ongoing hypercapnoea and are known as CO_2 retainers. For patients with hypoxaemia (reduced levels of arterial oxygen) in association with chronic lung disease, controlled oxygen therapy is used (see Chapter 35).

Mechanics of breathing

Although breathing is normally passive, muscular work is involved in moving the lungs and chest wall. Inspiration is an active process. During inspiration the respiratory

centre sends impulses along the phrenic nerve, causing the diaphragm to contract. Abdominal organs move downwards, increasing the volume of the chest cavity to move air into the lungs. The diaphragm moves approximately 1 cm, and the ribs retract upwards from the body's midline approximately 1.2–2.5 cm. During a normal, relaxed breath, an adult inhales approximately 500 mL of air. This amount is referred to as the tidal volume. During expiration, the diaphragm relaxes and the abdominal organs return to their original positions. The lung and chest wall return to a relaxed position (Figure 23-7). Normal breathing should be effortless.

Respirations

The accurate assessment of **respirations** depends on recognition of normal thoracic and abdominal movements (Skill 23-1). During quiet breathing, the chest wall gently rises and falls. Contraction of the intercostal muscles between the ribs or contraction of the muscles in the neck and shoulders, the accessory muscles of breathing, is not visible. During normal quiet breathing, diaphragmatic movement causes the abdominal cavity to rise and fall slowly. Prior to assessing respiratory rate, observe for difficulty breathing, accessory muscle use, asymmetrical chest movement and central cyanosis, which appears as a blue tinge to mucous membranes and lips (Clarke & Ketchell 2011).

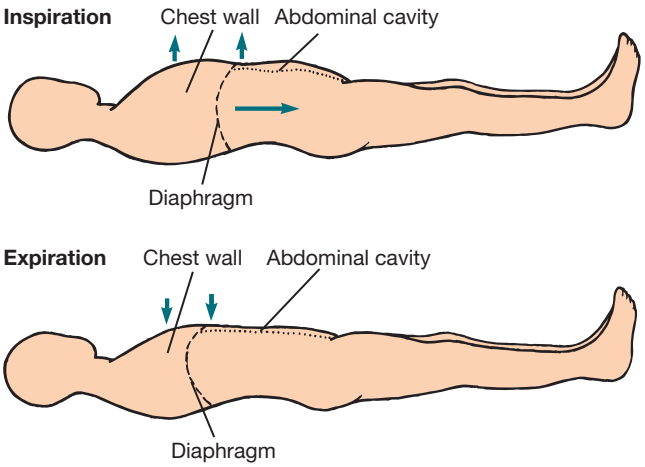

Figure 23-7 Mechanics of breathing.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Rate

Measurement of respiratory rate can best be done before assessing the pulse with your hand on the patient's wrist as it rests over the chest or abdomen. This approach allows assessment of respiratory rate, pattern and depth without drawing the patient's attention to the assessment. If the patient is aware, they may unintentionally alter their rate and depth of breathing. Observe a full inspiration and

SKILL 23-1

Assessing respirations

Delegation considerations

Respiration measurement can be delegated to enrolled nurses who are informed of:

- patient history or risk of increased or decreased respiratory rate or irregular respirations
- frequency of respirations measurement
- the reportable levels for the patient
- the need to report any abnormalities.

Equipment

- Watch with second hand or a digital display
- Pen, observation chart

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine the frequency of monitoring respirations:	
a. Consider previous medical conditions for respiratory alterations.	Certain conditions place patient at risk of alterations in ventilation detected by changes in respiratory rate, depth and rhythm.
b. Assess for signs and symptoms of respiratory alterations such as bluish or cyanotic appearance of nail beds, lips, mucous membranes and skin; restlessness, irritability, confusion, reduced level of consciousness; pain during inspiration; laboured or difficult breathing; adventitious breath sounds (see Chapter 24), inability to breathe spontaneously; thick, frothy, blood-tinged or copious sputum produced on coughing, use of accessory muscles to breathe, grunting sounds.	Physical signs and symptoms may indicate alterations in respiratory status related to ventilation.
c. Pulse oximetry (SpO_2). Acceptable SpO_2 > 95% on room air. 88–92% may be acceptable for patients with chronic obstructive pulmonary disease.	SpO_2 less than 90% is clinically significant and often accompanied by changes in respiratory rate, depth and rhythm.
2. Determine previous baseline respiratory rate (if available) from patient's record.	Assess for change in condition. Provides comparison with future respiratory measurements.
3. Be sure patient is in comfortable position, preferably sitting or lying with the head of the bed elevated 45–60 degrees.	Sitting erect promotes full ventilation.
4. Perform hand hygiene.	Prevents transmission of microorganisms.
5. Draw curtains or close door to the patient's room prior to exposing the patient.	To ensure privacy during assessment procedure.
6. Be sure patient's chest is visible. If necessary, move bedclothes or gown.	Ensures clear view of chest wall and abdominal movements.
7. Place patient's arm in relaxed position across the abdomen or lower chest, or place nurse's hand directly over patient's upper abdomen (see illustration).	A similar position used during pulse assessment allows respiratory rate assessment to be inconspicuous. Patient's or nurse's hand rises and falls during respiratory cycle.

Step 6 Position of hands for assessing respirations.

8. Observe complete respiratory cycle (one inspiration and one expiration).	Rate is accurately determined only after nurse has viewed respiratory cycle.

STEPS	RATIONALE
9. After cycle is observed, look at watch's second hand and begin to count rate: when second hand hits number on dial, begin timeframe, counting 1 with first full respiratory cycle.	Timing begins with count of 1. Respirations occur more slowly than pulse; thus timing does not begin with 0.
10. If rhythm is regular, count number of respirations in 30 seconds and multiply by 2. If rhythm is irregular, < 12 or > 20, count for 1 full minute.	Respiratory rate is equivalent to number of respirations per minute. Suspected irregularities require assessment for at least 1 minute.

■ **Critical decision point: Respiratory rate < 12 or > 20 requires further assessment (see Chapter 24) and may require immediate intervention.**

11. Note depth of respirations, subjectively assessed by observing degree of chest wall movement while counting rate. Can also objectively assess depth by palpating chest wall excursion or auscultating the posterior thorax after rate has been counted. Depth is described as shallow, normal or deep.	Character of chest movement may reveal specific disease state restricting volume of air from moving into and out of the lungs.
11. Note rhythm of respirations. Normal breathing is regular and uninterrupted.	Character of ventilations can reveal specific types of alterations.

■ **Critical decision point: Occasional periods of apnoea, the cessation of respiration for several seconds, are a symptom of underlying disease in the adult and should be reported. An irregular respiratory rate and short apnoeic spells are usual in a newborn.**

12. Replace bedclothes and patient's gown.	Restores comfort and promotes sense of wellbeing.
13. Perform hand hygiene.	Reduces transmission of microorganisms.
14. Discuss findings with patient as needed.	Promotes participation in care and understanding of health status.
15. If respirations are assessed for the first time, establish rate, rhythm and depth as baseline if within normal range.	Used to compare future respiratory assessment.
16. Compare respirations with patient's previous baseline and normal rate, rhythm and depth.	Allows assessment for changes in patient's condition and for presence of respiratory alterations.

RECORDING AND REPORTING

- Record respiratory rate and character in nursing notes and observation chart. Indicate type and amount of oxygen therapy if used by patient during assessment.
- Report abnormal findings to nurse in charge or medical practitioner.

expiration when counting ventilation or respiration rate. The respiratory rate varies with age (Table 23-2).

Depth

The depth of respiration is measured by observing the degree of excursion or movement in the chest wall. Respirations are described as *deep*, *normal* or *shallow*. A deep respiration involves a full expansion of the lungs with full exhalation. Respirations are shallow when only a small quantity of air passes through the lungs and this may be difficult to visualise. You may have to feel the chest rise and fall, or listen with a stethoscope over the central airways, if you observe that respirations are unusually shallow. Table 23-3 summarises types of respiratory alterations.

TABLE 23-2 Acceptable respiratory rates by age group

Age group	Rate (breaths per minute)
Newborn	30–60
Infant (6 months)	30–50
Toddler (2 years)	25–32
Child	20–30
Adolescent	16–19
Adult	12–20

TABLE 23-3 Alterations in breathing pattern

Alteration	Description
Apnoea	Respirations cease for several seconds. Persistent cessation results in respiratory arrest
Bradypnoea	Rate of breathing is regular but abnormally slow (fewer than 12 breaths per minute)
Cheyne-Stokes respiration	Respiratory rate and depth are irregular, characterised by alternating periods of apnoea and hyperventilation. Respiratory cycle begins with slow, shallow breaths that gradually increase to abnormal rate and depth. The pattern reverses, breathing slows and becomes shallow, climaxing in apnoea before respiration resumes
Hyperventilation	Rate and depth of respirations increase. Respiratory alkalosis may occur
Hypoventilation	Depth of ventilation may be shallow and depressed
Kussmaul's respirations	Respirations are abnormally deep, regular and increased in rate. Associated with metabolic acidosis
Tachypnoea	Rate of breathing is regular but abnormally rapid (more than 20 breaths per minute)

Pattern

Determine breathing pattern by observing the chest or abdomen. Diaphragmatic breathing results from the contraction and relaxation of the diaphragm and is best observed by watching abdominal movements. Men and children usually demonstrate diaphragmatic breathing. Women tend to use thoracic muscles to breathe; movements are observed in the upper chest. Laboured respirations usually involve the accessory neck muscles. When a foreign body or tracheal trauma interferes with the movement of air into the lungs, the intercostal spaces retract during inspiration. A longer expiration phase is evident when the outward flow of air is obstructed (e.g. in asthma).

With normal breathing, a regular interval occurs after each respiratory cycle. Infants tend to breathe less regularly. The young child may breathe slowly for a few seconds and then suddenly breathe more rapidly. While assessing respirations, estimate the time interval after each respiratory cycle. Respiration is *regular* or *irregular* in pattern.

Respiratory sounds

An integral part of respiratory assessment is listening to the sounds of breathing. *Snoring*, *stridor*, *wheezing* and *inspiratory grunt* are indicators of a respiratory obstruction. Snoring occurs when parts of the upper airway lose tone and partially block the airway. In some circumstances, this may result in full obstruction such as in obstructive sleep apnoea. Stridor is an inspiratory wheeze or crowing sound occurring with upper airway obstruction (e.g. croup, inhalation of foreign objects, laryngeal oedema after extubation). Wheezing is a high-pitched musical sound occurring when there is a partial obstruction in smaller airways and bronchioles (e.g. bronchiolitis and asthma). Absence of wheezing can only be confirmed by auscultation with a stethoscope (see Chapter 24).

Respiratory monitoring devices that aid your assessment include the apnoea monitor and pulse oximeter. Apnoea monitoring is used frequently with infants in the hospital and at home to observe for prolonged apnoeic events. Leads attached to the infant's chest wall sense movement; the absence of chest wall movement is interpreted by the monitor as apnoea and triggers an alarm.

Oxygen saturation

Arterial oxygenation (**oxygen saturation**) can be non-invasively measured using a pulse oximeter (Skill 23-2). Blood flows through the pulmonary capillaries where oxygen attaches to red blood cells. After oxygen diffuses from the alveoli into the pulmonary blood, most of the oxygen attaches to haemoglobin molecules in red blood

SKILL 23-2

Measuring oxygen saturation (SpO_2)

Delegation considerations

Oxygen saturation measurement can be delegated to enrolled nurses, who are informed of:

- the need to notify the registered nurse immediately of any reading lower than SpO_2 of 95%
- appropriate sensor site, probe and patient position for measurement of oxygen saturation
- frequency of oxygen saturation measurements
- factors that can falsely lower SpO_2 (see Box 23-2).

Equipment

- Oximeter
- Oximeter probe appropriate for patient and recommended by manufacturer
- Pen, observation chart

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine the frequency of monitoring oxygen saturation:	
a. Consider previous medical conditions for alteration of oxygen saturation.	Certain conditions place patients at risk of decreased oxygen saturation: acute or chronic compromised respiratory function, recovery from general anaesthesia or conscious sedation or traumatic injury to chest wall with or without collapse of underlying lung tissue, ventilator dependence, changes in supplemental oxygen therapy.
b. Assess for signs and symptoms of alterations in oxygen saturation such as altered respiratory rate, depth or rhythm; adventitious breath sounds (see Chapter 24); cyanotic appearance of nail beds, lips, mucous membranes and skin; restlessness, irritability, confusion; reduced level of consciousness; laboured or difficulty breathing.	Physical signs and symptoms may indicate abnormal oxygen saturation.
2. Assess for factors that normally influence measurement of SpO_2, such as oxygen therapy, haemoglobin level and temperature.	Allows for accurate assessment of oxygen saturation variations. Peripheral vasoconstriction related to hypothermia can interfere with SpO_2 determination.
3. Determine previous baseline SpO_2 (if available) from patient's record.	Baseline information provides basis for comparison and helps in assessment of current status and evaluation of interventions.
4. Explain purpose of procedure to patient and how oxygen saturation will be measured.	Promotes patient cooperation and understanding.

STEPS	RATIONALE
5. Assess site most appropriate for sensor probe placement (e.g. digit, earlobe) (see Box 23-3). Site must have adequate local circulation and be free of moisture.	Peripheral vasoconstriction can interfere with SpO_2 determination. Dark nail polish and acrylic nails impede sensor detection of emitted light and produce falsely elevated SpO_2.
6. Perform hand hygiene.	Reduces transmission of microorganisms.
7. Position patient comfortably. If finger is chosen as monitoring site, support lower arm.	Ensures probe positioning and decreases movement that interferes with SpO_2 determination.
8. If finger is to be used, remove any fingernail polish with acetone from digit to be assessed. If earlobe is to be used, remove any earrings. Wash site, swab with alcohol and air-dry.	Ensures accurate readings. Opaque coatings decrease light transmission; nail polish containing blue pigment can absorb light emissions and falsely alter saturation.
9. Attach sensor probe to monitoring site. Explain to patient that clip-on probe feels like a clothes peg on the finger but should not hurt.	Pressure of sensor probe's spring tension on a peripheral digit or earlobe may be unexpected.
10. Once the sensor probe is attached ask the patient to remain still during the assessment.	Moving the finger during the assessment can affect the sensor probe's ability to reach a constant value (pulse, SpO_2) and will affect accurate monitoring of the patient.

■ **Critical decision point: Do not attach probe to finger, ear or bridge of nose if area is oedematous or skin integrity is compromised. Do not attach probe to fingers that are hypothermic. Select ear or bridge of nose if adult patient has history of peripheral vascular disease. Earlobe and bridge of nose sensors are not used for infants and toddlers because of skin fragility. Disposable adhesive probes contain latex and should not be used if patient has latex allergy.**

11. Turn on oximeter by activating power. Observe pulse waveform/intensity display and audible beep. Correlate oximeter pulse rate with patient's radial pulse. Differences require re-evaluation of oximeter probe placement and may require reassessment of pulse rates.	Pulse waveform/intensity display enables detection of valid pulse or presence of interfering signal. Pitch of audible beep is proportional to SpO_2 value. Double-checking pulse rate ensures oximeter accuracy. Oximeter pulse rate, patient's radial pulse and apical pulse rate should be the same.
12. Leave probe in place until oximeter readout reaches constant value and pulse display reaches full strength during each cardiac cycle. Read SpO_2 on digital display. Inform patient that oximeter will sound alarm if the probe falls off or if patient moves the probe.	Reading may take 10–30 seconds, depending on site selected.
13. If continuous SpO_2 monitoring is planned, verify SpO_2 alarm limits. Limits for SpO_2 and pulse rate should be determined as indicated by patient's condition. Verify that alarms are on. Assess skin integrity under sensor probe and relocate sensor probe at least every 4 hours (every 2 hours for a spring-tension probe).	Alarms must be set at appropriate limits and volumes to avoid frightening patients and visitors. Spring tension of sensor probe or sensitivity to disposable sensor probe adhesive can cause skin irritation and lead to disruption of skin integrity.
14. Discuss findings with patient as needed.	Promotes participation in care and understanding of health status.
15. If intermittent or spot-checking SpO_2 measurements are planned, remove probe and turn oximeter power off. Clean probe following manufacturer's instructions and store in appropriate location.	Batteries can be depleted if oximeter is left on. Sensor probes are expensive and vulnerable to damage.

STEPS	RATIONALE
16. Help patient return to comfortable position.	Restores comfort and promotes sense of wellbeing.
17. Perform hand hygiene.	Reduces transmission of microorganisms.
18. Compare SpO_2 readings with patient baseline and acceptable values.	Comparison reveals presence of abnormality.
19. Correlate SpO_2 with SaO_2 obtained from arterial blood gas measurements (see Chapter 35) if available.	Documents reliability of non-invasive assessment.
20. Correlate SpO_2 reading with data obtained from respiratory rate, depth and rhythm assessment.	Measurements assessing ventilation, perfusion and diffusion are interrelated.

RECORDING AND REPORTING

- Record SpO_2 value on patient progress notes and observation chart, indicating type and amount of oxygen therapy used by patient during assessment. Also record any signs and symptoms of oxygen desaturation in progress notes. Measurement of SpO_2 after administration of specific therapies should be documented in narrative form in progress notes.
- Report abnormal findings to nurse in charge or medical practitioner.

cells. Red blood cells carry the oxygenated haemoglobin molecules through the left side of the heart and out to the peripheral capillaries, where the oxygen detaches.

The percentage of haemoglobin bound with oxygen in the arteries is the percentage of saturation of haemoglobin (or SaO_2). For a healthy adult breathing room air it is usually between 95% and 100%. SaO_2 is affected by factors that interfere with ventilation and perfusion (see Chapter 40). Always interpret the measurement in relation to the patient's oxygen requirement and record the amount of supplemental oxygen being delivered (e.g. a patient who needs supplemental oxygen to maintain oxygen saturation > 90% is hypoxaemic). The pulse oximeter (Figure 23-8) emits light wavelengths that are absorbed by the oxygenated and deoxygenated haemoglobin molecules. The light reflected from the haemoglobin molecules is processed by the oximeter, which calculates *peripheral oxygen saturation* (SpO_2). SpO_2 is a reliable estimate of SaO_2 when it is over 90%, but is less accurate at saturations below 80%. The measurement of SpO_2 is affected by factors that affect light transmission or peripheral arterial pulsations (Box 23-2). Selecting the appropriate probe is important for reducing measurement error (Box 23-3). Movement is the most common cause of inaccurate readings.

Figure 23-8 Pulse oximeter with probe.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Observing work of breathing, measurement of respiratory rate, pattern and depth, along with oxygen saturation using the pulse oximeter (SpO_2), are critical elements when assessing breathing. Each measurement provides cues in determining the nature of a patient's problem. It is important to note that pulse oximetry is not a replacement for nursing assessment of respirations

BOX 23-2 Factors affecting determination of peripheral oxygen saturation (SpO_2)

Interference with light transmission

- Outside light sources can interfere with the oximeter's ability to process reflected light.
- Carbon monoxide (caused by smoke inhalation or poisoning) artificially elevates SpO_2 by absorbing light similar to oxygen.
- Movement can interfere with the oximeter's ability to process reflected light.
- Jaundice may interfere with the oximeter's ability to process reflected light.
- Intravascular dyes (methylene blue) absorb light similar to deoxyhaemoglobin and artificially lower saturation.

Reduction of arterial pulsations

- Peripheral vascular disease (Raynaud's disease, atherosclerosis) can reduce pulse volume.
- Hypothermia at assessment site decreases peripheral blood flow.
- Pharmacological vasoconstrictors (adrenaline, phenylephrine, dopamine) will decrease peripheral pulse volume.
- Low cardiac output and hypotension decrease blood flow to peripheral arteries.
- Peripheral oedema can obscure arterial pulsation.

BOX 23-3 Characteristics of pulse oximeter sensor probes and sites

Reusable probe

- Digit probe
- Easy to apply, conforms to various sizes
- Yields strong correlation with SaO_2

Earlobe

- Clip-on is smaller and lighter though more positional than digit probe
- Greater accuracy at lower saturations
- Good when uncontrollable movements (e.g. hand tremors) are present
- Least affected by decreased blood flow

Disposable sensor pad

- Can be applied to a variety of sites: earlobe of adult, nose bridge, palm or sole of infant
- Less restrictive for continuous SpO_2 monitoring
- Expensive
- Contains latex
- Risk that skin under adhesive may become moist and harbour pathogens
- Available in variety of sizes; can be matched to infant weight

CLINICAL EXAMPLE

Mrs Winter, a 65-year-old woman, has been admitted to the ward following a stroke 5 days previously, which has left her with a mild but improving right-sided weakness, some dysarthria (disordered speech) and dysphagia (difficulty swallowing). She has also been diagnosed with a chest infection that was believed to be improving with antibiotic therapy. Mrs Winter is known to have chronic obstructive pulmonary disease (COPD) and to sometimes experience angina on exertion.

At afternoon handover, she is reported to have become confused and restless in the last 2 hours. The nurses found it difficult to record vital signs, but oxygen saturations were low and therefore oxygen therapy has been applied with a simple face mask. The ICU outreach nurse has been called to see the patient, but has not arrived yet. You are taking over the patient's care and so begin an ABCDE assessment:

AIRWAY: You see that the patient is partly sitting up, although leaning to one side. She does not answer when you speak to her, but does open her eyes when you touch her on the shoulder. You can hear and feel air entry but there is a rattling sound when she breathes. You ask her to try and cough to clear her throat, but it makes no difference to the rattling sound and she does not seem to clear anything from her airway. You try to reposition her in a more upright position and check to see if there is any material at the back of her mouth. Using a Yankeur sucker, you suction thick yellowy-green secretions, and her breathing seems to become less laboured.

BREATHING: You can see the chest moving symmetrically and the respiratory rate is 26 breaths/minute. The patient is still receiving oxygen via a face mask at 8L/min, and the pulse oximeter shows an oxygen saturation of 88% (very low given that she is receiving high-concentration oxygen). Auscultation of the chest reveals breath sounds (and therefore air entry) in both lungs. There are coarse crackles and some expiratory wheeze in the right upper zone, with reduced sounds of air entry in the right lower zone as compared with the left.

Adapted from Scenario 5.2 in Adam S, Odell M, Welch J 2010 Rapid assessment of the acutely ill patient. Wiley-Blackwell, Oxford, pp.89-94.

BOX 23-4 Respiratory rate: summary of evidence and recommendations

- Respiratory rate is the vital sign least often recorded and most frequently completely omitted from hospital documentation.
- A raised respiratory rate is a strong and specific predictor of serious adverse events such as cardiac arrest and unplanned intensive care unit admission.
- Pulse oximetry measurement is not a replacement for respiratory rate measurement.
- All staff should be educated to measure the respiratory rate as an easy and specific assessment for critical illness, and should be given guidance on appropriate action to be taken when abnormally high respiratory rates are recorded.

Cretikos MA, Bellomo R, Hillman K et al 2008 Respiratory rate: the neglected vital sign. Medical Journal of Australia 188(11):657-659. © Copyright 2008 The Medical Journal of Australia - reproduced with permission.

(Box 23-4). Pulse oximetry only gives us half the story about a patient's oxygenation and ventilation: it determines oxygen saturation and can detect hypoxaemia, but it is not an indicator of adequate ventilation (ability to exhale CO_2).

Circulation

Physiology and regulation

The pulse is the palpable bounding of blood flow noted at various points on the body. It is an indicator of the fluid wave created by ventricular contraction and therefore of the adequacy of circulatory status (**circulation**). Electrical impulses originating from the sinoatrial node travel through heart muscle to stimulate cardiac contraction. Approximately 60–70 mL of blood enters the aorta with each ventricular contraction, known as the stroke volume (SV). With each stroke volume ejection, the walls of the aorta distend, creating a pulse wave that travels rapidly towards the distal ends of the arteries. When a pulse wave reaches a peripheral artery, it can be felt by palpating the artery lightly against underlying bone or muscle. The number of pulsing sensations occurring in 1 minute is the **pulse** rate. The volume of blood pumped by the heart during 1 minute is the cardiac output (CO). The heart's ability to meet the demands of the body's tissue for nutrients is determined by palpating a peripheral pulse or by using a stethoscope to listen to heart sounds (apical heart rate).

While several arteries can be assessed for pulse rate (Skill 23-3), the radial artery is usually the most practical site at which to palpate the pulse (Figure 23-9). Other peripheral pulses, such as the brachial or femoral arteries, are assessed when surgery or treatment has impaired blood flow to a body part, there are clinical indications of impaired peripheral blood flow, or when a focused cardiovascular physical examination is conducted (Table 23-4). When CO declines significantly, peripheral pulses weaken and are difficult to palpate. The carotid site is the best in this situation because the heart will continue delivering blood through the carotid artery to the brain as long as possible.

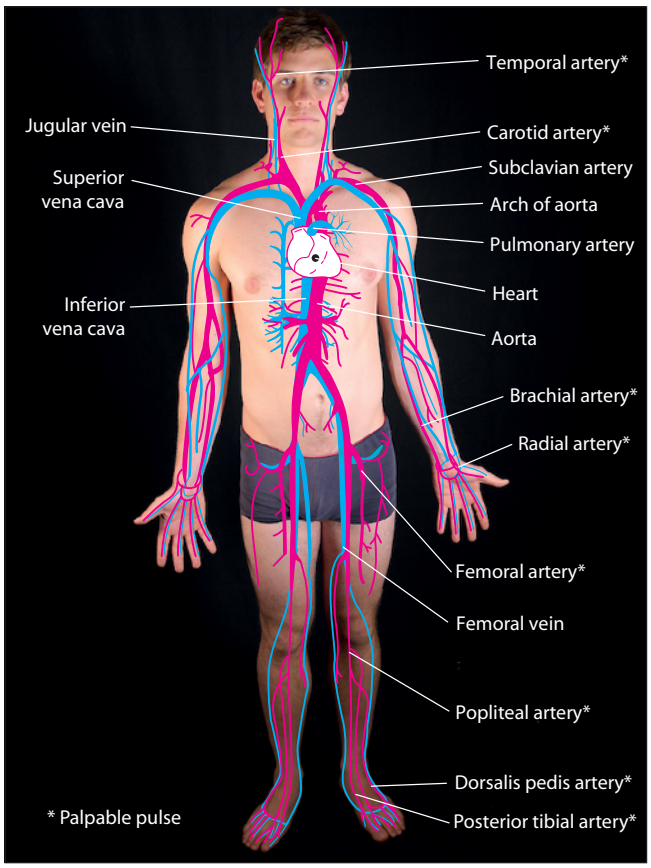

Figure 23-9 The palpable arteries (pulses) and the venous system.

Talley NJ, O'Connor S 2016 Clinical examination essentials, 4th edn. Elsevier, Chatswood, NSW.

In normal adults, **heart rates** average 60 to 100 beats per minute. *Bradycardia* is a heart rate less than 60 per minute and *tachycardia* is greater than 100 per minute (Talley & O'Connor 2014). If the radial pulse is abnormal, irregular or unattainable because of a dressing, a cast or patient-prescribed medication affecting the heartbeat, the apical pulse is assessed. The brachial or apical pulses are the best sites for assessing an infant's or young child's pulse, because other peripheral pulses are deep and difficult to palpate accurately.

TABLE 23-4 Pulse sites

Site	Location	
Apical	Fourth to fifth intercostal space at left mid clavicular line	Site used to auscultate apical heart rate
Brachial	Groove between biceps and triceps muscles at antecubital fossa	Site used to assess status of circulation to lower arm and auscultate blood pressure
Carotid	Along medial edge of sternocleidomastoid muscle in neck	Easily accessible site used during physiological shock or cardiac arrest when other sites are not palpable
Dorsalispedis	Along top of foot, between extension tendons of great and first toe	Site used to assess peripheral circulation to foot
Femoral	Below inguinal ligament, midway between symphysis pubis and anterior superior iliac spine	Site used to assess character of pulse during physiological shock or cardiac arrest when other pulses are not palpable; used to assess status of circulation to leg
Popliteal	Behind knee in popliteal fossa	Site used to assess status of circulation to lower leg
Posterior tibial	Inner side of ankle, below medial malleolus	Site used to assess peripheral circulation to foot
Radial	Radial or thumb side of forearm at wrist	Common site used to assess character of pulse peripherally and assess status of circulation to hand
Temporal	Over temporal bone of head, above and lateral to eye	Easily accessible site used to assess pulse in children
Ulnar	Ulnar side of forearm at wrist	Site used to assess status of circulation to hand; used to perform Allen's test before accessing the radial artery

SKILL 23-3

Assessing the radial and apical pulses

Delegation considerations

Pulse measurement can be delegated to enrolled nurses who are informed of:

- patient history or risk of irregular pulse
- frequency of pulse measurement
- the usual reportable levels for the patient
- the need to report any abnormalities.

Equipment

- Stethoscope (apical pulse only)
- Watch with second hand or a digital display
- Pen, observation chart
- Alcohol swab

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine the frequency of monitoring the radial or apical pulse: a. Consider previous medical conditions for alterations in apical pulse.	Certain conditions place patients at risk of pulse alterations. Heart rhythm can be affected by heart disease, cardiac arrhythmias, onset of sudden chest pain or acute pain from any site, invasive cardiovascular diagnostic tests, surgery, sudden infusion of large volume of intravenous fluid, internal or external haemorrhage and administration of medications that alter heart function.
b. Assess for signs and symptoms of altered cardiac output such as dyspnoea, fatigue, chest pain, orthopnoea, syncope, palpitations (person's unpleasant awareness of heartbeat), jugular venous distension, oedema of dependent body parts, cyanosis or pallor of skin.	Physical signs and symptoms may indicate alteration in cardiac function.
2. Assess for factors that normally influence apical pulse rate and rhythm:	Allows for accurate assessment of presence and significance of pulse alterations.
a. Age	Acceptable range of heart rate changes with age (see Table 23-5).
b. Exercise	Physical activity requires an increase in cardiac output that is met by an increased heart rate and stroke volume.
c. Position changes	Heart rate increases temporarily when changing from lying to sitting or standing position.
d. Medications	Anti-arrhythmics, sympathomimetics and cardiotonics affect rate and rhythm of pulse; opioid analgesics and general anaesthetics slow heart rate; central nervous system stimulants such as caffeine increase heart rate.
e. Temperature	Fever or exposure to warm environments increases heart rate; heart rate declines with hypothermia.
f. Emotional stress, anxiety, fear	Results in stimulation of the sympathetic nervous system, which increases heart rate.
3. Determine previous baseline apical rate (if available) from patient's record.	Allows nurse to assess for change in condition. Provides comparison with future apical pulse measurements.
4. Explain that pulse or heart rate is to be assessed. Encourage patient to relax and not speak.	Activity and anxiety can elevate heart rate. Patient's voice interferes with nurse's ability to hear sound when apical pulse is measured.
5. Perform hand hygiene.	Reduces transmission of microorganisms.
6. If necessary, draw curtains around bed and/or close door.	Maintains privacy.

STEPS	RATIONALE
7. Obtain pulse measurement.	
A. Radial pulse	
(1) Help patient assume a supine or sitting position.	Provides easy access to pulse sites.
(2) If supine, place patient's forearm straight alongside or across lower chest or upper abdomen with wrist extended straight (see illustration). If sitting, bend patient's elbow 90 degrees and support lower arm on chair or on nurse's arm. Slightly flex the wrist with palm down.	Relaxed position of lower arm and extension of wrist permits full exposure of artery to palpation.
(3) Place pads of first 2–3 fingers of hand over groove along radial or thumb side of patient's inner wrist (see illustration).	Fingertips are the most sensitive parts of hand to palpate arterial pulsation.
 Step 7A(2) Measuring radial pulse in supine patient.	 Step 7A(3) Position of fingertips for obtaining radial pulse.
(4) Lightly compress against radius, so pulse becomes easily palpable.	Pulse is more accurately assessed with moderate pressure. Too much pressure occludes pulse and impairs blood flow.
(5) Determine strength of pulse. Note whether thrust of vessel against fingertips is bounding, strong, weak or thready.	Strength reflects volume of blood ejected against arterial wall with each heart contraction.
(6) After pulse can be felt, look at watch's second hand and begin to count rate; when second hand hits number on dial, start counting with 0, then 1, 2 and so on.	Rate is determined accurately only after nurse is assured pulse can be palpated. Timing begins with 0. Count of 1 is first beat palpated after timing begins.
(7) If pulse is regular, count rate for 30 seconds and multiply total by 2.	A 30 second count is accurate for rapid, slow or regular pulse rates.
(8) If pulse is irregular, count rate for 60 seconds. Assess frequency and pattern of irregularity. Check the apical heart rate with stethoscope.	Inefficient contraction of heart fails to transmit pulse wave, interfering with cardiac output, resulting in irregular pulse. Longer time ensures accurate count.

STEPS	RATIONALE
Critical decision point: If pulse is irregular or rapid, assess for pulse deficit that may indicate alteration in cardiac output. Count apical pulse while palpating radial pulse. If pulse rate differs by more than 2, a pulse deficit exists and should be reported.	
B. Apical pulse	
(1) Help patient into supine or sitting position. Move aside bedclothes and gown to expose sternum and left side of chest.	Exposes portion of chest wall for selection of auscultation site.
(2) Locate anatomical landmarks to identify the point of maximal impulse (PMI), also called the apical impulse. Heart is located behind and to left of sternum with base at top and apex at bottom. Find angle of Louis just below suprasternal notch between sternal body and manubrium; can be felt as a bony prominence. Slip fingers down each side of angle to find second intercostal space (ICS). Carefully move fingers down left side of sternum to fifth ICS and laterally to the left mid-clavicular line (MCL). A light tap felt within an area 1–2 cm of the PMI is reflected from the apex of the heart.	Use of anatomical landmarks allows correct placement of stethoscope over apex of heart, enhancing ability to hear heart sounds clearly. If unable to palpate the PMI, reposition patient on left side. In the presence of serious heart disease, the PMI may be located to the left of the MCL or at the sixth ICS.
(3) Clean diaphragm of stethoscope prior to use.	Reduces transmission of microorganisms and cross-contamination with shared equipment.
(4) Place diaphragm of stethoscope in palm of hand for 5–10 seconds.	Warming of metal or plastic diaphragm prevents patient from being startled and promotes comfort.
(5) Place diaphragm of stethoscope over PMI at the fifth ICS, at left MCL, and auscultate for normal S_1 and S_2 heart sounds (heard as 'lub-dub') (see illustration).	Allow stethoscope tubing to extend straight without kinks that would distort sound transmission. Normal sounds S_1 and S_2 are high-pitched and best heard with the diaphragm.

Step 7B(4) Auscultating for heart sounds.

(6) When S_1 and S_2 are heard with regularity, use watch's second hand and begin to count rate: when second hand hits number on dial, start counting with 0, then 1, 2 and so on.	Apical rate is determined accurately only after nurse is able to auscultate sounds clearly. Timing begins with 0. Count of 1 is first sound auscultated after timing begins.
(7) If apical rate is regular, count for 30 seconds and multiply by 2.	Regular apical rate can be assessed within 30 seconds.

STEPS	RATIONALE
(8) If heart rate is irregular or patient is receiving cardiovascular medication, count for 1 minute (60 seconds).	Irregular rate is more accurately assessed when measured over longer interval.
(9) Note regularity of any dysrhythmia (S_1 and S_2 occurring early or later after previous sequence of sounds; e.g. every third or every fourth beat is skipped).	Regular occurrence of dysrhythmia within 1 minute may indicate inefficient contraction of heart and alteration in cardiac output.
(10) Replace patient's gown and bedclothes; help patient return to comfortable position.	Restores comfort and promotes sense of wellbeing.
(11) Clean earpieces and diaphragm of stethoscope with alcohol swab as needed (optional).	Controls transmission of microorganisms when nurses share stethoscope.
8. Discuss findings with patient as needed.	Promotes participation in care and understanding of health status.
9. Perform hand hygiene.	Reduces transmission of microorganisms.
10. Compare readings with previous baseline and/or acceptable range of heart rate for patient's age.	Checks for change in condition and alterations.
11. Compare peripheral pulse rate with apical rate and note discrepancy.	Differences between measurements indicate pulse deficit and may warn of cardiovascular compromise. Abnormalities may require therapy.
12. Compare radial pulse equality and note discrepancy.	Differences between radial arteries indicate compromised peripheral vascular system.
13. Correlate pulse rate with data obtained from blood pressure and related signs and symptoms (palpitations, dizziness).	Pulse rate and blood pressure are interrelated.

RECORDING AND REPORTING

- Record pulse, noting the site used, in observation chart.
- Report abnormal findings to nurse in charge or medical practitioner.

Pulse

Palpate the pulse for rate, rhythm, strength and equality (Figure 23-10). Before measuring a pulse, the patient's baseline rate is reviewed for comparison (Table 23-5). When assessing the pulse it is important to consider the variety of factors influencing the heart rate (HR) (Table 23-6). A combination of these factors may cause significant changes. Consideration needs to be given to postural changes, which cause changes in pulse rate because of alterations in blood volume and sympathetic activity. The HR temporarily increases when a person changes from a lying to a sitting or standing position. If an abnormal rate is detected while palpating a peripheral pulse, the next step is to assess the apical rate. The apical rate provides a more accurate assessment of cardiac contraction.

Figure 23-10 Palpation of arterial pulses.

A, Carotid. **B**, Brachial. **C**, Radial. **D**, Femoral. **E**, Popliteal. **F**, Dorsalis pedis. **G**, Posterior tibial.

Ball J et al 2015 Seidel's guide to physical examination, 8th edn. Elsevier, St Louis.

TABLE 23-5 Acceptable heart rates by age group

Age group	Heart rate (beats per minute)
Infants	120–160
Toddlers	90–140
Preschoolers	80–110
School-aged	75–100
Adolescents	60–90
Adults	60–100

Apical rate

Measure the apical rate by listening to heart sounds with a stethoscope (see Box 23-5). The first and second heart sounds (S_1 and S_2) are identified. At normal rates, S_1 is low-pitched and dull, sounding like '*lub*'. S_2 is higher-pitched and shorter, creating the sound '*dub*'. Each set of heart sounds is counted as one heartbeat. Using the diaphragm or bell of the stethoscope, count the number of heart sounds occurring in 1 minute. This method may be the primary option to ascertain heart rate in small children or those patients who are not well perfused in the periphery.

TABLE 23-6 Factors influencing pulse rates

Factor	Increase pulse rate	Decrease pulse rate
Drugs	Positive chronotropic drugs such as adrenaline	Negative chronotropic drugs such as digitalis
Emotions	Acute pain and anxiety increase sympathetic stimulation, affecting heart rate	Unrelieved severe pain increases parasympathetic stimulation, affecting heart rate; relaxation
Exercise	Short-term exercise	A conditioned athlete who participates in long-term exercise will have a lower heart rate at rest
Haemorrhage	Loss of blood increases sympathetic stimulation	
Postural changes	Standing or sitting	Lying down
Pulmonary conditions	Diseases causing poor oxygenation	
Temperature	Fever and heat	Hypothermia

Rhythm

Normally, a regular interval occurs between each heartbeat. An interval interrupted by an early or late beat or a missed beat indicates an abnormal rhythm or *arrhythmia*. Arrhythmia threatens the heart's ability to provide adequate cardiac output, particularly if it occurs repetitively. If an arrhythmia is present, the regularity of its occurrence should be assessed. Arrhythmias may be described as *regularly irregular* or *irregularly irregular*. To diagnose arrhythmia, an electrocardiogram (ECG) as well as other cardiac investigations may be needed. Children often have a *sinus arrhythmia*, which is an irregular heartbeat that speeds up with inspiration and slows down with expiration. This is a normal finding and can be verified by having the child hold their breath; the heart rate should then become regular.

An inefficient contraction of the heart that fails to transmit a pulse wave to the peripheral pulse site creates a *pulse deficit*. To assess a pulse deficit, assess radial and apical rates simultaneously and compare rates. The difference between the apical and radial pulse rates is the pulse deficit. For example, an apical rate of 92 with a radial rate of 78 leaves a pulse deficit of 14 beats. Pulse deficits are frequently associated with dysrhythmias.

Strength

The strength or amplitude of a pulse reflects the volume of blood ejected against the arterial wall with each heart contraction and the condition of the arterial vascular system leading to the pulse site. Normally the pulse strength remains the same with each heartbeat. Pulse strength may be graded or described as *bounding*, *strong*, *weak* or *thready*.

BOX 23-5 Using a stethoscope

- The five major parts of the stethoscope are the earpieces, binaurals, tubing, bell chestpiece and diaphragm chestpiece.
- To ensure the best reception of sound:
  - the earpieces should fit snugly and comfortably and follow the contour of the ear canal, pointing towards the face
  - the binaurals should be angled and strong enough so that the earpieces stay firmly in the ears without causing discomfort.
- As longer tubing decreases the transmission of sound waves, the polyvinyl tubing should be flexible and no longer than 30 cm in length. The tubing should be thick-walled and moderately rigid to eliminate transmission of environmental noise and to prevent the tubing from kinking, which distorts sound-wave transmission.
- Stethoscopes can have single or dual tubes. Dual tubes promote sound clarity by minimising the number of turns the sound wave makes before reaching the earpiece.
- The diaphragm is the circular, flat portion of the stethoscope chestpiece covered with a thin plastic disc. It transmits high-pitched sounds created by the high-velocity movement of air and blood.
  - Position the diaphragm to make a tight seal against the patient's skin.
  - Enough pressure is exerted to leave a temporary red ring on the patient's skin when the diaphragm is removed.
- The bell is the bowl-shaped chestpiece usually surrounded by a rubber ring. The bell transmits low-pitched sounds created by the low-velocity movement of blood. Heart and vascular sounds are auscultated using the bell.
  - To test, lightly tap to determine which side is functioning. Newer stethoscope models have one chestpiece that combines features of the bell and diaphragm. When light pressure is exerted the chestpiece is a bell, whereas exerting more pressure converts the bell into a diaphragm.
  - Apply the bell lightly, resting the chestpiece on the skin. Compressing the bell against the skin reduces low-pitched sound amplification and creates a 'diaphragm of skin'.
- The bell and diaphragm are rotated into position on the chestpiece, depending on which part you choose to use.
- The diaphragm or bell must be in proper position during use for you to hear sounds through the stethoscope.

Equality

Pulses on both sides of the peripheral vascular system can be assessed simultaneously. For example, both radial pulses are taken and the characteristics of each compared. A pulse in one extremity may be unequal in strength or absent in many disease states (e.g. peripheral arterial disease). All symmetrical pulses can be assessed simultaneously, except for the carotid pulse. Both carotid pulses should never be assessed at the same time because excessive pressure may occlude blood supply to the brain.

Blood pressure

Knowledge of the structure and function of the cardiovascular system in combination with an understanding of the patient's clinical situation facilitate accurate assessment of blood pressure (BP). **Blood pressure** is the lateral force on the walls of an artery from the blood pulsing under pressure from the heart. Systemic or arterial blood pressure, the blood pressure in the system of arteries in the body, is a good indicator of cardiovascular health. Blood flows throughout the circulatory system because of pressure changes. It moves from an area of high pressure to an area of low pressure. The heart's contraction forces blood under high pressure into the aorta. The peak of maximum pressure, when ejection occurs, is the systolic BP. When the ventricles relax, the blood remaining in the arteries exerts a minimum or diastolic BP.

Even though most sphygmomanometers are now either aneroid (using no fluid) or electronic, the standard unit for measuring blood pressure is millimetres of mercury (mmHg). The measurement indicates the height to which the blood pressure can raise a column of mercury. Blood pressure is recorded with the systolic reading before the diastolic (e.g. 120/80 mmHg). The difference between systolic and diastolic pressure is the *pulse pressure*. For a blood pressure of 120/80 mmHg, the pulse pressure is 40 mmHg. The pulse pressure varies with arterial elasticity. A decreased or narrow pulse pressure reflects reduced stroke volume or increased peripheral vascular resistance (e.g. hypovolaemic shock). A widened pulse pressure indicates increased stroke volume or decreased peripheral vascular resistance (e.g. septic shock).

Physiology of arterial blood pressure

Short-term regulation of blood pressure involves *baroreceptors* (pressure receptors) located in the aortic arch and carotid sinus which detect changes in blood pressure and inhibit or activate the sympathetic nervous system to maintain stability. For example, when a fall in blood pressure is sensed by baroreceptors, a sympathetic response is activated, including peripheral vasoconstriction, increased HR, and increased contractility of the heart, all causing an increase in blood pressure. Long-term regulation of blood pressure includes renal and hormonal processes that cause changes in blood volume and peripheral vascular resistance.

Blood pressure reflects the interrelationships of cardiac output, peripheral vascular resistance, blood volume, blood viscosity and artery elasticity. Knowledge of these haemodynamic variables helps in the assessment of blood pressure alterations.

Cardiac output

A person's cardiac output is the volume of blood pumped by the heart during 1 minute. The blood pressure (BP) depends on the cardiac output (CO) and the systemic vascular resistance (SVR):

$$BP = CO \times SVR$$

When volume increases in an enclosed space, such as a blood vessel, the pressure in that space rises. As output increases, more blood is pumped against arterial walls, causing the BP to rise. Cardiac output can increase as a result of an increase in heart rate, greater heart muscle contractility or an increase in blood volume. Changes in heart rate can occur faster than changes in muscle contractility or blood volume. An increase in heart rate may decrease diastolic filling time and end-diastolic volume. As a result, there is a decrease in blood pressure.

Peripheral resistance

The blood circulates through a network of arteries, arterioles, capillaries, venules and veins. Arteries and arterioles are surrounded by smooth muscle that contracts or relaxes to change the size of the lumen. The size of arteries and arterioles changes to adjust blood flow to the needs of local tissues. For example, when more blood is needed by a major organ, the peripheral arteries constrict, decreasing their supply of blood. More blood becomes available to the major organ because of the resistance change in the periphery. Normally, the vascular tone of arteries and arterioles remain partially constricted to maintain a constant flow of blood. *Peripheral vascular resistance* is the resistance to blood flow determined by the tone of vascular musculature and the diameter of blood vessels. The smaller the lumen of a vessel, the greater peripheral vascular resistance to blood flow. As resistance rises, arterial blood pressure rises. As vessels dilate and resistance falls, blood pressure drops.

Blood volume

The volume of blood circulating within the vascular system affects blood pressure. Most adults have a circulating blood volume of 5000 mL. Normally, the blood volume remains constant. However, if volume increases, more

pressure is exerted against arterial walls. For example, the rapid, uncontrolled infusion of intravenous fluids elevates blood pressure. When circulating blood volume falls, as in the case of haemorrhage or dehydration, blood pressure falls.

Viscosity

The viscosity of blood affects the ease with which blood flows through small vessels. The haematocrit, or percentage of red blood cells in the blood, measures blood viscosity. When the haematocrit rises and blood flow slows, arterial blood pressure increases. The heart must contract more forcefully to move the more viscous blood through the circulatory system.

Elasticity

Normally, the walls of an artery are elastic and easily distensible. As pressure within the arteries increases, the diameter of vessel walls increases to accommodate the pressure change. The ability of arteries to distend prevents wide fluctuations in blood pressure. However, in certain diseases, such as arteriosclerosis, the vessel walls lose their elasticity and are replaced by fibrous tissue that cannot stretch well. With reduced elasticity there is greater resistance to blood flow. As a result, when the left ventricle ejects its stroke volume, the vessels no longer yield to pressure. Instead, a given volume of blood is forced through the rigid arterial walls, and the systemic pressure rises. Systolic pressure is more significantly elevated than diastolic pressure as a result of reduced arterial elasticity.

Each haemodynamic factor significantly affects the others (Figure 23-11). For example, as arterial elasticity declines, peripheral vascular resistance increases. The complex control of the cardiovascular system normally prevents any single factor from permanently changing the blood pressure. For example, if the blood volume falls, the body compensates with an increased vascular resistance.

Factors influencing blood pressure

Blood pressure is not constant, but is continually influenced by many factors during the day. One measurement cannot adequately reflect a patient's blood pressure. Even under the best conditions, blood pressure changes from heartbeat to heartbeat. Blood pressure trends, not individual measurements, guide nursing interventions. Understanding these factors ensures a more accurate interpretation of blood pressure readings.

Age

Normal blood pressure levels vary and gradually increase throughout life (Table 23-7). The level of a child or adolescent's blood pressure is assessed with respect to

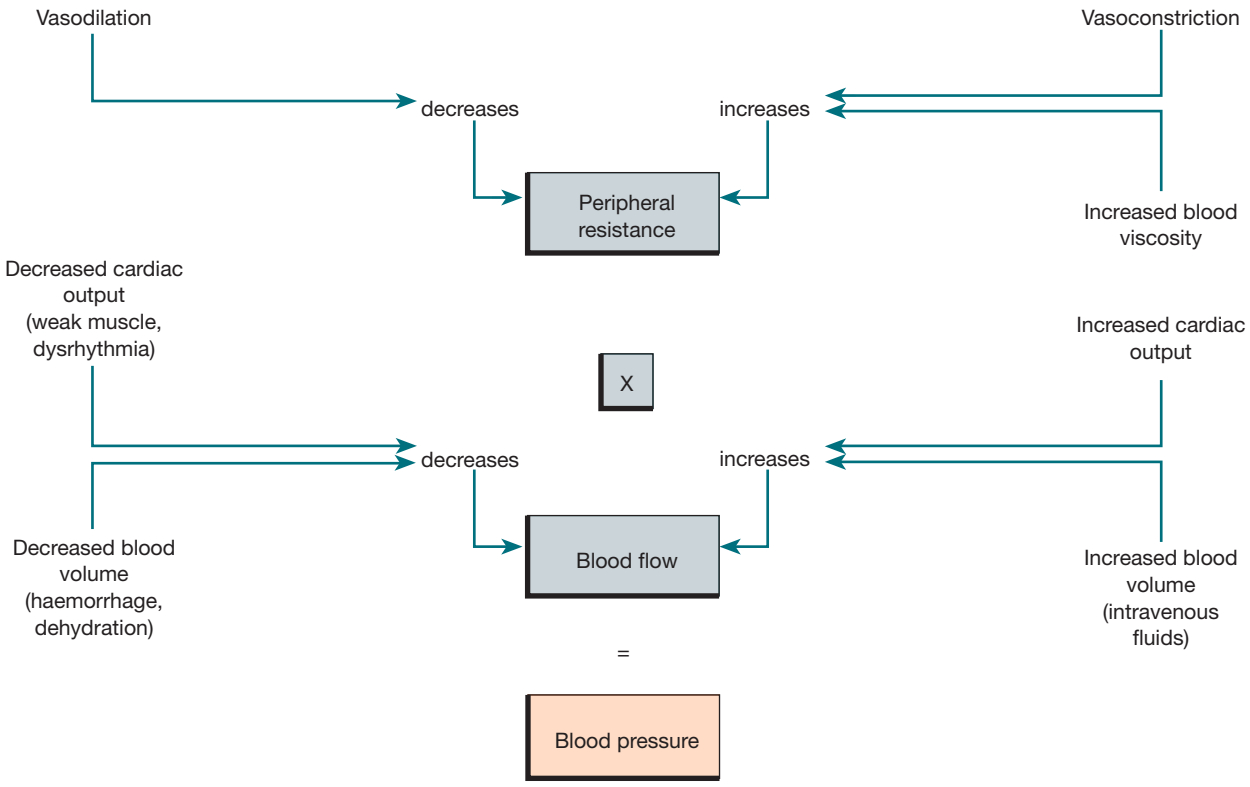

Figure 23-11 **Haemodynamic factors that affect blood pressure.**

body size and age (Hockenberry & Wilson 2011). Larger children (heavier and/or taller) have higher blood pressure than smaller children of the same age. An adult's blood pressure tends to increase with advancing age. Older adults have a rise in systolic pressure related to decreased vessel elasticity.

Stress

Anxiety, fear, pain and emotional stress result in sympathetic stimulation, which increases heart rate, cardiac output and peripheral vascular resistance and ultimately increases blood pressure.

TABLE 23-7 Average optimal blood pressure by age group

Age group	Blood pressure (mmHg)
Newborn (3000 g)	40 (mean)
1 month	85/54
1 year	95/65
6 years	105/65
10–13 years	110/65
14–17 years	120/75
Adult	< 120/80

National Institutes of Health: National Heart, Lung and Blood Institute (NHLBI) Joint National Committee 2004 The Seventh Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure, Bethesda, MD, NHLBI.

Medications

Some medications can directly or indirectly affect blood pressure. During blood pressure assessment, ask whether the patient is receiving antihypertensive or other cardiac medications, which lower blood pressure (Table 23-8). Opioid analgesics also lower blood pressure through vasodilation, especially morphine. High blood pressure (hypertension) may be caused by fluid overload or hypertensive disease. Most often, lower than normal blood pressure (hypotension) can seriously threaten life.

Blood pressure measurement

To ensure reliable results you will need to become familiar with the equipment and the principles of blood pressure measurement (Skill 23-4). The blood pressure is measured by auscultation or palpation. Auscultation is the most widely used technique. The process of taking a blood pressure reading will differ depending on your knowledge of the patient and their previous readings. You will also need to learn how to use automatic blood pressure equipment, as this is readily available in most settings. Finally, you will need to understand how to manage challenging situations by selecting the most suitable equipment and sites for measuring the blood pressure. Accurate recording and interpretation of results and knowledge of when to report changes are critical to patient safety.

Equipment

A *sphygmomanometer* comprises a pressure manometer, an occlusive cloth or vinyl cuff that encloses an inflatable rubber bladder, and a pressure bulb with a release valve that inflates the bladder. The aneroid manometer has a

TABLE 23-8 Antihypertensive medications

Medication type	Examples	Action
Angiotensin-converting enzyme (ACE) inhibitors	Captopril, enalapril, lisinopril	Lower blood pressure by blocking the conversion of angiotensin I to angiotensin II, preventing vasoconstriction; reduce aldosterone production and fluid retention, lowering circulating fluid volume
Angiotension II receptor blockers (ARBs)	Candesartan, irbesartan	Block angiotensin receptor and have similar actions to ACE inhibitors
Beta-adrenergic blockers	Atenolol, carvedilol, propranolol	Block beta-adrenergic receptors in the heart, arteries and arterioles to block response to sympathetic nerve impulses; reduce heart rate and thus cardiac output
Calcium channel blockers	Amlodipine, verapamil	Inhibit calcium influx into cells in vascular smooth muscle, myocardium and cardiac conduction system. Reduce peripheral vascular resistance by systemic vasodilation
Diuretics	Frusemide, spironolactone, hydrochlorothiazide	Lower blood pressure by reducing reabsorption of sodium and water by the kidneys, thus lowering circulating fluid volume
Vasodilators	Glyceryl trinitrate (GTN), isosorbide dinitrate	Act on vascular smooth muscle to cause relaxation and reduce peripheral vascular resistance

SKILL 23-4

Measuring blood pressure (BP)

Delegation considerations

Blood pressure measurement can be delegated to enrolled nurses who are informed of:

- patient's risk of orthostatic hypotension
- frequency of blood pressure measurement
- reportable levels for the patient
- the need to report any abnormalities.

Equipment

- Aneroid or mercury sphygmomanometer
- Cloth or disposable vinyl pressure cuff of appropriate size for patient's extremity
- Stethoscope
- Alcohol swab
- Pen, observation chart

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine the frequency of monitoring BP:	
a. Consider previous medical conditions for alterations in BP.	Certain conditions place patients at risk of BP alteration: history of cardiovascular disease, renal disease, diabetes, circulatory shock, acute pain, rapid intravenous infusion of fluids or blood products, increased intracranial pressure, postoperative conditions, pregnancy induced hypertension.
b. Observe for signs and symptoms of BP alterations: (1) High BP (hypertension) is often asymptomatic until pressure is very high. Assess for headache (usually occipital), flushing of face, nosebleed, and fatigue in older adults. (2) Low BP (hypotension) is associated with: dizziness; mental confusion; restlessness; pale, dusky or cyanotic skin and mucous membranes; cool, mottled skin over extremities.	Physical signs and symptoms may indicate alterations in BP. (See Table 23-7 for average optimal blood pressure for age.)
2. Determine best site for BP assessment. Avoid applying cuff to extremity when: intravenous fluids are infusing; an arteriovenous shunt or fistula is present; breast or axillary surgery has been performed on that side; extremity has been traumatised, is diseased or requires a cast or bulky bandage. The lower extremities (leg BP) may be used when the brachial arteries are inaccessible.	Inappropriate site selection may result in poor amplification of sounds, causing inaccurate readings. Application of pressure from inflated bladder temporarily impairs blood flow and can further compromise circulation in extremity that already has impaired blood flow.

STEPS	RATIONALE
3. Select appropriate cuff size.	Improper cuff size results in inaccurate readings (see Table 23-9). If cuff is too small, it tends to come loose while being inflated or results in false high readings. If the cuff is too large, false low readings may be recorded.
4. Determine previous baseline BP (if available) from patient's record.	Allows assessment for change in condition. Provides comparison with future BP measurements.
5. Have patient assume sitting or lying position. Be sure room is warm, quiet and relaxing.	Maintains patient's comfort during measurement. The patient's perception that the physical or interpersonal environment is stressful affects the BP measurement.
6. Explain to patient that BP is to be assessed and have patient rest at least 5 min before measurement. Ask patient not to speak when BP is being measured.	Reduces anxiety that can falsely elevate readings. Blood pressure readings taken at different times can be objectively compared when assessed with patient at rest. Talking to a patient when the BP is being assessed increases readings by 10–40%.
7. Perform hand hygiene.	Reduces transmission of microorganisms.
8. With patient sitting or lying, position patient's forearm or thigh, supported if needed. For arm, turn palm up; for thigh, position with knee slightly flexed.	If extremity is unsupported, patient may perform isometric exercise that can increase diastolic blood pressure.
9. Consider drawing curtains or closing door to the patient's room prior to exposing the patient.	To ensure privacy during assessment procedure.
10. Expose extremity (arm or leg) fully by removing constricting clothing.	Ensures proper cuff application.
11. Palpate brachial artery (arm) (see illustration); or popliteal artery (leg). Position cuff 2.5 cm above site of pulsation (antecubital or popliteal).	Inflating bladder directly over artery ensures proper pressure is applied during inflation.

Step 10 Position of cuff above site of pulsation of brachial artery.

12. Apply bladder of cuff above artery by centring arrows marked on cuff over artery. If there are not centre arrows on cuff, estimate the centre of the bladder and place this centre over artery. With cuff fully deflated, wrap cuff evenly and snugly around extremity.	Loose-fitting cuff causes false high readings.
13. Position manometer vertically at eye level. Observer should be no further than 1 m away.	Accurate readings are obtained by looking at the meniscus of the mercury at eye level. The meniscus is the point where the crescent-shaped top of the mercury column aligns with the manometer scale. Looking up or down at the mercury results in distorted readings.

STEPS	RATIONALE
14. If you do not know the patient's baseline BP, estimate systolic pressure by palpating the artery distal to the cuff, i.e. radial artery, with fingertips of one hand while inflating cuff rapidly to pressure 30 mmHg above point at which pulse disappears. Slowly deflate cuff and note point when pulse reappears. Deflate cuff fully and wait 30 seconds.	Estimating prevents false low readings, which may result in the presence of an auscultatory gap. Maximal inflation point for accurate reading can be determined by palpation. If unable to palpate artery because of weakened pulse, an ultrasonic stethoscope can be used. Deflating cuff prevents venous congestion and false high readings.
15. Place stethoscope earpieces in ears and be sure sounds are clear, not muffled.	Each earpiece should follow angle of ear canal to facilitate hearing.
16. Relocate brachial or popliteal artery and place bell or diaphragm chestpiece of stethoscope over it. Do not allow chestpiece to touch cuff or clothing.	Proper stethoscope placement ensures optimal sound reception. Stethoscope improperly positioned causes muffled sounds that often result in false low systolic and false high diastolic readings.
17. Close valve of pressure bulb clockwise until tight. Rapidly inflate cuff to 30 mmHg above palpated systolic pressure.	Tightening of valve prevents air leak during inflation. Inflation ensures accurate measurement of systolic pressure.
18. Slowly release pressure bulb valve and allow mercury or needle of aneroid manometer gauge to fall at rate of 2 mmHg/second.	Too rapid or slow a decline in mercury level or aneroid pressure can cause inaccurate readings.
19. Note point on manometer when first clear sound is heard. The sound will slowly increase in intensity.	First Korotkoff sound indicates systolic pressure.
20. Continue to deflate cuff, noting point at which muffled or dampened sound appears.	Fourth Korotkoff sound involves distinct muffling of sounds and is recommended as indication of diastolic pressure in children.
21. Continue to deflate cuff gradually, noting point at which sound disappears in adults. Listen for 10–20 mmHg after the last sound, and then allow remaining air to escape quickly.	Beginning of the fifth Korotkoff sound is recommended as indication of diastolic pressure in adults.
22. Remove cuff from extremity unless measurement must be repeated. If this is the first assessment of patient, it may be necessary to repeat procedure on other extremity.	Continuous cuff inflation causes arterial occlusion, resulting in numbness and tingling of patient's arm. Comparison of BP in both extremities detects circulation problems. (Normal difference of 5–10 mmHg exists between extremities.)
23. Help patient return to comfortable position and cover upper arm if previously clothed.	Restores comfort and promotes sense of wellbeing.
24. Clean BP cuff after use.	Reduces transmission of microorganisms and cross-contamination with shared equipment.
25. Discuss findings with patient as needed.	Promotes participation in care and understanding of health status.
26. Perform hand hygiene.	Reduces transmission of microorganisms.
27. Compare reading with previous baseline and/or acceptable value of BP for patient's age.	Checks for change in condition and alterations.

STEPS	RATIONALE
28. Correlate BP with data obtained from pulse assessment and related cardiovascular signs and symptoms.	Blood pressure and heart rate are interrelated.

RECORDING AND REPORTING

- Inform patient of value and need for periodic reassessment.
- Record blood pressure on observation chart and in progress notes if necessary.
- Report abnormal findings to nurse in charge or medical practitioner.

glass-enclosed circular gauge containing a needle that registers millimetre calibrations. Cloth or disposable vinyl compression cuffs contain the inflatable bladder and come in several sizes. The size selected is proportional to the circumference of the limb being assessed (Figure 23-12). Ideally, the width of the cuff should be 40% of the circumference (or 20% wider than the diameter) of the midpoint of the limb on which the cuff is to be used. The bladder, enclosed by the cuff, should encircle at least two-thirds of the arm of an adult and the entire arm of a child. In children, the lower edge of the cuff should be above the antecubital fossa, allowing room for placement of the stethoscope bell or diaphragm. Blood pressure measurements will not be accurate unless the correct size cuff is applied.

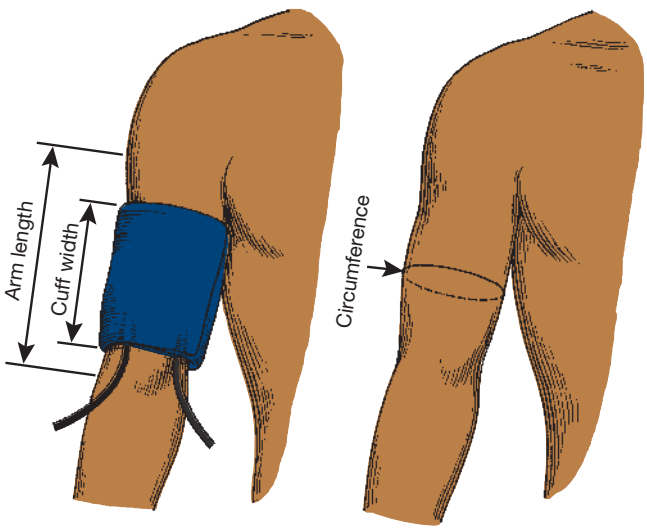

Figure 23-12 Guidelines for proper blood-pressure cuff size. Cuff width = 20% more than the upper arm diameter; or 40% of circumference and two-thirds of arm length.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Before using a sphygmomanometer, inspect the parts of the release valve and the pressure bulb. The valve should be clean and freely moveable in either direction. If it sticks or becomes too tightly closed, the deflation of the pressure cuff will be hard to regulate. The pressure bulb is made of tough rubber and should be free of leaks. Aneroid manometers have the advantage of being lightweight, portable and compact, but the tendency for metal parts to expand or contract in response to environmental temperature changes can affect their reliability. Aneroid sphygmomanometers require biomedical calibration at routine intervals to verify their accuracy. Before using the aneroid model, be sure that the needle points to zero and that the manometer is correctly calibrated.

Principles of blood pressure measurement

Measurement of arterial blood pressure works on a basic principle of pressure. Blood flows freely through an artery until an inflated cuff applies pressure to tissues and causes the artery to collapse. After the cuff pressure is released, the point at which blood flow returns and sound appears through auscultation is the systolic pressure. In 1905, Korotkoff first described the sounds heard over an artery distal to the blood pressure cuff (Figure 23-13):

1. The first Korotkoff sound (KS) is a clear rhythmical tapping corresponding to the pulse rate that gradually increases in intensity. Onset of the sound corresponds to the systolic pressure.
2. With the second KS, a murmur or swishing sound occurs as the cuff continues to deflate. As the artery distends, there is turbulence in blood flow.
3. The third KS is a crisper and more intense tapping.
4. The fourth KS becomes muffled and low-pitched as the cuff is further deflated. Cuff pressure falls below the pressure within the vessel walls; this sound is the diastolic pressure in infants and children.

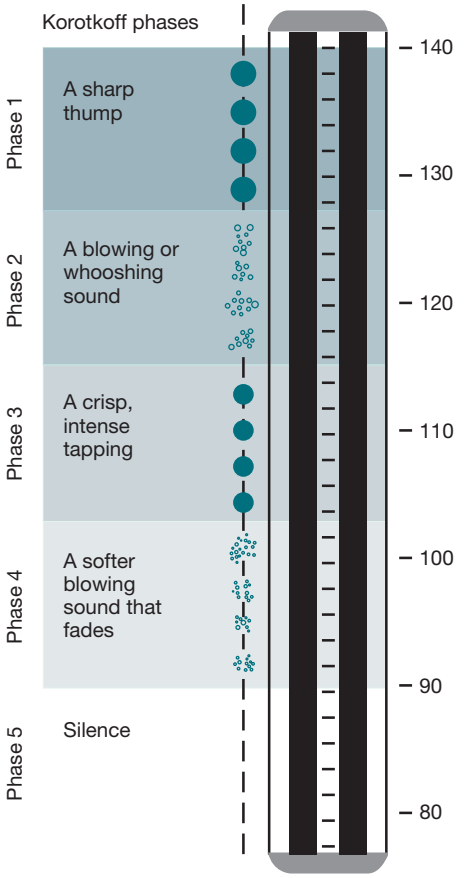

Figure 23-13 **The sounds auscultated during blood pressure measurement can be differentiated into five Korotkoff phases. In this example, blood pressure is 140/90 mmHg.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

5. The fifth KS is the absence of sound. In adolescents and adults, the fifth sound corresponds to the diastolic pressure.

In some patients, the sounds are clear and distinct. In other patients, only the beginning and ending sounds are clear.

Palpation technique

The palpation technique is often used when the patient's usual blood pressure reading is unknown. This approach is useful for determining how high to inflate the cuff. The palpation technique is also used for patients whose arterial pulsations are too weak to create Korotkoff sounds. Severe blood loss and decreased heart contractility are examples of conditions that result in blood pressures too low to auscultate accurately. Only the systolic blood pressure can be easily assessed by palpation (Box 23-6). When the palpation technique is used, the systolic value and the manner in which it was measured are recorded (e.g. RA 90/–, palpated, supine).

BOX 23-6 Palpating the systolic blood pressure

1. Apply blood pressure cuff to the upper arm in the same manner as the auscultation method (Skill 28-5).
2. Continually palpate the radial artery.
3. Inflate blood pressure cuff 30 mmHg above the point at which the radial pulse can no longer be palpated.
4. Release valve and allow mercury to fall 2 mmHg/second.
5. As soon as the radial pulse is palpable, note the manometer reading – this is the systolic blood pressure.

The palpation technique is used *with* auscultation in some instances. In some hypertensive patients, the sounds usually heard over the brachial artery when the cuff pressure is high disappear as pressure is reduced and then reappear at a lower level.

Auscultation

The best environment for blood pressure measurement by auscultation is a quiet room at a comfortable temperature. Although the patient may lie or stand, sitting is the preferred position. If auscultation is not performed correctly (Table 23-9), blood pressure readings will be incorrect. When unsure of a reading, a colleague should reassess the blood pressure.

Automatic blood pressure devices

Electronic devices are commonly used to determine blood pressure (Figure 23-14). Whereas the auscultation technique relies on the detection of Korotkoff sounds, some electronic devices rely on the principle of oscillometry. The system includes either a microphone or a pressure sensor built into the inflatable cuff. The microphone or acoustic system hears Korotkoff sounds and registers diastolic and systolic readings. The pressure sensor or ultrasonic system responds to the pressure waves generated by the movement of blood through the artery. The sensor determines the initial burst of oscillations and translates the information into a systolic pressure reading. The diastolic pressure is measured when the oscillations are lowest, just before they stop.

Electronic devices work automatically and are applied when frequent blood pressure assessment is required, such as in the critically ill or potentially unstable patient, during or after invasive procedures or when therapies require frequent monitoring (e.g. intravenous heart and blood pressure medications). However, some patient conditions are not appropriate for automatic blood pressure devices (Box 23-7).

TABLE 23-9 Common errors in blood pressure measurement

Error	Effect
Arm above heart level	False low reading
Arm below heart level	False high reading
Arm not supported	False high reading
Bladder or cuff too narrow	False high reading
Bladder or cuff too wide	False low reading
Cuff wrapped too loosely or unevenly	False high reading
Deflating cuff too quickly	False low systolic and false high diastolic readings
Deflating cuff too slowly	False high diastolic reading
Inaccurate inflation level	Inaccurate interpretation of systolic and diastolic readings
Inflating cuff too slowly	False high diastolic reading
Multiple examiners using different Korotkoff sounds for diastolic readings	False high systolic and low diastolic readings
Repeating assessments too quickly	False low systolic reading
Stethoscope applied too firmly against antecubital fossa	False low diastolic reading
Stethoscope that fits poorly or impairment of the examiner's hearing, causing sounds to be muffled	False low systolic and false high diastolic readings

Figure 23-14 Automatic vital-signs monitor.

Connex® Vital Signs Monitor, courtesy of Welch Allyn.

BOX 23-7 Patient conditions not appropriate for electronic blood pressure measurement

- Irregular heart rate
- Peripheral vascular obstruction (e.g. clots, narrowed vessels)
- Shivering (e.g. postoperative shivering)
- Seizures
- Excessive tremors
- Blood pressure less than 90 mmHg systolic

The advantages of automatic devices are the ease of use and efficiency when repeated or when frequent measurements are indicated. However, automatic devices are more sensitive to outside interference and are very susceptible to error. The microphone or pressure sensor must be positioned directly over the artery for proper function. Patient movements, vibration or outside noise can interfere with the microphone or sensor signal.

A baseline blood pressure should be obtained using the auscultation method before applying automatic devices. A comparison helps evaluate a patient's status and allows proper programming of the device. Once the blood pressure cuff is applied, the device is programmed to obtain and record blood pressure readings at preset intervals. Alarm limits can be programmed to be activated if the blood pressure measurement is outside desired parameters. If readings do not match your understanding of the patient's situation and other assessment data, correlate your finding with a manual blood pressure to reduce the potential for error.

Position

The patient's position during routine blood pressure measurement should be the same each time to permit a meaningful comparison of values. Controlling factors responsible for artificially high readings, such as pain, anxiety or exertion, are an important part of blood pressure measurement. The patient's perception of a stressful physical or interpersonal environment will affect blood pressure measurement. For example, blood pressure measurements taken at the patient's place of employment or in a medical practitioner's office are often higher than those taken in the patient's home.

Documenting blood pressure readings

Two numbers are usually recorded for a blood pressure measurement:

- The point on the manometer when the first Korotkoff sound is heard for systolic, and

- The point on the manometer when the fifth Korotkoff sound is heard for diastolic.

Document blood pressure (e.g. 120/80 mmHg) and the patient's position (e.g. sitting). The importance of obtaining an accurate blood pressure cannot be overemphasised, because many clinical decisions and interventions are made on the basis of findings. In most clinical situations, blood pressure is recorded graphically on a standardised observation chart alongside other vital signs (Figure 23-2).

Hypertension

A common alteration in blood pressure is hypertension. As a major factor underlying deaths from stroke, hypertension is often asymptomatic but characterised by persistently elevated blood pressure. Categories of hypertension have been developed and determine intervention (see Table 28-10). One elevated blood pressure measurement does not qualify as a diagnosis of hypertension. However, if the first blood pressure measurement shows a high systolic or diastolic reading (e.g. 150/90 mmHg), repeated measurements are required. A diagnosis of hypertension in adults is made when: (1) Average diastolic measurement on at least two subsequent occasions is at least 90 mmHg (diastolic hypertension), or (2) Average of multiple systolic blood pressures on two or more occasions is consistently higher than 135 mmHg (systolic hypertension).

Hypertension is associated with the thickening and loss of elasticity in the arterial walls. Peripheral vascular resistance increases within thick and inelastic vessels. The heart must continually pump against greater resistance. As a result, blood flow to vital organs such as the heart, brain and kidney decreases. People with a family history of hypertension are at significant risk. Obesity, cigarette smoking, heavy alcohol consumption, high sodium (salt) intake, sedentary lifestyle and continued exposure to stress are also linked to hypertension. The incidence of hypertension is greater in patients with diabetes, older adults and Indigenous Australians.

TABLE 23-10 Classification of blood pressure for adults

Diagnostic category	Systolic (mmHg)	Diastolic (mmHg)
Normal	< 120	< 80
High normal	120–139	80–89
Hypertension*		
Grade 1 (mild)	140–159	90–99
Grade 2 (moderate)	160–179	100–109
Grade 3 (severe)	≥ 180	≥ 110
Isolated systolic hypertension	≥ 140	< 90
Isolated systolic hypertension with widened pulse pressure	≥ 160	≤ 70

Reproduced with permission from National Heart Foundation of Australia (National Blood Pressure and Vascular Disease Advisory Committee). Quick reference guide for health professionals. Guide to management of hypertension 2008. Updated December 2010. Melbourne: National Heart Foundation of Australia, 2010. New guidelines will be released in mid to late 2016.

Hypotension

Hypotension is generally considered present when the systolic blood pressure falls to 90 mmHg or below. Although some adults have a low blood pressure normally, for the majority of people low blood pressure is an abnormal finding associated with illness. Hypotension occurs because of the dilation of the arteries in the vascular bed, the loss of a substantial amount of blood volume (e.g. haemorrhage) or the failure of the heart muscle to pump adequately (e.g. cardiac failure). Hypotension associated with pallor, skin mottling, clamminess, confusion, increased heart rate or decreased urine output is life-threatening and should be reported immediately.

Orthostatic hypotension, also referred to as *postural hypotension*, occurs when a normotensive person (one with normal blood pressure) develops symptoms and low blood pressure when rising to an upright position. When a healthy individual changes from a lying to a sitting to a standing position, the peripheral blood vessels in the legs constrict. Constriction of the lower-extremity vessels when standing prevents the pooling of blood in the legs due to gravity. When patients have a decreased blood volume, their blood vessels are already constricted. When a volume-depleted patient stands there is a significant drop in blood pressure with an increase in heart rate to compensate for the drop in cardiac output. Patients who are dehydrated or anaemic or who have experienced prolonged bed rest or recent blood loss are at risk of orthostatic hypotension. Some medications can cause orthostatic hypotension, especially in older adults or young patients. Blood pressure should always be measured before administering such medications.

Orthostatic vital sign measurements include obtaining blood pressure and pulse with the patient supine, sitting and standing. When recording orthostatic blood pressure measurements, record the patient's position in addition to the blood pressure measurement (e.g. 140/80 supine, 132/72 sitting, 108/60 standing). The readings are obtained at least 2–3 minutes after the patient changes position. If your findings are positive for orthostatic hypotension, the patient is helped to a lying position and the medical practitioner or nurse in charge is notified. While obtaining orthostatic measurements, observe for other symptoms of hypotension such as dizziness, weakness or light-headedness.

CLINICAL EXAMPLE CONTINUED

You note on the observation chart that Mrs Winter's oxygen saturations are normally > 93%, so you increase the oxygen therapy. The coarse crackles and wheeze you heard are probably due to the presence of secretions in the lower airways. The reduced sounds may be caused by an area of local collapse or consolidation. You remember that Mrs Winter was diagnosed with a chest infection, but it is evident now that this is worsening. After maintaining a clear airway and ensuring that she is taking in enough oxygen, you continue the ABCDE assessment:

CIRCULATION: Her pulse rate is 98 beats/minute (which has been trending upwards from a baseline of 70 bpm over the past shift), and the pulse is irregular (this has not been noted before). Mrs Winter is already attached to an automatic vital signs monitor, but you know it is important to take a manual BP for an accurate reading in a deteriorating patient. Her manual BP is 100/50 mmHg and she feels warm and sweaty. You are unable to determine urine output accurately without an indwelling catheter, but there is no record that she has passed urine over the past shift on the fluid balance chart.

Adapted from Scenario 5.2 in Adam S, Odell M, Welch J 2010 Rapid assessment of the acutely ill patient. Wiley-Blackwell, Oxford, pp.89-94.

Disability

Physiology

Disability refers to assessment of conscious state. The central nervous system (brain and spinal cord) is the primary regulator of all body functions; somatic and autonomic nervous systems (peripheral nervous system) are controlled by the central nervous system to regulate muscular tone and function, respiratory rate and effort, cardiac output and body temperature. Many patient situations can impair the function of the central nervous system. Common causes of impaired consciousness are summarised in Box 23-8.

BOX 23-8 Common causes of decreased level of consciousness

Hypoxia
Alterations in blood glucose
Decreased blood perfusion
Metabolic and electrolyte disorders
Altered body temperature
Brain injury or disease
Epilepsy
Drugs: opioid analgesics, sedatives

Level of consciousness

Assessment of **level of consciousness** must be documented on the standard observation chart each time you conduct a primary survey, most often using the AVPU scale:

A = Alert
V = Responsive to Verbal stimuli
P = Responsive to Pain
U = Unresponsive

Focused neurological assessment, including the Glasgow Coma Scale (GCS), is explained in Chapter 24. To use the AVPU scale, first conduct a general survey of the patient. They are considered alert if their eyes are open and they are taking in their surroundings. Basic mental status assessment includes asking simple questions about orientation, such as whether the patient knows who they are, where they are and what month/date it is (Adam et al 2010). As level of responsiveness decreases, the patient may only respond to voice or gentle shaking, recorded as 'responsive to verbal stimuli'. If application of pain is required to elicit a response, or the patient is unresponsive, call for help and stay with your patient to maintain ABCs.

CLINICAL EXAMPLE CONTINUED

You have not yet done a formal assessment of consciousness following the ABCDE approach, but your first interaction with Mrs Winter might suggest she has a reduced level of consciousness – so you talk to her again to check her mental status, particularly as she has already suffered a stroke.

DISABILITY: Mrs Winter slumps to one side of the bed and although this may be no different from how she has been previously, it is also possible that she may have had another stroke. She opens her eyes and responds only when you call her name and gently shake her shoulder, and so you score her as 'responds to voice' on the AVPU scale. Staff on the previous shift reported that she had become more confused and restless over the past 2 hours, but now she appears drowsy as she is starting to tire from increased respiratory effort. Her responses to simple orientation questions do not make sense.

Adapted from Scenario 5.2 in Adam S, Odell M, Welch J 2010 Rapid assessment of the acutely ill patient. Wiley-Blackwell, Oxford, pp.89-94.

Exposure

Exposure refers to measurement of body temperature and also involves a general head-to-toe scan for obvious problems (Adam et al 2010). A general survey should include observation of the skin, including risks or signs of pressure injury, any wounds, dressings or drains, and invasive lines. Basic clinical assessments over your shift can also reveal important changes in patient status that are early signs of clinical deterioration. Observe the patient's

ability to stand, transfer and mobilise. Bowel movements provide vital information on how the body is functioning (Holl 2014). Routinely ask about the patient's last bowel movement.

Body temperature

Physiology and regulation

The **body temperature** is the difference between the amount of heat produced by body processes and the amount of heat lost to the external environment:

Body temperature = Heat produced – Heat lost

Despite extremes in environmental conditions and physical activity, temperature control mechanisms keep the body's core temperature (temperature of the deep tissues) relatively constant (Figure 23-15). Surface temperature fluctuates depending on blood flow to the skin and the amount of heat lost to the external environment. While there is no single temperature that is 'normal' for all people, the body's tissues and cells function best within a relatively narrow temperature range, the normal range being approximately 36.2–37.5°C (Gordon & Craft 2011).

Nurses can use knowledge of temperature-control mechanisms to understand and promote temperature regulation. The balance between heat lost and heat produced, or thermoregulation, is precisely regulated by physiological and behavioural mechanisms.

Neural and vascular control

Body temperature is controlled in the anterior portion of the hypothalamus at a *set point* that is normal for each individual. This thermoregulatory centre is monitored by peripheral thermoreceptors in the skin and mucous membranes and central thermoreceptors in internal organs including the hypothalamus. A fall in environmental temperature activates heat-production mechanisms such as vasoconstriction of blood vessels to reduce blood flow to the skin and extremities. When vasoconstriction is ineffective in preventing additional heat loss, compensatory heat production is stimulated through voluntary muscle contraction and muscle shivering.

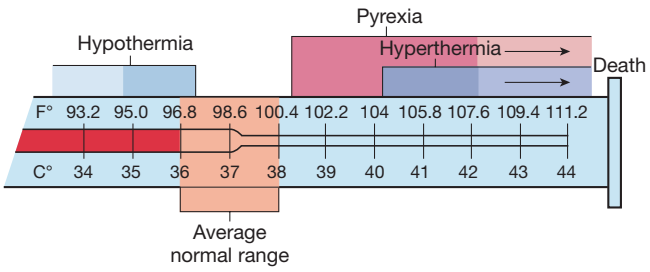

Figure 23-15 Ranges of normal temperature values and abnormal body temperature alterations.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Heat production

Heat production within the body is the by-product of metabolism, skeletal muscle tone and contraction, and chemical thermogenesis. Metabolism refers to the chemical reactions in all body cells. Chemical reactions require energy in the form of adenosine triphosphate (ATP). Any ATP metabolic process results in the production of heat. Food is the main fuel source for metabolism; its energy is transferred to ATP, which in turn transfers energy to body cells. When metabolism increases, additional heat is produced and vice versa.

Heat loss

Heat loss and heat production occur simultaneously. The skin's structure and exposure to the environment result in constant normal heat loss through radiation, conduction, convection and evaporation (Figure 23-16). Diaphoresis is profuse sweating associated with an elevated body temperature, physical exertion, exposure to heat, and mental or emotional stress.

Behavioural control

Individuals voluntarily act to maintain a comfortable body temperature when exposed to temperature extremes. An essential aspect of the nurse's role is the assessment and modification of risk factors for ineffective thermoregulation. Infants can sense uncomfortable warm conditions, but need help to change their environment. Older adults may need help in detecting cold environments and minimising heat loss. Illness, a decreased level of consciousness or impaired thought processes, all result in an inability to recognise the need to change behaviour for temperature control. When temperatures become

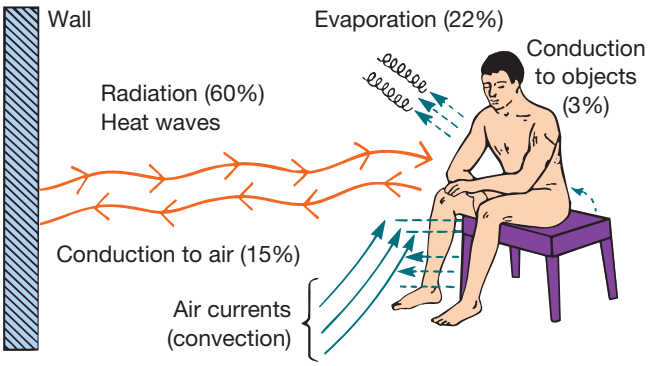

Figure 23-16 Mechanisms of heat loss from the body.

Modified from Guyton AC, Hall JE 2011 Textbook of medical physiology, 12th edn. Saunders, Philadelphia.

extremely high or low, health-promoting behaviours, such as removing or adding clothing, have a limited effect on controlling temperature.

Factors affecting body temperature

Age

At birth the newborn leaves a warm, relatively constant environment and enters one in which temperatures fluctuate widely. Extra care is needed to protect the newborn because their temperature-control mechanisms are immature. A newborn loses up to 30% of body heat through the head and therefore needs to wear a cap to prevent heat loss. When protected from environmental extremes, the newborn's body temperature is maintained within the range of 35.5–37.5°C.

The older adult has a narrower range of body temperatures than the younger adult. The average body temperature of older adults is approximately 36°C. Older adults are particularly susceptible to temperature extremes because of deterioration in control mechanisms, particularly poor vasomotor control (control of vasoconstriction and vasodilation), reduced amounts of subcutaneous tissue, reduced sweat gland activity and reduced metabolism.

Exercise

Muscle activity requires an increased blood supply and increases carbohydrate and fat breakdown. This increased metabolism increases heat production and thus body temperature. Prolonged strenuous exercise, such as long-distance running, can temporarily raise body temperatures up to 40°C.

Hormone level

Women generally experience greater fluctuations in body temperature than men. Menstrual cycle hormonal variations cause body temperature fluctuations. When progesterone levels are low, the body temperature is a few tenths of a degree below the baseline level; the lower temperature persists until ovulation occurs. During ovulation, greater amounts of progesterone raise the body temperature to previous baseline levels or higher. These variations can predict the most fertile time to achieve pregnancy.

Circadian rhythm

Body temperature follows a circadian pattern, peaking late afternoon (1800–2200 hours) and falling early morning (0200–0400 hours). Interestingly, temperature patterns are not automatically reversed in people who work at night and sleep during the day; it takes 1–3 weeks for the cycle to reverse. In general, the circadian temperature rhythm does not change with age.

Stress

Physical and emotional stress increases body temperature through hormonal and neural stimulation. These physiological changes increase metabolism, which increases heat production.

Environment

Environment influences body temperature. If temperature is assessed in a very warm room, a person may be unable to regulate body temperature by heat-loss mechanisms, and the body temperature will be elevated. If the person has just been outside in the cold without warm clothing, body temperature may be low because of extensive radiant and conductive heat loss. Infants and older adults are most likely to be affected by environmental temperatures, because their thermoregulatory mechanisms are less efficient.

Sites for measuring body temperature

There are several sites for measuring core and surface body temperature. The non-invasive sites used most commonly for temperature measurement include the tympanic membrane, mouth and axilla (Box 23-9). The rectum is an invasive site, which is occasionally used.

Oral, axillary and skin temperature sites rely on effective blood circulation at the measurement site. The heat of the blood is conducted to the thermometer probe. Non-invasive, chemically prepared thermometer patches can also be applied to the skin. Tympanic temperature relies on the radiation of body heat to an infrared sensor. Tympanic temperature is considered a core temperature because the tympanic membrane shares the same arterial blood supply as the hypothalamus.

The temperature obtained varies, depending on the site used, but should be between 36°C and 38°C. Research findings from numerous studies are contradictory; however, it is generally accepted that rectal temperatures are usually 0.5°C higher than oral temperatures, and axillary temperatures are usually 0.5°C lower than oral temperatures (Guyton & Hall 2011). Each of the common temperature measurement sites has advantages

BOX 23-9 Core and surface temperature measurement sites

Core	Surface
Tympanic membrane	Skin
Oesophagus	Axillae
Urinary bladder	Oral
Pulmonary artery	

and disadvantages (Box 23-10). Choose the safest and most accurate site for the patient (Skill 23-5). The same site should be used when repeated measurements are necessary.

Thermometers

The electronic thermometer consists of a rechargeable battery-powered display unit, a thin wire cord and a temperature-processing probe covered by a disposable plastic sheath (Figure 23-17). One form of electronic thermometer uses a pencil-like probe. Separate non-breakable probes are available for oral and rectal use. The oral probe can also be used for axillary temperature measurement. Within 20–50 seconds of insertion a reading appears on the display unit. A sound signals when the peak temperature reading has been measured.

Another form of electronic thermometer is used exclusively for tympanic temperature (Figure 23-18). An otoscope-like speculum with an infrared sensor tip detects heat radiated from the tympanic membrane. The head is

BOX 23-10 Advantages and disadvantages of select temperature measurement sites

Tympanic membrane sensor

Advantages:
- Easily accessible site
- Minimal patient repositioning required
- Very rapid measurement (2–5 seconds)
- Can be obtained without disturbing or waking patient
- Unaffected by oral intake of food, fluids, smoking
- Can be used for tachypnoeic patients
- More accurately reflects core temperature than any other method (Nimah et al 2006).

Disadvantages:
- Requires removal of hearing aids before measurement
- Should not be used with patients who have had surgery of the ear or tympanic membrane
- May have lower readings with cerumen impaction (Lu et al 2010).

Oral

Advantages:
- Accessible – requires no position change
- Minimal patient repositioning required
- Provides accurate surface temperature reading

Disadvantages:
- Affected by ingestion of fluids or foods, smoke and oxygen delivery (Guyton & Hall 2011)
- Should not be used with patients who have had oral surgery, trauma, history of epilepsy or shaking chills
- Should not be used with infants, small children or confused, unconscious or uncooperative patients
- Risk of body fluid exposure
- Uncomfortable for patients with nausea

Axilla

Advantages:
- Safe and non-invasive
- Can be used with newborns and uncooperative patients

Disadvantages:
- Long measurement time
- Requires continuous positioning by nurse
- Lags behind core temperature during rapid temperature changes
- Requires exposure of thorax
- Not recommended to detect fever in infants and young children

Skin

Advantages:
- Inexpensive
- Provides continuous reading
- Safe and non-invasive
- Does not require disturbing of patient
- Can be used for neonates
- Easy to read

Disadvantages:
- Lags behind other sites during temperature changes, especially during hyperthermia
- Adhesion can be impaired by diaphoresis or sweat
- Can be affected by environmental temperature
- Unreliable during chill phase of fever

Infrared

Advantages:
- Rapid measurement
- Safe and non-invasive
- Does not require disturbing of patient
- Can be used for neonates
- Easy to read

Disadvantages:
- May need advanced techniques for core measurement in assessment of hypothermia less than 35 degrees Celsius.

Adapted from: Guyton AC, Hall J 2011 Textbook of medical physiology,12th edn. Saunders, Philadelphia; Lu S-H et al 2010 A systematic review of body temperature variations in older people. J ClinNurs 19(1–2):4–16; Nimah MM et al 2006 Infrared tympanic thermometry in comparison with other temperature measurement techniques in febrile children. PediatrCrit Care Med 7(1):48–55.

SKILL 23-5

Measuring body temperature

Delegation considerations

Temperature measurement can be delegated to enrolled nurses who are informed of:

- the frequency of temperature measurement
- the reportable levels for patient
- the need to report any abnormalities that should be reconfirmed by the nurse.

Equipment

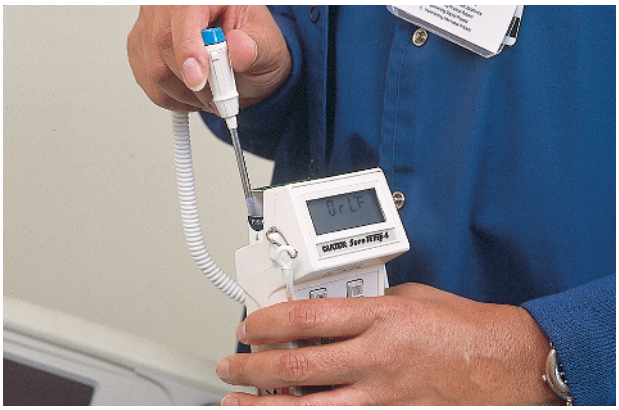
- Appropriate thermometer
- Pen, observation chart
- Plastic thermometer sleeve or disposable probe cover

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine the frequency of monitoring body temperature. Assess for signs and symptoms of temperature alterations and for factors that influence body temperature.	Physical signs and symptoms may indicate abnormal temperature.
2. Determine any previous activity that would interfere with accuracy of temperature measurement. When taking oral temperature, wait 15–20 minutes before measuring temperature orally if patient has smoked or ingested hot or cold liquids or foods.	Smoking or oral intake of food or fluids can cause false temperature readings in oral cavity.
3. Determine appropriate temperature site and device for patient.	Chosen based on patient requirements, advantages and disadvantages of each site (see Box 23-10).
4. Explain how temperature will be taken and importance of maintaining proper position until reading is completed.	
5. Perform hand hygiene.	Reduces transmission of microorganisms.
6. Help patient assume comfortable position that provides easy access to temperature site.	Ensures comfort and accuracy of temperature reading.
7. Obtain temperature reading.	
A. Oral temperature measurement with electronic thermometer	
(1) Put on oral probe cover.	Use of oral probe cover, which can be removed without physical contact, minimises need to wear gloves.

STEPS	RATIONALE
(2) Remove thermometer pack from charging unit. Attach oral probe (blue tip) to thermometer unit. Grasp top of probe stem, being careful not to put pressure on the ejection button.	Charging provides battery power. Ejection button releases plastic probe cover from tip.
(3) Slide disposable plastic probe cover over thermometer probe until cover locks in place (see illustration).	Soft plastic cover will not break in patient's mouth and prevents transmission of microorganisms between patients.



Step 7A(3) Sliding disposable probe cover over thermometer probe.

(4) Ask patient to open mouth; then gently place thermometer probe under tongue in posterior sublingual pocket lateral to centre of lower jaw.	Heat from superficial blood vessels in sublingual pocket produces temperature reading. With electronic thermometer, temperatures in right and left posterior sublingual pocket are significantly higher than in area under front of tongue.
(5) Ask patient to hold thermometer probe with lips closed.	Maintains proper position of thermometer during recording.
(6) Leave thermometer probe in place until audible signal occurs and patient's temperature appears on digital display; remove thermometer probe from under patient's tongue.	Probe must stay in place until signal occurs to ensure accurate reading.
(7) Push ejection button on thermometer stem to discard plastic probe cover into appropriate receptacle.	Reduces transmission of microorganisms.
(8) Return probe to storage position of thermometer unit.	Protects probe from damage. Returning probe automatically causes digital reading to disappear.
(9) Perform hand hygiene.	Reduces transmission of microorganisms.
(10) Return thermometer to charger.	Maintains battery charge.

STEPS	RATIONALE
B. Axillary temperature measurement with electronic thermometer	
(1) Draw curtain around bed and/or close door.	Provides privacy.
(2) Position patient lying supine or sitting.	Provides easy access to axilla.
(3) Move clothing or gown away from shoulder and arm.	Exposes axilla for correct thermometer probe placement.
(4) Remove thermometer pack from charging unit. Be sure oral probe (blue tip) is attached to thermometer unit. Grasp top of probe stem, being careful not to apply pressure on the ejection button.	Charging provides battery power. Ejection button releases plastic cover from probe.
(5) Slide disposable plastic probe cover over thermometer probe until cover locks in place.	Soft plastic cover prevents transmission of microorganisms between patients.
(6) Raise patient's arm away from torso, inspect for skin lesions and excessive perspiration. Insert probe into centre of axilla, lower arm over probe and place arm across patient's chest (see illustration).	Maintains proper position of probe against blood vessels in axilla.

Step 7B(6) Axillary temperature measurement.

(7) Leave probe in place until audible signal occurs and temperature appears on digital display.	Probe must stay in place until signal occurs to ensure accurate reading.
(8) Remove probe from axilla.	
(9) Push ejection button on thermometer stem to discard plastic probe cover into appropriate receptacle.	Reduces transmission of microorganisms.
(10) Return probe to storage position of thermometer unit.	Protects probe from damage. Returning probe automatically causes digital reading to disappear.
(11) Help patient assume a comfortable position.	Restores comfort and promotes privacy.
(12) Perform hand hygiene.	Reduces transmission of microorganisms.

STEPS	RATIONALE
(13) Return thermometer unit to charger.	Maintains battery charge.
C. Tympanic membrane temperature with electronic thermometer	
(1) Help patient assume comfortable position with head turned towards side, away from nurse. Right-handed people should obtain temperature from patient's right ear. Left-handed people should obtain temperature from patient's left ear. The less acute the angle of approach, the better the probe seal.	Ensures comfort and exposes auditory canal for accurate temperature measurement.
(2) Remove thermometer handheld unit from charging base, being careful not to apply pressure on the ejection button.	Base provides battery power. Removal of handheld unit from base prepares it to measure temperature. Ejection button releases plastic probe cover from tip.
(3) Slide clean disposable speculum cover over otoscope-like lens tip until it locks into place, being careful not to touch lens cover.	Lens cover must be unimpeded by dust, fingerprints or earwax to ensure clear optical pathway.
(4) Insert speculum into ear canal following manufacturer's instructions for tympanic probe positioning:	Correct positioning of the probe with respect to ear canal ensures accurate readings.
(a) Pull ear pinna backwards for a child, up and out for an adult. (b) Fit probe snugly into canal and do not move. (c) Point towards nose.	The ear tug straightens the external auditory canal, allowing maximum exposure of the tympanic membrane.
(5) As soon as probe is in place depress scan button on handheld unit. Leave thermometer probe in place until audible signal occurs and patient's temperature appears on digital display.	Depression of scan button causes infrared energy to be detected. Otoscope tip must stay in place until signal occurs to ensure accurate reading.
(6) Carefully remove speculum from auditory meatus.	
(7) Push ejection button on handheld unit to discard plastic probe cover into appropriate receptacle.	Reduces transmission of microorganisms. Automatically causes digital reading to disappear.
(8) If a second reading is necessary, replace probe lens cover and wait 2–3 min before inserting the probe tip.	Lens cover must be free of cerumen to maintain optical path.
(9) Return handheld unit to charging base.	Protects sensory tip from damage.
(10) Help patient assume a comfortable position.	Restores comfort and sense of wellbeing.
(11) Perform hand hygiene.	Reduces transmission of microorganisms.

STEPS	RATIONALE
8. Discuss findings with patient as needed.	Promotes participation in care and understanding of health status.
9. If temperature is assessed for the first time, establish temperature as baseline if it is within normal range.	Used to compare future temperature measurements.
10. Compare temperature reading with patient's previous baseline and acceptable temperature range for patient's age group.	Normal body temperature fluctuates within narrow range; comparison reveals presence of abnormality. Improper placement or movement of thermometer can cause inaccuracies. Second measurement confirms initial findings of abnormal body temperature.

RECORDING AND REPORTING

- Record temperature in observation chart.
- Report abnormal findings to nurse in charge or medical practitioner.

Figure 23-17 Electronic thermometer. Blue probe is for oral or axillary use. Red probe is for rectal use.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

stabilised, the ear pulled straight back (children) or up and back (adults), and within 2–5 seconds of placement of the speculum in the auditory canal a reading appears on the display unit. A sound signals when the peak temperature reading has been measured.

A recent inclusion to body temperature measurement is the infrared non-touch thermometer (Figure 23-19). Temperature can be ascertained by holding the thermometer near the patient's head and activating the device.

Disposable, single-use thermometers are thin strips of plastic with a temperature sensor at one end. The sensor consists of a matrix of dot-like indentations that contain chemicals which melt and change colour at different temperatures. They are used for oral or axillary temperatures, particularly with children (Figure 23-20). Single-use thermometers are inserted the same way as any oral or axillary thermometer. The thermometer is removed after 3 minutes and read after waiting about 10 seconds for the colour change to stabilise.

Another form of disposable thermometer is a temperature-sensitive patch or tape. Applied to the forehead or abdomen, the patch changes colour at different temperatures. Both forms of disposable thermometers are useful for screening patients, especially infants, for altered

Figure 23-19 **Infrared thermometer.**

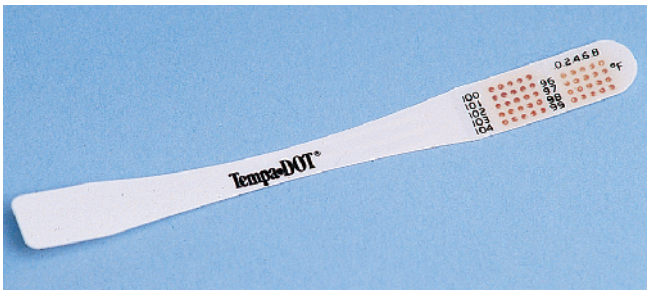

Figure 23-20 **Disposable, single-use thermometer strip.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

temperature, and are not appropriate for monitoring temperature therapies.

Fever

Fever (or pyrexia) occurs as a part of the inflammatory response caused by trauma, surgery, infection, immune responses and tissue damage. For example, in the immediate postoperative period it is common for a patient to develop a fever as part of the normal inflammatory response to surgery. During fever, white blood cell production is stimulated and there is a decrease in the concentration of iron in the blood plasma, suppressing bacterial growth. Fever also stimulates the production of antiviral interferon.

Fever is a host defence response, a *febrile response*, to invasion from exogenous pyrogens, including microbial pathogens such as bacteria, viruses, mycobacteria and fungi as well as non-microbial antigens such as inflammatory agents and drugs. During the febrile response, the set point in the thermoregulatory centre is reset to maintain a higher level of body temperature. This higher temperature is maintained through increased heat production, especially through peripheral vasoconstriction and behavioural measures such as covering oneself with blankets in response to chills even though the body temperature is elevated.

The febrile response is a coordinated series of events to defend the body against these invading organisms through the intentional elevation of the body's core temperature – a mean 1°C increase in body temperature (for that specific measurement site). Fever is an *adaptive* response, even though it places substantial demands on the body through

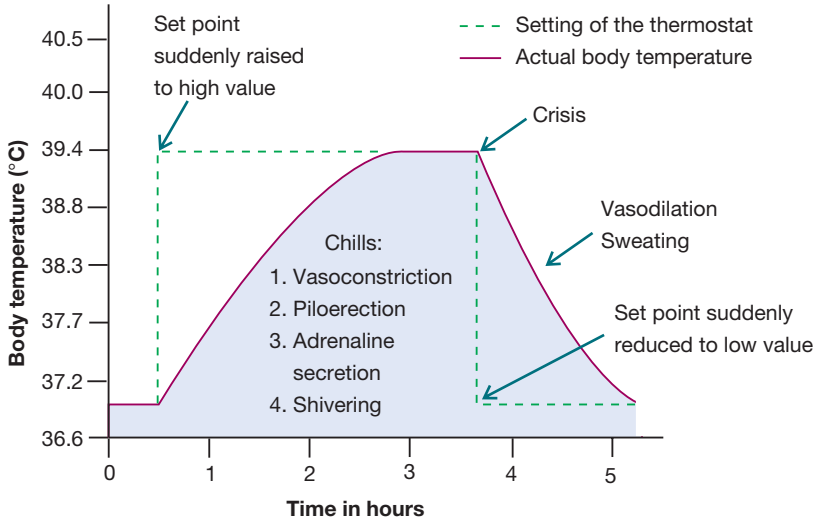

Figure 23-21 **Effect of changing the setpoint of the hypothalamic temperature control during a fever.**

Modified from Guyton AC, Hall JE 2011 Textbook of medical physiology, 12th edn. Saunders, Philadelphia.

increased metabolic demands. Fever has an upper limit ranging from 41°C to 42°C. Most infections produce fevers between 38.5°C and 40.5°C, and an average fever of 39.5°C.

Three phases of fever

The cold phase begins as the hypothalamic set point is reset to a higher level (Figure 23-21). This phase lasts approximately 10–40 minutes, during which all heat-producing mechanisms are activated and there is a rapid, steady rise in temperature. Heat production increases oxygen demands by 3–5 times normal resting levels, contributing to a hypermetabolic state. In this state there are associated increases in heart and respiratory rates and thirst. Vasoconstriction causes the skin to look pale with cyanotic nail beds, and to feel cool and dry. During this period, the person experiences chills and rigors, and feels cold even though the body temperature is rising.

During the *hot phase* the body has reached a new set point and maintains the body temperature at this new higher temperature. The length of this phase depends on the time it takes to eradicate the pyrogenic cytokines responsible for the raised set point. Higher temperatures in this phase are maintained through a balance in heat production and heat loss. Skin is flushed and warm and the individual feels hot. Basal metabolic rate remains high, so tachycardia and thirst continue. Other symptoms associated with this phase include drowsiness, headache, photophobia, reduced activity and appetite, feelings of weakness and/or restlessness and sometimes convulsions. This phase ends when the underlying cause of fever has been treated and/or eliminated by the body, resulting in a decrease in set point to normal.

The *defervescence phase* or the 'breaking' of the fever occurs when there is a sudden decline in circulating pyrogenic cytokines and resetting of the hypothalamic set point back to normal. Heat-loss mechanisms take over and heat production is inhibited. The skin feels warm and is flushed due to vasodilation and sweating, which can exacerbate existing dehydration. Finally, the temperature returns to normal and the patient becomes afebrile.

Benefits and costs of fever

Fever is beneficial in a normal healthy person in the home setting, but seriously ill children and adults can become severely compromised by the additional physiological strain of fever. For every 1°C above normal temperature there are associated physiological changes. There is an associated increase in oxygen consumption of 10–12% and an insensible fluid loss of 20%. Increased fluid loss associated with reduced intake leads to dehydration, the most common and dangerous side effect of fever. During the cold stage, blood pressure increases and glomerular filtration rates decrease; this reverses during the hot phase. Increased urine output assists in the removal of the additional metabolic wastes from the catabolic febrile state.

When fever is prolonged, the risk of dehydration increases and anorexia, secondary to generalised weakness and malaise, is common. Psychological effects include apathy, confusion, delirium and withdrawal from people and activities. These physiological and psychological effects of fever are important considerations for nurses and those caring for febrile children and adults. Fever should be reduced in those who are placed at risk due to the additional physiological burden from the febrile response. This includes children and adults who are seriously ill, and those who have cardiorespiratory, neurological or metabolic disorders or are malnourished, dehydrated or have epileptic lesions and may not tolerate the additional physiological demands during fever. In children, fever may trigger convulsions in those with a seizure disorder or a predisposition to febrile convulsions.

Hypothermia

Heat loss during prolonged exposure to cold overwhelms the body's ability to produce heat, causing hypothermia or temperature less than 35° Celsius (Talley & O'Connor 2014). In *hypothermia* the body at first increases metabolic rate (to increase heat production), increases vasoconstriction (to decrease heat loss), shunts blood from the peripheral vascular bed to the core (to reduce heat loss) and increases shivering (to increase heat production). Hypothermia is classified by core temperature measurements (Box 23-11). Some people are more prone to hypothermia than others (Box 23-12). Hypothermia may also be intentionally induced during surgical procedures, to reduce metabolic demand and the body's need for oxygen.

Hypothermia usually develops gradually and may go unnoticed for several hours. When skin temperature drops to 35°C, the person suffers uncontrolled shivering, loss of memory, depression and poor judgement. As the body temperature falls below 34.4°C, cyanosis occurs,

BOX 23-11 Classification of hypothermia

Mild	33.1–35°C
Moderate	30.1–33°C
Severe	27–30°C
Profound	< 27°C

BOX 23-12 Patients at risk of hypothermia

Neonates

Can lose as much as 4.5°C immediately after delivery, as a result of heat evaporation. They also have a larger surface-to-mass ratio and a small amount of subcutaneous tissue.

Older patients

Often have a decrease in level of thyroxine and therefore a decreased ability to increase metabolic rate and heat production. Have a decreased ability in vasomotor response, including decreased ability to produce heat through shivering.

Patients with alcohol problems

Alcohol increases peripheral vasodilation (increases heat loss), and long-term use may affect the hypothalamic response to cold.

Surgical patients

Patients can lose as much as 0.3°C per hour by loss of heat through an open cavity in a theatre where the ambient temperature is less than the body temperature. Anaesthetics block the activity of shivering and decrease the body's ability to produce heat.

and heart and respiratory rates and blood pressure fall. If hypothermia progresses, cardiac dysrhythmias, loss of consciousness and unresponsiveness to painful stimuli occurs. In cases of severe hypothermia, a person may demonstrate clinical signs similar to death (e.g. lack of response to stimuli and extremely slow respirations and pulse). The assessment of core temperature is critical when hypothermia is suspected. A special low-reading thermometer may be required, because standard devices often do not register below 35°C.

CLINICAL EXAMPLE CONTINUED

Mrs Winter is acutely unwell and at high risk of further deterioration. Following the ABCDE approach, you take a body temperature and begin a head-to-toe scan for other important assessment data:

EXPOSURE: The tympanic body temperature reading confirms Mrs Winter is febrile at 38.9°C and she feels hot and sweaty to touch. You are worried that taken together, the trends in vital signs suggest her chest infection is worsening and she is developing sepsis. Her skin is flushed. There are no wounds, dressings or drains. But you note an IV cannula in the left arm.

The ICU outreach nurse arrives and you are able to hand over your assessment and initial interventions using the ABCDE framework.

Adapted from Scenario 5.2 in Adam S, Odell M, Welch J 2010 Rapid assessment of the acutely ill patient. Wiley-Blackwell, Oxford, pp.89-94.

Conclusion

This chapter has introduced you to the ABCDE approach, which forms the foundation of patient assessment in any setting. It provides a simple framework so that clinical problems can be identified and addressed in priority order. Even during complex and stressful situations such as acute patient deterioration, taking time out to work through each step of the ABCDE approach will help you make sense of the situation and guide initial interventions. When patient problems are identified, a focused assessment will be triggered. The next chapter builds on the primary survey by explaining how to perform a focused body systems assessment.

Key concepts

- The ABCDE approach to assessment is a simple, structured process to improve the early recognition of clinical deterioration. It is the first element of patient assessment in any setting. The core skills during each step are to look, listen, feel and measure.
- Airway patency is the first priority. Look, listen and feel for any airway obstruction.
- Breathing focuses on assessment of respirations, work of breathing, and measurement of oxygen saturation.
- Circulation focuses on feeling the pulse, checking peripheral perfusion, and measuring blood pressure. Assess urine output if possible.
- Disability (level of consciousness) is quickly assessed from the outset using the AVPU scale. Simple questions can be used to evaluate mental status and speech. Ask about pain.
- Exposure includes measurement of body temperature and a general head-to-toe scan to identify any obvious problems. Assess skin colour, wounds, dressings or drains, invasive lines. Note ability to stand and move. Determine last bowel movement.

CHAPTER

24

Undertaking a focused assessment: physical assessment of body systems

Anthony Schoenwald and Clint Douglas

Learning outcomes

Mastery of content will enable you to:

- explain the importance of undertaking systematic health assessment as the basis for nursing care
- identify key considerations and patient preparations required before and during physical assessment
- apply core physical assessment skills relevant to each focused body system assessment and reflect on the use of these skills in your nursing practice
- differentiate normal from abnormal assessment findings
- analyse assessment data to determine the patient's health problems and clinical priorities
- document and communicate your health assessment.

KEY TERMS

Auscultation, p. 585

Respiratory system, p. 603

Introduction

Developing health assessment skills is one of the most important and challenging aspects of becoming a registered nurse (RN). While often invisible to others, patient assessment comprises a major part of what expert RNs do in their daily practice. Particularly in acute care settings, RNs are usually the first healthcare professional to recognise and respond to changes in a patient's condition (see Chapter 39). It can be argued that 'nurses are the professional group that carry the highest level of responsibility for patient assessment, accurate data collection and interpretation' (Considine & Currey 2015:300). They are responsible for implementing most of the hands-on patient care, monitoring patients for complications of illnesses and adverse reactions to treatment, as well as protecting them from deadly healthcare errors. RNs use their knowledge and clinical assessment skills at the bedside to diagnose and manage rapidly-developing, life-threatening emergencies. Well-developed physical assessment skills are also equally important for recognising subtle trends and early changes in a patient's condition to prevent clinical deterioration (Osborne et al 2015). Through this continuous cycle of 24/7 clinical monitoring, decision-making and intervention, RNs save lives and improve patient outcomes every day (Considine & Currey 2015).

As a student nurse you will learn to constantly observe and analyse situations to make clinical judgements. Learning to assess patients systematically and comprehensively is important because your assessment drives all components of patient care. *Objective data*, collected by performing a physical assessment, builds on the *subjective data*, gathered when taking a patient history (see Chapter 5), and is the foundation for clinical decisions, interventions and evaluations. This chapter presents an introduction to the fundamental knowledge and skills you will need as a beginning RN to conduct patient physical assessment. Other chapters will build on this with common focused assessments you will undertake, such as assessment of mobility, fluid and electrolyte balance and nutritional status.

Building on the primary survey approach to patient assessment

A framework provides a logical structure for learning the process of assessment and communication of your findings. Using a structured patient assessment framework has been shown to enhance clinician performance of patient assessment and has the potential to improve patient care and outcomes (Munroe et al 2013). There are multiple frameworks available and you must decide which

RESEARCH HIGHLIGHT

Research question

What is the clinical relevance of routine nursing physical assessment of body systems for hospitalised patient outcomes?

Research abstract

Rothman and colleagues' (2012) large US cohort study of over 42,000 inpatient visits examined whether the nursing physical assessment of body systems captured each shift in the electronic hospital record was a sensitive predictor of all-cause in-hospital and post-discharge mortality. Because nurses charted by exception, the investigators were able to create binary data indicating whether standard normal adult ranges were 'met' or 'not met' for each of the 12 areas of patient assessment.

Analysis of crude odd ratios (OR) revealed that the odds of in-hospital death was more than 9-fold greater for patients with abnormal neurological findings on admission (OR = 9.4), 8-fold for abnormal respiratory findings (OR = 8.1), and approximately 7-fold for abnormal food/nutrition (OR = 7.0), musculoskeletal (OR = 6.9) and psychosocial findings (OR = 6.7). Except for pain assessment, not meeting a minimum standard for the remaining body systems was also significantly associated with a 2.3- (gastrointestinal) to 5.6-fold (safety/falls risk) higher odds of death in hospital, regardless of medical history and diagnosis. Similarly, abnormal physical assessment findings on the final nursing assessment before discharge were strongly correlated with mortality at 2 days, 30 days and 1 year.

Evidence-based practice

- Signs of early deterioration identified during routine nursing physical assessment are strongly associated with patient mortality.
- Nursing physical assessment of functional deteriorations that often precede changes in vital signs are clinically valid and sensitive indicators of patient status during hospitalisation and after discharge.

Reference

Rothman MJ, Solinger AB, Rothman SI, Finlay GD 2012 Clinical implications and validity of nursing assessments: a longitudinal measure of patient condition from analysis of the electronic medical record. BMJ Open2, e000849. doi:10.1136/bmjopen-2012-000849

is the most relevant to the clinical situation. This chapter builds on the primary survey discussed in Chapter 23 and follows a body systems framework.

The key to a successful nursing assessment is to be organised and systematic. In the acute hospital setting the bedside assessment begins with a *primary survey* to determine the vital functioning of the patient and signs of acute deterioration, such as loss of consciousness (see Chapter 23). A *focused* **body systems assessment** can then be initiated once the patient is stable, using the core physical assessment skills in Box 24-1. Skill 24-1 reflects this approach to patient assessment and provides a framework to discuss the core skills you will need as a beginning RN in this chapter.

Fundamental physical assessment skills

Physical assessment is defined as the collection of objective patient data using the skills of inspection, palpation, percussion and auscultation (Fennessey & Wittmann-Price 2011).

Inspection

Inspection is the process of careful observation and visual examination of the patient and relevant body region or part. To use inspection effectively:

- position and expose body parts so that essential surfaces can be viewed (use adequate lighting) while maintaining the patient's dignity
- compare each area inspected with the same area on the opposite side of the body for symmetry
- be aware of normal physical characteristics related to age and gender
- always pay attention to the patient, watching all movements and non-verbal cues
- do not hurry inspection – be thorough and pay attention to detail.

BOX 24-1 Core nursing physical assessment skills for early recognition of patient deterioration in general wards

Vital signs
Measure body temperature
Palpate pulse rate and rhythm
Measure respiratory rate
Measure blood pressure by auscultation
Measure oxygen saturation
Assess for pain

Neurological
Assess level of consciousness
Evaluate speech
Check pupils are equal and reactive to light
Assess muscle strength

Cardiovascular
Inspect and palpate for skin colour and temperature
Palpate capillary refill
Palpate extremities for distal pulses and oedema
Palpate calves for tenderness
Auscultate heart sounds and apical pulse
Perform and interpret ECG for abnormal changes

Respiratory
Assess airway patency
Assess ability to cough
Evaluate work of breathing
Auscultate lung sounds

Gastrointestinal
Inspect abdomen
Auscultate bowel sounds
Palpate abdomen
Assess bowel movements

Nutritional
Inspect oral cavity
Assess ability to swallow
Estimate amount of meals eaten
Measure blood glucose levels
Measure body weight

Renal
Measure 24-hour fluid balance
Measure daily weight
Assess urine output
Palpate bladder
Perform and interpret urinalysis

Skin
Inspect skin integrity
Inspect and palpate skin for signs of pressure injury
Observe any wounds, dressings or drains, invasive lines

Musculoskeletal
Observe ability to transfer and mobilise
Observe gait
Inspect major joints for range of motion

Adapted from Douglas C, Booker C, Fox R et al 2016 Nursing physical assessment for patient safety in general wards: reaching consensus on core skills. Journal of Clinical Nursing, doi: 10.1111/jocn.13201

SKILL 24-1

Nursing physical assessment using a body systems framework

Delegation and other considerations

- Comprehensive patient assessment is the basis for the development of the nursing care plan and therefore should not be delegated by the registered nurse.
- Perform hand hygiene and apply personal protective equipment when appropriate before, during and after patient assessment.

Equipment

- Pen, relevant documentation
- Penlight torch
- Pulse oximeter
- Stethoscope
- Sphygmomanometer
- Thermometer

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Before you begin the active part of the physical examination, perform a rapid visual assessment of the patient and their environment for important cues.	Based on your nursing knowledge and information from handover, some of your observations will be expected. Allows you to determine if there is equipment in use that you need education about before you take over care.
2. **Primary survey** **A. Airway** – Is the airway clear? (1) Listen for noisy or obstructed breathing. (2) Feel for airflow over the mouth. • If indicated, assess whether artificial airway is patent and secure (e.g. Guedel, nasopharyngeal, tracheostomy, endotracheal tube, non-invasive mask). **B. Breathing** – Is the patient breathing spontaneously? (1) Look for rise and fall of the chest. **C. Circulation** – Does the patient have adequate circulation? (1) Observe skin colour. (2) Feel for a pulse. **D. Disability** – What is the patient's level of consciousness? (1) Determine if the patient is alert, responsive to voice, responsive to pain, or unresponsive (unconscious).	The primary survey is concerned with identifying life-threatening circumstances that require immediate attention. It should take about 1 minute to complete. The ABCDE approach is used.

STEPS	RATIONALE
E. Exposure – perform a quick head-to-toe scan of the patient and their environment: (1) Does the patient look well, sick or critical? (2) What treatments are in progress and how might these affect your assessment findings (e.g. medications, infusions, oxygen)? (3) What monitoring devices or equipment are attached to the patient or in their environment, and what do they reveal?	

■ **Critical decision point: Any problems identified during the primary survey need to be managed as a clinical priority before further patient assessment. Determine whether it is safe to proceed with a body systems assessment or whether you need to call for help and manage ABCs first.**

3. Neurological a. Perform hand hygiene. b. Assess level of consciousness and mental status. • If indicated, perform a focused neurological assessment (see Skill 24-2), including Glasgow Coma Scale, pupil size and reaction, limb assessment and vital signs. • If indicated, perform a mental state examination (see Skill 40-1). c. Assess for pain or discomfort. • If indicated, perform a focused pain assessment using a pain assessment tool (see Skill 36-1).	Prevents transmission of microorganisms. Applying the knowledge of normal neurological parameters to the patient's assessment enables identification of normal and abnormal values and immediate intervention.
4. Cardiovascular a. Perform hand hygiene. b. Inspect and palpate skin colour, temperature and capillary refill. c. Palpate peripheral pulses for rate, rhythm and strength (see Skill 23-3). d. Measure blood pressure (see Skill 23-4). e. Auscultate apical pulse and heart sounds. f. Palpate calves for tenderness. g. Palpate for oedema in feet and dependent areas (e.g. sacrum). • If indicated, perform a focused cardiovascular assessment (see Skill 24-3). • Other considerations: (1) Observe and interpret the electrocardiogram (ECG) (see Skill 35-2). (2) Observe for permanent pacemaker (PPM), pacing wires, external pacing, implantable defibrillator. (3) Observe for compression stockings and sequential compression devices.	Prevents transmission of microorganisms. Applying the knowledge of normal cardiovascular parameters to the patient's assessment enables identification of normal and abnormal values and immediate intervention.

STEPS	RATIONALE
5. Respiratory a. Perform hand hygiene. b. Inspect chest and work of breathing. c. Measure respiratory rate, rhythm and depth (see Skill 23-1). d. Assess ability to cough; examine sputum if indicated. e. Auscultate lung sounds. f. Measure oxygen saturation (see Skill 23-2). • If indicated, perform a focused respiratory assessment (see Skill 24-4). • Other considerations: (1) Observe for intercostal catheters and underwater seal drains. Is catheter/drain swinging, bubbling and/or draining freely? Is there wall suction? (2) Identify the colour and volume of any drainage from chest drains.	Prevents transmission of microorganisms. Applying the knowledge of normal respiratory parameters to the patient's assessment enables identification of normal and abnormal values and immediate intervention.
6. Gastrointestinal a. Perform hand hygiene. b. Inspect the abdomen for symmetry, masses or distension. c. Auscultate for bowel sounds. d. Palpate the abdomen lightly noting any tenderness, guarding or rigidity; feel for any masses or pulsations. e. Assess most recent and frequency of bowel action. • If indicated, perform a focused abdominal assessment (see Skill 24-5). • Other considerations: (1) Is the patient nil by mouth (NBM)? If oral diet: normal, soft, smooth/minced? Percent of meal eaten? (2) Observe for enteral feeding tubes (e.g. nasogastric or orogastric tube (NGT/OGT), percutaneous endoscopic gastrostomy (PEG) tube. Continuous, intermittent or bolus feeds? Central or parenteral total parenteral nutrition (TPN)? (3) Observe for stomas. Pink? Active? Consistency and volume of effluent. Intact faecal containment device? Integrity of surrounding skin?	Prevents transmission of microorganisms. Applying the knowledge of normal gastrointestinal parameters to the patient's assessment enables identification of normal and abnormal values and immediate intervention.

STEPS	RATIONALE
7. Renal a. Perform hand hygiene. b. Observe current intake and output 24-hour fluid balance. Assess and interpret fluid status (see Skill 24-6). • If indicated, measure and compare daily weight to determine fluid balance. c. Measure and observe urine output, colour, presence of sediment. • If indicated, palpate bladder for distension. • If indicated, perform urinalysis. • Other considerations: (1) Observe and interpret blood urea and electrolytes. (2) Assess and interpret fluid status (see Skill 34-1). (3) Observe for urostomy, indwelling urinary catheter (IDC), suprapubic catheter (SPC). (4) Observe for peritoneal or haemodialysis. Arteriovenous fistula thrill/bruit? Fluid and sodium restrictions?	Prevents transmission of microorganisms. Applying the knowledge of normal renal parameters to the patient's assessment enables identification of normal and abnormal values and immediate intervention.
8. Musculoskeletal a. Perform hand hygiene. b. Inspect major joints for range-of-motion. c. Assess muscle strength and compare sides. d. Observe safe use of mobility aids. e. Observe ability to transfer and mobilise. • If indicated, perform a focused musculoskeletal assessment (see Skill 24-7).	Prevents transmission of microorganisms. Applying the knowledge of normal musculoskeletal parameters to the patient's assessment enables identification of normal and abnormal values and immediate intervention.
9. Integumentary a. Perform hand hygiene. b. Inspect and palpate the skin for general colour, temperature, moisture and turgor and capillary refill. c. Inspect and palpate for signs of pressure injury such as non-blanchable redness, localised heat, oedema and induration. d. Observe any wounds, dressings and drains for warmth, redness, swelling, exudate and odour. • If indicated, perform a focused wound assessment (see Chapter 26). • If indicated, perform a focused skin assessment (see Skill 24-8). • Other considerations: (1) Observe invasive lines (e.g. peripheral intravenous catheter (IVC), central venous catheter (CVC), peripherally inserted central line (PICC), Vascath, Portacath).	Prevents transmission of microorganisms. Applying the knowledge of normal integumentary parameters to the patient's assessment enables identification of normal and abnormal values and immediate intervention.

STEPS	RATIONALE
10. Compare assessment findings with patient's baseline assessment data. Analyse for important changes or trends over time.	Allows you to make decisions about whether there are clinically significant changes in the patient's condition.
11. Discuss your findings with the patient.	Promotes involvement in care and understanding of health status.

RECORDING AND REPORTING

- Document assessment findings in patient's healthcare record following a structured nursing assessment framework.
- Report any significant abnormal data to senior nurse and/or medical officer.

HOME CONSIDERATIONS

- Health assessment provides an opportunity for patient and family education related to their clinical problems and management.
- Identifies patient's healthcare needs for discharge planning.
- Discharge planning information communicated to all stakeholders.

An example of inspection is observing the patient's work of breathing during your assessment of respiratory rate. Beyond increased respiratory rate, you may observe increased work of breathing with use of accessory muscles, soft tissue retraction (tracheal tug, rib or abdominal recession), or an inability to speak in sentences or cough properly. These represent signs of respiratory distress in your patient that you would identify through the use of inspection.

Palpation

Further assessment is made through the use of touch. Through **palpation**, the fingers or hands can be used to examine underlying body structures. For example, palpation is a major component of gastrointestinal assessment. The abdomen is lightly palpated and should feel soft, non-tender and without masses.

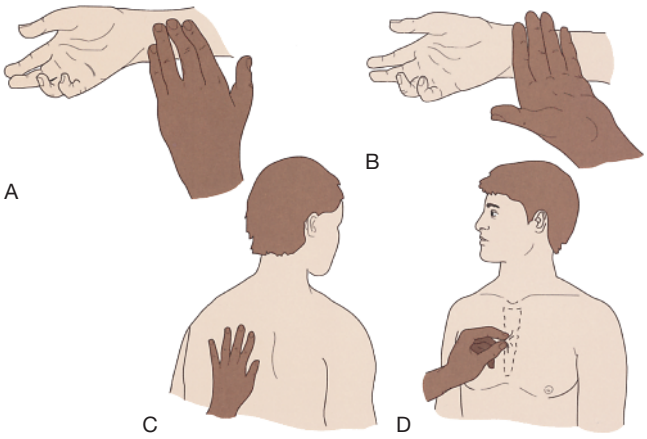

Figure 24-1 Palpation.

A, The radial pulse is detected with the pads of the fingertips, the most sensitive part of the hand. B, The dorsum of the hand allows the nurse to detect temperature variations in skin. C, The palms can be used to detect vibration. D, Grasp the skin with the fingertips to assess turgor.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Percussion

Percussion involves tapping the body with the fingertips to evaluate the size, borders and consistency of body organs and to discover fluid or air in body cavities. When the examiner strikes the middle finger of the non-dominant hand resting against the body's surface with the tip of the middle finger of the dominant hand, percussion tones are generated which can be heard and felt (Figure 24-2). Use a loose swinging motion at the wrist of the percussing hand. With practice you can hear different sounds depending on the density of the underlying tissue (Table 24-1). For example, percussion of fluid in the abdomen can elicit a dull sound over structures that should sound tympanic. Ascites from liver failure would be an example of stony dullness on percussion.

Auscultation

Auscultation is listening to sounds produced by the body. Some sounds may be audible without a stethoscope, such as stridor with a partial airway obstruction. However, lung, heart and bowel sounds are routinely assessed with

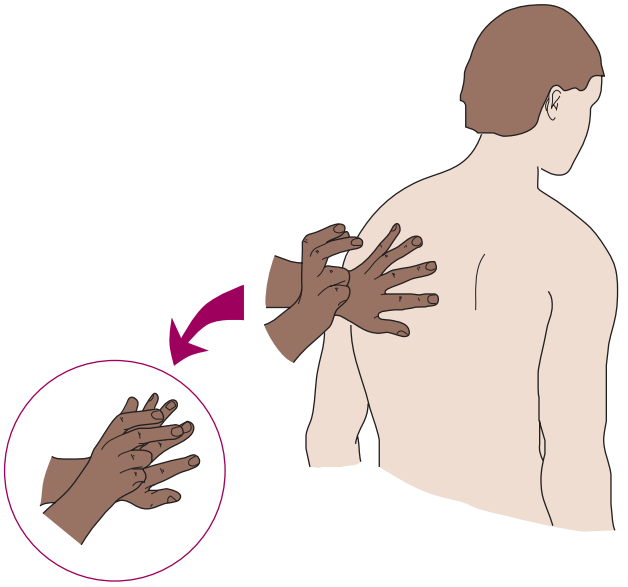

Figure 24-2 Percussion.
To perform indirect percussion, place your middle finger of the non-dominant hand against the body's surface. The tip of the middle finger of the dominant hand strikes the top of the middle finger of the non-dominant hand.

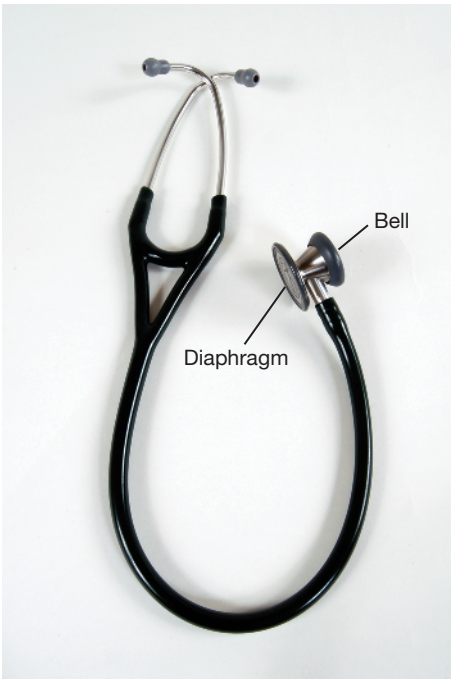

Figure 24-3 Stethoscope diaphragm (front) and bell (back).
Forbes H, Watt E 2016 Jarvis's physical examination and health assessment, 2nd edn. Elsevier, Chatswood, NSW.

TABLE 24-1 Percussion tones

Sound	Quality	Common location
Tympanic	Drum-like	Abdominal areas
Resonance	Hollow	Normal lung
Dullness	Thud-like	Urine in the bladder, liver, spleen
Flatness	Flat	Muscle

a stethoscope. A good quality stethoscope and correct technique is necessary to hear sounds easily (Figure 24-3). When the ear tips are in your ears, the ear pieces should be pointed forward (towards your nose). Place the chest piece directly against the skin, because clothing obscures sound. The diaphragm is used most often and is best for *high-pitched sounds*, such as lung sounds, whereas the bell (held lightly against the skin) is best for *low-pitched sounds*, such as heart murmurs. A number of extraneous sounds created by movement of the tubing or chest piece interfere with auscultation. You will learn to recognise and disregard them during the actual examination.

Preparing for patient assessment

A few simple considerations can make physical assessment easier, while improving data collection and patient safety:

BOX 24-2 Equipment used for health assessment

Clean gloves
Healthcare record for documentation
Sphygmomanometer and cuff
Stethoscope
Penlight torch
Pulse oximeter
Thermometer
Watch

- Ensure patient privacy and protect the patient's dignity at all times.
- Consider the cultural and developmental needs of the patient and how the assessment might need to be adapted (refer to Chapters in Part 4).
- Explain the purpose of the assessment and obtain verbal consent.
- Make sure there is adequate lighting in the room and minimal noise (difficult in most settings).
- Have all the equipment and documentation available at hand (Box 24-2).
- Infection control: Always wash your hands before and after the activity. Use precautions as per facility policy.

WORKING WITH DIVERSITY

Age and developmental stage of patients will determine how you approach physical assessment. Young children aged 2–7 may pose a challenge when undertaking physical assessment. It may be difficult, for example, for you to gain cooperation from the child to sit in a particular position or just to obey any instructions. Often, this may be due to anxiety and so it is imperative for you to gain the child's trust by engaging a parent or caregiver throughout the process. Using aids, such as toys and play, may also help you to perform an accurate assessment. Elderly patients may tire easily during procedures such as lung auscultation and so skill is necessary to ensure comfort and swiftness in obtaining health assessment data. All patients will feel more comfortable with appropriate explanations regarding the assessment.

Neurological system

The rapid primary survey provides you with some basic information about the patient's level of consciousness based on the AVPU scale (Alert, responds to Voice, responds to Pain, or is Unresponsive). Changes in vital signs can also reflect important neurological changes and are always completed first during the primary survey. A more focused assessment of the **neurological system** is then needed to examine the functioning of the central nervous system (CNS). The three most important components covered in this chapter include (1) the Glasgow Coma Scale, (2) pupil size and reaction to light, and (3) limb assessment. You should also evaluate the patient's speech and screen for normal functioning of the special senses such as vision and hearing. Skill 24-2 demonstrates how to perform these steps in a neurological assessment. More advanced skills, such as evaluation of cranial nerves or deep tendon reflexes, are needed for a comprehensive neurological examination, but are not discussed here.

Glasgow Coma Scale

Changes in mental state or level of consciousness are major signs of patient deterioration. The Glasgow Coma Scale (GCS) is the most widely used tool to assess level of consciousness and is incorporated in standard neurological observation charts. It provides a standardised approach to assessment of level of consciousness and a common language for healthcare workers, although consistency in scoring between staff can be unreliable (Reith et al 2015). It is best that the same RN monitors the patient's neurological status each time and performs the GCS together with the oncoming staff during handover. You can watch a video that demonstrates how to correctly perform the GCS (see *Online resources*).

Figure 24-4 shows how the GCS is divided between the eye (E), verbal (V) and motor (M) responses of the patient. It is best to describe the patient responses you actually observed and document a score for each response,

SKILL 24-2

Focused neurological assessment

Delegation and other considerations

- Comprehensive patient assessment is the basis for the development of the nursing care plan and therefore should not be delegated by the registered nurse.
- Perform hand hygiene and apply personal protective equipment when appropriate before, during and after patient assessment.

Equipment

- Penlight torch
- Neurological observation chart
- Pen

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review the patient's baseline assessment data.	The key point of clinical examination is to determine if something has changed. Refer to baseline or previous findings to determine an acute change in patient status.
2. Perform hand hygiene.	Prevents transmission of microorganisms.
3. Ensure comfort and privacy. Explain procedure and clarify any concerns.	Promotes patient's cooperation and comfort during the assessment.
4. Approach the patient with a structured Glasgow Coma Scale (GCS) assessment to determine level of consciousness (see Figure 24-4). Score and describe the patient's responses according to: a. Eye opening b. Best verbal response c. Best motor response	A subtle change in level of consciousness or mentation is usually the earliest and most sensitive indicator of neurologic deterioration. A decrease in total GCS score of 2 or more points is a critical finding and should trigger a rapid response call.
5. Check pupils for size (mm), shape and reaction to light. a. Measure pupil size (which should be equal). b. Use a pen torch to elicit a reflex response from the pupils (Figure 24-6), which should be brisk constriction to light in both eyes.	Changes in pupillary function can indicate cranial nerve dysfunction associated with increased intracranial pressure.
6. Assess limb power (Table 24-2): Upper limbs a. Ask the patient to take your fingers and squeeze. b. Ask the patient to pull your hands towards them against resistance. c. Ask the patient to push your hands away against resistance.	All four extremities are tested for muscle strength and for any asymmetry that could indicate neurological deficit.
Lower limbs a. Ask the patient to push down with their foot onto your hands against resistance. b. Ask the patient to lift up their foot against your hand with resistance. c. Apply gently pressure to the shins and ask the patient to extend and flex their legs against resistance.	
7. Determine the frequency of neurological monitoring required based on the patient's condition.	Certain conditions place patients at high risk of neurological alterations (e.g. stroke, seizures, head injuries).

RECORDING AND REPORTING

- Score and describe GCS findings for each domain, size of each pupil (mm) and response to light, and muscle strength in arms and legs.
- Report acute changes in level of consciousness or mental activity, or any neurological deficit as a priority to senior nursing or medical staff.

GLASGOW COMA SCALE : Do it this way

GCS at 40 EYES VERBAL MOTOR

Institute of Neurological Sciences NHS Greater Glasgow and Clyde

CHECK

For factors interfering with communication, ability to respond and other injuries

OBSERVE

Eye opening, content of speech and movements of right and left sides

STIMULATE

Sound: spoken or shouted request
Physical: Pressure on fingertip, trapezius or supraorbital notch

RATE

Assign according to highest response observed

Eye opening

Criterion	Observed	Rating	Score
Open before stimulus	✔	Spontaneous	4
After spoken or shouted request	✔	To sound	3
After fingertip stimulus	✔	To pressure	2
No opening at any time, no interfering factor	✔	None	1
Closed by local factor	✔	Non testable	NT

Verbal response

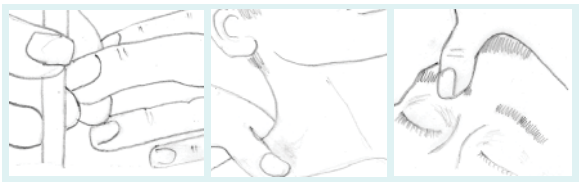
Criterion	Observed	Rating	Score
Correctly gives name, place and date	✔	Orientated	5
Not orientated but communication coherently	✔	Confused	4
Intelligible single words	✔	Words	3
Only moans / groans	✔	Sounds	2
No audible response, no interfering factor	✔	None	1
Factor interfering with communication	✔	Non testable	NT

Best motor response

Criterion	Observed	Rating	Score
Obey 2-part request	✔	Obeys commands	6
Brings hand above clavicle to stimulus on head neck	✔	Localising	5
Bends arm at elbow rapidly but features not predominantly abnormal	✔	Normal flexion	4
Bends arm at elbow, features clearly predominantly abnormal	✔	Abnormal flexion	3
Extends arm at elbow	✔	Extension	2
No movement in arms / legs, no interfering factor	✔	None	1
Paralysed or other limiting factor	✔	Non testable	NT

Sites For Physical Stimulation

Fingertip pressure | Trapezius pinch | Supraorbital notch



Features of Flexion Responses

Figure 24-4 Glasgow Coma Scale.

Glasgow Coma Scale © Sir Graham Teasdale 2014.

such as 'E = 2, V = 2, M = 5'. A total score can be added up, although this score should not be used alone because it does not indicate changes in each area of functioning (Teasdale et al 2014). A fully responsive, awake, alert and oriented patient will score 15/15 (highest possible score), whereas a completely unresponsive patient in a deep coma will score 3/15 (lowest possible score). A patient with a score of 8 or less requires airway management. A drop in overall score by 2 or more points requires a medical emergency team response.

The GCS is scored according to the patient's *best response* and you need to use adequate stimulation to elicit the patient's best response, otherwise your assessment will be incorrect. Teasdale and colleagues (2014) provide an updated, simple and structured approach to GCS assessment. After checking for factors that could interfere with assessment (e.g. hearing loss, injury or sedation with medication), observe for spontaneous behaviour in each of the three response domains. If stimulation is required, begin by speaking in a normal voice. If they do not respond, call the patient's name loudly. Then try applying increasing peripheral fingertip pressure over the nail bed for up to 10 seconds to assess eye opening. To determine the best motor response with stimulation, use a trapezius squeeze/pinch by twisting the muscle with the thumb and two fingers where the head meets the shoulder, followed by pressure over the supraorbital notch if needed. Always start with the least noxious irritation or pressure and proceed to more painful stimulation for up to 10 seconds if the patient does not respond. Explain what you are doing to the patient even if they are unresponsive.

Assess whether the patient's eyes open *spontaneously* when you approach the patient (score 4), only to *sound*, including spoken or shouted requests (score 3), only *to fingertip pressure* (score 2), or *not at all* (score 1). Wake a sleeping patient before evaluation and if they require ongoing verbal stimulation to keep eyes open, then score a 3.

Assess verbal response to evaluate speech and orientation to person, place and time. Ask open-ended questions, such as 'What is your name?' 'Where are you at the moment?' and 'What month is it?' Remember patients may have moved from ward to ward and been unwell for a number of days, so they may not be able to identify the exact location, day or date. The patient is *orientated* if they are able to correctly report who they are, where they are (e.g. in hospital or other specific location) and why they are there, and the month (score of 5). A patient may be able to hold a conversation but cannot correctly answer your questions, indicating they are *confused* (score 4), only replies with inappropriate *words* (score 3), only makes *sounds* such as moaning and groaning (usually with physical stimulus; score 2), or makes *no verbal response* to any stimulus (score 1).

Assess the patient's best motor response only in the upper limbs. Ask the patient to follow simple commands such as 'squeeze my fingers and let go' or 'stick out your tongue and pull it in again' and assess if they can *obey commands*, even weakly (score 6). If unable, with an increasing central pain stimulus described above (trapezius squeeze), assess the patient's ability to move their hand to *localise* to pain by bringing their hand up to above clavicle level (score 5). Withdrawal from pain – also called *normal flexion* (score 4) – occurs when patient rapidly flexes or bends their arm towards the source of the pain, but does not actually localise or try to remove the source of the pain (they do not manage to get their arm up to clavicle level or to the point where the central pain stimulus is coming from). Follow up by checking whether the hand quickly withdraws from fingertip pressure. Abnormal posturing (see Figure 24-3) in response to pain includes *abnormal flexion* where the arm bends at the elbow, the forearm rotates and wrist and fingers are flexed (score 3) and *extension* where the patient straightens the arm at the elbow (score 2). No response to a central pain stimulus is scored as 'none' (score 1).

Pupil size and reaction to light

Inspect both eyes for pupil size (normal range 2–6 millimetres in diameter) and symmetry. Left and right pupils should be equal in size (although slight differences may be a normal variation). Patients with normal neurology demonstrate a brisk and consensual pupillary reaction to light. Ask the patient to look straight ahead past your shoulder and then briefly shine a penlight torch from the side of the face into each eye. The pupils of both eyes should briskly constrict. Repeat the procedure with the other eye and record this on the neurological observation chart:

- Reacts '+' if there is a brisk constriction of the pupil.
- Sluggish 'SL' if the pupil takes longer to constrict.
- No reaction '–' if the pupil is non-reactive and has not changed in size.

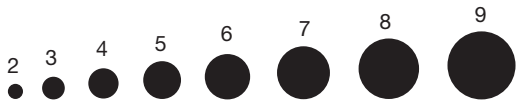

Figure 24-5 Measuring pupil size.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Figure 24-6 Testing pupil reflexes.

A, To check pupillary reflexes, first hold the penlight to the side of the patient's face. B, Illumination of the pupil normally causes brisk constriction.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Limb assessment: Motor and sensory function

Evaluating muscle strength in each limb is also a key component of neurological assessment. Limb power should be present in all major and minor joints. Diminished function may indicate a lesion in the central or peripheral nervous system. You may ask the patient to flex each knee one at a time and get the person to try and straighten the leg or push against resistance applied by you (Figure 24-7). Similarly, ask to flex each elbow while you gently hold the arm in the straight position. Unlike the GCS where you are assessing for the 'best response' in either arm, here you are carefully assessing for bilateral equality of muscle strength in the arms and legs. Note any neurologic deficit such as weakness in one limb. Record upper and lower extremity power on both sides of the body using a scale ranging from 'normal power' to 'none', as in Table 24-2.

For most patients, a quick screening of sensory function is sufficient unless there are symptoms of reduced sensation, motor impairment or paralysis. Sensations along the body's surface are felt equally on both sides of the face, trunk and extremities. Sensation to light touch is usually sufficient to conduct a basic assessment. Ask the patient to close their eyes and indicate when they feel light touch in each sensory distribution, comparing side to side. Try to map the area of any sensory loss to a single peripheral nerve territory (see neurovascular assessment) or sensory dermatomes (Chapter 36) of the spinal nerves, such as when assessing epidural blockade for pain management. There may be loss of sensation on one side of the body (hemisensory loss) with some types of stroke or spinal cord injury.

Assessing the special senses: Vision, hearing and speech

Speech is a function of the higher centres of the brain and is a core part of your neurological assessment. Routinely *evaluate speech* during general interaction and communication with the patient, noting abnormally slurred speech or abnormal responses to the conversation. Facial structures, including the mouth, should appear symmetrical.

Screening for sensory-perceptual deficits will help you identify problems that will interfere with activities of daily living and put patients at risk for injury. The assessment of *visual acuity* – the ability to see small details – tests central vision. If the patient wears glasses, they should wear them during the examination. Assess distant vision by asking the patient to read or identify objects in the distance. If patients cannot identify objects in the distance, their ability to count upraised fingers or distinguish light is assessed. A hand is held 30 cm from the patient's face and they count the upraised fingers. Near vision can be assessed by asking patients to read from a newspaper, wristwatch or similar item. Ask the patient to hold the item at a comfortable distance (5–6 cm) from the eyes and read the smallest line possible.

As the patient looks straight ahead, all objects in the periphery can normally be seen. To assess *visual fields*, the patient stands or sits 60 cm away, facing you at eye level (Figure 24-8). The patient closes or covers one eye (e.g. the left) and looks at your eye directly opposite. Close your opposite eye (in this case the right) so that your left eye aligns with the patient's right eye. Move your left finger outside the field of vision, then slowly bring it back into

Talley NJ, O'Connor S 2016 Clinical examination essentials, 4th edn. Elsevier, Chatswood, NSW.

TABLE 24-2 Scoring limb power based on the Medical Research Council (MRC) scale for muscle strength

Score		Explanation
5	Normal power	Active movement of the limb against gravity with full resistance. Muscle strength is equal to the examiner.
4	Active movement against resistance	Active movement of the limb against gravity with some resistance. Muscle strength is weak and the examiner easily overpowers the patient when resistance is applied.
3	Active movement against gravity	Active movement of the limb against gravity, not resistance. The patient can lift the extremity, but it collapses as soon as the examiner applies resistance.
2	Active movement of limb with gravity eliminated	Active movement of the limb when effect of gravity is eliminated (limb can roll in bed but not lift). The patient can move the limb, but cannot lift the limb from the bed.
1	Flicker of movement	Weak muscle contraction observed or palpated without active movement.
0	None	No detectable muscle contraction or movement of the extremity.

TABLE 24-3 Assessment of sensory function

Function	Equipment	Method	Precautions
Light touch	Cotton ball or cotton-tip applicator	Apply light wisp of cotton to different points along skin's surface. Ask patient to say when sensation is felt.	Apply at areas where skin is thin or more sensitive (e.g. face, neck, inner aspect of arms, top of feet and hands).
Position sense	None	Grasp finger or toe, holding it by its sides with thumb and index finger. Alternate moving finger or toe up and down. Ask patient to state when finger is up or down. Repeat with toes.	Avoid rubbing adjacent appendages as finger or toe is moved. Do not move joint laterally; return to neutral position before moving again.
Pain	Broken tongue blade or wooden end of cotton applicator	Ask patient to say when dull or sharp sensation is felt. Alternately apply sharp and blunt ends of tongue blade to skin's surface. Note areas of numbness or increased sensitivity.	Remember that areas where skin is thickened, such as heel or sole of foot, may be less sensitive to pain.

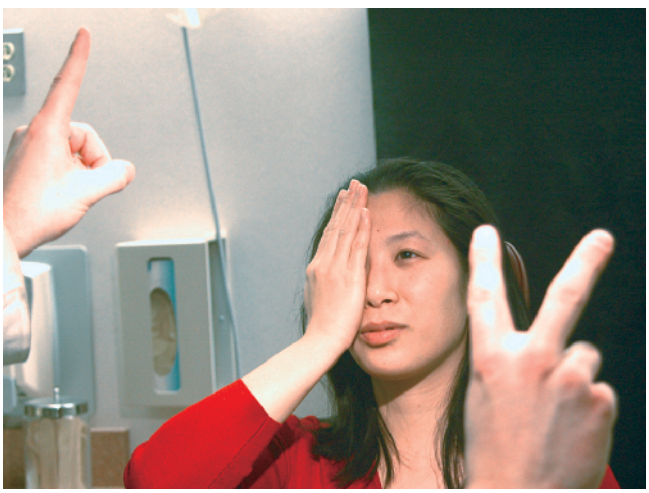

Figure 24-8 Visual field assessment.

Forbes H, Watt E 2016 Jarvis's physical examination and health assessment, 2nd edn. Elsevier, Chatswood, NSW.

the visual field. Ask the patient to tell you when they first see your finger. Repeat the test for the opposite eye and if you detect your finger before the patient does, the patient's visual field is reduced.

Hearing acuity can be grossly assessed from the patient's response to normal conversation or using the whisper test. Explain to the patient that you are testing their hearing and that you will come close to their face. Whisper a different word in both ears and ask the person to repeat it back to you. Loss of hearing may indicate a blocked external ear or neurological deficit relating to the acoustic nerve (cranial nerve VIII).

Cardiovascular system

The rapid primary survey and vital signs establish adequate perfusion. A focused assessment of the **cardiovascular system** may be further divided into *cardiac assessment* (the heart) and *peripheral vascular*

BOX 24-3 Early and late warning signs associated with neurological deterioration

Early warning signs

SBP 80–100 mmHg	SpO_2 90–95%
SBP 180–240 mmHg	PaO_2 50–60 mmHg, $PaCO_2$ 50–60 mmHg
GCS 9–11 or alteration in mentation/a drop of 2 points in GCS	BSL 1–2.9 mmol/L
Any seizure	BSL 16–25 mmol/L

Late warning signs

SBP < 80 mmHg	SpO_2 < 90%
SBP > 240 mmHg	PaO_2 < 50 mmHg, $PaCO_2$ > 60 mmHg
Unresponsive to verbal command	BSL < 1 mmol/L
GCS ≤ 8	BSL > 25 mmol/L
2 or more seizures with no return to baseline state of consciousness	

Data from: Jacques T, Fisher M, Hillman K et al (eds) 2011 DETECT Manual: Detecting deterioration, evaluation, treatment, escalation and communicating in teams, 3rd edn. NSW Health and Clinical Excellence Commission, Neutral Bay.

assessment (arteries and veins). An efficient approach is to start with the hands and nails (inspect and palpate skin colour, temperature, capillary refill), move up to the arms (palpate radial pulses and measure BP) and neck (inspect neck veins), then the chest (auscultate heart sounds) and finally lower limbs (palpate for distal pulses, tenderness, oedema). Skill 24-3 demonstrates how to perform a focused cardiovascular assessment.

Inspection and palpation

Start with a general survey of the patient's appearance and activity tolerance to assess perfusion. Look for any obvious signs of distress, such as chest pain or shortness of breath. *Skin colour/temperature*, *urine output* and *mental status* are three clinical indicators of *end-organ perfusion*. Is the patient's skin cool, pale, dusky or mottled (patchy discolouration)? Is it warm, flushed and sweaty (diaphoretic)? Blue extremities (peripheral cyanosis) can be a sign of poor peripheral perfusion (Figure 24-9). Blue lips and tongue (central cyanosis) is a late sign of serious respiratory or cardiac compromise and oxygen therapy should be started if not already in place (Adam et al 2010). Measure the urine output if possible (see renal system assessment) because it reflects renal perfusion, which in turn is an extremely important measure of systemic perfusion. A reduced urine output may be the earliest sign of shock. Altered mental status (agitation and confusion)

SKILL 24-3

Focused cardiovascular assessment

Delegation and other considerations

- Comprehensive patient assessment is the basis for the development of the nursing care plan and therefore should not be delegated by the registered nurse.
- Perform hand hygiene and apply personal protective equipment when appropriate before, during and after patient assessment.

Equipment

- Stethoscope
- Sphygmomanometer
- Watch
- Pen

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review the patient's baseline assessment data.	The key point of clinical examination is to determine if something has changed. Refer to baseline or previous findings to determine an acute change in patient status.
2. Perform hand hygiene.	Prevents transmission of microorganisms.
3. Ensure comfort and privacy. Explain procedure and clarify any concerns.	Promotes patient's cooperation and comfort during the assessment.
4. Approach from the right side with patient appropriately positioned (sitting at 45 degrees/supine when possible) for examination.	Assists with performance and interpretation of data.
5. Begin with a general observation of skin colour/temperature and mental status.	These are indicators of adequate tissue perfusion.
6. Inspect and palpate upper limbs for colour, warmth, movement and sensation.	
7. Check peripheral and central capillary refill time.	
8. Palpate radial pulses for rate, rhythm and strength.	
9. Measure manual blood pressure.	
10. Observe neck veins with patient at 45 degrees.	An indicator of volume status.
11. Auscultate apical heart sounds, noting rate and rhythm. Determine normal heart sounds. Listen for any acute changes such as added sounds and murmurs.	New abnormal findings require further clinical investigations.
12. Inspect and palpate lower limbs for colour, warmth, movement and sensation. Palpate pedal pulses and check for pitting ankle oedema.	These are indicators of adequate tissue perfusion.
13. Inspect and palpate the calves for redness, warmth, tenderness.	An indicator of venous thromboembolism.
14. Observe urine output and any losses in drains.	
15. Observe ECG for abnormal changes.	New abnormal findings require further clinical investigations.
16. Determine the frequency of cardiovascular monitoring required based on the patient's condition.	Certain conditions place patients at high risk of cardiovascular alterations (e.g. chest pain, arrhythmias, bleeding).

RECORDING AND REPORTING

- Core documentation includes pulse rate and rhythm, blood pressure, capillary refill time, and urine output. Note any new abnormal findings or investigations.
- Report early and late warning signs associated with cardiovascular deterioration (Box 24-6) as a priority to senior nursing or medical staff.

Figure 24-9 **Peripheral cyanosis.**

By James Heilman, MD – CC BY-SA 3.0, https://commons.wikimedia.org/w/index.php?curid=17978808.

with low blood pressure also suggests decreased cerebral perfusion.

The nails are palpated for *capillary refill* that should return within 2 seconds after blanching the nail bed and releasing pressure in an adult (Figure 24-10). Palpate the radial pulses for rate, rhythm and strength. Feel the patient's hands and feet: are they warm or cold? If the feet and knees are warm the cardiac output is nearly always okay (Jacques et al 2011). Inspect for any inserts, such as central venous catheters or arterial lines, to measure blood pressure directly. Check all drains for any fluid losses. Measure blood pressure manually if not already completed (Skill 23-4). Determine correct positioning and functioning of monitoring equipment (e.g. cardiac monitoring). With the patient sitting at 45 degrees, inspect the neck for *jugular venous distension* (Figure 24-11), which is an abnormal sign associated with fluid overload and heart failure.

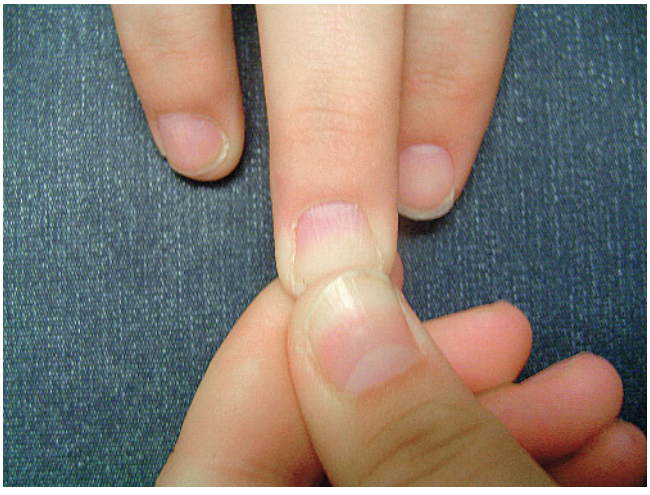

Figure 24-10 **Testing peripheral capillary refill time.**

Wilson S, Giddens J 2013 Health assessment for nursing practice, 5th edn. Elsevier Mosby, St Louis.

Cardiac auscultation

To understand the significance of cardiac assessment findings, you will need to have a working knowledge of the cardiac cycle (Figure 24-12). The heart normally pumps blood through its four chambers during two phases. During *systole*, the ventricles contract and eject blood from the left ventricle into the aorta and from the right ventricle into the pulmonary artery. During *diastole*, the ventricles relax and the atria contract to move blood into the ventricles and fill the coronary arteries.

At the beginning of systole the ventricles contract and the mitral and tricuspid valves close to prevent regurgitation of blood into the atria, creating the first heart sound (S_1). When the ventricles empty, pressure within the

Figure 24-11 **Jugular venous distention.**

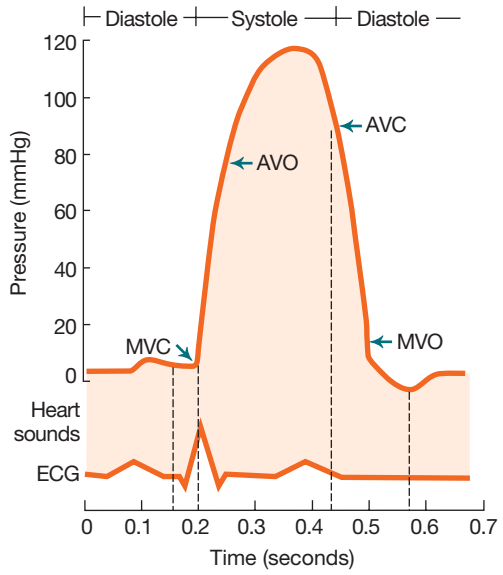

Figure 24-12 Cardiac cycle.

MVC, mitral valve closes; AVO, aortic valve opens; AVC, aortic valve closes; MVO, mitral valve opens.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

chambers fall. At the beginning of diastole the aortic and pulmonic valves close, creating the second heart sound (S_2). Auscultation of the normal heart therefore reveals dual heart sounds (S_1 and S_2), with a regular rate and rhythm. Abnormal findings include added sounds such as extra heart sounds and murmurs.

As a beginning RN you should be able to identify normal heart sounds (S_1 and S_2) from abnormal, which need to be validated by more experienced staff (Box 24-4). Begin by listening over the apex of the heart with the diaphragm of the stethoscope, palpated at approximately the fourth to fifth intercostal space just medial (to the left) of the mid-clavicular line (Figure 24-13). It may be necessary to ask an adult female to lift their left breast while you locate the apex. You should palpate the carotid pulse while you listen to heart sounds to identify S_1, which correlates with the timing of the pulse wave. Normally no sound is heard between S_1 and S_2 during the periods of systole and diastole. Count the *apical heart rate* for 1 minute and determine whether the rhythm is regular or irregular while listening and feeling.

Peripheral vascular

A focused peripheral vascular assessment is normally undertaken as an extension to cardiac evaluation. For example, it may be necessary if there are cues from the health history that there may be peripheral vascular disease or deep vein thrombosis. Or a neurovascular assessment may be indicated by the patient's presentation or type of surgery (e.g. orthopaedic or vascular). The most important neurovascular assessment skills are summarised in Figure 24-14. Look and feel for colour,

Brown D, Edwards H, Seaton L, Buckley T 2015 Lewis's medical-surgical nursing: assessment and management of clinical problems, 4th edn. Elsevier, Chatswood, NSW.

BOX 24-4 Abnormal heart sounds

Abnormal heart sounds and murmurs are described by where they occur in the cardiac cycle. The normal sequence of events in the cardiac cycle can be diagrammed as follows:

$S_1 \rightarrow$systole$\rightarrow S_2 \rightarrow$diastole$\rightarrow S_1 \rightarrow$etc.

To determine if an abnormal sound occurs in systole or diastole, determine if the sound occurs after S_1 or after S_2.

- During diastole, when 80% of the blood in the atria rapidly fills the ventricles, a third heart sound may be heard (S_3). It is often heard at the apex. An S_3 occurs just after the S_2 and lasts about the same time as it takes to say 'me too'. The 'me' is the S_2, and the 'too' is the S_3. An S_3 is normal in children and young adults. However, when an S_3 is heard in adults over 30 years of age, it signifies fluid volume overload to the ventricle that may be caused by heart failure or mitral or tricuspid regurgitation.
- At the end of diastole, when atrial contraction completes the filling of the ventricle, a fourth heart sound may be heard (S_4). An S_4 occurs just before the S_1 and lasts about the same time as it takes to say 'middle.' The 'mi' is the S_4, and the 'ddle' is the S_1. An S_4 is normal in children and young adults. However, when an S_4 is heard in adults over 30 years of age, it signifies a non-compliant or 'stiff' ventricle. Hypertrophy of the ventricle precedes a non-compliant ventricle. Coronary artery disease is also a major cause of a stiff ventricle. Useful mnemonics for remembering the cadence and pathophysiology of the third and fourth heart sounds are as follows.

SLOSH'ing-in	SLOSH'ing-in	SLOSH'ing-in
$S_1\ S_2\ S_3$	$S_1\ S_2\ S_3$	$S_1\ S_2\ S_3$
a-STIFF'-wall	a-STIFF'-wall	a-STIFF'-wall
$S_4\ S_1\ S_2$	$S_4\ S_1\ S_2$	$S_4\ S_1\ S_2$

Another way to remember the cadence of the S_3 and S_4 heart sounds is to use the words 'Kentucky' and 'Tennessee'.

Ken-tuck-y	Ken-tuck-y	Ken-tuck-y
$S_1\ S_2\ S_3$	$S_1\ S_2\ S_3$	$S_1\ S_2\ S_3$
Ten-ness-ee	Ten-ness-ee	Ten-ness-ee
$S_4\ S_1\ S_2$	$S_4\ S_1\ S_2$	$S_4\ S_1\ S_2$

Thus the third and fourth heart sounds can be abnormal when they occur in adults over 30. Both sounds occur in diastole.

The opening *snap* caused by the opening of the mitral or tricuspid valves is another abnormal sound heard in diastole when either valve is thickened, stenotic or deformed. The sounds are high-pitched and occur early in diastole.

- In systole *ejection clicks* may be heard if either the aortic or pulmonic valve is stenotic or deformed. The aortic valve ejection click is heard at either the apex or base of the heart and does not change with respiration. The less common pulmonic valve ejection click is heard over the second or third left intercostal space. It increases with expiration and decreases with inspiration.
- *Pericardial friction rubs* are caused by inflammation of the layers of the pericardial sac. A rubbing sound is usually present in both diastole and systole and is best heard over the apical area.

Wilson S, Giddens J 2013 Health assessment for nursing practice, 5th edn. Elsevier Mosby, St Louis.

warmth, movement and sensation. Palpate distal pulses and capillary refill time. Monitor for swelling and ooze from any wound. Every student nurse should be able to recall the signs of an acute ischaemic limb in Box 24-5 – known as *the six Ps of acute limb ischaemia* – indicating a limb-threatening medical emergency.

To examine the peripheral vascular system, first assess the adequacy of blood flow to the extremities by measuring arterial pulses and inspecting the condition of the skin and nails. Use a head-to-toe approach, starting with the carotid arteries in the neck and moving down to the arteries in the upper and lower extremities. The wall of an artery is normally elastic, making it easily palpable. After the artery is depressed, it will spring back to shape when pressure is released. The arterial pulses to be palpated include the carotid, brachial, radial, femoral, popliteal, posterior tibial and dorsalis pedis. Compare left and right sides of the body for equal strength.

Each peripheral artery is examined using the distal *pads* of the fingers. Gentle pressure is applied without

NEUROVASCULAR OBSERVATION CHART – LOWER LIMB

Figure 24-14 Neurovascular assessment chart.

BOX 24-5 Six Ps of acute limb ischaemia

Pallor

Pale in colour, can be dusky or mottled in appearance. Severe ischaemia may present as marble white or gangrene.

Pain

Sudden onset with pain starting distally. Pain can eventually decrease if nerves die from ischaemia.

Pulselessness

Absence of distal pulses.

Paralysis

Loss of function of the affected limb and late paralysis.

Paraesthesia

Burning, tingling feeling that may develop to complete loss of sensation.

Perishing cold

Limb feels cool (compare with other side).

Freezing cold pain.

Smith et al 2014 The role of the community clinician in the early detection, referral and treatment of critical limb ischaemia. British Journal of Community Nursing 19(6):269.

occluding the pulse. When it is difficult to find a pulse, it is helpful to vary pressure and feel all around the pulse site.

Carotid arteries

For palpation of the carotid pulse, the patient turns the head slightly towards the side being examined. This manoeuvre relaxes the neck muscles for easier palpation. Slide the tips of your index and middle fingers around the medial edge of the sternocleidomastoid muscle.

Both carotid arteries should be equal in pulse rate, rhythm and strength, and should be equally elastic (never palpate both together as they provide the main blood supply to the brain). The carotid is commonly auscultated using the bell of the stethoscope for abnormal vascular sounds indicating stenosis. When the lumen of a blood vessel is narrowed, blood flow is turbulent sometimes causing a *bruit* (pronounced *brew-ee*), which is a soft, blowing sound.

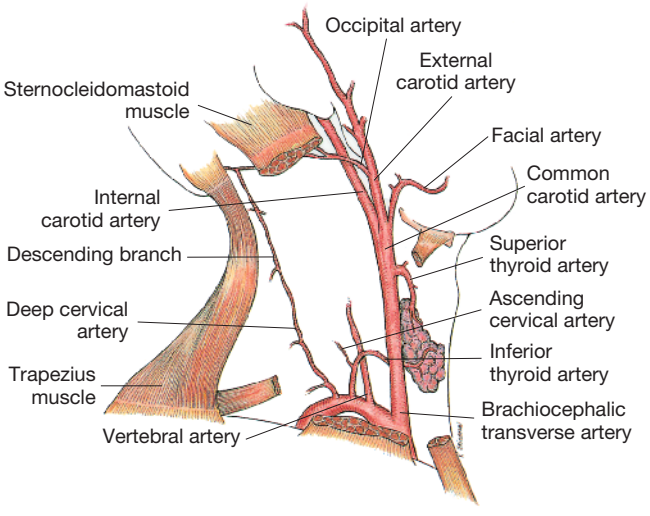

Figure 24-15 Palpation of carotid pulse.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Brachial arteries

In the upper extremities the main artery is the brachial artery, which channels blood to the radial and ulnar arteries of the forearm and hand. To palpate the brachial pulse, find the groove between the biceps and triceps muscles above the elbow at the antecubital fossa (Figure 24-16). The artery runs along the medial side of the extended arm. Palpate the artery with the fingertips of the first three fingers in the muscle groove. If circulation in this artery becomes blocked, the circulation in the radial or ulnar arteries will be impaired and the hands will not receive adequate blood flow.

Radial arteries

To locate pulses in the arm and hand, have the patient sit or lie down. The radial pulse is found along the radial side of the forearm, at the wrist. In a thin person, a groove is formed lateral to the flexor tendon of the wrist. The radial pulse can be felt with light palpation in the groove (Figure 24-17).

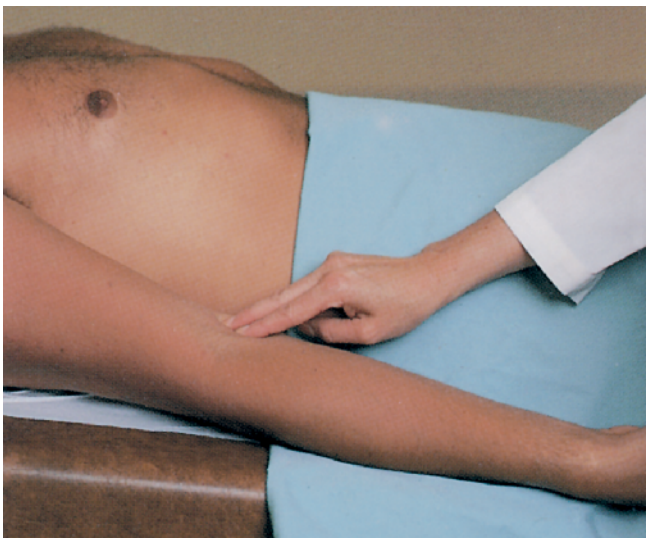

Figure 24-16 Palpation of brachial pulse.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Figure 24-17 **Palpation of radial pulse.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Femoral arteries

The femoral artery is the main artery in the leg, delivering blood to the popliteal, posterior tibial and dorsalis pedis arteries (Figure 24-18). It is one of the strongest arteries in an infant or small child. An interconnection between the posterior tibial and dorsalis pedis arteries guards against local arterial occlusion.

Popliteal arteries

The popliteal pulse is found behind the knee and is difficult to locate. The patient should slightly flex the knee, with the foot resting on the bed, or assume a prone position with the knee slightly flexed and leg muscles relaxed (Figure 24-19). With the fingers of both hands, palpate deeply into the popliteal fossa, just lateral to the midline. The popliteal pulse sometimes used to take a leg BP measurement with the cuff placed on the thigh.

Figure 24-18 **Palpation of femoral pulse.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Figure 24-19 **Palpation of popliteal pulse.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Dorsalis pedis arteries

With the patient's foot relaxed, locate the dorsalis pedis pulse. The artery runs along the top of the foot in line with the groove between the extensor tendons of the great toe and first toe (Figure 24-20). Locate the pulse by placing the fingertips between the great and first toe and slowly inching up the foot. This pulse may be congenitally absent.

Figure 24-20 **Palpation of dorsalis pedis pulse.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Posterior tibial arteries

The posterior tibial pulse is found on the inner side of each ankle (Figure 24-21). Place the fingers behind and below the medial malleolus. The artery is easily located with the foot relaxed and slightly extended.

Doppler ultrasound

Factors influencing the ability to assess a pulse include obesity, reduction in the heart's stroke volume, diminished blood volume or arterial obstruction. A Doppler can amplify the sounds of a pulse wave. A thin layer of transmission gel is applied to the patient's skin at the pulse site or directly onto the transducer tip of the probe. The volume control is then turned to 'on', and the tip of the probe placed at an angle of 45–90 degrees on the skin (Figure 24-22). The probe is moved until a pulsating 'whooshing' sound is heard, indicating the presence of arterial blood flow.

Peripheral veins

The status of the peripheral veins is assessed by asking the patient to assume sitting and standing positions. Assessment includes inspection and palpation for abnormal findings. For example, varicosities are superficial veins that become dilated, especially when the legs are in a dependent position. They are common in older adults and people who spend a lot of time standing.

Deep vein thrombosis (DVT) is characterised by pain and swelling in one of the extremities. Feel for increased warmth and palpate the calves for tenderness. It is of utmost importance that you report this finding to prevent emboli to the lungs and central nervous system. Prevention and early detection of DVT and pulmonary embolism (PE) is a priority in health facilities as patients become more at risk due to immobility and venous stasis. Health facilities should have policies and procedures for venous thromboembolism prophylaxis (VTE) and this usually involves the application of compression stockings, administration of anticoagulants and postoperative pressure devices that deliver gentle pressure sequentially to both limbs to increase venous blood flow (see Chapter 39).

The upper and lower extremities should be inspected and palpated for any signs of oedema. Areas of the skin become swollen or oedematous from a build-up of fluid in the tissues as a result of impaired venous return, systemic diseases (e.g. cardiac, hepatic, renal) or some drugs. Typical sites for dependent oedema caused by poor venous return are the feet, ankles and sacrum. In particular, bilateral oedema in the lower extremities may signify cardiac failure or fluid overload from intravenous fluids. Inspection for oedema is a fundamental component of cardiovascular assessment.

Oedematous skin looks stretched and shiny. Palpate areas of oedema against bony structures with your thumb for at least 10 seconds. Oedema may be *pitting* (the skin is indented and only slowly refills, see Figure 24-23) or *non-pitting*. If oedema is present note the upper level (e.g. 'pitting oedema to mid-calf' or 'pitting oedema to

mid-thigh'). Severe pitting oedema can begin to weep exudate.

Respiratory system

Because respiratory changes are often the first sign of patient deterioration, RNs frequently perform assessment of the **respiratory system**. Your rapid primary survey will have examined airway and breathing. The airway is patent if the patient can talk normally and is conscious and alert. The work of breathing and peripheral oxygen saturation (SpO_2) are routinely assessed with vital signs (see Chapter 23). Skill 24-4 demonstrates how to then perform a focused respiratory assessment.

Inspection

Once again, start with general observation of appearance and behaviour of the patient and observe for signs of respiratory distress (see Box 24-7). Is the respiratory rate fast, slow or normal? Are they able to talk in sentences without stopping to take a breath? What is the patient's oxygen requirement to maintain adequate oxygen saturation? Anxiety, agitation and confusion can be due to hypoxia. Examine the face, looking at the colour of the skin for central cyanosis (blue-tinged tongue and mucous membranes: a late sign and medical emergency). Inspect the nose for symmetry of nares, presence of discharge and evidence of nasal flaring. Assess the patient's ability to cough and whether it is productive of sputum. Inspect the nail beds for *clubbing* (Figure 24-24) which is a sign of chronic respiratory disease. Note oxygen saturation if a monitor is attached.

Inspect the chest for pattern, depth and symmetry of breathing. Note barrel chest associated with air trapping in COPD (Figure 24-25). There should be no audible respiratory sounds, such as wheezing or stridor. Use of accessory muscles like neck muscles and retraction of intercostal muscles are signs of distress. If the patient has a chest drain, observe for swinging of dependent fluid in the chest tube and the amount and colour of drainage (see Chapter 35).

Palpation

If chest movement is only present on one side, the trachea can be gently palpated to identify if it is midline. Locate the trachea above the sternal notch and gently palpate

BOX 24-6 Early and late warning signs associated with cardiovascular deterioration

Early warning signs	
Poor peripheral circulation	pH 7.2–7.3
SBP 80–100 mmHg	Base deficit –5 to –8 mmol/L
Pulse rate 40–49 or 120–140/min	Reports chest pain
SBP 180–240 mmHg	> Expected blood loss
Note of decreased urine output	New bleeding any site
Urine output < 200 mL/8 hours	> Expected drain fluid loss
Alteration in mentation	SpO_2 90–95%
Late warning signs	
Cardiac arrest	Unresponsive to verbal command
SBP < 80 mmHg	pH < 7.2
Pulse rate < 40 or > 140 bpm	Base deficit < –8 mmol/L
SBP > 240 mmHg	Failure to reverse warning sign within 1 hour
Urine output < 200 mL/24 hours	Excess blood loss unable to be controlled by local staff
SpO_2 < 90%	

Data from Jacques T, Fisher M, Hillman K et al (eds) 2011 DETECT Manual: Detecting deterioration, evaluation, treatment, escalation and communicating in teams, 3rd edn. NSW Health and Clinical Excellence Commission, Neutral Bay.

SKILL 24-4

Focused respiratory assessment

Delegation and other considerations

- Comprehensive patient assessment is the basis for the development of the nursing care plan and therefore should not be delegated by the registered nurse.
- Perform hand hygiene and apply personal protective equipment when appropriate before, during and after patient assessment.

Equipment

- Stethoscope
- Pen
- Watch
- Portable pulse oximeter

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review the patient's baseline assessment data.	The key point of clinical examination is to determine if something has changed. Refer to baseline or previous findings to determine an acute change in patient status.
2. Perform hand hygiene.	Prevents transmission of microorganisms.
3. Ensure comfort and privacy. Explain procedure and clarify any concerns.	Promotes patient's cooperation and comfort during the assessment.
4. Approach from the right side with patient appropriately positioned (high Fowlers' when possible) for examination.	Assists with performance and interpretation of data.
5. Observe airway patency, ability to speak and cough.	Identify signs of respiratory distress that require immediate intervention.
6. Observe work of breathing, skin colour and mental status.	These are indicators of adequate ventilation and oxygenation.
7. Measure respiratory rate, depth and pattern of breathing.	
8. Measure peripheral oxygen saturation. Note the patient's oxygen requirement.	
9. Auscultate anterior and posterior lung sounds. Determine normal sounds over each lung field. Listen for any acute changes such as adventitious sounds, decreased or absent lung sounds.	New abnormal findings require further clinical investigations.
10. Determine the frequency of respiratory monitoring required based on the patient's condition.	Certain conditions place patients at high risk of respiratory alterations (e.g. post-anaesthesia, acute exacerbation of COPD or asthma).

RECORDING AND REPORTING

- Core documentation includes respiratory rate, effort of breathing, oxygen saturation and any oxygen requirement. Note any new abnormal findings or investigations.
- Report early and late warning signs associated with respiratory deterioration (Box 24-8) as a priority to senior nursing or medical staff.

BOX 24-7 Signs associated with increased work of breathing (respiratory distress)

Increased respiratory rate
Use of accessory muscles
Soft tissue recession: tracheal tug, rib or abdominal recession
Increased pulse rate
Increased sweating or clammy skin
Anxiety, agitation and confusion

Figure 24-24 Finger clubbing.

Talley NJ, O'Connor S 2014 Clinical examination: a systematic guide to physical diagnosis, 7th edn. Elsevier, Chatswood, NSW.

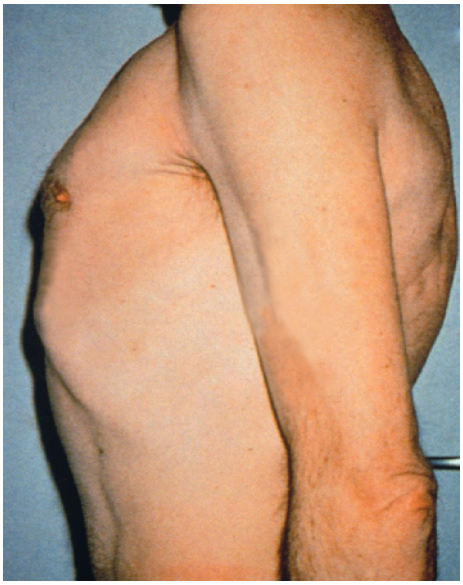

Figure 24-25 Barrel chest.

Talley NJ, O'Connor S 2014 Clinical examination: a systematic guide to physical diagnosis, 7th edn. Elsevier, Chatswood, NSW.

with two fingers. Tracheal deviation would usually be accompanied by respiratory distress due to significant disease such as lung collapse.

Auscultation

Chest percussion is not covered here and is only useful in very quiet environments. In acute care settings, clinicians usually move straight to auscultation of the chest. Normal lung sounds differ in character, depending on the area of the chest being auscultated and normally include bronchovesicular and vesicular sounds (Table 24-4 and Figure 24-26). Position the patient sitting upright if possible and ask them to breathe through the mouth. It is easier to hear air entry over the main bronchi, so it is often useful to start there. It is important to auscultate in an ordered sequence over upper, middle and lower lung zones, comparing each side with the other (Figure 24-27 and Figure 24-28). Then listen over the posterior chest, which contains primarily the lower lobes. During each breath listen to whether lung sounds can be heard at all, the volume of sound is more or less than normal, and is similar on both sides. If abnormal sounds are heard, ask the patient to cough to see whether they clear.

Abnormal lung sounds result from air passing through moisture, mucous or narrowed airways. Adventitious (abnormal) lung sounds often occur superimposed over normal sounds. The two types of adventitious sounds which beginning RNs should be able to identify are *crackles* and *wheezes*. Crackles are fine or coarse, discontinuous, crackling or moist sounds and are associated with small airways and alveoli popping open during inspiration with secretions or fluid as in heart failure. Wheezes are continuous musical sounds that occur with airway narrowing and are a key sign of asthma or COPD. Diminished or absent sounds may occur with collapse or consolidation. This may be a common finding on both sides if there is postoperative atelectasis caused by reduced respiratory effort. Table 24-5 explains the mechanisms and characteristic features of key abnormal lung sounds.

Gastrointestinal system

After a rapid primary survey, an abdominal (**gastrointestinal system**) assessment is a major component of any body systems assessment. Abdominal pain is also a common indication for a focused assessment and the beginning RN needs to be able to distinguish an *acute abdomen* (a medical emergency) from benign causes. Taking an elimination history is important to interpret your physical assessment findings. You should also routinely assess the most recent bowel movement and frequency of bowel movements each shift (see Chapter 32).

TABLE 24-4 Normal lung sounds

Description	Location	Origin
Vesicular		
Vesicular sounds are soft, breezy and low-pitched. Inspiratory phase is three times longer than expiratory phase	Best heard over lung's periphery (except over scapula or clavicles)	Created by air moving through smaller airways
Bronchovesicular		
Bronchovesicular sounds are blowing sounds that are medium-pitched and of medium intensity. Inspiratory phase is equal to expiratory phase	Best heard posteriorly between scapulae and anteriorly over bronchioles lateral to sternum at first and second intercostal space	Created by air moving through large airways
Bronchial		
Bronchial sounds are loud and high-pitched with hollow quality. Expiration sometimes longer than inspiration	Best heard over trachea	Created by air moving through trachea close to chest wall

Talley NJ, O'Connor S 2014 Clinical examination: a systematic guide to physical diagnosis, 7th edn. Elsevier, Chatswood, NSW.

TABLE 24-5 **Abnormal (adventitious) lung sounds**

Sound	Site auscultated	Cause	Character
Crackles	Most commonly heard in dependent lobes: right and left lung bases	Random, sudden re-inflation of groups of alveoli; disruptive passage of air	Fine crackles are high-pitched fine, short, interrupted crackling sounds heard during end of inspiration, usually not cleared with coughing Medium crackles are lower, more moist sounds heard during middle of inspiration; not cleared with coughing Coarse crackles are loud, bubbly sounds heard during inspiration; not cleared with coughing
Wheeze	Can be heard over all lung fields	High-velocity airflow through severely narrowed bronchus	High-pitched, continuous musical sounds like a squeak heard continuously during inspiration or expiration; usually louder on expiration

Based on: Ball J et al 2015 Seidel's guide to physical examination, 8th edn. Elsevier, St Louis.

BOX 24-8 Early and late warning signs associated with respiratory deterioration

Early warning signs

Pulse rate 40–49 or 120–140/min	SpO_2 90–95%
Alteration in mentation	PaO_2 50–60 mmHg
Partial airway obstruction	$PaCO_2$ 50–60 mmHg
RR 5–9 or 30–40 breaths/min	pH 7.2–7.3

Late warning signs

Pulse rate < 40 or > 140 bpm	PaO_2 < 50 mmHg
Unresponsive to verbal command	$PaCO_2$ > 60 mmHg
Airway obstruction/stridor	pH < 7.2
RR < 5 or > 40 breaths/min	Failure to reverse warning sign within 1 hour
SpO_2 < 90%	

Data from Jacques T, Fisher M, Hillman K et al (eds) 2011 DETECT Manual: Detecting deterioration, evaluation, treatment, escalation and communicating in teams, 3rd edn. NSW Health and Clinical Excellence Commission, Neutral Bay.

Skill 24-5 demonstrates how to perform a focused gastrointestinal (GIT) assessment.

By dividing the abdomen into four imaginary quadrants (Figure 27-29), you can then record assessment findings in relation to each quadrant. For example, you may determine that the patient is experiencing tenderness over the left lower quadrant (LLQ) with normal bowel sounds present.

Inspection

The order of an abdominal examination, or inspection, differs slightly from that in other assessments: inspect and auscultate before you feel the abdomen. Inspect the skin over the abdomen for colour, scars, lesions, wounds, stomas and drains. Inspect for contour and symmetry of the abdomen, noting any masses, bulging or *abdominal distension*. Common causes of acute abdominal distension are found in Box 24-9. Note bleeding or ooze from surgical wounds and drains. Inspect for the correct functioning of wound vacuum devices and stomas.

Auscultation

Peristalsis, or intestinal motility, is a normal function of the small and large intestine. Bowel sounds are the audible passage of air and fluid created by peristalsis. The warmed

SKILL 24-5

Focused gastrointestinal assessment

Delegation and other considerations

- Comprehensive patient assessment is the basis for the development of the nursing care plan and therefore should not be delegated by the registered nurse.
- Perform hand hygiene and apply personal protective equipment when appropriate before, during and after patient assessment.

Equipment

- Stethoscope
- Pen
- Documentation

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review the patient's baseline assessment data.	The key point of clinical examination is to determine if something has changed. Refer to baseline or previous findings to determine an acute change in patient status.
2. Perform hand hygiene.	Prevents transmission of microorganisms.

STEPS	RATIONALE
3. Ensure comfort and privacy. Explain procedure and clarify any concerns.	Promotes patient's cooperation and comfort during the assessment.
4. Approach from the right side with patient appropriately positioned (supine when possible) for examination.	Assists with performance and interpretation of data.
5. Inspect abdomen contour and symmetry. Note any wounds or drains.	These are indicators of normal gastrointestinal function.
6. Auscultate for the presence of bowel sounds with diaphragm of stethoscope.	
7. Gently percuss over abdomen for tympany. Note any tenderness.	
8. Lightly palpate each quadrant. Normally, the abdomen should feel soft, non-tender and without masses. Note any guarding.	
9. Assess most recent and frequency of bowel movements. After bowel surgery, assess whether the patient is passing flatus.	Identify changes in bowel habit that suggest need for intervention.
10. Determine the frequency of abdominal assessment required based on the patient's condition.	Certain conditions place patients at high risk of gastrointestinal alterations (e.g. post-surgery, critical illness).

RECORDING AND REPORTING

- Core documentation includes presence of bowel sounds, findings on abdominal palpation, and assessment of bowel movements. Note any new abnormal findings or investigations.
- Report any acute changes such as signs of peritonism as a priority to senior nursing or medical staff.

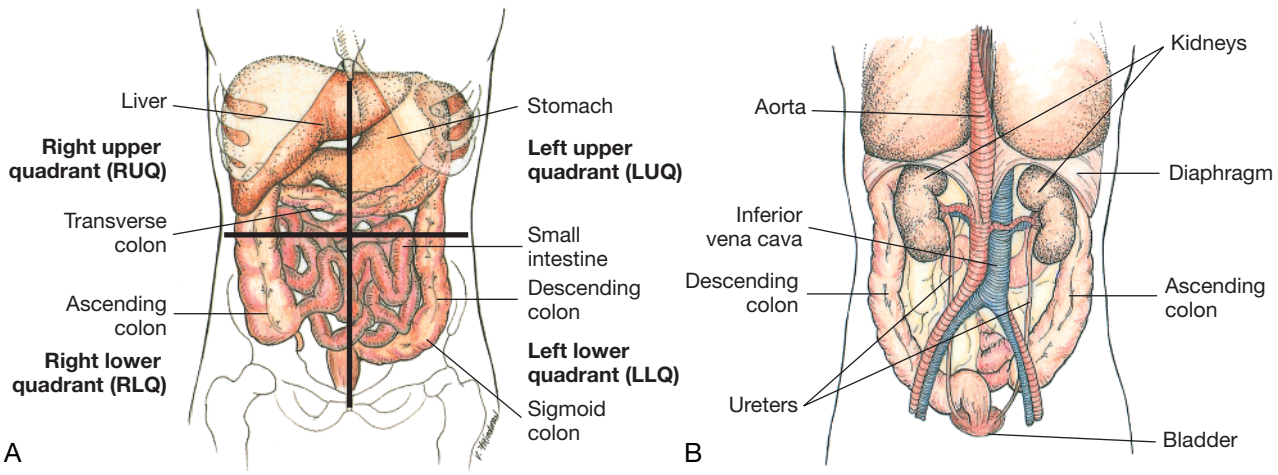

Figure 24-29 Abdominal quadrants.

diaphragm of the stethoscope is placed lightly over the middle of the abdomen. Because bowel sounds are easily transmitted over the abdomen there is no need to listen in more than one place (Talley & O'Connor 2014).

Normally, air and fluid move through the intestines, creating soft gurgling or clicking sounds that occur irregularly, depending on when the last meal was eaten. Bowel sounds should be described as either *present* or *absent*. It normally takes 5–20 seconds to hear a bowel sound, but may take up to 5 minutes of continuous listening before determining the absence of bowel sounds. Absent bowel sounds indicates ileus, or the absence of peristalsis in the bowel. Loud tinkling bowel sounds may be heard with a bowel obstruction.

Percussion

Percussion of the abdomen is done less often, but helps reveal the presence of fluid and air in the stomach and intestines or urine in the bladder. Each quadrant is systematically percussed to assess tympanic areas, dullness and for any pain. A tympanic sound usually predominates because of air in the stomach and intestines. Eliciting pain during percussion is an important sign known as *percussion tenderness* and suggests peritoneal inflammation.

To assess urinary elimination, percuss the abdomen starting at the symphysis pubis and move towards the umbilicus. A dull percussion note is heard over a distended bladder. Dullness when percussing outwards from the midline over the abdominal flanks signifies fluid. Dullness on percussion may shift with patient position when there are significant ascites and is called *shifting dullness* (Figure 24-31).

Palpation

Palpation is aimed mainly at detecting areas of abdominal tenderness and noting the quality of abnormal distension or masses. After rubbing your hands together to warm them, use *light palpation* over each quadrant. Lay the palm of the hand with fingers extended and close together lightly on the abdomen, keeping the palm and forearm horizontal (Figure 24-32). The pads of the fingertips depress approximately 1.5 cm in a gentle dipping motion. Avoid quick jabs and use smooth, coordinated movements. A systematic palpation of each quadrant assesses for muscular resistance, distension, tenderness and

Figure 24-32 Light palpation of the abdomen.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

superficial masses. While palpating, observe the patient's face for signs of discomfort. The abdomen is normally smooth with consistent softness and non-tender without masses. The older adult often lacks abdominal tone.

If a sensitive area is palpated, *guarding* or voluntary muscle contraction may occur. Involuntary guarding may be localised or generalised (*rigid abdomen*) and is a sign of acute peritonitis. A distended bladder is easy to detect with light palpation. Normally the bladder lies below the umbilicus and above the symphysis pubis. Palpate for a distended bladder if the patient has been unable to void, has been incontinent or if an indwelling urinary catheter is not draining well.

Most organs in the abdomen (liver, kidneys, spleen, bladder) are not normally palpable. For example, easy palpation of the spleen may signify splenomegaly and liver enlargement may accompany ascites in liver failure (Figure 24-33).

Renal system

The kidneys play a central role in maintaining homeostasis. The glomeruli filter blood and excrete unwanted solutes, including the products of metabolism. Hormones act on the kidneys to control body water and help to regulate blood pressure and electrolyte balance. Renal function is closely related to the cardiovascular system and blood pressure regulation. Clinically, investigations such as the estimated glomerular filtration rate (eGFR) and blood urea, creatinine and electrolyte values are the mainstay of routine kidney assessment. However, your bedside-focused fluid balance assessment (see Chapter 33) and **renal system** assessment skills are critical to detect changes in kidney function (Skill 24-6).

Most important is measurement of *urine output*, which should be at least > 0.5 mL/kg/hour in adults. Of course,

Figure 24-33 Ascites.

Talley NJ, O'Connor S 2014 Clinical examination: a systematic guide to physical diagnosis, 7th edn. Elsevier, Chatswood, NSW.

always check that the IDC is patent and draining properly (check for blocked catheter, kinks or a misplaced catheter) before concluding your patient is not producing urine. Remember to palpate the bladder for distension (see above) or do a bladder scan. Measure and observe urine output for colour and presence of sediment. Is it clear, dark or blood-stained? For example, dark concentrated urine can indicate dehydration and blood-tinged urine (haematuria) is always abnormal. A pungent smell of urine may be a sign of urinary tract infection. Urinalysis needs to be performed (see Chapter 34). If there is no IDC, determine the last time the patient voided (e.g. since returning from surgery).

Determine the patient's volume status (see Box 24-10). *Fluid balance charts* are used to record all input and output as well as the results of urinalysis. Recording the *daily weight* of patients each morning at the same time is often the most accurate way to determine fluid shifts (remember 1 kg = 1 L fluid). Measurement of abdominal girth (cm) and oedematous limbs may also be conducted.

Part of your hydration assessment includes *mucous membranes* and *skin turgor*. Grasp a fold of skin on the back of the forearm or over the sternal area with your fingertips and release (Figure 24-34). Normally the skin lifts easily and recoils immediately to its resting position.

SKILL 24-6

Focused renal assessment

Delegation and other considerations

- Comprehensive patient assessment is the basis for the development of the nursing care plan and therefore should not be delegated by the registered nurse.
- Perform hand hygiene and apply personal protective equipment when appropriate before, during and after patient assessment.

Equipment

- Fluid balance chart
- Urinalysis test kit
- Watch
- Pen

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review the patient's baseline assessment data. Review recent blood results for urea and electrolytes (U&Es) and creatinine.	The key point of clinical examination is to determine if something has changed. Refer to baseline or previous findings to determine an acute change in patient status.
2. Perform hand hygiene.	Prevents transmission of microorganisms.
3. Ensure comfort and privacy. Explain procedure and clarify any concerns.	Promotes patient's cooperation and comfort during the assessment.
4. Approach from the right side with patient appropriately positioned (supine when possible) for examination.	Assists with performance and interpretation of data.
5. Measure urine output (when possible) or determine last time patient voided.	Reduced or increased urine output may be the earliest signs of impaired renal function.
6. If indwelling urinary catheter (IDC) in situ, determine patency. If required, gently palpate for a distended bladder or perform bladder scan for residual volume (will be zero if patent IDC in situ).	
7. Observe urine for colour, offensive smell or presence of sediment.	New abnormal findings require further clinical investigations.
8. Perform urinalysis (see Chapter 33).	
9. Assess fluid volume status: a. Calculate 24-hour fluid balance from recorded input and output, or daily weight. b. Assess hydration of oral mucous membranes and skin turgor.	

STEPS	RATIONALE
c. Assess adequate intravascular volume with capillary refill time, heart rate, systolic BP, pulse pressure, and JVP. d. Note signs of fluid volume deficit or excess (see Box 24-10).	
10. Determine the frequency of renal assessment required based on the patient's condition.	Certain conditions place patients at high risk of renal alterations (e.g. chronic kidney disease, nephrotoxic medications, shock).

RECORDING AND REPORTING

- Core documentation includes urine output, colour and positive findings on urinalysis, and cumulative fluid balance. Note any new abnormal findings or investigations.
- Report early and late warning signs associated with renal deterioration (Box 24-11) as a priority to senior nursing or medical staff.

BOX 24-10 Signs and symptoms of fluid volume imbalances

Fluid volume deficit	Fluid volume excess
Dry skin and mucous membranes, decreased skin turgor	Peripheral oedema with taught, non-compliant skin, pre-sacral or ankle oedema
Weight loss	Weight gain
Negative fluid balance (fluid output exceeding fluid intake)	Positive fluid balance (fluid intake exceeding fluid output)
Hypotension, postural drop	Hypertension
Tachycardia	Bradycardia
Flat neck veins with patient sitting at 45-degrees	Pulmonary congestion (lung crackles), dyspnoea
Raised haematocrit	Distended neck veins with patient sitting at 45-degrees
	Decreased haematocrit with haemodilution

Poor skin turgor is when skin is slow to resume its normal contour or shape. With worsening dehydration the skin remains pinched up, called *tenting*.

Chronic kidney disease patients receiving dialysis treatment may have an arteriovenous fistula observed on the forearm (Figure 24-35) or a Tenkhoff catheter in the abdomen for peritoneal dialysis. Inspect the skin for any signs of infection.

Figure 24-34 Assessing skin turgor.

Wilson S, Giddens J 2013 Health assessment for nursing practice, 5th edn. Elsevier Mosby, St Louis.

Musculoskeletal system

Following a systematic approach, once the head (CNS), neck and chest (CVS and RESP) and abdomen (GIT and RENAL) are examined, the extremities and skin are carefully assessed. You will have already collected a significant amount of data about these systems. The neurological and musculoskeletal systems are closely interrelated, so assessment is often conducted simultaneously (e.g. limb assessment for Tone/Power/Reflexes/Sensory). General skin inspection also occurs during each system and body region examination.

Figure 24-35 Arteriovenous (AV) fistula in a patient with chronic kidney disease.

Talley NJ, O'Connor S 2014 Clinical examination: a systematic guide to physical diagnosis, 7th edn. Elsevier, Chatswood, NSW.

Key components of a focused musculoskeletal assessment include examination of gait, arms, legs and spine (Skill 24-7). A focused assessment of the **musculoskeletal system** is especially important when the patient reports pain or loss of function in a joint or muscle. Musculoskeletal assessment is also part of your mobility and falls risk assessment (see Chapter 28).

BOX 24-11 Early and late warning signs associated with renal deterioration

Early warning signs	
Poor peripheral circulation	pH 7.2– 7.3
Note of decreased urine output	Base deficit –5 to –8 mmol/L
Urine output < 200 mL/8 hours	
Late warning signs	
Urine output < 200 mL/24 hours	pH < 7.2
Anuric	Base deficit < –8 mmol/L

Data from Jacques T, Fisher M, Hillman K et al (eds) 2011 DETECT Manual: Detecting deterioration, evaluation, treatment, escalation and communicating in teams, 3rd edn. NSW Health and Clinical Excellence Commission, Neutral Bay.

Inspection

You can integrate portions of the musculoskeletal assessment when observing the patient walking (to assess gait), moving in bed or performing any type of physical

SKILL 24-7

Focused musculoskeletal assessment

Delegation and other considerations

- Perform hand hygiene and apply personal protective equipment when appropriate before, during and after patient assessment.

Equipment

- Pen
- Documentation

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review the patient's baseline assessment data.	The key point of clinical examination is to determine if something has changed. Refer to baseline or previous findings to determine an acute change in patient status.
2. Perform hand hygiene.	Prevents transmission of microorganisms.
3. Ensure comfort and privacy. Explain procedure and clarify any concerns.	Promotes patient's cooperation and comfort during the assessment.
4. Ensure patient appropriately positioned for examination.	Assists with performance and interpretation of data.
5. Observe patient's ability to safely stand, transfer and mobilise. Note how much assistance is necessary.	Basic clinical assessment of mobility and falls risk. May indicate need for safety interventions and need for mobility aid.
6. Observe gait.	
7. Inspect and gently palpate major joints for range of motion in arms, legs and (when possible) spine. Note any pain, swelling, warmth or crepitus.	
8. Assess muscle strength. Compare the right and left of paired muscle groups. Note involuntary movements.	
9. Determine the frequency of musculoskeletal assessment required based on the patient's condition.	Certain conditions place patients at high risk of musculoskeletal alterations (e.g. immobility, trauma, risk of falls).

RECORDING AND REPORTING

- Core documentation includes mobility, range of motion and ability to perform activities of daily living. Note any new abnormal findings or investigations.
- Report acute changes in musculoskeletal status such as loss of function as a priority to senior nursing or medical staff.

activity, including self-care activities. Normally, walking is initiated in a smooth and rhythmic motion. The foot is lifted and propelled forwards in a straight line; as the heel strikes the floor, bodyweight is shifted to the ball of the foot. The patient remains erect and balanced during all stages of gait. Routinely observe your patient's ability to transfer and mobilise during the course of each shift. Observe safe use of mobility aids and need for patient teaching and/or referral to physiotherapist.

The assessment of musculoskeletal function focuses on inspecting major joints for range of motion (ROM). During general inspection, look at the extremities for overall size, alignment and symmetry. Note any deformities, swelling, erythema, bruising, and muscle atrophy. Ask the patient to put each major joint through active full ROM. If passive joint movement is required, then gently support and move the joints of the extremities through their normal ROM. Do not force a joint if there is pain or muscle spasm. Knowledge of each joint's normal range and the extent to which it can be moved is important to detect abnormal findings (see Chapter 33). Describe your findings using the correct clinical terminology (Table 24-6). Normal joints are non-tender, without swelling and move freely. If a joint appears swollen and inflamed, palpate it for warmth.

Palpation

Apply gentle palpation to bones, joints and surrounding muscles of the extremities and the spine. As you palpate, note any heat, tenderness, oedema or resistance to pressure. Feel for joint *crepitus* during ROM, which is

TABLE 24-6 Clinical terminology for normal range of motion

Term	Range of motion	Examples of joints
Abduction	Movement of extremity away from midline of body	Leg, arm, fingers
Adduction	Movement of extremity towards midline of body	Leg, arm, fingers
Dorsiflexion	Flexion of toes and foot upwards	Foot
Eversion	Turning of body part away from midline	Foot
Extension	Movement increasing angle between two adjoining bones	Elbow, knee, fingers
External rotation	Rotation of joint outwards	Knee, hip
Flexion	Movement decreasing angle between two adjoining bones; bending of limb	Elbow, fingers, knee
Hyperextension	Movement of body part beyond its normal resting extended position	Head
Internal rotation	Rotation of joint inwards	Knee, hip
Inversion	Turning of body part towards midline	Foot
Plantar flexion	Bending of toes and foot downwards	Foot
Pronation	Movement of body part so that front or ventral surface faces downwards	Hand, forearm
Supination	Movement of body part so that the front or ventral surface faces upwards	Hand, forearm

a grating sensation caused by the rubbing together of synovial surfaces of the joints, such as in osteoarthritis. For assessment of muscle strength, each muscle group is examined comparing left with right, following a routine (e.g. starting with the hand and working upward towards the shoulder). Ask the patient to first flex the muscle to be examined and then resist when opposing force is applied against that flexion (Table 24-7).

Musculoskeletal assessment is also closely tied to neurovascular assessment. Trauma or surgery to limbs increases the risk of compartment syndrome from swelling and sometimes bleeding in the affected limb. This may cause compartments to put excessive pressure on nerves and vascular structures which can result in irreversible tissue injury. For these reasons, neurovascular observations are routine after orthopaedic surgery or trauma as well as in vascular assessment (Figure 24-14).

Integumentary system

RNs are responsible for regular assessment of the skin each shift to prevent skin breakdown and pressure injuries. Patients most at risk of significant skin lesions are those suffering from neurological impairments, chronic illnesses, orthopaedic problems, diminished cognitive and/or mental status, poor tissue oxygenation, low cardiac output, inadequate nutrition and immobility (see Chapter 26). The skin is routinely assessed for colour, temperature, moisture, turgor and oedema (see renal and cardiovascular assessment), as well as for any vascular changes or lesions (Skill 24-8).

TABLE 24-7 Assessing muscle strength

Muscle group	Manoeuvre
Neck (sternocleidomastoid)	Place hand firmly against patient's upper jaw. Ask patient to turn head laterally against resistance
Shoulder (trapezius)	Place hand over midline of patient's shoulder, exerting firm pressure. Have patient raise shoulders against resistance
Biceps	Pull down on forearm as patient attempts to flex arm.
Triceps	As patient's arm is flexed, apply pressure against forearm. Ask patient to straighten arm
Quadriceps	When patient is sitting, apply downward pressure to thigh. Ask patient to raise leg up from table
Gastrocnemius	Patient sits, holding shin of flexed leg. Ask patient to straighten leg against resistance

Barkauskas VH et al 2002 Health and physical assessment, 3rd edn. Mosby, St Louis.

SKILL 24-8

Focused skin or integumentary assessment

Delegation and other considerations

- Comprehensive patient assessment is the basis for the development of the nursing care plan and therefore should not be delegated by the registered nurse.
- Perform hand hygiene and apply personal protective equipment when appropriate before, during and after patient assessment.

Equipment

- Good lighting
- Pen
- Documentation

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review the patient's baseline assessment data.	The key point of clinical examination is to determine if something has changed. Refer to baseline or previous findings to determine an acute change in patient status.
2. Perform hand hygiene.	Prevents transmission of microorganisms.
3. Ensure comfort and privacy. Explain procedure and clarify any concerns.	Promotes patient's cooperation and comfort during the assessment.
4. Ensure patient appropriately positioned for examination with good lighting.	Assists with performance and interpretation of data.
5. Expose each body region from head-to-toe to inspect and palpate skin, hair and nails, noting: a. General colour b. Temperature c. Moisture and turgor d. Capillary refill time	These are indicators of skin integrity.
6. Inspect and palpate for signs of pressure injury or skin lesions, noting: a. Non-blanchable redness b. Localised heat c. Oedema and induration	Identify abnormal changes that require intervention.
7. Observe any wounds, dressings or drains, and invasive lines, noting: a. Warmth b. Redness c. Swelling d. Exudate and odour	Identify abnormal changes that require intervention.

STEPS	RATIONALE
8. Determine the frequency of skin assessment required based on the patient's condition.	Certain conditions place patients at high risk of skin alterations (e.g. immobility, malnutrition, invasive procedures).

RECORDING AND REPORTING

- Core documentation includes general skin condition, assessment of any lesions or wounds. Note any new abnormal findings or investigations.
- Report acute changes in integumentary status such as the development of a pressure injury or greater than expected drain loss as a priority to senior nursing or medical staff.

Inspection and palpation are used to assess the function and integrity of the **integumentary system** and mucous membranes, which includes the skin, hair, scalp, oral cavity and nails. Initially either inspect all skin surfaces or assess the skin gradually while other parts of the body are being examined. Remember that the skin is most of what we can see about a patient and skin abnormalities are often associated with other body system disorders.

Colour

The skin is normally free of lesions, except for common freckles or age-related changes such as skin tags, senile keratosis (thickening of skin), cherry angiomas (ruby-red papules) and atrophic warts. Jaundice is a yellowish skin colour that may indicate liver disease, often noticed first in the sclera of the eyes (Figure 24-36). Pallor of the conjunctiva may be a sign of anaemia.

Temperature

The temperature of the skin depends on the amount of blood circulating through the dermis. Therefore a reduction in skin temperature reflects a decrease in blood flow. Use the back of your hands to assess skin temperature. Skin infections, such as cellulitis, result in an area that is red, hot and painful (Figure 24-37).

Moisture

Skin and mucous membranes are assessed for hydration. The skin is normally smooth and dry. Skin folds, such as the axillae, are normally moist. Flaking is the appearance of flakes resembling dandruff when the skin surface is

TABLE 24-8 Skin colour variations

Colour	Condition	Causes	Assessment locations
Cyanosis (bluish)	Increased amount of deoxygenated haemoglobin (associated with hypoxia)	Heart or lung disease	Nail beds, lips, mouth, skin (severe cases)
Pallor	Reduced amount of oxyhaemoglobin Reduced visibility of oxyhaemoglobin resulting from decreased blood flow	Anaemia Shock	Face, conjunctivae, nail beds, palms of hands Skin, nail beds, conjunctivae, lips
Loss of pigmentation	Vitiligo	Congenital or autoimmune condition causing lack of pigment	Patchy areas on skin over face, hands, arms
Jaundice (yellow-orange)	Increased deposit of bilirubin in tissues	Liver disease, destruction of red blood cells	Sclera, mucous membranes, skin
Erythema (redness)	Increased visibility of oxyhaemoglobin caused by dilation or increased blood flow	Fever, direct trauma, blushing, alcohol intake	Face, area of trauma, sacrum, shoulders, other common sites for pressure ulcers
Tan-brown	Increased amount of melanin	Suntan, pregnancy	Areas exposed to sun

Figure 24-36 **Jaundice.**

lightly rubbed. Scaling involves fishlike scales that are easily rubbed off the skin's surface. Both flaking and scaling are common in older adults, people who use excessive amounts of soap and in skin conditions such as eczema and dermatitis. Other factors causing dry skin include lack of humidity, exposure to sun, smoking, stress, excessive perspiration and dehydration.

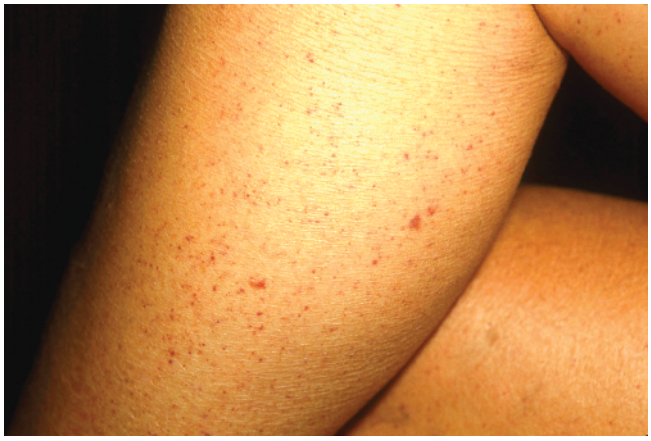

Figure 24-38 **Petechial rash.**

Figure 24-39 **Venous staining.**

Talley NJ, O'Connor S 2014 Clinical examination: a systematic guide to physical diagnosis, 7th edn. Elsevier, Chatswood, NSW.

Vascularity

Look for signs of vascular changes during skin assessment. Localised pressure areas, found after a patient has been in one position for a time, appear reddened, pink or pale (see Chapter 30). Petechiae are tiny, pinpoint-sized red or purple spots on the skin caused by small haemorrhages in the skin layers (Figure 24-38). Petechiae may indicate serious blood-clotting disorders, drug reactions or liver disease. You might observe the brownish discolouration of the lower legs in older adults with chronic venous stasis (Figure 24-39).

Skin eruptions can be a sign of acute systemic illness such as allergy and anaphylaxis. Allergy may start simply with an urticarial rash (known as hives; Figure 24-40) and progress rapidly to angioedema (commonly seen in

Figure 24-40 Urticarial hives.

Habif T 2016 Clinical dermatology: A color guide to diagnosis and therapy, 6th edn. Elsevier.

Figure 24-41 Angiooedema. The lips are a common site.

the lips; Figure 24-41) and anaphylactic shock. Quickly notify relevant staff if you see any of these potentially life-threatening signs of allergy.

Documentation and communication of assessment findings

An important aspect of patient assessment is your documentation and communication of events. These are essential for the continuity of effective care of the patient. Your clinical judgement about the patient's condition based on your assessment, as well as a management plan, must be clearly stated. This defines professional nursing practice and the contribution of nursing to patient care. Clearly document your assessment findings and care plan in the healthcare record or progress notes:

- Nursing notes should be written in a logical, structured way (following your assessment framework).
- Avoid narrative progress notes. They are confusing to other members of the team.
- Use headings to make it thorough but concise.
- There is no clinical requirement to complete every line in the progress notes.
- Some organisations have an electronic health record system. Review this and consider how you might adapt your style of nursing documentation.

Always communicate significant abnormal findings to appropriate nursing and medical staff as a priority. Report data that indicate deterioration in the patient's condition such as any abnormal finding in your primary survey (ABCDE), as well as clinically significant problems identified during body system assessment. It is imperative that your findings are reported urgently and action taken to keep the patient safe. We recommend you use the ISBAR (identify, situation, background, assessment, recommendation) communication tool when you call to inform a colleague about a problem (see Chapter 13).

• CRITICAL REFLECTION POINT

Think about current nursing documentation in your clinical area. Imagine you are a busy clinician trying to read about a patient in the notes. Reflect on whether current nursing notes are helpful to a thorough assessment of the situation. How could this be improved?

Conclusion

The importance of learning how to correctly perform and integrate physical assessment of body systems into your nursing practice cannot be overstated. Patient assessment begins with a primary survey, including vital signs, which then triggers the need for a more focused body systems assessment. The fundamental physical assessment skills for each body system include inspection, palpation, percussion and auscultation. With a little practice, it takes much less time to integrate these skills into a head-to-toe, body systems assessment.

Patient assessment should be targeted or focused on the individual's needs, so you don't need to perform every step in every situation. We have focused on the most important skills that a beginning RN will need to apply in everyday practice – but there is much more to learn! Consult a textbook on physical examination when you encounter the need for more advanced or specialist skills.

Communicate your assessment findings in the healthcare record using a logical framework and verbally using an ISBAR approach. Again, use critical thinking skills to be selective in what you report including the most salient positive and negative findings. Always consider how you would like to be treated during a clinical examination: ensure privacy and respect the patient's preferences.

Key concepts

- Neurological assessment includes the level of consciousness (Glasgow Coma Scale), pupil size and reaction to light, and limb assessment. Evaluate speech and screen for normal vision and hearing.
- Cardiovascular assessment includes the hands and nails (skin colour, temperature, capillary refill), arms (pulse and BP), then the chest (auscultate heart sounds) and lower limbs (palpate for distal pulses, tenderness, oedema).
- Respiratory assessment also includes general observation (skin colour, respirations and work of breathing). Assess the airway and ability to speak and cough. Inspect the chest and auscultate lung sounds. Measure oxygen saturation (SpO_2) noting the patient's oxygen requirement.
- Gastrointestinal assessment includes abdominal inspection and auscultation for bowel sounds. Gently palpate the abdomen. Assess the last bowel movement.
- Renal assessment includes clinical investigations such as the glomerular filtration rate, blood urea and electrolytes, creatinine. Bedside assessment focuses on urine output and fluid balance.
- Musculoskeletal assessment includes examination of gait, arms, legs and spine. Inspect, feel and move each major joint.
- Skin assessment includes colour, temperature, moisture, turgor and oedema, as well as for any vascular changes or lesions.

Pathogens, p. 624
Standard precautions, p. 628
Sterilisation, p. 625
Surgical asepsis, p. 660
Transmission-based precautions, p. 623

Learning outcomes

Mastery of content will enable you to:

- recognise individual, cultural and age-related similarities and differences in patients' response to infection and infection control
- explain the chain of infection concept relating to transmission of infection
- identify the body's normal defences against infection
- discuss the events in the body's inflammatory response
- explain the difference between cell-mediated and humoral immunity
- describe the signs and symptoms of a localised infection and a systemic infection
- identify patients most at risk of infection
- explain conditions that promote the transmission of healthcare-associated infection
- explain the difference between medical and surgical asepsis
- identify nursing interventions that target each element in the chain of infection
- explain the rationale for standard and transmission-based precautions
- correctly perform hand hygiene procedures
- explain how infection control measures in the home may differ from those in the hospital
- correctly don a surgical mask, sterile gown and sterile gloves.

It has been estimated that approximately 175,000 healthcare-associated infections (HAIs) occur annually in Australia, accounting for almost one million bed-days lost to HAIs per year (Graves et al 2009). Patients in all healthcare settings are at risk of acquiring infections because of their lowered resistance to infectious micro-organisms, increased exposure to disease-causing microorganisms and invasive procedures. In acute care or daycare facilities, or even in the home, patients can be exposed to pathogens, some of which may be resistant to most antibiotics. Surgical site infection (SSI) and catheter-associated urinary tract infection (CAUTI) are two of the most common HAIs (Graf et al 2011).

Effective infection prevention and control techniques can minimise transmission of infection and protect patients and health workers from disease. Patient education, including information concerning infections, modes of transmission and methods of prevention, is essential if patients and their families are to recognise sources of infections and implement protective measures. Infection can be transmitted through *direct contact* (touch), *droplet contact* (body fluids), *airborne spread* (air currents), *contaminated articles*, *food*, *water* and *vectors* (insects or rodents). Understanding the modes of transmission of infectious organisms and knowing how and when to apply the basic principles of infection prevention and control, such as standard and **transmission-based precautions**, is critical to the success of an infection control program. Health workers can also protect themselves from contact with infectious material or exposure to communicable diseases by understanding the infectious process and implementing appropriate infection prevention and control practices.

Nature of infection

Colonisation is the sustained presence of replicating infectious agents on or in the body, without the production of an immune response or disease (National Health and Medical Research Council 2010). An **infection** involves the entry and multiplication of an infectious agent within the tissues of a host, resulting in an immune response with or without symptomatic disease (NHMRC 2010). If the infectious agent (pathogen) fails to cause injury to cells or tissues, the infection is *asymptomatic*. If the pathogens multiply and cause clinical signs and symptoms, the infection is *symptomatic*. If the infectious disease can be transmitted directly from one person to another, it is a *communicable* or *contagious* disease.

Chain of infection

The presence of a pathogen does not always result in an infection. Development of an infection is dependent on the following elements (NHMRC 2010):

- a source (or reservoir) of infectious agents (or pathogens) and an exit portal out of the reservoir
- a mode of transmission for the pathogen
- a susceptible host with a portal of entry receptive to the pathogen.

The potential for infection is enhanced by the inter-relationship of these elements, which together form a process known as the **chain of infection** (Figure 25-1). An infection will develop if the chain remains intact. Adherence to infection prevention and control practices can break the chain and prevent infection.

Infectious agents

Most infectious agents are **microorganisms**, including bacteria, viruses, fungi, protozoa and prions (Table 25-1). Microorganisms on the skin may be resident (also called **normal flora**) or transient flora. *Resident* flora are the microorganisms that normally reside under the superficial cells of the stratum corneum or on the surface of the skin. *Transient* microorganisms colonise the superficial layers of the skin and attach to the skin when a person has contact with another person or object. For example, when a nurse touches a bed pan or a contaminated dressing, transient bacteria from these objects adhere to the nurse's skin. Transient organisms attach loosely to the skin in

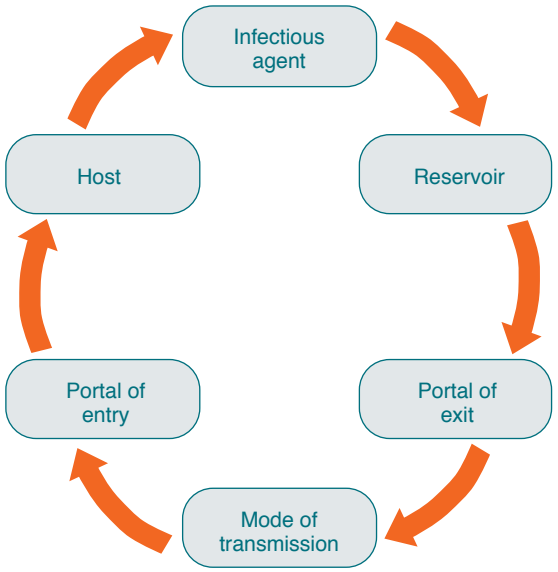

Figure 25-1 Chain of infection.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

debris and oils, or under the fingernails, and are readily transmitted unless removed by adequate hand hygiene.

When microorganisms cause disease in their host, they are considered infectious agents or **pathogens**. Infection is the result of a complex interrelationship between a host and an infectious agent, and individuals vary in their response to exposure to an infectious agent. The potential for microorganisms or parasites to cause disease depends on the following factors:

- sufficient number of organisms
- virulence, or ability to produce disease
- ability to enter and survive in the host
- susceptibility of the host.

Although normal flora is usually non-pathogenic, serious infection can occur from resident skin microorganisms. For example, when surgery or other invasive procedures breach the integrity of skin and allow the transfer of microbes to deeper tissues, or when a patient is severely immune-compromised, resident skin flora can cause infection.

CRITICAL REFLECTION POINT

Mrs Atkins is attending an outpatient clinic to have a venous ulcer on her left leg reviewed. The ulcer is large, with wound fluid visible through the dressing. Mrs Atkins is slightly confused. You notice that the registered nurse attending to the dressing is using tap water to cleanse the wound and is not wearing gloves. When you ask why, he says, 'These wounds are heavily colonised anyway – a few more bugs won't hurt.'

1. **Is this practice justifiable based on the registered nurse's rationale?**
2. **How and when would you respond to this comment?**

TABLE 25-1 Common pathogens and some infections or diseases they produce

Organism	Major reservoir(s)	Major infections/diseases
Bacteria		
Escherichia coli	Colon	Gastroenteritis, urinary tract infection
Mycobacterium tuberculosis	Droplet nuclei from lungs	Tuberculosis
Neisseria gonorrhoeae	Genitourinary tract, rectum, mouth	Gonorrhoea, pelvic inflammatory disease, infectious arthritis, conjunctivitis
Rickettsia rickettsia	Wood tick	Rocky Mountain spotted fever
Staphylococcus aureus	Skin, hair, anterior nares	Wound infection, pneumonia, food poisoning, cellulitis
Staphylococcus epidermidis	Skin	Wound infection, bacteraemia, line infection
Streptococcus (beta-haemolytic group A) organisms	Oropharynx, skin, perianal area	'Strep throat', rheumatic fever, scarlet fever, impetigo, wound infection
Streptococcus (beta-haemolytic group B) organisms	Adult genitalia	Urinary tract infection, wound infection, postpartum sepsis, neonatal sepsis
Viruses		
Hepatitis A virus	Faeces	Hepatitis A
Hepatitis B virus	Blood and body fluids	Hepatitis B
Hepatitis C virus	Blood	Hepatitis C
Herpes simplex virus (type I)	Lesions of mouth or skin, saliva, genitalia	Cold sores, aseptic meningitis, sexually transmitted disease, herpetic whitlow
Human immunodeficiency virus (HIV)	Blood, semen, vaginal secretions (also isolated in saliva, tears, urine and breast milk, but not proved to be sources of transmission)	Acquired immune deficiency syndrome (AIDS)
Fungi		
Aspergillus organisms	Soil, dust, mouth, skin, colon, genital tract	Aspergillosis, pneumonia, sepsis
Candida albicans	Mouth, skin, colon, genital tract	Moniliasis, pneumonia, sepsis
Protozoa		
Plasmodium falciparum	Blood	Malaria

Reservoir

A *reservoir* is a place where a pathogen can survive and may or may not multiply. For example, hepatitis A virus survives in shellfish but does not multiply; *Pseudomonas* organisms may survive and multiply in nebuliser reservoirs. Infectious agents transmitted during health care come primarily from human sources, including patients, healthcare workers and visitors. Although a variety of microorganisms live on the skin, within body cavities and within body fluids, the presence of microorganisms does not always cause illness. People or animals with no symptoms of illness but with evidence of pathogens on or in their bodies that can be transferred to others are termed *carriers*. For example, a person can be a carrier of the hepatitis B virus without having signs or symptoms of the infection. Animals, insects, food, water and inanimate objects (fomites) can also be reservoirs for infectious organisms. For example, shellfish can also become contaminated with *Vibrio cholerae*, the bacterium that causes cholera. *Clostridium botulinum* toxin survives in incorrectly processed foods and can cause botulism. The bacterium *Legionella pneumophila* causes Legionnaire's disease and can reside in contaminated water, cooling towers and water systems.

Microorganisms and parasites require a favourable environment in which to thrive. This can include food, the presence or absence of oxygen, water, an appropriate temperature, pH and light.

Food

Although microorganisms differ in their food requirements, all require nourishment from some source. Most require an external source of food, but a few rare microorganisms are capable of manufacturing their own energy through the same photosynthesis process used by plants. For example, *Clostridium perfringens*, the microbe that causes gas gangrene, thrives on organic matter and *Escherichia coli* consumes undigested food in the bowel. Soil provides nourishment for other types of organisms such as *Clostridium tetani*, which can cause tetanus.

Oxygen

Aerobic bacteria require oxygen for survival and sufficient multiplication to cause disease. Aerobic organisms such as *Staphylococcus aureus* and strains of *Streptococcus* commonly cause infections in humans, compared with the less common anaerobic organisms, for example, those that cause tetanus, gas gangrene and botulism. Anaerobic bacteria flourish where little or no free oxygen is available. Traumatic wounds, such as stab wounds, compound fractures and burns, can be infected with anaerobic bacteria (e.g. *C. perfringens*) or aerobic bacteria (e.g. *S. aureus*).

Water

Most organisms require water or moisture for survival. For example, a common place for microorganisms to multiply is within the moist drainage from a surgical wound. The spirochete causing syphilis, *Treponema pallidum*, only survives in a moist environment. However, spore-forming bacteria (endospores), such as those that cause anthrax, botulism and tetanus, are resistant to drying and can survive without water.

Temperature

Microorganisms survive in specific temperature ranges. The ideal temperature for most human pathogens is 37°C. However, some microorganisms can survive temperature extremes that are usually fatal to humans. Cold temperatures tend to prevent growth and reproduction of bacteria (bacteriostasis). A temperature that destroys bacteria is classified as *bactericidal*. For example, steam **sterilisation** of correctly pre-cleaned items occurs at a temperature of 134°C, under 203 kPa of pressure, when maintained in a steriliser with these parameters for 3 minutes (Standards Australia 2014).

pH

The acidity of an environment affects the viability of microorganisms. Most survive in a pH environment range of 5–8. In particular, bacteria thrive in urine with an alkaline pH. Most organisms cannot survive the acidic environment of the stomach. However, administration of acid-reducing medications such as an antacid or H_2-receptor antagonist may cause an overgrowth of a gastrointestinal organism such as *Candida albicans*, resulting in a nosocomial, treatment-related disease.

Light

Microorganisms multiply in dark, moist, warm conditions, such as under dressings and within body cavities. This environment also predominates on a nurse's hands when gloves are worn. Gloves may contain microscopic perforations permitting the entry of microbes, which proliferate in the moist, warm environment created. It is therefore essential for health workers to wash their hands or liberally apply an antimicrobial alcohol hand rub immediately after the removal of protective gloves.

Portal of exit

Once microorganisms find a site in which to grow and multiply, they must locate a portal of exit if they are to enter a host and cause disease. Microorganisms can

exit through a variety of sites, for example, the skin and mucous membranes, as well as the respiratory, urinary, gastrointestinal and reproductive tracts.

Skin and mucous membranes

Any break in the integrity of the skin and mucous membranes should be considered to be a portal of exit for pathogens. Direct contact with skin lesions can be a source of infection. Often the body responds to a pathogenic organism with the creation of purulent (pus-containing) drainage. For example, *S. aureus* causes a characteristic yellow, creamy drainage and *Pseudomonas aeruginosa* causes a greenish, creamy drainage.

Respiratory tract

Pathogens infecting the respiratory tract, such as *Mycobacterium tuberculosis*, can be released from the body when an infected person sneezes, coughs, talks or even breathes. Microorganisms exit through the mouth and nose in healthy people. Artificial airways, such as tracheostomy or endotracheal tubes (see Chapter 40), facilitate easy transmission of organisms via the respiratory tract.

Urinary tract

Normally, urine is sterile. However, when a patient has a urinary tract infection (UTI), microorganisms exit during urination or through urinary diversions such as urethral catheters, ileo conduits and suprapubic catheters (see Chapter 38).

Gastrointestinal tract

The mouth is one of the most bacterially contaminated sites of the body, although most of the organisms are normal flora – bacteria that normally reside within the body and defend against infection. However, the transfer of normal flora between people can create an infection. For example, organisms exit when a person spits (expectorates) or kisses another person. Bowel elimination, drainage from abdominal surgical wounds or drainage tubes and escape of gastric contents during vomiting are additional portals of exit.

Reproductive tract

Organisms such as *Neisseria gonorrhoeae*, *Chlamydia* species and human immunodeficiency virus (HIV) may exit through the male urethral meatus or a woman's vaginal canal. Semen and vaginal secretions are common pathogenic vehicles for sexually transmitted infections (see Chapter 24).

Blood

Blood-borne diseases, such as HIV or hepatitis B or C, can be transmitted when a break in the skin allows pathogens to exit the body. Caregivers can easily become infected unless precautions are taken, for example, by wearing personal protective equipment such as eyewear, gloves and masks.

Modes of transmission

There are many ways microorganisms can be transmitted from the reservoir to the host, such as contact, droplet or airborne transmission. Table 25-2 summarises the most common modes of transmission. Certain infectious diseases tend to be more transmissible by specific modes. The same microorganisms may also be transmitted by more than one route. Chickenpox (varicella), for example, is caused by primary infection with the varicella zoster virus (VZV). Although the primary mode of VZV transmission is via droplets or airborne particles, it is also spread through direct contact with contaminated secretions or the vesicular fluid from skin lesions of varicella or herpes zoster (shingles) (Weaver 2009). The most common mode of transmission of microorganisms to patients is via the hands of health workers. However, almost any object in the environment, for example, a stethoscope or thermometer, can transmit pathogens (see *Research highlight*).

Nurses have the most direct and continuous role in performing the procedures and interventions on which the risk of infection often hinges, making them a critical component of infection prevention. Studies demonstrate a strong association between nurse staffing and the risk of healthcare-associated infections (Stone et al 2008). Other hospital personnel that provide direct patient care or those performing diagnostic and support services also play an important role in minimising the spread of infection. Caregivers can easily become infected unless precautions are taken, such as wearing protective apparel such as eyewear, gloves and masks. In addition, infection control procedures must be followed for the safe handling of equipment and supplies used by each patient; for example, hand hygiene before working with each patient and disposing of soiled equipment appropriately.

Certain medical equipment and devices or diagnostic procedures provide avenues for the spread of pathogens. Invasive procedures such as cystoscopy (instrumentation and examination of the bladder) facilitate diagnosis but also increase the risk of transmitting infection. Therefore, the used cystoscope must be reprocessed and sterilised to prevent cross-infection. As many factors promote the spread of infection, health workers must conscientiously adhere to infection control practices such as hand hygiene. All equipment used on patients must be correctly decontaminated to prevent cross-infection.

TABLE 25-2 Modes of transmission

Routes and means	Examples of organisms
Contact	
Direct: Person-to-person direct transfer of infectious agent (e.g. faecal, oral, blood) from physical contact between source and susceptible host (e.g. touching patient, patient's blood entering healthcare worker through break in skin)	Influenza A (avian influenza, H5N1 virus, 'bird flu'), hepatitis A virus, *Shigella*, *Staphylococcus*, herpes simplex, multi-resistant organisms (MROs), SARS-associated coronavirus norovirus, respiratory syncytial virus (RSV), highly contagious skin infections/infestations (e.g. impetigo, scabies)
Indirect: Personal contact of susceptible host with contaminated inanimate object (e.g. needles or sharp objects, dressings)	Hepatitis B virus, *Staphylococcus*, *Pseudomonasaeruginosa*, MRSA, VRE, *C. difficile*
Droplet	
Large particles that travel up to 1 metre and come in contact with susceptible host (e.g. coughing, sneezing, talking or other procedures); droplets can also be transmitted indirectly to mucosal membranes (i.e. by contact from hands)	Rubella virus (measles), varicella zoster virus (chickenpox), influenza virus, rubella virus, *Bordetella pertussis*, adenovirus, rhinovirus, *Mycoplasma pneumonia*, SARS-associated coronavirus, group A streptococcus, *Neisseria meningitidis*
Airborne	
Small-particle aerosols, droplet nuclei or residue or evaporated droplets created (e.g. by breathing, coughing, sneezing, talking) and suspended in air or carried on dust particles	*Mycobacterium tuberculosis* (TB), varicella zoster virus (chickenpox), *Aspergillus* spp.
Vehicles (contaminated)	
Water	*Vibrio cholerae*
Medications, solutions	*Pseudomonas*
Blood	Hepatitis C virus
Food (improperly handled, stored or cooked, fresh or thawed meats)	Salmonella, *Escherichia coli*, *C. botulinum*
Vector	
External mechanical transfer (flies; birds, e.g. chickens, ducks; rats)	*Vibrio cholera*, Hendra virus
Internal transmission such as parasitic conditions between vector and host, such as mosquito, louse and flea	*Plasmodium falciparum* (malaria), *Rickettsia typhi*, *Yersinia pestis* (plague)

MRSA = methicillin-resistant *Staphylococcus aureus*; SARS = severe acute respiratory syndrome; TB = tuberculosis; VRE = vancomycin-resistant enterococci.

Portal of entry

Organisms can enter the body through the same routes as they exit. For example, as a contaminated needle pierces a patient's skin, microorganisms enter the body. Contamination of bandages placed over an open wound permits pathogens to enter exposed tissues. These are examples of factors that impair the body's normal defences and increase the opportunity for pathogens to enter and infect the body. Urinary tract infection (UTI) is one of the most common healthcare-associated infections (HAI). Eighty per cent of UTIs are caused by indwelling urinary catheters (IDCs), and the risk of acquiring a catheter-associated urinary tract infection (CAUTI) increases between 3% and 7% every day an IDC remains in situ (Parker et al 2009, Traunter 2010).

• CRITICAL REFLECTION POINT

Mrs Ng has had an indwelling urethral catheter (IDC) in situ for 1 week. The IDC was removed 24 hours ago; she now complains of urinary frequency and pain on urination. Mrs Ng suggests reinsertion of the IDC because of the need to urinate frequently and the distress this is causing her.

1. **What can frequency or dysuria indicate?**
2. **Should the IDC be reinserted? Justify your answer.**
3. **What evidence-based nursing interventions could you use to prevent catheter-associated urinary tract infections in the acute care setting?**

Susceptible host

Whether a person acquires an infection or not depends on their *susceptibility* to an infectious agent. Important predictors of an individual's outcome after exposure include (NHMRC 2010):

RESEARCH HIGHLIGHT

Research focus

Identity badges and lanyards worn by healthcare workers (HCWs) frequently come into contact with patients and the clinical environment, and it is reasonable to expect that they could become colonised with nosocomial pathogens. This Australian study was the first to examine whether identity badges and lanyards worn by HCWs are capable of harbouring potentially pathogenic bacteria.

Research abstract

Design, setting and participants

Cross-sectional study of 71 HCWs (59 clinical ward staff and 12 infection control staff) at Monash Medical Centre, a university teaching hospital. Samples from lanyards, identity badge surfaces and connections (e.g. clips, keys, pens) were cultured.

Main outcome measures

Presence of pathogenic bacteria on identity badges and lanyards; differences in bacterial counts on items carried by nurses and doctors.

Results

A total of 27 lanyards were identified with pathogenic bacteria, compared with 18 badges. Analysing lanyards and badges as a combined group, seven had methicillin-resistant *Staphylococcus aureus* 29 had methicillin-sensitive *S. aureus* (MSSA), 4 had *Enterococcus* spp and 5 had aerobic Gram-negative bacilli. Lanyards were found to be contaminated with 10 times the median bacterial load per area sampled compared with identity badges. There were no significant differences between nurses and doctors in total median bacterial counts on items carried, but doctors had 4.41 times the risk of carrying MSSA on lanyards (95% CI, 1.14–13.75).

Conclusion

Identity badges and lanyards worn by HCWs may be contaminated with pathogenic bacteria, which could be transmitted to patients.

Implications for practice

- Identity badges are constantly touched by HCWs' hands and this action can recontaminate hands with pathogens, even after hand hygiene procedures have been followed.
- Based on these data the authors suggest HCWs remove non-essential connections and clean identity badges frequently.
- Lanyards should be changed frequently or disposed of altogether in preference to clipped-on identity badges.

- immune status at the time of exposure (including whether immune status is compromised by medical treatment such as immunosuppressive agents or irradiation)
- age (e.g. neonates and elderly patients are more susceptible)
- health status (e.g. when a patient has other underlying disease such as diabetes or is a smoker)
- the virulence of the agent
- other factors that increase the risk of transmission of infection (e.g. undergoing surgery, requiring an indwelling device such as a catheter or remaining in hospital for lengthy periods).

Susceptibility depends on the individual's degree of resistance to a pathogen. Although everyone is constantly in contact with large numbers of microorganisms, an infection will not develop until an individual becomes susceptible to the strength and numbers of micro-organisms capable of producing infection. The more virulent an organism is, the greater the likelihood of a person becoming susceptible to infection. Organisms with greater virulence and resistance to antibiotics are becoming more common in acute care settings, associated with the frequent and sometimes inappropriate use of antibiotics. A person's natural defences against infection, as well as a number of other factors, influence resistance. A person's resistance to an infectious agent is enhanced by vaccines or by actually contracting the disease and developing a natural immunity.

The infectious process

Understanding the chain of infection enables the nurse to intervene and help prevent the development of infection. All patients should be treated as potentially infectious and the nurse should employ **standard precautions**, which are measures to minimise spread of infection. When a patient acquires an infection, the nurse observes for signs and symptoms of infection and takes appropriate action to prevent its spread. Infections follow a progressive course (Box 25-1). The severity of a patient's illness depends on the extent of the infection, the pathogenicity of the microorganisms and the susceptibility of the host.

BOX 25-1 Course of infection by stage

Incubation period

Interval between entry of pathogen into body and appearance of first symptoms (e.g. chickenpox, 2–3 weeks; common cold, 1–2 days; influenza, 1–3 days; mumps, 18 days).

Prodromal stage

Interval from onset of non-specific signs and symptoms (malaise, low-grade fever, fatigue) to more-specific symptoms (during this time, microorganisms grow and multiply, and patient is more capable of spreading disease to others).

Illness stage

Interval when patient manifests signs and symptoms specific to type of infection (e.g. common cold manifested by sore throat, sinus congestion, rhinitis; mumps manifested by earache, high fever, parotid and salivary gland swelling).

Convalescence

Interval when acute symptoms of infection disappear (length of recovery depends on severity of infection and patient's general state of health; recovery may take several days to months).

If infection is *localised*, such as a wound infection, appropriate use of standard precautions will help control its spread and minimise the illness. The patient may experience localised symptoms such as pain and tenderness at the wound site. An infection affecting the entire body instead of a single organ or limb is termed *systemic* and can be fatal.

The severity of an infection influences the level of nursing care provided. The nurse is responsible for implementing appropriate infection control measures, administering antibiotics and monitoring the patient's response to medication therapy (see Chapter 31). Supportive therapy includes providing adequate nutrition and rest to bolster defences against the infectious process. The complexity of care will also depend on the body systems affected by the infection.

Regardless of whether the infection is localised or systemic, the nurse plays an important role in minimising its spread. For example, the organism causing a simple wound infection can spread to involve an intravenous (IV) cannula insertion site if the nurse does not adhere to principles of standard precautions while performing routine patient-care procedures. Nurses with breaks in their own skin integrity can also acquire infections from patients if techniques for controlling infection transmission are inadequate.

Healthcare-associated infections

Patients in healthcare settings have an increased risk of acquiring infections. **Healthcare-associated infections** (HAIs), previously referred to as nosocomial infections, are contracted by patients during their admission to a healthcare facility. HAIs are often transmitted by health workers, for example, if they fail to wash their hands in between patients. A hospital is one of the most likely places for acquiring an infection because it harbours a high population of virulent, potentially antibiotic-resistant strains of microorganisms. It is estimated that up to 70% of some types of HAIs are preventable through improved infection control practices among healthcare providers. The intensive care unit (ICU) is an area where the risk of acquiring an HAI is increased, due to the high acuity of patients and the prevalent use of antibiotics (Box 25-2).

BOX 25-2 Risk of healthcare-associated infection in critical-care units

Healthcare-associated infection is a major problem in critical-care areas which may affect up to 20% of patients, with a mortality rate of around 30% (Orsi et al 2005).

Healthcare workers in critical-care areas should therefore be vigilant with hand hygiene and infection control practices. Critical-care patients are 5–10 times more likely to become infected than ward patients (Lim & Webb 2005).

Nurses working in intensive care units (ICUs) should be particularly conscious of aseptic practices. Patients are at risk of infection for a variety of reasons, including:

- patients are compromised by their disease or trauma and are more susceptible to infection
- patients often have comorbidities or a history of prolonged medical treatment
- invasive devices, such as intravenous, arterial and central venous lines, are often inserted
- a greater number of invasive procedures are performed in critical-care areas
- occasionally emergency surgical procedures are performed in ICUs instead of the operating room, because of a patient's critical condition
- overuse of broad-spectrum antibiotics increases the formation of resistant microorganisms both in patients and within the environment
- staff shortages and the fast pace in critical-care areas can often cause healthcare providers to become less diligent with hand hygiene and asepsis.

Lim SM, Webb SAR 2005 Nosocomial bacterial infections in intensive care units 1: organisms and mechanisms of antibiotic resistance. Anaesthesia 60:887–902; Orsi GB, Raponi M, Franchi C et al 2005 Surveillance and infection control in an intensive care unit. Infect Control Hosp Epidemiol 26:321–5.

Iatrogenic infections are a type of HAI that result from a diagnostic or therapeutic procedure. For example, intravascular catheters (IVCs) are the most frequently used medical devices in hospitals, yet they are associated with life-threatening catheter-associated bloodstream infection (CABSI). You should always consider the patient's risk of infection during procedures and implement the most appropriate intervention to decrease the opportunity for contamination.

HAIs may be exogenous or endogenous. An *exogenous* infection, for example, *Salmonella* organisms and *C. tetani*, arises from microorganisms external to the individual that do not exist as the person's normal flora. An *endogenous* infection, for example, enterococci, yeasts and streptococci, can occur when part of the patient's flora becomes altered and overgrowth results. When sufficient numbers of microorganisms normally found in one body cavity or lining are transferred to another body site, an endogenous infection develops; for example, transmission of enterococci normally found in faecal material can cause a wound infection.

The number of microorganisms required to cause an HAI depends on the virulence of the organism, the host's susceptibility and the site affected. The number of health workers in direct contact with a patient, the type and number of invasive procedures, the therapy received and the length of hospitalisation all influence the risk of infection. Major sites for HAI include surgical or traumatic wounds, urinary and respiratory tracts and the bloodstream (Box 25-3).

HAIs significantly increase costs to the patient, the healthcare institution and funding bodies, for example, Medicare and private health insurance. Infections can result in increased pain, disability, increased costs of antibiotics, procedures and laboratory tests and prolonged recovery times. Hospitals may not be reimbursed by health-insurance companies for costs relating to HAIs, and therefore prevention has a beneficial financial effect for healthcare facilities and the wider community.

Multi-resistant organisms

Multi-resistant organisms (MROs) are, for the most part, bacteria resistant to multiple classes of antimicrobial agents (e.g. antibiotics), which can become established as endemic pathogens in healthcare institutions. Resistance to antibiotics increases the morbidity and mortality associated with infections (Struelens 1998). The CDC has classified MROs into three threat levels: urgent, serious or concerning, based on key factors including health and economic impact, how common the infection is and how common it is projected to become in 10 years, how

BOX 25-3 Sites and causes of healthcare-associated infections

Urinary tract

(e.g. catheter-associated urinary tract infection)

- Insertion of urinary catheter
- Open drainage system
- Catheter and tube becoming disconnected
- Drainage bag port touching contaminated surface
- Improper specimen-collection technique
- Obstruction or interference with urinary drainage
- Urine in catheter re-entering the bladder (reflux)
- Improper or absent hand hygiene, e.g. handwashing or antimicrobial hand rub technique
- Failure to wash hands or apply an antimicrobial 'rub' solution following removal of gloves
- Repeated catheter irrigations with solutions, altering the pH of urine

Surgical or traumatic wounds

(e.g. surgical site infection)

- Improper skin preparation prior to surgery
- Improper or absent surgical hand antisepsis techniques
- Failure to clean the patient's skin surface properly
- Failure to use a correct aseptic technique during dressing changes
- Reuse of antiseptic solutions

Respiratory tract

(e.g. ventilator-associated pneumonia)

- Contaminated respiratory therapy equipment
- Failure to use correct aseptic technique while suctioning a patient's airway
- Improper disposal of mucous secretions
- Improper or absent hand hygiene, e.g. handwashing or antimicrobial hand rub technique

Bloodstream

(e.g. catheter-associated bloodstream infection)

- Contamination of IV fluids by tubing or inserting needles
- Insertion of drug additives to IV fluids
- The addition of tube or stopcocks to IV system
- Improper care of needle insertion sites
- Use of contaminated needles or catheters
- Failure to resite an IV when inflammation first appears at the IV site
- Improper technique during the administration of multiple blood products
- Improper care of peritoneal or haemodialysis shunts
- Improper or absent hand hygiene, e.g. handwashing or antimicrobial hand rub technique

easily it spreads, the availability of effective antibiotics and barriers to prevention (CDC 2013). Resistant organisms of particular epidemiological significance include all methicillin-resistant *Staphylococcus aureus* (MRSA), all vancomycin-resistant enterococci (VRE) and a range of Gram-negative bacteria with multiple classes of drug resistance (e.g. *Pseudomonas aeruginosa* and *Acinetobacter baumannii*). In Australia, other new challenges have emerged with the increase of *Clostridium difficile* infections and other multi-resistant Gram-negative bacteria, including those producing extended-spectrum beta-lactamases (ESBLs) or carbapenemases (ACQSHC 2012).

The National Health and Medical Research Council (NHMRC) guidelines on infection control recommend a two-level approach for prevention and control of MROs, which includes core strategies and organism-based or resistance-based approaches, assuming that an institution already has basic infection prevention and control processes in place (NHMRC 2010). Core strategies include compliance with standard and transmission-based precautions such as diligent hand hygiene and use of appropriate personal protection equipment, isolating in single rooms or cohorting colonised or infected patients, contact precautions that include environmental cleaning and disinfecting of patient surroundings and frequently touched items and equipment, use of disposable or patient-dedicated equipment and ongoing monitoring. If the use of these core strategies is ineffective in reducing the incidence and prevalence of an MRO outbreak, a more targeted, or organism-specific, approach needs to be enacted. A more targeted approach includes a risk management strategy that takes into account the organism, patient factors, the healthcare environment and availability and access to resources needed to control the outbreak. Additionally, an organism-specific approach would include: targeted screening to identify colonised patients and extension of contact precautions to include new cases; decolonisation via topical, systemic or combination interventions; and increased surveillance and timely feedback to healthcare workers.

It is every healthcare professional's responsibility to minimise the risk of infection for patients and staff by identifying risk factors for transmission of pathogenic organisms and implementing appropriate infection prevention and control practices.

Defences against infection

The body has normal defences against infection. Each organ system has defence mechanisms to protect against exposure of infectious microorganisms (see Figure 25-2). *Normal flora*, *body system defences* and *inflammation* are non-specific defences that protect against microorganisms, regardless of previous exposure. Separate cells and molecules of the *immune system* help the body to resist disease. Immune-system responses are either pathogen-specific or non-pathogen-specific defences. If any of the body's defences fail, an infection can quickly progress into a serious health problem.

Normal flora

Microorganisms normally reside on the surface and in the deep layers of the skin, in the saliva and oral mucosa, in the respiratory tract and in the gastrointestinal and genitourinary tracts. Normal flora do not generally cause disease when residing in their usual location within the body. Instead, they help maintain health by creating an environment which inhibits colonisation by other organisms – by altering the pH, thereby inhibiting the growth of other bacteria; by excreting antibacterial chemicals; and by producing vitamins which benefit the host.

The skin contains a large population of resident flora. These organisms are permanent residents of the skin, where they survive and multiply. The skin's normal flora exert a protective action by inhibiting multiplication of other microorganisms. Large numbers of normal skin flora live in warm, moist areas of the body, for example, nasal passages, axillae, groin, hair follicles and sweat glands, with fewer normal flora found on exposed skin surfaces. Resident organisms are not easily removed by washing with plain soaps and detergents unless considerable friction is used.

Resident microorganisms in the mouth and pharynx impair growth of invading microbes. Upper-respiratory normal flora include streptococci, staphylococci, diphtheroids and Gram-negative cocci.

A person normally excretes trillions of microbes daily through the intestines. A large number of normal flora exists in the large intestine without causing disease. These serve a protective function by competing with disease-producing microorganisms for food, thereby limiting colonisation and disease. Normal flora also secrete antibacterial substances within the intestinal wall.

In the genitourinary tract, the lower portion of the urethra contains microorganisms similar to those present on the skin. Although usually flushed out by acidic urine, microorganisms can increase in alkaline urine, causing UTIs. The action of lactobacilli can lower the pH of the vaginal fluid to 5 (acidic), which inhibits the growth of other organisms. A decrease in lactobacillus through

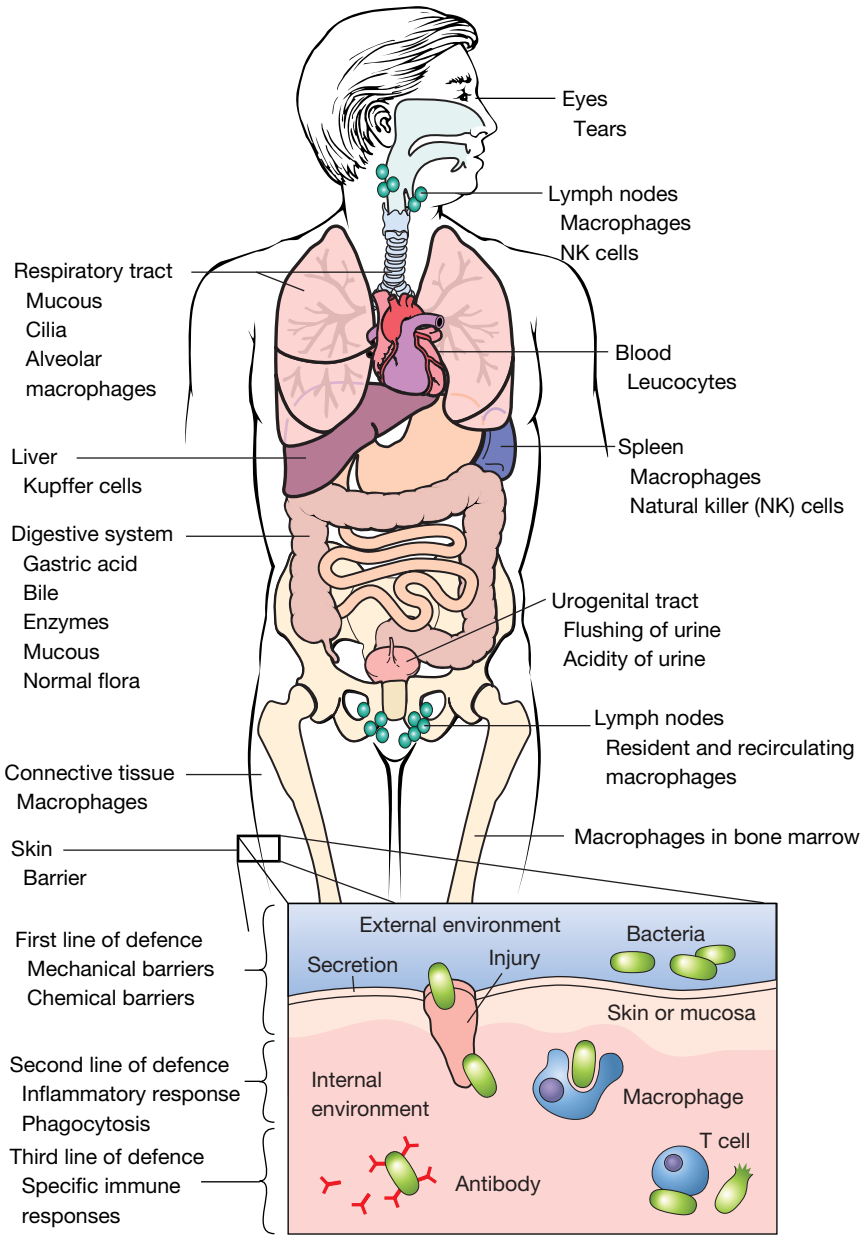

Figure 25-2 Normal defences against infection.

Craft J et al 2011 Understanding pathophysiology: ANZ edition. Mosby, Sydney.

long-term antibiotic use allows the colonisation of other organisms, for example, *C. albicans*.

The mass of normal flora within the body maintains a sensitive balance with other microorganisms to prevent infection. Any factor disrupting this balance places a person at increased risk of acquiring an infectious disease. For example, the use of broad-spectrum antibiotics for the treatment of infection can lead to *suprainfection* – normal bacterial flora are eliminated, allowing disease-producing microorganisms to multiply.

Body system defences

A number of the body's organ systems have unique defences against infection (Table 25-3). The skin, respiratory tract and gastrointestinal tract are easily accessible to microorganisms. Pathogenic organisms can adhere to the skin's surface, be inhaled into the lungs or be ingested with food. Each organ system has defence mechanisms physiologically suited to their structure and function. Although the lungs cannot completely control the entrance of microorganisms, the airways are lined with

TABLE 25-3 Normal defence mechanisms against infection

Defence mechanism	Action	Factors that may alter defence
Skin		
Intact multilayered surface (body's first line of defence against infection)	Provides barrier to microorganisms	Cuts, abrasions, puncture wounds, areas of maceration
Shedding of outer layer of skin cells	Removes organisms that adhere to skin's outer layers	Failure to bathe regularly
Sebum	Contains fatty acid that kills some bacteria	Excessive bathing
Mouth		
Intact multilayered mucosa	Provides mechanical barrier to microorganisms	Lacerations, trauma, extracted teeth
Saliva	Washes away particles containing microorganisms Contains microbial inhibitors (e.g. lysozyme)	Poor oral hygiene, dehydration
Respiratory tract		
Cilia lining upper airway, coated by mucous	Traps inhaled microbes and sweeps them outwards in mucous to be expectorated or swallowed	Smoking, high concentration of oxygen and carbon dioxide, decreased humidity, cold air
Macrophages	Engulfs and destroys microorganisms that reach lung's alveoli	Smoking
Urinary tract		
Flushing action of urine flow	Washes away microorganisms on lining of bladder and urethra	Obstruction to normal flow by urinary catheter placement, obstruction from growth or tumour, delayed micturition
Intact multilayered epithelium	Provides barrier to microorganisms	Introduction of urinary catheter, continual movement of catheter in urethra
Gastrointestinal tract		
Acidity of gastric secretions	Chemically destroys microorganisms incapable of surviving low pH	Administration of antacids
Rapid peristalsis in small intestine	Prevents retention of bacterial contents	Delayed motility resulting from impaction of faecal contents in large bowel or mechanical obstruction by masses
Vagina		
At puberty, normal flora causing vaginal secretions to achieve low pH	Inhibits growth of many microorganisms	Antibiotics and oral contraceptives disrupting normal flora

hair-like projections, termed cilia, which rhythmically beat to move a blanket of mucous and adherent organisms up the respiratory tract to the pharynx, to be exhaled or expectorated.

Inflammatory response

The body's cellular response to injury or infection is inflammation. The **inflammatory response**, a protective vascular and cellular reaction, neutralises pathogens and repairs body cells. The inflammatory response may be triggered by physical agents such as mechanical trauma, temperature extremes and radiation, chemical agents, external and internal irritants such as harsh poisons, gastric acid or by microorganisms. When tissues are injured, a well-coordinated inflammatory response occurs.

Vascular and cellular responses

Acute inflammation is an immediate response to cellular injury. This protective vascular reaction delivers increased blood products and nutrients to interstitial tissues in an area of injury. The process neutralises and eliminates pathogens or dead (necrotic) tissues and establishes a

means of repairing body cells and tissues. Arterioles supplying the injured area dilate, allowing more blood into the local circulation. The increase in local blood flow causes the characteristic redness of inflammation. The symptoms of localised warmth and swelling result from a greater volume of blood accumulating at the inflamed site. Local vasodilation delivers blood and white blood cells (WBCs) to injured tissues.

Injury causes tissue necrosis and, as a result, the body releases histamine, bradykinin, prostaglandin and serotonin. These chemical mediators or transmitters increase the permeability of small blood vessels. Fluid, protein and cells then enter interstitial spaces. Accumulated interstitial fluid results in localised swelling, termed *oedema*.

The cellular response of inflammation involves WBCs arriving at the site. WBCs pass through blood vessels and into the tissues. Through the process of *phagocytosis*, specialised WBCs, called *neutrophils* and *monocytes*, ingest and destroy microorganisms or other small particles. As inflammation becomes systemic, other signs and symptoms develop. *Leucocytosis* – an increase in the number of circulating WBCs – is evident as the body responds to WBCs leaving blood vessels. A serum WBC count is normally in the range of 4–11 × 10^9/L; this may rise to 14–22 × 10^9/L or higher during inflammation. Fever is caused by the phagocytic release of pyrogens from bacterial cells, causing a rise in the hypothalamic set point, which regulates temperature (see Chapter 28).

Inflammatory exudates

Exudates include a serous, protein-rich, pale pink liquid in which blood cells are suspended, known as *haemoserous exudate*, containing both serous liquid and some blood cells or frank blood. Inflammatory exudate, consisting of an accumulation of fluid, dead microorganisms, tissue cells and WBCs, forms at the site of inflammation. Platelets and plasma proteins such as fibrinogen produce a mesh-like matrix at the site of inflammation to prevent its spread. Eventually the exudate is cleared away through lymphatic drainage. *Purulent exudate*, termed pus, consists of dead cells and microorganisms and is indicative of infection.

Tissue repair

Injury to tissue cells initiates a healing process involving defensive, reconstructive and maturative stages (see Chapter 30).

Immune response

When an invading microorganism enters the body, it is initially attacked by monocytes. Foreign material – *antigens* – are remnants of the microorganism that triggered the **immune response**. Antigens are usually composed of proteins not normally found in a person's body and which often exist as part of the bacterium or virus structure. The series of immune responses changes the body's biological make-up. Reactions to subsequent exposure to this particular antigen, therefore, are different from the initial reaction. These altered immune responses ensure a repeated antigen is neutralised, destroyed or eliminated. After an antigen enters the body it travels in the blood or lymph and initiates *cell-mediated immunity* or *humoral immunity*.

Cell-mediated immunity

There are two classes of lymphocytes: T lymphocytes (CD4 T-cells) and B lymphocytes (B-cells). T-cells play a major role in cell-mediated immunity. There are antigen receptors on the surface membranes of CD4 T-cells. When an antigen identifies a cell with surface receptors that fit the antigen, binding occurs. This binding activates the CD4 T-cell to divide rapidly to form sensitised cells. Sensitised CD4 T-cells travel to the area of inflammation or injury, bind with antigens and release chemical compounds called *lymphokines*. The lymphokines attract macrophages and stimulate them to attack antigens. Eventually the antigens are killed. The cell-mediated response is altered by HIV infections, which cause AIDS (Figure 25-3).

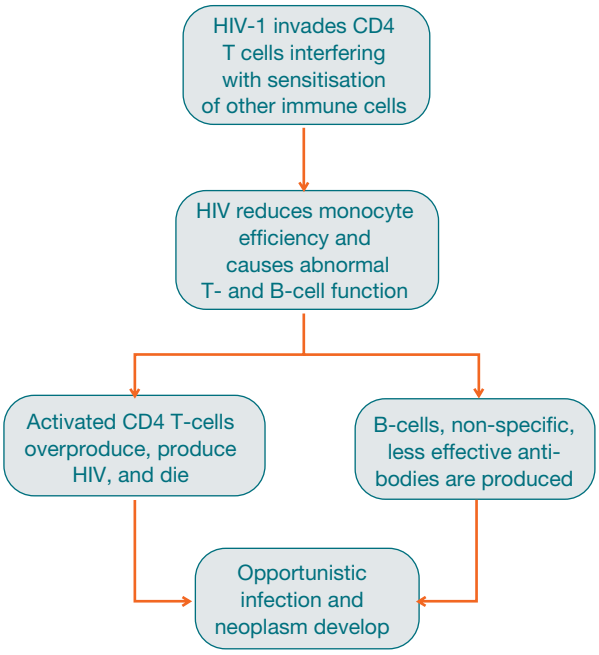

Figure 25-3 Pathological responses of HIV infection.

Humoral immunity

Stimulation of B-cells triggers the humoral immune response, causing synthesis of immunoglobulins or antibodies that destroy antigens. After a B-cell binds with an antigen it causes formation of plasma and memory B-cells. Plasma cells synthesise and secrete large amounts of antibodies. Memory B-cells prepare the body against future antigen invasion. When an antigen enters the body a second time, antibodies form more rapidly than during the first exposure, and immunoglobulin levels remain high to attack the antigen.

Antibodies

Antibodies are large protein molecules. The five classes of antibody immunoglobulins are identified by the letters M, G, A, E and D. Immunoglobulin M (IgM) is the predominant early antibody formed after initial contact with an antigen. This initial contact is the primary immune response, and the presence of IgM denotes current inflammation. The most abundant circulating antibody is IgG, which is formed after subsequent contact with antigens or during the secondary immune response, and its presence denotes past contact with a particular antigen.

The basis of immunisation against disease involves the formation of antibodies. This is either a natural or an artificially induced event. *Natural immunity* results after having a certain disease, such as measles, and usually lasts a lifetime. *Artificial immunity* follows the receipt of a vaccine, such as tetanus or polio vaccine. Depending on the duration of immunity, a booster vaccine may be required. *Passive immunity* is usually of short duration and can occur transplacentally, from mother to child.

Complement

A *complement* is an inactive protein compound found in blood serum. It is activated when an antigen and an antibody bind together. After a complement is activated, a rapid sequence of catalytic activity changes the shape of antigenic cells; for example, the foreign bacteria assume the shape of a doughnut. The complement actually makes a hole through the antigen's cell membrane. Ions and water enter the cell, causing it to burst. This process is called *cytolysis*.

Interferon

When viruses invade certain cells, they synthesise the protein *interferon*. Interferon interferes with the ability of viruses to multiply and protects body cells from simultaneous infection with other viruses. Interferon also directly inhibits the growth and division of tumour cells.

• CRITICAL REFLECTION POINT

Mrs Tendulka accompanies her 12-year-old daughter to have her viral meningitis strain C immunisation. She asks you to explain how a virus causes disease. How would you explain this to her?

CLINICAL REASONING PROCESS

GATHERING RELEVANT INFORMATION AND DATA

The nurse assesses the patient's defence mechanisms, susceptibility and knowledge of infections. By recognising the early signs and symptoms of infection, a nurse can alert others in the healthcare team about the need for therapy and can implement appropriate nursing measures.

Status of defence mechanisms

A review of physical assessment findings and the patient's medical condition can reveal the status of normal defence mechanisms against infection. For example, any break in the skin or mucosa is a potential site for infection. Similarly, a patient who is a chronic smoker is at greater risk of acquiring a respiratory tract infection following general anaesthesia because the cilia of the lung are generally less active or able to propel retained mucous from the lungs. Any reduction in the body's primary or secondary defences against infection places a patient at risk (Box 25-4).

Patient susceptibility

Many factors influence susceptibility to infection. The nurse gathers information about each factor by assessing the patient, including their family history. A review of disease history with the patient and family may reveal an exposure to a communicable disease. Analysis of laboratory findings may

BOX 25-4 Risk factors for infection

Inadequate primary defences

- Broken skin or mucosa
- Traumatised or burnt tissue
- Decreased respiratory ciliary action
- Obstructed urine outflow
- Altered gastrointestinal peristalsis
- Change in pH of secretions
- Decreased mobility

Inadequate secondary defences

- Reduced haemoglobin level
- Suppression of white blood cells (WBCs) (drug- or disease-related)
- Suppressed inflammatory response (drug- or disease-related)
- Low WBC count (leucopenia)

provide information about a patient's defence against infection. Knowledge of the factors that increase patient susceptibility or risk of infection enables the nurse to effectively plan infection prevention and control techniques.

Age

Throughout the life span susceptibility to infection changes. An infant has immature defences against infection. Born with only the antibodies provided by the mother, the immune system of an infant is incapable of producing the necessary immunoglobulins and WBCs to adequately fight some infections. Breastfed infants have greater immunity than bottle-fed infants, because they receive the mother's antibodies through breast milk. As the child grows, their immune system matures, but the child is still susceptible to organisms that cause the common cold, intestinal infections and, if not vaccinated, infectious diseases such as mumps and measles.

The young or middle-aged adult has refined defences against infection. Normal flora, body system defences, inflammation and the immune response provide protection against invading microorganisms. Viruses are the most common cause of infectious illness in young or middle-aged adults.

Defences against infection may change with ageing. The immune response, particularly cell-mediated immunity, declines; this leaves elderly patients with a lower resistance to infection (Weiskopf et al 2009). Older adults also undergo alterations in the structure and function of the skin, urinary tract and lungs. Loss of skin turgor and thinning of the epithelium increases the risk of abrasions and tears and subsequent invasion by pathogens (Table 25-4).

Not only does immunity to infection decrease with advancing age, but alterations in the immune system may even trigger events associated with the ageing process (Gomez et al 2008). Cells of the immune system, such as lymphocytes, become more diversified with age, and the body undergoes a progressive loss of cellular regulation. When viruses or other antigens and corresponding antibodies lodge in sites such as the kidney and arteries, factors injurious to the tissues are released and deterioration begins. With ageing and autoimmune diseases, cellular changes, such as depletion of lymphoid tissues, occur. The basic mechanism for the ageing process is not well understood.

Nutritional status

When protein intake is inadequate due to poor diet or a debilitating disease, the rate of protein breakdown exceeds that of tissue synthesis. A reduction in the intake of protein and other nutrients such as carbohydrates and fats reduces the body's defences against infection and impairs wound healing (see Chapter 30).

Patients with illnesses or problems that increase protein requirements are at further risk. Such problems include

TABLE 25-4 Assessing the risk of infection in older adults

Component	Possible changes with age	Outcome
Skin	Thinner dermal and epidermal layers, decreased collagen strength, decreased skin elasticity, decreased ability to perspire (sweat)	Pressure ulcers
Peripheral nerves	Reduced sensitivity, particularly in patients with history of alcohol abuse, vitamin B_{12} deficiency and diabetes mellitus	Pressure ulcers, ignored trauma leading to infection
Circulation	Heart disease: congestive heart failure, calcified mitral and aortic valves	Pneumonia, bacterial endocarditis
Peripheral circulation	More-elastic veins, less-effective venous valves, blood pooling in lower extremities, dependent oedema in lower limbs	Venous stasis ulcers
Mouth	Dehydration, loss of saliva production, functional inability to maintain oral hygiene	Parotid gland infection, periodontal disease, localised abscess, bacteraemia
Gastrointestinal tract	Loss of ability to secrete stomach acid in 30% of persons over 70 years of age	Salmonella diarrhoea
Pulmonary system	Increased colonisation of oropharynx, impaired mucociliary clearance, decreased macrophage function, decreased cough reflex	Viral and bacterial pneumonia
Urinary tract	Prostatic hyperplasia, urethral strictures, age-related hormonal changes in vaginal wall, pelvic floor relaxation, ureterocele or cystocele, degeneration of nerves leading to neurogenic bladder, use of tricyclic antidepressants, dehydration	Asymptomatic bacteriuria, cystitis, pyelonephritis
Nutrition	Malnutrition, vitamin deficiency (vitamin A, pyridoxine and riboflavin), protein and caloric malnutrition	Impaired immune response to infection
Drug therapy	Corticosteroid and cytotoxic drugs	Impaired immune response to infection
Nursing home residency	Exposure to nosocomial infections, including influenza, *Proteus* and *Providencia* organisms with an indwelling catheter, tuberculosis and wound infections	Frequent serious infection, increased risk of pneumonia

Modified from Tideiksaar R 1987 Infections in the elderly: I. Diagnosis and treatment. Physician Assist 11(2):17.

traumatic injury, extensive burns and conditions causing fever. Patients who have had surgery also require increased protein.

The nurse must assess each patient's dietary intake and their ability to tolerate solid foods. Patients with swallowing difficulties or alterations in digestion, or those who are too confused or weak to feed themselves, are at increased risk of nutritional deficits. A dietitian may be consulted to calculate the energy value of foods ingested. In preparation for discharge, the nurse should evaluate the patient's and carers' understanding of nutrition in relation to health.

Stress

The body responds to emotional or physical stress (surgery, trauma or hospitalisation) via the general adaptation syndrome (see Chapter 42). Stress increases the body's basal metabolic rate and use of energy stores. Adrenocorticotrophic hormone (ACTH) and the release of cortisone increases serum glucose levels and decreases unnecessary anti-inflammatory responses. If stress continues, elevated cortisone levels decrease resistance to infection. Continued stress leads to exhaustion, depletion of energy stores and decreased resistance to invading organisms.

Heredity

Certain hereditary conditions impair a person's response to infection. Pre-existing medical problems may reveal known hereditary disorders. For example, agammaglobulinaemia is a rare inherited or acquired disorder characterised by the absence of serum antibodies. A patient with this disorder has virtually no ability to initiate defences.

Disease process

Patients with diseases of the immune system are at particular risk of infection. Leukaemia, AIDS, lymphoma and aplastic anaemia are conditions that compromise a host by weakening their defences against infectious organisms. Patients with leukaemia, for example, are unable to produce enough WBCs to ward off infection.

Patients with chronic diseases such as diabetes mellitus and multiple sclerosis are also more susceptible to infection because of the disease process and impaired health status. Diseases such as pulmonary emphysema and bronchitis cause impaired ciliary action and thickened mucous. Cancer alters the immune response; peripheral vascular disease reduces blood flow to injured tissues; and burns or damage to skin surfaces impair body system defences and increase a person's susceptibility to infection.

Medical therapy

A review of medical and medication therapies will reveal potential for compromised immunity to infection. Glucocorticoids, for example, prednisolone, can cause protein breakdown and impair the inflammatory response against bacteria and other pathogens. Cytotoxic or antineoplastic drugs attack cancer cells but cause side effects, including bone marrow depression and normal cell toxicity. Bone marrow depression renders the body unable to produce sufficient lymphocytes and WBCs. When antineoplastic agents alter normal cells, cellular defences against infection fail. Cyclosporin and other immunosuppressant drugs can decrease the body's immune response, and are commonly prescribed for recipients of organ transplants. Immunosuppressants prevent organ and tissue rejection but increase a person's susceptibility to infection. The massive doses of radiation received by patients with cancer destroy cancerous cells but increase their risk of infection by depressing bone marrow and destroying normal cells.

Clinical examination: signs and symptoms of infection

Signs of local infection may include swelling, redness, localised heat, pain or tenderness, accumulation of body fluids (serous, haemoserous or purulent) and loss of function in the affected body part. Localised infections most commonly occur in areas of skin or mucous membrane breakdown, such as surgical and traumatic wounds, pressure ulcers and mouth lesions. Infections can also develop locally in cavities beneath the skin, for example, an abscess. Assessment for localised infection requires inspection for redness and swelling caused by inflammation and drainage from open lesions or wounds. Infected drainage may be yellow, green or brown, depending on the infecting pathogen. The nurse should ask the patient to describe the pain, tenderness or discharge experienced around the site of infection.

Swollen, inflamed tissues increase pressure on nerve endings and this causes pain. Chemical substances such as histamine are released and stimulate nerve endings. The physiological changes associated with infection can cause a temporary loss of function to the involved body part. For example, a localised infection of the hand causes the fingers to become swollen, painful and discoloured. Joints may become stiff as a result of swelling, but function returns to the fingers once the inflammation subsides. If the nurse suspects a patient's hand may swell, they are advised to ensure the patient removes all rings, watches and bracelets from the hand, to prevent constricting damage to tissues.

When inflammation becomes systemic, other signs and symptoms can develop. These include fever, increased pulse and respiratory rate, leucocytosis, malaise, anorexia, lymph node enlargement (lymphadenopathy) and an increase in antibodies (e.g. IgM is elevated for a current infection and IgG is elevated for a past infection). Lymph nodes that drain the area of infection often become enlarged, swollen and tender to palpation. For example, an abscess in the peritoneal cavity may cause enlargement of lymph nodes in the groin. An infection of the upper respiratory tract may cause cervical lymph node enlargement. If an infection is serious and widespread, all major lymph nodes may enlarge.

Systemic infections develop after treatment for localised infection has failed and may initially result in changes in the patient's level of activity and responsiveness. As a systemic infection develops, the patient may become lethargic, complain of decreased energy, or present with an elevation in temperature, increased pulse and increased respiratory rates and hypoxia. Involvement of major body systems may produce specific signs. For example, a pulmonary infection may result in a productive cough with purulent sputum. A CAUTI may result in cloudy, foul-smelling urine.

Older adults may not present with typical signs and symptoms of an infection because of reduced inflammatory and immune responses. Their temperature may not elevate initially if they regularly use aspirin or non-steroidal anti-inflammatory drugs (NSAIDs). Atypical symptoms such as confusion, incontinence

or agitation may be the only symptoms of an infectious illness. For example, some older adults with the influenza complication of pneumonia do not present with typical signs and symptoms such as fever, rigors, chills and productive sputum. Their only symptoms may be tachycardia, aching joints or generalised fatigue.

Laboratory data

A review of laboratory test results may reveal infection (Table 25-5). Laboratory values alone are not enough to detect infection and should be combined with an interpretation of other clinical signs and symptoms. Factors other than infection may alter test values. For example, trauma and physical stress can cause an elevation in the number of neutrophils. However, a culture result may show growth of an organism in the absence of clinical signs and symptoms of infection.

Patients with infection

A patient with infection may have a variety of health problems. Infection may affect the patient and family's physical, psychological, social or economic needs. For example, a patient with a chronic disease such as AIDS may experience serious psychological problems as a result of self-imposed isolation or rejection by their family and friends. Assessment of the patient and family's ability to adjust to the disease and initial and ongoing resources is required.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

During assessment, the nurse gathers objective findings (e.g. an open incision or a reduced kilojoule intake) and subjective data (such as a patient's complaint of tenderness over a surgical wound site). The nurse then interprets the data carefully, looking for defining characteristics or risk factors that suggest a specific nursing problem (Box 25-5). Data should then be validated (e.g. by inspecting the integrity of a wound) and additional data, such as laboratory findings, assessed. Selection of appropriate nursing problems depends on correct analysis of data (Box 25-6).

The identified problem must take into account aetiological factors in the establishment of an appropriate comprehensive plan. For example, minimising the risk of infection related to impaired skin integrity requires modified hygiene measures and wound care. Minimising the risk of infection related to malnutrition requires nutritional support and fluid balance.

BOX 25-5 Example of priority problems associated with infection

Body image disturbance
Infection
Injury
Altered nutrition
Altered oral mucous membrane
Impaired skin integrity
Social isolation
Impaired tissue integrity

TABLE 25-5 Laboratory tests to screen for infection*

Laboratory test	Normal (adult) values	Indication of infection
C-reactive protein (CRP)	Negative or < 5 mg/L	Increased in acute and chronic inflammatory conditions
Cultures of urine and blood	Normally sterile, without microorganism growth	Presence of infectious microorganism growth
Cultures of wound, sputum and throat	Possible normal flora	Presence of infectious microorganism growth
Erythrocyte sedimentation rate	Up to 15 mm/h for men and 20 mm/h for women	Elevated in presence of inflammatory process
Iron level	13–36 micromol/L (males) 12–31 micromol/L (females)	Decreased in chronic infection
WBC count	4–11 × 10^9/L	Increased in acute infection, decreased in certain viral or overwhelming infections
Differential count (percentage of each type of WBC)		
Basophils	0.06–0.1 × 10^9/L	Normal during infection
Eosinophils	0.04–0.4 × 10^9/L	Increased in parasitic infection
Lymphocytes	1.5–4.0 × 10^9/L	Increased in chronic bacterial and viral infection, decreased in sepsis
Monocytes	0.2–0.8 × 10^9/L	Increased in protozoal, rickettsial and tuberculosis infections
Neutrophils	2.0–7.5 × 10^9/L	Increased in acute suppurative infection, decreased in overwhelming bacterial infection (older adult)

*Values may vary slightly depending on the laboratory.

BOX 25-6 Sample clinical reasoning process

Infection

Assessment activities	Defining characteristics	Priority problem associated with
Check results of laboratory tests	White cell count < 4 × 10^9/L	Risk of infection related to lowered immunity
Review current medications	Patient receiving azathioprine (Imuran), an immunosuppressant	Risk of infection related to lowered immunity
Identify potential sites of infection	Central venous catheter in place for 3 days Foley catheter draining amber-coloured urine	Risk of CLABSI or UTI
Inspect condition of dependent pressure points	Reddened area 2 cm in diameter, superficial broken skin over sacrum	Impaired skin integrity related to pressure and exposure to faecal irritants
Observe for skin contamination	Patient incontinent (semi-liquid stool)	Risk of incontinence-associated dermatitis

Nursing problems may include a risk of infection or the impact of an infection on the patient's health status. The nurse's success in planning appropriate nursing interventions depends on the accuracy of the diagnosis and the ability to implement effective care to meet the patient's needs.

SETTING PRIORITIES AND ESTABLISHING GOALS

The patient's care plan is based on each nursing problem and related factors. The plan should set attainable outcomes and purposeful, appropriate interventions. Caring for a patient with a nursing problem of risk of infection related to impaired skin integrity includes skin care measures to promote healing. The expected outcomes of 'reduction in wound size by 1 cm' and 'absence of drainage' enables improvements to be measured. Once these outcomes are met, the goal of 'skin intact and without drainage' can be set. Interventions are selected in collaboration with the patient, the family and other healthcare providers. Common goals of care may include the following:

- prevention of exposure to infectious agents
- controlling or reducing the spread of infection
- maintaining resistance to infection
- educating the patient and family about infection prevention and control techniques
- educating the patient and family about nutritional requirements for healing.

The nurse establishes priorities for the goals of care. If a patient has an open wound, suffers a debilitating disease such as cancer and has been unable to tolerate solid foods, administering therapies to promote wound healing would take priority over educating the patient to assume self-care therapies at home. When the patient's condition improves, the priorities will change and patient education becomes an essential intervention prior to discharge.

The nurse may initiate appropriate referrals, for example, to a dietitian, infection control professional or home health nurse, to collaborate with the patient's care. The nurse plans for the home environment to be consistent with informed infection control practice. Educating patients and families about the importance of infection control is also an important preventive measure.

Infection control guidelines

The development of a care plan includes infection prevention and control practices. Refer to the current infection control guidelines published by the NHMRC (2010) and the Australian Commission on Quality and Safety in Healthcare (ACQSHC) (2012) in Australia and the standards for infection prevention and control published by Standards New Zealand (2008). These guidelines provide recommendations that outline the critical aspects of infection prevention and control (see Box 25-7). It is recognised that the level of risk differs in different healthcare settings and therefore some recommendations should be justified by risk assessment.

PREPARING FOR AND TAKING ACTION

By recognising and assessing each patient's risk factors and implementing measures that break the chain of infection, the nurse can help minimise infection.

Standard and transmission-based precautions

The risk of transmitting HAIs or infectious diseases among patients is high. When a patient has a suspected or known infection, health workers follow infection control practices. However, health workers may not be aware that some patients have infections, as the majority of organisms causing HAIs are found in the colonised body substances of patients, regardless of whether a culture has confirmed infection and a diagnosis has been made. Both Australia and New Zealand have endorsed the use of standard precautions to minimise the risk of transmission of infectious organisms. Standard precautions include the use of barrier measures in all situations to prevent cross-contamination (NHMRC 2010, Standards New Zealand 2008). The NHMRC recommends standard precautions as the minimum requirement in work practices to promote infection control (see Box 25-8).

Standard precautions are recommended for the treatment and care of all patients, regardless of their perceived infectious status. Standard precautions should be used in the handling

BOX 25-7 Summary of recommendations of the Australian guidelines for the prevention and control of infection in health care

Standard precautions

Hand hygiene

1. Routine hand hygiene

Hand hygiene must be performed before and after every episode of patient contact. This includes:

- before touching a patient
- before a procedure
- after a procedure or body substance exposure risk
- after touching a patient
- after touching a patient's surroundings.

Hand hygiene must also be performed after the removal of gloves.

2. Choice of product for routine hand hygiene practices

For all routine hand hygiene practices in healthcare settings, use alcohol-based hand rubs that:

- contain between 60% and 80% v/v ethanol or equivalent
- meet the requirements of EN1500.

3. Choice of hand hygiene product when hands are visibly soiled

If hands are visibly soiled, hand hygiene should be performed using soap and water.

4. Hand hygiene for *C. difficile* and non-enveloped viruses

Hand hygiene should be performed using soap and water when *C. difficile* or non-enveloped viruses such as norovirus are known or suspected to be present and gloves have not been worn. After washing, hands should be dried thoroughly with single-use towels.

Personal protective equipment

5. Wearing of aprons/gowns

Aprons or gowns should be appropriate to the task being undertaken. They should be worn for a single procedure or episode of patient care and removed in the area where the episode of care takes place.

6. Use of face and protective eyewear for procedures

A surgical mask and protective eyewear must be worn during procedures that generate splashes or sprays of blood, body substances, secretions or excretions into the face and eyes.

7. Wearing of gloves

Gloves must be worn as a single-use item for:

- each invasive procedure
- contact with sterile sites and non-intact skin or mucous membranes
- any activity that has been assessed as carrying a risk of exposure to blood, body substances, secretions and excretions.

Gloves must be changed between patients and after every episode of individual patient care.

8. Sterile gloves

Sterile gloves must be used for aseptic procedures and contact with sterile sites.

Handling and disposal of sharps

9. Safe handling of sharps

Sharps must not be passed directly from hand to hand and handling should be kept to a minimum. Needles must not be recapped, bent or broken after use.

10. Disposal of single-use sharps

The person who has used the single-use sharp must be responsible for its immediate safe disposal. Used disposable sharps must be discarded into an approved sharps container at the point-of-use. These must not be filled above the mark that indicates the bin is three-quarters full.

Routine environmental cleaning

11. Routine cleaning of surfaces

Clean frequently touched surfaces with detergent solution at least daily, and when visibly soiled and after every known contamination.

Clean general surfaces and fittings when visibly soiled and immediately after spillage.

12. Cleaning of shared clinical equipment

Clean touched surfaces of shared clinical equipment between patient uses with detergent solution. Exceptions to this should be justified by risk assessment.

13. Surface barriers

Use surface barriers to protect clinical surfaces (including equipment) that are:

- touched frequently with gloved hands during the delivery of patient care
- likely to become contaminated with blood or body substances
- difficult to clean.

14. Site decontamination after spills of blood or other potentially infectious materials

Spills of blood or other potentially infectious materials should be promptly cleaned as follows:

- wear utility gloves and other PPE appropriate to the task
- confine and contain spill, clean visible matter with disposable absorbent material and discard the used cleaning materials in the appropriate waste container
- clean the spill area with a cloth or paper towels using detergent solution.

Use of chemical disinfectants such as sodium hypochlorite should be based on assessment of risk of transmission of infectious agents from that spill.

continued

Transmission-based precautions

Contact precautions

15. Implementation of contact precautions

In addition to standard precautions, implement contact precautions in the presence of known or suspected infectious agents that are spread by direct or indirect contact with the patient or the patient's environment.

16. Hand hygiene and personal protective equipment to prevent contact transmission

When working with patients who require contact precautions:

- perform hand hygiene
- put on gloves and gown upon entry to the patient-care area
- ensure that clothing and skin do not contact potentially contaminated environmental surfaces
- remove gown and gloves and perform hand hygiene before leaving the patient-care area.

17. Patient-care equipment for patients on contact precautions

Use patient-dedicated equipment or single-use non-critical patient-care equipment.

If common use of equipment for multiple patients is unavoidable, clean the equipment and allow it to dry before use on another patient.

Droplet precautions

18. Implementation of droplet precautions

In addition to standard precautions, implement droplet precautions for patients known or suspected to be infected with agents transmitted by respiratory droplets that are generated by a patient when coughing, sneezing or talking.

19. Personal protective equipment to prevent droplet transmission

When entering the patient-care environment, put on a surgical mask.

20. Placement of patients requiring droplet precautions

Place patients who require droplet precautions in a single-patient room.

Airborne precautions

21. Implementation of airborne precautions

In addition to standard precautions, implement airborne precautions for patients known or suspected to be infected with infectious agents transmitted person-to-person by the airborne route.

22. Personal protective equipment to prevent airborne transmission

Wear a correctly fitted P2 respirator when entering the patient-care area when an airborne-transmissible infectious agent is known or suspected to be present.

23. Placement of patients requiring airborne precautions

Patients on airborne precautions should be placed in a negative pressure room or in a room from which the air does not circulate to other areas.

Exceptions to this should be justified by risk assessment.

24. Implementation of core strategies in the control of MROs (MRSA, MRGN, VRE)

Implement transmission-based precautions for all patients colonised or infected with a multi-resistant organism, including:

- performing hand hygiene and putting on gloves and gowns before entering the patient-care area
- using patient-dedicated or single-use non-critical patient-care equipment
- using a single-patient room or, if unavailable, cohorting patients with the same strain of multi-resistant organism in designated patient-care areas
- ensuring consistent cleaning and disinfection of surfaces in close proximity to the patient and those likely to be touched by the patient and healthcare workers.

MRO = multi-resistant organisms; MRGN = multi-resistant Gram-negative bacilli; MRSA = methicillin-resistant *Staphylococcus aureus*; VRE = vancomycin-resistant enterococci.

National Health and Medical Research Council (NHMRC) 2010 Australian guidelines for the prevention and control of infection in healthcare. NHRMC, Canberra. Online. Available: www.nhmrc.gov.au/_files_nhmrc/publications/attachments/cd33_exec_summary.pdf; accessed 16 Feb 2016.

BOX 25-8 Standard precautions

Standard precautions include:

- hand hygiene, before and after every episode of patient contact (i.e. five moments for hand hygiene)
- the use of personal protective equipment
- the safe use and disposal of sharps
- routine environmental cleaning
- reprocessing of reusable medical equipment and instruments
- respiratory hygiene and cough etiquette
- aseptic non-touch technique
- waste management
- appropriate handling of linen.

National Health and Medical Research Council (NHMRC) 2010 Australian guidelines for the prevention and control of infection in healthcare. NHMRC, Canberra. Online. Available: www.nhmrc.gov.au/guidelines/publications/cd33; accessed 16 Feb 2016.

of blood, including dried blood; all other body substances, secretions and excretions (excluding sweat), regardless of whether they contain visible blood; non-intact skin; and mucous membranes (NHMRC 2010).

• CRITICAL REFLECTION POINT

You are a graduate registered nurse working in a post-anaesthesia care unit (PACU) in an adult public hospital and notice it is normal practice for nurses to highlight patients on the operating room lists with known infectious diseases such as hepatitis C or HIV with red pen and highlighter. You find that medical and nursing staff emphasise this information during handover (e.g. 'This patient is an IV drug user.') and take 'extra precautions', such as wearing additional PPE, during care and clinical procedures with these patients.

1. **Are these actions justifiable?**
2. **What are the possible implications of this practice for patients and staff?**

Transmission-based precautions are recommended in addition to standard precautions for patients with a known or suspected infection or colonisation with highly transmissible pathogens that can cause infection (see Box 25-9 for an example).

This second tier of additional precautions focuses on three transmission categories: airborne, droplet and direct or indirect contact with skin in accordance with a patient's diagnosis and the suspected organism (see Box 25-10). *Airborne precautions* are implemented for infections spread in small particles in the air, such as chickenpox (varicella). *Droplet precautions* are implemented for infections spread in large droplets by coughing, talking or sneezing, such as rubella, pharyngitis or influenza. *Contact precautions* are implemented for infections spread by skin or mucous membrane contact, such as herpes simplex virus.

Transmission-based precautions should be used in combination with standard precautions. This two-tiered approach to infection control ensures a high level of protection for patients, family members and staff involved in the care of infectious patients (see Figure 25-4).

Hand hygiene

Hand hygiene is the single most important intervention for reducing HAIs and preventing the spread of infection. While hand hygiene may be the cornerstone of infection prevention and control today, it is interesting to note that the original proponents of clinical handwashing during the 19th century were rejected by the medical community (Stewardson & Pittet 2011). Despite its central importance, compliance with hand hygiene among healthcare workers is poor (Gould et al 2010, WHO 2009). In Australia, national compliance audits estimate the average hand hygiene compliance rate is approximately 82% (HHA 2015).

Hand hygiene is a general term referring to any action of hand cleansing which includes washing hands with the use of water and soap or a soap solution, either non-antimicrobial or antimicrobial; or applying a waterless antimicrobial hand rub to the surface of the hands (e.g. alcohol-based hand rub).

The purpose of handwashing is to remove debris and transient microorganisms from the hands and to reduce total microbial counts over time. Handwashing must last for at least 15 seconds and the hands should be patted dry rather than rubbed, to preserve skin integrity. A more thorough, lengthy surgical hand and arm scrub is performed preoperatively by surgical personnel to remove transient bacteria and reduce resident microorganisms.

Contaminated hands commonly cause cross-infection. For example, a nurse caring for a patient with excessive pulmonary secretions may help the patient expectorate sputum and dispose of tissues in a bedside container. The patient's roommate may ask the nurse to open a container of food on their meal tray; the nurse then leaves the room to prepare a

BOX 25-9 Airborne precautions for a patient with active tuberculosis (TB)

The Australian infection control guidelines recommend:

- Single-patient room maintained under negative pressure
- Doors kept closed except when entering or leaving the room
- Negative pressure monitored daily using a differential pressure-sensing device
- Minimum of 12 air exchanges per hour
- HEPA filtration of air to 99% clean, as it exits the isolation room
- Use of appropriate personal respiratory protective devices capable of efficient filtration of the infecting organism, applied prior to entering the room (Figure 25-7)
- Use of a mask by the patient when out of the room (with the patient leaving the room only if necessary)
- Screening of health workers for TB before commencement of employment, regular surveillance for TB, offering BCG vaccination for staff with positive Mantoux tests and follow-up chest X-rays.

Regardless of the type of isolation system, the nurse must follow these basic principles:

- Wash hands thoroughly before entering and leaving the room of a patient in isolation
- Dispose of contaminated supplies and equipment in a manner that prevents spread of microorganisms to other persons as indicated by the mode of transmission of the organism
- Apply knowledge of disease processes and the mode of infection transmission when using protective barriers
- Protect all people who might be exposed during transport of patients outside their private room.

BCG = bacille Calmette-Guérin; HEPA = high-efficiency particulate air; TB = tuberculosis.

Adapted from National Health and Medical Research Council (NHMRC) 2010 Australian guidelines for the prevention and control of infection in healthcare. NHMRC, Canberra. Online. Available: www.nhmrc.gov.au/guidelines/publications/cd33; accessed 16 Feb 2016.

BOX 25-10 Transmission-based precautions

Transmission-based precautions may include one or any combination of the following:

- Continued implementation of standard precautions
- Appropriate use of personal protective equipment (including gloves, apron or gowns, surgical masks or P2 respirators and protective eyewear)
- Patient-dedicated equipment
- Allocation of single rooms or cohorting of patients
- Appropriate air-handling requirements
- Enhanced cleaning and disinfecting of the patient environment
- Restricted transfer of patients within and between facilities.

National Health and Medical Research Council (NHMRC) 2010 Australian guidelines for the prevention and control of infection in healthcare. NHMRC, Canberra. Online. Available: www.nhmrc.gov.au/guidelines/publications/cd33; accessed 16 Feb 2016.

dose of medication due in 5 minutes. If the nurse fails to wash their hands before opening the container of food or preparing medication, organisms from the first patient's sputum can easily be transmitted to the roommate's food or to the medication container.

Fingernails of health workers should be kept short, clean and free from infection. Research has linked long fingernails, artificial nails, nail additives and nail polish to the harbouring and transmission of pathogens, including bacteria and fungi (Boyce & Pittet 2002, Grayson et al 2010).

National programs established in both Australia (Hand Hygiene Australia 2013) and New Zealand (Hand Hygiene New Zealand 2009) have been developed to target and monitor hand hygiene behaviour. Consistent with the World Health Organization guidelines (WHO 2009), both countries advocate, and have incorporated into their respective national hand hygiene programs, the 'five moments for hand hygiene' (Figure 25-5) as critical to the prevention and control of infections.

Routine hand hygiene (Skill 25-1) may be performed with the use of water and soap or a soap solution, either non-antimicrobial or antimicrobial; or applying a waterless antimicrobial hand rub to the surface of the hands (e.g. alcohol-based hand rub). Use of antimicrobial solutions is encouraged in certain high-risk situations to reduce the microbial load on nurses' hands. These include situations where nurses are

Type of precaution	Examples of infectious agents	Single room or cohort	Gloves	Gown	Mask	Eye protection	Handling of equipment	Visitors*
Standard	Standard precautions apply for all work practices to prevent the likelihood of infection							Hand hygiene Respiratory hygiene and cough etiquette
Contact	MROs, *C. difficile*, intestinal tract pathogens (e.g. norovirus), highly contagious skin infections	✓	✓	✓	♣	☆	Single use or reprocess before reuse on next patient	Same precautions as staff
Droplet	Influenza, RSV, norovirus, pertussis (whooping cough), meningococcus	✓	☆	☆	✓ Surgical mask	☆	Single use or reprocess before reuse on next patient	Restrict visitor numbers and precautions as for staff
Airborne	Pulmonary TB, chickenpox (varicella)†, measles (rubeola)†, SARS	✓ Negative pressure	☆	☆	✓ P2 (N95) respirator	☆	Single use or reprocess before reuse on next patient	Restrict visitor numbers and precautions as for staff

Notes:

✓ Essential component of transmission-based precautions.

♣ Surgical mask required if infectious agent isolated in sputum

☆ As required – Gloves to be worn wherever there is the potential of direct or indirect contact with blood or body substances

Gowns to be worn for procedures when there is the potential of direct or indirect contact with body substances

Face and eye protection to be worn when there is the potential of exposure to splashes or sprays to mucous (including during aerosol generating procedures)

* Visitors should be given instruction about correct procedures when transmission-based precautions are applied and given appropriate resources to support them in meeting those requirements.

† If staff or visitor HAVE HAD chickenpox/measles in the past or vaccination for these diseases, masks, gown and gloves are not required.

Environmental cleaning has not been addressed in this table but it is an essential component of infection prevention and control.

Figure 25-4 Application of standard and transmission-based precautions.

SKILL 25-1

Handwashing

Delegation considerations

All staff caring for patients must wash their hands using correct handwashing techniques. All staff and carers should:

- gain instruction and demonstrate competency in correct handwashing techniques
- report any skin irritation from soaps or antimicrobial solutions immediately
- gain instruction regarding the importance of caring for and maintaining the integrity of their skin.

Equipment

- Accessible sink with warm running water
- Antimicrobial or regular soap solution
- Paper towels or air dryer
- Disposable plastic nail pick (optional)

STEPS	RATIONALE
1. Assess patient's risk of or extent of infection, e.g. white blood cell count, extent of open wounds, known medical diagnosis.	Transmission-based precautions, such as the wearing of a mask and clean gown, may be required for immunocompromised patients.
2. Inspect surface of hands for breaks or cuts in skin or cuticles. Report and cover lesions before providing patient care.	Open cuts or wounds can harbour high concentrations of microorganisms. Agency policy may prevent nurses from caring for high-risk patients.
3. Inspect hands for heavy soiling.	Requires more-lengthy handwash.
4. Ensure nails are short and free of nail polish and/or artificial nails. Do not tear or cut skin under or around nail.	Most microbes on hands come from beneath the fingernails.
5. Remove all jewellery, including wristwatch, rings and bracelets.	Jewellery can harbour microbes and rub against skin causing shedding of skin cells.
6. Stand in front of sink, keeping hands and uniform away from sink surface. (If hands touch sink during handwashing, repeat.)	The inside of the sink is considered a contaminated area. Reaching over sink increases risk of touching edge, which is contaminated.
7. Turn on water and regulate flow and temperature so that temperature is warm.	Warm water is more comfortable and it removes less of the skin's protective oils than hot water.
8. Avoid splashing water against uniform.	Microorganisms multiply in moisture.
9. Regulate temperature and intensity of flow.	Warm water is most comfortable.
10. Wet hands and wrists thoroughly under running water. Keep hands and forearms higher than elbows during washing.	Keeping hands elevated allows water to flow from least to most contaminated areas.
11. Apply a small amount of soap or antimicrobial solution, lather thoroughly.	The amount applied should be as per the manufacturer's instructions.
12. Wash hands using plenty of lather and friction for at least 15 seconds. Interlace fingers and rub palms, sides and back of hands with circular motion at least 5 times each (see illustration).	Soap cleans by emulsifying fat and oils. Friction and rubbing mechanically will loosen and remove debris and transient bacteria. Interlacing the fingers and thumbs helps to ensure all surfaces are cleaned.
13. Areas underlying fingernails are often soiled. Clean fingernails with a plastic, disposable nail pick.	Most microbes on hands come from beneath the fingernails.
14. Rinse hands and wrists thoroughly (see illustration).	Rinsing mechanically washes away debris and microorganisms.

STEPS	RATIONALE
 Step 11 Lathering hands.	 Step 14 Rinsing hands.
15. Gently pat hands dry from fingers to wrists and forearms with paper towel.	Drying from cleanest (fingertips) to least clean (forearms) area avoids contamination. Gently patting hands dry helps prevents chapping and roughened skin.
16. Discard paper or towel into the proper receptacle.	Prevents transfer of microorganisms.
17. Turn off water with foot or knee pedals. To turn off hand tap use clean, dry paper towel; avoid touching handles with hands (see illustration).	Minimises contamination of hands.
 Step 17 Turning off hand tap.	
18. Inspect hands for obvious signs of debris and contamination.	If found, indicates poor technique. Handwashing should be repeated.
19. Inspect hands for dermatitis or cracked skin as this may indicate complications from excessive handwashing or an allergic reaction to the antimicrobial or soap solution.	Seek advice from infection control professional. Note: use small, single-use containers of barrier cream because large, refillable containers have been associated with hospital-acquired infections.
20. If hands are dry or chapped, a small amount of lotion or barrier cream can be applied.	If dermatitis occurs, additional interventions may be needed.

RECORDING AND REPORTING

- It is not necessary to record or report this procedure.
- Report any dermatitis to employee health services and/or infection control professional per agency policy.

HOME CARE CONSIDERATIONS

- Evaluate the handwashing facilities in the home to determine the possibility of contamination, the proximity of the facilities to the patient and available supplies in the area.
- Evaluate the availability of warm running water and soap when conducting home visits and anticipate the need for alternative handwashing products such as alcohol-based hand rubs and antimicrobial-impregnated, disposable towels.
- Instruct the patient and primary caregiver in proper techniques and situations for handwashing.

in contact with patients who are immunocompromised or have damaged skin and mucous membranes. In addition, an antimicrobial solution should be used before performing an invasive procedure such as insertion of an intravenous catheter. There are a number of effective antimicrobial solutions, including chlorohexidine gluconate, povidone–iodine and alcohol. Certain antimicrobial solutions can irritate the skin of some staff. Nurses are advised to consult an infection control consultant in this situation.

WHO hand hygiene guidelines recommend use of an alcohol-based hand rub solution, when the hands are not visibly soiled or dirty (WHO 2009). When using an alcohol-based hand rub solution, the skin surface should be wet with the solution, and the hands rubbed together for at least 20–30 seconds (or as per manufacturer's instructions for use), ensuring contact of the solution with all skin surfaces. The solution should be allowed to dry naturally.

Handwashing is required when hands are visibly soiled or dirty. Effective handwashing with water and an antimicrobial or non-antimicrobial soap or soap solution should last at least 15–20 seconds unless the hands are visibly soiled, in which case additional time may be required. Following handwashing, the hands should be thoroughly dried with a disposable towel. The towel or elbow should be used to turn off the tap. Using hot water should be avoided, as repeated exposure may increase the risk of dermatitis (Boyce & Pittet 2002). Fingernails should be cleaned with a disposable nail pick at the commencement of the shift if nails are dirty (NHS 2014, Tanner et al 2008). The use of scrub brushes is not recommended unless hands are grossly soiled; brushes can cause microscopic abrasions to the outer layer of the skin, breaching the protective barrier and providing a portal of entry for normal flora to penetrate, thus increasing the risk of allergic reactions to antimicrobial solutions.

Nurses can ensure that patients and visitors understand the appropriate technique and rationale for handwashing. Teaching handwashing is particularly important if health care is to continue at home. Patients should wash their hands before eating or handling food, after handling contaminated equipment, linen or organic material and after elimination. Visitors are encouraged to wash their hands before eating or handling food, after coming into contact with patients with an infection and after handling contaminated equipment or organic material.

Health promotion

An infection can be prevented from developing or spreading by minimising the organisms transmitted to potential infection sites. Eliminating reservoirs of infection, controlling portals of exit and entry and avoiding actions that transmit microorganisms prevent the colonisation of bacteria. The correct use of sterile supplies, barrier protection and appropriate hand hygiene practices can control the spread of microorganisms. Strengthening a potential host's defences against infection by nutritional support, rest, maintenance of physiological protective mechanisms and recommended immunisations can protect them from invasion by pathogens.

When a patient develops an infection, the nurse continues preventive care to ensure that healthcare personnel and other patients are not exposed to the infection. Patients with communicable diseases may need to be isolated or have barriers in place to prevent transmission of infection. Nurses are well placed to educate patients and their families about the proper use of antibiotics to decrease the risk of antibiotic-resistant infections (Box 25-11).

Acute care measures

Treatment of an infectious process includes eliminating the infectious organisms and supporting the patient's defences. To identify the causative organism, the nurse may collect specimens of body fluids or drainage from infected body sites for microbiological culture. When the disease process or causative organism has been identified, a medical or nurse practitioner will prescribe the most effective treatment for the situation. The nurse correctly administers antibiotics and other treatments as ordered, while observing for adverse reactions and assessing progress of the infection and the patient's response to treatment.

Systemic infections require measures to prevent complications from the stress of fever. Maintaining intake of fluids prevents dehydration resulting from diaphoresis. The patient's increased metabolic rate requires an adequate nutritional intake. Rest preserves energy and allows the healing process to occur.

BOX 25-11 Decreasing the risk of antibiotic-resistant infection

Include these instructions when teaching patients and/or their carers how to decrease the risk for antibiotic-resistant infection:

1. *Do not take antibiotics to prevent illness* – Doing this increases your risk of developing resistant infection. Exceptions include taking antibiotics before certain surgeries and taking antibiotics before dental work if you have a heart valve disorder.
2. *Wash your hands frequently* – Handwashing is the single most important thing you can do to prevent an infection.
3. *Follow directions* – Not taking your antibiotic as prescribed or skipping doses can allow antibiotic-resistant bacteria to develop.
4. *Do not request an antibiotic for the flu or colds* – If your healthcare provider says that you do not need an antibiotic, chances are that you do not. Antibiotics are effective against bacterial infections but not viruses, which cause colds and flus.
5. *Finish your antibiotic* – Do not stop taking your antibiotic when you feel better. If you stop taking your antibiotic early, you allow the hardiest bacteria to survive and multiply. Eventually, you could develop an infection resistant to many antibiotics. You should never have leftover antibiotics.
6. *Do not take leftover antibiotics* – Do not save unfinished antibiotics for later use or borrow leftover drugs from family or friends. This is dangerous because: (1) the leftover antibiotic may not be appropriate for you; (2) your illness may not be a bacterial infection; (3) old antibiotics can lose their effectiveness and in some cases can even be fatal; and (4) there will not be enough doses in a leftover bottle to allow a full therapeutic dose.

Brown D, Edwards H 2012 Lewis's Medical–surgical nursing: assessment and management of clinical problems. Mosby, Sydney.

BOX 25-12 Infection control: protecting the susceptible host

Protecting normal defence mechanisms

- Regular bathing removes transient microorganisms from the skin's surface. Lubrication helps keep the skin hydrated and intact.
- Regular oral hygiene removes proteins in the saliva that attract microorganisms. Flossing removes tartar and plaque that can build up on teeth.
- Maintenance of adequate fluid intake promotes normal urine formation and a resultant outflow of urine to flush the bladder and urethral lining of microorganisms.
- Physically dependent or immobilised patients should be encouraged to perform regular coughing and deep breathing to expectorate and keep lower airways clear of mucous.
- Correct immunisation of children or adults exposed to or potentially exposed to certain infectious microorganisms should be encouraged in accordance with the relevant health authorities. Children should be vaccinated for smallpox, measles, mumps, rubella and diphtheria.
- Human papilloma virus (HPV) immunisation is recommended for adolescent and young adult females.
- Adults should have tetanus–diphtheria boosters every 10 years.
- Influenza vaccines are recommended for health workers and older adults.

Maintaining healing processes

- The nurse promotes intake of adequate fluids and a well-balanced diet containing essential proteins, vitamins, carbohydrates and fats. The nurse also uses measures to increase the patient's appetite.
- The nurse promotes a patient's comfort and sleep so that energy stores are replaced daily.
- The nurse assists the patient to learn stress management techniques.

Localised infections often require measures to facilitate removal of debris to promote healing. The nurse applies strict principles of infection control and wound care to remove infected drainage from wound sites and support the integrity of healing wounds. Various dressings (see Chapter 30) can be applied to facilitate removal of infectious drainage and promote the healing of wound margins. Drainage tubes may be inserted to remove infected discharge from body cavities. The nurse must wear personal protective equipment, use an aseptic technique to manage wounds and carefully ensure the correct handling and disposal of exudate.

During the course of an infection, the nurse supports the patient's body defence mechanisms. For example, if a patient has infectious diarrhoea, the nurse employs hygiene measures to maintain skin integrity to prevent tissue breakdown and entry of microorganisms. Other routine hygiene measures include cleansing and bathing to protect the skin and mucous membranes from invasion and overgrowth of opportunistic microorganisms.

Generally, infection control and prevention interventions are employed to minimise cross-infection by targeting components of the chain of infection.

Protection of the susceptible host

The nurse intervenes to maintain the body's normal healing processes (Box 25-12). Nurses also protect themselves and others from cross-infection through vigilant use of standard and transmission-based precautions. Decisions concerning the level of precaution required in specific circumstances are not always straightforward.

CRITICAL REFLECTION POINT

Mrs Niles is 83 years old and lives alone. She has multiple comorbidities and uses a wheelie-walker to mobilise herself. She relies on a church volunteer group to deliver lunches to her during the week. Her fixed income limits her ability to buy food. She has therefore been dividing each lunch so that it will provide her with two meals. Last week, Mrs Niles's 79-year-old sister died. The two sisters had been very close.

Explain the factors that might increase Mrs Niles's risk of infection.

Protective environment

Private rooms used for isolation may have negative-pressure airflow to prevent infectious particles from flowing out of the room. Air leaving the room is filtered using high-efficiency particulate air (HEPA) filters to 99% clean it, ensuring air is free of microbes as it is released into the atmosphere (Siegel et al 2007). Conversely, positive-pressure airflow is used in surgical operating rooms and for highly susceptible patients such as organ transplant recipients. Air in these rooms is HEPA-filtered as it enters from the ceiling, and used air is extracted through vents located on the walls close to floor level. A notice listing the additional transmission-based precautions can be posted outside the room (Figure 25-6). This notice is a handy reference for healthcare personnel and visitors and alerts anyone who might enter the room that special precautions must be followed.

The private isolation room or an adjoining anteroom should contain soap and antiseptic solutions and toilet facilities. Personnel and visitors are required to wash their hands before approaching the patient's bedside and again before leaving the room. If toilet facilities are unavailable, infection control procedures for handling portable commodes, bed pans or urinals are implemented. Personal protective equipment should be stored in an anteroom between the room and hallway or in a convenient location close to the point of use.

An impervious bag for soiled or contaminated linen, as well as a rubbish container with plastic liners, should be readily available and never overfilled. Impervious receptacles prevent transmission of microorganisms by preventing seepage to and soiling of the outside surface. A disposable, rigid 'sharps' container should be available in the room to discard used needles, syringes and sharp objects.

Depending on the microorganism and the mode of transmission, the nurse must evaluate what articles or equipment may be taken into the patient's room. For example, the NHMRC (2010) recommends the dedicated use of articles such as stethoscopes, sphygmomanometers and thermometers in the room of a patient infected or colonised with vancomycin-resistant enterococci (VRE). These devices should not be used on other patients unless they are first adequately cleaned and disinfected. If, after bringing any article into the room, the nurse exposes an article to infected material and then touches or removes the article, the risk of transmitting infection to other patients or personnel is increased. Box 25-13 describes the procedures commonly performed in a protective environment.

Personal protective equipment

Personal protective equipment (PPE) should be readily available for staff involved in patient care. A summary of PPE

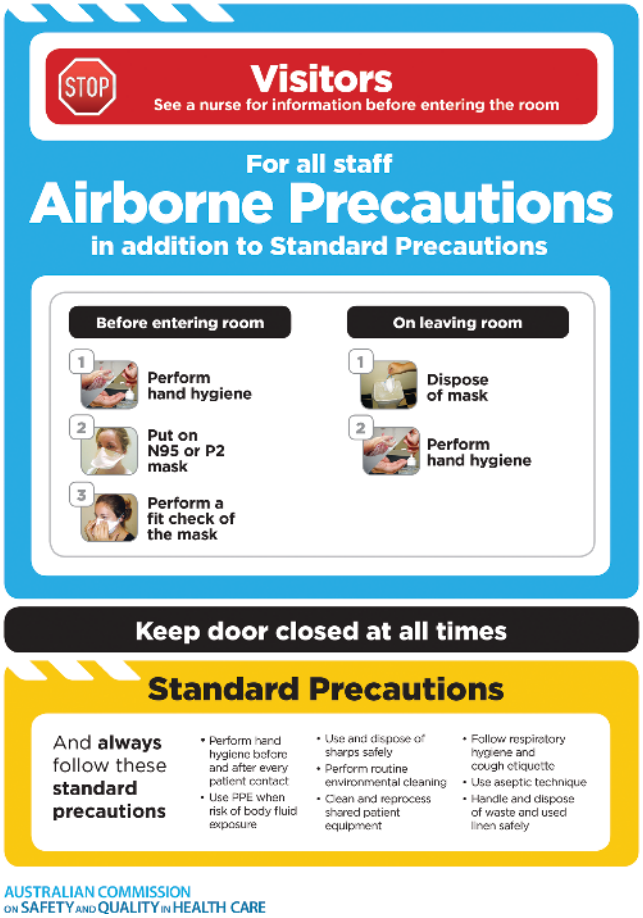

Figure 25-6 Example of transmission-based precautions poster for door of patient room.

The Australian Commission on Safety and Quality in Health Care, Airborne Standard Precautions poster (2012). Sydney. ACSQHC.

requirements for different clinical procedures according to the NHMRC (2010) guidelines is presented in Table 25-6. The main reason for wearing a gown is to prevent soiling of clothes during contact with the patient. Gowns protect healthcare personnel and visitors from coming into contact with infected material and blood or body fluids. Gowns may also be required for contact precautions, depending on the expected amount of exposure to infectious material. Gowns used for barrier protection are made of a fluid-resistant material and should be changed immediately if damaged or contaminated. Depending on agency policy, gowns can be disposable or reusable.

Gowns usually open at the back and have ties or snaps at the neck and waist to keep the gown closed and secure and are long enough to cover all outer garments. Long sleeves with tight-fitting cuffs provide added protection and prevent cross-contamination from skin cells shed from the wearer to the patient. There is no special technique for donning clean gowns, provided they are fastened securely. The nurse must carefully remove and discard gowns to minimise contamination of the hands and uniform. The gown should be removed first and placed in a receptacle, followed by the gloves. The nurse's hands must then be washed immediately.

BOX 25-13 Procedural guidelines for caring for a patient on isolation precautions

1. Assess isolation indications, e.g. current laboratory tests or patient's history of exposure.
2. Review agency policies and precautions necessary for the specific isolation system, and consider care measures to be performed while in patient's room.
3. Review nurses' notes or confer with colleagues regarding patient's emotional state and adjustment to isolation.
4. Wash hands and prepare all equipment to be taken into patient's room.
5. Prepare for entrance into isolation room:
   a. Place either surgical mask or respirator around mouth and nose. (Type will depend on type of isolation and facility policy.)
   b. Wear protective eyewear.
   c. Wear a freshly laundered or clean disposable gown and cover all outer garments. Pull sleeves down to the wrist. Tie securely at neck and waist (see illustration).
   d. Put on disposable gloves. If gloves are worn with gown, bring glove cuffs over edge of gown sleeves. Note: If the patient is allergic to latex, nitrile, non-latex gloves should be worn.
6. Enter patient's room. Arrange supplies and equipment. If equipment being removed from the room requires reprocessing, place in a container with a well-fitting lid for transfer.
7. Explain the purpose of isolation and necessary precautions to the patient and family. Offer an opportunity to ask questions. Assess for evidence of emotional problems due to isolated state.

Step 5c Tying gown at waist.

Step 5d Applying gloves over gown sleeves.

8. Assessing vital signs: wear personal protective equipment, including gown, gloves, eye and face protection.
   a. If patient is infected or colonised with a resistant organism, e.g. vancomycin-resistant enterococcus (VRE) or methicillin-resistant *S. aureus* (MRSA), assessment equipment must remain in the room. Assess vital signs routinely. Avoid contact of stethoscope or blood-pressure cuff with infected material.
   b. Clean the diaphragm or bell of the stethoscope with an antimicrobial solution after each use to reduce contaminants. Set it aside on clean surface.
   c. Individual or disposable thermometers should be used.
9. Administer medications (see Chapter 31):
   a. Administer oral medications in wrapper or using a cup.
   b. Dispose of the wrapper or cup in a plastic-lined receptacle.
   c. Administer injections as ordered.
   d. Do not remove the needle from the syringe. Discard the syringe and needle into a puncture-resistant container designated for sharp items.
   e. Gloves must be worn at all times to avoid contact of hands with contaminated articles, blood, tissue or body fluids.
10. Administer hygiene, encouraging the patient to raise questions or concerns about their isolation. This time can often be effectively used for informal teaching.
    a. Avoid allowing gown to become wet.
    b. Remove linen from the patient's bed; avoid contact with gown and place in an impervious linen bag.
    c. Change gloves and wash hands or apply an antimicrobial, alcohol hand rub until dry.

continued

11. Collect specimens:
    a. Place a specimen container on clean paper towel. The speciman container should be labelled with the patient's name, date of birth, date and time of specimen collection and the exact contents of the specimen to be collected.
    b. Follow non-touch technique to collect the specimen.
    c. Transfer the specimen to the container without soiling outside of container. Place the container in a plastic bag and register the specimen as per facility policy.
12. Dispose of linen and rubbish bags as they become full.
    a. Use sturdy, moisture-resistant, single-use bags to contain soiled articles.
    b. Tie bags securely at top in knot (see illustration).
13. Resupply the isolation room with equipment and consumables to ensure an adequate supply.
14. Leaving the isolation room:
    a. Untie waist and neck strings of gown. Allow gown to fall from shoulders. Remove hands from sleeves without touching outside of gown. Hold gown inside at shoulder seams and fold inside out and dispose of.
    b. Remove gloves. Remove one glove by grasping cuff and pulling glove inside out over hand. Discard glove. With ungloved hand, tuck finger inside cuff of remaining glove and pull it off, inside out (see illustration).
    c. Untie the top mask string and then bottom strings, pull mask away from face and place in a rubbish receptacle. Do not handle outer surface of mask.

Step 12B Tie rubbish bag securely.

Step 14b Removing gloves.

Step 14c A, Untying top strings of mask. B, Dropping mask into rubbish bin.

    d. Wash hands for minimum of 15 seconds.
    e. Explain to the patient when you plan to return to room. Ask whether the patient requires any personal-care items, books or magazines.
    f. Leave room and close the door.
    g. All contaminated supplies and equipment should be disposed of in a manner that prevents spread of microorganisms to other persons (see agency policy).
    h. Remove protective eyewear and wash hands for minimum of 15 seconds.

TABLE 25-6 Summary of personal protective equipment requirements

Procedure	Hand hygiene	Gloves	Sterile gloves	Surgical mask	Eye protection	Gown
Activities of daily living (washing, toilet etc)	✓	✓ if risk of contamination with urine or faeces likely	–	–	–	✓ gown or apron if risk of contamination with urine or faeces likely
Routine observations (e.g. blood pressure measurement)	✓	–	–	–	–	–
General medical examination	✓	✓ for contact with broken skin/ rash/mucous membrane	–	✓ if splash risk likely	✓ if splash risk likely	✓ if splash risk likely
Wound examination/dressing	✓	✓ for contact with body substances	✓ for direct contact with wound	✓ for wound irrigation if splash likely	✓ for wound irrigation if splash likely	✓ for grossly infected wounds
Blood glucose and haemoglobin monitoring	✓	✓	–	–	–	–
Vaginal delivery	✓	–	✓	–	✓	✓
Intravenous cannula insertion	✓	✓	–	–	✓ if splash risk likely	–
Intravascular access device insertion	✓	–	✓	✓	✓	✓ where maximum barrier precautions are used
Intravascular access device care	✓	–	✓	–	–	–
Surgical aseptic technique procedure (e.g. lumbar puncture)	✓	–	✓	✓	✓	✓
Insertion of urinary catheter	✓	–	✓	✓ if exposure risk likely	✓ if exposure risk likely	✓ if exposure risk likely
Urinary catheter care	✓	✓	–	–	✓ when emptying drainage bag	✓ if exposure risk likely
Suctioning: endotracheal tube, tracheostomy	✓	–	✓ dominant hand (open suction system)	✓	✓	✓ if exposure risk likely
Major dental procedures*	✓		✓	✓	✓	✓
Routine intra-oral dental procedures	✓	✓	–	✓	✓	✓ if exposure risk likely

* Including most dental implants, surgical removal or exposure of completely impacted teeth or tooth fragment, vital endodontics, surgical periodontics, maxillo-facial surgery.

National Health and Medical Research Council (NHMRC) 2010 Australian guidelines for the prevention and control of infection in healthcare. NHRMC, Canberra. Online. Available: www.nhmrc.gov.au/guidelines/publications/cd33; accessed 16 Feb 2016.

Masks or masks with face shields should be worn when it is possible that blood or body fluids may be splashed or sprayed into the healthcare worker's face and when patient airborne or droplet precautions are implemented. A correctly applied mask fits snugly over the mouth and nose so that pathogens and body fluids cannot enter or escape through the sides (Box 25-14), thereby preventing contamination by droplet nuclei. A mask discourages the wearer from touching the eyes, nose or mouth. If a person wears glasses, the top edge of the mask fits below the glasses to prevent fogging of eyewear as the person exhales. A mask protects the nurse from inhaling microorganisms from a patient's respiratory tract and prevents transmission of pathogens from the nurse's respiratory tract to the patient. The surgical mask protects the wearer from inhaling large-particle aerosols that travel short distances (1 metre) and small-particle droplet nuclei that remain suspended in the air and travel longer distances. At times, a patient who is susceptible to infection may wear a mask to prevent inhalation of pathogens. Patients with droplet or airborne infections, transported outside their room, should wear a mask to protect other patients and personnel. Masks may prevent transmission of infection by direct contact with mucous membranes.

Talking should be kept to a minimum while wearing a mask to reduce respiratory airflow. When a mask is worn, moisture increases around the mouth and nose, diminishing its effectiveness as a barrier to microorganisms. The mask should be discarded and never reused, as it is a contaminated filter. Staff must wash their hands immediately after discarding a mask. Patients and family members should be warned that a mask might cause a sensation of smothering. If family members are uncomfortable, they should leave the room, discard the mask and immediately wash their hands.

P2-rated respirators that meet the requirements of AS/NZS 1716 (Standards Australia 2012) are required when caring for a patient with known or suspected tuberculosis (TB), avian influenza or severe acute respiratory syndrome (SARS). These masks have a suitable filtration rating and face-fit performance not achieved by a regular surgical mask and must be fit-tested to ensure an effective seal on the face of each wearer to control leakage around the edges of the mask. P2 masks are recommended for use against infections, aerosols and mechanically and thermally generated particulates, so also provide protection from surgical plume generated intraoperatively by electrosurgery and lasers (ACORN 2014). The nurse should be aware of agency policy regarding the type of respiratory protective devices required.

When full protective apparel is necessary, the nurse first washes and dries the hands, applies a mask and protective eyewear, applies a gown and then applies gloves. Gloves help to prevent the transmission of pathogens by direct and indirect contact. Clean, non-sterile gloves should be worn when handling body fluids and contaminated items. Clean gloves should be donned before touching mucous membranes and non-intact skin. Gloves should be changed between tasks and procedures on the same patient after contact with material that may contain a high concentration of microorganisms. Gloves should be removed promptly after use and disposed of appropriately. The wearer's hands should be washed for 15 seconds using an antimicrobial solution or rubbed with an alcohol-based antimicrobial solution until it dries, before touching non-contaminated items and environmental surfaces and before nursing another patient. Washing hands immediately after glove removal helps prevent transfer of microorganisms.

Disposable gloves are easily applied and are designed to fit either hand. The glove can easily be torn. If a break or tear is detected in a glove while providing care, the nurse should change gloves. The nurse should explain the use of gloves to the patient's family members and emphasise the importance of hand hygiene after the removal of gloves.

Nurses must wear protective equipment, including eyewear and a mask or a face shield, when:

- handling toxic chemicals, for example, cytotoxic drugs, formalin
- reprocessing contaminated equipment or instruments
- handling or working in the presence of blood or body fluids, such as the operating room or postoperative care

BOX 25-14 Procedural guidelines for donning a surgical mask

1. Find top edge of mask (usually has thin metal strip along edge). Pliable metal fits snugly against bridge of nose.
2. Hold mask by top two strings or loops. Tie two top ties at top of back of head (see illustration), with ties above ears. (Alternative: slip loops over each ear.)

3. Tie two lower ties snugly around neck with mask well under chin (see illustration).
4. Gently pinch upper metal band around bridge of nose.

Note: mask should be changed if wet, moist or contaminated.

Potter PA, Perry AG 2004 Fundamentals of Nursing, 6th edn. Mosby, St Louis.

unit, for example, when irrigating a large abdominal wound or assisting with the insertion of an arterial catheter.

Protective eyewear, available as shields, plastic glasses or goggles, or reusable headbands with disposable shields (Figure 25-7) should fit snugly around the forehead and face to prevent fluids from entering between the face and the eyewear.

Specimen collection

Laboratory studies are required when a patient is suspected of having an infectious disease. Body fluids and secretions suspected of containing infectious organisms are collected for culture and sensitivity tests (Box 25-15). The specimen is placed in a medium that promotes growth of organisms. A laboratory technologist then assesses the microorganisms growing in the culture. Sensitivity test results indicate antibiotics to which organisms are resistant or sensitive.

The nurse wears eye protection and uses disposable gloves and sterile equipment to obtain patient specimens. When collecting fresh material from the site of an infection, such as wound drainage, it is important to ensure the specimen is uncontaminated by neighbouring microbes. Specimen containers should be sealed tightly to prevent spillage and contamination of the outside of the container and be placed in a leak-proof bag (NHMRC 2010). Specimens must be clearly labelled on the body of the container (not the lid, as this can easily be discarded in the pathology department). The date

BOX 25-15 Specimen collection techniques

Wound specimen

- Clean site with sterile water or saline before wound specimen collection.
- Wear gloves and use cotton-tipped swab or syringe to collect as much drainage as possible. Have clean test tube or culture tube on clean paper towel.
- After swabbing centre of wound site, hold collection tube with paper towel. Carefully insert swab without touching outside of tube. After securing the top of the tube, transfer tube into bag for transport and then wash hands.

Blood specimen

- Use a syringe and culture media bottles to collect up to 10 mL of blood per culture bottle (check agency policy).
- After prepping, perform venepuncture at two different sites to decrease likelihood of both specimens being contaminated with skin flora.
- Place blood culture bottles on bedside table or other surface; swab off bottle tops with alcohol. Inject appropriate amount of blood into each bottle.
- Remove gloves and transfer specimen into clean, labelled bag for transport. Wash hands.

Stool specimen

- Wearing gloves, use clean cup with seal top (need not be sterile) and tongue blade to collect small amount of stool, approximately the size of a walnut.
- Place cup on clean paper towel in patient's bathroom. Using tongue blade, collect needed amount of faeces from patient's bed pan. Transfer faeces to cup without touching cup's outside surface.
- Dispose of tongue blade, and place seal on cup. Transfer specimen into clean bag for transport. Remove gloves and wash hands.

Urine specimen

- Wearing gloves, use sterile cup to collect 1–5 mL of urine.
- Place cup or tube on clean towel in patient's bathroom. Have patient follow procedure to obtain a clean voided specimen (see Chapter 38).
- Transfer urine into sterile container by drawing up urine using a syringe or pouring it from used collection cup. Secure top of container and transfer specimen into clean, labelled bag for transport.
- Alternatively, use a Monovette to draw up the urine from the collection cup, recap, break off plunger and send the labelled Monovette to the laboratory.
- If patient has a urinary catheter, use syringe to collect specimen. If there is an interlink port on urinary catheter drainage bag, use a Monovette to obtain urine specimen, recap, break off plunger, label and send to laboratory.
- Remove gloves and wash hands.

and time of collection and exact title of the specimen, along with the correct patient details, should be documented on the label. Always confirm with the attending doctor whether the specimen is required to be sent fresh, in a specific medium or in a fixative solution such as formalin.

Bagging rubbish or linen

Nurses use special bagging procedures for removing contaminated items from a patient's environment. Bagging prevents accidental exposure of personnel and prevents contamination of the surrounding environment.

The NHMRC (2010) recommends a single bag for discarding items if the bag is impervious and sturdy and if the article can be placed in the bag without contaminating the outside of the bag. Soiled or wet linen should be placed in an impervious laundry bag (to prevent seepage) in the patient's room. This should be removed from the clinical environment as soon as possible. Double-bagging is only recommended if it is impossible to prevent contamination of the bag's outer surface. All linen and rubbish bags must be securely tied and never overfilled.

Transporting patients

Before transferring a patient to a wheelchair or trolley, the nurse should ensure the patient is dressed in a clean gown to serve as a robe. Patients infected with organisms transmitted by the airborne route should leave their rooms only for essential purposes, such as diagnostic procedures or surgery. These patients must also wear masks, as previously discussed. Personnel transporting these patients should also wear barrier protection.

An extra layer of sheets should be used to cover the trolley or seat of the wheelchair as body fluids can leak onto transport equipment. The nurse must ensure that all transport equipment, including IV poles, is thoroughly disinfected immediately after use to prevent cross-infection to other patients.

Personnel in diagnostic or procedural areas or the operating room should be notified of a patient's precautionary care and document this in the patient's chart. The nurse explains ways in which the patient can help prevent transmission of their infection during transport; for example, a patient with a respiratory infection is provided with tissues and a bag to allow appropriate disposal of secretions.

The operating suite should be notified as soon as possible if an infectious patient requires surgery, as transmission-based precautions may be required and the order of the operating list may need to be altered to ensure the most infectious patient is operated on last. The operating room is then thoroughly cleaned and 'rested' to enable adequate HEPA-filtered air changes to remove airborne microorganisms.

Psychosocial implications of isolation

The use of contact precautions or isolation as strategies for infection prevention and control may have negative impacts on several aspects of patient care. Contact precautions and isolation can not only affect patient safety because of decreased time spent with healthcare workers (Abad et al 2010), but can also increase patients' risk for unintended psychological consequences such as loneliness, anxiety and depression (Abad et al 2010, Morgan et al 2009). When a patient needs to be cared for in a private room, a sense of loneliness may develop because usual social relationships are disrupted. As a result of the infectious process, a patient's body image may be altered. They may feel unclean, rejected, lonely or guilty. Infection prevention and control practices further intensify these beliefs of difference or undesirability. Being alone in a private room limits sensory contact and can lead to sensory deprivation. This situation can be psychologically harmful, especially for children. Patient education prior to initiation of contact precautions, as well as staff education regarding the potential shortcomings of care received by patients in isolation, may decrease the risk for unintended negative consequences (Abad et al 2010, Morgan et al 2009). The nurse can act to minimise feelings of psychological and physical isolation to improve patients' emotional state and recovery (see *Research highlight*).

Prior to implementing isolation procedures, the patient and family should clearly understand the nature of the disease or condition, how infectious organisms are transmitted, the difference between contaminated and clean objects and the purposes of isolation and specific precautions. If they can participate in maintaining infection prevention, the chances of reducing the spread of infection are increased. The patient and family should be taught when and how to wash their hands correctly and how to wear and discard barrier protection, if appropriate. Each procedure should be demonstrated and the patient and family should be given an opportunity to practise. Participation of the patient and family in the treatment of the disease can provide a positive sense of purpose and empowerment.

The nurse also takes measures to improve the patient's sensory stimulation while confined to a private room. The room environment should be clean and pleasant. Curtains or blinds should be open, and excess supplies and equipment removed. The nurse can effectively listen to the patient's concerns or interests. If the nurse rushes through care or shows a lack of interest, the patient will feel rejected and even more isolated. Mealtime is a particularly good opportunity for conversation. Measures such as repositioning increase comfort. Recreational and diversional activities such as board games or cards may be an option to keep the patient mentally stimulated. Depending on the patient's condition, the nurse should encourage the patient to sit out of bed and mobilise in order to minimise the chance of deep vein thrombosis formation. The nurse must explain to the family the patient's risk of depression or loneliness. Visiting family members should be encouraged to avoid expressions or actions that convey revulsion or disgust. The nurse can explain ways to provide meaningful stimulation and a positive approach.

Control or elimination of infectious agents

If an object or instrument is labelled 'disposable' it is considered 'single use' and must be discarded after use. Reusable instruments or objects used in patient care must be appropriately reprocessed after use. Correct reprocessing, which includes cleaning and either high-level disinfection or sterilisation of contaminated objects, significantly reduces microorganisms. Australia and New Zealand have a National Standard (AS/NS 4187:2014) to guide the cleaning and disinfection/sterilisation of reusable items (Standards Australia 2014).

CLEANING Reusable objects must first be cleaned after use, before further reprocessing occurs. Cleaning involves the removal of all foreign materials, such as soil and organic

RESEARCH HIGHLIGHT

Research focus

Methicillin-resistant *S. aureus* (MRSA) is one of the leading multi-resistant organisms (MROs) concerning clinicians worldwide. Preventing and controlling the increase and spread of MRSA within the healthcare environment is an imperative for the infection control team. The prevention and control of MRSA requires strict use of both standard and transmission-based precautions, which include effective hand hygiene practices, stewardship in antimicrobial prescribing and source isolation.

Research abstract

This paper presents a review of the literature on the patient experience of source isolation for MRSA or other infectious diseases. The review yielded five major interconnected themes: (1) psychological effects of isolation; (2) coping with isolation; (3) social isolation; (4) communication and information provision; and (5) physical environment and quality of care. It found that the experience of isolation by patients has both negative and positive elements. Isolation may result in detrimental psychological effects including anxiety, stress and depression, but may also result in the patient receiving less or substandard care. However, patients may also benefit from the quietness and privacy of single rooms.

Evidence-based practice

- The psychological effects of isolation in the form of stress, anxiety and depression are clearly documented in the literature.
- Having some control over their isolation experience appears to provide some means by which patients can cope with the situation.
- Social restrictions placed on patients in source isolation may contribute to feelings of loneliness, abandonment and social isolation.
- Effective communication and the adequate provision of information to patients is important in improving their experience of being in source isolation.
- Patients' perceptions, both negative and positive, of isolation are often influenced by their physical surroundings and environment.
- Nurses and other healthcare workers must look for ways to improve the experience of isolation and contact precautions of patients in source isolation, particularly in improving the environment and the patient's self-control of the situation and in providing adequate information.

material, from objects. In larger healthcare facilities, central supply department personnel manually remove gross debris and then, if recommended by the manufacturer, ultrasonically remove debris from crevices and joints in instruments and equipment. Generally, cleaning requires a mild detergent and water combined with the mechanical action of rubbing or scrubbing (NHMRC 2010).

When cleaning and handling used items and equipment soiled by organic material, for example, blood, faecal matter, sputum or pus, or by chemicals, the nurse must take care to minimise exposure to contaminated surfaces, which may include wearing a face shield, plastic apron and disposable gloves. These barriers help provide protection from infectious organisms.

The following general steps help ensure the cleanliness of an object:

1. Clean the instrument or object as close to the point of use as possible to prevent contaminated debris from drying on the object.
2. Fully dismantle the equipment or instrument to ensure all surfaces are subjected to reprocessing.
3. Rinse the contaminated item with warm running water to remove organic material. Hot water causes the protein in organic material to coagulate and adhere to objects, making removal difficult.
4. After rinsing well, wash the object with soap and warm water. Soap or detergent reduces the surface tension and emulsifies debris. Rinse the object thoroughly to remove the emulsified debris.
5. Use a bristled brush to remove material in grooves or seams. Friction dislodges contaminated material for easy removal. Open any hinged items for cleaning.
6. Place the item in an ultrasonic machine (if acceptable in accordance with manufacturer's instructions) to remove debris or bioburden from crevices and joints.
7. Turn off the ultrasonic machine, remove the item and rinse in warm water.
8. Dry the object and prepare it for sterilisation or disinfection.
9. The sink in which the equipment is cleaned is contaminated and should be cleaned and dried.
10. The apron and gloves should be discarded. The face shield is discarded if disposable; if reusable, it should be disinfected prior to reuse.
11. Cleaning brushes should be cleaned and sterilised after use to minimise microbe populations.

It is recommended that a written description of the process and procedures for cleaning contaminated items should be available in all areas where this activity is likely to occur (Standards Australia 2014).

DISINFECTION AND STERILISATION After thorough cleaning, reusable objects are then, ideally, sterilised. If the item cannot

withstand sterilisation, high-level disinfection may be used in accordance with manufacturer's instructions.

Disinfection describes the process of eliminating microorganisms, with the exception of bacterial spores, by thermal or chemical means. *Thermal disinfection* is a simple, cost-effective method that uses heat and water at temperatures that would destroy pathogens (NHMRC 2010). *Chemical disinfection* is generally accomplished by a chemical disinfectant, such as glutaraldehyde, which may or may not be used in conjunction with an automated washer-steriliser (NHMRC 2010). Disinfectants, such as alcohols, chlorines, glutaraldehydes and phenols, can be caustic to equipment and toxic to tissues. Care must be taken to ensure all residual disinfectant is removed prior to use. The disinfected item must be thoroughly dried prior to storage.

Sterilisation involves the complete elimination or destruction of all microorganisms, including spores. Steam under pressure, ethylene oxide (ETO) gas, hydrogen peroxide plasma and chemicals such as periacetic acid are the most common sterilising agents. Once cleaned and disinfected or sterilised, reusable items are then appropriately repackaged, accurately labelled and diligently stored for next use.

It is important for the nurse to be aware of and recognise occupational risks associated while working with chemicals used in disinfection and sterilisation and take appropriate precautions, such as the use of a respirator mask to minimise exposure to toxic fumes when working with glutaraldehydes.

Whether an item is to be simply cleaned, cleaned and disinfected or cleaned and sterilised depends on the intended use of the item. There are three categories of classification: *critical*, *semi-critical* and *non-critical* (Box 25-16). National Standard Australian/New Zealand Standard 4187 (Standards Australia 2014) recommends that all items used within a body cavity be sterile and all items used within the **aseptic field** be documented, so they can be tracked should a product recall be necessary in the event of sterilisation failure.

Nurses should be familiar with the relevant standards, policies and procedures for cleaning, handling and reprocessing items and be competent in correct cleaning, disinfection and sterilisation techniques. Nurses may be required to perform these processes and must be competent to do so. The following factors influence the effectiveness of the disinfecting or sterilising method:

- *Concentration of sterilising or disinfecting solution and duration of contact*. A weakened concentration or shortened exposure time may lessen effectiveness.
- *Type and number of pathogens*. Certain organisms are killed more easily than others by disruption. The greater the number of pathogens on an object, the longer the disinfecting time required.
- *Surface areas to treat*. All contaminated surfaces and areas must be fully exposed to disinfecting or sterilising agents.
- *Temperature of the environment*. Disinfectants tend to work best at room temperature.
- *Presence of soap*. Soap may render certain disinfectants ineffective. Thorough rinsing of an object is necessary to remove soap prior to disinfecting or sterilisation.
- *Presence of organic materials*. Disinfectants can be rendered ineffective in the presence of organic material, for example, blood, saliva, pus or other body fluids. All items should therefore be thoroughly cleaned, rinsed and dried prior to disinfection.

Selection of the appropriate method for disinfecting or sterilising an item depends on its intended use and the nature of the item; for example, delicate fibre-optic instruments such as endoscopes cannot tolerate steam and must be processed using gas, plasma or periacetic acid to achieve sterilisation (Table 25-7).

Control or elimination of reservoirs

To control or eliminate reservoir sites of infection, the nurse should eliminate or contain sources of body fluids, drainage or solutions that can potentially harbour microorganisms. Articles contaminated with infectious material are carefully discarded (Box 25-17). Mandatory standards exist for minimising occupational exposure to blood-borne pathogens or other potentially infectious materials. All healthcare institutions must have policies and procedures to ensure the safe disposal of infectious waste according to local and state regulations. Health workers must adhere to standard precautions and wear protective equipment to prevent cross-contamination.

BOX 25-16 Categories of sterilisation, disinfection and cleaning

Critical items

Items that enter sterile tissue or the vascular system present a high risk of infection if the items are contaminated with microorganisms, especially bacterial spores. Critical items must be sterile, e.g.:

- surgical instruments
- intravascular catheters
- urinary catheters
- needles.

Semi-critical items

Items that come in contact with mucous membranes or skin that is not intact also present risks. These objects must be free of all microorganisms. Semi-critical items must be disinfected or sterilised, e.g.:

- respiratory suction tubing and catheters
- endotracheal tubes
- gastrointestinal endoscopes.

Non-critical items

Items that come in contact with intact skin but not mucous membranes must be clean. Non-critical items must be disinfected, e.g.:

- bed pans
- blood-pressure cuffs
- bedclothes
- stethoscopes
- food utensils.

TABLE 25-7 Examples of disinfection and sterilisation processes

Characteristics	Examples of use
Moist heat	
Moist heat includes steam (moist heat under pressure). When exposed to high pressure, water vapour can attain temperatures above boiling point to kill pathogens and spores	Autoclave is used to sterilise surgical instruments, parenteral solutions and surgical dressings
Radiation	
Ionising radiation penetrates deeply into objects for effective sterilisation and disinfection	Radiation is used in sterilising drugs, foods and other heat-sensitive items
Chemicals	
Chemicals are effective disinfectants because they attack all types of microorganisms, act rapidly, work with water, are stable in light and heat, are inexpensive, are not harmful to body tissues, do not destroy article being disinfected and are not inactivated by organic material	Chemicals are used for disinfection of instruments and equipment Chlorine is useful for disinfecting water and for housekeeping purposes
Ethylene oxide gas	
This gas destroys spores and microorganisms by altering cells' metabolic processes. Fumes are released within an autoclave-like chamber. Ethylene oxide gas is toxic to humans, and aeration time varies with products	This gas sterilises some rubber and plastic items
Boiling water	
Boiling is least expensive for use in the home. Bacterial spores and some viruses resist boiling. It is not used in hospitals	The items (e.g. glass baby bottles) should be boiled for at least 15 minutes

BOX 25-17 Infection control to reduce reservoirs of infection

Bathing
Use soap and water to remove drainage, dried secretions or excess perspiration.

Dressing changes
Change dressings that become wet and/or soiled (see Chapter 30).

Contaminated articles
Place tissues, soiled dressings or soiled sheets in moisture-resistant bags for disposal in accordance with healthcare facility infection control guidelines.

Contaminated needles
- Place syringes, uncapped hypodermic needles, suture needles, skin staples and IV needles in puncture-resistant container, ideally located in patients' rooms or treatment areas so that exposed, contaminated, sharp equipment is not carried long distances (see Chapter 34).
- Do not recap needles.

Bedside unit
Clean table surfaces regularly with antiseptic and ensure they are kept clean and dry.

Skin preparation solutions
Use single-use skin preparation solutions.

Surgical wounds
Keep drainage tubes and collection bags patent to prevent accumulation and backflow of drained fluids.

Drainage canisters and bags
- Dispose of full drainage suction canisters according to facility policy.
- Empty drainage systems at least once per shift or as required, unless otherwise ordered by a doctor.
- Never raise a drainage system, e.g. urinary drainage bag or thoracic drainage reservoir, above the level of the site being drained unless it is clamped off, as the contents of the tubing/reservoir may re-enter the wound.

Control of portals of exit

The nurse must follow infection control practices to minimise or prevent infectious organisms from exiting the body. To control organisms exiting via the nurse's respiratory tract, avoid talking, sneezing or coughing directly over surgical wounds or sterile dressings. Nurses should thoroughly wash their hands after coughing, sneezing, touching their hair, applying a face mask, removing gloves or contacting any potentially contaminated surface. The nurse is also responsible for teaching patients infection control practices when they sneeze or cough and for

providing patients with disposable wipes or tissues to help control the spread of microorganisms.

A nurse with an upper respiratory tract infection or open wound can infect immunocompromised patients and other staff. They should seek medical advice, obtain a medical certificate and if necessary notify and not attend work.

Special attention by the nurse to hand hygiene is essential when dealing with patients who are highly susceptible to infection, for example, immunocompromised patients, patients with burns and neonates. Transmission-based precautions may be implemented for patients with known infections in conjunction with standard precautions.

Another way of controlling the exit of microorganisms is through the careful handling of urine, faeces, emesis and blood, as these can easily splash while being discarded. Disposable gloves, masks, gowns and protective eyewear should be worn. The nurse appropriately disposes of soiled items in contaminated waste bags. Patient laboratory specimens and all tissue, blood and body fluids must be considered potentially infectious and handled appropriately.

Control of transmission

Effective control of infection requires a nurse to remain aware of the modes of transmission and methods of control. In the hospital, home or extended-care facility, a patient should have a personal set of care items. Sharing bed pans, urinals, bath basins and eating utensils can easily lead to transmission of infection. Single-use chemical-strip thermometers or single-use covers on tympanic or electronic thermometers present less risk of infection, provided the reusable component is thoroughly cleaned and disinfected between patients.

To prevent transmission of microorganisms through indirect contact, soiled items and equipment must be kept from touching the nurse's clothing. A common error is to carry contaminated linen in the arms, thus touching the nurse's uniform. Fluid-resistant linen bags should be located at the point of use, or soiled linen should be carried with hands held away from the body. Linen containers should be placed close to the area of use and replaced before they are overflowing.

Control of portals of entry

Many measures that control the exit of microorganisms similarly control the entrance of pathogens. Maintaining the integrity of skin and mucous membranes reduces the opportunity for microorganisms to reach a host. Immobilised and debilitated patients are particularly susceptible to skin breakdown. Patients should not be positioned on tubes or objects that might cause breaks in the skin. Dry, wrinkle-free linen also reduces the chances of skin breakdown. Turning and repositioning of patients should be performed regularly before a patient's skin becomes reddened. Frequent oral hygiene prevents the drying of mucous membranes. A water-soluble ointment can help keep a patient's lips lubricated.

After elimination, a woman should clean the rectum and perineum by wiping from the urinary meatus towards the rectum. Cleansing in a direction from the least to the most contaminated area helps reduce genitourinary infections. Meticulous and frequent perineal care is especially important in older women who wear disposable incontinence pads.

Correct handling and management of urinary catheters and drainage sets includes maintaining a closed, intact system and minimising movement of the catheter in the urethra to prevent infection.

The nurse may care for patients with drainage systems collecting wound drainage, bile or other body fluids. The site from which a drainage tube exits should remain clear of excess moisture or accumulated drainage. All tubing should remain connected in a closed system throughout use. Drainage receptacles should only be opened to discard the volume of drainage. The amount, colour and consistency should be noted in the patient's documentation.

When specimens are required from drainage tubes or needles inserted into IV ports, disinfection should be achieved by initially washing one's hands, then carefully wiping the site outwards with an alcohol swab and allowing it to dry, before entering a tube or system.

Patients and healthcare personnel are at risk of infection from accidental needle-stick injuries. After administering an injection or inserting an IV catheter, needles should never be recapped but carefully disposed of in a puncture-resistant 'sharps' container. A stray needle lying in bedclothes or carelessly thrown into a wastebasket is a prime source of exposure to blood-borne pathogens, for example, hepatitis B and C. A needle-stick injury should be reported immediately, appropriate treatment implemented and an injury/incident report completed (Box 25-18).

A final method for minimising the entrance of microorganisms into a person is the technique of cleansing wounds, as described fully in Chapter 30.

Asepsis and aseptic technique

The nurse's efforts to minimise the onset and spread of infection during clinical procedures are based on the principles of aseptic technique. **Asepsis** is defined as the absence of pathogenic microorganisms. An **aseptic technique** 'aims to prevent pathogenic organisms, in sufficient quantity to cause infection from being introduced to susceptible sites by hands, surfaces and equipment' (NHMRC 2010:86). It is a method employed to help prevent contamination of wounds and other susceptible sites by organisms that could cause infection by ensuring that only aseptic parts of equipment and fluids come into contact with aseptic parts of the patient or susceptible body sites during certain clinical procedures. It is used during any procedure that bypasses the body's natural defences (e.g. peripheral and central intravenous access, wound care or urinary catheterisation).

BOX 25-18 Hepatitis B vaccination and follow-up after exposure

- Healthcare employers must make available hepatitis B vaccine to all employees at no cost. The serum level of those who may have had an occupational exposure should be tested for hepatitis B and HIV immediately. Evaluation and follow-up care must be available to all employees who have been exposed to blood or body fluids at no cost to employee.
- A confidential written medical evaluation and counselling should be available to employees with exposure incidents.

Principles of aseptic non-touch technique

Aseptic non-touch technique (ANTT) is the framework for promoting and ensuring asepsis adopted in the current Australian infection control guidelines (NHMRC 2010). In ANTT, asepsis is ensured by: identifying and then protecting key parts and key sites; effective hand hygiene; effective non-touch technique; appropriate glove choice; and use of aseptic fields (Rowley et al 2010).

'Key parts' – the aseptic key parts of procedure equipment – must be identified and protected at all times. Key parts must only come into direct contact with other aseptic key parts and/or key sites, such as wounds or insertion sites (Rowley et al 2010). While effective hand hygiene is also an essential component of ANTT, it is known that hand hygiene is not always correctly performed; and that even when correctly performed, hand hygiene cannot always remove all pathogenic organisms. Therefore, a non-touch technique – identifying key parts and not touching them directly or indirectly – is a vital component of achieving asepsis. In other words, the optimal way of protecting key parts is never to touch them (Rowley et al 2010). If it is necessary to touch key parts/sites directly, then sterile gloves should be used to minimise the risk of contamination. Otherwise, wear non-sterile gloves.

Even well-cleaned hospitals can be said to be 'dirty' – busy and dynamic environments resident with unusual antibiotic-resistant organisms. Consequently, aseptic fields are important in providing a controlled aseptic working space to help promote or ensure the integrity of asepsis during clinical procedures. It is also important that aseptic fields are fit for purpose. In ANTT, aseptic fields are increased in size and sterilised drapes added on the basis of procedure complexity. For example, in IV therapy, 'mobile' aseptic fields such as plastic trays should be large enough and with sides high enough to provide an adequate working space to contain equipment, sharps and spillages. ANTT employs two types of aseptic fields – general and critical – that require different management depending on whether the primary purpose is to promote or ensure asepsis. *General aseptic fields* are used when key parts can be easily protected, and *critical aseptic fields* are used when key parts cannot be protected at all times due to their size or number (Rowley et al 2010).

Ensuring and promoting asepsis using ANTT principles appropriately depends on the healthcare professional undertaking a risk assessment which takes into account: whether the procedure can be performed without touching key parts and key sites directly; the technical difficulty of the procedure and the competency of the healthcare professional; and risks posed by the immediate environment (Rowley et al 2010). Although the principles of ANTT remain constant, the level of practice will change according to the risk assessment (NHMRC 2010). The risk assessment will determine whether a 'standard' ANTT or a 'surgical' ANTT is required (Figure 25-8).

Principles of surgical asepsis

The principles of surgical ANTT encompass situations where procedures are technically complex, involve large or numerous key parts, involve large open key sites and entail extended periods of time. One such example is surgery in the operating room (Rowley et al 2010).

Surgical asepsis is used during surgical procedures to eliminate introduction of all additional microorganisms, including pathogens and spores, to an object or area, thus creating a critical aseptic field. In surgical asepsis an area or object is considered contaminated if touched by any object that has not been sterilised and treated in an aseptic manner. For example, a torn surgical glove exposes the outside of the glove to the skin surface; it is therefore contaminated. Nurses working within a critical aseptic field or with sterile equipment must rectify the slightest break in asepsis, because contamination can place a patient at risk of infection.

Standard ANTT and the use of a general main aseptic field (yellow outline) and critical micro-asceptic fields (red outline)

Surgical ANTT and the use of a main critical aseptic field

Figure 25-8 Use of standard and surgical aseptic non-touch technique.

A, Standard aseptic non-touch technique (ANTT). B, Surgical ANTT.

National Health and Medical Research Council (NHMRC) 2010 Australian guidelines for the prevention and control of infection in healthcare. NHRMC, Canberra. Online. Available: www.nhmrc.gov.au/guidelines/publications/cd33; accessed 16 Feb 2016.

Surgical asepsis is routinely practised in the operating room and the perioperative nurse follows a series of steps to promote and ensure asepsis, including donning fresh scrub clothes, hair covering, mask and protective eyewear, and performing a thorough surgical hand and arm scrub. The perioperative nurse then dons a sterile gown and gloves (see below).

PATIENT PREPARATION Surgical asepsis requires precision to avoid compromising the aseptic field; the nurse must therefore gain the patient's cooperation. The nurse must carefully prepare the patient before any procedure. Certain patients may fear moving or touching objects during an aseptic procedure, whereas others may even try to help. The nurse explains how a procedure is to be performed and what the patient can do to avoid compromising the aseptic field, including the following:

- Avoid sudden movements of body parts covered by surgical drapes within the aseptic field.
- Refrain from touching surgical supplies, drapes or the nurse's gloves and gown.
- Avoid coughing, sneezing or talking over an aseptic area. The nurse may suggest the patient gently raise their hand if they think they may cough, sneeze or move.

Certain aseptic procedures may last an extended time. The nurse assesses the patient's needs to anticipate factors that may disrupt a procedure. Analgesics should be administered proactively to ensure procedural pain relief. Patients must often assume relatively uncomfortable positions during aseptic procedures, so they are assisted to achieve the most comfortable position possible. To prevent wound contamination, the nurse should anticipate problems related to the patient's condition which may result in actions or events that can compromise an aseptic field, such as offering a mask to a patient with a respiratory infection.

ENSURING ASEPSIS When beginning a surgically aseptic procedure, the nurse should be guided by the following principles to ensure asepsis:

- *A sterile object is sterile inside its unopened, uncompromised sterile packaging* (Rowley et al 2010).
  - Sterile items are removed from their sterile packaging and aseptically presented to the surgical field (ACORN 2014).
  - In the course of constant exposure to airborne organisms, sterile items can no longer be considered sterile; but are considered aseptic.
- *A sterile object remains sterile only when touched by another sterile object*.
  - Aseptic items within the aseptic field touching each other enables the item to remain aseptic; for example, aseptic gloves or aseptic forceps are used to handle objects within the aseptic field.
  - Aseptic items touching clean items are considered contaminated; for example, if an aseptic object touches the surface of a clean disposable glove, the object is considered contaminated and must be discarded.
  - Aseptic item touching contaminated items occurs when the nurse touches an aseptic object with an ungloved hand.
- *Only sterile objects may be placed on a sterile field.* A package that is torn, punctured, wet or open is considered unsterile. Where there is a tear, break or puncture in the covering of a sterile item, the item cannot be used on the sterile field as it is not sterile (it is considered contaminated). The nurse should carefully check the integrity of the packaging of all items when preparing for a sterile procedure.
- *Aseptic objects on aseptic fields should be kept in view.* Aseptic gloved hands should be held above waist level. Nurses never turn their backs on an aseptic tray or leave it unattended. Aseptic objects should be kept in front with the hands as close together as possible. Items held below waist level are considered contaminated. Contamination can occur accidentally by a dangling piece of clothing, falling hair or a patient touching an aseptic object.
- *An aseptic object or field becomes contaminated by prolonged exposure to air*. The nurse avoids activities that create air currents, such as excessive movements, rearranging aseptic items or rearranging linen after an aseptic object or field is exposed. The number of people walking into the area and talking, laughing, sneezing or coughing when gathering and using aseptic equipment should be minimised, to reduce contamination by airborne transmission. When opening sterile packages, the nurse holds the item or piece of equipment close to the aseptic field, without touching the aseptic surface. An aseptic field must be prepared immediately prior to use. It must not be left unattended, as sterility cannot be guaranteed. Ideally, a second nurse aseptically opens items to be placed on the aseptic field and the nurse performing the procedure, wearing aseptic gloves and/or using an aseptic instrument, receives the items, to minimise contamination.
- *When an aseptic field comes in contact with a wet, contaminated surface, the aseptic object or field becomes contaminated by a 'wicking' action.* If moisture seeps through an aseptic package's protective covering, microorganisms can travel onto the aseptic object. When stored sterile packages become wet, the nurse discards the objects immediately or sends the equipment for reprocessing. Any spill from pouring sterile or aseptic solutions can be a source of contamination unless the object or field rests on an aseptic surface that cannot be penetrated by moisture. For example, urinary catheterisation trays, once opened, contain aseptic supplies that rest in an aseptic, plastic container – if aseptic solutions are spilled within the container, they will not contaminate the catheter or other objects. In contrast, if sterile gauze is left in its wrapper on a wet bedside table the gauze is considered contaminated.
- *The edges of an aseptic field or tray are considered to be contaminated*. Frequently a nurse places sterile objects on an aseptic drape. The edges of the drape touch an unsterile surface, such as a table or bedclothes; a 2.5 cm border around the drape is therefore considered contaminated. The edges of sterile containers become exposed to air after they are open and are also considered contaminated. A sterile item removed from its protective container must not touch the container's edge.
- *Fluid flows in the direction of gravity.* A sterile object becomes contaminated if gravity causes unsterile liquid to flow over the object's surface. To avoid contamination during a surgical hand scrub, hands are held above elbows,

allowing water to flow downwards, without allowing water to flow back from the elbow area and over hands and fingers. After performing a surgical hand scrub, scrubbed personnel dry their hands from fingers to elbows, with their hands held upwards and using one end of the towel, then repeat the process using the other end of the towel; the towel is then discarded.

Performing aseptic procedures

All equipment required, plus extra supplies in case of accidental contamination, should be assembled before a procedure. The nurse then avoids leaving the area unattended. If an object is contaminated during the procedure, it should be discarded immediately. Prior to commencement of the aseptic procedure, each step should be carefully explained to the patient to help gain their cooperation.

DONNING AND REMOVING CAPS, MASKS AND EYEWEAR Nurses generally wear a surgical mask and protective eyewear without a cap when performing aseptic procedures in a ward environment. During surgical procedures, perioperative staff wear freshly laundered attire, a cap or balaclava to cover all hair, protective eyewear and a surgical mask. Post-procedure, the contaminated gloves are removed first, then the gown and finally the mask. This order aims to prevent contamination of the hair, neck and facial area. After untying the mask, the nurse holds it by the ties to discard it. Masks should not be worn hanging from the neck after removal, as they are a contaminated filter. After removing all protective wear, the nurse washes hands thoroughly.

OPENING STERILE PACKAGES Sterile items such as syringes, gauze dressings and catheters are packaged in paper or plastic containers, impervious to microorganisms provided they remain dry and intact. Reusable supplies may be wrapped in packaging that is permeable to steam, to allow steam, gas or plasma penetration during sterilisation. Sterile items are kept in clean, enclosed storage systems and must be separated from unsterile or contaminated equipment.

Sterile supplies generally have chemical indicators or tapes that change colour during the sterilisation process. Failure of the tapes to change colour signifies that the item is unsterile and must not be used. A sterile supply should never be used if the integrity of the packaging is compromised. Healthcare facilities label each item with the date processed, a load number and the steriliser number. If an item is found to be unsterile – the chemical indicator has not changed colour to indicate sterilisation has taken place – a product recall of all items processed by that steriliser during that load must commence immediately. In accordance with AS/NZS 4187 (Standards Australia 2014), healthcare facilities are required to demonstrate the ability to competently track all items sterilised within the facility. Double-sided stickers or barcoding systems may be used to identify when items were sterilised and in which steriliser, and on which patients the items was used.

Before opening a sterile item, the nurse should disinfect and dry the work area, then thoroughly wash their hands. Supplies are inspected for integrity and sterility and assembled in the work area, such as the bedside table or treatment room, before opening packages. A bedside table or counter top can provide a large, clean working area for opening items. The work area should be above waist level. Sterile supplies should not be opened in a wet, contaminated or confined space.

OPENING A STERILE ITEM ON A FLAT SURFACE Sterile packaged items must be opened without contaminating the contents by use of aseptic technique. Commercially packaged items are usually designed to allow the nurse to open or separate the paper or plastic cover, opening the wrapper away from the body (Figure 25-9). The following steps are used when opening items wrapped in polypropylene, paper or linen:

1. Ensure the surface of the trolley or table has been disinfected and dried.
2. Check the integrity of the packaging, the date, sterilisation indicator and contents.
3. Place the item flat in the centre of the work surface.
4. Remove the steriliser indicator label and affix to patient documentation. Then remove sterilisation tape or seal.
5. Grasp the outer surface of the tip of the outermost flap.
6. Open the outer flap away from the body, keeping the arm outstretched and away from the aseptic field (Figure 25-10A) and pull the packaging firmly.
7. Grasp the outside surface of the first side flap.
8. Open the side flap, allowing it to lie flat on the table surface. Keep the arm to the side and not over the sterile surface (Figure 25-10B). Do not allow the flaps to spring back over the sterile contents.
9. Grasp the outside surface of the second side flap and allow it to lie flat on the table surface (Figure 25-10C).
10. Grasp the outside surface of the last and innermost flap.
11. Stand away from the sterile package and pull the flap back, allowing it to fall flat on the surface (Figure 25-10D).
12. Use the inner surface of the package (except for the 2.5 cm border around the edges) as an aseptic field to add additional sterile items. The 2.5 cm border can be grasped to manoeuvre the field on the table surface.

OPENING A STERILE ITEM WHILE HOLDING IT To open small sterile items, the package is held in the non-dominant hand while the top flap is opened and pulled away from the nurse. Using the dominant hand, carefully open the sides and top flaps away from the enclosed sterile item in the order previously mentioned. Open the item aseptically and retrieve the item for transfer to the aseptic field.

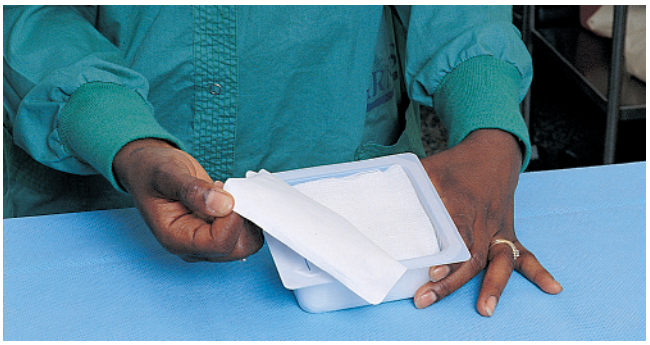

Figure 25-9 When opening a commercially packaged sterile item, the nurse tears the wrapper away from the body.

PREPARING AN ASEPTIC FIELD When performing aseptic procedures, the nurse requires an aseptic work area that provides room for handling and placing sterile items. An aseptic field is an area free of additional microorganisms and prepared to receive sterile items. The field may be prepared by using the inner surface of a sterile wrapper as the work surface or by using a sterile drape. Skill 25-2 describes preparation of an aseptic field. After the surface of the field is created, the nurse adds sterile items by placing them directly on the field or by transferring them with aseptic forceps. When transferring

SKILL 25-2

Preparing an aseptic field

Delegation considerations

Preparing an aseptic field requires specialised knowledge regarding surgical asepsis.

Equipment

- Sterile drapes
- Assorted sterile supplies

STEPS	RATIONALE
1. Prepare aseptic field just before planned procedure. Supplies are to be used immediately.	Prevents exposure of aseptic field and supplies to air and contamination.
2. Work surfaces should be above waist level. Clean the work surface with an antiseptic solution and dry thoroughly.	An aseptic object held below waist level is considered contaminated.
3. Check all necessary equipment is present and inspect the integrity of packaging.	Preparation of equipment in advance prevents break in technique.
4. Check chemical indicators on supplies that indicate sterility of equipment. Scan barcodes of items or attach labels to patient documentation to enable effective tracking of sterilised items.	
5. Apply personal protective equipment.	
6. Wash and dry hands thoroughly.	Prevents transmission of infection.
7. Place pack containing sterile drape on work surface and open as shown in Figure 25-10.	Ensures sterility of packaged drape.
8. With fingertips of one hand, pick up folded top edge of sterile drape.	2.5 cm border around drape is considered unsterile and may be touched.
9. Gently lift drape up from its outer cover and let it unfold by itself without touching any object. Discard outer cover with your other hand.	If sterile object touches any other non-sterile object, it becomes contaminated.
10. With other hand, grasp adjacent corner of drape and hold it straight up and away from your body (see illustration).	Drape can now be properly placed while using two hands. Drape must be held away from unsterile surfaces.
11. Holding drape, first position and lay bottom half over intended work surface (see illustration).	
12. Allow top half of drape to be placed over work surface last (see illustration).	Prevents nurse from reaching over aseptic field.
13. Grasp 2.5 cm border around edge to position as needed.	Creates aseptic work surface.

Step 10 Hold drape straight up and away from body.

Step 11 Lay bottom half over work surface.

Step 12 Place top half of drape over work surface.

STEPS	RATIONALE
ADDING STERILE ITEMS	
14. Open sterile item (following package directions) while holding outside wrapper in non-dominant hand.	Frees dominant hand for unwrapping outer wrapper.
15. Carefully peel wrapper onto non-dominant hand.	Item remains sterile. Inner surface of wrapper covers hand, making it sterile.
16. Being sure wrapper does not fall down on aseptic field, place item onto field at angle. Do not hold arm over aseptic field (see illustration).	Prevents reaching over field and contaminating its surface.
17. Dispose of outer wrapper.	Prevents accidental contamination of aseptic field.
18. Pouring sterile solutions:	
a. Verify contents and expiration date of solution.	Ensures correct solution and sterility of contents.
b. Ensure receiving container for solution is on or near edge of aseptic field. Some aseptic field kits have cups or moulded plastic sections into which fluids can be poured.	Prevents reaching over aseptic field.
c. Remove sterile seal and cap from bottle in an upward motion. Holding bottle away from aseptic field with label facing up and the bottle lip 3–4 cm over inside of receiving container, slowly pour contents into container (see Figure 25-11).	Prevents contamination of bottle lip and keeps inside of cap aseptic. Edge and outside of bottle are considered contaminated. Slow pouring prevents splashing of liquids which causes fluid permeation of aseptic field and results in contamination.
19. Perform procedure using aseptic non-touch technique.	Prevents transmission of infection to patient.

Step 16 Placing sterile item on aseptic field.

RECORDING AND REPORTING

- It is not necessary to record or report this procedure.

aseptic items, the nurse must carefully place objects onto the aseptic field. An object that comes in contact with the 2.5 cm border around the field is considered contaminated and must be discarded.

Sterile gloves may be worn while preparing items on the aseptic field. If this is done, the nurse can touch the entire drape, but sterile items must be handed over by an assistant. The nurse's gloves cannot touch the wrappers of sterile items.

POURING STERILE SOLUTIONS Often sterile solutions must be poured into aseptic containers. The patient's allergy status, the type, strength and expiry date of the solution should first be checked. A bottle containing a sterile solution is sterile on the inside and contaminated on the outside; the bottle's neck is also contaminated, but, once opened, the inside of the bottle cap is considered aseptic. After a cap or lid is removed, it is held in the hand or placed aseptic side (inside) up on a clean surface so the inside of the lid can be seen as it rests on the table surface. A bottle cap or lid should never rest on an aseptic surface as the cap's outer edge is unsterile and would contaminate the surface. Similarly, placing an aseptic cap down on an unsterile surface contaminates the cap. A single-use solution is recommended; any remaining solution is discarded.

The bottle should be held with its label in the palm of the hand to prevent the possibility of the solution wetting and fading the label. The nurse pours the solution slowly to avoid splashing the underlying aseptic drape or aseptic field. The bottle should never be held so high above the container that even slow pouring will cause splashing. The bottle should be held outside the edge of the aseptic field (Figure 25-11).

SURGICAL HAND ANTISEPSIS Patients undergoing operative procedures are at an increased risk of infection. Nurses working in the operating rooms perform surgical hand antisepsis to decrease and suppress the growth of skin microorganisms in case of glove tears (ACORN 2014, Ghorbani et al 2012, WHO 2009, Widmer et al 2013). Surgical hand antisepsis can be achieved by a surgical hand antiseptic scrub or an alcoholic-based surgical hand rub. Regardless of the method, the Australian College of Operating Room Nurses (2014) recommends that standardised and correct procedures will ensure all members of the team minimise transmission.

Figure 25-11 **Pouring a sterile solution into a receiving container on the aseptic field.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

All jewellery should be removed from the arms, wrists and hands, including rings, as these may harbour microorganisms. Fingernails must be kept clean, short and free of nail fillers, artificial nails and nail polish (ACORN 2014). Nurses with active skin infections, open lesions or respiratory infections should be excluded from the surgical team. The efficacy of surgical hand antisepsis is influenced by the choice of skin disinfectant and the duration and coverage of the product (Ghorbani et al 2012, Howard et al 2014). Surgical hand antisepsis products should be used in accordance with the manufacturer's recommendations for use, including volume of product used and contact time of product on skin (ACORN 2014). During **surgical hand antiseptic scrub** (Skill 25-3), the nurse washes from fingertips to elbows with an antiseptic solution under tepid running water. The three (3) minute surgical hand scrub has been shown to be as effective as the five (5) minute surgical hand scrub, depending on selection of surgical handwash (Widmer 2013). Using a standardised procedure, an initial wash that takes 5 minutes would include the cleaning of fingernails with a disposable nail pick. Use of a sterile scrub brush is not

SKILL 25-3

Surgical hand antisepsis ('scrubbing'): preparing for gowning and gloving

Delegation considerations

The role of the circulating and instrument nurse can be delegated to a surgical technologist or licensed practical nurse in some countries. In Australia, registered nurses (RNs) typically perform these roles, but the roles can be delegated to an enrolled nurse (EN) with the requisite education and preparation. Individual healthcare organisations will determine the level of competency required for the role of the circulating and instrument nurse.

Equipment

- Deep scrub sink with automatic, foot or knee controls for dispensing water and antiseptic soap (taps should be high enough for hands and forearms to fit comfortably).
- Non-irritating, broad-spectrum, fast-acting antimicrobial scrub solutions with ensured persistent or sustained activity should be used. Note: the same antimicrobial solution used for the initial scrub of the day should be used for

subsequent scrubs during the day, to maximise the residual cumulative antimicrobial effects. Staff using antimicrobial solutions should have direct access to the manufacturer's material safety data sheet (MSDS) which outlines directions for use and first aid.

- Surgical scrub sponge with nail pick. Note: a scrub brush should only be used if hands are grossly contaminated, e.g. following gardening, painting, etc. Routine use damages the outer dermal layer of skin causing abrasions which breach the skin barrier enabling penetration of microbes into deeper tissue, increasing the risk of skin reactions.
- Other: personnel are required to remove jewellery and don protective equipment: freshly laundered scrub attire, appropriate footwear, shoe covers as required, hair covering, appropriate surgical face mask and protective eyewear prior to scrubbing.

STEPS	RATIONALE
1. Scrub all surfaces of hands and forearms working from the nail beds and between fingers before proceeding to wash the forearms. The first hand and arm wash (scrub) for the day should take 5 minutes; subsequent scrubs should take 3 minutes (ACORN 2014).	Allows sufficient time to ensure the effectiveness of the surgical scrub.
2. Ensure fingernails are short, clean, healthy and free of artificial nails, nail polish and nail fillers.	Long nails and chipped or old polish increase number of bacteria residing on the fingernails. Long fingernails can puncture gloves, causing contamination.
3. Inspect hands for presence of abrasions, cuts or open lesions. Consult infection control professional as necessary.	Damaged tissue may have a greater number of microbes residing on skin surfaces.
4. Don surgical face mask and protective eyewear.	Protects from splashes of chemicals and patient blood and body fluids.
5. Turn on water using knee or foot controls and adjust to comfortable temperature.	Taps should be high enough to allow hands and forearms to fit comfortably underneath.
6. Start timing. Wet hands and arms under running lukewarm water and lather with an antimicrobial solution to 5 cm below the elbows. Keep hands higher than elbows at all times.	Water runs by gravity from fingertips to elbows. Hands become cleanest part of upper extremity. Keeping hands elevated allows water to flow from least to most contaminated areas.
7. Under running water, clean under nails of both hands with either a nail pick or the bristled side of a scrub brush (see illustration). Discard after use.	This removes debris that may harbour large numbers of microorganisms. Note: WHO guidelines recommend that a surgical hand scrub with a medicated soap, such as chlorhexidine or povidone–iodine for 2 or 3 minutes, reduces bacterial counts to acceptable levels and the time required for surgical alcohol-based hand rubbing depends on the compound used (WHO 2009). WHO guidelines also state that for preoperative hand preparation, alcohol-based formulations have better antimicrobial effectiveness than all other currently available methods (WHO 2009).

STEPS	RATIONALE

Step 7 Cleaning under fingernails.

8. Rinse hands and arms thoroughly under running warm water. Remember to keep hands above the elbows.	Rinsing removes transient microorganisms from fingers, hands and forearms.
9. Wash arms using a circular motion, from hands to elbows, without returning to hands (see illustration). Discard brush. This 'pre-wash' should take 3 minutes initially, then 2 minutes for subsequent scrubs.	This step allows the antimicrobial solution time to work.
10. Re-apply the antimicrobial solution and wash all surfaces of hands including between fingers (see illustration) and around wrists. Wash arms using a circular motion from hands to elbows, without returning to hands. This process should take 2 minutes initially, then 1 minute for subsequent scrubs.	Scrubbing in a circular motion loosens resident bacteria that adhere to skin and helps ensure full coverage of surfaces.
11. Ensure hands are elevated above the elbows. Carefully rinse hands and arms thoroughly under running water, without touching taps (see illustration).	Correct rinsing to remove antimicrobial solution helps prevent skin irritation.
12. Turn off taps without touching them with the scrubbed parts of the hands and arms. Shake off excess water, clasp hands together and hold away from the body.	Keeping hands and arms elevated and away from clothing avoids contamination.

Step 9 Washing arms.

Step 10 Scrubbing sides of fingers.

STEPS	RATIONALE

Step 11 Rinsing arms.

13. Walk carefully into the operating or set-up room to dry hands and arms in preparation for donning a sterile gown and gloves.	Floors around scrub sink can be slippery.
14. Obtain a sterile hand towel and stand back from the aseptic field. Lean forwards, outstretch hands and allow the towel to unfold. Use one half of the towel to thoroughly pat dry, from the hand to the elbow using a circular motion, on one side of the towel, then use the other half of the towel to repeat the process for the other hand and arm (ACORN 2014).	Leaning forwards prevents accidental contact of arms with clothing. Drying hands thoroughly makes donning gloves easier.
15. Finally, drop the towel into the appropriate receptacle (ACORN 2014) and proceed with gowning.	

RECORDING AND REPORTING

- Scan barcodes of sterile items or apply tracking stickers to documentation.
- Report any dermatitis to employee health services or infection control professional as per agency policy.

recommended; continued use can damage the outer layer of the skin. The recommended duration of subsequent surgical scrubs is 3 minutes, as the residual antimicrobial solution on the skin surface reduces the microbe population (ACORN 2014, NHMRC 2010). The light friction created by scrubbing effectively removes microorganisms; however, vigorous scrubbing may remove outer layers of the epidermis, exposing deeper layers to bacterial flora (Rothrock 2007). If undertaking an alcoholic-based surgical hand rub, the nurse must ensure adequate skin contact/coverage with the solution according to the manufacturer's recommended instructions for use.

DONNING STERILE GLOVES Sterile gloves are an additional barrier to bacterial transfer. Nurses who work on general nursing wards use open gloving (Skill 25-4) for aseptic procedures such as urinary catheter insertion. The closed gloving method (Skill 25-5) is performed after nurses put on sterile gowns and is practised in operating rooms and procedure rooms. Once out of their original packaging, gloves and gowns are no longer considered sterile, but aseptic.

The appropriate glove size should be selected; the glove should not stretch so tightly that it constricts hand movement or tears easily. Double gloving is recommended to maximise glove integrity and reduce the microbial load of contaminated needles perforating gloves. Gloves one size larger are applied first, with the nurse's usual size of glove worn on top (Tanner & Parkinson 2009).

DONNING A STERILE GOWN Nurses must don sterile gowns when assisting at the aseptic field in the operating room and delivery room so that aseptic objects can be comfortably handled with less risk of contamination. The aseptic gown acts as a barrier to decrease shedding of microorganisms from skin surfaces. Nurses caring for patients with large open wounds or

SKILL 25-4

Open gloving

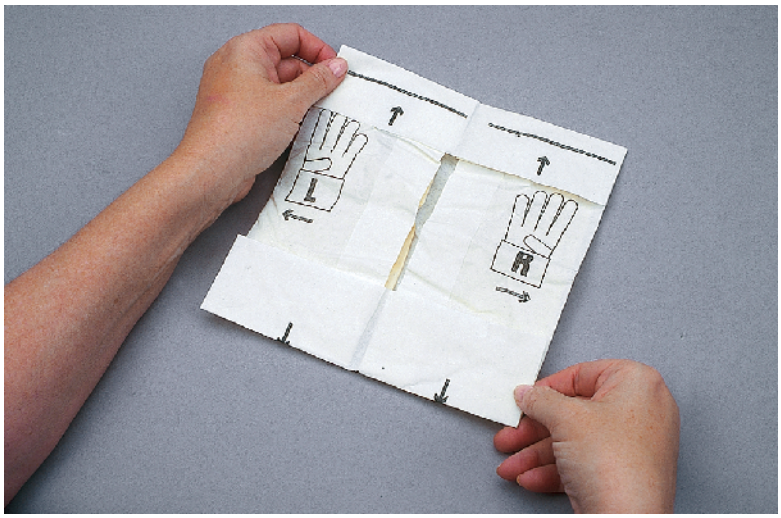
Delegation considerations

Requires knowledge of aseptic technique.

Equipment

- Sterile gloves of the correct size
- A clean surface on which to open the glove packet. Wipe over the surface with an antiseptic and allow it to dry thoroughly before use

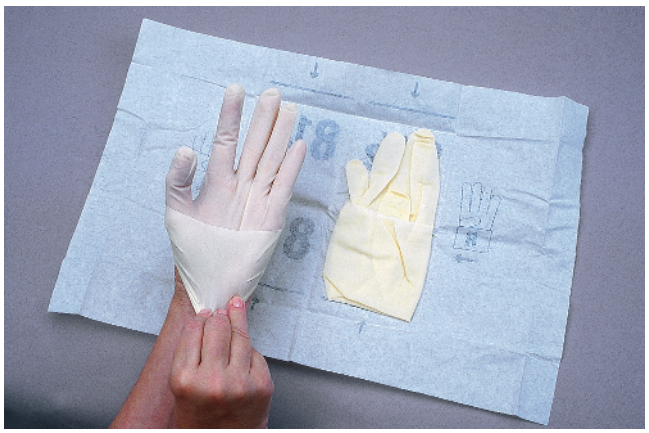
STEPS	RATIONALE
OPEN GLOVING	
1. Perform hand hygiene.	Removes bacteria from skin surfaces and reduces transmission of infection.
2. Open the glove packet by carefully separating and peeling apart the sides, on a recently cleaned surface.	Maintains the integrity of the sterile gloves.
3. Grasp the inner package, keeping the gloves on the sterile inside of the wrapper surface (see illustration).	Inner surface of glove package must remain sterile.



Step 3 Opening glove package.

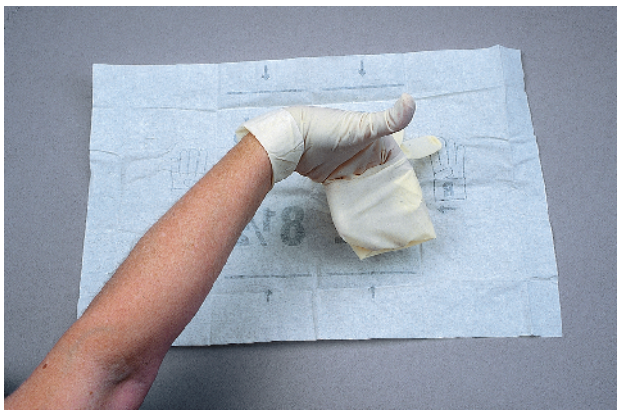
4. Identify right and left glove. Each glove has cuff approximately 5 cm wide. Glove the dominant hand first.	Proper identification of gloves enables efficient, correct gloving. Gloving the dominant hand first improves dexterity.

STEPS	RATIONALE
5. With thumb and first two fingers of the non-dominant hand, grasp edge of the cuff of the glove for dominant hand. Touch only glove's inside surface.	Inner edge of cuff will lie next to skin and is therefore not sterile.
6. Carefully pull glove over dominant hand, leaving cuff and being sure cuff does not roll up wrist. Be sure thumb and fingers are in proper spaces (see illustration).	If the outer surface of the glove touches the skin it is considered contaminated and must be replaced with a sterile glove.



Step 6 Pulling glove over dominant hand.

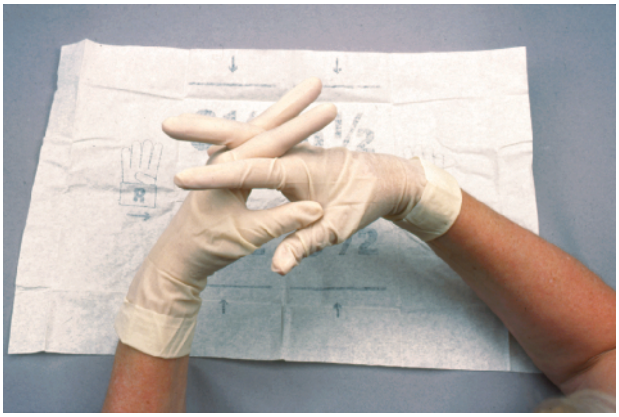
7. With gloved dominant hand, slip the fingers underneath second glove cuff (see illustration).	Cuff protects gloved fingers. Ensures aseptic items only touch aseptic surfaces, thus avoiding contamination.
8. Carefully pull second glove over non-dominant hand. Do not allow the fingers and thumb of the gloved, dominant hand to touch any part of exposed non-dominant hand. Keep the thumb of the dominant hand abducted back (see illustration).	Contact of gloved hand with exposed skin of ungloved hand causes contamination. Unsterile glove must then be removed and replaced with a sterile glove.



Step 7 Slipping fingers under cuff of second glove.

Step 8 Pulling second glove over non-dominant hand.

STEPS	RATIONALE
9. Once the second glove is applied, ensure a smooth fit over fingers and interlock the gloved hands, taking care not to touch the uniform (unless the nurse has donned a sterile gown). The cuffs usually fall down after application. Be sure to touch only sterile sides (see illustration).	Ensures a smooth fit over fingers.



Step 9 Interlocking gloved hands.

GLOVE DISPOSAL

10. Grasp the outside of one cuff with the other gloved hand; avoid touching wrist.	Minimises contamination of underlying skin.
11. Pull the glove off, turning it inside out. Place the removed glove in the remaining gloved hand.	Outside of glove does not touch skin surface.
12. Use the fingers of the bare hand to pull the remaining glove from the cuff over the hand. This will remove the glove and tuck the other glove inside.	Contaminated gloves are contained.
13. Discard in an appropriate infectious waste receptacle.	Used gloves are contaminated with the microbes of the wearer and handled contaminants.
14. Ensure hands are washed thoroughly, or apply an antimicrobial alcohol hand rub immediately after the removal of gloves.	Microorganisms multiply in dark, moist, warm conditions such as on hands when gloves are worn. Gloves may contain microscopic perforations permitting the entry of microbes, which can proliferate on the wearer's hands.

RECORDING AND REPORTING

- It is not necessary to record or report this procedure.

SKILL 25-5

Donning a sterile gown and performing closed gloving

Delegation considerations

The role of the circulating and instrument nurse can be delegated to a surgical technologist or licensed practical nurse in some countries. In Australia, RNs usually perform these roles. Individual healthcare organisations will determine the level of competency required for the role of the circulating and instrument nurse.

Equipment

- Freshly laundered scrub attire
- Appropriate, non-slip, clean shoes or shoes worn with shoe covers
- Hair covering: hat or balaclava (to contain facial hair)
- Two pairs of sterile gloves, the inner pair one size larger, the outer pair being the nurse's correct size
- Surgical mask
- Appropriate eye protection: for infection control. Protective eyewear specific to various types of lasers may also be required
- Sterile gown that complies with national requirements

STEPS	RATIONALE
DONNING A STERILE GOWN	
1. Personnel are required to don protective equipment: freshly laundered scrub attire, appropriate footwear, shoe covers as required, hair covering, appropriate surgical face mask and protective eyewear, prior to gowning and gloving.	Prevents hair and air droplet nuclei from contaminating the aseptic field. Eyewear protects staff from inadvertent splashes of chemicals, blood and body fluids.
2. Perform thorough surgical hand antisepsis (see Skill 25-3).	Removes transient and resident bacteria from fingers, hands and forearms.
3. The circulating nurse aseptically opens a sterile gown pack containing a sterile gown, which is folded inside out.	Outer surface of gown remains sterile.
4. The circulating nurse peels open glove package without contaminating the sterile inner contents. Inner glove package is then placed on sterile outer created by sterile outer wrapper.	Inner packaging and gloves remain sterile, allowing instrument nurse to handle aseptically.
5. Reach down to sterile gown package; lift folded gown directly up and step back away from table.	Provides sufficient space to don gown without contamination.
6. Hold the folded gown away from the scrub suit, locate neckband and allow the remainder of the gown to unfold without being touched.	Outside of gown remains sterile.
7. Use both hands to find the arm holes of the gown and push the hands and arms through simultaneously (see illustration), without allowing the hands to protrude out from the wrist cuffs. Once the gown is pulled on, the sleeves should cover hands.	Clean hands may touch the inside of the gown without contaminating the outer surface. Gown covers hands to prepare for closed gloving.
8. Circulating nurse may reach inside gown to arm seams to bring gown over shoulders. Ask the circulating nurse to securely tie up the back of the gown (see illustration).	Gown must completely enclose underlying garments. The front tie or tab of the gown is handed to another sterile person to 'turn' the gown. This allows a sterile flap to cover the back.

STEPS	RATIONALE
 Step 7 Placing arms in sleeves with hands kept inside cuffs.	 Step 8 Circulating nurse tying back of gown.
CLOSED GLOVING	
1. With hands still covered by the gown sleeves, open the inner package of the larger sized gloves (see illustration). The right glove will be located on the right side of the package, and the left glove will be located on the left side of the package.	Outside of gown remains sterile. Double gloving is recommended to minimise pathogen transmission.
2. With the dominant hand inside gown cuff, pick up the glove for the non-dominant hand by grasping the folded cuff.	Sterile gown touches sterile glove.
3. Extend non-dominant hand and forearm, with the palm facing upwards and place the palm of the glove against the palm of non-dominant hand. Glove fingers will point towards the elbow.	Positions glove for application over cuffed hand, maintaining glove sterility.
4. Grasp back of glove cuff with covered dominant hand. Turn glove cuff over end of non-dominant hand and gown cuff (see illustration).	Seal created by glove cuff over gown prevents exit of microorganisms over operative aseptic field.
5. Grasp the cuff of the glove and the underlying gown sleeve, with the gown cuff still covering dominant hand. Carefully extend fingers into the sterile glove.	
6. Glove the dominant hand in same manner, reversing hands (see illustration). Use gloved non-dominant hand to pull the other glove at the cuff of the gown and extend fingers into the glove. Keep the hand inside sleeve cuff at all times to ensure 'closed gloving'. Ensure fingers are fully extended into both gloves.	When both hands are covered by sterile gloves, fingers can more easily be manipulated into the gloves. A seal is created by the glove cuff over the gown to prevent exit of microorganisms onto the operative aseptic field.

STEPS	RATIONALE
 Step 1 Opening glove package with covered hands.	 Step 4 Applying glove to non-dominant hand as dominant hand remains inside gown cuff.
 Step 6 Applying second glove.	
7. The second outer pair of gloves can be applied by the instrument nurse; the sterile gloved hands touch the second sterile pair of gloves.	
8. Undo the fastener or ties in front of the gown and hand to a gowned and gloved 'sterile' member of the surgical team. They will stand still while the instrument nurse turns around to cover their back, with extended gown flap. The instrument nurse retrieves their gown tie from sterile surgical team member and securely ties the gown (see illustration).	Contact with an unsterile team member can risk contamination of sterile gown or gloves. Gown must completely enclose underlying garments.
9. The scrub team must ensure they either pass each other face to face or back to back, to avoid the unsterile back of the gown contaminating the aseptic field or personnel.	Scrubbed personnel are considered aseptic from mid-chest to waist and elbows to glove tips only. The back of the gown, the area under the arms, the collar, the area below the waist and the sleeves above the elbows are considered unsterile, as the nurse cannot keep these areas in constant view to ensure their sterility.

STEPS	RATIONALE

Step 8 Handing tie to 'sterile' team member.

RECORDING AND REPORTING

- It is not necessary to record or report this procedure.

assisting medical staff during invasive procedures, for example, inserting an epidural catheter, may also don sterile gowns.

A hair cover, mask and eye protection are worn, a surgical hand scrub or rub performed and then a sterile gown and gloves are applied (see Skill 25-5). The nurse picks up the gown from a sterile pack without touching the outside of the packaging. Once donned, only certain parts of the gown are considered aseptic: the gloved fingertips to elbows and the gown front from waist to mid-chest. The back of the gown, the area under the arms, the collar, the area below the waist and the sleeves above the elbows are considered unsterile, as the nurse cannot keep these areas in constant view to ensure their aseptic integrity.

Infection prevention and control for hospital personnel

In Australia and New Zealand, legislation exists to promote the health and safety of people in the workplace through the elimination, reduction and control of hazards, including transmission of infection. Exact details can be found in the relevant national and state Acts and other legislation. Although each state has individual legislation, they share common goals and contain common elements:

- *Exposure control plan*. Institutions must have plans designed to eliminate or minimise employee exposure to hazardous material. The plan must be accessible to all employees and describe how to avoid exposure to infectious agents, including how and when to use protective equipment.
- *Compliance with standard precautions*. Employees must be informed of precautions to prevent contact with blood and body fluids or other potentially infectious material during the routine care of patients. Personal protective equipment must be provided for the employees by the employer.
- *Housekeeping*. Workplaces must be maintained in a clean and sanitary condition. Cleaning and decontamination procedures and routines must be in place.
- *High-risk exposure*. If health workers sustain a needle stick, sharps injury or mucous membrane exposure to blood or other body fluids, the incident should be reported immediately. Evaluation and appropriate preventive treatment for hepatitis B and HIV infection are critical.
- *Training*. Employers must ensure that all employees at risk of occupational exposure participate in a training program that presents the exposure control plan for the institution and specifically explains the measures to be taken by employees for their safety. Written policies and guidelines must be provided for all personnel, outlining prevention and control activities.

Role of the infection control professional

Many hospitals employ professionals, most of whom are registered nurses, with postgraduate qualifications in infection control and prevention. These infection control professionals are responsible for advising hospital personnel and monitoring infections within the hospital. Roles of an infection control professional may include the following:

- provision of staff education on infection prevention and control
- development and review of infection prevention and control policies and procedures
- recommending implementation of appropriate standard and transmission-based precautions

- screening patients for community-acquired infections that may be reportable to the public health department
- consulting with health departments to implement recommendations to prevent and control the spread of infection among personnel, such as TB testing
- gathering statistics regarding the epidemiology of nosocomial or hospital-acquired infections
- notifying the public health department of communicable diseases diagnosed within a hospital
- conferring with all hospital departments to investigate unexpected or clustered infections
- educating patients and families
- identifying infection control risks with equipment and instrumentation
- monitoring antibiotic-resistant organisms in the institution.

An infection control professional can be a valuable resource for helping nurses control and prevent nosocomial infections.

Patient education

Often, patients must learn to use infection control practices at home (Box 25-19). Preventive techniques become almost second nature to nurses who practise them daily, but patients may be less aware of the factors that promote the spread of infection or ways to prevent its transmission. The home environment does not always lend itself to infection prevention, and nurses can help patients adapt to maintain hygienic techniques. Generally, patients in a home care setting have a decreased risk of infection because of decreased exposure to resistant organisms, such as those found in a hospital.

When patients are at home, nurses determine their ability to comply with infection control practices through education about infection and techniques to prevent or control its spread.

Topics in a teaching session include:

- patient susceptibility to infection
- the chain of infection, with specific reference to means of transmission
- hygiene practices to minimise organism growth and spread, emphasising hand hygiene
- preventive health care, for example, immunisation, nutrition, diet and exercise
- use of antibiotics and how to decrease the risk of antibiotic-resistant infection
- appropriate methods for handling and storing food
- identifying family members who are at risk of acquiring infection, and prevention strategies.

It is important to involve family members who care for patients in the teaching plan.

BOX 25-19 Client teaching for infection control

Objective

- Patient will assume self-care using proper infection control techniques.

Teaching strategies

- Instruct the patient about decontaminating equipment using soap and water and disinfecting with an appropriate disinfectant.
- Demonstrate proper handwashing, and explain rationale, e.g. before and after all treatments and following contact with infected body fluids.
- Instruct the patient about signs and symptoms of wound infection.
- Explain the importance of preparing adequate formula no longer than 8 hours in advance for patients who receive commercially prepared enteral tube feedings at home.
- Explain to the patient how contaminated enteral feeding can cause infections.
- Demonstrate how to cleanse their stoma site with mild soap and water daily and how to dry the area well.
- Instruct the patient to place contaminated dressings and other disposable items containing infectious body fluids in impervious plastic bags and securely tie them off.
- Instruct the patient to place used needles and other contaminated sharp items into a commercially available sharps container – these are usually supplied by local councils or community health nurses.
- Clean noticeably soiled sheets separately from other laundry. Wash in water that is as hot as possible. Add 1 cup of colourfast bleach to the detergent. Ideally dry outside in the sun, as the ultraviolet rays of sunlight have an antimicrobial effect. Otherwise, set the clothes dryer temperature as high as fabric will allow.

Evaluation

- Ask patient or family member to describe and demonstrate the techniques you have explained to reduce transmission of infection.
- Have patient demonstrate various techniques discussed.
- Ask patient to explain the signs and symptoms of infection and their plan of action should an infection arise.

EVALUATING IMPACTS AND OUTCOMES

The success of infection control techniques is measured by achievement of the goals for reducing the risk of or preventing infection. A comparison of the patient's response (absence of fever or development of wound drainage) with expected outcomes determines the success of nursing interventions (Figure 25-12) and whether interventions should be revised or eliminated. The ability to correctly assess wound healing and conduct a physical assessment of body systems is an important evaluation skill. The nurse closely monitors a patient for signs and symptoms of infection. For example, a patient who has undergone a surgical procedure is at risk of a wound infection at the surgical site, as well as at other invasive sites, such as drainage tube sites or arterial line sites. The patient is also at risk of developing a respiratory tract infection due to decreased mobility, or a UTI if an indwelling catheter is in situ. All invasive and surgical sites should be carefully monitored for signs of infection such as redness, swelling or purulent drainage. Temperature, breath sounds and sputum character should be

Acute Management of Suspected Meningococcal Disease Clinical Pathway

Facility: .....

(Affix identification label here)

URN:

Family name:

Given name(s):

Address:

Date of birth: Sex: ☐ M ☐ F ☐ I

Clinical Pathways never replace clinical judgement. Care outlined in this Pathway ***must be varied*** if it is not clinically appropriate for the individual patient.

Signs and Symptoms suggestive of meningococcal disease on presentation may or may not include (tick as appropriate):

☐ Photophobia ☐ Neck stiffness ☐ Headache ☐ Depressed consciousness
☐ Fever ☐ Hypotension ☐ Petechial non-blanching rash (may not be present)

Early Management	Completed	Initial	Time	Date
Move to appropriate resuscitation room				
Perform Primary Survey (ABCD)				
Document vital signs - temp, HR, RR, BP, SpO_2, central capillary refill time				
Notify senior medical officer immediately				
Gain IV or IO access using aseptic technique				
Collect blood for the following tests: • Meningococcal **PCR:** Adult: collect 4mL in a mauve top tube Child: collect 1mL in a paediatric EDTA pink top tube • FBC, coagulation tests, LFT, UE, glucose • Collect blood cultures using an aseptic technique				
Commence fluid resuscitation as appropriate within 30 minutes				
Commence recommended antibiotics within 30 minutes (see table below)				
If clinical picture is suggestive of meningitis, follow **meningitis flowchart** (see page 2) (note contraindications to a lumbar puncture)				
If clinical picture is suggestive of meningococcal sepsis seek senior medical advice immediately				
For retrieval, contact RSQ (Retrieval Services Queensland) 1300 799 127				
Notify public health unit (PHU) within 6 hours (see PHU contact details below)				

For clinical advice

Child: If facility is level 6 contact ICU or ≤ level 5 call RSQ

Adult: Contact medical officer at relevant regional or tertiary facility. If unavailable and pt likely to require retrieval contact RSQ 1300 799 127

Recommended Early Empirical Antibiotic Treatment

- **Start antibiotic therapy within 30 minutes**
- **This should not be delayed awaiting results of diagnostic tests or fluid resuscitation**
- **Discuss antibiotic choice with senior clinician**

Age Group	Drug		Route	Dose / Frequency
Neonates and infants less than 3 months	Ampicillin	plus	IV	50mg/kg, 6 hourly
	cefOTAXIME		IV	50mg/kg, 6 hourly
Children 3 months or more	cefTRIAXONE	or	IV	50mg/kg (up to 2g), 12 hourly
	cefOTAXIME		IV	50mg/kg (up to 2g), 6 hourly
Adults	cefTRIAXONE	or	IV	2g, 12 hourly
	cefOTAXIME		IV	2g, 6 hourly

These recommendations are based on those in Therapeutic Guidelines: Antibiotic, along with recent state and national antibiotic sensitivity profiles of bacterial isolates

Emergency Management of Children with Meningitis

Assessment

Child presents to emergency service with clinical features suggesting meningitis

Assess Severity
Consider pre-hospital management given

Consider differential diagnoses:
- viral encephalitis
- intra-cranial collections
- eosinophilic meningitis
- acute disseminated encephalomyelitis (ADEM)
- "mimics" of meningitis, e.g. other infectious diseases.

STABLE

Is an LP contraindicated?* (Y / N)

***Contraindications for LP:**
- child unstable
- altered LOC or obtundation
- seizures
- suspicion of space occupying lesion or ↑ ICP
- localised infection in the lumbar region
- coagulopathy

Can LP be performed within 30 mins? (N / Y)

UNSTABLE
- altered level of consciousness or obtundation
- signs of shock
- coagulopathy
- refractory seizures

Emergency Management (Resuscitate using **ABCD**)
Call emergency &/or paediatric consultant
- **A** Provide high-flow oxygen
- **B** Support ventilation (BVM)
- **B** Consider ETT intubation if not responding
- **C** Obtain IV or IO access
- **C** Give IV fluid boluses 20mL/kg 0.9% NaCl as required
- **D** Check BSL and give IV 10% Dextrose (2mL/kg) as required

Other treatment:
- Blood cultures
- Meningococcal PCR (blood) if meningococcal disease suspected
- Administer Dexamethasone plus empirical IV antibiotics
- Add IV Acyclovir if clinical suspicion of HSV meningoencephalitis#

Investigation and treatment

Perform LP
- Add viral studies depending on clinical suspicion
- Blood cultures
- Meningococcal PCR (CSF + blood) if meningococcal disease suspected)

- Administer Dexamethasone plus empirical IV antibiotics
- Add IV Acyclovir if clinical suspicion of HSV meningoencephalitis#

Delay LP
Within 30 mins of assessment:
- Call emergency &/or paediatric senior doctor
- Blood cultures and if meningococcal disease suspected perform meningococcal PCR
- Administer Dexamethasone plus empirical IV antibiotics
- Add IV Acyclovir if clinical suspicion of HSV meningoencephalitis#

Review

Review CSF results
Negative / Positive

Is an LP contraindicated?* (Y)

Improvement?

***Contraindications for LP:**
- child unstable
- altered LOC or obtundation
- seizures
- suspicion of space occupying lesion or ↑ ICP
- localised infection in the lumbar region
- coagulopathy

Continue observation in ED or SSU

Disposition

Meets discharge criteria? (N / Y)

Discharge

Admit to children's inpatient service

Arrange transfer to PICU (Level ≤ 5 call RSQ)

Medications

Dexamethasone (IV)	**Children ≥ 3 months:** 0.15mg/kg (up to 10mg), 6 hourly	
Acyclovir (IV) If HSV meningoencephalitis suspected	**Neonates:**	20mg/kg, 8 hourly
	Children:	10mg/kg, 8 hourly
	Adults:	10mg/kg, 8 hourly

Clinical features of meningitis (at any age)
- Fever
- Vomiting and/or nausea
- Lethargy or irritability
- Photophobia and/or headaches
- Anorexia
- Nuchal rigidity (often not present, especially in young children and infants
- Positive Kernig's or Brudzinski's sign
- Altered mental status
- Shock
- Seizures
- Meningeal signs
- Focal neurological deficit
- Petechial rash

Additional clinical features of meningitis in infants less than 3 months
- Bulging fontanelle
- High pitched cry
- Poor feeding
- Apnoea
- Seizures

#Consider HSV meningoencephalitis if a history of maternal HSV infection and predominance of lymphocytes in the CSF

monitored for changes and signs of infection. Laboratory test results are reviewed; for example, leucocytes in the urine may indicate a UTI. The absence of signs or symptoms of infection is the optimal outcome of infection prevention and monitoring activities.

The patient at risk of infection must understand measures implemented to reduce or prevent microorganism growth and spread. Patients or family members should be provided with the opportunity to discuss infection control measures and their ability to comply with therapy. The nurse may determine whether patients require additional information or reinforcement of information given previously.

The nurse documents the patient's response to therapies implemented for infection control. A clear description of any signs and symptoms of systemic or localised infection is necessary to provide a baseline for comparative evaluation. The efficacy of interventions that reduce infection should be reported.

Key concepts

- Hand hygiene is the most important technique in preventing and controlling transmission of infection.
- The potential for microorganisms to cause disease depends on the number of organisms, their virulence, their ability to enter and survive in a host and susceptibility of the host.
- Nurses need to recognise the difference between signs of local inflammation and infection.
- Microorganisms are transmitted by direct and indirect contact, airborne spread, vectors and contaminated articles.
- Increasing age, poor nutrition, stress, inherited conditions, chronic disease, medical conditions and medical treatments can compromise the immune response and may increase a person's susceptibility to infection.
- The major sites for healthcare-associated infections (HAIs) include the urinary and respiratory tracts, bloodstream and surgical or traumatic wounds.
- Invasive procedures, medical therapies, long hospitalisation and contact with healthcare personnel increase a patient's risk of acquiring HAIs.
- Patients in an intensive care unit are at greater risk of infection compared with other patients because of the prevalent use of antibiotics and patients' increased exposure to invasive procedures.
- Isolation practices may prevent personnel and patients from acquiring infections and may prevent the transmission of microorganisms or cross-infection to others.
- Patients confined to their rooms are at risk of loneliness, anxiety and depression because of the restricted and socially isolated environment.
- Standard precautions are implemented for all patients, based on the assumption that all patients are potentially infectious. Hand hygiene and vigilant use of personal protective equipment is essential for standard precautions.
- Thorough cleansing requires mechanical removal of all foreign material from an object or area.
- If a procedure involves breaching the skin integrity or an invasive procedure entering a body cavity (normally free of microorganisms), aseptic practices must be followed.
- An infection control professional monitors the incidence of infection in an institution and provides both educational and consultative services to maintain infection prevention.

CHAPTER

26

Maintaining skin integrity and undertaking wound care

Damian Wilson and Michelle Gibb

Learning outcomes

Mastery of content will enable you to:

- describe the anatomy and physiology of the skin
- discuss normal phases of wound healing
- describe the modes of wound healing
- discuss abnormal wound healing
- outline the factors affecting wound healing
- conduct a head-to-toe skin assessment and pressure injury risk assessment
- describe the differences between nursing care of acute and chronic wounds
- describe the principles of wound assessment and management
- discuss the assessment, management and prevention strategies for common wound types.

KEY TERMS

Subcutaneous layer, p. 682
Venous leg ulcers, p. 737
Wound, p. 687

The skin, or the integumentary system, is the body's largest organ. It comprises 15% of the total bodyweight, has an area of approximately 7600 square centimetres and receives one-third of circulating blood volume in the average adult (Shores 2007).

Maintaining skin integrity is a complex process, one that is often taken for granted until damage occurs. As is shown in Table 26-1, the skin has to perform many different functions. Having a good understanding of the layers of the skin and the functions of normal skin is important so that you are able to recognise risk factors for poor skin integrity and undertake actions to prevent skin breakdown or to improve wound-healing outcomes.

The following *Clinical example* will be used throughout this chapter for you to reflect on the key concepts and how they apply to nursing practice.

• CRITICAL REFLECTION POINT

What factors in the *Clinical example* below might have contributed to the development of this skin tear?

CLINICAL EXAMPLE

Mr Bukowski, aged 78 years, is a widower who lives at home; his daughter lives nearby. Mr Bukowski usually uses a wheelie walker to mobilise because he often becomes unsteady on his feet. One day he decides to leave his wheelie walker inside when he goes to check his mailbox, feeling confident that he won't be walking very far. On his way to the mailbox he trips and falls, sustaining a large skin tear on his left arm.

When he gets back inside he applies some paper towel to stop the bleeding, knowing that his daughter is coming over for morning tea and can fix it up then. A few hours later, Mr Bukowski's daughter arrives and decides to take her father to his general practice clinic because she isn't sure what to do.

On arrival at the clinic Mr Bukowski is taken straight through to the treatment room to be seen by the practice nurse. This is not the first time that he has sustained skin tears. On examination, the registered nurse notices that Mr Bukowski has multiple skin tears on the left forearm with extensive bruising (see Figure 26-1 below). She helps Mr Bukowski to lie down on the examination couch and goes to collect equipment and to take a look at his health records.

Mr Bukowski has a past medical history of heart failure, chronic obstructive pulmonary disease and hypertension and he has had a deep vein thrombosis (DVT) of his left leg. His medications include aspirin, salbutamol inhaler, lisinopril, carvedilol, furosemide and a multivitamin. Mr Bukowski currently smokes 15 cigarettes a day and has done so ever since leaving school at the age of 16.

Normal integument

The thickness of the skin varies depending on location, with skin thickness ranging from 0.05 to 0.3 mm. The thickest skin is on the soles of the feet and the palms of the hands. The thicker the skin, the better it is able to withstand injury. The skin consists of three layers (see Figure 26-2):

- **epidermis** (outermost layer of the skin)
- **dermis** (middle layer)
- **subcutaneous layer** (bottom layer of the skin).

The epidermis and dermis are separated by a basement membrane, which is often referred to as the *dermal–epidermal junction*. The epidermis, or outer layer, is avascular and approximately 0.04 mm thick, and has several layers depending on the body location. The *stratum corneum* is the thin, outermost layer of the epidermis. It consists of flattened, dead, keratinised cells. The cells originate from the epidermal layer called the *stratum basale*. Cells in the stratum basale divide, proliferate and migrate towards the epidermal surface.

TABLE 26-1 Functions of the skin

Function of the skin	Explanation
Protection	The skin provides a covering that is designed to protect us from damage or injury
Temperature control (thermoregulation)	Sweat evaporates and cools the skin. Blood vessels also dilate and constrict to prevent heat loss and maintain a stable body temperature
Sensation and communication	Nerve endings and receptors are found in the skin and these help us to respond to touch, pain, heat or cold
Metabolism	The skin helps us to metabolise vitamin D through exposure of the skin to sunlight

Figure 26-1 Skin tear on Mr Bukowski's arm.

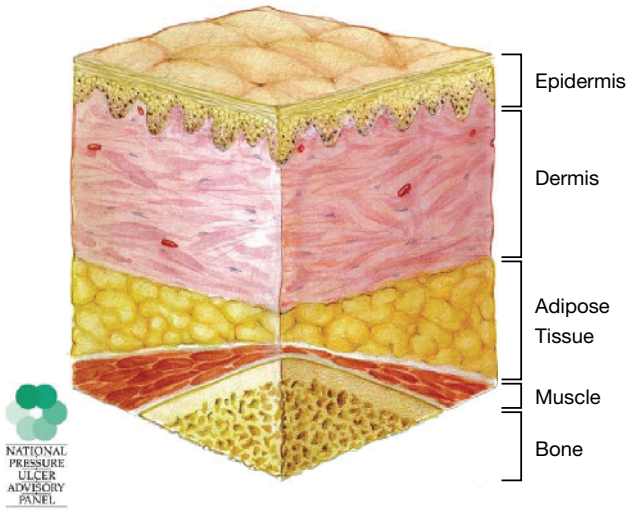

Figure 26-2 Layers of the skin.

© National Pressure Ulcer Advisory Panel (NPUAP). Used with permission.

After cells reach the stratum corneum, they flatten and die. This constant movement ensures replacement of surface cells sloughed off during normal desquamation. The thin stratum corneum protects underlying cells and tissues from dehydration and prevents entrance of certain chemical agents. However, the stratum corneum does allow evaporation of water from the skin and permits absorption of certain topically applied medications.

The dermis is the middle layer of the skin, which provides the tensile strength, mechanical support and protection to the underlying muscles, bones and organs. It differs from the epidermis in that it contains connective tissue and few skin cells. Collagen (a tough, fibrous protein), blood vessels and nerves are composed of it. **Fibroblasts**, which are responsible for collagen formation, are the only distinctive cell type within the dermis.

The *subcutaneous layer* is the thickest layer of the skin; it provides a supporting framework for the skin and is an attachment and protective layer for underlying organs and structures. It is made up of adipose and connective tissue and blood vessels. The subcutaneous layer of the skin helps to regulate the temperature of the skin and store lipids.

Understanding the integument's layers is essential in order to identify factors affecting the wound-healing process. The epidermis functions to resurface wounds and restore the barrier against invading organisms. The dermis responds to restore the structural integrity (collagen) and the physical properties of the skin. Even though a wound may close in the upper epidermal layer, the patient is at risk of infection, circulatory impairment and tissue breakdown if the underlying dermis fails to heal.

Skin changes associated with ageing

Skin problems are common among older people, so it is important to be able to recognise the characteristics of ageing skin (Lawton 2007). There are two types of skin ageing: *intrinsic ageing* – alterations in the structure and function of the skin due to normal maturity which occurs in all people; and *extrinsic ageing* – due to constant or repeated exposure to environmental elements such as the sun. A summary of the normal intrinsic changes in ageing skin can be found in Table 26-2.

TABLE 26-2 Skin changes associated with ageing

Type of problem	Explanation	Example
Decreased sensory perception	This means when an older person injures their skin they may not be aware they have done so	When an older person gets a skin tear, they may not realise that they have injured their skin until they see the injured body part  Skin tear

continued

TABLE 26-2 ***continued***

Type of problem	Explanation	Example
Increased dryness	The skin becomes drier and less supple because sebaceous and sweat gland activity decreases as you age	This is why many older people complain of dry, itchy skin
The skin becomes thinner and less elastic	The skin decreases in turgor or thickness because of reduced collagen and elastic fibre production. The collagen present becomes thinner and, when combined with less adipose or fatty tissue, the skin support structure is compromised and skin wrinkling occurs. Such skin is subject to friction and shearing trauma The skin on the back of the hands becomes thin and transparent while the skin on the back of the neck has a furrowed appearance	Ageing skin has more risk of skin tears and bruises and lesions as a result of thinner, less flexible skin and a lifetime of exposure to the sun  Decreased tissue turgor.
Decreased vitamin D synthesis	This is often due to inadequate exposure to sunlight, decreased dietary intake or a medical condition	It may take longer for skin to repair and older people have an increased risk of fractures
Reduction in immune response	Cells which trigger the immune system are slower to respond and less effective	Increased risk of infection for even minor injuries to the skin
Decrease in temperature control or thermoregulatory functioning	Older people are less able to regulate their body temperature due to changes in environmental temperature	This is why some older people complain of being cold even on a hot day
Vascularity or blood supply of the skin is diminished	Blood vessels in the dermis become more fragile and there is decreased peripheral circulation	This is why older people bruise more easily and may explain why fingernails lose their lustre and toenails thicken
Hormonal changes	Facial hair in males decreases and yet increases in females. Pubic and axillary hair thins, straightens, greys and lessens because of reduced hormonal functioning. Both males and females experience overall hair loss from the trunk and extremities. Hair loss on the lower limbs may also occur when peripheral vascular disease is present Hormonal changes also lead to drier skin	
Changes in hair colour and balding	Scalp hair greys and balding occurs because of a reduction in the number and functioning of melanocytes, the cells which give hair and skin their colour The density and rate of scalp hair growth also declines and the size of hair follicles change leading to baldness	Hair colour and wrinkled skin
The amount of subcutaneous tissue decreases	The amount of subcutaneous tissue decreases, particularly in the extremities, giving joints and bony prominences a sharp, angular appearance. The hollows in the thoracic (chest), axillary (under the arms) and supraclavicular (collar bone) regions deepen	 Loss of subcutaneous tissue.

Principles of skin assessment

A comprehensive assessment of the skin is essential, as a wide range of health conditions manifest in changes in the skin and can provide valuable diagnostic clues to the underlying disease process. Furthermore, recognising the characteristics of normal skin helps you to identify those at risk for compromised skin integrity. When undertaking a skin assessment, there are three important steps, outlined below.

Step 1. Prepare the environment

First, you need to create an environment that is suitable for conducting an assessment by ensuring:

- that the room is quiet, private and has a stable temperature; this helps to reduce anxiety
- adequate lighting, so that you can see the colour of the skin or any skin changes
- adequate exposure of the skin, especially areas not usually inspected such as the buttocks, axillae, back of thighs and feet.

Step 2. Gather relevant information

Second, you need to explain carefully what you are going to do and the purpose of assessing the skin. Typically, you obtain a history using a framework such as that shown in Table 26-3.

Step 3. Observe and feel the skin

The final step is to look at the skin (*inspection*) and feel (*palpation*) if there are any changes (Table 26-4). When conducting the physical assessment, proceed from head-to-toe and compare each body region for symmetry

TABLE 26-3 Skin assessment

Information required	Questions the nurse might ask the patient
Past medical history	*Tell me what other health conditions you may have.* When conducting the health assessment and a problem with the skin is identified, it is important to determine usual skin conditions, onset of any problems, changes since onset, specific known causes, alleviating factors, psychological reaction to skin changes, previous trauma and if the patient has had any surgery or prior disease that involves the skin
Medications (topical, systemic, over-the-counter)	*Are you taking any medications that might affect your skin?* For example, medications might include anticoagulants or steroids (taken for conditions such as rheumatoid arthritis)
Exposure to environmental or occupational hazards	*What sort of work do you do?* *Were you exposed to the sun a lot when you were younger?*
Substance abuse	*Do you smoke or have you ever smoked? How much did you smoke? When did you stop smoking?* *How much alcohol do you drink daily?* *Have you ever used illicit drugs?* Example: Fingernails are often stained yellow by nicotine exposure
Recent physiological or psychological stress	*Have you experienced a recent stressful event? Have you been unwell recently? How does this affect you?*
Hair, nail and skin care habits	*What methods do you use for cleansing your skin? How often do you moisturise? How do you dry your skin?* Example: Many soaps, oils, lotions, cosmetics and home remedies have preservatives that can irritate the skin and make it itchy or inflamed
Skin self-examination	*How often do you look at your skin? Are you able to see your skin properly? Can you reach to dry between your toes?*
Problems with the skin	*Have you noticed any changes in your skin (e.g. dryness, rashes, lumps, amount of perspiration)? When did the symptoms occur? Are these symptoms new or an old problem? What area of the body is affected (i.e. skin folds, localised or generalised)?* *Are there any associated symptoms (e.g. fever, relationship to stress or leisure activities)? What have you been doing for the problem?* Example: Eczema is a common problem that is often made worse by some creams and may be a lifetime problem for that person. Careful questioning will help to determine what the person has been doing to treat the condition, what works for them and what doesn't work to treat the problem

TABLE 26-4 Observation of the skin

Observation	Explanation
Skin temperature	If the skin around a wound is very hot to touch compared with the surrounding skin, this may indicate an infection If the feet are abnormally cold to touch, this may indicate a problem with circulation
Skin texture	The texture of the skin may be described as *rough*, *coarse*, *fine*, *flaky*, *scaly* or *smooth*. Rough skin may indicate that the skin is very dry and may occur normally on exposed areas such as the elbows and soles of the feet
Skin colour	The colour of the skin can indicate a person's general wellbeing Changes in colour are best obtained from the lips, mucous membranes of the mouth, earlobes, finger and toe nails and the extremities The colour of the skin indicates the degree of blood supply and temperature of the skin, and oxygen and fluid supply to the skin. Colour of the skin varies depending on the amount of melanin in the cells and with blood supply. Skin colour can be masked by cosmetics or tattoos Colour changes associated with the skin can be described as: • *erythema* (redness) due to vasodilation associated with blushing, heat, inflammation, fever, alcohol ingestion, extreme cold and heat and hot flushes • *pallor* (whiteness) due to vasoconstriction associated with peripheral arterial disease, or due to decreased oxygenation of blood from decreased haemoglobin as seen in anaemia, or loss of melanin as in vitiligo • *cyanosis* (bluish) due to deoxygenated haemoglobin noticed in earlobes, lips, mucous membranes of the mouth, nail beds; may be seen in cardiac or respiratory disease • *jaundice* (yellow) due to increased bile pigment in the blood distributed in the skin and mucous membranes and sclera of the eye, as seen in liver disease, obstruction of bile ducts, chronic uraemia and rapid haemolysis • *brownish* due to increased melanin deposits, which is normal in darker-skin-toned individuals and is also found in ageing, sunburn, anterior pituitary, adrenal cortex and liver diseases
Skin changes	The presence of growths, discolouration or changes in pigmentation, infections, broken areas, old scars, tattoos, rashes, eczema, dermatitis, senile purpura, cherry angiomas or thickened skin may be normal changes associated with ageing, indicate a person's risk of a wound recurring or indicate the presence of a clinical condition For example, changes in pigmentation may indicate a condition such as vitiligo, Addison's disease, arsenic toxicity or uraemia. Fungal infections such as tinea versicolor can cause pigmentation changes in the affected area. Pigmentation changes in naevi or moles may indicate the presence of skin cancers
Oedema	Assessment of swelling in the tissues can be assessed by location and degree. Oedema is graded as: + slight indentation with normal anatomical contours ++ deeper indentation which lasts longer than + with fairly normal contours +++ deep indentation which remains after several seconds with obvious swelling ++++ deep indentation that remains for minutes with frank swelling
Turgor (resilience and elasticity of tissue)	Skin turgor can give an indication of the person's nutrition and hydration status When pinched between the thumb and index finger for a few seconds, normal well-hydrated skin will snap back into place when released Dehydrated skin, particularly in an elderly patient, will form a small tent shape before gradually resuming its normal position
Hair distribution, colour and quantity (thick, thin, balding)	Uneven hair loss may indicate a person's psychological state For example, a person may unconsciously pull their hair out if they are traumatised. Excessive hair growth may be related to hormonal changes
Nail length, colour, configuration, symmetry and cleanliness	The colour of a person's fingernails may indicate certain problems For example, fingernails stained yellow indicate nicotine use. Blue fingernails can indicate a problem with circulation such as cardiac or respiratory disease In addition to nail-bed colour, check for clubbing and assess capillary refill. Capillary refill time can be affected by environmental conditions, vasoconstriction from smoking or peripheral oedema. Finger clubbing can be an indication of chronic tissue hypoxia
Lesions of the skin	Lesions are classified by type, colour, size, shape and configuration, texture, effect of pressure, arrangement, distribution and variety

(i.e. right side with left side to differentiate structural from pathological changes). If lesions are identified, palpate them for density, induration (hardening or thickening of tissues) and tenderness.

Now that you have a better understanding of how to assess the skin, you are ready to learn more about some strategies you can use to maintain skin integrity and prevent many skin problems from occurring. Review the suggested evidence-based strategies summarised in Table 26-5.

• CRITICAL REFLECTION POINT

As you read the next section, think about Mr Bukowski's skin tear:

- **Is this an acute or a chronic wound?**
- **How would you classify this skin tear?**
- **What is the phase of wound healing?**
- **Is this wound healing by primary or secondary intention?**

Wound classification

A **wound** can be defined as an injury to the skin or underlying structures that may or may not result in a loss of skin integrity and whereby physiological function of the tissue is impaired (Carville 2007). Although at first a wound may look like any other, it is imperative to know that *all wounds are not the same*. Understanding the aetiology of a wound is important, because the treatment varies depending on the underlying disease process (Ratliff 2006). Common wound types are presented in Table 26-6.

There are many ways to classify wounds. Wound classification systems describe the status of skin integrity, the cause of the wound, severity or extent of tissue injury or damage, cleanliness of the wound or descriptive qualities of the wound, such as colour. Wound classifications help you to understand the risks associated with a wound and implications for its care.

Wounds can be classified as either *acute* (e.g. surgical incisions, lacerations, blisters, abrasions) or *chronic* (e.g. leg ulcers, pressure ulcers, malignant or fungating wounds). Acute wounds heal fairly quickly (usually within 14 days), without complications and with limited interventions. They follow the normal healing process in an orderly and timely way (Celik 2007). Examples of some acute wounds are those caused by trauma or surgery. A chronic wound is a wound that has failed to proceed through an orderly and timely process for healing and whereby healing is delayed, repair fails to occur, and return to normal function is slowed (Harvey 2005).

TABLE 26-5 Preserving skin integrity

Prevention strategies	Explanation
Assess skin regularly	The nurse should assess the skin regularly so that correct and suitable preventive measures can be put in place and evaluated
Use emollient soap substitutes for washing or cleansing	This reduces the drying effects of soap and water Emollients restore the natural barrier function of the skin by replacing lost water and provide a protective film over the surface of the skin. Emollients include creams, ointments, lotions, bath oils and soap substitutes
Avoid products that may irritate the skin	Products such as perfumes, bubble baths and talcum powder can irritate the skin and cause itching or discomfort
Dry the skin thoroughly	Drying should involve a light patting and not rubbing as this may lead to abrasion and/or weakening of the skin If skin is left damp, it is vulnerable to excess drying from the environment and at risk of fungal and bacterial contamination
Apply a pH-neutral moisturiser and/or barrier cream at least twice daily	This will help to prevent dry skin A pH-neutral moisturiser is one that is neither acid or alkaline; it has a pH between 6.5 and 7.5 A barrier preparation can be a cream, ointment or spray which contains substances that repel water, such as silicone or zinc oxide
When applying moisturiser and/or barrier cream, follow the direction of body hair and gently smooth into the skin	Rubbing can cause irritation. Rubbing moisturiser against the direction of hair growth increases the risk of an infection occurring in the hair follicles
Encourage patient to wear loose, cotton clothing where possible	This helps the skin to breathe better and reduces the risk of sweating from nylon fabrics The use of limb protectors can also protect fragile limbs

TABLE 26-6 Common wound types

Wound type	Causes	Examples
Traumatic wounds	*Bruise or contusion:* injury to the underlying tissue but the skin remains intact. Usually caused by a blunt force against a body part *Abrasion:* superficial damage to the epidermis and dermis involving scraping or rubbing of the skin's surface *Laceration:* the tissues are torn with irregular wound edges	 Blisters  Bruises  Abrasions  Lacerations Bites

continued

TABLE 26-6 *continued*

Wound type	Causes	Examples
Thermal injuries	*Burn:* an injury caused by thermal, electrical, chemical or radiation mechanism	 Scald
Wounds inadvertently caused by a clinician, medical treatment or diagnostic procedure (iatrogenic)	*Incision:* caused by a cutting instrument	 Surgical incisions Biopsies Split skin grafts Radiation injury
Wounds caused by disease	*Tumour:* a malignant or benign growth	

TABLE 26-7 Phases of wound healing

Phase	Explanation
Vascular response	Initial bleeding, which should stop within 10 minutes
Inflammation	This stage lasts for around 3 days and is a normal process of wound healing. Signs include redness, heat, swelling, pain and functional disturbance 

continued

TABLE 26-7 ***continued***

Proliferation	This phase lasts for around 28 days. During this phase, the wound bed tissue experiences these states: 1. Granulation or new tissue growth occurs. Granulation tissue is characterised by the appearance of red, bumpy, shiny, granular and slightly uneven tissue in the wound bed as new blood vessels start to grow 2. Wound edges come together (i.e. contraction) 3. Epithelial tissue covers the wound bed or appears in patches throughout the wound bed as it starts to heal  Bumpy granulation tissue  Granulation tissue  Contraction of wound edges and islands of new epithelial tissue
Maturation	This is the final phase of wound healing and describes the process of the healed tissue regaining its previous levels of functional ability. This phase can last for longer than 1 year. Full return of strength in that tissue is never quite achieved. Complications such as contractures or excessive scar formation may occur during this phase

Phases of wound healing

The wound-healing process involves a complex series of cellular and biochemical events that act upon damaged tissues. These are interlinked and dependent on one another in a continuing process of regeneration and repair (Schultz et al 2003). Wound healing tends to follow a well-defined process involving four main stages:

1. Haemostasis
2. Inflammation
3. Proliferation or reconstruction
4. Maturation or remodelling of the scar tissue.

These stages of wound healing overlap and the entire process can last for many months.

Haemostasis

Immediately after injury, platelets initiate the wound-healing process by releasing a number of growth factors that rapidly disperse from the wound, drawing inflammatory cells to the area of injury. **Haemostasis** is comprised of three components:

1. *Vasoconstriction*, whereby bleeding is arrested by constriction of the arteries, arterioles and capillaries in or close to the wound.
2. *Formation of a platelet plug*, whereby the damaged endothelium of vessels exposes collagen fibres causing the platelets to stick to the collagen fibres in the wall of the vessels and to each other, resulting in a mechanical plug by the process of aggregation. The platelets release chemicals, including serotonin and prostaglandins, which enhance the vascular constriction and further reduce blood flow. Phospholipids and adenosine diphosphate (ADP) are also released and attract more platelets to the area, which increases the size of the platelet plug.
3. *A biochemical response* is then activated, initiating the clotting cascade. This is a complex process which sees the development of a clot, the retraction and compaction of the clot which causes the wound edges to come together and the breakdown of the clot by fibrinolysis.

Inflammation (0–3 days)

The inflammation phase of wound healing is a vascular and cellular response that removes microbes, foreign bodies and dying tissue in preparation for wound healing (Flanagan 1997). The inflammatory phase is characterised by vasodilation, increased capillary permeability, complement activation and polymorphonuclear leucocytes (PMN) and macrophage migration to the wound (Flanagan 1997, Traversa & Sussman 2001). The increase in blood flow into the wounded area produces erythema, oedema, heat and discomfort such as a throbbing sensation.

Macrophages regulate the events in wound healing by attracting further macrophages and induce the

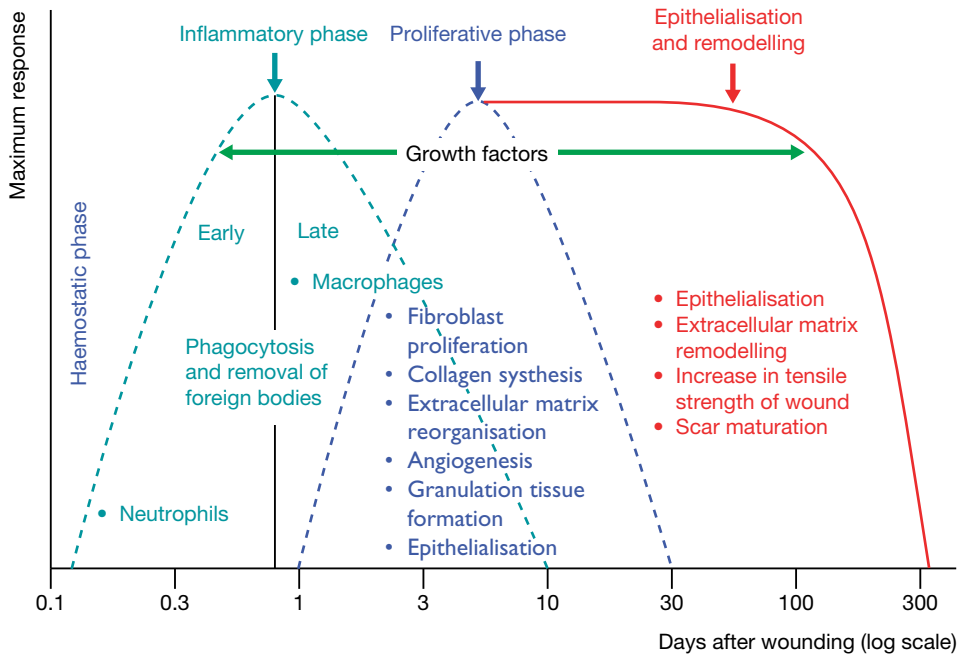

Figure 26-3 The four phases of wound healing.

Redrawn from Enoch S, Grey JE, Harding KG 2006 Recent advances and emerging treatments. Br Med J 332(7547):962–5.

proliferation of fibroblasts and endothelial cells. Macrophages release growth factors which stimulate endothelial cells lining the walls of capillaries to close the wounded area, and then divide and branch out to form new capillary loops (Flanagan 1997). Fibroblasts migrate along fibrin threads and synthesise collagen and other extracellular matrix (ECM) molecules to support new cells and fragile capillary buds which appear during angiogenesis. This continues until newly formed **granulation tissue** joins up with intact blood vessels (arterioles) to form a network of vessels that fill the wound bed (Flanagan 1997).

Proliferation (2–24 days)

The proliferation phase is characterised by extensive growth of epithelial cells, deposition by fibroblasts of collagen fibres in random patterns to form the ECM and ground substance and continued growth of blood vessels (Schulz et al 2003). Fibroblasts and endothelial cells proliferate in response to growth factors, including platelet-derived growth factor (PDGF) and transforming growth factor B (TGF-B), and cytokines which are released from macrophages, platelets and mesenchymal cells or have been stored in the fibrin clot (Krishnamoorthy et al 2001, Traversa & Sussman 2001). Macrophage-released growth factors produce glycosaminoglycans (GAGs). These include hyaluronic acid, chondroitin-4-sulfate, dermatan sulfate and heparin sulfate, which cross-link to protein and are termed proteoglycans. These form an amorphous gel where collagen fibres deposit and aggregate (Traversa & Sussman 2001). The ground substance secreted by fibroblasts determines the compliance, flexibility and integrity of the dermis. It provides compressive strength and support and density to tissue, reduces friction between collagen fibres during tissue stress or strain and protects tissue from invasion by microorganisms (McCulloch et al 1995).

During the proliferation phase, new capillary development is seen as ruddy, bumpy granulation tissue at the base of a wound, and wound contraction occurs. Epithelial cell migration occurs over the granulated wound bed. Epithelial cells migrate from surrounding wound edges or from hair follicles, sweat or sebaceous glands in the wound and appear as a thin, translucent film across the wound bed. At this stage, the epithelial tissue is very fragile and easily removed, even by gentle cleansing. Migration of epithelial cells ceases when the wound is covered; then mitosis thickens the epithelium to the four to five layers needed to form the epidermis.

Maturation (24 days to 1 year)

The combination of fibronectin and collagen forms the ECM essential for the development of granulation tissue that eventually fills the wound. The endothelial buds increase in vascularity in response to the large metabolic demand of the repair tissue (Traversa & Sussman 2001). The arrangement of collagen fibres in the wound is random, disorganised, and has a gel-like consistency that gradually matures to form cross-links which provide tensile strength to the wound (Flanagan 1997).

The remodelling of collagen fibres is regulated by growth factors including TGF-B, PDGF and fibroblast growth factor (FGF), interleukin-1 (IL-1) and interferon-gamma (INF-g). Depending on the type and severity of the wound, the maturation phase may take up to six months to a year (McCulloch et al 1995). Collagen synthesis continues after wound closure; but undergoes

RESEARCH HIGHLIGHT

Evidence-based practice

Much of our understanding of how wounds heal is derived from examination of the wound-healing process in acute wounds. It is widely accepted that acute wounds heal through an orderly process of haemostasis, inflammation, proliferation and maturation. However, chronic wounds such as leg ulcers and diabetic foot ulcers do not follow this trajectory and are often characterised by prolonged inflammation and, even if they do heal, frequently recur even with the highest standard of care.

The concept of wound-bed preparation has emerged as an important paradigm for the management of chronic wounds in order to identify factors that influence wound healing and to provide a framework for clinicians to maximise the potential for wound for healing. There are four main principles underpinning wound-bed preparation – TIME:

- Tissue management
- Inflammation and infection
- Moisture balance, and
- Epithelial (edge) advancement.

The TIME framework is a dynamic concept that can be translated into the practical management of different wound types by utilising a standardised framework.

Reference

Schultz G, Sibbald G, Falanga V et al 2003 Wound bed preparation: a systematic approach to wound management. Wound Repair Regen 11:1–28.

continual lysis to form a more organised lattice structure which gradually increases the tensile strength of scar tissue, fibroblast numbers decrease and blood vessels are restored to normal (Traversa & Sussman 2001). The tensile strength of scar tissue is never more than 80% of that of non-scar tissue (Flanagan 1997).

Modes of wound healing

Wounds can be broadly characterised into two groups: those with and without loss of tissue. A clean surgical incision is an example of a wound with little tissue loss and where the edges of the wound are held in close apposition by sutures, staples or tape. The surgical wound heals by **primary intention**. However, if a wound is infected or contains foreign bodies, primary wound closure may be delayed for three to five days. This is known as *delayed primary intention*. A wound that involves extensive loss of tissue, such as a pressure ulcer or severe laceration, heals through a process of granulation, contraction and epithelialisation, and scarring may result. This is known as healing by **secondary intention**.

Skin grafting is another method to achieve wound healing. A skin graft is a segment of epidermis and dermis which is surgically removed from one site (donor site) and transplanted to another site (recipient site) (Carville 2007). Skin grafts depend on the in-growth of capillaries from the recipient site for their survival. A skin graft is selected as a method of wound closure when healing by secondary intention or primary closure is not a suitable option, to speed up the healing process and reduce the risk of infection. There are two types of skin grafts: *full-thickness grafts* which consist of the epidermis and the full thickness of the dermis, and *split-skin grafts* consisting of the epidermis and a variable proportion of the dermis. Split-skin grafts are described as *thin*, *intermediate* or *thick* according to the thickness of the graft.

A wound may also be closed by the surgical relocation of tissue from one part of the body to another part in order to reconstruct a primary defect (*flap*). The relocation of tissue creates a secondary wound that will require skin grafting or primary closure.

Complications of wound healing

When a wound fails to heal properly, the layers of skin and tissue may separate. This most commonly occurs before collagen formation (3–11 days after injury). **Dehiscence** is the partial or total separation of wound layers. A patient who is at risk of poor wound healing (e.g. poor nutritional status, infection, obesity) is also at risk of wound dehiscence. However, obese patients have a higher risk because of the constant strain placed on their wounds and the poor healing qualities of fatty tissue. Dehiscence often involves abdominal surgical wounds and occurs after a sudden strain, such as coughing, vomiting or sitting up in bed. Patients often report feeling as though something has given way. An increase in the presence of haemoserous drainage from a wound may indicate wound dehiscence.

Hypergranulation

Hypergranulation is an accumulation of granulation tissue that extends beyond the wound surface and delays epithelialisation (Carville 2007). Hypergranulation tissue may bleed easily; it may be seen in surgical incisions or around tubes and devices and can occur in some malignant tumours. Biopsy of the tissue is essential if malignancy is suspected.

Hypertrophic scars

Hypertrophic scars are characterised by an overabundant deposition of collagen in healed skin wounds and present as a re-epithelialised, red, raised and firm scar that may be itchy (Carville 2007). Hypertrophic scars are usually contained within the original boundary of the wound, and are usually linear in appearance following a surgical scar or papular or nodular following inflammatory and ulcerating injuries (Gauglitz et al 2011). Hypertrophic scarring may occur if there is excess tension on a healing wound. It can occur within 4–8 weeks following a wound injury such as a burn injury, laceration, abrasion, surgery, piercing or vaccination and usually regresses spontaneously. Scarring grows rapidly for up to 6 months and then gradually regresses over a period of a few years, resulting in a raised, flat scar with no further symptoms (Gauglitz et al 2011).

Keloid scars

Keloid scars occur spontaneously to form firm, smooth, fibrous growths that result from abnormal connective tissue in response to trauma, inflammation, surgery or burns (Carville 2007). Similar to hypertrophic scars, they are characterised by an overabundant deposition of collagen in healed wounds where the scar extends beyond the boundary of the original wound margin. The wound margins are usually well demarcated but irregular in outline (Gauglitz et al 2011). They may be tender or painful with a shiny surface and sometimes have telangiectasia (commonly known as spider veins) and a pink or purple appearance accompanied by hyperpigmentation. Keloids occur more frequently in darkly pigmented individuals and may be associated with a family history of keloids. While they may form on any part of the body, keloids

appear more commonly on the upper chest and shoulders. Keloids may develop up to several years after even minor injuries and may even form spontaneously on the mid chest in the absence of any known injury (Gauglitz et al 2011). They usually persist for long periods of time and do not regress spontaneously.

Contractures

Contractures occur when soft tissue, such as muscles, become shortened and prevent the joint from moving through a normal range of movement. Contraction of the wound edges is a normal process of wound healing, but when contracture is excessive, it may cause cosmetic and functional deformity. The degree of contraction is influenced by the flexibility and mobility of the surrounding tissue structures.

Haemorrhage

Haemorrhage (bleeding) from a wound site is normal during and immediately after the initial trauma. Haemostasis occurs within several minutes unless large blood vessels are involved or the patient has poor clotting function. Haemorrhage occurring after haemostasis indicates a slipped surgical suture, a dislodged clot, an infection, or erosion of a blood vessel by a foreign object (e.g. a drain). Haemorrhage may occur externally or internally. For example, if a surgical suture slips off a blood vessel, bleeding occurs internally within the tissues and there are no visible signs of blood unless a surgical drain, which is inserted into tissues beneath a wound to remove fluid that collects in underlying tissues, is present. Internal bleeding may be detected by looking for distension or swelling of the affected body part, a change in the type and amount of drainage from a surgical drain or signs of hypovolaemic shock.

External haemorrhaging is obvious. If bleeding is extensive, the dressing soon becomes saturated, and often blood escapes along the sides of the dressing and pools beneath the patient. The risk of haemorrhage is greatest during the first 24–48 hours after surgery.

Haematoma

A **haematoma** is a localised collection of blood underneath the tissues. It appears as a swelling or mass that often takes on a bluish discolouration. A haematoma near a major artery or vein is dangerous because pressure from the expanding haematoma may obstruct blood flow.

Evisceration

Evisceration is when there is a total separation of wound layers or protrusion of visceral organs through a wound opening. The condition is a medical emergency that requires surgical repair and immediate patient support.

Fistula

A **fistula** is an abnormal passage between two organs or between an organ and the outside of the body. A surgeon may create a fistula for therapeutic purposes (e.g. making an opening between the stomach and the outer abdominal wall to insert a gastrostomy tube for feeding). Most fistulas, however, form as a result of poor wound healing or as a complication of diseases, such as Crohn's disease or regional enteritis. Trauma, infection, radiation exposure and diseases such as cancer prevent tissue layers from closing properly and allow the fistula tract to form. Fistulas increase the risk of infection and fluid and electrolyte imbalances from fluid loss. Chronic drainage of fluids through a fistula can also predispose a person to skin breakdown.

Wound infection

Wound infection is defined as the clinical syndrome of bacteria and other microbial organisms impairing wound healing (Australian Wound Management Association (AWMA) 2011). Wound infection is a serious problem in hospitals and the community. Clinically a wound can exhibit signs of local infection, but a wound swab may show 'no growth'. Furthermore, positive culture findings do not always indicate an infection because many wounds contain colonies of non-infective resident bacteria. In fact, all chronic wounds are considered contaminated with bacteria. What differentiates *contaminated wounds* from *infected wounds* is the number of bacteria present. There are several different classification systems used to categorise the impact of bacteria on a wound and the patient. Some clinicians use the concept that $> 10^5$ microorganisms per gram of tissue constitutes an infection (AWMA 2011), although this is not always an accurate indicator of the presence of an infection. The effect of bacteria on wound healing is best conceptualised by the following algorithm:

$$\frac{\text{Number of bacteria} \times \text{Virulence}}{\text{Patient resistance}}$$

Table 26-8 outlines a classification system that can be used to assist clinicians to understand how bacteria might be affecting the wound-healing process in wounds healing by secondary intention. This classification system considers the effect of bacteria on the wound and on the patient.

There are several broad indicators of infection available to assess the degree of bacterial impairment on wound healing. The clinical indicators of infection are outlined in Table 26-9.

TABLE 26-8 Bacterial impact on wounds healing by secondary intention

Level of bacterial impairment	Bacterial activity	Degree of impairment to wound healing and clinical signs
Contamination	Bacteria are on the wound surface No division is occurring	No impairment to healing No obvious clinical signs of infection
Colonisation	Bacteria are dividing	No impairment to healing No obvious clinical signs of infection (Clinical wound appearance does not usually differ from contamination)
Topical infection (critical colonisation)	Bacteria are dividing. Bacteria and/or their products have invaded the wound surface. There might be an increasing variety of bacteria present. Biofilm may be present	Impairment to healing Clinical signs of infection may not be obvious or are subtle (see Table 26-9)
Local infection	Bacteria and/or their products have invaded the local tissues	Impairment to healing Usually obvious clinical signs of infection localised to wound environment and immediate peri-wound tissue (see Table 26-9)
Regional/spreading infection/cellulitis	Bacteria and/or their products have invaded surrounding tissues	Impairment to healing Usually obvious clinical signs of infection. May have systemic signs
Sepsis	Bacteria and/or their products have entered the bloodstream and may spread to distant sites or organs	Impairment to healing Usually obvious systemic clinical signs: patient usually acutely unwell Damage to organs may occur

Position Document of the Australian Wound Management Association: Bacterial impact on wound healing: From contamination to infection. Australian Wound Management Association Inc, July 2009, p. 5. www.awma.com.au/publications/2009/bacterial_impact_position_document_V_1_0.pdf. Reproduced with permission of AWMA. All rights reserved.

TABLE 26-9 Indicators of infection

Level of bacterial impairment	Clinical indicators of bacterial impairment to wound healing
Topical infection/critical colonisation	Dull wound tissue – absence of vibrant granulation tissue Slough Failure of wound to decrease in size, or increase in wound size Increased exudate Hypergranulation/friable tissue Demarcated and/or rolled and/or raised wound margins
Local infection	Erythema – usually localised to periwound tissue Increased pain or unexplained pain Oedema – usually localised to periwound tissue Purulent or discoloured, viscous exudate Malodour Bridging and/or pocketing within the tissue Increased temperature of periwound tissue Increase in wound size
Regional/spreading infection	Spreading erythema – more than 2 cm from wound margin Cellulitis Induration of regional tissues Fever Oedema of regional tissues Malaise and/or general feeling of unwellness
Sepsis	High fever or hypothermia Lymphangitis and regional lymphadenopathy Delirium Organ compromise or failure Septic shock – hypotension, tachypnoea, tachycardia

Position Document of the Australian Wound Management Association: Bacterial impact on wound healing: From contamination to infection. Australian Wound Management Association Inc, July 2009, p. 7. www.awma.com.au/publications/2009/bacterial_impact_position_document_V_1_0.pdf. Reproduced with permission of AWMA. All rights reserved.

It must be remembered that bacterial impairment of wound healing is a continuum, and worsening of infection may or may not include some or all of the factors outlined in Table 26-9. In some people, the traditional clinical signs of inflammation – erythema, oedema, pain, heat – may not be present due to suppression of the immune response as a result of ischaemia, neuropathy or immunosuppression, which can result from age, poor nutrition, other comorbidities and medications.

The development of infection must be reported as a clinical indicator in most hospitals. Surgical site infections (SSIs) are defined as either:

- *a superficial incision SSI*, whereby infection involves only skin or subcutaneous tissue of the incision and occurs within 26 days after the operative procedure, or
- *a deep incisional/organ/space SSI*, whereby infection involves deep soft tissues (e.g. fascial and muscle layers) and/or organs or spaces opened or manipulated during an operation, and occurs within 26 days after the operative procedure if an implant is not present or within 1 year if an implant is in situ (AWMA 2011).

The chances of wound infection are greater when the wound contains dead or necrotic tissue, there are foreign bodies in or near the wound, and the blood supply and local tissue defences are reduced.

Bacterial wound infection inhibits wound healing. Now that you have a better understanding of how to recognise wound infection, you are ready to learn how to obtain a bacterial wound swab – see Skill 26-1.

SKILL 26-1

Performing a bacterial wound swab

Delegation considerations

A bacterial wound swab can be undertaken by all healthcare professionals if infection is suspected. Check organisational policies regarding which wound care interventions can be delegated to health workers. The assessment of wound infection requires the problem-solving and knowledge-application skills of a registered nurse.

Equipment

- Examination gloves
- Apron
- Face mask and protective eyewear
- Sheet or towel for draping
- Contaminated waste bag
- Normal saline or potable water
- Bacterial swab
- Specimen bag
- Dressing pack

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess wound for suspected clinical signs and symptoms of wound infection, including quantity and type of exudate, presence of malodour, wound deterioration, increasing wound size and deterioration of periwound skin.	Helps to determine need for wound swab. Clinical signs of infection may be overt or subtle, and may be indicated by wound deterioration, increasing wound size or wound that fails to make satisfactory progress.
2. Assess patient's level of comfort and offer analgesia if appropriate.	Removal of dressing and the presence of a wound infection may be associated with pain requiring analgesia.

STEPS	RATIONALE
3. Explain procedure to patient.	Decreases anxiety.
4. Close room or cubicle curtains and windows.	Provides privacy and reduces airborne microorganisms.
5. Position patient comfortably and drape with a sheet or towel to expose only wound site.	Provides access to wound while minimising unnecessary exposure.
6. Place disposable contaminated waste bag within reach of work area. Fold top of bag to make cuff.	Ensures easy disposal of soiled dressings.
7. Put on face mask and protective eyewear and wash hands thoroughly. Put on clean, disposable gloves.	Protects nurse from splashes and reduces risk of transfer of microorganisms.
8. Carefully remove dressings. If dressing is adhered, moisten to facilitate removal. Observe dressing for exudate, odour and colour. Remove gloves over contaminated dressings (see Skill 26-2) and discard into prepared bag. Perform hand hygiene.	Reduces transmission of microorganisms. Moistening dressing upon removal decreases pain and trauma to tissue. Glove removal prevents contact of nurse's hands with material on gloves.
9. Cleanse wound with Normal saline or potable tap water.	Removes exudate, slough, necrotic tissue or dressing product from the wound bed to ensure a more accurate result.
10. Avoid touching the wound surface, sterile swab surface or swab container opening.	Reduces transmission of microorganisms.
11. Move swab across the surface of the wound in a zig-zag motion at the same time as rotating the swab between the fingers. A representative area of the wound should be sampled, i.e. at least 1 cm^2 from the wound bed. Gentle downward pressure may be applied.	The Z-stroke technique involves rotating the swab in a 10-point zig-zag fashion (side to side across the wound without touching the wound edges or periwound skin). Downward pressure helps to release fluid from the wound surface.
12. Immediately following collection, return the swab carefully to the specimen container and accurately label as per laboratory guidelines.	The specimen must be labelled to provide laboratory staff with information required to process results. It is important to transport the specimen to the laboratory as soon as possible for processing.
13. Put on clean disposable gloves. Cover wound with appropriate dressing (see Skill 26-2).	Provides a moist wound environment to facilitate wound healing, absorbs exudate, reduces risk of bacterial colonisation and pain.
14. Remove gloves by pulling them inside out. Dispose of in prepared bag.	Reduces transmission of microorganisms.
15. Assist patient to a comfortable position.	Promotes patient comfort.

RECORDING AND REPORTING

Document all relevant information in patient's chart, including the location the specimen was taken from and the date and time. In most organisations a bacterial wound swab will require prescription from a medical professional.

Factors affecting wound healing

Being able to recognise factors that can affect the wound-healing process is essential so that you can take steps to either remove the factors slowing down this process or, if possible, minimise their impact. Some factors that may affect the wound-healing process are outlined in Table 26-10.

CRITICAL REFLECTION POINT

Refer to the photo of Mr Bukowski's skin tear on p. 682.

- **What characteristics would indicate whether or not this wound was infected?**
- **What is the predominant tissue type in the wound bed?**
- **How would you describe the wound edges?**
- **How would you describe the skin around the wound?**

Wound assessment

Knowledge of different types of wounds, the wound-healing process and factors that affect wound healing inform the nurse's wound assessment. Key elements of a wound assessment include those outlined below.

Wound history

This includes a history of the present wound or symptoms. You might like to ask:

- How and when did the wound start?

TABLE 26-10 Factors affecting wound healing

Factor	Explanation
Comorbidities	Illnesses such as renal failure, heart failure, stroke, diabetes, malignancy, rheumatoid arthritis and autoimmune disorders increase a person's risk of suffering impaired wound healing because of the way these diseases affect all body systems For example, poorly controlled diabetes can lead to neuropathy, ischaemia and infection, and anaemia reduces the supply of circulating red blood cells and the oxygen-carrying capacity of blood to the wound
Nutrition and hydration	Poor nutrition and hydration will slow down the wound-healing process because the body will not have enough nutrients to promote wound healing. A wound increases the body's need for nutrients, protein and energy Patients need to drink at least 6–8 glasses of fluid per day because a lack of fluids impairs the blood flow, which reduces oxygen and nutrients needed in the tissue to promote wound repair. Dry skin is less elastic and more likely to break down. Sources of fluid include water, juice, milk, jelly, ice cream, yoghurt, soup, tea and coffee
Medications	Some medications that make the blood less likely to clot (e.g. anticoagulants) or steroids (e.g. taken for conditions such as rheumatoid arthritis) make the skin thinner and more likely to tear and suppress the inflammatory phase of healing
Age	Blood flow decreases with age, and the older a person is, the more likely they are to have problems with their skin
Obesity	Adipose tissue is poorly vascularised and can delay wound healing or lead to dehiscence of the wound edges
Psychological state	There is a link between high levels of stress and impaired wound healing The presence of a wound can affect a person's body image, self-concept and sexuality
Decreased blood supply	Hardened, narrowed or blocked arteries reduce blood supply to the skin. This slows down wound healing because blood carries nutrients and oxygen
Infection	The presence of a wound infection slows down healing
Foreign bodies	A foreign body such as wound debris, sutures, dirt, hair, dressing products or infection in a wound delays wound healing
Pressure, friction, shear	Dry skin is more likely to tear due to friction, shearing or pressure
Temperature	Wounds need a stable temperature, approximately 37°C, to heal more rapidly
Exudate and moisture	High volumes of wound exudate can delay wound healing and increase the risk of wound infection and breakdown of periwound tissue Wounds need a moist wound environment to heal so that epithelial cells can migrate across the wound surface. Achieving optimal moisture balance in the wound bed is a key goal of wound healing Scab formation in the wound bed delays epithelialisation because epithelial cells have to migrate under the scab
Loss of sensation	Decreased sensation, loss of consciousness, an injury to the central nervous system, a stroke, major surgery, spinal cord injury or medications such as steroids or anticoagulants increase the risk of skin damage. This is because the patient may not be aware that an injury to the skin has occurred
Smoking	Cigarette smoking is a well-known risk factor for impaired wound healing because it leads to atherosclerosis and coronary heart disease

- How long have you had it for and what does the current treatment involve? (i.e. who is treating the wound, with what, and how often?)
- Is there any past history of wounds?
- Do you have any pain and how would you describe the pain?
- What provokes or relieves the pain?

It is also important to ask about any medical conditions the person may have, as well as their smoking history, mobility, medication and nutritional status.

Cause of the wound

It is important to determine the cause of the wound (e.g. due to an accident or surgery), the type of wound (e.g. skin tear, venous leg ulcer or pressure injury) and the classification of wound (e.g. the category of skin tear or the stage of pressure injury).

The extent of tissue loss can help to predict wound-healing outcomes. For example, a wound healing by primary intention, where there is minimal loss of tissue and the edges of the wound can be reapproximated by sutures or staples, will heal much more quickly than a wound healing by secondary intention.

The extent of tissue loss is often described using the following terminology.

- *superficial*: a wound involving the epidermis
- *partial-thickness*: a wound involving the epidermis and dermis
- *full-thickness*: a wound which involves the epidermis, dermis, subcutaneous tissue and may extend into the muscle, bone or tendon.

A wound may also be described using a classification system. Classification systems have been developed to assist clinicians identify appropriate information about the risk factors for certain wound types. A classification system is useful in promoting a consistent approach to clinical examination and provides a common language to facilitate communication between clinicians. Classification systems have been developed for burns, pressure injuries, leg ulcers, diabetic foot ulcers and skin tears. The various classification systems for each wound type will be discussed later in this chapter.

Wound size

The size of a wound should be assessed when it first occurs. Measurement of a wound enables you to track progress over time. It is recommended that chronic wounds should be assessed at least monthly or whenever there is any significant change in wound progress (Grey et al 2006). Wounds can be measured using two-dimensional methods such as by tracing the margins of the wound using a transparent acetate grid and marking pen. If a metric graph sheet is used for tracing the wound, the size can be determined by counting the number of squares on the graph paper. A ruler can also be used to measure the length and width of a wound. Assessment of the depth or length of a wound can be performed using a probe. It is preferable that wound depth is recorded using a probe with a rounded tip and measurement calibrations along the length of the probe. In a cavity wound with undermining, tracking or sinus formation occurring, record the direction of the sinuses or tracking by drawing the direction using times on a clock face. In recent years, a number of computerised wound measurement systems have been developed.

Wound photography

Digital photography is becoming increasingly used in wound management. Wound photography provides an accurate and objective means of assessment and evaluation of wound treatments, can aid in diagnosis of a wound, reduces the risk of misinterpretation of wound assessment and progress between clinicians, provides a documented record for medico-legal purposes and assists in teaching, research and publication. It is essential that written consent is obtained from the patient/relative or carer prior to taking photographs.

Wound edge

The wound edge or border can give important clues as to the type of wound that you are treating:

- venous leg ulcers are characterised by a sloping wound edge (Figure 26-4)
- arterial leg ulcers have a punched-out wound edge (Figure 26-5)
- undermining is a typical feature of a pressure injury (Figure 26-6)
- diabetic foot ulcers have a calloused wound edge (Figure 26-7)
- skin cancers have a raised wound edge (Figure 26-8).

Wound location

The location of the wound can aid diagnosis. For example:

- diabetic foot ulcers occur on the sole of the foot and toes
- venous ulcers occur on the lower third of the leg below the knee
- arterial leg ulcers occur on the top of the foot, toes or ankle bones

Figure 26-4 **Venous leg ulcer.**

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

Figure 26-5 **Arterial leg ulcer.**

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

- pressure injuries occur over bony prominences such as the sacrum, hips or heels
- skin cancers tend to occur in sun-exposed areas.

Clinical appearance

The colour of the tissue in the wound gives an indication of the health of the wound, and this guides treatment options. For example, healthy granulation tissue is beefy

Figure 26-6 **Pressure injury located on right ischium.**

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

Figure 26-7 **Diabetic ulcer on foot.**

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

Figure 26-8 **Skin cancer.**

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

red in colour and is an indicator of healing. However, unhealthy granulation tissue appears darker in colour and bleeds easily, indicating that an infection may be present.

There are five main colours that you can use to describe the predominant type of tissue in the wound bed:

- black necrotic tissue (Figure 26-9)
- yellow sloughy tissue (Figure 26-10)
- red granulating tissue (Figure 26-11)
- pink epithelialising tissue (Figure 26-12)
- green infected tissue (Figure 26-13).

Figure 26-9 Necrotic tissue.

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

Figure 26-10 Yellow sloughy tissue.

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

Some wounds may have a component of each colour present (e.g. yellow sloughy and red granulating), but when doing a wound assessment, it is the predominant tissue colour present that you need to be concerned with.

Figure 26-11 Red granulating tissue.

Figure 26-14 **Infected leg ulcer.**

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

Wound exudate

The type, amount, colour, consistency and odour of wound leakage or exudate should be noted. Types of **exudate** include:

- **serous**: clear, straw-coloured fluid
- **haemoserous**: slightly blood-stained serous fluid
- **sanguineous**: frank or heavily blood-stained
- **purulent**: containing pus.

The amount of wound exudate is important to quantify, and is usually described as light, moderate or heavy. The colour relates to the type of exudate, but may also indicate the type of bacteria present in a wound. For example, the bacteria *Pseudomonas aeruginosa* has a blue-green colour. Consistency refers to the thickness or composition of exudate; for example, fistulae may produce a thick fluid. Odour emanating from a wound may indicate the presence of a wound infection or contamination by body fluids.

Surrounding skin

The condition of the surrounding skin is important to assess, because this can assist you when selecting an appropriate wound dressing. The wound margin and surrounding skin should be assessed for callous formation, maceration, oedema or erythema (Schultz et al 2003). In patients with diabetes, there may be a build-up of callus on the bottom of the foot, which indicates higher plantar pressures and is a barrier to wound healing. If the skin around the wound is white and boggy (maceration, see Figure 26-15), this indicates that the wound is producing moderate to large amounts of leakage (exudate) and you need to select an absorbent dressing.

Wound infection

If a patient has a wound, it may have the following clinical manifestations:

- heat in the skin around the wound or extending more than 2 cm beyond the wound margins
- redness (erythema) around the wound or extending more than 2 cm beyond the wound margins
- swelling (oedema) around the wound or extending more than 2 cm beyond the wound margins
- pain that has changed in intensity
- delayed healing

Figure 26-15 Maceration.

Courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

- wound tissue that bleeds easily on contact
- an offensive odour
- abnormal granulation tissue.

Pain

Pain is a characteristic of all wounds and it is important to routinely assess pain and attempt to determine its cause. Pain is often related to dressing removal, or the result of an underlying condition such as infection or poor blood supply (World Union of Wound Healing Societies 2004).

The nature and type of pain should be identified and treated appropriately. Wound pain can be classified as *nociceptive* or *neuropathic*. Nociceptive pain is an appropriate physiological response to a painful stimulus and may involve acute or chronic inflammation. Acute nociceptive pain can occur as a result of tissue damage and is usually time-limited. In wounds that are slow to heal, prolonged inflammation may cause heightened sensitivity in the wound (primary hyperalgesia) and in the surrounding skin (secondary hyperalgesia).

Neuropathic pain is an inappropriate response caused by a primary lesion or dysfunction in the nervous system and can occur after surgical or traumatic wounds. Neuropathic pain is associated with altered or unpleasant sensations whereby any sensory stimulus such as light touch or pressure can cause intense pain (allodynia).

Chapter 41 provides an overview of useful pain assessment tools that should be incorporated into the nursing assessment to provide measures of pain and the success of wound and analgesic choices.

Psychosocial impact of wounds

The presence of a wound can have a significant impact on an individual's psychosocial functioning. Factors such as social isolation, gender, economic status and pain affect wound healing. Stress, anxiety and depression have been linked to alterations in immune function which can negatively affect wound healing (European Wound Management Association 2008).

Wound documentation

Recording the wound assessment and evaluating the effectiveness of the wound management plan is essential. The information captured from a wound assessment is commonly documented using a wound assessment tool. Wound assessment tools facilitate communication and continuity of care between clinicians and fulfil legal requirements (Hess 2005). Risk assessment tools are often used in wound management as a tool to predict a patient's level of risk of developing a wound such as a pressure injury or diabetic foot ulcer.

• CRITICAL REFLECTION POINT

As you read the next section, think about how you would decide on the management of Mr Bukowski's skin tear:

- **How would you cleanse this wound?**
- **What type of management strategies would you employ for a skin tear?**
- **What dressing regimen would you choose at this point, and why?**
- **How would you manage the skin around the wound?**

Principles of wound management

Many factors affect the wound-healing process. Therefore, wound management strategies must be tailored to meet the individual holistic needs of the patient, their wound and their environment.

Assess and correct cause of tissue damage

The health status of the patient has a significant impact on the wound-healing process; therefore, a general health history, including a medication history, is essential in order to identify factors that may affect wound healing.

There are many medications that can impair wound healing, including systemic steroids, immunosuppressive drugs and non-steroidal anti-inflammatories (Schultz et al 2003). Chronic diseases such as diabetes mellitus and rheumatoid arthritis and autoimmune disorders such as systemic lupus erythematosus, vasculitis and pyoderma gangrenosum also delay wound healing.

Assess wound history and characteristics

Ongoing assessment and evaluation of the wound is an essential step in promoting wound healing.

Ensure adequate tissue perfusion

It is essential that the tissue is well perfused, as a well-vascularised wound bed provides nutrients and oxygen to promote granulation tissue formation and to maintain active immunological response to bacteria. Decreased oxygen levels impair the ability of leucocytes to kill bacteria, lower production of collagen and reduce epithelialisation (Schultz et al 2003).

Wound-bed preparation

Wound-bed preparation is the management of the wound to promote wound healing or to facilitate the effectiveness of other therapeutic measures (Schultz et al 2003). Wound-bed preparation involves four fundamental principles which provide a systematic approach to the management of wounds by focusing on each stage of wound healing:

1. *Tissue*: removal of non-viable tissue or replacement of deficient tissue.
2. Control of *infection* or *inflammation*.
3. *Moisture imbalance*: correction of excessive moisture and prevention of desiccation.
4. Revision of the *edge of the wound* to stimulate healing.

These principles will now be explored in further detail.

Wound cleansing

Wounds should be cleaned with a neutral, non-irritating, non-toxic solution such as clean tap water or Normal saline (Whitney et al 2006). Cleaning should be undertaken with minimal chemical or mechanical trauma. The ultimate aim of wound cleansing is to remove both organic and inorganic debris while maintaining the optimum local environment to facilitate wound healing (Fernandez & Griffiths 2012). Before performing wound cleansing, consider the purpose of wound cleansing and whether the advantages of cleansing outweigh the disadvantages; the most appropriate method of wound cleansing; whether the wound requires cleansing at each dressing change; and the type of wound-cleansing product that is most appropriate.

Common reasons for cleansing a wound are to help prevent wound infection and remove excess debris or foreign bodies from the wound; to rehydrate the wound to provide a moist environment; to make wound assessment easier so that the size and extent of the wound can be visualised; before applying a dressing, to minimise trauma when removing adherent dressings; and to promote patient comfort and psychological wellbeing.

The decision to cleanse a wound should be based on the shape, size and location of the wound; condition of the wound bed and stage of healing; availability and effectiveness of different methods of cleansing; availability and effectiveness of different cleansing agents; and the patient's perceptions and needs.

Wound-cleansing solutions and techniques

The decision to use tap water to cleanse wounds should be based on clinical judgement and take into account the quality of water, the nature of the wound and the patient's general condition (Fernandez & Griffiths 2012). It is recommended that tap water should not be used if it is not suitable for drinking and the tap should be run for 15 seconds prior to use (Joanna Briggs Institute 2006). If potable tap water or Normal saline is not available, cooled boiled water is an effective wound-cleansing solution (Joanna Briggs Institute 2006). In wounds that are contaminated or infected, irrigation with 1% povidone–iodine is effective at reducing the infection rate, although there is no evidence of the optimal time that povidone–iodine should be left in situ (Joanna Briggs Institute 2006).

Gentle irrigation is effective at reducing infection and inflammation in patients with lacerations and traumatic wounds without causing tissue trauma (Joanna Briggs Institute 2006). There is no evidence to support or refute swabbing and scrubbing as effective wound-cleansing techniques (Fernandez & Griffiths 2012). When considering the method of wound cleansing, evidence suggests that showering patients does not affect infection and healing rates of postoperative wounds and may benefit patients with a feeling of wellbeing and health associated with cleanliness (Joanna Briggs Institute 2006). Showering for cleansing other wounds should be undertaken with caution.

Wound debridement

Wound debridement is an essential component of optimal wound management. **Debridement** describes any method that facilitates the removal of dead or devitalised tissue, metabolic waste, fibrin and foreign material from a

wound (Gethin et al 2010). Removal of necrotic and devitalised tissue can be undertaken through surgical, sharp, mechanical, autolytic, biological or enzymatic debridement techniques (Hopf et al 2006, World Union of Wound Healing Societies 2007). If dry gangrene or **eschar** (leathery brown or black necrotic tissue) is present, however, debridement should not be undertaken until arterial flow has been re-established (Whitney et al 2006). There is insufficient evidence to conclude that any one debriding agent is more effective than another (Gethin et al 2010, Williams et al 2005).

When selecting an appropriate method of debridement a number of factors must be considered, including the patient's individual wishes and concerns, medical history, factors affecting the wound-healing process, pain, wound characteristics, skill and knowledge of the clinician and available resources (Kirshen et al 2006). Specific wound characteristics that influence debridement decisions include size, depth and amount of exudate, as well as the characteristics of wound tissue, potential for bleeding, and infection. Methods of debridement that are selective are generally preferred because they remove only necrotic tissue.

- *Autolytic debridement* is the most frequently used method of debridement whereby there is breakdown and removal of devitalised tissue by the body's own cells and enzymes, and this is facilitated by the provision of a moist wound environment (Ayello & Cuddigan 2004, Royal College of Nursing 1998). Maceration of periwound tissue may be problematic. For autolytic debridement to be effective, the wound requires some level of exudate, and it is a slow method of debridement. It is not recommended for clinically infected wounds and in those with a high potential for anaerobic infection, or if there is ischaemia of the limb or digits (Gethin et al 2010).
- *Sharp debridement* may be performed at the bedside and involves selective removal of dead or devitalised tissue from within and around the wound to expose healthy tissue using sterile instruments such as a scalpel, scissors or curette. This procedure involves similar risk factors to surgical debridement, although it is less aggressive, and must be performed by a skilled and experienced clinician.
- *Surgical debridement* is performed in an operating theatre usually under regional or general anaesthetic. It is indicated if there is extensive necrotic tissue, advancing cellulitis, infected bone or sepsis. This method of debridement is the most rapid and highly selective; however, the number of personnel and degree of expertise required increase cost and limit the availability of the procedure. There is also an increased risk of pain, bleeding, transient bacteraemia, damage to vital structures, tendon sheaths and nerves and anaesthesia risks. Surgical debridement must be used with caution in patients with clotting disorders or on anticoagulant therapy and in patients with diabetes and peripheral vascular disease.
- *Mechanical debridement* is the process of physically removing debris from the wound bed. The most commonly used methods of mechanical debridement include wet-to-dry dressings, whirlpool therapy, pulsed lavage and ultrasound. Mechanical debridement is non-selective, time-consuming, frequently painful and associated with an increased risk of infection, damage to granulation tissue, prolonged inflammation and periwound maceration.
- *Biological debridement* involves the application of sterile maggots, specifically the larvae of the green bottle fly (*Luciliasericata*), to the wound bed.
- *Enzymatic debridement* is the topical application of an exogenous enzyme to the wound bed to facilitate a host response. Topical enzymatic agents may be plant-, animal- or microbe-derived. They are not commercially available in Australia or New Zealand at present.

When selecting the most appropriate method of debridement, the indications and contraindications for the different types of debridement options must be considered. Evidence supports that debridement is an important step in preparing the wound bed for healing (Ayello & Cuddigan 2004, Kirshen et al 2006, Moffatt et al 2008).

Provision of a moist wound environment

A **moist wound environment** is essential to promote wound healing because cells need moisture to be able to migrate across a wound bed. Extreme wetness or dryness may delay healing. Application of dressings to a wound may help to facilitate wound healing by providing the optimal wound environment. Wound dressings may also be applied to:

- provide rapid and cosmetically acceptable healing
- remove or contain odour
- reduce pain
- prevent or treat infection
- contain exudate
- cause minimum distress or disturbance to the patient.

Before applying a dressing, it is essential that you know:

- the action of the dressing
- when it should be used

- the limitations or contraindications to its use, and
- the correct method of application and removal.

There are two different categories of wound dressings: *primary dressings* – those in direct contact with a wound; and *secondary dressings* – those not in contact with a wound but covering the primary dressing (Xue 2008). When selecting a secondary dressing, it is important to ensure that it is compatible with the primary wound-contact layer.

Multiple factors inform the selection of a wound dressing: the type or aetiology of the wound, location or position of the wound, extent of tissue damage and size of the wound, phase of wound healing, presence of debris or infection, level of exudate, odour, pain, patient-centred concerns, cost-effectiveness, the indication/contraindication of the dressing, condition of the surrounding skin and desired patient outcomes (Xue 2008).

Evidence suggests that dressings should:

- maintain a moist wound-healing environment (Griggs 2008, Whitney et al 2006, Xue 2008)
- manage wound exudate and protect the skin surrounding the wound (Whitney et al 2006, Xue 2008)
- remain in place if possible and minimise shear, friction, skin irritation and pressure (Whitney et al 2006)
- be non-adherent to reduce trauma on removal (World Union of Wound Healing Societies 2004)
- be cost-effective, acceptable to the client and changed less often where possible (Hopf et al 2006, World Union of Wound Healing Societies 2004).

Topical antimicrobial dressings may be beneficial when wounds are infected (Hopf et al 2006).

Unfortunately, there is no one dressing that is ideal for every wound. Dressings are classified according to their properties into generic groups. The main classes of wound-dressing products and their properties are outlined in Table 26-11.

Now that you have a better understanding of the principles of wound assessment, wound cleansing and

TABLE 26-11 Wound dressings

Classification	Properties	Clinical considerations	Examples
Semi-permeable film	Made from a thin sheet of polyurethane coated with a layer of adhesive Permeable to moisture, vapour and gases but impermeable to liquids Different types of film dressings differ in their moisture/vapour permeability (MVP), method of application, extensibility, weight and thickness	Excessive exudate may pool under the dressing and result in maceration Care must be taken when removing film dressings. Many have a specific method to break the adhesive bond to ensure atraumatic removal Reaction/sensitivity to adhesive may occur If used on thin, fragile skin, damage can occur on removal	OpSite (Smith & Nephew) Tegaderm (3M)
Tulle gras non-medicated dressings and medicated dressings	Open mesh, cotton, rayon, viscose or gauze impregnated with white or yellow soft paraffin and/or medicated antiseptic	Few indications for use as a primary wound dressing – often fail to meet the criteria of an ideal dressing Low to moderate exuding wounds, i.e. clean superficial wounds, split-thickness skin grafts, minor burns Reduces adhesion and allows non-traumatic removal Provides a moist environment that facilitates epithelial cell migration Does not absorb exudate Requires a secondary dressing Cotton products can shed fibres into the wound Synthetic fabric or paraffin products can cause allergic reactions in sensitive people Requires frequent dressing changes to avoid drying out and damage to granulation tissue Ineffective release of antimicrobials from the paraffin base has been reported Antiseptic may cause allergic reaction in some people	Jelonet (Smith & Nephew) Adaptic (Johnson & Johnson) Xeroform (contains bismuth) (Kendall) Bactigras (contains chlorhexidine) (Smith & Nephew)

continued

TABLE 26-11 ***continued***

Classification	Properties	Clinical considerations	Examples
Alginate	Derived from seaweed Produce a moist gel in the presence of exudate Highly absorbent Facilitate autolytic debridement of moist slough and necrotic tissue Act as a haemostat Reduce pain by keeping nerve endings moist Mostly insoluble Available as a rope or pad Conformable	Useful for filling irregularly shaped wounds such as cavities, abscesses and sinuses Used on moderate to heavily exuding wounds – pressure sores, leg ulcers, graft donor sites Can be used on infected wounds Useful for debriding moist devitalised tissue Requires a secondary dressing	Kaltostat (ConvaTec) Algisite M (Smith & Nephew)
Hydrofibre	Synthetic fibre composed of 100% carboxymethylcellulose Available as sheet or ribbon Absorb exudate vertically, resulting in moisture being drawn up and away thus preventing its spread to surrounding skin Highly absorbent Conformable Facilitate autolytic debridement of slough and necrotic tissue Promote pain relief by keeping nerve endings moist	Moderate to heavily exuding wounds – pressure sores, leg ulcers Can be used on infected wounds Can be used at all stages of healing, from debridement to protection of granulation tissue Requires a secondary dressing	Aquacel (ConvaTec)
Hydrocolloid	Occlusive or semi-occlusive Contain gelatine, pectin and sodium carboxymethylcellulose in a polymer matrix Provide a moist healing environment and facilitate autolytic debridement Available in all shapes, sizes, adhesive properties and forms including wafers, pastes and powders Absorbent – low to high levels of exudate Promote pain relief by keeping nerve endings moist Impermeable to bacteria and other contaminants	May be used as a primary or secondary dressing to manage select pressure ulcers and wounds with necrosis or slough Produce a liquid that resembles pus and may have a strong smell Not recommended for wounds with heavy exudate, sinus tracts or infections, wounds surrounded by fragile skin or wounds with exposed tendon or bone May curl at the edges May injure fragile skin upon removal	Duoderm (ConvaTec) Comfeel (Coloplast) Replicare (Smith & Nephew)
Hydrogel	Have a high water content and contain insoluble polymers Designed to hydrate wounds and promote autolytic debridement Promote pain relief	*Sheet gels* have a solid shape and can be placed on top of the wound without being cut to size – low to moderately exuding flat wounds, i.e. pressure sores, leg ulcers, minor burns, traumatic wounds *Amorphous* (no shape) *gels* – low to moderately exuding wounds, necrotic or sloughy wounds, i.e. pressure sores, sinuses, cavity wounds *Hydrogel-impregnated dressings* are non-woven gauze impregnated with amorphous gel – good for packing low-exudate cavity wounds Useful for rapid debridement of both dry and moist devitalised tissue Sometimes associated with increased skin maceration at wound edges, especially if exudate levels are high Should not be used in blind sinuses where extent of tracking cannot be identified Some people have experienced sensitivity to the preservative agents in some products	*Amorphous gels:* Intrasite Gel (Smith and Nephew) SoloSite Gel (Smith and Nephew) *Gel sheets:* Aquaclear (Hartmann) Curagel (Kendall) *Gel-impregnated:* Curafil (Kendall) IntraSite Conformable (Smith and Nephew)

continued

TABLE 26-11 ***continued***

Classification	Properties	Clinical considerations	Examples
		Used for low to moderate levels of exudate and require a secondary dressing. As hydrogels release water to any dry surface, the use of secondary dressings that are dry or high-absorbency, such as polyurethane foam, is not recommended	
Low-adherent, absorbent dressings and non-absorbent dressings	Made from a variety of materials such as cotton/acrylic fibres and knitted viscose Some are coated with low-adherent materials, e.g. aluminium or perforated films Some have an absorbent layer Some are composed of non-adherent materials such as silicone and polyamide net	Dry to medium exuding wounds, i.e. surgical wounds healing by primary intention, superficial wounds Can be used to protect surgical incisions and recently healed wounds Remove carefully – low-adherent not non-adherent Skin maceration may occur Not suitable for highly exudating wounds unless specified	*Low-absorbent:* Melonin (Smith & Nephew) Release (Johnson & Johnson) *Absorbent:* Exu-Dry (Smith & Nephew) Mesorb (Mölnlycke)
Foam dressings	Mostly polyurethane foams with a hydrophilic action Low-adherent Absorbent dressings for low to high levels of exudate Good thermal insulating properties Permeable to water vapour, preventing the wound from drying out Available as non-adherent and adherent, occlusive and semi-occlusive Conform to body shape Protect and cushion	Low to heavily exuding wounds – pressure sores, leg ulcers, burns, graft donor sites Moist wound environment may not be enough to allow autolysis to occur May macerate periwound skin if they become saturated	Allevyn or Allevyn adhesive (Smith & Nephew) Biatain (Coloplast)
Silicone dressings	Polymer with a structure that consists of alternate atoms of silicon and oxygen with organic groups attached to the silicon atoms A soft silicone dressing is one coated with soft silicone as an adhesive or wound-contact layer The intrinsic properties of the soft silicone mean that they can be removed without causing trauma to the skin	Suitable where it is important to prevent trauma to the wound and the surrounding skin and pain to the patient There are a number of different types of soft silicone dressings that meet different clinical needs – skin grafts, skin tears, prophylaxis of skin during radiotherapy, burns, donor sites, leg ulcers, pressure ulcers, traumatic wounds All of the dressings help to maintain a moist environment May require a secondary dressing	Mepilex (Mölnlycke) Allevyn Gentle (Smith & Nephew) Biatain Silicone (Coloplast)
Hypertonic saline dressings	100% cotton gauze impregnated with crystalline (dry) or solution (wet) saline When placed into a wound the exudate releases the sodium chloride from the dressing, creating a hypertonic environment, absorbing exudate, bacteria and necrotic tissue, reducing oedema and permitting the formation of granulation tissue Technically hypertonic saline does not actually absorb exudate, but rather draws out fluid and debris via a steep osmotic gradient	Moist necrotic, draining and infected wounds Needs to be changed at least daily May cause discomfort or stinging Not recommended for wounds with actual or potential bleeding Not recommended on exposed tendon, muscle or bone Should be discontinued in the presence of healthy granulating or epithelialising wounds	Mesalt (Mölnlycke) Curasalt (Kendall)

continued

TABLE 26-11 ***continued***

Classification	Properties	Clinical considerations	Examples
Cadexomer iodine	Made up of starch micro-beads that contain 0.9% iodine The cadexomer base absorbs exudate, swells and forms a gel Iodine is released progressively into the wound Iodine exerts an antimicrobial effect and bacteria are removed from the wound surface by the process of capillary action Available as a powder, paste or ointment	Low to heavily exuding, sloughy wounds Can be used on infected wounds Changes colour from brown to white when the iodine has been absorbed, indicating the need for a dressing change Not for use during pregnancy or with thyroid disease or suspected iodine sensitivities owing to the risk of systemic absorption Some patients report slight discomfort when dressing first applied The maximum single application is 50 g and weekly maximum must not exceed 150 g Treatment duration should not exceed 3 months in a single course of treatment Will require a secondary dressing	Iodosorb powder, Iodosorb paste, Iodoflex (Smith & Nephew)
Silver dressings	All silver-based dressings, whether alginates, foams, films, hydrofibres or other materials, achieve their antimicrobial action by generating and releasing silver into the wound Silver is a potent antimicrobial; bactericidal mechanisms of action of silver are not fully understood Silver dressings are active against a variety of microorganisms including *Staphylococcus aureus*, methicillin-resistant *S. aureus* (MRSA), *Pseudomonas aeruginosa* and vancomycin-resistant enterococci (VRE)	To reduce the risk of wound infection and to treat infected wounds; provide sustained antimicrobial activity Can dry and adhere if minimal exudate Should not be used with other antimicrobials Do not dilute with saline (deactivates silver) Should not be used with zinc- or oil-based emollients Very expensive May mask host response to infection Should be used for short periods of time, i.e. 3–4 weeks, and the effectiveness re-evaluated Contraindicated in patients with known hypersensitivity to any of the components of the product. If signs of a sensitivity reaction develop during use, treatment should be discontinued	Acticoat (Smith & Nephew) Aquacel-Ag (ConvaTec) Biatain Ag (Coloplast) Actisorb Silver (Johnson & Johnson) Atraumann-Ag (Hartmann) Mepilex Ag (Mölnlycke)
Medicated honey	Comprised of 82% carbohydrate, enzymes and amino acids Acidic pH between 3.2 and 4.5; low enough to be inhibitory to many pathogens Possesses natural anti-inflammatory effects and stimulates granulation tissue Antimicrobial activity mainly through component of hydrogen peroxide Reduces odour Provides a moist environment and produces rapid tissue regeneration and debridement of non-viable tissue	For use on infected or highly contaminated wounds, malodorous wounds Apply honey liberally to either the surface of the wound or a dressing Frequency of dressing changes depends on how rapidly the gel is diluted by exudate Honey is not sterile and there is a perceived risk of wound contamination from the presence of *Clostridium botulinum* spores and *Bacillus* spp. in honey Only honey that has been sterilised/treated by gamma irradiation should be used on wounds Contraindications: Allergies to bees Hypersensitivity reactions Transient stinging/burning on application	Medihony (Comvita)
Odour-absorbing dressings	Contain activated charcoal to absorb odour, bacteria and exudate	Infected or malodorous wounds Malignant or fungating wounds May need a secondary dressing	Actisorb Plus (Johnson and Johnson) Carbonet (Smith and Nephew) CarboFlex (ConvaTec)

wound dressings, you are ready to learn how to perform a simple wound dressing – see Skill 26-2.

CRITICAL REFLECTION POINT

As you read the next section, consider the following questions:

- **What self-help advice would you give to Mr Bukowski?**
- **What strategies would you recommend to prevent skin tear recurrence in the future?**
- **Are there any other healthcare professionals you would liaise with in this case?**

SKILL 26-2

Performing a wound dressing

Delegation considerations

A wound dressing can be undertaken by all healthcare professionals. Check organisational policies regarding which wound care interventions can be delegated to health workers. The assessment of a wound requires the problem-solving and knowledge-application skills of a registered nurse.

Equipment

- Examination gloves
- Apron
- Face mask and protective eyewear
- Sheet or towel for draping
- Normal saline
- Contaminated waste bag
- Acetate grid for wound tracing
- Black fine-tip permanent marker
- Sterile wound probe
- Adhesive remover (optional)
- Wound dressing (choice is dependent on wound characteristics including level of exudate, condition of wound bed, location of wound, mobility, etc)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess size and location of wound.	Helps to plan for type and amount of supplies required.
2. Assess patient's level of comfort.	Removal of dressing may cause pain and discomfort requiring pain medication.
3. Explain procedure to patient.	Decreases anxiety.
4. Close room or cubicle curtains and windows.	Provides privacy and reduces airborne microorganisms.
5. Position patient comfortably and drape with sheet or towel to expose only wound site.	Provides access to wound while minimising unnecessary exposure.
6. Place disposable contaminated-waste bag within reach of work area. Fold top of bag to make cuff.	Ensures easy disposal of soiled dressings.
7. Put on face mask and protective eyewear, if required, and wash hands thoroughly. Put on clean, disposable gloves.	Protects nurse from splashes and reduces risk of transfer of infection between patients.

STEPS	RATIONALE
8. Carefully remove dressing. If dressing is adhered, moisten to facilitate removal. Note the amount of exudate present on the dressing removed, any odour and condition of periwound skin. Remove gloves over contaminated dressing (see illustration) and discard gloves and dressing into prepared bag.	Moistening dressing upon removal decreases pain and trauma to tissue. Observing the dressing as it is being removed helps to determine the capacity of the current dressing to contain exudate, odour and its impact on the periwound skin. Removal of gloves over dressing reduces transmission of pathogens.

Step 8 Remove gloves over contaminated dressing.

9. Cleanse wound with Normal saline or potable tap water. The decision to cleanse the wound should be based on the following: • The shape, size and location of the wound • Condition of the wound bed and stage of healing • Availability and effectiveness of different methods of cleansing • The patient's perceptions and needs.	The aim of wound cleansing is to remove both organic and inorganic debris from the wound and periwound skin to facilitate wound healing, and to make wound assessment easier so that the size and extent of the wound can be visualised.
10. Perform wound assessment. • Wound aetiology • Wound location • Wound dimensions and extent of tissue loss. Apply acetate grid to wound and trace the wound margin with the felt pen. If the wound is a cavity or there is undermining of the wound margins, gently insert a sterile wound probe to measure the depth of the wound • Evaluate the clinical appearance of the wound bed by estimating the percentages of tissue type in the wound bed (yellow/sloughy, red/granulating, black/necrotic, pink/epithelialising, green/infected tissue) • Wound edge (sloping, punched-out, undermining, calloused, raised or rolled) • Exudate (type, amount, colour, consistency and odour) • Condition of surrounding skin (maceration, erythema, oedema, warmth, capillary refill time) • Pain (amount, character, quality, relieving or exacerbating factors).	Provides a combination of subjective and objective data to assess effectiveness of wound management plan and to plan appropriate interventions.

STEPS	RATIONALE
11. Put on clean gloves. Cover wound with appropriate dressing to provide a moist wound healing environment. Dressing selection is based on the following factors: • Aetiology of the wound • Characteristics of the wound: – Location – Extent of tissue damage – Wound size – Phase of healing (epithelialising, granulating, sloughy, necrotic) – Level of exudate – Pain – Odour – Presence of infection • Factors affecting wound healing • Cost-effectiveness • Ease of application and removal • Dressing should cause minimum distress or disturbance to the patient • Awareness of the limitations/contraindications of dressings.	Provides a moist wound environment to facilitate wound healing, absorbs exudate, reduces risk of bacterial colonisation and pain.
12. Remove gloves by pulling them inside out. Dispose of in prepared bag.	Prevents contact of nurse's hands with material on gloves.
13. Assist patient to a comfortable position.	Promotes patient comfort.
14. Document all relevant information in patient's chart.	Provides relevant information about the patient and the wound, monitors healing process, guides wound management of the person as a whole, evaluates the success of management and fulfils legal requirements.

Assessment, management and prevention strategies for common wound types

Now that you have a better understanding of how to assess the skin and wounds, you are ready to learn more about assessing, managing and preventing conditions such as skin tears, leg ulcers, diabetic foot ulcers and pressure ulcers.

Acute wounds

Acute wounds are those that proceed through an orderly and timely reparative process to establish sustained anatomical and functional integrity (Franz et al 2008). Acute wounds are the most commonly encountered wound type, and healing of the acute wound is often taken for granted as it is expected to heal within a 'normal' wound-healing trajectory.

Acute surgical wounds healing by primary intention require minimal intervention apart from observation for complications as the wound edges are brought together (apposed) and then held in place by mechanical means (adhesive strips, staples or sutures). A wound dressing may be required in the first 24–48 hours postoperatively to protect the wound from physical or pathogenic invasion, to absorb exudate and to maintain wound temperature. Most incisions closed by primary intention are resurfaced within 2–3 days after surgery. A *healing ridge* is often palpable approximately 5–9 days after surgical incision; this is an area of induration beneath the skin extending to about 1 cm on either side of the wound. Lack of the healing ridge may indicate dehiscence.

Closure of surgical wounds

Surgical wounds are closed with staples or sutures. *Sutures* are available in a variety of materials, including silk, steel, cotton, linen, wire, nylon and Dacron. Sutures come with or without sharp surgical needles attached. Sutures are placed within tissue layers in deep wounds and superficially as the final means of wound closure. The deeper sutures are usually an absorbable material that disappears in several days. Sutures are foreign bodies and thus are capable of causing local inflammation. The surgeon can minimise tissue injury by using the finest suture possible and the smallest number necessary. Stainless-steel *staples* may also be used (Figure 26-16); these provide more strength than nylon or silk sutures and tends to cause less irritation to the skin.

Normally, for the first 2–3 days after surgery the skin around sutures or staples is swollen. Continued swelling may indicate that the closures are too tight. The skin can be cut by overly tight suture material, leading to wound separation. Sutures that are too tight are a common cause of wound dehiscence. Early suture removal reduces the formation of defects along the suture line and minimises chances of an unattractive scar formation.

Removal of wound closures

Policies vary within institutions as to who may remove sutures or staples, but usually a medical order is required. An order for suture removal is not written until the wound has closed (usually in 7–10 days). Usually, the number of sutures or staples to be removed is indicated. If the suture line appears to be healing in certain locations better than in others, only some sutures may be removed (e.g. every second one).

Figure 26-16 Incision closed by wire staples.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

To remove staples, the tip of the staple remover is inserted under each wire staple and then squeezed, freeing the staple from the skin (Figure 26-17).

To remove sutures, the type of suturing used must first be identified (Figure 26-18). With *intermittent suturing*, the surgeon ties each individual suture made in the skin. *Continuous suturing*, as the name implies, is a series of sutures with only two knots, one at the beginning and one at the end of the suture line. *Retention sutures* are placed more deeply than skin sutures and may or may not be removed by the nurse, depending on agency policy. The manner in which the suture crosses and penetrates the skin determines the method for removal.

The most important principle in suture removal is never to pull the visible portion of a suture through underlying tissue. Sutures on the skin's surface harbour microorganisms and debris; the portion of the suture beneath the skin is considered sterile. Pulling the contaminated (external) portion of the suture through tissues may lead to infection. The suture material is cut as

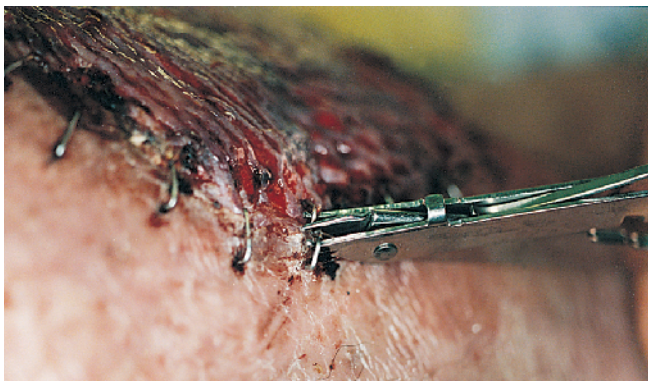

Figure 26-17 Staple remover.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

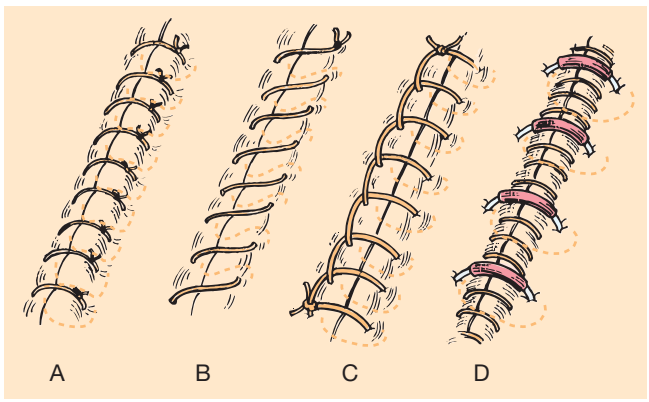

Figure 26-18 Examples of suturing methods.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

close to the skin edge on one side as possible and then the suture is pulled through from the other end.

Every second suture or staple is removed first, and the wound edges are then inspected for healing. The remaining sutures or staples are removed if the wound edges have adhered.

Drains

Drains may be inserted into a surgical wound if a large amount of drainage is expected and if keeping wound layers closed is especially important. Some drains are sutured in place. Caution should be exercised when changing the dressing over drains that are not sutured in place to prevent their being accidentally removed. A drain such as a Penrose drain may lie under a dressing, extend through a dressing or be connected to a drainage bag or a suction apparatus. The surgeon often places a pin or clip through the drain to prevent it from slipping further into a wound. It is usually a medical responsibility to pull or advance the drain as drainage decreases to permit healing deep within the drain site.

The nurse assesses the number of drains, drain placement, the character of drainage and the condition of collecting apparatus. The security of the drain and its location with respect to the wound are observed, and the character of the drainage noted. If there is a collecting device, the drainage volume is measured. Because a drainage system must be patent, drainage flow through the tubing as well as around the tubing should be looked for. A sudden decrease in drainage through the tubing may indicate a blocked drain, and the surgeon should be notified. When a drain is connected to suction, the system is assessed to ensure that the pressure ordered is being exerted. Evacuator units such as a Hemovac or Jackson-Pratt exert a constant low pressure as long as the suction device (bladder or bag) is fully compressed. These types of drainage devices are often referred to as *self-suction*. When the evacuator device is unable to maintain a vacuum on its own, the surgeon is notified, who can then order a secondary vacuum system (such as wall suction). If fluid is allowed to accumulate within the tissues, wound healing will not progress at an optimal rate, and the risk of infection is increased.

When drainage interferes with healing, drainage evacuation can be achieved by using either a drain alone or a drainage tube with continuous suction. Barrier preparations must be applied to protect the skin surrounding drain sites: drainage then flows on the barrier but not directly on the skin. Drainage evacuators are convenient, portable units that connect to tubular drains lying in a wound bed and exert a safe, constant, low-pressure vacuum to remove and collect drainage. The nurse ensures that suction is exerted and connection points between the evacuator and tubing are intact. The evacuator collects drainage, which is assessed for volume and character every shift and as needed. When the evacuator fills, the output is measured by emptying the contents into a graduated cylinder and immediately resetting the evacuator to apply suction.

Skin grafts

Ideally, wounds heal by primary intention. However, large, surgically created wounds and traumatic and chronic wounds can cause extensive tissue destruction, making primary intention healing impossible. Skin grafts may then be necessary to protect underlying structures or to reconstruct areas for cosmetic or functional purposes. Survival of skin grafts relies on revascularisation of the grafted skin (Beldon 2007).

Skin-graft take is the process by which the donor site is incorporated into a recipient or host bed. Successful graft take requires an unhindered process of restoration of vascular perfusion to the donor skin. A graft will take better if the donor site, the area from where the skin is harvested, is highly vascularised.

For a skin graft to take, it must be closely applied to the recipient bed. Any accumulation of oedema, haematoma or seroma between the skin graft and the recipient bed will prevent the skin graft from taking. Movement between the graft and the recipient bed damages the in-growth of capillaries and prevents revascularisation. When skin grafts are applied to movable body parts, splinting is used to immobilise adjacent joints. Bed rest and positioning of the patient to prevent distortion or tension and shearing forces between the graft and the wound bed is essential. Tie-over dressings that immobilise skin grafts, particularly on the face, may be sufficient to immobilise problematic areas.

Several methods are used to fixate the graft, including the open method, the closed method and topical **negative pressure wound therapy**. The *open method* is where the graft is laid onto the recipient site and left open to the air. Initially, the graft is pricked every hour with a sterile needle to express any seroma or haematoma that has built up under the graft. As the wound exudate decreases, the procedure is reduced to every few hours. The *closed method* of skin grafting is where a pressure dressing is applied over the skin to keep it well approximated to the recipient bed (Terrill 2003). There are many different techniques to achieve this; most involve using a non-adherent dressing on the surface of the graft, such as tulle gras or paraffin-impregnated gauze, and a stack of cotton gauze cut to

fit within the defect or a foam sutured/stapled onto the wound margins or a flexible polyamide net coated with soft silicone against the graft with a secondary absorbent dressing secured with sutures or staples (Terrill 2003, Young and Fowler 1998). Sutures or staples are not used if the skin graft is applied in the operating theatre. The fibrin that forms between the skin graft and the recipient bed binds the two surfaces together.

Topical negative-pressure wound therapy is utilised for skin grafts in complex anatomical areas where the base is irregular (Banwell & Teot 2003). A topical negative-pressure dressing achieves good apposition of the skin graft to the recipient site, absorbs exudate, reduces oedema, stimulates the formation of granulation tissue and decreases bacterial colonisation (Banwell & Teot 2003). Excellent graft take (> 95%) has been reported in the literature with this technique for graft fixation (Banwell & Teot 2003).

With the closed or topical negative-pressure wound therapy techniques, the skin grafts are usually reviewed after 5 days and assessed for graft take. A graft that has taken has a purple–pink hue and has adhered to the wound bed. The graft usually needs protection for at least 2 weeks or 3 months if located on the lower limbs. Any graft that has not taken is dressed using normal moist wound-healing principles. After 4–6 weeks, the graft is usually pale pink and the skin depression should be filling in. Further cosmetic improvement can continue with graft maturation over 6–12 months. Cosmesis can be improved using pressure therapy and silicone gel sheeting to soften scars and reduce erythema.

Skin flaps have their own blood supply, and the ability to monitor the status of the flap perfusion or its viability is essential in the prevention, recognition and treatment of complications. A healthy skin flap is similar in colour and texture to the donor site. The colour, temperature, capillary refill time, tissue turgor, dermal bleeding and quantity of exudate are techniques used to assess tissue flap viability.

Donor sites are frequently painful. Factors that affect the healing rate of donor sites are the site, size and depth of tissue excised (Beldon 2007). Healing of donor sites is primarily through re-epithelialisation of the exposed dermis. The sites tend to produce moderate amounts of exudate, and epithelial cells in the hair follicles, sebaceous and sweat glands migrate across the wound bed to form a new layer of epithelium. This process takes approximately 10–21 days. The ideal donor-site dressing should be easy to apply, reduce pain, minimise leakage of exudate, promote rapid wound healing and be inexpensive and acceptable to the patient (Beldon 2007).

Skin tears

A **skin tear** is a traumatic injury to the skin that occurs as a result of friction alone, or shearing and friction. It separates the epidermis from the dermis (known as a *partial-thickness wound*) or separates both the epidermis and the dermis from the underlying structures (known as a *full-thickness wound*). Most skin tears occur on the arms and hands. Other common sites are the lower legs, feet or the head, although they can occur anywhere on the body. Skin tears are the most common type of wound in older people, so it is important to understand why this is so and to be able to identify those most at risk. Most skin tears occur when the person accidentally bumps into an object such as a wheelchair or furniture when being transferred, or following a fall.

There are many risk factors for skin tears. These are explained in Table 26-12.

Classification of skin tears

Skin tears vary in size, location and the amount of tissue loss. It is important that you know how to classify the type of skin tear so that you can determine the appropriate management options.

The STAR Skin Tear Classification System (see Figure 26-19) was developed by the Silver Chain Nursing Association and the Curtin University of Technology (2007) to provide an evidence-based consensus on skin tear classification. This means that if you use this system, you are more likely to be able to identify the type of skin tear and be able to select the correct treatment and prevention strategies. Skill 26-3 explains the assessment and management of a skin tear.

Sinus

A sinus is a cavity or a track that extends from the skin surface to underlying tissue. A sinus may be the result of an infection, ulceration or necrosis of the dermis and underlying tissue, or a surgical wound dehiscence. The goal of management is to gently pack the sinus from the base upwards to eliminate dead space in the wound, prevent abscess formation and facilitate granulation tissue formation (Joanna Briggs Institute 2011).

Fistula

A fistula is an abnormal passage between two or more structures or spaces. This can involve a communication tract from one body cavity or organ to another organ or to the skin. The goal of management is the closure of the fistula, either spontaneously or surgically. Fistulae may be internal or external and are often associated with inflammatory diseases or a postoperative complication.

STAR Skin Tear Classification System

STAR Skin Tear Classification System Guidelines

1. Control bleeding and clean the wound according to protocol.
2. Realign (if possible) any skin or flap.
3. Assess degree of tissue loss and skin or flap colour using the STAR Classification System.
4. Assess the surrounding skin condition for fragility, swelling, discolouration or bruising.
5. Assess the person, their wound and their healing environment as per protocol.
6. If skin or flap colour is pale, dusky or darkened reassess in 24–48 hours or at the first dressing change.

STAR Classification System

Category 1a
A skin tear where the edges **can** be realigned to the normal anatomical position (without undue stretching) and the skin or flap colour **is not** pale, dusky or darkened.

Category 1b
A skin tear where the edges **can** be realigned to the normal anatomical position (without undue stretching) and the skin or flap colour **is** pale, dusky or darkened.

Category 2a
A skin tear where the edges **cannot** be realigned to the normal anatomical position and the skin or flap colour **is not** pale, dusky or darkened.

Category 2b
A skin tear where the edges **cannot** be realigned to the normal anatomical position and the skin or flap colour **is** pale, dusky or darkened.

Category 3
A skin tear where the skin flap is completely absent.

Skin Tear Audit Research (STAR). Silver Chain Nursing Association and School of Nursing and Midwifery, Curtin University of Technology. Revised 4/2/2010.

STAR Skin Tear Classification System Glossary

- ***Skin Tear:*** "a traumatic wound occurring principally on the extremities of older adults, as a result of friction alone or shearing and friction forces which separate the epidermis from the dermis (partial thickness wound) or which separate both the epidermis and the dermis from underlying structures (full thickness wound)"[1].
- ***Pale, dusky or darkened skin or flap colour:*** when compared to the individual's 'normal' surrounding skin, may indicate ischaemia or the presence of haematoma, which may affect skin or flap viability.
- ***Ischaemia:*** inadequate tissue perfusion as evidenced by pale, dusky or darkened tissue.
- ***Haematoma:*** a collection of blood or clot under the flap or realigned skin.
- ***Realign:*** to replace the skin or flap into the normal anatomical position without undue stretching.
- ***Linear skin tear:*** a skin split or the skin splitting in a straight line.
- ***Flap skin tear:*** a segment of skin or skin and underlying tissue that is separated from the underlying structures.

TABLE 26-12 Risk factors for skin tears

Risk factor	Explanation
History of previous skin tears	If an older person has had one skin tear, they are more likely to have another one because their skin is more fragile.
Presence of bruising or discoloured skin (i.e. ecchymosis)	Skin that is bruised or discoloured is likely to tear more easily. This is because the dermis is thinner and there is less connective tissue to support blood vessels. It then takes very little trauma to cause a tear in the skin.
Advanced age	With an increase in age, the skin becomes thinner and less elastic because of reduced collagen and elastic fibre production. Collagen provides the strength and structure to the skin. When the skin of an older person is put under pressure, such as when the person is being moved, the small force applied to the skin can cause the layers of the skin to separate or tear apart resulting in a skin flap with jagged edges.
Poor nutritional status	Older people are more likely to be malnourished and dehydrated because of reduced oral intake or other health conditions. Dehydrated skin is less elastic, more fragile and more likely to break down.
Cognitive impairment or dementia	Lack of awareness of the environment may mean that the person is more likely to bump into an object, resulting in a skin tear.
Dependency	Patients who are dependent (i.e. require care for all activities of daily living) are at greatest risk for skin tears. They tend to acquire frequent skin tears from the mechanical trauma involved from the routine activities of bathing, dressing, positioning and transferring.
Multiple medications	Some medications that make the blood less likely to clot (e.g. anticoagulants) or steroids (e.g. taken for conditions such as rheumatoid arthritis) make the skin thinner and more likely to tear.
Presence of friction or shearing	Dry skin is more likely to tear due to friction and shearing.
Impaired mobility	Poor mobility means that the person is more likely to fall and sustain a skin tear.
Disease processes	Illnesses such as renal failure, heart failure, a cerebral vascular accident and diabetes increase a person's risk of suffering a skin tear because of the way these diseases affect all body systems.

SKILL 26-3

Assessment, management and prevention of skin tears

Delegation considerations

The management and prevention of skin tears can be undertaken by all healthcare professionals. Check organisational policies regarding which wound care interventions can be delegated to health workers. The assessment of a person with or at risk of skin tears requires the problem-solving and knowledge-application skills of a registered nurse.

Equipment

- Examination gloves
- Apron
- Face mask and protective eyewear (optional)
- Normal saline
- Sterile cotton tip
- Contaminated-waste bag
- Black fine-tip permanent marker
- Limb protector
- Wound dressing (choice is dependent on wound characteristics including level of exudate, condition of wound bed, location and size of wound, condition of periwound skin, mobility, etc)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Explain procedure to patient.	Decreases anxiety.
2. Assess size and location of wound.	Helps to plan for type and amount of supplies required.
3. Position patient comfortably.	
4. Place disposable contaminated-waste bag within reach of work area. Fold top of bag to make cuff.	Ensures easy disposal of soiled dressings.
5. Put on face mask and protective eyewear, if required, and wash hands thoroughly.	Protects nurse from splashes and reduces risk of transfer of infection between patients.
6. Control bleeding and clean the wound: a. Stop bleeding by applying firm pressure. Elevate the limb, if applicable, above heart level. b. Clean the wound by gently irrigating with warm Normal saline. Carefully clean under the skin flap to remove foreign debris or blood clots. c. Pat dry the surrounding skin.	The aim of wound cleansing is to remove both organic and inorganic debris from the wound and periwound skin to facilitate wound healing, and to make wound assessment easier so that the size and extent of the wound can be visualised.
7. Realign (if possible) any skin or flap. a. Carefully realign by rolling the skin flap with a moist, sterile cotton bud. The use of a moistened cotton bud assists with approximation of the flap edge. b. Do not stretch the skin to 'make it fit'. Otherwise, the skin flap will shrink back on itself or it may tear off completely. c. If the skin flap cannot be realigned, apply moist wound dressing principles to promote wound healing.	
8. Assess the degree of tissue loss and skin or flap colour: a. Using the STAR Skin Tear Classification System (see Figure 26-19), select the skin tear category that best describes the type of skin tear you are treating. b. Note the colour of the skin flap. If the skin or flap colour is pale, dusky or darkened when compared with the person's normal surrounding skin, this may indicate reduced blood flow (ischaemia) or the presence of a blood clot (haematoma), which may affect the skin or flap viability. c. If the skin or flap colour is pale, dusky or darkened, reassess in 24–48 hours or during the first dressing change.	Provides a combination of subjective and objective data to assess effectiveness of wound management plan and to plan appropriate interventions.
9. Assess the surrounding skin condition for fragility, swelling, discolouration or bruising. This information will assist you when selecting an appropriate dressing.	

STEPS	RATIONALE
10. Assess the person, their wound and their healing environment.	A person's overall medical condition may affect how quickly the wound is likely to heal. This will guide the management and preventive strategies you decide to use.
11. Apply a dressing. Regardless of what type of dressing you select, you should follow these principles:	
• Ensure the dressing extends over the wound edge by at least 1.5–2 cm.	Reduces the risk of trauma on removal of the dressing and increases the ability of the dressing to absorb any leakage from the wound.
• Before applying the dressing, draw arrows on top of the dressing with a felt pen to indicate the direction of the skin flap and write the due date for removal. When removing the dressing, ensure that you remove it in the direction of the arrow to avoid pulling back the skin flap. • Leave in place for 5–7 days. Change earlier only if there is 75% leakage on the dressing. • Reapply a new dressing if healing is not established and leave the dressing intact for 5–7 days. • If the wound is healed, leave it open and moisturise twice daily with a pH-neutral emollient.	
12. Protect limbs: Apply a limb protector or tubular retention bandage to prevent further damage or to hold any dressing in situ.	
13. Document the skin tear: a. Document the skin tear category and location in the patient's record and wound care assessment chart. b. Submit an incident report as required.	Provides relevant information about the patient and the wound, monitors healing process, guides wound management of the person as a whole, evaluates the success of management and fulfils legal requirements.
14. Monitor the healing of the wound: a. Check the dressing and surrounding skin regularly for signs of complications or infection, but leave the dressing intact unless an inspection is clinically indicated. b. Educate the patient about the signs and symptoms of complications or infection. Advise them to report problems, especially any increase in pain, warmth, odour, redness, purulent exudate or fever.	
15. Implement skin-tear prevention strategies, including the following:	

STEPS	RATIONALE
• Assess and recognise risk.	People with fragile, thin, bruised or discoloured skin are at a high risk for further skin tears.
• Use extreme caution and a gentle touch. • Avoid direct contact with the skin: use slide sheets where possible to reduce the risk of friction or shearing forces on the skin, especially when transferring someone. • Protect fragile skin: if a person has fragile skin or has had repeated skin tears, encourage them to wear long sleeves and long trousers to protect their skin. • Apply a pH-neutral moisturiser and/or barrier cream at least twice daily. This will help to prevent dry skin. • Use soap-free alternatives; avoid using soaps and perfumed lotions as these can dry the skin. Instead, use a pH-neutral cleanser or moisturiser. • Avoid using adhesives. Adhesives may increase the risk of tearing the skin when they are removed. It is advisable to use a limb protector instead. • Use protective padding on furniture and equipment: pad bed rails, wheelchair arms and leg supports to reduce the risk of skin injuries. • Ensure adequate lighting. A well-lit environment helps to reduce risk of people bumping into furniture, doors or equipment.	Many skin tears occur when performing normal daily activities such as bathing, dressing and transferring individuals at risk. Avoid wearing jewellery or a watch.
16. Provide continuing education: Help other staff members, patients and their family members understand the importance of identifying those at risk for skin tears, appropriate treatment and prevention strategies.	
17. Document all relevant information in patient's chart.	Provides relevant information about the patient and the wound, monitors healing process, guides wound management of the person as a whole, evaluates the success of management and fulfils legal requirements.

External fistulae may be the result of trauma, infection, malignancy, obstruction, surgery or radiation damage. Management of patients with a fistula requires complex, multidisciplinary care.

Burns

The initial assessment of a burn injury informs the plan of care. Burn injury assessment is notoriously difficult, and therefore access to specialist services for guidance to appropriate assessment, definition/classification and treatment is essential. Types of burn injury include damage to the skin caused by heat (thermal), chemical, electrical or radiation sources. *Thermal burns* are the most frequent type of burn; severity is related to temperature and duration of contact. *Chemical burns* are more likely to be full-thickness in depth and it may take several days for the severity of burn injury to develop or 'declare' the extent of tissue injury. The severity depends on the manner and

duration of contact, the amount of skin and area of the body involved, the concentration of the chemical and how the incidence occurred. *Electrical burn injury* is most commonly caused by alternating current; severity is due to the voltage (force) and amperage (strength). Tissue injury occurs when electrical energy is converted to heat. Electrical burns have a point of entrance and exit, and the depth of injury can be difficult to determine.

Burn injury is classified according to the mechanism of injury, depth of injury and extent of total body surface area involved (see Table 26-13 and Figure 26-20).

There are several techniques for assessing the amount of tissue damage in relation to total body surface area (TBSA), which is important for clinical management (Joanna Briggs Institute 2010). Wallace's 'rule of nines' tool divides the body surface of adults into areas of 9% (or multiples of 9%), with the exception that the perineum is estimated at 1% (Figure 26-21). This allows the extent of the burn to be estimated with reproducible accuracy. Children have different body surface area (BSA) proportions, and the paediatric rule of nines is adjusted for age by taking 1% BSA from the head and adding 0.5% BSA to each leg for each year of life after 1 year of age, until age 10 years where adult proportions are reached.

Age-dependent burn graphs such as the Lund and Browder chart is the preferred method to estimate BSA burn, especially in children and neonates (Figure 26-22) (Joanna Briggs Institute 2010).

Small burns may be estimated using the area of the palmar surface (fingers and palm) of the patient's hand, which approximates to 1% BSA.

Chronic wounds

In Australia, it is estimated that more than 433,000 people suffer from chronic wounds such as leg ulcers, pressure ulcers or non-healing surgical wounds at any one time, although the actual incidence is unknown as many people never seek treatment for their wound problems (Australian Institute of Health and Welfare 2008). Chronic wounds are frequently long-term, painful and debilitating, resulting in reduced quality of life for sufferers. They can affect people of any age, although prevalence increases with age and wounds are estimated to affect up to 5–10% of people aged over 80 years in Australia (ABS 2008). Studies on individuals with chronic leg ulcers reveal the average duration is approximately 1 year, 60–70% have recurrent ulcers and most people suffer from the condition for an average of 15 years or more (Araujo 2003, Bergqvist et al 1999, Lindholm et al 1992). Studies with residents in aged care facilities have reported that 25% suffer from a wound (ABS 2008).

Pressure injuries are considered to be largely preventable and yet they are a significant health problem. The prevalence of pressure ulcers in Australia in the acute care hospital setting ranges from 5.4% to 15.6% (AWMA 2001). Foot ulceration affects 15–20% of all individuals with diabetes and precedes up to 85% of amputations in this patient group, and is the most common cause of non-traumatic lower-limb amputation (Australian Centre for Diabetes Strategies 2005). The annual incidence of foot ulcers in people with diabetes is estimated to be 2.5–10.7% in Australia, Finland, the United Kingdom and the United States, and the average age for lower-limb amputation in

TABLE 26-13 Classification of burn injury

Classification	Degree of tissue loss
Superficial	Involves the epidermis and is red in appearance with no blisters Usually heals within 7 days with no scarring
Superficial partial-thickness	Involves the epidermis and extends into the papillary or superficial layer of the dermis, and is red or pale pink in appearance with small blisters Usually heals within 14 days with no scarring, but there may be slight pigmentation changes
Deep partial-thickness	Extends into the reticular or deeper layer of the dermis and is dark pink in appearance with blisters present Usually takes 2–3 weeks to heal and grafting may be required; scarring may result
Full-thickness	Involves the epidermis, dermis and subcutaneous tissue and appears blotchy red or white in colour with or without blisters Grafting is required and scarring is likely
Subdermal	Involves the muscle, bone, tendon and interstitial tissue Appears as white, brown, black (charred) or deep red with no blisters. Grafting is required and scarring will occur.

Recognising Burn Depths

Epidermal Burn
(Erythema)

- Skin intact, blanch to pressure
- **Erythema not included in % TBSA assessment**
- Heal spontaneously within 3–7 days with moisturiser or protective dressing

Superficial Dermal Burn
(Superficial Partial Thickness)

- Blisters present or denuded
- Blanch to pressure (under blister)
- Should heal within 7–10 days with minimal dressing requirements

Mid Dermal Burn
(Mid Partial Thickness)

- Heterogeneous, variable depths
- Blanches to pressure may have slow capillary return
- Should heal within 14 days
- Deeper areas or over a joint may need surgical intervention and referral to a specialist unit

Deep Dermal Burn
(Deep Partial Thickness)

- Heterogeneous, variable depths
- Deeper areas may not blanch
- Generally need surgical intervention
- Refer to specialist unit

Full Thickness Burn

- Outer skin, and some underlying tissue dead
- Present as white, brick red, brown/black, **non-blanching**
- Surgical intervention and long-term scar management required
- Refer to specialist unit

For transfer criteria to a Severe Burn Unit and further information see NSW Burn Transfer Guidelines

Australia is 65–79 years (Australian Centre for Diabetes Strategies 2005). The 5-year recurrence rate for ulceration is 70%, and for those undergoing a lower-limb amputation there is a 50% chance of losing the remaining limb within 3 years (Australian Centre for Diabetes Strategies 2005).

Wounds commonly affect disadvantaged groups with the least resources to deal with the condition, such as the elderly, disabled and those in lower socioeconomic groups and with poor social support. Unfortunately, the burden of chronic wounds is rapidly growing globally (Harding 2010). In Australia, it is conservatively estimated that the problem of wounds costs the healthcare system more than $2.6 billion per year (Australian Institute of Health and Welfare 2008).

Assessment is the key to effective prevention and management of chronic wounds. Studies demonstrate that significant improvements in healing rates can occur when assessments are rationalised and based on research-based protocols (Carville & Smith 2004, Mulligan et al 2009). However, many patients have never been referred for specialist opinion despite suffering from ulceration for many years, and consequently may not have had the aetiology of the wound correctly diagnosed.

It must be recognised that there are many factors which need to be considered when caring for patients with

or at risk of a chronic wound, including other long-term, chronic health conditions affecting many wound sufferers, and psychosocial and quality-of-life issues affecting many individuals.

Pressure injuries

Pressure ulcer, pressure sore, decubitus ulcer and bed sore are terms commonly used to describe pressure injuries. A **pressure injury** is an injury to the skin and/or underlying tissue, usually over a bony prominence. It occurs as a result of pressure alone, or pressure in combination with shear and/or friction.

Shearing forces usually occur as a result of sliding or dragging the skin across a support surface such as a mattress. **Friction** is the abrasion of the epithelial surface of the skin by rubbing against an abrasive or resistant surface. Friction may occur if the patient repeatedly rubs their heels on their mattress or on wheelchair foot plates. The presence of constant moisture from perspiration, urinary and/or faecal incontinence or wound leakage affects the ability of the skin to resist this type of damage.

Pressure injuries can occur in any location, but are most commonly found on the sacrum or coccyx and heels. They may also occur on other bony prominences, including the ischium, toes, elbows, ears, ankles, nose or other areas of the body. All patients are at risk of developing a pressure injury. Table 26-14 reviews some key risk factors for the development of pressure injuries.

Pressure is the major cause of tissue injury and is related to the intensity and duration of pressure and the ability of the tissue to tolerate pressure. Sustained pressure on a localised area of tissue results in occlusion of blood flow to the vascular and lymph vessels that supply oxygen and nutrients to the tissues. This results in tissue ischaemia and reperfusion injury, leading to cell destruction and tissue death (Queensland Health 2009).

The likelihood of developing a pressure injury is dependent on a number of factors which affect tissue tolerance (see Table 26-12). The intensity and duration of pressure in combination with other risk factors determine a patient's capacity to tolerate pressure (Queensland Health 2009).

Stages of pressure injuries

Pressure injuries are staged to help determine how severe the damage to the skin and underlying tissue structures might be. The *Pan Pacific clinical practice guidelines for the prevention and management of pressure injury* (AWMA 2012) recommend the use of a pressure injury classification system to provide a consistent and accurate means by which the severity of a pressure injury can be communicated and documented. Presently there are four stages of pressure damage. The higher the stage, the deeper the tissue involvement.

STAGE 1 pressure injuries present as areas of persistent, non-blanchable redness when compared with the surrounding skin. The skin around the wound may be painful or itchy, firm or boggy, and warmer or cooler to the touch when compared to the surrounding skin.

Stage 1 pressure injury may be difficult to detect in individuals with dark skin tones. In lighter skin-toned individuals, if you press on the skin for a few seconds, normal skin typically goes white in colour (**blanching**) and then returns to a normal pink colour when the pressure is released. However, patients with more darkly pigmented skin may not have visible blanching and skin colour may differ from the surrounding area. This means

TABLE 26-14 Risk factors for pressure injuries

Risk factor	Explanation
Alteration in mobility or physical activity	Reduced mobility or physical activity due to contractures, fractures, injury, neurological disease or pain increase the risk of pressure injury developing. This is because the patient is unable to independently reposition themselves to off-load or relieve pressure
Malnutrition and dehydration	Malnutrition and dehydration increase the risk of pressure injury. The skin is much drier and less able to withstand the effects of pressure damage
Moisture	The presence of constant moisture from wound leakage, urinary or faecal incontinence and perspiration increases the risk of pressure damage. This is because the skin is less able to resist friction or shearing forces
Alteration in sensation and consciousness	Decreased sensation or loss of consciousness because of cognitive impairment such as a central nervous system injury, a cerebrovascular accident, degeneration, major surgery, spinal cord injury or medications which increase the risk of pressure damage. This is because the patient may not be aware that an injury to the skin has occurred
Other health conditions	Health conditions such as heart disease, diabetes, circulation disorders and a history of smoking can increase the risk of pressure injury

RESEARCH HIGHLIGHT

Research focus

Venous leg ulcers are slow to heal, frequently recur and are associated with pain, restricted mobility and decreased quality of life. Although chronic wound care consumes a large proportion of community nursing time and healthcare resources, there is little evidence available on the effectiveness of differing models of community care for this population.

Research abstract

The aim of this study was to determine the effectiveness of a new community nursing model of care on quality of life, morale, depression, self-esteem, social support, healing, pain and functional ability of clients with chronic venous leg ulcers. The investigators recruited a sample of 67 participants with venous leg ulcers referred for care to a community nursing organisation in Queensland, Australia, after obtaining informed consent. Participants were randomised to either the Lindsay Leg Club model of care (n = 34), emphasising socialisation and peer support; or the traditional community nursing model (n = 33) consisting of individual home visits by a registered nurse. Participants in both groups were treated by a core team of nurses using identical research protocols based on short-stretch compression bandage treatment. Data were collected at baseline, at 12 and at 24 weeks from commencement. Participants who received care under the Leg Club model demonstrated significantly improved outcomes in quality of life (p = 0.014), morale (p < 0.001), self-esteem (p = 0.006), healing (p = 0.004), pain (p = 0.003) and functional ability (p = 0.044).

Evidence-based practice

In this sample, the evaluation of the Leg Club model of care shows potential to improve the health and wellbeing of clients who have chronic leg ulcers. These results suggest that further evaluation and implementation of this model is warranted by community health organisations involved in the care of this population.

BOX 26-1 Skin assessment for pressure injury

Inspect the skin of all patients on admission and at each repositioning to identify indications of pressure injury including:

- erythema
- blanching response
- localised heat
- oedema
- induration
- skin breakdown.

Australian Wound Management Association (AWMA) 2012 Pan Pacific clinical practice guideline for the prevention and management of pressure injury. Cambridge Media, Osborne Park, WA.

that when you press on the skin, changes in skin colour are difficult to detect.

STAGE 2 pressure injuries represent a partial-thickness loss of the dermis, and present as shallow open ulcers with a red or pink wound bed; they may also present as an intact or open/ruptured fluid-filled blister. If a blister is found with clear fluid present and the epidermis is clearly separated from the dermis, this is recorded as a Stage 2 pressure injury.

Stage 2 pressure injuries present as shiny or dry shallow ulcers without any bruising present, since bruising represents suspected deep-tissue damage.

STAGE 3 pressure injuries represent full-thickness skin loss. Subcutaneous fat may be visible, but bone, tendons or muscle are not exposed. Thick yellow tissue (slough) may be present, but this does not obscure the depth of tissue loss. There may be undermining and tunnelling of the wound (i.e. the wound is deeper than it appears on the surface of the skin).

The depth of a Stage 3 pressure injury varies depending on where it is located anatomically. A pressure injury on the bridge of the nose, ear, scalp and ankle does not have subcutaneous tissue and Stage 3 pressure injuries can be shallow. In contrast, areas of significant adiposity or fatty tissue can develop extremely deep Stage 3 pressure injuries, although bone and/or tendon is not visible or directly palpable.

STAGE 4 pressure injuries are the most severe and represent full-thickness tissue loss with exposed bone, tendon or muscle. Thick yellow tissue (slough) or black necrotic tissue may be present in some parts of the wound bed. Often there is undermining and tunnelling of the adjacent tissue.

The depth of a Stage 4 pressure injury varies by anatomical location. The bridge of the nose, ear, scalp

and ankles do not have subcutaneous tissue, so ulcers in these locations can be shallow. Stage 4 pressure injuries can extend into muscle and/or supporting structures (e.g. fascia, tendon or joint capsule), making osteomyelitis (infection in the bone) possible. Exposed bone/tendon is visible or directly palpable.

In addition to the above stages of pressure injuries, there are two other categories of tissue damage. *Suspected deep tissue injury* presents as purple or maroon discoloured intact skin or a blood-filled blister due to damage of the underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, or warmer or cooler as compared with adjacent tissue.

Deep-tissue injury may be difficult to detect in individuals with dark skin tones. The tissue injury may develop into a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Changes may develop rapidly, exposing additional layers of tissue, even with optimal treatment.

Unstageable pressure injuries present as full-thickness tissue loss in which the base of the wound is covered

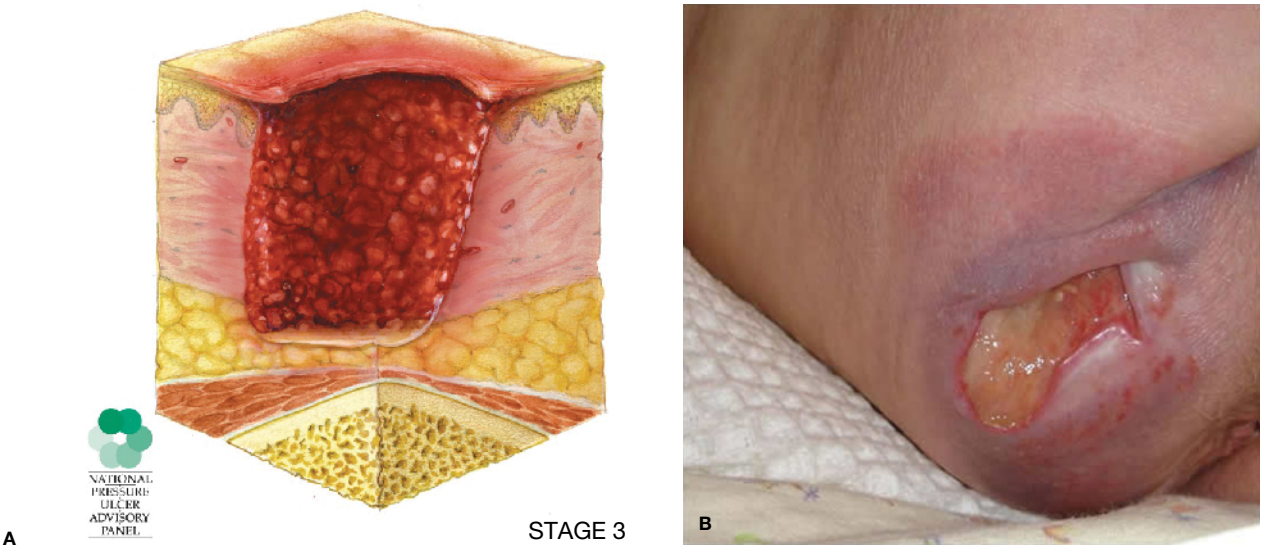

Figure 26-25 **Stage 3 pressure injury.**

by thick yellow, tan, grey, green or brown tissue and/or eschar (tan, brown or black) in the wound bed. Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (i.e. dry, adherent, intact without erythema/redness) eschar on the heels serves as 'the body's natural (biological) cover' and should not be removed.

There are limitations to the staging system for pressure injuries, including the following:

- Reactive hyperaemia may be mistaken for a Stage 1 pressure injury. The presence of non-blanching erythema requires the patient to be repositioned off the area of redness and reassessed in 26 minutes before diagnosing a Stage 1 pressure injury (Queensland Health 2009).
- Stage 1 pressure injury can be difficult to identify in patients with dark-coloured skin (see Figure 26-29).

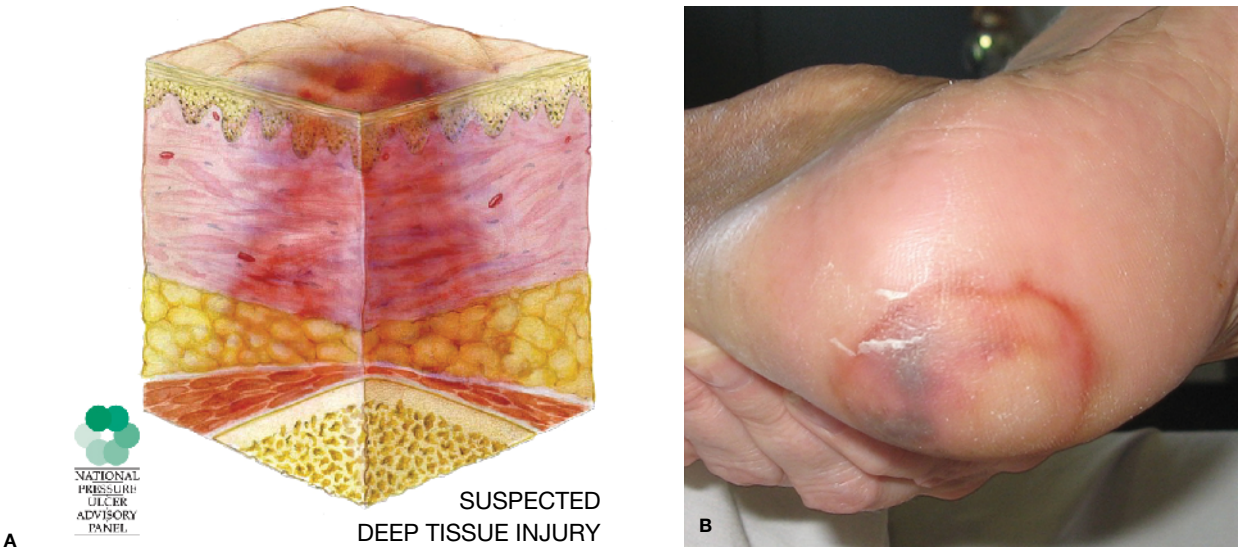

Figure 26-27 Suspected deep-tissue injury.

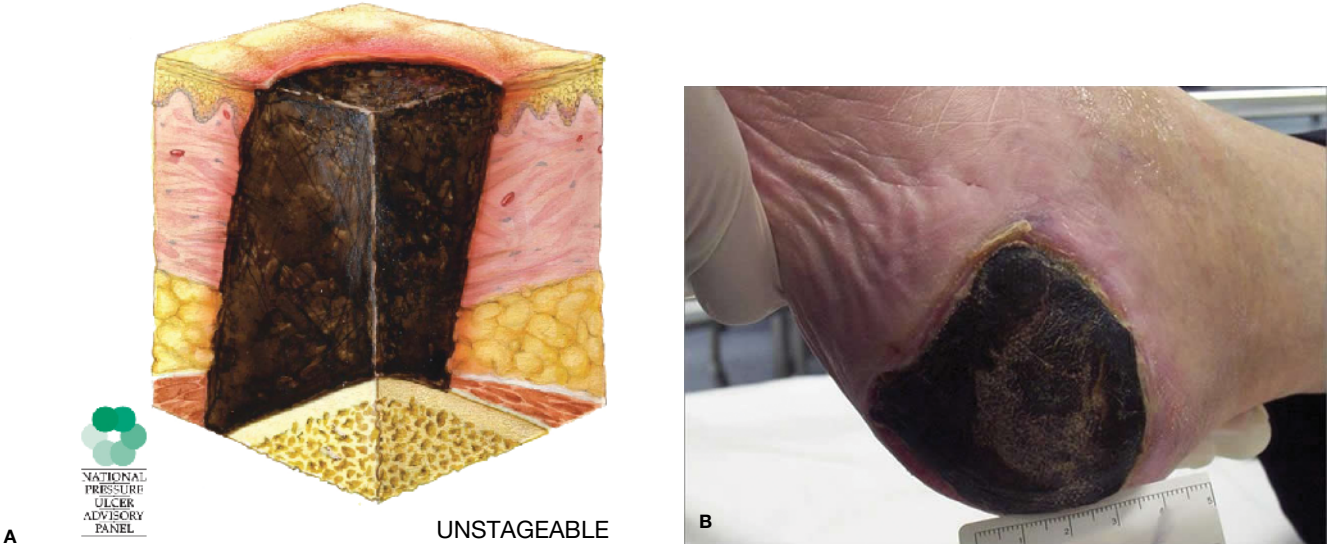

Figure 26-28 Unstageable pressure injury.

© National Pressure Ulcer Advisory Panel (NPUAP). Used with permission. Image courtesy Wound Healing Community Outreach Service, Queensland University of Technology.

- Necrotic tissue (eschar or slough) can conceal the extent of tissue injury, so should be debrided where possible to stage the degree of pressure injury correctly and then be reclassified once debridement has occurred.
- Reverse staging of a healing injury is not generally acceptable.
- The progress of pressure injury healing should be documented using objective parameters such as size, depth, amount of necrotic tissue, the amount of exudate and presence of granulation and epithelial tissue.
- The staging system depends on visual observation of tissue involvement. Factors such as location, wound dimensions, description of wound bed, edge of the wound, condition of periwound skin, pain and other factors which may delay wound healing should also be assessed (Australian Wound Management Association 2012).

Sites of pressure injuries

All parts of the body are at risk of pressure injury. The most common sites are those over bony prominences, as shown in Figure 26-30.

Risk assessment

In order to identify patients at risk of pressure injury, patients must all be screened for risk using an acceptable pressure ulcer risk assessment tool, on admission and regularly throughout their episode of care (Queensland Health 2009). Pressure ulcer risk assessment tools have

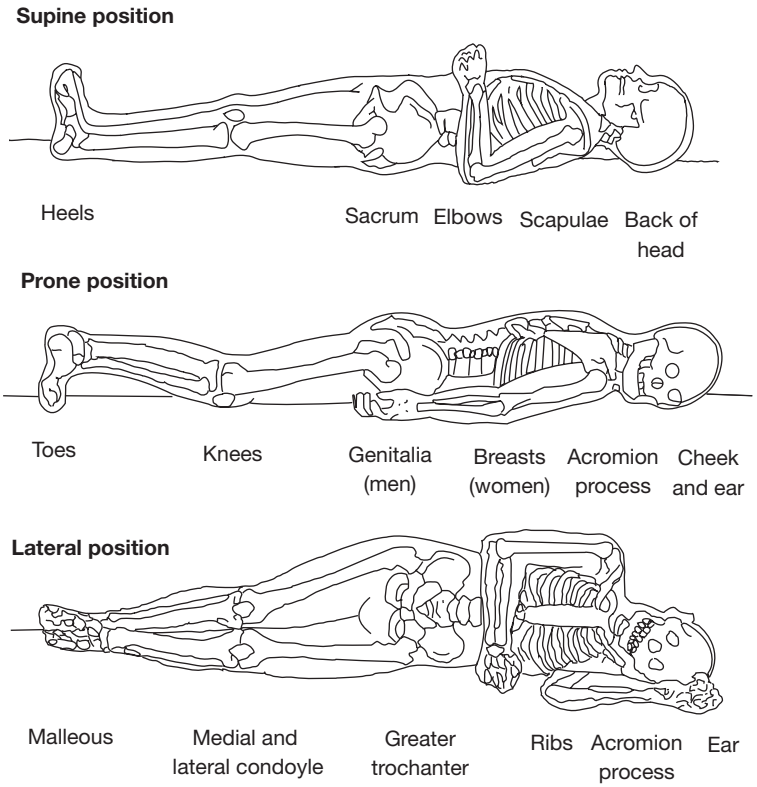

Figure 26-30 Bony prominences most frequently underlying pressure ulcer.

Grey J, Enoch S 2006 Pressure ulcers. Br Med J 332(7539):472–75.

been developed to assist in the identification and assessment of patients at risk for pressure injury. Examples of risk assessment tools include the Waterlow, Braden and Norton tools (copies of each of these tools are available from the Australian Wound Management Association guidelines; see *Online resources*). Risk assessment tools commonly use a rating scale to weight the severity of risk as *no risk*, *low*, *medium* or *high risk* (Queensland Health 2009). Risk assessment tools also commonly address risk factors such as mobility, nutritional status, sensory impairment, the level of consciousness, neurological status and incontinence (Queensland Health 2009). The presence of any condition that limits mobility to the point where a patient is unable to move independently or change position to relieve pressure means that the patient is automatically 'at risk'.

Skill 26-4 demonstrates how to perform an assessment to identify patients at risk of pressure injury; this risk assessment is part of the admission process and ongoing preventative management for each patient (AWMA 2012).

SKILL 26-4

Assessment for risk of pressure injury

Delegation considerations

The management and prevention of pressure injuries can be undertaken by all healthcare professionals. Check organisational policies regarding which wound care interventions can be delegated to health workers. The assessment of a person at risk for or with a pressure injury requires the problem-solving and knowledge-application skills of a registered nurse.

Equipment

- Pressure injury risk assessment tool

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. A comprehensive risk assessment for pressure injuries should be completed on admission for every patient using a risk assessment tool. Reassessment should be performed at the following intervals: • Acute care – at least every 24 hours or sooner if the patient's health condition changes • Long-term care – weekly for 4 weeks, then monthly in high care and quarterly in low care or whenever the patient's condition changes • Home care – weekly or at every nurse visit (if visiting less than weekly) and in response to changes in the patient's condition.	Document all skin assessments using a validated risk assessment tool to aid communication between professionals. Ongoing assessment of the skin is necessary to detect early signs of pressure damage.
2. Identify patient's risk of pressure injury including: • Alteration in mobility and activity – Contractures – Fractures – Injury – Neurological disease/deficit – Pain	

STEPS	RATIONALE
• Malnutrition – Dehydration – Oedema – Protein insufficiency – Weight loss – Obesity • Moisture – Drainage (fistulae, wounds) – Incontinence (urine, faeces) – Perspiration • Alteration in sensation and consciousness – Central nervous system injury – Cerebrovascular disease – Degenerative neurological disease – Drugs e.g. steroids, cytotoxics – Major surgery – Spinal cord injury • Comorbid conditions – Chronic heart failure – Chronic respiratory disease – Circulatory disease – Diabetes – Immune deficiency states – Impaired tissue oxygenation e.g. anaemia, smoking – Metastatic carcinoma – Peripheral arterial disease. Record the patient's level of risk (no risk/at risk/high risk/very high risk) on the risk assessment chart, patient's care plan and in the medical record.	
3. Skin assessment includes:	
a. Prepare the environment, e.g. close curtains.	Ensures privacy and patient comfort.
b. Explain procedure to patient.	Reduces anxiety.
c. Begin assessment with questioning and inspection to identify any existing wounds (refer to Table 26-4).	
d. Position patient comfortably to enable inspection of skin and ensure adequate lighting. Remove clothing as necessary to fully expose each area of skin being inspected.	

STEPS	RATIONALE
e. Conduct a head-to-toe skin assessment with particular focus on skin covering bony prominences, e.g. sacrum, heels and greater trochanters (hips). Inspection involves observation of the skin and palpation with hands to detect the presence of moisture and colour changes and temperature differences in areas of the skin being inspected.	
Check parts of the body covered by anti-embolic stockings, areas of the body where pressure, friction and shearing is exerted in the course of daily activities and other areas affected by equipment, footwear and clothing, i.e. skin around or under prosthetics, orthotics, skin traction, oxygen appliances, intravenous access, tapes and other objects in contact with the skin.	Many different types of medical devices have been reported as having caused pressure injury.
Look for the following characteristics: • Reactive hyperaemia: when a red mark is found, relieve the pressure, check for blanching (the skin whitens under light finger pressure, which indicates the microcirculation is intact). Review in 26 minutes and the redness should have faded substantially. If the skin does not blanch or the hyperaemia (redness) does not fade, then a stage 1 pressure injury has been identified. • Localised heat, oedema and induration.	Localised heat, oedema or induration (hardness), especially in darkly pigmented individuals, are early warning signs for pressure injury development.
f. Ask patient to identify any area of discomfort or pain.	A number of studies have identified pain as a major factor for patients with pressure injuries, and pain over the site is a precursor to tissue breakdown.
4. Reposition patient comfortably following procedure.	Promotes patient comfort.
5. Document all skin assessments using a validated risk assessment tool.	Documentation and communication allows for the timely intervention of preventive and therapeutic measures. This minimises the frequency of occurrence and the severity of pressure damage.
6. If evidence of pressure damage is noted, implement appropriate pressure off-loading and management strategies.	Timely implementation of pressure off-loading and management strategies is essential. Patients identified at risk for or with a pressure injury benefit from pressure off-loading strategies and a pressure injury prevention plan to reduce the risk of further tissue damage.
7. Document all relevant information in patient's chart.	Provides relevant information about the patient and the wound, monitors healing process, guides wound management of the person as a whole, evaluates the success of management and fulfils legal requirements.

An assessment to determine risk for pressure injury should be performed (Queensland Health 2009):

- on admission to the healthcare facility and regularly throughout the length of stay or episode of care. For patients in acute care, it is recommended that assessment is performed on admission and at least every 24 hours, or sooner if a patient's condition changes. In long-term care, assessment should be performed on admission, weekly for 4 weeks, and then quarterly and whenever the patient's condition changes. Patients in the community should be assessed on admission and at every nurse visit
- following any changes in a patient's condition that places that person at risk, for example, a sudden deterioration in health condition
- prior to, during and following prolonged procedures which involve reduced mobility and hardened surfaces.

All patients identified at risk of developing a pressure injury should have a comprehensive preventative management plan in place which aims to maintain tissue tolerance to pressure and protect the individual against the forces of pressure, shear and friction.

Prevention strategies

The Australian Wound Management Association (AWMA 2012) has recently released clinical guidelines to guide clinicians in identifying patients at risk and in selecting appropriate preventive interventions (see Figure 26-31). These guidelines are freely available online (see *Online resources*).

BOX 26-2 The Braden Scale for predicting pressure sore risk

Patient's name		**Evaluator's name**		**Date of assessment**
Sensory perception Ability to respond meaningfully to pressure-related discomfort	*1. Completely limited* Unresponsive (does not moan, flinch or grasp) to painful stimuli due to diminished level of consciousness or sedation OR Limited ability to feel pain over most of body surface	*2. Very limited* Responds only to painful stimuli Cannot communicate discomfort except by moaning or restlessness OR Has a sensory impairment which limits the ability to feel pain or discomfort over half of body	*3. Slightly limited* Responds to verbal commands, but cannot always communicate discomfort or need to be turned OR Has some sensory impairment that limits ability to feel pain or discomfort in 1 or 2 extremities	*4. No impairment* Responds to verbal commands Has no sensory deficit that would limit ability to feel or voice pain or discomfort
Moisture Degree to which skin is exposed to moisture	*1. Constantly moist* Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned	*2. Very moist* Skin is often, but not always, moist Sheets must be changed at least once a shift	*3. Occasionally moist* Skin is occasionally moist, requiring an extra sheet change approximately once a day	*4. Rarely moist* Skin is usually dry, sheets require changing only at routine intervals
Activity Degree of physical activity	*1. Bedfast* Confined to bed	*2. Chairfast* Ability to walk severely limited or non-existent. Cannot bear own weight and/or must be assisted into chair or wheelchair	*3. Walks occasionally* Walks occasionally during the day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair	*4. Walks frequently* Walks outside the room at least twice a day and inside room at least once every 2 hours during waking hours

Patient's name		**Evaluator's name**		**Date of assessment**	
Mobility Ability to change and control body position	*1. Completely immobile* Does not make even slight changes in body or extremity position without assistance	*2. Very limited* Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently	*3. Slightly limited* Makes frequent though slight changes in body or extremity position independently	*4. No limitations* Makes major and frequent changes in position without assistance	
Nutrition Usual food intake pattern	*1. Very poor* Never eats a complete meal. Rarely eats more than one-third of any food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement OR Is nil by mouth and/or maintained on clear liquids or intravenous fluids for more than 5 days.	*2. Probably inadequate* Rarely eats a complete meal and generally eats only about half of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement OR Receives less than optimum amount of liquid diet or tube feeding	*3. Adequate* Eats over half of most meals. Eats a total of 4 servings of protein (meat, dairy products) each day. Occasionally will refuse a meal, but will usually take a supplement if offered OR Is on a tube feeding or total parenteral nutrition regimen that probably meets most nutritional needs	*4. Excellent* Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation	
Friction and shear	*1. Problem* Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures or agitation leads to almost constant friction	*2. Potential problem* Moves feebly or requires minimum assistance. During a move, skin probably slides to some extent against sheets, chair, restraints or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down	*3. No apparent problem* Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during the move. Maintains good position in bed or chair at all times

There are many strategies that can be implemented to prevent pressure injuries.

- *Maintain regular skin inspections every day and with each repositioning or turn for signs of pressure injury.* On inspection, particular attention should be given to skin over bony prominences, for example, the sacral area, heels and greater trochanters, areas of the body where pressure, friction and shearing is exerted during normal daily activities and areas affected by equipment, footwear and clothing.
- *Skin hygiene should be maintained to preserve skin integrity.* The normal pH of the skin is between 4 and 6.8; maintaining a stable skin pH reduces the risk of infection and skin breakdown. Use of soap-free, pH-neutral cleansers and emollients keep the skin in better condition. Skin that is dry is less likely to be able to withstand the effects of friction and shear. Providing a stable environmental temperature and avoiding extremes of hot and cold decreases the risk of pressure injuries. Limit the patient's exposure to moisture. Ensure limited or no exposure to excessive moisture such as perspiration, urinary and/or faecal incontinence or wound fluid.
- *Avoid rubbing or massaging bony prominences.* Massaging or rubbing bony prominences increases the risk of tissue damage. Pillows and foam wedges can be used to reduce pressure on bony prominences if positioned correctly. Avoid using foam rings or donuts, as these increase the risk of pressure damage by pushing or forcing the tissue through a narrow opening. Discourage patients from sitting or lying in one position. Repositioning should occur every 15 to 60 minutes if possible. Use positioning and turning schedules where possible, and consider the patient's medical condition, comfort and overall plan of care as well as the support surface used.
- *Prevent shear and friction.* Elevate the foot of the bed 20 degrees when sitting to prevent the patient from sliding; also, limit the amount of time patients spend with the head of the bed elevated. Use of correct manual handling techniques, including slide sheets or equipment to transfer patients, reduces the risk of friction and shear.
- *Monitor the patient's nutrition and hydration.* Refer to a dietitian if you are concerned about the patient's nutritional status.

Working as part of a team is important to ensure that appropriate pressure ulcer-prevention strategies are implemented. Your team includes the patient, family members, general practitioner, nurses, care staff and allied health professionals. Education of the patient, family members and other healthcare professionals is essential so that they understand the causes of skin damage.

Support surfaces

The optimal support surface is one that relieves pressure, shear and friction and maintains a stable skin temperature (AWMA 2012). Support surfaces should distribute bodyweight over a large surface area or totally remove pressure from the body surface, thereby reducing point pressure and tissue damage. Support surfaces alone do not eliminate the risk of pressure injury, as pressure injury prevention requires comprehensive clinical care, regular repositioning and ongoing assessment.

There are many support surfaces available, such as mattresses, overlays or chair cushions, made up of a variety of different fabrics, including foam, gel or air. *Comfort equipment* includes overlays, pads, cushions and sheepskins; these are mostly used for comfort and in combination with existing mattresses or chairs that a patient is using. They may provide a degree of pressure reduction and reduce shearing and friction because of their low-resistance or non-abrasive properties. Comfort devices are suitable for low-risk patients who are relatively mobile and require minimal intervention.

Constant low-pressure devices conform to body contours and aim to redistribute weight over a wider area, thereby reducing tissue interface pressure (AWMA 2012). These devices include foam- or fibre-filled mattresses and overlays, water beds, gel pads, air overlays and mattresses with both static/constant air and low-air-loss devices (AWMA 2012). These devices may be powered, mechanical devices or non-powered, non-mechanical devices. Constant low-pressure devices may be appropriate for medium-risk patients who are able to reposition themselves or who receive frequent repositioning.

Alternating-pressure devices generate alternating high and low pressure between the body and the support surface by periodically deflating air cells under the body and redistributing the pressure on the tissue, which encourages reperfusion of previously supported areas (Queensland Health 2009). These devices are available as overlays or single or multi-layered mattress replacements. They are suitable for high-risk patients who are immobile or obese.

Specialty beds combine a bed and sleeping surface and are designed for patients at very high risk for pressure injury.

Pressure injury prevention and management requires a collaborative approach. The patient's risk status and risk factors provide the basis for the formation of an individualised prevention and management plan. The management plan should provide specific details of what

CLINICAL EXAMPLE

Mr Bukowski re-presents 6 months after the skin tear on his left arm with a new wound located on his left lateral leg (gaiter region). The wound is failing to heal despite using the strategies that were recommended to treat his skin tears. Mr Bukowski states that the wound has been present for approximately 4 months and started as a minor skin tear. The wound has gradually been increasing in size and it has been leaking a lot. He says that sometimes he has to change the dressings every day because it leaks that much. Mr Bukowski has noticed that his skin is very dry and scaly and that his skin looks like it is going rusty. He reports that the wound is sometimes painful, particularly after he has been standing for a while, and that the pain is worse when he first gets out of bed in the morning and by late in the afternoon. He has also noticed that his ankles have become quite swollen and finds that elevating his legs can help to reduce his pain and swelling. Mr Bukowski reports feeling a bit 'out of sorts'; he can't go out like he used to because he is worried that others can smell his wound, he is fearful that the leakage will ruin his good clothes and his wound might get worse. He hasn't told his daughter about his wound because he doesn't want to worry her.

Figure 26-32 **Mr Bukowski's leg ulcer.**

care is required, who is responsible for that care, frequency of turning, equipment required, referrals and expected outcomes (AWMA 2012). Clinical interventions must be monitored regularly and documented and communicated to staff, patients, families and carers.

• CRITICAL REFLECTION POINT

Based on the clinical scenario above, consider the following questions:

- **What factors are likely to have led to the development of this leg ulcer?**
- **Based on the history and clinical examination data, what type of leg ulcer might this be?**
- **Is this wound healing by primary or secondary intention?**
- **What characteristics would indicate if this wound was infected?**
- **What is the predominant tissue type in the wound bed?**
- **How would you describe the wound edges?**

Ulcers

Leg ulcers

A leg ulcer is a wound that occurs between the knee and ankle which takes more than 4 weeks to heal. There are two common types of leg ulcers: *venous* and *arterial* leg ulcers. Assessment is the key to effective management of leg ulcers, yet many people with leg ulcers have never had a specialist assessment to identify the type of leg ulcer they are suffering from. Hence, leg ulcers may last for many years and, even if they heal, may soon break out again if the correct treatment and prevention strategies have not been followed.

Every leg ulcer has key features or characteristics that help determine the type of leg ulcer the person is suffering from. The key characteristics for the most common types of leg ulcers are outlined in Table 26-17 on p. 740.

VENOUS LEG ULCERS are the most common type of leg ulcer. They occur because of high blood pressure in the veins in the lower limb (known as *venous hypertension*). Veins carry blood from the legs back to the heart. Veins in the lower leg have one-way valves to prevent blood from running backwards, and when the calf muscles contract, blood is moved along the veins back towards the heart.

However, sometimes the valves in the veins or the calf muscles fail to work properly, for a number of different reasons (e.g. damage from a past clot in the vein), leading to chronic venous insufficiency or venous disease. The constant high pressure in the veins eventually causes fluid to leak out of the veins and into the surrounding tissues and skin. Although the reason for ulcer formation is not fully understood, the combination of high pressure in the veins and particles in the fluid forced into the tissues causes inflammation. This results in the skin easily breaking down and forming an ulcer. Table 26-15 highlights some of the risk factors for venous leg ulcers.

Once you have identified the signs and symptoms of a venous leg ulcer, you then need to determine the appropriate treatment. Key evidence-based management strategies for venous leg ulcers are summarised here.

- *Dressings* used to treat venous leg ulcers vary depending on the condition of the ulcer and the goals of treatment. Dressings should maintain a moist wound-healing environment, manage wound leakage (exudate), protect the skin around the ulcer, be non-adherent to reduce trauma on removal, and be cost-effective, acceptable to the patient and able to be changed less often where possible.

TABLE 26-15 Risk factors for venous leg ulcers

Risk factor	Explanation
Age	Blood flow decreases as a person ages, and decreased mobility leads to the calf muscles becoming less effective and not being used as much as they should be
Obesity	Excess weight, particularly around the waist and thighs, puts extra pressure on the veins and they have to work harder to move blood flow back towards the heart. Note that multiple pregnancies may also be a cause of excess weight
Varicose veins	The one-way valves that stop blood from travelling backwards in the veins stop working and this leads to pooling of blood in the lower legs
Past deep-vein thrombosis or trauma to lower limbs	A history of deep-vein thrombosis (i.e. blood clot) or trauma may result in permanent damage to the veins
Jobs that involve sitting or standing for long periods of time	Occupations that involve sitting or standing for long periods of time may result in less-effective blood flow through the veins and pooling of blood in the lower legs
Family history or congenital valvular incompetence	There is a strong link between family history and leg ulcers. In addition, in rare cases some people are born with problems that affect their veins, placing them at higher risk of venous disease
Health conditions	Disorders such as congestive cardiac failure lead to swelling of the lower limbs because the heart is not able to process blood flow effectively

- *Apply graduated compression bandaging.* The key to healing a venous leg ulcer is to treat the underlying cause (i.e. reduce the high blood pressure in the veins). Graduated compression bandaging works by improving venous return, reducing swelling in the lower limb and improving foot- and calf-muscle pump action. Bandages are applied from the base of the toes to just below the knee. The bandage is said to be graduated because the *ankle* is smaller than the calf. Therefore, the pressure exerted by the bandage at the ankle is higher than that applied at the calf. You need special training in how to apply graduated compression bandages correctly because if they are applied incorrectly they can cause significant damage to the patient's circulation and may even make the ulceration worse.
- *Apply compression stockings.* Graduated compression stockings for life after wound healing help to prevent venous leg ulcers from recurring, because they continue to provide compression to treat the underlying cause of the leg ulcers (i.e. poor circulation). A venous leg ulcer is really a symptom of an underlying disease process. Compression stockings can also be used to prevent venous leg ulcers.

Failure to reach an accurate diagnosis and/or to recognise the signs and symptoms of venous disease may result in the unsafe application of the graduated compression bandaging.

ARTERIAL LEG ULCERS are less common than venous leg ulcers and are the result of peripheral arterial disease. Arteries supply blood and oxygen to the lower limbs; arterial leg ulcers result from inadequate blood supply and oxygen in the arteries. If the blood supply to the lower legs is poor, the leg is starved of oxygen and nutrients; the skin fails to function normally and an ulcer may develop. A patient with arterial disease may have very cool or cold feet, the skin may be pale, blue (cyanosed) or dusky red in colour and they may complain of pain in the foot or calf muscle. Pain is often worse at night when the lower leg is elevated in bed and pain is only relieved when the legs are lowered. During exercise, the muscles in the lower leg need more oxygen; when a person has arterial disease, the blood supply is decreased and pain occurs in the foot or calf muscle on exercising. This pain is known as *intermittent claudication*. Table 26-16 outlines the patient risk factors for developing arterial leg ulcers.

Patients with arterial leg ulcers may benefit from a review by a specialist. This is because restoring blood flow by revascularisation is the intervention most likely to heal arterial leg ulcers.

Improving oxygenation of the wound environment promotes healing. Steps to improve oxygen supply to the tissues include avoidance of dehydration, cold, stress and pain. Dressings used to treat arterial leg ulcers vary depending on the condition of the ulcer and goals of the treatment. Topical antimicrobial dressings may be helpful to prevent infection.

Controlling risk factors known to affect the arteries is essential. For example, the healthcare professional should try to ensure that blood glucose levels are kept within normal ranges, blood pressure is controlled, cholesterol levels are reduced, medications are reviewed and the

TABLE 26-16 Risk factors for arterial leg ulcers

Risk factor	Explanation
Atherosclerosis	Hardening, narrowing or blockage of the arteries because fatty deposits (plaques) or cholesterol reduces blood supply to the lower leg
Smoking	Cigarette smoking is a well-known risk factor for atherosclerosis and heart disease
Hypertension	High blood pressure leads to hardening of the arteries
Diabetes	Poorly controlled diabetes leads to high cholesterol levels in the blood and increased the risk of hardening of the arteries. There is also an increased risk of strokes, heart disease and ulceration of the lower limbs
High cholesterol	High cholesterol is a major risk factor for hardening of the arteries
Stress	There is a link between high levels of stress and arterial disease
A history of heart disease, heart attack or stroke	These conditions increase the risk of further problems with the peripheral arteries
Obesity	Excess weight, particularly around the waist and thighs, puts extra pressure on the arteries and the heart has to work harder to move blood flow around the body

patient has a healthy and balanced diet, stops smoking and is encouraged to maintain a healthy weight relative to their height.

Diabetic foot ulcers

A **diabetic foot ulcer** is an ulcer located on the foot and is associated with a loss of protective sensation (neuropathy) and/or the presence of ischaemia in a patient with diabetes. Diabetic foot ulcers are more likely to occur if the patient has uncontrolled or prolonged high blood-sugar levels (hyperglycaemia).

Once you have identified the signs and symptoms of a diabetic foot ulcer, you then need to determine the correct treatment. Key evidence-based management strategies for diabetic foot ulcers may include the following:

- *Recommend a medical review*: patients with diabetic foot ulcers may benefit from review by a specialist.
- *Use a team approach to care*: care of diabetic foot ulcers should be undertaken by a multidisciplinary team including podiatrists, orthotists, wound-care specialists, the patient's doctor, an endocrinologist, a dietitian and a diabetic educator.
- *Ensure adequate oxygenation*: improving oxygenation of the wound environment promotes healing. Steps to improve oxygen supply to the tissues include avoidance of dehydration, cold, stress and pain.
- *Ensure off-loading of pressure points*: it is essential to review the patient's footwear and ensure that pressure is relieved. Otherwise, the wound will fail to heal. Areas of abnormal pressure distribution on the diabetic foot are usually located on the plantar aspect of the foot under the hallux, first and fifth metatarsal heads and under the heel (Grey et al 2006).
- *Apply suitable dressings*: dressings used to treat diabetic foot ulcers vary depending on the condition of the ulcer and goals of treatment. Topical antimicrobial dressings may be helpful at preventing infection.
- *Control risk factors:* controlling risk factors known to affect the arteries is essential. For example, try to ensure that blood glucose levels are kept within normal ranges, the blood pressure is controlled, cholesterol is reduced, medications are reviewed, and the patient has a healthy and balanced diet, stops smoking and is encouraged to maintain a healthy weight relative to their height.

Assessment and management

Being able to recognise the key signs and symptoms of the different types of ulcers is very important to help obtain an accurate diagnosis. The following steps may assist during clinical examinations to determine the aetiology of ulceration. Table 26-17 compares the key characteristics of venous, arterial and diabetic ulcers. Assessing these characteristics can assist you to determine the aetiology of ulceration.

Prevention strategies

Once you have learned how to assess and manage venous, arterial and diabetic foot ulcers, there are some important evidence-based strategies that can be put in place to reduce the risk of the ulcer recurring. Box 26-3 highlights some of the key prevention strategies.

TABLE 26-17 Characteristics of leg ulcers

Characteristic	Venous	Arterial	Diabetic
Location	Above the ankle bones, on the lower third of the leg in the calf muscle region 	Toes, shin or over pressure points (i.e. sites subjected to trauma, the rubbing of footwear and ankle bones) 	Sole of the foot, the toes or over pressure points such as the ball of the foot 
Depth	Shallow, affecting the epidermis and dermis	Usually shallow but may be deep	Usually shallow but may be deep and may have tracking or undermining (i.e. probes to tendon or bone)
Appearance	Ruddy or beefy red, granular appearance	Pale grey or yellow in colour with no evidence of new tissue growth. May also be black (necrotic) and tendons may be exposed	Red granular, pale grey or yellow in colour. May also be black (necrotic) and tendons may be exposed
Wound shape and margins	Flat and irregular, often resembling the shape of a cartoon figure or country 	Smooth, even or punched-out appearance. The shape of the wound may conform to injury if caused by trauma 	Calloused wound margins
Exudate	Moderate to heavy	Low to moderate	Low to heavy. An infected ulcer may have purulent, foul-smelling leakage
Surrounding skin	Ankle flare or small veins concentrated around the ankles 	Pale, shiny, taut skin Cold legs and feet even in a warm environment Absence of hair on the legs or toes Legs dusky red or blue (cyanosed) Blackened toe nails Tendon exposed in wound bed	Dry, calloused skin around wound margins Cold legs and feet, even in a warm environment Absence of hair on the legs or toes Evidence of previous foot ulcers or amputation

continued

TABLE 26-17 ***continued***

Characteristic	Venous	Arterial	Diabetic
	Varicose veins 		
	Oedema or swelling around the ankle or calf muscle region  Atrophie blanche or absence of pigmentation in the tissue (sometimes indicating a history of previous ulcers) 		Foot deformities such as Charcot's foot, hammer toes or clawed toes Thickened toenails Redness of the affected area when the legs are dependent or 'dangled' and pallor when the foot is elevated

continued

TABLE 26-17 ***continued***

Characteristic	Venous	Arterial	Diabetic
	Hyperpigmentation or discolouration of lower limb 		
	Hyperkeratosis (dry, flaky skin) 		
	Venous stasis eczema 		

continued

TABLE 26-17 ***continued***

Characteristic	Venous	Arterial	Diabetic
	Haemosiderin staining, or red blood cells which have died and then build up under the skin, staining the skin a brown colour 		
Pain	Ranges from no pain to severe, constant pain Pain is often worse after standing for long periods May be described as an achy, dull pain or a feeling of pressure Pain is usually relieved by elevating the limb above heart level because this relieves the pressure on the veins and reduces swelling	Often accompanied by severe cramping pain in the foot or calf muscle at rest when the legs are elevated Pain may also increase when walking short distances (known as intermittent claudication)	Often painless
Referral criteria	Uncertainty in the diagnosis Low or high ankle–brachial pressure Index (ABPI) (i.e. less than 0.9 or greater than 1.2) The ulcer is complicated (e.g. multiple aetiology such as arterial or rheumatoid disease) There are signs of infection, the ulcer or lower limb appears ischaemic and/or the wound can be probed to bone The ulcer deteriorates or fails to improve after 3 months The patient has symptoms which limit their lifestyle and quality of life (e.g. rest pain) and would benefit from surgical revascularisation		

• CRITICAL REFLECTION POINT

Think about how you would decide on the management of Mr Bukowski's leg ulcer:

- **How would you cleanse this wound?**
- **What type of management strategies would you employ for this type of leg ulcer? What dressing regimen would you choose at this point, and why? How would you manage the skin around the wound?**
- **What self-help advice would you give to Mr Bukowski? What strategies would you recommend to prevent leg ulcer recurrence in the future?**
- **Are there any other healthcare professionals that you would liaise with in this case?**

Malignant/fungating wounds

Malignant fungating or cancerous wounds are those that affect people with cancer. Fortunately, they occur infrequently, but are typically described as a devastating, overwhelming and distressing experience (Alexander 2010). They are caused by the infiltration of the skin by a local tumour such as a squamous-cell carcinoma or melanoma; haematological malignancy such as cutaneous T-cell lymphoma; or metastatic spread from a primary tumour, for example, breast cancer where metastasis occurs along tissue planes, capillaries or lymph vessels (Adderley & Smith 2007, Naylor 2002). Lesions are characterised by a process of both *ulcerative* (crater-like) and *proliferative* (nodular or cauliflower-shaped) growth that can cause extensive damage to the skin and surrounding structures (Lewellyn et al 2002).

Although rare, malignant changes may develop in chronic wounds (Marjolin's ulcer) and are most commonly associated with burn-scar ulcers, pressure or venous ulcers (Naylor 2002). This type of malignancy is usually aggressive and has a high rate of metastatic spread

BOX 26-3 Leg ulcer prevention strategies

- Follow up and check the skin regularly.
- Apply a pH-neutral moisturiser to the skin at least twice daily.
- Ensure shoes are well-fitting, soft and comfortable.
- Be extremely careful when cutting toenails. Preferably, a podiatrist should do this.
- Avoid soaking the feet in hot water, using heating pads and applying harsh topical skin cleansers.
- Protect the toes and heels of patients with decreased mobility by using effective pressure-relief devices such as foam or gel pads.
- Use leg-protection devices to avoid injury (e.g. limb protectors or long trousers).
- Keep the lower legs warm. Passive warming of the lower legs and feet, such as covering the legs with a blanket, improves blood supply (perfusion). However, do not use hot water bottles, electric blankets or foot spas, or position the feet close to heating devices. This is because the person may not be able to feel if damage is occurring, which risks burning of their skin.
- Encourage lower-limb exercises, at least every hour. Simple exercises may include drawing figures with the toes, pushing the toes towards the floor and then pointing them up towards the nose, standing on the balls of the feet, tiptoeing up and down, walking or swimming. Any movement of the calf muscle helps to move blood back to the heart. Also discourage crossing of the legs, which reduces arterial blood flow.
- Elevate the affected limb at least 3–4 times every day for at least 15 minutes each time, to help reduce high blood pressure in the lower legs and reduce swelling. Elevation means placing the patient's legs on pillows, a chair or another object so that the feet are above the level of the knees, and the knees are above the level of the hips. Try to discourage patients from sitting with their legs down and stationary for more than an hour at a time. Patients should put their feet up while performing sit-down tasks. Elevating the legs to the level of the hips doesn't reduce swelling, but it keeps the swelling from getting worse. Elevating the legs above the level of the heart is needed to reduce swelling.
- Smoking cessation interventions are an important part of the treatment plan.
- Ensure the patient maintains a healthy weight relative to their height. A well-balanced diet and healthy weight reduce the risk of arterial disease.
- Manage any underlying diseases; ensuring that underlying diseases such as diabetes, heart disease or hypertension are well controlled helps to prevent complications such as arterial leg ulcers.
- Education of patients, family members and other staff helps to ensure that problems are identified early and strategies are implemented to reduce risk. It is especially important that the patient does not walk barefoot if they have diabetes or arterial disease, as they might tread on something and damage their skin and not be aware they have done so.
- For patients with venous leg ulcers, use of graduated compression stockings for life reduces ulcer recurrence rates. Compression stockings should be measured and fitted by a trained practitioner to ensure that they are the correct size for the person. Compression hosiery should be replaced at least every 6 months. Compression stockings must be worn every day except while in bed, bathing or swimming. Stockings should be applied as early in the day as possible to prevent the legs from swelling. Remove hosiery as close to bed-time as possible.

and local recurrence (Naylor 2002). Diagnosis can only be confirmed following biopsy of the wound, although signs of malignant change in a chronic wound are typically characterised by onset of pain or a change in the type or intensity of pain, malodour and change in character, volume or appearance of exudate.

Malignant wounds can have a significant impact on the patient and their family and greatly affect the quality of life. Wound management priorities vary considerably for each patient and strategies should be targeted according to the patient's preferences. Most patients with a malignant wound will be in the terminal stages of their illness and wound healing is unlikely to occur. The main aim of wound management is aimed at controlling or eliminating the distressing symptoms associated with these wounds.

Malignant wounds often produce copious amounts of exudate, which can be difficult to manage (Naylor 2002). Exudate production is secondary to increased permeability of blood vessels in the tumour and secretion of vascular permeability factor by tumour cells, or increased exudate due to the presence of infection (Naylor 2002). High volumes of exudate may result in maceration and irritation of the skin. There are many dressings available for the management of exudate (e.g. foams and alginates), and selecting a dressing that will absorb exudate but still maintain a moist environment is essential (Adderley & Smith 2007).

An offensive malodour caused by bacterial infection and/or the presence of devitalised tissue within the wound bed is frequently the most distressing aspect of a malignant wound; it can be socially isolating and cause loss of appetite and nausea (Alexander 2010). Debridement of necrotic or devitalised tissue is the main method of treatment for malodorous fungating wounds (Naylor 2002). However,

surgical sharp debridement is not recommended due to the high risk of bleeding; autolytic debridement is the preferred method of debridement (Naylor 2002). The use of antimicrobials (e.g. metronidazole gel) can help to reduce the amount of bacteria present in the wound, thereby reducing malodour. The use of topical activated-charcoal dressings and occlusive dressings may help to control odour, and environmental agents such as room deodorants and fragrances for control of odour may also assist (Carville 2007).

Bleeding can occur secondary to the erosion of blood vessels by malignant cells and may be exacerbated by decreased platelet function within the tumour (Naylor 2002). Profuse, spontaneous bleeding can be very distressing and careful management of the wound during dressing changes is essential to minimise the risk of bleeding. Preventative measures to reduce the risk of bleeding, such as the use of non-adherent dressings, maintaining a moist environment, haemostatic dressings (e.g. alginates or haemostatic sponges) and wound cleansing by irrigation, will help to reduce the risk of trauma and bleeding (Naylor 2002).

Pain is caused by a number of mechanisms, including pressure on nerves and blood vessels and exposure of the dermis (Naylor 2002). Pain frequently results in loss of sleep, distress and anxiety and may be exacerbated by wound-dressing changes. Pain should be assessed before, during and after wound-dressing changes and analgesia should be prescribed using the World Health Organization (WHO) guidelines (see Chapter 41) for the control of cancer pain and in accordance with local prescribing guidelines (Naylor 2002). The use of non-adherent dressings and dressings which maintain a moist environment may help to reduce pain associated with wound-dressing changes.

The position of the wound may be a significant source of distress for the patient, particularly if in a highly visible area such as the breast or face. Wound management strategies aimed at devising a cosmetically acceptable dressing may help to promote self-esteem and minimise distress.

The skin around the fungating wound is susceptible to breakdown and must be assessed for signs of bacterial infection, fungal infection, maceration and excoriation. The use of non-traumatic adhesives, skin sealants and creams or ointment barriers can help to provide protection to the periwound skin.

Palliative treatment may include radiotherapy and systemic or topical chemotherapy to reduce tumour size, exudate and malodour (Adderley & Smith 2007). *Radiotherapy* in the form of X-rays or radioactive substances is used as a localised cancer treatment or in combination with other treatments such as surgery or chemotherapy, and is used to reduce the size of a tumour, to control the spread of disease or to relieve symptoms of advanced disease (Regan 2007). Radiotherapy is unable to differentiate between normal and abnormal cancer cells, and the radiation can damage healthy tissue and may result in skin atrophy, soft-tissue fibrosis and microvascular damage or burn injury (Regan 2007). Skin reactions to radiotherapy typically occur 2 weeks into treatment; the likelihood of developing a reaction depends on a number of factors including the patient's age, skin integrity, type of radiation and amount of energy used, chemical and skin irritants used by the patient, nutritional status, presence of skin folds and concurrent chemotherapy (Regan 2007). Skin reactions may be mild such as dry skin or may lead to moist desquamation.

Strategies that can be taken to minimise the effects of radiation include preventing mechanical trauma caused by shaving, friction, pressure, adhesive tapes or constrictive clothing; avoiding the use of chemical trauma from soaps, deodorants, shaving creams, astringents or make-up; avoiding extremes of heat and cold to prevent thermal trauma; avoiding skin products that contain metallic substances, including zinc cream and talcum powder; avoiding exposure to the sun; moisturising the skin frequently with a pH-neutral emollient; and ensuring adequate nutrition and hydration (Carville 2007).

Chemotherapy may be used to reduce the size of a malignant wound; it involves the use of systemic or localised cytotoxic drugs (Regan 2007). Chemotherapy can cause skin reactions including transient erythema, hyper-pigmentation, photosensitivity, nail changes, palmar/plantar syndrome and inflammatory reactions in tissue that has been previously irradiated, resulting in blisters, vesicle formation, exfoliation and ulceration (Regan 2007). Chemotherapy can decrease the size of a malignant wound by destroying malignant cells, and reduce pressure on nerves and blood or lymph vessels, thereby reducing exudate production and potential to bleed (Regan 2007).

Extravasation of the skin can occur secondary to the use of chemotherapy drugs, resulting in ulceration of the skin, nerve damage, significant pain, disfigurement and potential limb loss (Regan 2007). Extravasation occurs over a few days with maximum severity over 2–3 weeks. The degree of tissue damage is secondary to the amount of drug extravasated, drug concentration, site, needle insertion device and technique (Regan 2007). The affected tissue may appear swollen, tender and red and progressively worsen into ulceration, and may involve tendons and nerves. Severe tissue damage may require surgical intervention (Regan 2007). Prevention of extravasation injuries includes a thorough assessment of the patient, venous access, related risk factors,

knowledge of the drug and early recognition of the signs of extravasation injury including burning pain, erythema and oedema at injection site.

Malignant fungating wounds are a significant problem and are challenging for both patients and healthcare professionals. The key to effective management is accurate assessment to improve quality of life through symptom control; however, there is insufficient evidence to provide clear direction for practice with regard to improving quality of life or managing wound symptoms associated with fungating wounds (Adderley & Smith 2007, Lo et al 2008, 2012).

Adjunct wound therapies

Hyperbaric oxygen therapy (HBOT) is a treatment designed to increase the supply of oxygen to wounds that are not responding to other measures to treat them. HBOT involves people breathing pure oxygen in a specially designed chamber (such as that used for deep-sea divers suffering pressure problems after resurfacing). Evidence suggests that HBOT seems to reduce the number of major amputations in people with diabetes who have chronic foot ulcers, and may reduce the size of wounds caused by venous disease, but at this stage there is no evidence to confirm or refute any effect on other wounds caused by lack of blood supply due to arterial disease or pressure injury (Goldman 2009, Kaur et al 2012, Kranke et al 2004).

Key concepts

- Having a good understanding of the anatomy and physiology of the skin is essential in order to determine whether a patient is at risk of compromised skin integrity.
- Wound healing is achieved through the process of vasodilation, inflammation, proliferation and maturation.
- There are various modes of wound healing, including primary intention or secondary intention.
- Wounds are classified as either acute or chronic depending on the duration of injury.
- There are many factors that affect the wound-healing process.
- Assessment is essential in order to recognise those at risk of skin breakdown and to aid in implementing appropriate wound management and prevention strategies.
- Regular evaluation of the effectiveness of the wound management plan is essential.

Administering medications

Vanessa Brotto

Learning outcomes

Mastery of content will enable you to:

- discuss the principles of quality use of medications
- identify members of the medication team and describe their role
- discuss the nurse's role and responsibilities in medication administration
- describe the physiological mechanisms of medication action, including absorption, distribution, metabolism and excretion
- differentiate between different types of medication actions
- discuss developmental factors that influence pharmacokinetics
- discuss factors that influence medication actions
- discuss methods for educating a client about prescribed medications
- describe factors to consider when choosing routes and times of medication administration
- calculate a prescribed medication dosage correctly
- discuss criteria for assessing a client's needs for and response to medication therapy
- apply the seven rights of safe medication administration
- explain the procedures for the correct preparation and administration of: subcutaneous, intramuscular and intradermal injections; intravenous medications; oral and topical skin preparations; eye, ear and nose drops; vaginal instillations; rectal suppositories; and inhalants.

KEY TERMS

Absorption, p. 755
Adverse effects, p. 757
Anaphylactic reactions, p. 758
Blood–brain barrier, p. 756
Bolus, p. 762

Sublingual (subling), p. 760
Tandem infusion, p. 841
Therapeutic effect, p. 757
Topical, p. 762
Toxic effects, p. 758
Trade name, p. 751
Verbal order, p. 766
Z-track method of injection, p. 825

A *medication* is a substance used in the diagnosis, treatment, cure, relief or prevention of health alterations. The medication may be a prescription, non-prescription (over-the-counter) or complementary/herbal preparation. Other terms which may be used to describe medications include 'medicines' and 'drugs', although medications and medicines are the currently preferred terms.

Administration of medications is a fundamental part of nursing practice and nurses draw on their scientific knowledge base to ensure safe, effective and appropriate medication outcomes for the client. Regardless of whether clients receive their health care in hospitals, clinics or the home, the nurse plays an essential role in medication therapy.

In the acute care setting the nurse also ensures that clients are adequately prepared to administer their medications when they leave hospital. In addition, a nurse teaches clients about their medications and any side effects, encourages clients to adhere to their medication regimen and oversees client self-administration of medications. The nurse assesses the effects of medications in restoring or maintaining health.

CLINICAL EXAMPLE

'A lesson for all nurses' by Vanessa Brotto, RN

Emergency nurses administer many different types of medications via numerous routes. Clients can present with various problems that may require urgent replacement of electrolytes. One oncology client presented in atrial fibrillation (AF) whose pathology results showed a dangerously low potassium (K+) level. The client had a PICC line (peripherally inserted cardiac catheter) for their chemotherapy treatment and had been vomiting so much that their electrolytes had dropped markedly, causing the rapid and irregular AF heart rhythm.

The doctor asked the nurse (a graduate nurse) to administer 10 mmol of KCl intravenously via the PICC line and wrote this up in the 'stat' order section of the medication chart. The graduate nurse had not given this before and although the department was very busy, she took the time to ask the nurse in charge if this was appropriate. The nurse in charge confirmed it was and she then prepared the potassium in a syringe before checking it with another senior nurse, who checked the medication ampule and the syringe and went through the medication order and confirmed the client's pathology results. They did the 'seven rights' together and then the graduate nurse took the medication to the client.

When she got there, another nurse stopped her to ask if she had prepared the KCl as it was 'urgent' so she confirmed it again with the other nurse as well. They again went through all the information and pathology results and checked all the seven rights together. She then went into the client room and administered the medication … and the client immediately went into cardiac arrest!!!!

The error??? She had given it as a bolus (i.e. rapidly injected it all into the intravenous line at one time) rather than infuse it over 60 minutes as is safely required. She didn't realise that a bolus of potassium like this is inherently dangerous and can cause the heart to immediately stop (in fact this is one of the medications administered in countries that execute prisoners with the death penalty by lethal injection i.e. some states in the USA).

This graduate nurse had checked the medication thoroughly with three senior nurses and they all went through the seven rights with her, except no one checked how she planned to actually administer the medication. They assumed she would realise the danger of intravenous potassium and she assumed they would tell her if there was something she should know. The client was eventually resuscitated and survived; however, the lesson should be learnt by all – checks must be thorough and not assume anything. It also reinforces that nurses should never administer unfamiliar medications and always look them up thoroughly.

Quality use of medications

The concept of 'quality use of medicines' stems from the 1985 World Health Organization (WHO) Rational Use of Medicines policy. The WHO found that a significant proportion of the global community were prescribing or using medicines inappropriately, and so it called for healthcare professionals and governments to do something about this (WHO 2010). Australia's response was the 1999 launch of the National Medicines Policy (Department of Health 2015a), which has 'quality use of medicines' (QUM) as a core objective.

Australia's National Medicines Policy aims to maximise an individual's benefit from a medication regimen, achieve safe, effective and appropriate use of medications, and optimise medicinal use of prescription and over-the-counter/complementary preparations to improve the health outcomes. Quality use of medications involves selection of a medication that is (Department of Health 2015b):

- *wise*: ensuring the best possible treatment plan is chosen
- *necessary*: ensuring that when medicines are needed they are carefully selected, managed, monitored and reviewed
- *safe and effective*: minimising misuse, overuse and underuse of medicines while ensuring that medicines achieve the goals of therapy by delivering beneficial changes in actual health outcomes.

Nurses have an important role to play in QUM. Nurses can help assess clients' use of medicines and their responses to them, to ensure they are being used appropriately and that the best possible treatment plan is in effect. In order to do this properly, nurses must have readily accessible resources on medicines and be able to share these with clients. Various health resources are available to help nurses learn about medicines and educate clients. The consumer medication information (CMI) leaflets which are produced by pharmaceutical companies (found in the packaging of medicines) are provided to help with this role. Nurses must also recognise the need to access evidence-based drug resources that have unbiased information, such as the *Australian Medicines Handbook* and *Therapeutic Guidelines* (which are often available online via universities and clinical agencies/hospitals).

Quality use of medicines is aimed more broadly than at healthcare professionals alone. The government and policy-makers are integral to QUM, as they make key decisions about the supply and subsidy of different medicines. Partnerships between all members of the 'medication team' are required for QUM to be in effect, as well as to improve/maintain best health. This team includes those who take medicines (consumers), those who prescribe medications (medical practitioners, nurse practitioners, eligible midwives and, in some cases, other nurses and other healthcare professionals), those who dispense medications (pharmacists) and those who administer and monitor the use of medications (nurses, family and other health workers).

• CRITICAL REFLECTION POINT

You are caring for a client who is admitted for a gastroscopy as a day procedure. While you are admitting her, she tells you that she doesn't take one of the 'little blue digoxin tablets' as directed by her general practitioner. Rather she takes half a tablet to make the prescription last twice as long so it is not as expensive. Is this quality use of medicines? How would you respond to this client?

WORKING WITH DIVERSITY

Focus on children

One of the difficulties facing the application of quality use of medicines (QUM) is in the area of paediatrics, where there is often 'off-label' use of medicines (meaning that they are prescribed for conditions or at doses other than as advertised in the prescribing information from the manufacturer). It has been reported that 3.3–100% of prescriptions in paediatric clients may use medicines in this way (Bellis et al 2013). This is due to a lack of research data on the effects of different medicines in children; as a result, prescribers working with children need to use medicines to treat them, but often do not have research data to support their use.

This is a challenge for QUM, as nurses working with paediatric clients may not find data supporting the use of medicines in some clinical cases. It is not prudent to say that these medicines should not be used 'off-label' at all, as their use may be life-saving, but it does present a challenge to QUM in paediatrics. Examples of this include giving meropenem to a neonate when it has been approved for use in children over 3 months of age (Kling 2011), or the use of psychotropic medicines when their effects in children have not been specifically investigated.

Kling S 2011 Off-label drug use in childhood asthma. Curr Allerg Clin Immunol 24(1):38–41.

• CRITICAL REFLECTION POINT

Off-label prescribing is often required in children, but what are some of the ethical implications of using a medicine in the way described in *Working with diversity*?

The medication team

Quality use of medications relies on cooperation and collaboration of all members of the medication team.

The prescriber's role

Medical practitioners are by far the main prescribers of medications. Increasingly, however, nurses working as nurse practitioners (NPs) or Eligible Midwives prescribe within a specific scope of practice and associated formulary. In addition, it is not uncommon to find some settings where registered nurses (RNs) initiate medications for a specific client and from an approved list of medications (e.g. a nurse-initiated opioid analgesia protocol in emergency departments). The prescriber writes a medication order on a medication chart in the client's health record, on a legal prescription pad or through a computer terminal.

The nurse's role

The nurse prescribing or administering medications is accountable for knowing the medications prescribed, their therapeutic and non-therapeutic effects and the client's need for the medication.

The nurse supervises the administration of the medication and provides education to the client and family about the medication and its effects. The nurse is responsible for assessing the client and their need for the medication before the dose, and then evaluating the

effects of the medication after the dose and evaluating the outcome of this therapy.

The nurse, as and when appropriate, assesses the client's ability to self-administer medications and provides client and family education about proper medication administration and monitoring. It is also important to note that different nursing roles may affect what a nurse can prescribe/administer. For example, NPs are able to prescribe certain medicines specifically relevant to their area of practice while enrolled nurses (ENs) may be limited in what they are able to administer by their agency's policy.

The pharmacist's role

The pharmacist prepares and dispenses prescribed medications. The pharmacist may also assess the medication plan, conduct 'medication-reconciliation' assessments (i.e. comparing medicines used at home with those prescribed in hospital) and evaluate the client's general medication-related needs. The pharmacist is responsible for filling prescriptions accurately and ensuring that prescriptions are valid. The pharmacist in a healthcare agency rarely has to mix compounds or solutions, except in the case of some intravenous additive solutions. Most pharmaceutical companies deliver medications in a form ready for use. Dispensing the correct medication, in the proper dosage and amount and with an accurate label is the pharmacist's responsibility. The pharmacist acts as a valuable community and professional resource, providing information about medication action, side effects, toxicity, interactions and incompatibilities.

Medications administered to clients are used, almost exclusively, to prevent, diagnose or treat disease. Nurses need to be familiar with the actions and effects of medications they administer to clients. Moreover, to administer medications safely and accurately to clients, nurses draw on an understanding of physiology, pharmacology including **pharmacokinetics** (the movement of drugs in the human body), **pharmacodynamics** (the biochemical and physiological effect of drugs on the body), human growth and development, human anatomy and physiology, nutrition and mathematics.

Application of pharmacology in nursing practice

Names

A medication may have as many as three different names – the chemical name, a generic (non-proprietary) name and a trade name. A medication's *chemical name* provides an exact description of the medication's composition and molecular structure; chemical names are rarely used in clinical practice. An example of a chemical name is 7-chloro-1,3-dihydro-1-methyl-5-phenyl-3H-1,4-benzodiazepin-2-one. The **generic name**, for example, diazepam, is given by the manufacturer that first develops the medication. The generic name (written with a lowercase initial letter) is the name listed in official publications, such as the *British Pharmacopoeia* and the *MIMS Annual*. The **trade name**, brand name or proprietary name (written with an uppercase initial letter) is the name under which a manufacturer markets a medication. The trade name has the symbol ® at the upper right of the name on the packaging, indicating that the manufacturer has registered the medication's name (e.g. Valium®). A drug may have several trade names. The following illustrates the three-name system:

- Chemical name: 7-chloro-1,3-dihydro-1-methyl-5-phenyl-3H-1,4-benzodiazepin-2-one
- Generic name: diazepam
- Trade names: Antenex, Diastat, Ducene, Valium.

Manufacturers choose trade names that are easy to pronounce, spell and remember so that the general public will recognise them and ask for specific brands. Many different companies may produce the same medication. It is best practice for medications to be prescribed and dispensed using the generic name to avoid confusion. The nurse finds medications documented under a variety of different names, however, and must be careful to obtain the exact name and spelling for a particular medication and check all trade names against the generic name to be sure the correct drug is given.

Nurses also need to be aware that some trade brands of the same generic medication may be able to be substituted safely (referred to as 'brand name substitution'); for example, Febridol (trade name) can usually be substituted for Panadol (trade name) when a client is ordered paracetamol (generic name). However, in some situations not all trade brands of the same generic drug are equal, and so the prescriber/pharmacist should be consulted before a nurse substitutes trade brands. For example, when a client is prescribed the medication warfarin (generic name) it is important that Coumadin (trade name) is not substituted for Marevan (trade name), as they are not deemed to be bioequivalent (i.e. warfarin 5 mg of Coumadin may not be the same as warfarin 5 mg of Marevan).

• CRITICAL REFLECTION POINT

A prescriber has ordered a number of prn (as required) medicines for a client postoperatively. Which of the following medicines should not be given together as they contain the same active ingredient: Fentanyl, Herron, Morphine, Panamax, Dymadon Co, Panadeine Forte?

Classification

Nurses must recognise the *category* or *class* to which medications with similar characteristics are allocated. Medication classification indicates the effect of the medication on a body system, the symptoms the medication relieves or the medication's desired effect. For example, clients who have type 2 diabetes often take oral hypoglycaemic agents to help control their blood glucose levels. Usually, each class contains more than one medication that can be prescribed for the type of health problem. For example, there are more than five different classes of oral hypoglycaemic agents. The physical and chemical composition of medications within a class may be slightly different. For example, two of the oral hypoglycaemic agents, a sulfonylurea and a biguanide, have different functions and are often prescribed together. A sulfonylurea stimulates the release of insulin from the pancreas, whereas a biguanide decreases the rate of hepatic glucose production. A prescriber chooses a particular oral hypoglycaemic medication based on how it works with the client's symptoms or the client characteristics, cost, efficacy and dosing frequency. The prescriber may also choose based upon their own experience with the medication in other clients. It is expected that prescribers will also consult with evidence-based guidelines to decide which medications to use. These guidelines may be found through various sources such as the 'Therapeutic Guidelines' and other specialty bodies such as the Royal Australian College of General Practitioners and eviQ from the Cancer Institute of NSW.

A medication may also be part of more than one class. For example, aspirin is an analgesic, an antipyretic, an anti-inflammatory and an anti-platelet medication. Often, the dose administered determines the class or action of the medication. An example of this is where a client may be prescribed antidepressants for neuropathic pain or the use of antihypertensive medicines for the treatment of heart failure.

Medications are available in a variety of forms or preparations (see Figure 27-1 and Box 27-1). The form of the medication determines its route of administration and speed of absorption. The composition of a medication is designed to enhance its absorption and metabolism. When administering a medication, the nurse must be certain to use the proper form that is appropriate to the client's condition (e.g. liquid if swallowing tablets is difficult).

Medication legislation and standards

The role of Australian governments in regulation of the pharmaceutical industry is to protect the health of the public by ensuring that medications are safe and effective.

Figure 27-1 Forms of oral medications.

Top row: Uniquely shaped tablet, capsule, scored caplet. Bottom row: Gelatin-coated liquid capsule, extended-release capsule, enteric-coated tablet.

Potter PA, Perry AG 2004 Fundamentals of nursing, 6th edn. Mosby, St Louis.

BOX 27-1 Forms of medication

Caplet: solid dosage form for oral use; shaped like capsule and coated for ease of swallowing.

Capsule: solid dosage form for oral use; medication in powder, liquid or oil form and encased in gelatin shell; capsule coloured to aid in product identification.

Elixir: clear fluid containing water and/or alcohol; designed for oral use; usually has sweetener added.

Enteric-coated tablet: tablet for oral use coated with materials that do not dissolve in the stomach; coatings dissolve in the intestine, where medication is absorbed.

Extract: concentrated medication form made by removing active portion of medication from its other components (e.g. fluid extract is medication made into solution from vegetable source).

Glycerite: solution of medication combined with glycerin for external use; contains at least 50% glycerin.

Intraocular disk: a small flexible oval consisting of two soft outer layers and a middle layer containing medication; when moistened by ocular fluid, releases medication for up to 1 week.

Liniment: preparation usually containing alcohol, oil or soapy emollient that is applied to skin.

Lotion: medication in liquid suspension applied externally to protect skin.

Ointment (salve): semi-solid, externally applied preparation, usually containing one or more medications.

Paste: semi-solid preparation, thicker and stiffer than ointment; absorbed through skin more slowly than ointment.

continued

Pessary: solid dosage form mixed with gelatin and shaped into form of pellet for insertion into the vagina; melts when it reaches body temperature, releasing medication for absorption.

Pill: solid dosage form containing one or more medications, in globule, ovoid or oblong shape; true pills are rarely used because they have been replaced by tablets.

Solution: liquid preparation that may be used orally, parenterally or externally; can also be instilled into body organ or cavity (e.g. bladder irrigations); contains water with one or more dissolved compounds; must be sterile for parenteral use.

Suppository: solid dosage form mixed commonly with gelatin or wax and shaped into form of pellet for insertion into the rectum; melts when it reaches body temperature, releasing medication for absorption.

Suspension: finely divided drug particles dispersed in liquid medium; when suspension is left standing, particles settle to bottom of container; commonly an oral medication and not given intravenously.

Syrup: medication dissolved in concentrated sugar solution; may contain flavouring to make medication more palatable.

Tablet: powdered dosage form compressed into hard disks or cylinders; in addition to primary medication, contains binders (adhesive to allow powder to stick together), disintegrators (to promote tablet dissolution), lubricants (for ease of manufacturing) and fillers (for convenient tablet size).

Tincture: alcohol or water–alcohol medication solution.

Transdermal disk or patch: medication contained within semi-permeable membrane disk or patch, which allows medications to be absorbed through the skin slowly over long period.

Troche (lozenge): flat, round dosage form containing medication, flavouring, sugar and mucilage; dissolves in the mouth to release medication.

Control is exercised at three levels. The Therapeutic Goods Act 1989 (amendments made often, last updated 2015; see www.tga.gov.au) regulates all drugs developed in or imported into Australia. It controls medication manufacture, sales and distribution, medication testing, naming and labelling, and the regulation of controlled substances. Advertising of some poisons to the public is also regulated by this Act.

The National Health Act 1953 applies to the Pharmaceutical Benefits Scheme that provides subsidised drugs to Australian residents. It also limits the amount of medicines that may be supplied, and the number of times and frequency the supply can be repeated. Not all medicines are available at subsidised rates. Administration of medications by nurses is subject to further control by various regulations; some of the most important are listed in Box 27-2.

Poisons (including medicines) are listed in schedules (Box 27-3) that detail their availability to the public. For example, medicines listed in Schedule 4 are restricted to medical, dental or veterinary prescription (also includes NP prescription in some states). Official publications, such

BOX 27-3 Standard for the uniform scheduling of drugs and poisons in Australia

Schedule 1
This Schedule is intentionally blank.

Schedule 2
Pharmacy Medicine – substances, the safe use of which may require advice from a pharmacist and which should be available from a pharmacy or, where a pharmacy service is not available, from a licensed person.

Schedule 3
Pharmacist Only Medicine – substances, the safe use of which requires professional advice but which should be available to the public from a pharmacist without a prescription.

Schedule 4
Prescription Only Medicine – substances, the use or supply of which should be by or on the order of persons permitted by state or territory legislation to prescribe and should be available from a pharmacist on prescription.

Schedule 5
Caution – substances with a low potential for causing harm, the extent of which can be reduced through the use of appropriate packaging with simple warnings and safety directions on the label.

Schedule 6
Poison – substances with a moderate potential for causing harm, the extent of which can be reduced through the use of distinctive packaging with strong warnings and safety directions on the label.

Schedule 7
Dangerous Poison – substances with a high potential for causing harm at low exposure and which require special precautions during manufacture, handling or use. These poisons should be available only to specialised or authorised users who have the skills necessary to handle them safely. Special regulations restricting their availability, possession, storage or use may apply.

Schedule 8
Controlled Drug – substances which should be available for use but require restriction of manufacture, supply, distribution, possession and use to reduce abuse, misuse and physical or psychological dependence.

Schedule 9
Prohibited Substance – substances which may be abused or misused, the manufacture, possession, sale or use of which should be prohibited by law except when required for medical or scientific research, or for analytical, teaching or training purposes with approval of Commonwealth and/or state or territory health authorities.

Schedule 10/Appendix C
Substances of such danger to health as to warrant prohibition of sale, supply and use – Substances which are prohibited for the purpose or purposes listed for each poison.

Based on content from the Federal Register of Legislation at 06.04.16. For the latest information on Australian Government law please go to www.legislation.gov.au.

as the *British Pharmacopoeia*, set standards for medication strength, quality, purity, packaging, safety, labelling and dose form.

Healthcare institutions and medication laws

Healthcare institutions establish individual policies that must meet national, state and local government laws and regulations. The size of an institution, the type of service it provides and the type of professional personnel employed all influence policy development. Institutional policies are often more restrictive than government controls. An institution is concerned mainly with preventing health problems that may result from medication use. For example, a common institutional policy is the automatic discontinuation of antibiotic therapy after a set number of days. Although the prescriber may reorder the antibiotic, this policy helps to control unnecessarily prolonged medication therapy.

Medication regulations and nursing practice

The nurse is responsible for following legal provisions when administering controlled substances or opioids (e.g. as listed under Schedule 8 of the Australian Poison Classification Schedule), which are carefully controlled through national and state regulations (see Chapters 10 and 11). Violations of the relevant Acts are punishable by fines or imprisonment and may lead to loss of nursing registration. Hospitals and other healthcare institutions have policies for the proper storage and distribution of controlled medicines (Box 27-4).

• CRITICAL REFLECTION POINT

Many healthcare professionals believe that the law dictates that two nurses need to double-check controlled substances from the medication safe to the bedside, but this is not the case. There are a number of hospitals and clinical agencies that have a single-checking policy, requiring the nurse to be both competent and accountable for their checking of these medicines.

What can a nurse do when single-checking medicines to ensure that medicines are administered safely?

BOX 27-4 Guidelines for safe administration of controlled drugs

In addition to the mandatory requirements set out under various state and federal legislation as well as those required by agency policy, it is good practice for the following guidelines to be instituted in clinical care:

- Store all controlled drugs in a locked, secured cabinet (computerised locked cabinets are available).
- A registered nurse carries a set of keys (or a special computer entry code) for the controlled drug cabinet.
- During an institution's change of shift, the nurse going off-duty counts all controlled drugs with the nurse coming on duty. Both nurses sign the controlled drug record to indicate that the count is correct.
- Discrepancies in drug counts are to be reported immediately to the department managers, pharmacy and on the incident reporting system.
- A special inventory record is used each time a controlled drug is dispensed.
- The record is used to document the client's name, date, time of drug administration, name of drug, dose and signature of nurse or medical practitioner administering the drug.
- The form provides an accurate ongoing count of controlled drugs used and what is remaining in the locked cupboard.
- If only one part of a pre-measured dose of a controlled drug is administered, a second nurse witnesses disposal of the unused portion and documents it on the record form.

Pharmacokinetics as the basis of medication actions

To be therapeutically useful, medications must be taken into the body, be absorbed and distributed to cells, tissues or a specific organ and alter the body's physiological functions. Pharmacokinetics is the study of how medications enter the body, reach their site of action in sufficient concentration and are metabolised and excreted from the body. Pharmacodynamics is the study of how a drug acts in the body to exert its action and side effects. The nurse uses knowledge of pharmacokinetics and pharmacodynamics when timing medication administration, selecting the route of administration, judging the client's risk of alterations in medication action and observing the client's response.

Absorption

Absorption refers to passage of medication molecules into the blood from the site of administration. Factors influencing medication absorption are the route of administration, ability of the medication to dissolve, blood flow to the site of administration, body surface area, pH and lipid solubility of the medication.

Route of administration

Medications can be administered by various routes. Each route has a different rate of absorption, as discussed in more depth later in the chapter.

Ability of the medication to dissolve

The ability of an oral medication to dissolve depends largely on its form or preparation. Solutions and suspensions, being already in a liquid state, are often absorbed more readily than tablets or capsules. The pH of a medication often determines whether absorption occurs via the gastric mucosa or the small intestine. Absorption can be delayed by the use of **enteric-coated** tablets, which are not dissolved in the acidic environment of the stomach, ensuring that the drug is absorbed in the alkaline environment of the small intestine. The degree of gastric motility determines the length of time the medication is in contact with the gastrointestinal (GI) mucosa and so will alter both the speed and the amount of medication absorbed.

Blood flow to the area of absorption

When the tissue in the area for absorption contains many blood vessels, medications are absorbed more rapidly. This occurs because blood is constantly moving in these vessels. This facilitates movement of the drug around the body.

Body surface area

When a medication is in contact with a large surface area, it will be absorbed at a faster rate as there are more sites where the drug can be absorbed. This explains why the majority of medications are absorbed in the small intestine rather than in the stomach, as the surface area of the small intestine is much greater than that of the stomach.

Lipid solubility of a medication

Highly lipid-soluble medications are absorbed more easily as they more readily cross the cell membrane. This is because the cell membrane is made of a lipid layer and will thus allow lipid-soluble medications to pass more readily than non-lipid-soluble medications.

Presence of food

Food may delay the passage of the medication through the GI system, and so absorption may be impaired. Some

oral medications are therefore absorbed more easily when administered between or before meals. In some cases, medications administered together may interfere with each other and impair the absorption of one or both.

Nurses use knowledge of factors that may alter or impair absorption of prescribed medications to ensure all medications are administered correctly for their clients. This information is based on an understanding of drug pharmacokinetics, the nursing history, physical examination and daily interactions with clients. The nurse consults and collaborates with the healthcare team to ensure the best therapeutic effect is achievable. Before administering any unfamiliar medication, pharmacology texts, E-MIMS, package inserts and the pharmacist or prescriber should be consulted. This identifies medication actions, interactions, medication–nutrient interactions or indications, contraindications, or indications that a medicine should not be given because of the client's current medical condition (e.g. oral medication if the client is nauseated or vomiting). The nurse may also use this knowledge in explaining to clients that enteric-coated medicines (protective coating) may not be crushed/halved as this would render the medicine unprotected in the GI tract.

Distribution

After a medication is absorbed, it is distributed in the body to tissues and organs and ultimately to its specific site of action. The rate and extent of distribution depend on the physical and chemical properties of medications and the physiology of the person taking the medication.

Blood circulation

Once a medication enters the bloodstream it is carried throughout the tissue and organs of the body. The speed of drug distribution depends on the vascularity of the various tissues and organs. Distribution will be enhanced in tissues with extensive blood supply (e.g. heart, liver and kidneys), and slower in less-well-perfused tissue (e.g. skin and fat). When conditions limit blood flow (e.g. hypovolaemic shock, peripheral vascular disease or solid tumours which have a poor blood supply), then distribution is inhibited.

Membrane permeability

To be distributed to an organ, a medication must pass through all of the biological membranes of that organ or tissue. Some membranes serve as protective barriers to the passage of medications. For example, the **blood–brain barrier** allows only fat-soluble medications to pass into the brain and cerebral spinal fluid. A disruption in the biological membrane barrier by disease or trauma allows drugs to cross the protective barrier. This situation may be used to advantage when treating infection of the central nervous system, but may also give rise to serious adverse effects. Older clients, for example, may experience adverse effects such as confusion as a result of the change in the permeability of the blood–brain barrier, and consequently easier passage of fat-soluble and water-soluble medications.

The placental membrane is an example of a non-selective barrier to medications. Fat-soluble and non-fat-soluble agents may cross the placenta and produce fetal deformities, respiratory depression and, in cases of maternal opioid abuse, withdrawal symptoms in the newborn. For example, if a mother is administered an opioid late in labour, then this may cross the placental membrane resulting in a sedated newborn with respiratory depression.

Protein binding

The degree to which medications bind to serum proteins (in the blood), such as albumin or globulin, affects medication distribution. Most medications bind to these proteins to some extent. When medications bind to these proteins, they cannot exert any pharmacological activity. Protein binding can therefore be regarded as a drug storage mechanism. The unbound or 'free' medication is the active form of the medication. Older adults have decreased levels of albumin in the bloodstream, probably caused by change in liver function; the same is true for clients with liver disease or malnutrition. Because of the potential for more unbound medication, these clients may be at risk of an increase in medication activity or toxicity, or both. There are commonly one or two protein-binding sites for a particular medication. When two medicines with the same common binding sites are given together, they will compete and the concentration of free drugs will change which could result in more or less of this medicine being available to the body. This could result in toxicity (if there is too much available) or inefficacy (if there is not enough available to work as intended).

Metabolism

Many medicines are metabolised into a less active or inactive form that is more easily excreted, either at the site of action or before the medication reaches its destination (hence the need for increased doses in some cases). This *biotransformation* occurs under the influence of enzymes that detoxify, degrade (break down) and remove biologically active chemicals. Most biotransformation occurs within the liver, although the lungs, kidneys, blood and intestines also metabolise medications. The liver is especially important, because its specialised structure oxidises and transforms many toxic substances

and degrades many harmful chemicals before they become distributed to the tissues. If a decrease in liver function occurs, a medication may be eliminated more slowly, resulting in an accumulation of the medication and increasing a client's risk of medication toxicity. For example, a small sedative dose of a barbiturate may cause a client with liver disease to lapse into a coma.

Excretion

After medications are metabolised, they exit the body through the kidneys, liver, bowel, lungs and exocrine glands.

The kidneys are the main organs for medication excretion. Some medications escape extensive metabolism and exit unchanged in the urine. Other medications must undergo biotransformation in the liver before being excreted by the kidneys. If renal function declines, then a client is at risk of medication toxicity. If the kidneys cannot adequately excrete a medication, it may be necessary to reduce the dose. Maintenance of an adequate fluid intake (50 mL/kg/day) promotes proper elimination of medications for the average adult.

The GI tract is another route for medication excretion. Many medications enter the hepatic circulation to be broken down by the liver and excreted into the bile. After chemicals enter the intestines through the biliary tract, the intestines may reabsorb them. Factors increasing peristalsis (e.g. laxatives and enemas) accelerate medication excretion through the faeces, whereas factors that slow peristalsis (e.g. inactivity and improper diet) may prolong a medication's effects.

Gaseous and volatile compounds, such as anaesthetic gases and alcohol, exit through the lungs. Deep-breathing and coughing helps the postoperative client eliminate anaesthetic gases more rapidly. The exocrine glands excrete lipid-soluble medications. Good hygiene to promote cleanliness and skin integrity can prevent skin irritation when medications exit through sweat glands.

Nurses and mothers should check the safety of medications used while breastfeeding, as medications excreted through the mammary glands increase risk that a nursing infant will ingest the chemicals.

• CRITICAL REFLECTION POINT

What would happen to the absorption of a medicine if a client is also on metoclopramide (an antiemetic medicine that speeds up gastric emptying)?

Types of medication action

Medications vary considerably in the way they act and the types of action. Factors other than characteristics of the medication also influence medication actions. These include therapeutic effects, adverse effects, idiosyncratic reactions, toxic reactions and allergic reactions.

Therapeutic effects

The **therapeutic effect** is the expected or predictable physiological response a medication causes. Each medication has a desired therapeutic effect for which it is prescribed. For example, glyceryl trinitrate (Anginine) is used to reduce the cardiac workload and increase myocardial oxygen supply. A single medication may have many therapeutic effects. For example, morphine is an opioid analgesic, a vasodilator and releases antidiuretic hormone. The nurse must know the therapeutic effect of each prescribed medication so they can monitor the response of the medication and teach the client about the medication's intended effect.

Adverse effects

Adverse effects are generally unexpected effects of the medication. These may be related to the pharmacological effect, the way an individual takes the medication or the individual's response to the medication. When adverse responses to medications occur, the prescriber may modify the therapy or discontinue the medication. These effects may be called 'side effects' by consumers and non-healthcare professionals; however, it is important to note that these are *unwanted effects* rather than 'allergic effects'. For example, a client may say they are 'allergic' to codeine as it makes them constipated. This is an adverse effect (i.e. unwanted effect), but it is not an allergic reaction.

Idiosyncratic reactions

Idiosyncratic reactions are adverse effects to which the client under- or over-reacts, or has a reaction which is different from that expected. For example, a child receiving an antihistamine (e.g. Phenergan) may become extremely agitated or excited instead of drowsy. Other medicines can have effects ranging from a mild skin rash to a life-threatening reaction. Although it is impossible to assess clients for idiosyncratic responses when they first take a medication, the nurse must always assess the client's response to a medicine if it has been previously prescribed. For example, if a client is ordered penicillin (an antibiotic), the nurse must ask if the client has taken the medicine before and, if so, what was the outcome (i.e. did they have any reaction?), because many people have allergic reactions to this group of medicines. Healthcare providers are encouraged to report adverse effects to the authorities so that information can be used in predicting and preventing adverse drug effects. The risk of adverse drug effects increases with multiple drug regimens (polypharmacy).

• CRITICAL REFLECTION POINT

Polypharmacy is defined as the concurrent use of five or more medicines by a client at one time. These may be prescription, over-the-counter or complementary medicines. The risk of dangerous adverse effects and interactions increases when more than one medicine is used, as the medicines may interact with each other and produce toxic effects. The problem is that polypharmacy is often necessary for clients with chronic health conditions and sometimes it is important to use medicines to treat symptoms caused by other drugs the client is taking. For example, a client who requires a diuretic (e.g. frusemide) for heart failure may then require a potassium supplement in response to the excess loss of potassium through diuresis.

Polypharmacy can make it difficult to take a medication history from a client (who may have trouble remembering all the different medicines they have used), and it can be costly for the client. Nurses should be aware of the risks of polypharmacy and should actively work to try to implement quality use of medicines (i.e. assessing the use of medicines and their appropriateness) for their clients.

What would you do if a client you are admitting spoke of taking many medicines for various health complaints? Is it enough to document these alone? What else could you do?

Adverse drug reactions (ADRs)

The most recent report on medication safety in Australia from the Australian Commission on Safety and Quality in Health Care suggests that 10% of clients who see a general practitioner will have experienced an adverse medication event within the past 6 months (Roughhead et al 2013).

The WHO defined an ADR as 'a response to a medicine which is noxious and unintended, and which occurs at doses normally used in man' (Thong & Tan 2011:684). These may be 'Type A' which are predictable and dose dependent or they may be 'Type B' which are unpredictable and not usually related to the dose administered (i.e. allergic reactions).

Adverse drug reactions (ADRs) are different to 'adverse drug events' (ADEs) in that ADEs is a broader term that can also include medication errors or interactions between medicines (Thong & Tan 2011).

Predictable reactions: toxicity

An example of a predictable adverse effect of a medication is a toxic reaction. These reactions are related to the pharmacological properties of the medication. **Toxic effects** may develop after prolonged intake of a medication or when a medication accumulates in the blood because of impaired metabolism or excretion. Lethal effects depend on the medication's action. For example, toxic levels of digoxin (an anti-arrhythmic medicine used to slow down heart rate) may cause severe bradycardia and death. Antidotes are available to treat specific types of medication toxicity; for example, naloxone (Narcan) is used to reverse the effects of opioid toxicity.

Unpredictable reactions: allergic reactions

Allergic reactions are an unpredictable response to a medication, and may represent as many as 24% of reported adverse drug reactions (Lazarou et al 1998) though current research suggests the true number is hard to establish since many studies look at all adverse drug events (ADRs) versus focusing on true allergic reactions (Thong & Tan, 2011). A client can become immunologically sensitised to the initial dose of a medication. With repeated administration, the client develops an allergic response to the medication, its chemical preservatives or a metabolite. The medication or chemical acts as an antigen, triggering the release of the body's antibodies. Allergic symptoms vary from mild (Box 27-5) to severe, depending on the individual and the medication. Antibiotics cause a high incidence of allergic reactions.

Severe or **anaphylactic reactions** are characterised by sudden constriction of bronchiolar muscles, oedema of the pharynx and larynx, severe wheezing and shortness of breath. The client may also become severely hypotensive, necessitating emergency resuscitation measures. Adrenaline, antihistamines and bronchodilators may be used to treat anaphylactic reactions. A client with a known history of a **medication allergy** should avoid re-exposure and wear an identification bracelet or medal (Figure 27-2) which alerts nurses, medical staff and emergency personnel to the allergy.

Medication interactions

When one medication modifies the action of another medication, a **medication interaction** occurs. These interactions are common in people taking several medications. A medication may increase or diminish the action of other medications, and may alter the way another medication is absorbed, metabolised or eliminated from the body. When two medications have a *synergistic effect*,

BOX 27-5 Mild allergic reactions

Urticaria: raised, irregularly shaped skin eruptions with varying sizes and shapes; eruptions have reddened margins and pale centres.

Rash: small, raised vesicles that are usually reddened; often distributed over entire body.

Pruritus: itching of skin; accompanies most rashes.

Rhinitis: inflammation of mucous membranes lining nose; causes swelling and clear, watery discharge.

Figure 27-2 Allergy identification bracelet and medal.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

that is, work together, the effect of the two medications combined is greater than the effect of the medications when given separately. For example, alcohol is a central nervous system depressant that has a synergistic effect on antihistamines, antidepressants, barbiturates and opioid analgesics, making the client more sedated and lowering blood pressure/consciousness further.

A medication interaction is not always undesirable. Often the prescriber orders a combination of medications to create an interaction that will have a beneficial effect on the client's condition. For example, where hypertension cannot be controlled with one medication, the client typically receives several medications that act together to control the blood pressure (e.g. diuretics and vasodilators). Multimodal analgesia is another good example of this (see Chapter 36).

Medication dose responses

After a medication is administered, it undergoes absorption, distribution, metabolism and excretion. The quantity and distribution of a medication in different body compartments change constantly. When a medication is prescribed, the goal is to maintain a constant and safe therapeutic serum level and take into account peaks, troughs, duration of action and plateaus (Box 27-6). Repeated doses are required to achieve this constant *therapeutic plasma concentration* of a medication because a part of a medication is always being excreted. The highest serum concentration (peak concentration) of the medication occurs when the rate of administration equals the rate of excretion. After peaking, the serum medication concentration falls progressively. With intravenous administration, the peak concentration occurs quickly but the serum level also begins to fall immediately (Figure 27-3).

BOX 27-6 Terms associated with medication actions

Duration of action: time during which the medication is present in concentration great enough to produce a response.

Half-life: time taken for the **plasma concentration** of a drug to fall to half of its original value.

Onset: time it takes after a medication is administered for it to produce a response.

Peak: time it takes for a medication to reach its highest effective concentration.

Plateau: blood serum concentration of a medication reached and maintained after repeated fixed doses.

Trough: minimum blood serum concentration of medication reached just before the next scheduled dose.

All medications have a **serum half-life**, which is the time it takes for excretion processes to lower the serum medication concentration by half. This half-life is different for each medication. To maintain a therapeutic plateau, the client must receive regular fixed doses, the timing of which is based on the serum half-life. For example, analgesia is most effective when given on a regular around-the-clock basis, rather than a prn (as needed) basis in response to a client's report of pain. In this way, an almost constant level of analgesia is maintained. After an initial loading dose,

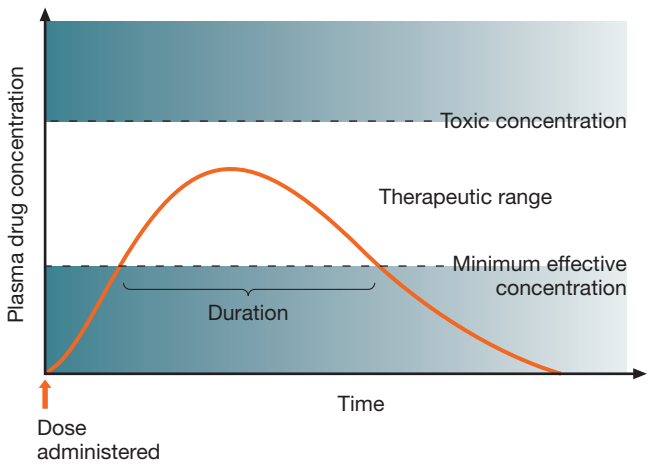

Figure 27-3 The therapeutic range of a medication occurs between the minimum effective concentration and the toxic concentration.

Lehne RA 2010 Pharmacology for nursing care, 7th edn. Saunders, St Louis.

the client receives each successive dose when the previous dose reaches its half-life.

The client and nurse must follow regular dosage schedules and adhere to prescribed doses and dosage intervals. The prescriber, or the agency in which the nurse is employed, will often set the dosage schedules. When teaching clients about dosage schedules, the nurse should use language that is familiar to the client, for example, 'Take a dose in the morning and again in the evening'. Knowledge of the time of medication action also helps the nurse and client to anticipate a medication's effect and the time of a therapeutic response. For example, when administering oral frusemide (Lasix), the nurse is aware a diuresis should occur in 1–2 hours; whereas when administering IV frusemide, a diuresis is expected in 20 minutes.

• CRITICAL REFLECTION POINT

1. **How can knowledge of a medication's serum half-life be used to determine the frequency of drug administration?**
2. **Do nurses need to understand how a dosing schedule is calculated or should they rely on the knowledge of the prescriber?**

Routes of administration

The route prescribed for administering a medication depends on the medication's properties and desired effect and on the client's physical and mental condition (Table 27-1). A nurse collaborates with the prescriber in determining the best route for a client's medication, as in the following *Clinical example*.

CLINICAL EXAMPLE

Mr Jensen has progressively deteriorated over your shift. His oral temperature is 39.5°C. He complains of nausea and is unable to tolerate oral fluids. You check Mr Jensen's medication chart, which contains the order 'Paracetamol 1 g orally PRN for temperature above 38.5°C'. On the basis of your assessment that Mr Jensen is nauseous, you consider that he will not be able to tolerate an oral dose of paracetamol. You decide to contact the medical officer to request an order for intravenous paracetamol instead. This enables you to administer the medicine to decrease fever without increasing the client's symptoms of nausea.

Oral routes

Oral administration

The oral route is the easiest and the most commonly used. Medications are given by mouth and swallowed with fluid. Oral medications usually have a slower onset of action and a more prolonged effect than parenteral (injected) medications, and their effect may be more unpredictable than other routes as many factors can affect GI absorption. Oral medicines enter the hepatic circulation once absorbed from the GI tract, and then travel to the liver where they need to 'clear' the liver before travelling on throughout the body. Some medicines are nearly totally destroyed by the liver (i.e. there is nothing left to travel throughout the body to act on their target cells) and so these medicines cannot be given orally (e.g. glyceryl trinitrate (GTN) or insulin). This situation is called the 'first-pass effect'. Clients generally prefer the oral route, which is suitable for tablet or liquid forms of medications.

Sublingual administration

Some medications are designed to be readily absorbed after being placed under the tongue to dissolve (Figure 27-4). A medication given by the **sublingual (subling)** route should not be swallowed, as the desired effect will not be achieved (i.e. it will not be absorbed into the bloodstream under the tongue where it can work immediately, but will travel to the stomach where it may be destroyed by the acidic environment or by the extensive liver metabolism). Glyceryl trinitrate is commonly given this way, by tablet or spray. The client should not take a drink until the medication is completely dissolved.

Buccal administration

Administration of a medication by the buccal route – **buccal administration** – involves placing the solid medication in the mouth against the mucous membranes of the cheek, where it stays until it dissolves (Figure 27-5). Clients should be taught to alternate cheeks with each dose to avoid mucosal irritation. Clients are also warned not to chew or swallow the medication or to take it with any liquids, for the same reason as the sublingual route above. A buccal medication acts locally on the mucosa or systemically as it is swallowed in a person's saliva.

Parenteral routes

Parenteral administration

Parenteral administration involves injecting a medication into body tissues. The major sites of injection are:

- **subcutaneous (subcut)**: injection into tissues just below the dermis of the skin
- **intramuscular (IM)**: injection into a muscle
- **intravenous (IV)**: injection into a vein
- **intradermal (ID)**: injection into the dermis immediately below the epidermis

Some medications are administered into body cavities other than the types listed above. Institutions vary regarding whether nurses are responsible for the administration

TABLE 27-1 Factors influencing choice of administration routes

Advantages	Disadvantages or contraindications
Oral, buccal, sublingual routes	
Routes are convenient and comfortable for client Routes are economical Medications may produce local or systemic effects Routes rarely cause anxiety for client	These routes are avoided when client has alterations in gastrointestinal function (e.g. nausea, vomiting), reduced motility (after general anaesthesia or bowel inflammation) and surgical resection of part of gastrointestinal tract Some medications are destroyed by gastric secretions. Oral administration is contraindicated in clients unable to swallow (e.g. clients with neuromuscular disorders, oesophageal strictures, mouth lesions) Oral medications cannot be given when client has gastric suction and are contraindicated in clients before some tests or surgery Unconscious or confused client is unable or unwilling to swallow or hold medication under tongue Oral medications may irritate lining of gastrointestinal tract, discolour teeth or have unpleasant taste
Subcutaneous (subcut), intramuscular (IM), intravenous (IV), intradermal (ID) routes	
Routes provide means of administration when oral medications are contraindicated More-rapid absorption occurs than with topical or oral routes IV infusion provides medication delivery when client is critically ill or long-term therapy is required. If peripheral perfusion is poor, IV route is preferred over injections	There is risk of introducing infection, and some medications are expensive. Clients must experience repeated needle-sticks. The subcut, IM and ID routes are avoided in clients with bleeding tendencies There is risk of tissue damage with subcut injections IM and IV routes are dangerous because of rapid absorption These routes cause considerable anxiety in many clients, especially children
Skin	
Topical	
Topical skin applications mainly provide local effect Route is painless Limited side effects occur	Clients with skin abrasions are at risk of rapid medication absorption and systemic effects
Transdermal	
Transdermal applications provide prolonged systemic effects, with limited side effects	Application leaves oily or pasty substance on skin and may soil clothing
*Mucous membranes**	
Therapeutic effects are provided by local application to involved sites Aqueous solutions are readily absorbed and capable of causing systemic effects Mucous membranes provide route of administration when oral medications are contraindicated	Mucous membranes are highly sensitive to some medication concentrations Insertion of rectal and vaginal medication often causes embarrassment Client with ruptured eardrum cannot receive irrigations Rectal suppositories are contraindicated if client has had rectal surgery or if active rectal bleeding is present
Inhalation	
Inhalation provides rapid relief for local respiratory problems Route provides easy access for introduction of general anaesthetic gases	Some local agents can cause serious systemic effects

* Includes eyes, ears, nose, vagina, rectum, buccal and sublingual routes.

of medications through these advanced techniques. The nurse often remains responsible for monitoring the integrity of advanced systems of medication delivery, for understanding the therapeutic value of the medication and for evaluating the client's response to it, even when they do not administer the medication.

Epidural

A common body cavity route is into the epidural space via a catheter placed by an anaesthetist. The epidural route is most commonly used for the administration of analgesia peri- and postoperatively (see Chapter 41). Nurses and midwives working in specialised areas (e.g. acute pain nurses, recovery room nurses) may administer medicines in **bolus** form (a small dose) or by continuous **infusion**.

Intrathecal

Intrathecal medicines are administered by an anaesthetist through a catheter placed into the subarachnoid space or into one of the ventricles of the brain. Intrathecal administration is often associated with long-term medicine administration through surgically implanted catheters.

Intraperitoneal

In the intraperitoneal technique, medicines (chemotherapeutics and antibiotics) are administered into the peritoneal cavity where they are absorbed into the circulation. One method of dialysis also uses the peritoneal route for the removal of fluid, electrolytes and waste products.

Intrapleural

In the intrapleural method, medicines are administered by a medical practitioner either directly through the chest wall or through a chest tube. Chemotherapeutics are the most common medications administered via this method. Medical staff also instil medicines that help resolve persistent pleural effusion to promote adhesion between the visceral and parietal pleura (*pleurodesis*).

Intra-arterial

Intra-arterial infusions are administered directly into the arteries, and are used in clients with arterial clots. The nurse manages a continuous infusion of fibrinolytic (clot-dissolving) agents. The nurse must carefully monitor the integrity of this infusion to prevent inadvertent disconnection of the system and subsequent bleeding. It is important to note that nurses are not usually required to administer medicines intra-arterially and that inadvertent administration via this route will often result in severe tissue damage and amputation (in the cases of intra-arterial injections into limbs).

Intraosseous

Intraosseous infusions are commonly given via the anterior surface of the tibia or alternatively into the iliac crest or spinal processes. They allow delivery of fluids, medication or blood into the bone marrow. Medication absorption is similar to the IV route.

Other parenteral routes

Other methods of medicine administration that are usually limited to medical staff are intracardiac (injection of a medicine directly into the cardiac tissue) and intra-articular (injection of a medicine into a joint).

Topical administration

Medications applied to the skin and mucous membranes generally have local effects.

Skin

Topical medications are applied to the skin by painting or spreading them over an area, applying moist dressings,

soaking body parts in a solution or giving medicated baths. Systemic effects can occur if a client's skin is thin, if the medication concentration is high or if contact with the skin is prolonged. Some medications (e.g. GTN and oestrogens) have systemic effects (i.e. work throughout the body, not just in the area where the medicine is applied) when applied topically by a transdermal disc or patch. The disc secures the medicated ointment to the skin. These topical applications may be applied for as little as 24 hours or as long as 7 days.

Mucous membranes

Medications can be applied to mucous membranes in a variety of ways:

- application of a liquid or ointment (e.g. eye drops, gargling, swabbing the throat)
- insertion of a medication into a body cavity (e.g. rectal suppository, vaginal pessary or medicated packing)
- **instillation** of fluid into a body cavity (e.g. ear drops, nose drops, or bladder and rectal instillation where fluid is retained)
- irrigation of a body cavity (e.g. flushing eye, ear, vagina, bladder or rectum with medicated fluid where fluid is not retained)
- spraying (e.g. instillation into nose and throat).

Inhalation

The deeper passages of the respiratory tract provide a large surface area for medication absorption. Medications can be administered through the nasal passages, oral passage or less frequently via endotracheal tubes via the client's mouth or nose into the trachea (Figure 27-6). Medications administered by the **inhalation** route are readily absorbed into the bloodstream and work rapidly (they have local as well as systemic effects) because of the rich vascular alveolar–capillary network present in the pulmonary tissue.

Intraocular

Intraocular medication delivery involves inserting a medication similar to a contact lens into the client's eye. The eye medication disc (usually an ocular lubricant) has two soft outer layers in which the medication is enclosed. The disc can remain in the client's eye for up to a week.

• CRITICAL REFLECTION POINT

You are caring for a client taking a medicine via the sublingual route. She admits that sometimes it is easier to swallow the tablet rather than wait for it to dissolve. She says it is 'mostly dissolved' anyway. What is the risk with this? What could you do?

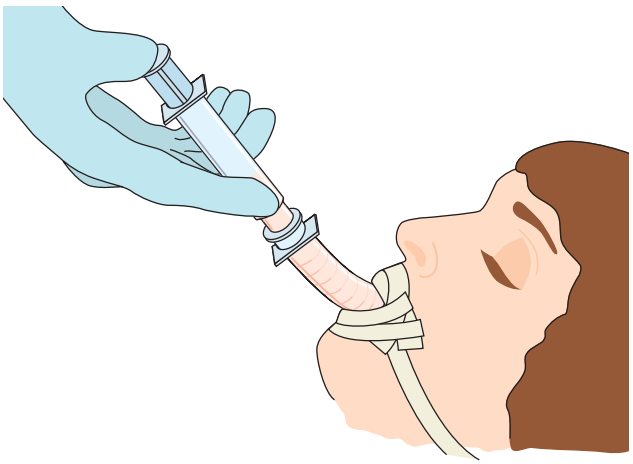

Figure 27-6 Medication being instilled through endotracheal tube.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

System of medication measurement

The proper and safe administration of a medication depends on the nurse's ability to calculate and measure medication doses accurately. Placing a decimal point or adding a zero to a dose can lead to a fatal error. The nurse is responsible for checking the correctness and appropriateness of a dose before administration. In Australia and New Zealand, the metric system is the standard of measurement.

Metric system

The metric system has the advantage of being logically organised. Metric units can easily be converted and calculated through simple multiplication and division, as each basic unit of measurement is organised into units of 10.

Multiplying or dividing by 10 produces secondary units. In multiplication, the decimal point moves to the right; in division, the decimal moves to the left. For example:

$$10.0 \text{ mg} \times 10 = 100 \text{ mg}$$
$$10.0 \text{ mg} \div 10 = 1.0 \text{ mg}$$

The basic units of measurement in the metric system are the *litre* (volume) and the *gram* (weight). The basic unit symbols are:

gram = g
litre = L

Symbols for derived units include:

milligram = mg
millilitre = mL
microgram = microg, mcg or µg (the latter two abbreviations are avoided, as they can be confused with mg)

Latin prefixes designate subdivision of the basic units: *deci-* (1⁄10 or 0.1), *centi-* (1⁄100 or 0.01) and *milli-* (1⁄1000 or 0.001). Greek prefixes designate multiples of the basic units: *deca-* (10), *hecto-* (100) and *kilo-* (1000). Medicines which require very small doses are usually written in micrograms (1000 micrograms = 1 milligram). Fractions or multiples of a unit are used when writing medication doses; fractions are always in *decimal form*. A zero is always placed in front of the decimal point to prevent error:

500 mg or 0.5 g, not ½ g
10 mL or 0.01 L, not 1⁄100 L
1 microgram (mcg or μg) = 0.000 001 g
1 milligram (mg) = 0.001 g
1000 micrograms (mcg or μg) = 1000 × 0.000 001 g
= 0.001 g or 1 mg

Solutions

The nurse uses solutions of various concentrations for injections, irrigations and infusions. A solution is a *given mass* of substance (often solids, but may be liquids or even gases) dissolved in a *known volume* of fluid.

When a solid is dissolved in a fluid, the concentration is in units of mass per units of volume, for example, g/mL, g/L or mg/mL. When a liquid is dissolved in a fluid, the concentration may be in units of volume, with the dissolved liquid written first: for example, mL/L. The concentration of a solution may also be expressed as a percentage. A 10% solution, for example, is 10 g of solid dissolved in 100 mL of solution. A proportion or ratio also expresses concentrations: a 1⁄1000 solution represents a solution containing 1 g of solid in 1000 mL of liquid or 1 mL of liquid mixed with 1000 mL of another liquid.

Clinical calculations

The nurse must possess an understanding of basic arithmetic to calculate medication dosages, mix solutions and perform a variety of other activities. This skill is important because a medication is not always dispensed in the unit of measure in which it is ordered. This occurs because pharmaceutical companies package and bottle certain standard equivalents. For example, the prescriber may order 250 mg of a medication that is available only in grams. The nurse is responsible for converting available units of volume and weight to the desired doses. Therefore, the nurse should be aware of approximate equivalents in all major measurement systems.

Conversions

Converting measurements is relatively easy. To change milligrams to grams, divide by 1000, moving the decimal point three places to the left:

1000 mg = 1 g
350 mg = 0.35 g

To convert litres to millilitres, multiply by 1000 or move the decimal point three places to the right:

1 L = 1000 mL
0.25 L = 250 mL

Dosage calculations

Many formulae can be used to calculate medication dosages. The following basic formulae can be applied when preparing solid or liquid forms.

Tablets:

$$\text{Amount to be administered} = \frac{\text{Dose required}}{\text{Stock strength}}$$

Mixtures and injectables:

$$\text{Amount to be administered} = \frac{\text{Dose required}}{\text{Stock strength}} \times \text{Volume}$$

- 'Dose required' is the amount of pure medication prescribed.
- 'Stock strength' is the weight or volume of medication supplied by the pharmacy; it may be expressed on the medication label as the contents of a tablet or capsule or as the amount of medication dissolved per unit volume of liquid.
- 'Volume' is the basic unit or quantity of the medication that contains the dose on hand. The volume of a liquid may be in millilitres or litres, depending on the container.
- 'Amount to be administered' is the actual amount of available medication the nurse will administer.

Examples

The following example illustrates how to apply the formula. The prescriber orders the client to receive pethidine 75 mg IM. Thus the dose required is 75 mg. The medication is available only in ampoules containing 100 mg per 2 mL. Thus the stock strength is 100 mg in a volume of 2 mL. The formula is applied as follows:

$$\text{Amount to be administered} = \frac{\text{Dose required}}{\text{Stock strength}} \times \text{Volume}$$

$$\text{mL to be administered} = \frac{75 \text{ mg}}{100 \text{ mg}} \times 2 \text{ mL}$$

Answer: The easiest approach involves using a calculator to do 75 divided by 100 multiplied by 2 which gives 1.5mL; however, another approach is shown in steps A to D below.

A. To simplify the 75⁄100 fraction, divide both numerator and denominator by 25:
¾ × 2 mL = mL to be administered

B. Multiply the numerators:
6⁄4 = mL to be administered

C. Divide the numerator (6) by the denominator (4):
6 ÷ 4 = 1½ mL to be administered

D. Since syringes are calibrated in decimals, the nurse must convert the fraction 1½ mL to 1.5 mL to accurately draw up the correct dose.

Solids

The following example demonstrates how the formula applies to solid dose forms. The prescriber orders 0.125 mg PO of digoxin. The medication is available in tablets containing 0.25 mg.

$$\text{Amount to be administered} = \frac{\text{Dose required}}{\text{Stock strength}}$$

$$\text{Tablets to be administered} = \frac{0.125 \text{ mg}}{0.25 \text{ mg}}$$

= ½ or 0.5 tablet to be administered

Many tablets come with scores or indentations across the centre of the tablet (Figure 27-7). A scored tablet is easy to break in half for divided doses. Unscored tablets should not be broken because of the potential for giving an incorrect dosage. Evidence-based reference guides such as 'Don't rush to crush' by the Society of Hospital Pharmacists of Australia (www.shpa.org.au, 2015) are available to help deduce if a tablet may be broken or crushed.

Liquids

Often, liquid medications come prepared in volumes greater than 1 mL. The formula still applies. For example, the order is erythromycin suspension 250 mg PO. The pharmacy delivers bottles containing 100 mL with the labels stating '5 mL contains 125 mg of erythromycin'.

$$\text{Amount to be administered} = \frac{\text{Dose required}}{\text{Stock strength}} \times \text{Volume}$$

$$\text{Volume to be administered} = \frac{250 \text{ mg}}{125 \text{ mg}} \times 5 \text{ mL}$$

2 × 5 mL = 10 mL to be administered

Here the nurse may disregard the total volume available and instead uses the values (i.e. '5 mL contains …') noted on the label. If the nurse calculated the dose on the basis of 100 mL available, the following error would occur:

$$\frac{250 \text{ mg}}{125 \text{ mg}} \times 100 \text{ mL} = 200 \text{ mL to be administered [incorrect]}$$

On the basis of this calculation, the client would receive 20 times the desired dose.

Figure 27-7 Scored medication.
Dreamstime/Invisibleviva.

Paediatric dosages

Children are unable to metabolise many medications as readily as adults, as their liver and kidneys are not fully developed (WHO 2007). Children also have a higher body water content than adults (WHO 2007). These factors combine to make the accurate calculation of paediatric doses very important. In most cases, the prescriber will calculate the dose for a child before ordering the medication. However, nurses should be aware of the formulae used to calculate paediatric dosages and should recheck all dosages before administration. Most medication references list the normal ranges of paediatric dosages.

The most common way of calculating medicine doses for children is in milligrams/grams per kilogram (otherwise referred to as 'weight per kilo'). This is where the child's weight (in kilograms) is multiplied by the recommended dose for that medicine.

Another accurate method of calculating paediatric dosages is based on a child's body surface area. Body surface area is estimated on the basis of the child's height and/or weight. A standard *nomogram* is used to estimate a child's body surface area (Figure 27-8). To calculate a paediatric dose, the nurse uses the formula below. The formula is a ratio of the child's body surface area compared with the body surface area of an average adult (1.7 square metres, or 1.7 m^2):

$$\text{Child's dose} = \frac{\text{Surface area of child} \times \text{Normal adult dose}}{1.7 \text{ m}^2}$$

CLINICAL EXAMPLE

A child is prescribed oral ibuprofen (Nurofen) at a dose of 10 mg/kg every 6 hours for pain. The child weighs 9 kilograms.

Child's dose = 10 mg (recommended dose per kilo) × 9 kg (child's weight)
= 90 mg every 6 hours.

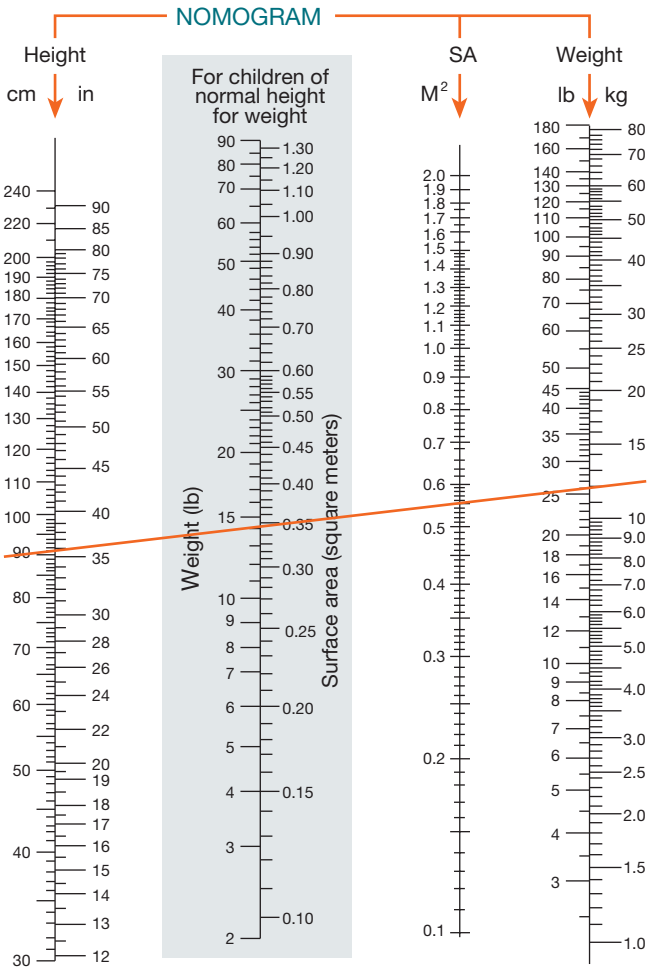

Figure 27-8 **West nomogram for estimation of surface areas in children. A straight line is drawn between height and weight. The point where the line crosses the surface area is the estimated body surface area.**

Behrman RE, Vaughan VC (eds), 1987 Nelson textbook of pediatrics, 13th edn. Saunders, Philadelphia; modified from data of Boyd E, by West CD.

CLINICAL EXAMPLE

A prescriber orders ampicillin for a child weighing 12 kg. The normal adult dose for ampicillin is 250 mg. Using the nomogram shown in Figure 27-8, the nurse calculates that a child who is 12 kg and 92 cm tall has a surface area of 0.54 m^2. Using this information, the nurse can then calculate the appropriate child's dosage:

$$\text{Child's dose} = \frac{0.54\ m^2 \times 250\ mg}{1.7\ m^2}$$
$$= 0.3 \times 250\ mg$$
$$= 75\ mg$$

Medication administration

Generally, in a hospital environment it is the NP or medical practitioner who prescribes medications. Where allowed, a prescriber may also order a medication by talking to the nurse in person or by telephone (**verbal order**). There is a very real possibility of a verbal order being misunderstood and it is difficult to verify a verbal order after the event. When the nurse receives a verbal order, it is usually repeated to the prescriber with a second nurse also confirming the order with the prescriber (according to agency policy). The order should be entered into the client's healthcare record immediately and signed by the nurse and the checking nurse, indicating the time and the name of the prescriber. It is a statutory and institutional requirement that a prescriber confirm the order by signing it within 24 hours. Institutional policies vary regarding the personnel who can take verbal or telephone orders. Generally, nursing students may not take these types of medication orders without proper direct supervision from a qualified nurse or midwife.

Common abbreviations and symbols are used when writing orders to indicate dosage frequencies or times, routes of administration and special information for giving the medication (see Table 27-2). Administering medications to infants and children can be particularly challenging, and the nurse needs to consider the best approach in each circumstance (see *Working with diversity*).

Orders in acute care agencies

Four common types of medication orders are based on the frequency and/or urgency of medication administration.

Standing orders or routine medication orders

A **standing order** is carried out until cancelled by the prescriber, or until a prescribed number of days elapse. A standing order is usually written up in the client's chart by the nurse who administers it and is countersigned by another nurse. A standing order may indicate a final date or a number of treatments or dosages. Many institutions have policies for automatically discontinuing standing orders. It may be practice for oncology medical staff to have standing orders with regard to their clients' nausea treatment. In these cases, all of these clients will be given a particular antiemetic unless instructions to the contrary are given. Routine medication orders are written up by the medical officer and continue for the prescribed time, or number of doses, or until cancelled.

prn orders

A medication may be ordered to be given when required by a client. This is a *pro re nata* order (**prn order**). The

TABLE 27-2 Acceptable terms and abbreviations

The following table lists the terms and abbreviations that are commonly used and understood and therefore considered acceptable for use; where there is more than one acceptable term, the preferred term is shown first in the right-hand column.

Intended meaning	Acceptable terms or abbreviations
Dose frequency or timing	
(in the) morning	morning, mane
(at) midday	midday
(at) night	night, nocte
twice a day	bd
three times a day	tds
four times a day	qid
every 4 hours	every 4 hrs, 4 hourly, 4 hrly
every 6 hours	every 6 hrs, 6 hourly, 6 hrly
every 8 hours	every 8 hrs, 8 hourly, 8 hrly
once a week	once a week and specify the day in full, e.g. 'once a week on Tuesdays'
three times a week	three times a week and specify the exact days in full, e.g. 'three times a week on Mondays, Wednesdays and Saturdays'
when required	prn
immediately	stat
before food	before food
after food	after food
with food	with food
Route of administration	
epidural	epidural
inhale, inhalation	inhale, inhalation
intraarticular	intraarticular
intramuscular	IM
intrathecal	intrathecal
intranasal	intranasal
intravenous	IV
irrigation	irrigation
left	left
nebulised	NEB
nasogastric	NG
oral	PO
percutaneous enteral gastrostomy	PEG
per vagina	PV
per rectum	PR
peripherally inserted central catheter	PICC
right	right
subcutaneous	subcut
sublingual	subling
topical	topical
Units of measure and concentration	
gram(s)	g
International unit(s)	International unit(s) (IU)
unit(s)	unit(s)
litre(s)	L
milligram(s)	mg
millilitre(s)	mL
microgram(s)	microgram, microg
percentage	%
millimole(s)	mmol
Dose forms	
capsule	cap
cream	cream
ear drops	ear drops
ear ointment	ear ointment
eye drops	eye drops
eye ointment	eye ointment
injection	inj
metered dose inhaler	metered dose inhaler, inhaler, MDI
mixture	mixture
ointment	ointment, oint
pessary	pess
powder	powder
suppository	supp
tablet	tablet, tab
patient controlled analgesia	PCA

WORKING WITH DIVERSITY

Focus on infants and children

Oral medications

- Liquid forms are safer to swallow to avoid aspiration.
- Juice, a soft drink or a frozen juice bar may be offered after a medication is swallowed.
- Carbonated beverages poured over finely crushed ice may reduce nausea.
- When mixing medications with palatable flavourings such as syrup or honey, the nurse uses only a small amount. The child may refuse to take all of a larger mixture. The nurse avoids mixing a medication with foods or liquids that the child is taking well because the child may in turn refuse them.
- A plastic disposable syringe is the most accurate device for preparing liquid doses, especially those less than 10 mL. (Cups, teaspoons and droppers are inaccurate.)
- When administering liquid medications, a spoon, plastic cup or oral syringe (without needle) is useful.

Injections

- The nurse is very careful when selecting intramuscular injection sites. Infants and small children have underdeveloped muscles.
- Children can be unpredictable and uncooperative. Someone should be available to comfort and physically support the child if needed.
- The nurse always wakes a sleeping child before giving an injection.
- Distracting the child with conversation, blowing bubbles or a toy may reduce pain perception.
- Play therapists may be able to help reduce a child's anxiety.
- The nurse gives the injection quickly and does not fight with the child.

Overpowering and restraining a child is unnecessarily traumatic and often constitutes poor practice. Enlist the aid of a play therapist or use injection aids such as a 'buzzy bee' (http://buzzy4shots.com/what-is-buzzy/), local anaesthetic creams, an icepack or even light sedation under medical supervision.

nurse uses assessment skills and clinical judgement in determining whether a client needs the medication. Often, minimum intervals are set for the time of administration. This means the medication cannot be given more often than prescribed. Examples of prn orders are: 'morphine sulfate 2 mg IV 4 hrly prn for pain' or 'metoclopramide 20 mg IM 8 hrly prn for nausea'.

When medications are administered, the nurse documents the assessment made and the time of medication administration. The nurse should frequently evaluate the effectiveness of the medication and record findings in the appropriate record. Often, prn orders include a *range order* (e.g. 7.5–10 mg) where nurses decide on the actual dose.

Single (one-time) orders

A prescriber may order a medication to be given only once at a specified time. This is common for preoperative medications or medications given before diagnostic examinations. An example is 'temazepam 10 mg at 0900' (preoperative medication).

Stat (statim) orders

A **stat order** signifies the immediate and once-only administration of a single dose of a medication. Stat orders are often written for emergencies when the client's condition changes suddenly. For example: 'Give hydralazine 10 mg IV stat' (antihypertensive medication).

Some conditions change the status of a client's medication orders. For example, surgery may necessitate a review of all of a client's preoperative medications. Because the client's condition changes after surgery, the prescriber may write new orders. When a client is transferred to another healthcare agency or to a different service within a hospital, or is discharged, the prescriber should review the medications and write new orders as indicated.

Prescriptions

The prescriber writes **prescriptions** (a prescription order) for clients who are to take medications outside the hospital. The prescription includes more-detailed information than a regular order because the client must understand how to take the medication and when to refill the prescription if necessary. The information contained in a prescription is regulated under national or state poison laws. Mandatory information includes at least two identifiers with client information (name and address), date, medication name and dosage strength, frequency, dispensing information, directions for the client and the prescriber's name and signature (Figure 27-9). The prescription must be legible and written in ink.

• CRITICAL REFLECTION POINT

A prescription on a medication chart is unclear. You ask the prescriber to clarify and they tell you that it clearly says 'amoxycillin', but you cannot read it. They refuse to rewrite it, saying it is 'clear enough' and you should 'just give the medicine now'.

What should you do? What are the risks here?

Distribution systems

Systems for storing and distributing medications vary. Pharmacists supply the medications, but nurses administer medications to clients. Institutions have special areas for stocking and dispensing medications, including dedicated medication rooms, portable locked medication trolleys, and individual storage units next to clients' rooms or in a bedside locker. Nurses must make sure that storage areas are locked when unattended.

Stock supply system

With a stock system, medications are available in quantity in large multidose containers. This system is time-consuming and costly because a nurse must dispense each medication separately for a client. The stock system has been associated with a high rate of medication errors, and for this reason its use has declined. Opioids are often provided in stock supply and kept in a secure cupboard (for controlled or dangerous medicines) that complies with statutory requirements.

Unit-dose system

The unit-dose system uses portable medication trolleys containing a drawer with a 24-hour supply of medications for each client. The *unit dose* is the ordered dose of medication the client receives at one time. Each tablet or capsule is wrapped in a foil or paper container. At a designated time (daily, or in some cases weekly), the pharmacist refills the drawers in the trolley with a fresh supply. The trolley also contains limited amounts of prn stock medications for special situations. The unit-dose system is designed to reduce medication errors and saves steps in dispensing medications.

Client bedside storage system

In many clinical settings, medications are stored and dispensed from a locked cupboard at the client's bedside. The nurse administers the medication at the required time. This system reduces the possibility of incorrect medication being given to the client, because only medicines required by the client are kept in the locked cupboard. Opioids and other Schedule 8 medicines are not legally able to be stored in this way.

Clinical reasoning in administering medications

Accountability and responsibility

Nurses accept full responsibility for all actions performed while caring for clients, including the administration of medications. If the nurse administers a medication incorrectly or administers the wrong medication, the nurse is held responsible for that action and its consequence. The nurse accepts the responsibility of ensuring that the medication and associated nursing actions will not harm the client. Therefore, the nurse must not assume that the medication ordered for the client is the correct medication or the correct dose. Nurses must be familiar with the therapeutic effect, usual dosage, laboratory results and side effects of all medications administered.

Nurses are also responsible for ensuring that clients who will self-administer medications have been properly informed and monitored.

Demonstrating accountability and acting responsibly in professional practice includes acknowledging errors in professional practice. Most of the errors made by nurses are medication errors. A **medication error** is any event that could cause or lead to incorrect administration according to the prescriber's orders as written on the client's chart. Medication errors may occur when a nurse fails to follow routine procedures, such as checking dosage calculations, deciphering handwriting that is illegible or administering medications with which the nurse is unfamiliar (see Table 27-3). All medication errors can be linked, in some way, to an inconsistency in adhering to the 'seven rights' (see below) of medication administration. Hospital medication delivery systems should be designed so that there is a system of checks and balances, which helps to reduce medication errors. Consider the following *Clinical example*.

CLINICAL EXAMPLE

The medical officer writes an order for a medication. The nurse receives the order and checks it for completeness and appropriateness. The nurse may question the order; for example, if the written order is illegible, the dose seems unusually low or high, or the medication seems inappropriate for the client's condition. The order is sent to the pharmacy, where it may be read by a pharmacy technician and may be prepared by the technician. The pharmacist checks the technician's work, that the medication is the appropriate dosage, and for medication interactions and medication allergies. When a medication order seems inappropriate, e.g. a medication order written for 2000 mg when the proper dosage calls for 200 mg, the pharmacist may call the prescriber for clarification. When the order is appropriate, the medications are sent

continued

TABLE 27-3 Ways to prevent medication administration errors

Precaution	Rationale
Read medication labels carefully	Many products come in similar containers, colours and shapes
Question administration of multiple tablets or vials for single dose	Most doses are one or two tablets or capsules or one single-dose vial. Incorrect interpretation of order may result in excessively high dose
Be aware of medications with similar names	Many medication names sound alike
Check decimal point	Some medications come in quantities that are multiples of one another
Question abrupt and excessive increases in dosages	Most dosages are increased gradually so that prescriber can monitor therapeutic effect and response
When new or unfamiliar medication is ordered, consult resource	If prescriber is also unfamiliar with drug, there is greater risk of inaccurate dosages being ordered
Do not administer medication ordered by nickname or unofficial abbreviation	Many prescribers refer to commonly ordered medications by nicknames or unofficial abbreviations. If nurse or pharmacist is unfamiliar with name, wrong medication may be dispensed and administered
Do not attempt to decipher illegible writing	When in doubt, ask prescriber. Unless the nurse questions an order that is difficult to read, the chance of misinterpretation is great
Know clients with same last names. Also have clients state their full names Check name bands carefully	It is common to have two or more clients with same or similar last names. Special labels on client's record and medication order can warn of potential problem
Do not confuse equivalents or units of measurement	When in a hurry, it may be easy to misread equivalents (e.g. milligram instead of millilitre)

to the nursing unit. The nurse receives the medication and checks the administration record against what the pharmacy has sent and what the prescriber ordered. Before administration, the nurse performs the seven rights of medication administration. The nurse allows the client to be the final check by reviewing the name of the medication, the dosage and why the client is receiving the medication.

The *Clinical example* above illustrates that the nurse is the essential link in the prevention of medication errors. Unfortunately, many medication errors are never identified or reported. When an error is recognised it should be acknowledged immediately and reported to the appropriate hospital personnel, for example, the nurse manager, and documented according to institutional policy (usually including a report in the incident management system). Measures to counteract the effects of the error may be necessary. The nurse is also responsible for completing an incident report describing the nature of the error. Incident reports help administrative personnel identify problems in the hospital system that contribute to medication errors.

Nurses may be asked to administer medications of which they have limited knowledge. They should recognise their knowledge limits and consult more-expert nurses, a pharmacist or pharmacology texts.

Institutional policy may place limitations on the nurse's ability to administer certain types of medications, by certain routes or in certain clinical units. For example, in most agencies, only nurses with specialised training can administer chemotherapeutic medications. Not all prescribers are aware of all the limitations and may prescribe these medications in ward areas where these are not usually administered. Nurses must recognise the limitations, and ensure that the prescriber is informed and that appropriate actions are taken to ensure the client receives the medications as prescribed and within the time prescribed.

Safe medication administration

As a nursing student, you may read about the 'five', 'six' or 'seven' rights of medication administration, which refer to the steps involved in checking a medicine for administration to a client. However, the most important point is to use this as a prompt to think through the principles of safe medication administration in clinical practice; not simply rote-learning a sequence of steps. The well-known 'five rights of medication administration' have been expanded upon in order to ensure safe medication administration; these **seven rights of medication administration** are (Brotto & Rafferty 2015):

1. The right medication
2. The right dose
3. The right client (three identifiers)
4. The right route
5. The right time
6. The right reason
7. The right documentation.

Right medication

When administering medications, the nurse compares the label of the medication container with the medication chart. The nurse does this three times: once before removing the container from the drawer or shelf; once as the amount of medication ordered is removed from the container; and again before returning the container to storage. With unit-dose prepackaged medications, the nurse checks the label with the medication order a third time even though there is no permanent container. Unit-dose medications must be checked before being opened at the client's bedside.

Nurses should only administer the medications they prepare. If an error occurs, the nurse who administers the medication is responsible for its effects. If a client questions the medication a nurse prepares, it is important not to ignore these concerns, as an alert client will know whether a medication is different from those received before. In most cases, the client's medication order may have been changed, but the client's questions might reveal an error. An alert client or carer can play an important role in the safe administration of medications and should not be underestimated. The nurse should withhold the medication until the preparation can be rechecked against the prescriber's orders to ensure the medication ordered is congruent with the client's condition.

Clients who self-administer medications should keep them in their original labelled containers, separate from other medications, to avoid confusion. The nurse should never prepare medications from unmarked containers or from containers with illegible labels. If a client refuses a medication, the nurse must discard it rather than return it to the original container. Unit-dose packaged medications can be saved if they are unopened.

Right dose

The unit-dose system is designed to minimise errors. When a medication must be prepared from a larger volume or strength than needed, or when the prescriber orders a system of measurement that is different from that supplied by the pharmacist, the chance of error increases. When performing medication calculations or conversions, the nurse should have another qualified nurse

check the calculated doses if unsure. After calculating dosages, the nurse prepares the medication using standard measurement devices. Graduated cups, syringes and scaled droppers can be used to measure medications accurately. At home, clients should use kitchen measuring spoons or calibrated measures rather than ordinary teaspoons and tablespoons, which vary in volume.

When it is necessary to break a scored tablet, the break should be even. A tablet may be cut in half by using a knife edge or by using a cutting device. Tablets that are not scored must not be cut, as they rarely break evenly and the correct dose cannot be guaranteed. Discard tablets that do not break evenly. The two halves are given in successive doses if the second half is repackaged and labelled.

Preparing a tablet by crushing is not always safe or appropriate. Consultation with the pharmacy is essential to determine whether a medication can be crushed and if it can be mixed with very small amounts of food or liquid. The client's favourite foods or liquids should not be used, because a medication may alter their taste and thus change the client's desire for them. The nurse should use a more suitable form of the medication (such as a liquid). If an alternative form is unavailable, the crushing device should always be completely cleaned, as remnants of previously crushed medications may increase a medication's concentration or result in the client receiving a portion of an unprescribed medication. Not all medications are suitable for crushing; those with enteric coatings or hard shells should be given whole, as crushing them may cause inadvertent side effects or overdose. In all cases, it is preferable to request that the medication be supplied in the correct dose format rather than breaking tablets, which may result in the administration of an incomplete or uneven dose.

Right client

An important step in administering medications safely is being sure the medication is given to the right client. It is difficult to remember every client's name and face, and so the nurse should not rely on memory to identify the client. Rather, the nurse checks the medication order form (also called a 'drug chart') against the client's identification bracelet (Figure 27-10) and asks the client to state their name. The client is also asked if they have any medication allergies. If an identification bracelet is smudged or illegible or is missing, the nurse must get a new one for the client. When identifying a client verbally, the nurse should not merely say the name and assume that the client's response indicates that they are the right person. Instead, the nurse asks the client to state their full name, explaining that the question is routine when giving medication.

Figure 27-10 **Before administering any medications, the nurse checks the client's identification and allergy bracelet.**

In aged care or residential facilities, residents might not wear an identification band. It is important that the nurse uses some other reliable method for resident identification. If residents are unable to identify themselves (due to confusion or dementia), a photographic ID is necessary.

Right route

If orders do not designate a route of administration, the specified route is not recommended or the route is inappropriate for the specified client, the nurse consults the prescriber. When the nurse administers injections, precautions are necessary to ensure that the medications are given correctly. The injection of a liquid designed for oral use can produce local complications such as a sterile abscess, or fatal systemic effects. Medication companies label parenteral medications 'for injection only'. Care must be taken to ensure that an injectable medication is prepared according to the manufacturer's instructions and administered with appropriate technique by the recommended route.

Right time

The nurse must know why a medication is ordered for certain times of the day and whether the time schedule can be altered. For example, two medications are ordered, one 8 hrly (every 8 hours) and the other tds (3 times a day). Thus both medications are to be given 3 times within a 24-hour period. The prescriber intends the 8 hrly medication to be given around the clock to maintain therapeutic blood levels of the medication, whereas the tds medication may sometimes be given only during the waking hours. Each institution has a recommended time schedule for medications ordered at frequent intervals. Selection of the time of administration must also consider the absorption of the medication, for example, whether it needs to be given with food.

The prescriber often gives specific instructions about when to administer a medication. A preoperative medication to be given on call means the nurse is to administer the medication when the operating room notifies the ward or unit. A medication ordered PC (after food) is to be given within half an hour after a meal, when the client has a full stomach. A stat medication is to be given immediately.

Medications that must act at certain times are given priority. For example, insulin should be given at a precise interval before a meal. All routinely ordered medications should be given within 30 minutes of the times ordered (30 minutes before or after the prescribed time).

Some medications require the nurse's clinical judgement in determining the proper time for administration. A prn sleeping medication should be administered when the client is prepared for bed or at a time appropriate for maximum benefit. A nurse also uses judgement when administering prn analgesics. For example, the nurse may need to obtain a stat order from the prescriber if the client requires a medication before the prn interval has elapsed.

The nurse helps clients to plan post-discharge schedules based on preferred medication intervals, taking into account their usual daily activities at home. For clients who have difficulty remembering when to take medications, the nurse can make a chart that lists the administration times or prepare a special container to hold each timed dose.

Right reason

This is where the nurse must assess if the reason for the medicine is valid. This links with QUM where the medicine needs to be assessed as being appropriate for the client in their current state. The nurse must assess the client and their need for this particular medicine, and evaluate if this medicine is being given for the right reason. If no reason for this medicine is apparent, then they should contact the prescriber.

Right documentation

The nurse must check the medication chart to ensure that the prescription is legal and clearly written. If anything is unclear, then they must check with the prescriber and have the documentation made clear. The nurse must also check to see if the medicine has already been given or if there is anything else wrong with the documentation before administering the medicine and signing the necessary documentation themselves.

• CRITICAL REFLECTION POINT

You receive a prescription for a medication with which you are very familiar. It does not seem clear to you, however, why this medication was ordered for your client, as she does not have a condition for which this medication is commonly used.

How would you proceed in this case? Reflect upon the 'seven rights' and think of what could happen to cause a medication error if these are not considered. What factors could increase your chances of making a medication error?

CLINICAL REASONING PROCESS

GATHERING RELEVANT INFORMATION AND DATA

To determine the need for and potential response to medication therapy, the nurse assesses many factors.

History

Before administering medications, the nurse obtains or reviews the client's medical history, which may provide indications or contraindications for medication therapy. Disease or illness may place clients at risk of adverse medication effects. For example, if a client has a gastric ulcer, compounds containing aspirin will increase the likelihood of bleeding. Long-term health problems such as diabetes or arthritis, which require medications, suggest to the nurse the type of medications a client is taking. A client's surgical history may indicate use of medications; for example, after a thyroidectomy a client may require thyroid hormone replacement.

If the client has a history of allergies to medication, the nurse documents this to inform other members of the healthcare team. Food allergies should also be carefully documented because many medications have ingredients also found in food sources. For example, a client allergic to shellfish may be sensitive to any product containing iodine, such as Betadine (povidone–iodine topical antiseptic) or dyes used in radiological testing. All allergies should be noted on the nurse's admission notes, medication records and medical history, and the client's file should carry a medication alert warning of allergies. The client should also wear an allergy armband.

Medication data

The nurse assesses information about each medication the client takes, including length of time the medicine has been taken, the current dosage and whether the client has experienced adverse effects from the medication. In addition, the nurse reviews medicine data, including action, purpose, normal dosages, routes, side effects and nursing implications for administration and monitoring. Useful questions to ask are: 'What is the smallest possible dose that can be ordered?' (a question pertinent to older adults); 'Can a certain medication interact with other medications being used?'; and 'Are there special instructions for administering the medication?' Often, several resources must be consulted to gather the information. Pharmacology textbooks, nursing medicine reference guides, the *MIMS Annual*, medication package inserts and the pharmacist are valuable resources. The nurse is responsible for knowing as much as possible about each medication given.

As well as taking note of any prescribed medication, the nurse must ask clients if they are currently or have recently taken any **over-the-counter (OTC) medications** or complementary

preparations. Many commonly available preparations (e.g. from a supermarket) have the potential to interact with prescribed medications and must be identified.

Diet history

A diet history reveals usual eating patterns and food preferences. With this knowledge, the nurse can plan the dosage schedule more effectively and advise the client to avoid foods that may interact with medications.

Client's perceptual or coordination problems

For a client with perceptual or coordination limitations, self-administration may be difficult. The nurse must assess the client's ability to prepare doses and take medications correctly. If the client is unable to self-administer medications, the nurse needs to assess whether family or friends are available to help, or arrange community services as required.

Client's current condition

The ongoing physical or mental status of a client may affect whether a medication is given or how it is administered. The nurse should assess a client carefully before giving any medication. For example, the nurse may check blood pressure before giving an antihypertensive, or respiratory rate before administering an opioid. A client with nausea may be unable to swallow a tablet. Assessment findings also serve as a baseline in evaluating the effects of medication therapy.

Client's attitude to medication use

The client's attitude to medications may reveal a level of medication dependence or drug avoidance. Clients may not express their feelings about taking a particular medication, particularly if dependence or fear of dependence is a problem. The client's behaviour should be observed for evidence or indicators of medication dependence or avoidance. The nurse should also be aware of the influence of a client's cultural beliefs on medication compliance (see Chapter 17).

Client's knowledge and understanding of medication therapy

The client's knowledge and understanding of medication therapy influence the willingness or ability to follow a medication regimen. Unless a client understands a medication's purpose, the importance of regular dosage schedules and proper administration methods, and the possible side effects, compliance is unlikely. When assessing knowledge of a medication, the nurse asks: 'What is it for? How is it taken? When is it taken? What side effects have there been? Has the client ever stopped taking doses? Is there anything else the client does not understand and would like to know about the medication?' When the client has a history of poor compliance, the nurse should also review resources available for purchase of medications.

Client's learning needs

By assessing the client's level of knowledge about a medication and ability to take medications regularly, the nurse determines the need for education. It may be necessary for the nurse to explain the action and purpose of the medication, expected side effects, correct administration techniques and ways to help the client remember the medication regimen. If a client has been placed on a newly prescribed medication, more-comprehensive education may be required.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Assessment provides data about the client's condition, ability to self-administer medications and medication-use patterns, which can be used to determine actual or potential problems with medication therapy. Certain data are defining characteristics which, when clustered together, reveal nursing diagnoses (Box 27-7). For example, if a client admits missing a dose and there is evidence a medication has not decreased symptoms or there is limited clinical improvement, this may indicate non-adherence with a medication regimen. Once the diagnosis is selected, the nurse identifies influencing factors. Different interventions will be required for different factors, for example, inadequate finances versus lack of knowledge. In the community, the nurse ensures that the client knows where and how to obtain medications. The nurse also assesses the client's ability to read medication labels.

SETTING PRIORITIES AND ESTABLISHING GOALS

The nurse organises care activities to ensure the safe administration of medications. Hurrying to give clients medications can lead to errors. The nurse can also plan to use time during medication administration to teach clients about their medications. It is important to collaborate with the client's family or support persons when instruction is given. Family members will often reinforce the importance of medication regimens in the home setting.

When clients are hospitalised, it is important to complete any education well before the day of discharge. Early planning is critical to allow time for questions and discussion so that the client understands medications and self-administration guidelines.

Whether a client self-administers or the nurse assumes responsibility for administering medications, the following goals and expected outcomes must be met:

- Client and family understand medication therapy.
- Client gains therapeutic effect from the prescribed medications without discomfort or complications.
- Client has no complications related to the route of administration.
- Client safely self-administers medications.

BOX 27-7 Priority problems associated with people requiring medication therapy for anxiety

Knowledge deficit regarding a medication regimen
Mobility, impaired physical
Non-adherence regarding a medication regimen
Sensory/perceptual alterations, visual
Swallowing, impaired

• CRITICAL REFLECTION POINT

There has been much debate in Australia and in the United Kingdom over nurses wearing 'Do not disturb – nurse administering medications' signs during medication rounds in an attempt to reduce medication errors caused by constant interruptions. Many of the comments in the media about this say it encourages nurses to ignore their clients/families. What are the pros and cons of this strategy?

PREPARING FOR AND TAKING ACTION

Health promotion activities

The nurse, in promoting or maintaining the client's health, identifies factors that may improve or diminish wellbeing. Health beliefs, personal motivations, socioeconomic factors and habits (e.g. smoking) can influence the client's compliance with a medication regimen. Teaching the client and family about the benefit of a medication and the knowledge needed to take it correctly can promote adherence to the regimen and foster independence. Integrating the client's health beliefs and cultural practices into the treatment plan can help the nurse establish a schedule or routine with the client. The nurse may make referrals to community resources if the client is unable to afford, or is not sufficiently mobile to obtain, necessary medications or requires special assistance. Nurses need to incorporate health promotion into their approach to medicines, as otherwise (for example) valuable time spent teaching a client how to use their insulin injector is less meaningful if the client's poor diet is not addressed!

Client and family education

Unless clients are properly informed about medications, they may take the medications incorrectly or not at all. The nurse provides information about the purpose of medications and their actions and effects. Many healthcare facilities offer easy-to-read leaflets on specific types of medications. Clients must know how to take a medication properly and the consequences of failing to do so. For example, after receiving a prescription for an antibiotic, a client must understand the importance of taking the full prescription. Failure to do this can lead to a worsening of the condition, as well as the development of bacteria resistant to the medication.

Nurses teach proper self-administration of medications to clients who depend on daily injections. Clients learn to prepare and administer injections correctly using aseptic technique. Family members or friends should be taught to give injections in case the client becomes ill or is physically unable to handle a syringe.

Clients must be aware of the symptoms of medication side effects or toxicity. For example, clients taking anti-coagulants learn to notify their primary care providers immediately when signs of bleeding or bruising develop. Family members or friends should be informed of medication side effects, such as changes in behaviour, because they are often the first people to recognise such effects. Clients are better able to cope with problems caused by medications if they understand how and when to act.

All clients should learn the basic guidelines for medication safety. These guidelines ensure the proper use and storage of medications in the home (Box 27-8).

BOX 27-8 Teaching for safe medication administration

- Keep each medication in its original labelled container.
- Protect medication from exposure to heat and light, as required.
- Check that labels are legible.
- Discard outdated medications.
- Always finish a prescribed medication unless otherwise instructed, and never save a medication for future illnesses.
- Dispose of medications in a sink or toilet or take them to a chemist/pharmacy, and never place medications in the rubbish bin within reach of children.
- Never give a family member a medication prescribed for another.
- Refrigerate medications that require it.
- Read labels carefully and follow all instructions.
- Notify prescriber of side effects.

Acute care activities

When a nurse receives a medication order, several nursing interventions are essential for safe and effective medication administration.

Receiving medication orders

A medication order is required for almost all medications to be administered by a nurse. Before any other interventions, the nurse ensures that the medication order contains all of the elements in Box 27-9. If the medication order is incomplete, the nurse should inform the prescriber and ensure completion before carrying out any orders. Some medication or treatment orders can be given verbally or by telephone by the prescriber to the nurse.

Correct transcription and communication of orders

Generally, nurses in Australia and New Zealand are not responsible for the transcription of medication orders. If orders need reviewing or transferring to a new medication order sheet, it is the responsibility of the prescriber. There may be some exceptions in remote and rural practice and in specialist units, or in the role of the NP.

Accurate dosage calculation and measurement

When measuring liquid medications, the nurse uses standard measuring containers. The procedure for medication measurement is systematic to reduce the chance of error. The nurse calculates each dose when preparing the medication, pays close attention to the process of calculation and avoids any distractions.

Correct administration

For safe administration, the nurse washes hands and uses non-touch or aseptic techniques and proper procedures when handling and giving medications. Certain medications require the nurse to perform assessments, for example, assessing heart rate before giving antidysrhythmic medications. It is also essential that the nurse witnesses the client taking the medication.

BOX 27-9 Components of medication orders

A medication order is incomplete unless it has the following parts:

- *Client's full name.* The client's full name distinguishes the client from other persons with the same last name. Two identifiers are legally required (i.e. full name and address or date of birth), but it is best practice to use more than two with some agencies requiring the nurse to check three or four identifiers.
- *Date the order is written.* The day, month, year and time must be included. Designating the time an order is written helps clarify when certain orders are to stop automatically. If an incident occurs involving a medication error, it is easier to document what happened when this information is available.
- *Medication name.* The prescriber will order a generic or trade-name medication. Correct spelling is essential in preventing confusion with medications with similar spelling.
- *Dose.* The amount or strength of the medication is included.
- *Route of administration.* The prescriber uses common abbreviations for medication routes. Accuracy is important because some medications are administered by more than one route.
- *Time and frequency of administration.* The nurse needs to know when to initiate medication therapy. Orders for multiple doses establish a routine schedule for medication administration.
- *Signature and name of medical officer or nurse practitioner.* Signature makes the order a legal request and the name enables the other staff to know who has ordered this medicine for the client.

Recording medication administration

After administering a medication, the nurse records it immediately on the appropriate record form (Figure 27-11). The nurse never charts a medication before its administration – recording immediately after administration prevents errors, especially if the client refused the medication. The nurse needs only to record the time and initial the medication chart which already has the name of the medication, dosage, route, exact time of administration. Agency policies may also require the nurse to record the location of an injection.

If a client refuses a medication or is undergoing tests or procedures that result in a missed dose, the nurse explains in the client's progress notes the reason the medication was not given. Most agencies require the nurse to circle the prescribed administration time on the medication record when a dose is missed and, using the correct abbreviation, document the reason for the missed dose; for example, the client may be fasting before going to the operating theatre. It is also important to notify the prescriber, as missing some medicines may cause the client harm (e.g. refusing insulin when a blood-glucose level is high).

• CRITICAL REFLECTION POINT

It is a client's right to refuse treatment or medication. Should a nurse try to cajole or manipulate a client into taking their medicine? When might you be tempted to do this, and what should you do?

Restorative/rehabilitation care activities

Because of the numerous types of restorative and rehabilitation care settings, medication administration activities vary. Clients with functional limitations may require the nurse to administer all medications, whereas in the home healthcare setting clients usually administer their own medications. Regardless of the type of medication activity, the nurse remains responsible for instructing clients and families in medication action, administration and side effects. The nurse is also responsible for monitoring compliance with medication regimens and determining the effectiveness of medications that have been prescribed.

Administering medications to specific age groups

A client's developmental level is a factor in how nurses administer medications. Knowledge of a client's developmental needs helps the nurse anticipate responses to medication therapy.

Infants and children

Children vary in age, weight, surface area and the ability to absorb, metabolise and excrete medications (see *Working with diversity*). Children's medication dosages are generally lower than those of adults, so special caution is needed when preparing medications for them. Medications are usually not prepared and packaged in standardised dose ranges for children, so preparing an ordered dosage from an available amount requires careful calculation. A child's parents/caregivers are valuable resources for learning the best way to give medication to the child. Sometimes it is less traumatic for the child if a parent gives the medication and the nurse supervises.

All children require special psychological preparation before receiving medications. The nurse explains the procedure to the child using language appropriate to the child's level of comprehension. Long explanations may increase a child's anxiety, especially for painful procedures such as an injection. The young child who consistently refuses to cooperate, or resists despite explanation and encouragement, may require physical coercion. If so, it is carried out quickly and carefully. If possible, involve the child in decision-making by saying, 'It's time to take your tablet now. Do you want it with water or fruit juice?' Never give the child the option of not taking a medication. After a medication is given, the nurse praises the child and may even offer a simple reward such as a sticker or token. It is important to check that the child has swallowed the medication.

Box 27-7 contains some useful tips for administering medication effectively to children.

Older adults

Older adults also require special consideration during medication administration (see *Working with diversity*).

WORKING WITH DIVERSITY

Focus on children and adolescents

From birth to adolescence, the paediatric client undergoes continuous physical growth and psychosocial development, much of which influences the outcomes of medication therapy.

Physical considerations

- *Absorption* – gastrointestinal tract may decrease the bioavailability of some drugs and the absorption of others. Absorption from intramuscular injection sites can produce widely differing responses due to the size of the muscle mass and the blood flow to the injected area. Topical administration may produce variable results because the immature and relatively thin epidermis of infants and young children enables quick absorption of topically applied drugs.
- *Distribution* – body fat and water content vary widely with age, e.g. water as a percentage of bodyweight varies from 80% at birth to 56% at 12 months; it is 55% for adults. This variation determines absorption and distribution of the drug.
- *Metabolism* – immature liver function may affect drug metabolism and the half-life of a drug.
- *Excretion* – renal development reaches adult level at around 12 months of age. Immaturity and relative lack of renal excretion can prolong the action of drugs.

Accuracy in paediatric dose calculation is essential to avoid possibly fatal errors.

WORKING WITH DIVERSITY

Focus on older adults

Physical considerations

- *Absorption* – may be increased by age-related slowing of peristalsis, decreased gastrointestinal blood supply and decreased pepsin.
- *Distribution* – increased duration and magnitude of action may occur as a result of decreased body water and an increase in fatty tissue. Decreased plasma protein may also increase the activity of the drug.
- *Elimination* – impaired renal and hepatic functioning may alter the elimination of the drug and lead to increased effect.
- *Failing sight* – may make it difficult for clients to read the labels on medication containers. This may lead to dosage errors.

Sociocultural aspects

- Use of over-the-counter (OTC) medications is common in the elderly. This may put them at increased risk of drug interactions, adverse effects and side effects.
- Many elderly clients attend more than one prescriber, e.g. hospital outpatient departments and their personal general practitioner. It is important that each prescriber is aware of all the medications the client is taking in order to avoid interactions, overuse and duplication.
- Multiple suppliers may lead to confusion between the use of generic and trade names and may result in the client taking extra doses, not realising they are the same drug.
- Financial considerations can result in the client not taking a drug or reducing the amount taken in order to reduce costs.

Psychological and behavioural factors

- Memory loss is common in the elderly and the client may miss doses or take the drug again.
- Dementia may affect compliance with medication regimens.

In addition to the physiological changes of ageing (Figure 27-12), behavioural, cultural and economic factors influence an older person's use of medications. In 2004, Ebersole and Hess described five behavioural patterns characteristic of the older client in relation to medication use. These are still relevant today:

- *Polypharmacy*. The client takes several prescribed or over-the-counter (OTC) preparations to treat several disorders/symptoms simultaneously. There exists a high risk of medication interactions with other medications and with foods, and an increased risk of adverse medication reactions.
- *Self-prescribing of medications*. A variety of symptoms experienced by elderly clients, such as pain, constipation, insomnia and indigestion, are amenable to OTC medications. Older adults often seek relief from problems by OTC preparations and/or complementary medicines and herbs.
- *Over-the-counter medications*. These medications, which can be purchased without a prescription, are available from pharmacies, supermarkets and health shops. It is known that OTC medications are widely used by older people to relieve symptoms. Many of these preparations have ingredients which, when used inappropriately, may cause undesirable side effects, adverse reactions or may be contraindicated for the client's condition. Clients should be asked specifically about 'other things you are taking'.
- *Misuse of medications*. Forms of misuse by older clients include overuse, underuse, erratic use, contraindicated use and using medication prescribed for others.
- *Non-adherence (non-compliance)*. Non-adherence is defined as a deliberate misuse of medication. Many older adults intentionally do not adhere to their medication regimen; they often alter the dose because of cost, ineffectiveness or uncomfortable side effects. Non-adherence may also be a result of poor eyesight, cognitive factors or inadequate education.

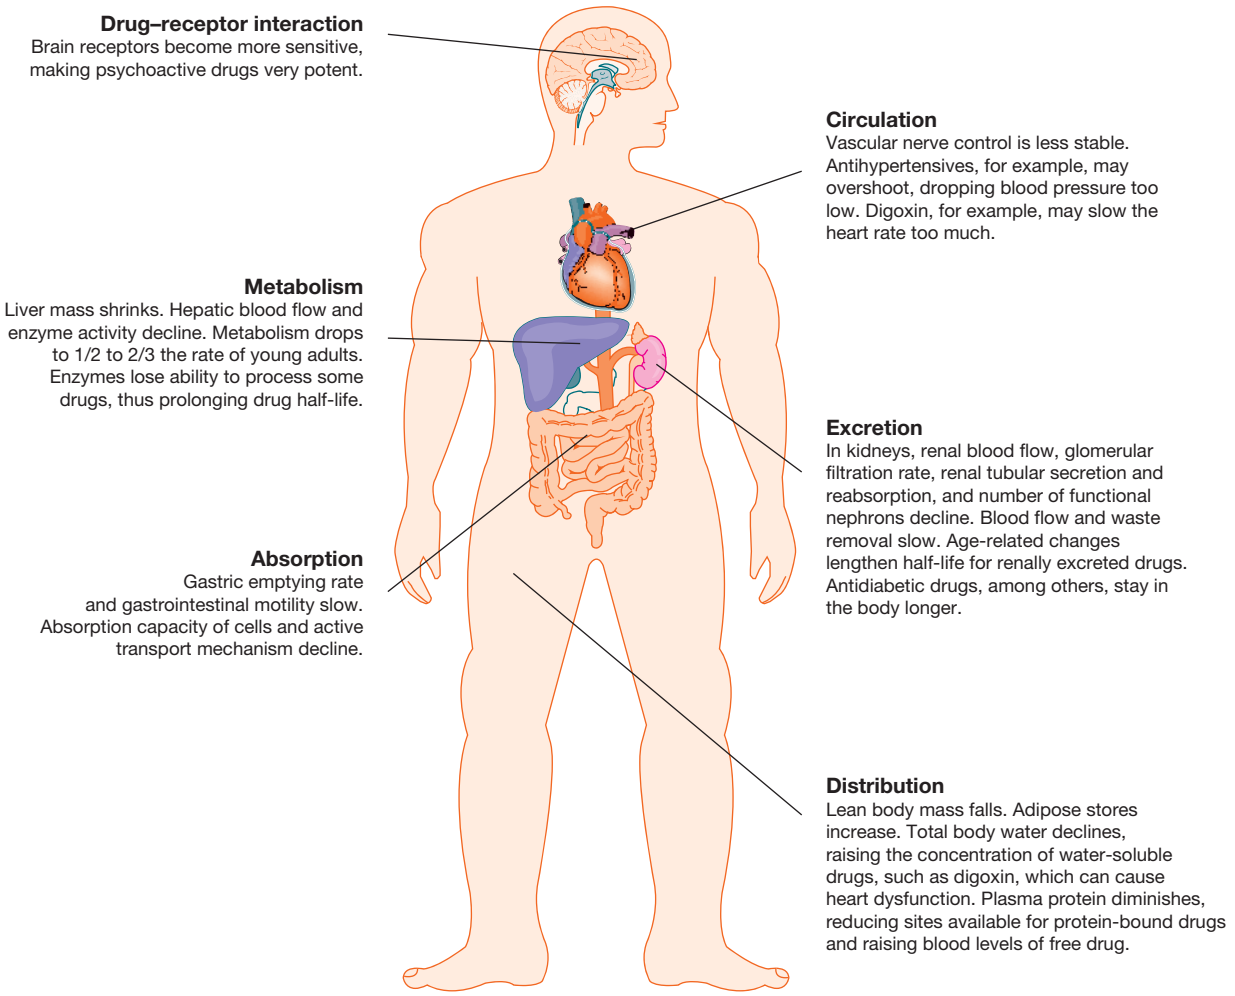

Figure 27-12 Ageing body and drug use.

Lewis SM et al 2003 Medical–surgical nursing, 6th edn. Mosby, St Louis.

EVALUATING IMPACTS AND OUTCOMES

The nurse monitors a client's response to medications on an ongoing basis, so must know the therapeutic action and common side effects of each medication. A change in a client's condition can be physiologically related to health status or may result from medications, or both. The nurse must be alert for reactions in a client taking several medications. The goal of safe and effective medication administration involves a careful evaluation of technique, as well as the client's response to therapy and ability to assume responsibility for self-care.

To evaluate the effectiveness of nursing interventions, the nurse identifies whether nominated client outcomes were met using evaluative measures (Table 27-4). Direct observation of behaviour or response, rating scales (e.g. the numerical pain rating scale), checklists and oral questioning are all of use when evaluating the outcome of medication administration. The reading skill and knowledge level of the client, and cognitive and psychomotor ability, must also be considered. Physiological measures (e.g. blood pressure, heart rate and visual acuity) are the most common type of measurement used by the nurse. Client statements can also be used as evaluative measures. The findings of an evaluation should be measured against baseline information gained before the medication was given (e.g. pain scores before and after the administration of analgesics).

Methods of administration

Oral administration

The easiest and most desirable way to administer medications is by mouth, known as **oral administration** (Skill 27-1). Clients are usually able to ingest or self-administer oral medications with few problems. Most tablets and capsules should be swallowed and administered with approximately 60–100 mL of fluid (as allowed). There may, however, be times when receiving medications by mouth is contraindicated for a client, such as the presence of GI alterations (e.g. nausea), the inability of a client to swallow food or fluids and the use of nasogastric tubes on free drainage or suction.

TABLE 27-4 Example evaluation of goals

Goal	Expected outcomes	Evaluative measure with example
Client and family understand medication therapy	Client and family describe information about medication, dosage, schedule, purpose and adverse effects	Written measurement: Have client write out medication schedule for a 24-hour period Oral questioning: Ask client to describe purpose, dosage and adverse effects of each prescribed medication
	Client and family identify situations that require medical intervention	Oral questioning: Have family describe what to do when a client has adverse effects from a medication
	Client and family demonstrate appropriate administration technique	Direct observation: Have client demonstrate filling of an insulin syringe and self-injection
Client safely self-administers medications	Client follows prescribed treatment regimen	Anecdotal notes: Have family keep log of client's use of medicines for 1 week
	Client performs techniques correctly	Direct observation: Observe client instil eye drops
	Client identifies available resources for obtaining necessary medication	Oral questioning: Ask family to identify how to contact local pharmacy, community clinic, etc

SKILL 27-1

Administering oral medications

Delegation considerations

Administering medications by the oral route requires the problem-solving and knowledge-application abilities of professional nurses. In some states of Australia and New Zealand, client care attendants or enrolled nurses may legally be able to administer medications via this route. For this procedure, client assessment by the registered nurse is required as delegation may be inappropriate.

Equipment

- Medication trolley (if applicable)
- Disposable medication cups
- Glass of water, juice or preferred liquid
- Drinking straw
- Clean pill-crusher (if required)
- Paper towels (for liquid medicines)
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess for any contraindications to client receiving oral medication: Is client able to swallow? Is client suffering from nausea/vomiting? Is client diagnosed as having bowel inflammation or reduced peristalsis? Has client had recent gastrointestinal (GI) surgery? Does client have a nasogastric tube in situ on gastric drainage/suction?	Alterations in GI function interfere with medication distribution, absorption and excretion. Clients with GI suction might not receive benefit from the medication because it may be suctioned from the GI tract before it can be absorbed.

STEPS	RATIONALE
a. Check the client's swallow, cough and gag reflexes if in doubt about client's ability to manage oral medications. Withhold medication if swallow, cough or gag is impaired and notify prescriber.	
2. Assess client's medical history, history of allergies, medication history and diet history.	These factors can influence how certain medications act. Information also reflects client's need for medications.
Critical decision point: Drug allergies should be listed on each page of the MAR, on an identification armband and prominently displayed on the client's medical record.	
3. Gather physical examination and laboratory data that may influence medication administration (e.g. checking blood pressure before administering antihypertensives).	Physical examination or laboratory data may contraindicate medication administration.
Critical decision point: If contraindications exist, withhold medication and inform prescriber.	
4. Assess client's knowledge of health and medication use.	Determines client's need for medication education. Also helps to identify adherence to medication therapy at home. Assessment may reveal medication problems such as medication tolerance (where medication fails to achieve the desired effect), non-compliance, abuse, addiction or dependence.
5. Assess client's preferences for fluids.	Fluids ease swallowing and facilitate absorption from the GI tract. Fluid restrictions must be maintained.
6. Check accuracy and completeness of each MAR or computer printout with prescriber's written medication order. Check client's name, medication name and dose, route of administration and time for administration.	The medication order sheet is the most reliable source and only legal record of medications client is to receive.
7. **Prepare medications:**	
a. Perform hand hygiene.	Reduces transfer of microorganisms.
b. Arrange medication tray and cups in medication preparation area (medication room or at the client's bedside if medicines are stored in a locked drawer there) or move medication trolley to outside client's room.	Organisation of equipment saves time and reduces error.
c. Unlock medicine drawer or trolley.	Medications are safeguarded when locked in cabinet or trolley.
d. Prepare medication for one client at a time. Keep all pages of MARs for one client together.	Prevents preparation error.
e. Select correct medication. Compare label of medication with MAR.	Reading label and comparing it with order reduces error.

STEPS	RATIONALE
f. Calculate medication dose as necessary. Double-check calculation.	Double-checking will help reduce risk of error.
g. To prepare tablets or capsules, pour required number into bottle cap and transfer medication to medication cap. Do not touch medication with fingers. Extra tablets or capsules may be returned to bottle. For medications that need to be broken, use a gloved hand, or cut with a clean pill-cutting device (see illustration). Tablets that are to be broken in half must be pre-scored (identified by a manufactured line across the centre of the tablet).	Medications are very expensive; avoid waste. Some medicines may degrade if touched or may be harmful to the nurse (i.e. cytotoxic drugs).

Step 7g Pill-cutting device.

h. To prepare unit-dose tablets or capsules, place packaged tablet or capsule directly over medicine cup and compress the wrapper to release medication (see illustration).	
i. If the client has difficulty swallowing, ask prescriber to substitute with liquid or dissolvable preparation. If liquid medications are not an option, use a clean pill-crushing device such as a mortar and pestle to grind tablets. Mix ground tablet in small amount of soft food.	Large tablets can be difficult to swallow. Ground tablet mixed with palatable soft food is usually easier to swallow. Note that not all tablets are safe to break up or crush, so this must be checked beforehand. Pill-crushing devices should be clean to prevent inadvertent exposure to other medicines that may have been in the pill-crusher previously.

■ **Critical decision point: Not all medications can be crushed (e.g. capsules, enteric-coated drugs). Consult with pharmacist when in doubt. Choking or aspiration of particles of medication can also occur.**

STEPS	RATIONALE
 Step 7h Placing medications packaged in blister packs in medicine cup.	 Step 7i Pill-crushing device.
j. Prepare liquids:	
(1) Remove bottle cap from container and place cap upside down.	Prevents contamination of inside of cap.
(2) Hold bottle with label against palm of hand while pouring.	Spilled liquid will not soil or fade label.
(3) Hold medication cup at eye level and fill to desired level on scale (see illustration). Scale should be even with fluid level at its surface or base of meniscus, not edges.	Ensures accuracy of measurement.
(4) Discard any excess liquid into sink. Wipe lip and neck of bottle with paper towel.	Prevents contamination of bottle's contents and prevents bottle cap from sticking.
(5) Some liquid medications are in unit-dose containers. Draw up volumes of less than 10 mL in syringe without needle (see illustration).	
 Step 7j(3) Pouring liquid medication into medication cup; base of meniscus should be level with line on scale.	 Step 7j(5) Liquid-medication syringes for preparing small amounts.

STEPS	RATIONALE
k. When preparing Schedule 8 medicines, check drug record for previous medication count and compare with supply available. Note that some clinical agencies require two staff to check controlled drugs at the bedside, but this is agency policy and is not regulated by law (except for blood products).	Controlled substance laws require careful monitoring of dispensed controlled drugs.
l. Check expiration date on all medications.	Medications used past expiration date may be inactive or harmful to client.
m. Compare MAR with prepared medication and container.	Reading label second time reduces error.
n. Return stock containers or unused unit-dose medications to shelf or drawer and read label again.	Third check of label reduces administration errors.
o. Do not leave medications unattended.	Nurse is responsible for safekeeping of drugs.
8. **Administering medications:**	
a. Take medications to client at correct time. All tablets or capsules to be given to client at same time may be placed in one medicine cup except for those requiring pre-administration assessments (e.g. pulse rate or blood pressure).	Medications are administered within 30 minutes before or after prescribed time to ensure intended therapeutic effect. Stat or single-order medications should be given at time ordered. Keeping medications that require pre-administration assessments separate from others makes it easier for the nurse to withhold medications as necessary.
b. Identify client by comparing name on MAR with name on client's identification bracelet. Ask client to state name and any known allergies.	Identification bracelets are made at time of client's admission and are the most reliable source of identification. Replace any missing or faded identification bracelets.
c. Explain purpose of each medication and its action to client. Allow client to ask any questions about drugs.	Client has right to be informed, and client's understanding of purpose of each medication improves compliance with medication therapy.
d. Help client to sit or to lie on the side if sitting is contraindicated.	Sitting position prevents aspiration during swallowing.
e. Administer medications properly:	
(1) Client may wish to hold solid medications in hand or cup before placing in mouth.	Client can become familiar with medications by seeing each drug.
(2) Offer water or juice to help client swallow medications. You may offer cold carbonated water if available and not contraindicated.	Choice of fluid promotes client's comfort and can improve fluid intake. Carbonated water helps passage of tablet through oesophagus.

STEPS	RATIONALE
(3) For sublingually administered medications, have client place medication under tongue and allow it to dissolve completely. Caution client against swallowing tablet.	Medication is absorbed through blood vessels of undersurface of tongue. If swallowed, medication is destroyed by gastric juices or so rapidly detoxified by liver that therapeutic blood levels are not attained.
(4) For bucally administered drugs, have client place medication in mouth against mucous membranes of the cheek until it dissolves (see Figure 27-5). Avoid administering liquids until buccal medication has dissolved.	Buccal medications act locally on mucosa or systemically as they are swallowed in saliva.
(5) Mix powdered medications with liquids at bedside and give to client to drink.	When prepared in advance, powdered medications may thicken and even harden, making swallowing difficult.
(6) Caution client against chewing or swallowing lozenges.	Medication acts through slow absorption through oral mucosa, not gastric mucosa.
(7) Give effervescent powders and tablets immediately after dissolving.	Effervescence improves unpleasant taste of medication and often relieves GI problems.
f. If client is unable to hold medications, place medication cup to the lips and gently introduce each drug into the mouth, one at a time. Do not rush.	Administering single tablet or capsule eases swallowing and decreases risk of aspiration.
g. If tablet or capsule falls to the floor, discard it appropriately and repeat preparation.	Medication is contaminated when it touches floor.
h. Stay until client has completely swallowed each medication.	Nurse is responsible for ensuring that client receives ordered dosage. If left unattended, client may not take dose or may save medications, causing risk to health.
i. For highly acidic medications (e.g. aspirin), offer client non-fat snack (e.g. crackers) if not contraindicated by client's condition. (Check medication reference resource first to ensure the medication can be administered with food.)	Reduces gastric irritation.
j. Help client return to comfortable position.	Maintains client's comfort.
k. Dispose of soiled supplies and perform hand hygiene.	Reduces transmission of microorganisms.
9. Return within 30 minutes to evaluate client's response to medications.	Evaluates medication's therapeutic benefit and can detect onset of side effects or allergic reactions.
10. Ask client or family member to identify medication name and explain purpose, action, dosage schedule and potential side effects of drug.	Determines level of knowledge gained by client and family.
11. Always notify prescriber when the client exhibits an adverse effect or allergic reaction, or with the onset of side effects. Withhold further doses.	Notification alerts prescriber to modify or discontinue medication.

RECORDING AND REPORTING

- Record administration of oral medications on MAR, and add nurse's initials or signature.
- Record the reason any drug is withheld and follow agency's policy for proper recording.

HOME CARE CONSIDERATIONS

- All clients should learn the basic guidelines for medication safety:
  - Keep each medication in its original, labelled container.
  - Be sure labels are legible.
  - Discard any outdated medications.
  - Always finish a prescribed medication unless otherwise instructed. Never save a medication for future illnesses.
  - Dispose of medications by taking them to the pharmacy. Do not place drugs in the bin within reach of children.
  - Do not give a family member a medication prescribed for another.
- Refrigerate medications that require it.
- Read labels carefully and follow all instructions.

Preparation for tests or surgery may mean that the client is fasting (nil by mouth).

It is important to protect clients from aspiration. Aspiration occurs when medication intended for GI administration is inadvertently administered or inhaled into the respiratory tract. The nurse protects the client from aspiration (Box 27-10) by evaluating the client's ability to manage/swallow oral medications. In this regard, proper positioning of the client is essential. If not contraindicated by a client's condition, the nurse positions the client in a seated position when administering oral medications.

A client who has difficulty swallowing should be evaluated by appropriate personnel (e.g. speech therapist) before receiving oral preparations. For clients with naso-gastric feeding tubes, liquid medications are preferred so they can be easily injected through the tube, but some tablets can be crushed and capsules opened to mix in a solution with water for administration via the tube (Box 27-11).

Topical medication applications

Topical medications are applied locally, most often to intact skin.

Skin applications

Many locally applied medications such as lotions, pastes and ointments (see Box 27-1) can create systemic and local effects. Nurses should wear gloves or use an applicator when applying these medications to avoid absorbing the medication through their own skin. Aseptic technique may be appropriate if the client has an open wound.

BOX 27-10 Assessments to protect the client from aspiration

Determine the client's ability to swallow

- Ask the client to repeat certain sounds that require the same muscle movements as swallowing: 'me-me-me' (for the lips); 'la-la-la' (for the tongue); 'ga-ga-ga' (for the soft palate and pharynx).
- Assess the swallowing reflex by having the client slide the tongue backwards along the palate.
- Position your thumb and index finger on the client's larynx, and ask the client to swallow. Normally the larynx will elevate.

Assess the client's cough

See Chapter 40 on proper techniques of coughing.

Determine the presence of a gag reflex

- Assess the gag reflex by stroking the posterior pharyngeal wall with a tongue blade. Never check the gag reflex in a client who does not exhibit an intact cough or swallow reflex.
- To protect the airway the client must have all three of: a positive cough, gag and swallow reflex.

Note: Prescriber and/or speech therapist should be consulted if there is any question of a client's ability to swallow safely.

Modified from Gauwitz DG 1995 How to protect the dysphagic stroke client. Am J Nurs 95:34. For further information see www2.health.vic.gov.au/hospitals-and-health-services/patient-care/older-people/nutrition-swallowing/swallowing/swallowing-identifying.

BOX 27-11 Guidelines for giving medications through a nasogastric tube, I-tube, G-tube or small-bore feeding tube

- Administer medications in a liquid form (suspension, elixir or solution) when possible to prevent tube obstruction.
- Read medication labels carefully before crushing a tablet or opening a capsule. (Crushed medications may obstruct small-bore tube. Check agency policy.)
- Do not crush buccal or sublingual tablets. Do not crush enteric-coated or sustained-action medications.
- Dissolve crushed tablets and powders in warm water.
- Dissolve soft gelatin capsules in warm water.
- Irrigate the tube before and after all medication is given with 50–150 mL of water.
- Do not use pigtail vent for irrigation or instillation of fluid.
- Avoid giving syrups or medications with a pH of less than 4.
- Do not attempt to give whole or undissolved medications.

Simply applying new medications over previously applied medications does little to prevent infection or offer therapeutic benefit. Before applying medications, the nurse thoroughly cleans and assesses the skin. When applying ointments or pastes, the nurse spreads the medication evenly and thinly over the involved surface and covers the area well. Opaque ointments prevent the underlying skin from being seen. Prescribers may order a light dressing to be applied over the medication to prevent soiling of clothes and wiping away of the medication.

Each type of medication, whether an ointment, lotion or powder, should be applied in a specific way to ensure proper penetration and absorption. Lotions and creams are applied by lightly smearing onto the specified skin's surface; the lotion or cream should not be rubbed in, as rubbing may cause irritation. A liniment is applied by rubbing it gently but firmly into the skin. A powder is dusted lightly to cover the affected area with a thin layer.

Recording of the treatment should include the type of administration, the area concerned, the name of the medication and the condition of the skin. Care must be taken to apply the treatment only to the affected area, as some medications can damage or irritate normal skin.

Nasal instillation

Clients with nasal (allergic rhinitis) or sinus (sinus infection) alterations may receive medications by spray, drops or packing (Skill 27-2). Another example is intranasal fentanyl, which is used for analgesia in children older than 12 months for moderate to severe pain. The most commonly administered form of nasal instillation is decongestant spray or drops, used to relieve symptoms of sinus congestion and colds. Clients must be cautioned to avoid overuse of such medications, because a rebound effect may cause increased nasal congestion. When excess decongestant solution is swallowed, serious systemic effects may also develop, especially in children. Saline drops are safer as a decongestant for children than nasal preparations that contain sympathomimetics, for example, pseudoephedrine.

It is easier for clients to self-administer sprays, since they can control the spray and inhale as it enters the nasal passages. For clients who use nasal sprays repeatedly, the nurse checks the nares for irritation. The nurse learns the proper way of positioning clients to permit the medication to reach the affected sinus.

SKILL 27-2

Administering nasal instillations

Delegation considerations

Administration of nasal drops and ointments requires the problem-solving and knowledge-application abilities of professional nurses. In some states of Australia and New Zealand, client care attendants or enrolled nurses may legally be able to administer medications via this route. For this procedure, client assessment by the registered nurse is required as delegation may not be appropriate.

Equipment

- Prepared medication with clean dropper or spray container
- Facial tissue
- Disposable gloves (optional, only if client has extensive nasal drainage)
- Medication administration record (MAR)
- Penlight (to inspect nares; if ointment is to be applied to a specific lesion inside the nares)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent

- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. For nasal drops, determine which sinus is affected by referring to healthcare record.	Affects client's position during drug instillation.
2. Assess client's history of hypertension, heart disease, diabetes mellitus and hyperthyroidism.	These conditions can contraindicate use of decongestants that stimulate central nervous system (CNS). Side effects of transient hypertension, tachycardia, palpitations and headache may occur.
3. Identify client; compare name on MAR with client's ID bracelet. Ask client to state name.	Ensures that correct client receives medication.
4. Using a penlight, inspect condition of nose and sinuses. Palpate sinuses for tenderness.	Provides baseline to monitor effects of medication. Presence of discharge interferes with medication absorption.
5. Assess client's knowledge regarding use of nasal instillations and technique for instillation and willingness to learn self-administration.	May necessitate health teaching regarding use of medications. Motivation influences teaching approach.
6. Explain procedure to client regarding positioning and sensations to expect, such as burning or stinging of mucosa or choking sensation as medication trickles into throat.	Helps client anticipate experience of procedure to reduce anxiety.
7. Perform hand hygiene. Arrange supplies and medications at bedside.	Reduces transmission of microorganisms; ensures smooth, orderly procedure.
8. Instruct client to clear or blow nose gently unless contraindicated (e.g. risk of increased intracranial pressure or nosebleeds).	Removes mucous and secretions that can block distribution of medication.
9. **Administer nasal drops:**	
a. Help client to supine position.	Position provides access to nasal passages.
b. Position head properly:	
■ **Critical decision point: Do not hyperextend the neck of a client with a known neck problem or suspected cervical spine injury.**	
(1) For access to posterior pharynx, tilt client's head backwards. (2) For access to ethmoid or sphenoid sinus, tilt head back over edge of bed or place small pillow under client's shoulder and tilt head back (see illustration).	Position allows medication to drain into affected sinus.

STEPS	RATIONALE
(3) For access to frontal and maxillary sinus, tilt head back over edge of bed or pillow with head turned towards side to be treated (see illustration).	
 Step 9b(2) Patient position for medication administration to ethmoid or sphenoid sinus.	 Step 9b(3) Patient position for medication administration to frontal and maxillary sinus.
c. Support client's head with non-dominant hand.	Prevents straining of neck muscles.
d. Instruct client to breathe through mouth.	Mouth breathing reduces chance of aspirating nasal drops into trachea and lungs.
e. Hold dropper 1 cm above nares and instil prescribed number of drops towards midline of ethmoid bone.	Avoids contamination of dropper. Instilling towards ethmoid bone facilitates distribution of medication over nasal mucosa.
f. Have client remain in supine position for 5 minutes.	Prevents premature loss of medication through nares.
g. Offer facial tissue to blot runny nose, but caution client against blowing nose for several minutes.	Allows maximal amount of medication to be absorbed.
10. Help client into a comfortable position after medication is absorbed.	Restores comfort.
11. Dispose of soiled supplies in appropriate container and wash hands.	Maintains neat, orderly environment. Reduces spread of microorganisms.
12. Observe client for onset of side effects 15–30 minutes after administration.	Drugs absorbed through mucosa can cause systemic reaction.
13. Ask if client is able to breathe through nose after decongestant administration. May be necessary to have client occlude one nostril at a time and breathe deeply.	Determines effectiveness of decongestant medication.

STEPS	RATIONALE
14. Inspect condition of nasal passages between instillations.	Condition of mucosa reveals response to medication.
15. Ask client to review risks of overuse of decongestants and methods for administration.	Feedback ensures that client can self-administer medications properly.
16. Have client demonstrate self-medication.	Feedback demonstrates learning.

RECORDING AND REPORTING

- Record medication name, concentration, number of drops, nostril into which medication was instilled and time of administration on MAR.
- Record client's response in nurses' notes.
- Report any unusual systemic effects to nurse in charge or medical officer.

HOME CARE CONSIDERATIONS

- Instruct client to expect timely resolution of problems. Instruct client on signs to observe of persistent or worsening problem. Clear nasal discharge indicates sinus problem. Yellow or greenish discharge indicates infection.
- Use OTC nasal sprays or nose drops for only one client; bottles become easily contaminated with bacteria.

Eye instillation

Eye drops and ointments are common medications used by clients, including OTC preparations such as artificial tears. Many clients receive prescribed ophthalmic medications for glaucoma and after cataract extraction. A large percentage of clients receiving eye medications are older people. Age-related problems, including poor vision, hand tremors and difficulty grasping or manipulating containers, affect the ease with which the older person can self-administer eye medications. The nurse instructs clients and family members about the proper techniques for administering eye medications (Skill 27-3). The nurse may determine the client and family's ability to self-administer through a return demonstration of the procedure. Showing clients each step of the procedure for instilling eye drops can improve their compliance.

The following principles should be followed when administering eye medications:

- The cornea of the eye is richly supplied with pain fibres and is thus very sensitive to anything applied to it. Avoid instilling any form of eye medication directly onto the cornea.
- The risk of transmitting infection from one eye to the other is high. Avoid touching the eyelids or other eye structures with eye droppers or ointment tubes.
- Use eye medication only for the client's affected eye unless ordered otherwise.
- Never allow a client to use another client's eye medications.

Some medications are administered intraocularly. Medications delivered this way resemble a contact lens. The nurse places the medication disc into the conjunctival sac, where it remains in place for up to 1 week. The client receiving intraocular medications requires teaching about monitoring for adverse reactions to the disc. Clients will also need to be taught how to insert and remove the disc.

SKILL 27-3

Administering ophthalmic medications

Delegation considerations

Administration of eye drops and ointments requires the problem-solving and knowledge-application abilities of professional nurses. In some states of Australia and New Zealand, client care attendants or enrolled nurses may legally be able to administer medications via this route. For this procedure, client assessment by the registered nurse is required as delegation may not be appropriate.

Equipment

- Medication bottle with sterile eye dropper or ointment tube
- Medicated intraocular disc
- Cotton ball or tissue
- Washbasin filled with warm water, and washcloth
- Eye patch and tape (optional)
- Disposable gloves
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

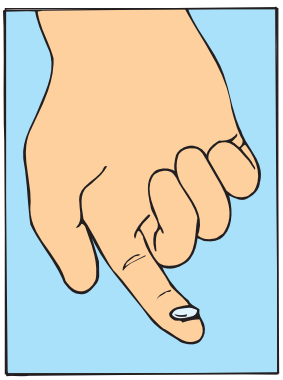
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review prescriber's medication order for number of drops (if a liquid) and eye/s to receive medication.	Ensures correct administration of medication.
2. Identify client. Compare name on MAR with client ID band. Ask client to state name.	Ensures that correct client receives medication.
3. Assess condition of external eye structures. (May also be done just before drug instillation.)	Provides baseline data with which to compare response to medications. Indicates need to clean eye before medication.
4. Determine known allergies to any medications or to latex.	Protects client from risk of allergic medication response. May require use of non-latex gloves.
5. Determine whether client has any symptoms of visual alterations.	Certain eye medications act to either lessen or increase these symptoms.
6. Assess client's level of consciousness and ability to follow directions.	Restlessness during procedure increases risk of accidental eye injury.
7. Assess client's knowledge regarding medication therapy and desire to self-administer medication.	Client's level of understanding may indicate need for health teaching.
8. Assess client's ability to manipulate and hold dropper.	Reflects client's ability to learn to self-administer medication.
9. Explain procedure to client.	Relieves anxiety about medication being instilled into eye.
10. Perform hand hygiene and arrange supplies at bedside; put on disposable gloves.	Reduces transmission of microorganisms; ensures a smooth, orderly procedure.
11. Ask client to lie supine or sit back in chair with head slightly hyperextended.	Position provides easy access to eye for medication instillation and minimises drainage of medication through tear duct.

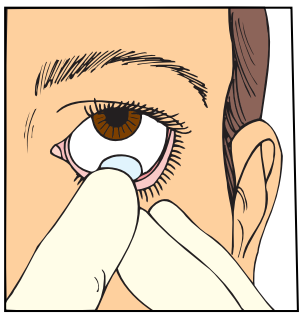
■ **Critical decision point: Do not hyperextend the neck of a client with a known neck problem or suspected cervical spine injury.**

STEPS	RATIONALE
12. If crusts or drainage are present along eyelid margins or inner canthus, gently wash away. Soak any crusts that are dried and difficult to remove by applying damp washcloth or cotton ball over eye for a few minutes. Always wipe from inner to outer canthus.	Crusts or drainage harbour microorganisms. Soaking allows easy removal and prevents pressure from being applied directly over eye. Cleaning from inner to outer canthus avoids entry of microorganism into lacrimal duct.
13. Hold cotton ball or clean tissue in non-dominant hand on client's cheekbone just below lower eyelid.	Cotton or tissue absorbs medication that escapes eye.
14. With the tissue or cotton ball resting below lower lid, gently press downwards with thumb or forefinger against bony orbit.	Technique exposes lower conjunctival sac. Retraction against bony orbit prevents pressure and trauma to eyeball and prevents fingers from touching eye.
15. Ask client to look at ceiling and explain steps to client.	Action retracts sensitive cornea up and away from conjunctival sac and reduces stimulation of blink reflex.
A. Instil eye drops:	
(1) With dominant hand resting on client's forehead, hold filled medication eye dropper or ophthalmic solution approximately 1–2 cm above conjunctival sac (see illustration).	Helps prevent accidental contact of eye dropper with eye structures, thus reducing risk of injury to eye and transfer of infection to dropper. Ophthalmic medications are sterile.
(2) Drop prescribed number of medication drops into conjunctival sac.	Conjunctival sac normally holds 1 or 2 drops. Provides even distribution of medication across eye.
(3) If client blinks or closes eye or if drops land on outer lid margins, repeat procedure.	Therapeutic effect of drug is obtained only when drops enter conjunctival sac.
(4) After instilling drops, ask client to close eye gently.	Helps to distribute medication. Squinting or squeezing of eyelids forces medication from conjunctival sac.
(5) When administering medications that cause systemic effects, apply gentle pressure with finger and clean tissue on the client's nasolacrimal duct for 30–60 seconds.	Prevents overflow of medication into nasal and pharyngeal passages. Prevents absorption into systemic circulation.
B. Instil eye ointment:	
(1) Holding ointment applicator above lower lid margin, apply thin stream of ointment evenly along inner edge of lower eyelid on conjunctiva (see illustration) from the inner canthus to the outer canthus.	Distributes medication evenly across eye and lid margin.
(2) Have client close eye and rub lid lightly in circular motion with cotton ball, if rubbing is not contraindicated.	Further distributes medication without traumatising eye.

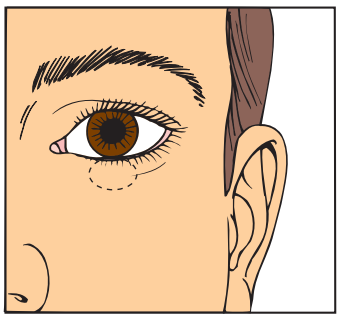
STEPS	RATIONALE
 Step 15A(1) Instilling eye drops.	 Step 15B(1) Instilling eye ointment.
C. Intraocular disc (1) Application:	
(a) Open package containing the disc. Gently press your fingertip against the disc so that it adheres to your finger. Position the convex side of the disc on your fingertip (see illustration).	Allows nurse to inspect disc for damage or deformity.
(b) With your other hand, gently pull the client's lower eyelid away from the eye. Ask client to look up.	Prepares conjunctival sac for receiving medicated disc.
(c) Place the disc in the conjunctival sac, so that it floats on the sclera between the iris and lower eyelid (see illustration).	Ensures delivery of medication.
(d) Pull the client's lower eyelid out and over the disc (see illustration).	Ensures accurate medication delivery.



Step 15C(1)(a) Positioning intraocular disk on finger.



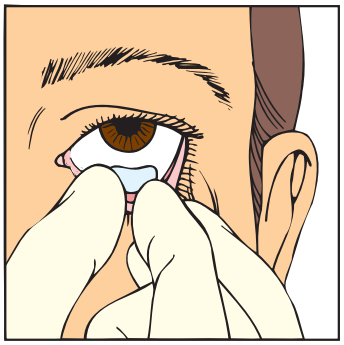
Step 15C(1)(c) Placing disc in conjunctival sac.



Step 15C(1)(d) Disc in position underneath lower eyelid.

■ **Critical decision point: You should not be able to see the disc at this time. Repeat Step 15C(1)(d) if you can see the disc.**

STEPS	RATIONALE
(2) Removal: (a) Wash hands and put on gloves. (b) Explain procedure to client. (c) Gently pull on the client's lower eyelid to expose the disc. (d) Using your forefinger and thumb of your opposite hand, pinch the disc gently and lift it out of the client's eye (see illustration).	



Step 15C(2)(d) Pinching disc to remove it from patient's eye.

16. If excess medication is on eyelid, gently wipe it from inner to outer canthus.	Promotes comfort and prevents trauma to eye.
17. If client had eye patch, apply clean one by placing it over affected eye so entire eye is covered. Tape securely without applying pressure to eye.	Clean eye patch reduces chance of infection.
18. Remove gloves, dispose of soiled supplies in proper receptacle, and wash hands.	Maintains neat environment at bedside and reduces transmission of microorganisms.
19. Note client's response to instillation; ask if any discomfort was felt.	Determines whether procedure was performed correctly and safely.
20. Observe response to medication by assessing visual changes and noting any side effects.	Evaluates effects of medication.
21. Ask client to discuss medication's purpose, action, side effects and technique of administration.	Determines client's level of understanding.
22. Have client demonstrate self-administration of next dose.	Provides feedback regarding competency with skill.

RECORDING AND REPORTING

- Record medication, concentration, number of drops, time of administration and eye (left, right or both) that received medication on MAR.
- Record appearance of eye in nurses' notes.

HOME CARE CONSIDERATIONS

- If eye drops are stored in refrigerator, re-warm to room temperature before administering.
- Many clients lack confidence in their ability to instil drops without supervision. The nurse teaches others, such as a family member, to instil drops into the client's eye.

Ear instillation

Internal ear structures are very sensitive to temperature extremes. Failure to instil ear drops or irrigating fluid at room temperature may cause vertigo (severe dizziness) or nausea. Although the structures of the outer ear are not sterile, it is wise to use sterile drops and solutions in case the eardrum is ruptured. The entry of non-sterile solutions into middle-ear structures could result in infection. If any ear drainage is present, the nurse should check with the prescriber to be sure the client does not have a ruptured tympanic membrane (eardrum). A nurse should never occlude the ear canal with the dropper or irrigating syringe. Also, forcing medication into an occluded ear canal creates pressure that may injure the eardrum. Box 27-12 reviews guidelines for administering ear drops.

The external ear structures of children differ from those of adults. When instilling drops or irrigating solutions in infants and young children, the nurse must straighten the cartilaginous canal by grasping the auricle of the ear and pulling it gently *down and back*. In adults the ear canal is longer and composed of underlying bone, and is straightened by pulling the auricle *up and back*. Failure to straighten the canal properly may prevent medicinal solutions from reaching the deeper external ear structures.

• CRITICAL REFLECTION POINT

Sometimes when administering ear drops it is possible that the medicine does not go into the ear but, rather, drips out of the ear without entering. Should you administer the drop again? What should you do?

Vaginal instillation

Vaginal medications are available as pessaries (vaginal suppositories), foam, jellies or creams. Pessaries come individually packaged in foil wrappers. Storage in a refrigerator prevents the solid oval-shaped pessaries from melting. After a suppository is inserted into the vaginal cavity, body temperature causes it to melt so that it can be absorbed and distributed. Foam, jellies and creams are administered with an applicator inserter (Skill 27-4). A pessary is given with an applicator inserter in accordance with standard precautions. Clients often prefer administering their own vaginal medications and should be given privacy. After instillation of the medication, a client may wish to wear a perineal pad to collect drainage. Vaginal medications are often given to treat infection; discharge may be foul-smelling. Aseptic technique should be followed and the client should be offered frequent opportunities to maintain perineal hygiene.

BOX 27-12 Procedural guidelines for administering ear medications

Ear drops

1. Have client assume side-lying position (if not contraindicated by client's condition) with ear to be treated facing up, or client may sit in chair or at the bedside.
2. Straighten ear canal by pulling auricle down and back (children) or upwards and outwards (adult).
3. Instil prescribed drops holding dropper 1 cm above ear canal (see illustration).
4. Ask client to remain in side-lying position for 2–3 minutes. Apply gentle massage or pressure to tragus of ear with finger unless contraindicated due to pain.
5. At times the prescriber orders insertion of portion of cotton ball into outermost part of canal. Do not press cotton into canal. Remove cotton after 15 minutes.

Ear irrigations

1. Assess the tympanic membrane or review medical record for history of eardrum perforation, which would contraindicate ear irrigation.
2. Help client assume sitting or lying position with head tilted or turned towards affected ear. Place towel under client's head and shoulder and have client hold basin under affected ear.
3. Fill irrigating syringe with solution (approximately 50 mL).
4. Gently grasp auricle and straighten ear canal by pulling it down and back (children) or upwards and outwards (adult).
5. Slowly instil irrigating solution by holding tip of syringe 1 cm above opening of ear canal. Allow fluid to drain out during instillation. Continue until canal is cleansed or all solution is used.

Adapted from Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

SKILL 27-4

Administering vaginal medications

Delegation considerations

Administering medications by the vaginal route requires the problem-solving and knowledge-application abilities of professional nurses. Although in some states of Australia and New Zealand client care attendants or enrolled nurses are legally able to administer medications via this route, delegation may be inappropriate and client assessment by registered nurses is essential.

Equipment

- Vaginal creams, foam, jelly or suppositories or irrigating solutions
- Applicators
- Disposable gloves
- Tissues
- Paper towel
- Perineal pad
- Drape
- Water-soluble lubricants
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review prescriber's order, including client's name, medication name, form (cream or suppository), route, dosage and time of administration.	Ensures safe and correct administration of medication.
2. Perform hand hygiene.	Reduces transfer of microorganisms.

■ **Critical decision point: Rectal and vaginal suppositories may be stored near one another in the refrigerator. Vaginal suppositories are larger and more oval.**

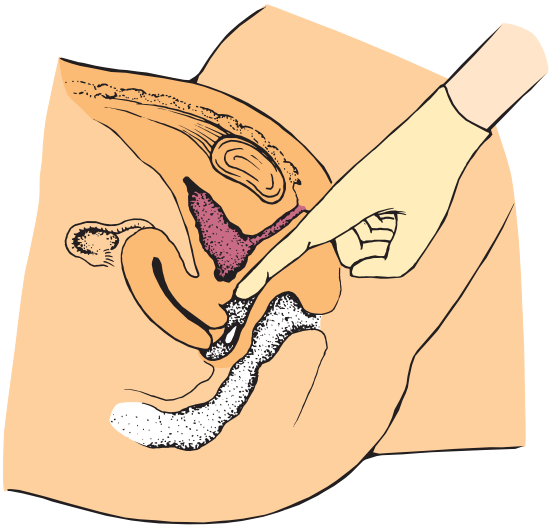
3. Identify client; compare name on MAR with identification bracelet and ask name.	Ensures that correct client receives medication.
4. Inspect condition of external genitalia and vaginal canal (see Chapter 21).	Findings provide baseline data for monitoring effect of medication.

■ **Critical decision point: Avoid using during the menstrual cycle. If vaginal medication is to be administered during the menstrual period, sanitary pads should be used, not tampons.**

5. Assess client's ability to manipulate applicator or suppository and to position self to insert medication.	Mobility restriction indicates level of assistance required from nurse.
6. Explain procedure to client and gain their consent. Be specific if client plans to self-administer medication. (e.g. 'Please remove the foil covering before insertion'.)	Promotes understanding. Will enable client to self-administer medication if physically able.

STEPS	RATIONALE
7. Arrange supplies at bedside.	Ensures smooth procedure.
8. Close room curtain or door.	Provides privacy.
9. Assist client to lie in dorsal recumbent position.	Provides easy access to and good exposure of vaginal canal. Also allows suppository to dissolve without escaping through orifice.
10. Keep abdomen and lower extremities draped.	Minimises embarrassment.
11. Put on disposable gloves.	Prevents transmission of microorganisms between nurse and client.
12. Be sure vaginal orifice is well illuminated by room light or gooseneck lamp.	Proper insertion requires external genitalia to be seen.
13. Insert suppository with applicator:	
a. Remove suppository from foil wrapper and place suppository into the tip of the applicator; apply liberal amount of lubricant to smooth or rounded end. Lubricate applicator.	Lubrication reduces friction against mucosal surfaces during insertion.
b. With non-dominant gloved hand, gently retract labial folds.	Exposes vaginal orifice.
c. Hold the applicator by the cylinder and direct applicator initially down (towards the spine) and then back and up (towards the cervix). The aim is to insert the applicator along the posterior wall of vaginal canal 5 cm into vaginal canal.	Correct placement ensures equal distribution of medication along walls of vaginal cavity.
d. When the applicator is in the appropriate position depress the plunger, remove the applicator with the plunger depressed and wipe away remaining lubricant from around orifice and labia.	Maintains comfort.
14. Apply cream or foam:	
a. Fill cream or foam applicator following package directions.	Dose is prescribed by volume in applicator.
b. With non-dominant gloved hand, gently retract labial folds.	Exposes vaginal orifice.
c. With dominant gloved hand, insert applicator approximately 5–7.5 cm. Push applicator plunger to deposit medication into vagina (see illustration).	Allows equal distribution of medication along vaginal walls.
d. Withdraw applicator and place on paper towel. Wipe off residual cream from labia or vaginal orifice.	Residual cream on applicator may contain microorganisms.

STEPS	RATIONALE



Step 14c Instillation of medication into vaginal canal.

15. Remove gloves by pulling them inside out and discard in appropriate receptacle. Perform hand hygiene.	Reduces transfer of microorganisms.
16. Instruct client to remain on back for at least 10 minutes.	Medication will be distributed and absorbed evenly throughout vaginal cavity and not be lost through orifice.
17. If reusable applicator is used, wash with soap and warm water, rinse and store for this client's future use.	Vaginal cavity is not sterile. Soap and water help remove bacteria and residual cream.
18. Offer client perineal pad when client resumes mobility.	Prevents vaginal discharge from spreading to clothing.
19. Inspect appearance of discharge of vaginal canal and condition of external genitalia between applications.	Evaluates whether vaginal medication effectively reduced irritation or inflammation of tissues.

RECORDING AND REPORTING

- Record medication name, dose, route and time of administration on MAR.
- Record character of discharge on nurses' notes.

HOME CARE CONSIDERATIONS

- Suppositories should be kept refrigerated but in a container away from children.

Rectal instillation

Rectal suppositories are thin and bullet-shaped with a rounded end which prevents anal trauma during insertion. Rectal suppositories contain medications that exert local effects such as promoting defecation, or systemic effects such as reducing nausea. Rectal suppositories often need to be refrigerated.

The client should usually be positioned in the left lateral position (Sims' position) and the suppository placed past the internal anal sphincter and against the rectal mucosa (Skill 27-5), otherwise the suppository might be expelled before it can dissolve and be absorbed into the mucosa. With practice, a nurse learns to recognise the sensation of the sphincter relaxing around the finger. The suppository should not be forced into a mass of faecal material. It may be necessary to clear the rectum with a small cleansing enema before a suppository can be inserted.

SKILL 27-5

Administering rectal suppositories

Delegation considerations

Administering medications by the rectal route requires the problem-solving and knowledge-application abilities of professional nurses. In some states of Australia and New Zealand, client care attendants or enrolled nurses may legally be able to administer medications via this route. For this procedure, client assessment by the registered nurse is required as delegation may not be appropriate.

Equipment

- Rectal suppository
- Lubricating jelly (water soluble)
- Disposable gloves
- Tissue
- Drape
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

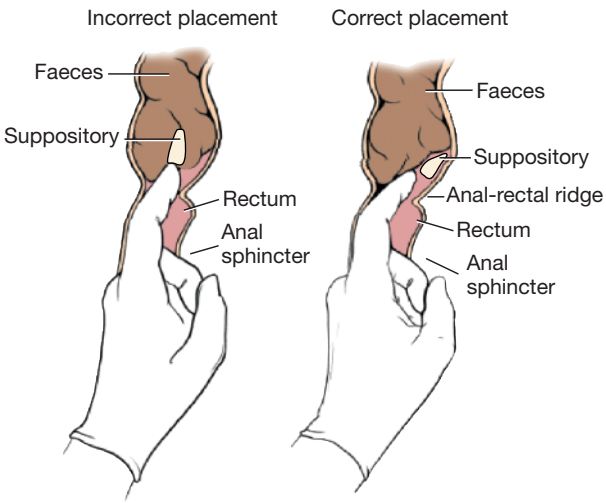
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review prescriber's order, including client's name, medication name, form, route and time of administration.	Ensures safe and correct administration of medication.
2. Review healthcare record for relevant contraindications such as rectal surgery or bleeding.	Conditions contraindicate use of suppository.
3. Perform hand hygiene.	Reduces transfer of microorganisms.
4. Put on disposable gloves.	Prevents contact with infected faecal material.
5. Identify client; check name on MAR with client's identification bracelet and ask client's name.	Ensures that correct client receives medication.
6. Explain procedure to the client and gain their consent. Be specific if client wishes to self-administer medication.	Promotes understanding and cooperation. Will enable client to self-administer medication if physically able.
7. Arrange supplies at bedside.	Ensures smooth procedure.
8. Close room curtain or door.	Maintains privacy and minimises embarrassment.
9. Help assume left lateral (Sims') position. Keep client draped with only anal area exposed.	Exposes anus and helps client relax external anal sphincter. Maintains privacy and facilitates relaxation.
10. Examine condition of anus externally and palpate rectal walls as needed (see Chapter 24). If gloves become soiled, dispose of them by turning them inside out and placing them in appropriate receptacle.	Determines presence of active rectal bleeding. Palpation determines whether rectum is filled with faeces, which may interfere with suppository placement. Reduces transmission of infection.

STEPS	RATIONALE
Critical decision point: Generally, rectal suppository is contraindicated in the presence of active rectal bleeding. Unless suppository is for constipation, medication placed in a rectum filled with faeces may be poorly absorbed or prematurely expelled with defecation.	
11. Put on disposable gloves (if previous gloves were discarded).	Minimises contact with faecal material and reduces transmission of microorganisms.
12. Remove suppository from wrapper and lubricate rounded end (see illustration). Lubricate index finger of dominant hand.	Lubrication reduces friction as suppository enters rectal canal.

Step 12 Lubricating rounded end of suppository.

13. Ask client to take slow deep breaths through mouth and relax anal sphincter.	Forcing suppository through constricted sphincter causes pain.
14. Retract buttocks with non-dominant hand. Insert suppository gently through anus, past internal sphincter and against rectal wall, 10 cm in adults, 5 cm in children and infants. May need to apply gentle pressure to hold buttocks together momentarily.	Suppository must be placed against rectal mucosa for eventual absorption and therapeutic action.



Step 14 Inserting rectal suppository.

15. Withdraw finger and wipe anal area with tissue.	Provides comfort.

STEPS	RATIONALE
16. Discard gloves by turning them inside out, and dispose of them in appropriate receptacle.	Reduces transfer of microorganisms.
17. Ask client to remain flat or on side for 5 minutes.	Prevents expulsion of suppository.
18. If suppository contains laxative or faecal softener, place call light within reach.	Provides client with sense of control over elimination. Allows client to obtain assistance to bed pan or toilet.
19. Perform hand hygiene.	Reduces risk of transfer of infection.
20. Return within 5 minutes to determine whether suppository was expelled.	Reinsertion may be necessary.
21. Observe for effects of suppository (e.g. bowel movement, relief of nausea) 30 minutes after administration.	Evaluates effectiveness of medication and relief of client's symptoms.

RECORDING AND REPORTING

- Report occurrence of rectal bleeding to medical officer.

CRITICAL REFLECTION POINT

It is *very* important to ask clients to explain in their own words how they take their prescribed medications. For example, there have been instances of clients being prescribed suppositories and then inserting them into their rectum still wrapped in their foil packaging! What teaching points would you include when instructing a client how to administer their own suppository?

Administering medications by inhalation

Medications administered by handheld inhalers are dispersed through an aerosol spray, mist or powder via a metered-dose inhaler or by nebulisation so that the medication is delivered directly to the membranes of the airways. The alveolar–capillary network absorbs medications rapidly.

Metered-dose inhalers

Metered-dose inhalers (MDIs) are usually designed to produce local effects such as bronchodilation. Clients who have chronic respiratory disease such as asthma, emphysema or bronchitis often receive medications by inhalation. Such medications can help control airway obstruction. Because the clients depend on medications for disease control, their knowledge must include ways to administer them safely (Skill 27-6), as some medications can have serious systemic side effects.

SKILL 27-6

Using metered-dose inhalers (MDIs)

Delegation considerations

Administering MDI and supervising clients who self-administer MDIs require the problem-solving and knowledge-application abilities of professional nurses. In some states of Australia and New Zealand, client care attendants or enrolled nurses may legally be able to administer medications via this route. For this procedure, client assessment by the registered nurse is required as delegation may not be appropriate.

Equipment

- MDI with medication canister
- Spacer (e.g. Volumatic) (optional)
- Facial tissues (optional)

- Washbasin or sink with warm water
- Paper towel
- Medication administration report (MAR)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Review prescriber's order, including client's name, medication name, number of inhalations.	Ensures safe and correct administration of medication.
2. Identify client, compare name on MAR with client's ID bracelet and ask client's name.	Ensures that correct client receives medication.
3. Assess client's ability to hold, manipulate and depress canister and inhaler. Assess respiration and level of dyspnoea, and auscultate chest.	Any impairment of grasp or presence of hand tremors interferes with client's ability to depress canister within inhaler.
4. Assess client's readiness and ability to learn: client asks questions about medication, disease or complications; requests education in use of inhaler; is mentally alert; participates in own care. Client should not be fatigued, in pain or in respiratory distress. Assess level of understanding of technical vocabulary terms, and purpose and action of prescribed medications.	Affects client's ability to understand explanations and actively participate in teaching process. Mental or physical limitations affect client's ability to learn and the methods nurse uses for instruction. Knowledge of disease is essential for client to realistically understand use of inhaler.
5. Assess medication schedule and number of inhalations prescribed for each dose.	Influences explanations nurse provides for use of inhaler.
6. If previously instructed in self-administration of inhaled medicine, assess client's technique in using an inhaler.	Nurse's instruction may require only simple reinforcement, depending on client's level of dexterity.
7. Instruct client in comfortable environment by sitting in chair in hospital room or sitting at kitchen table in home.	Client will be more likely to remain receptive of nurse's explanations.
8. Provide adequate time for teaching session.	Prevents interruptions. Instruction should occur when client is receptive.
9. Perform hand hygiene and arrange equipment needed.	Reduces transfer of microorganisms; saves time.
10. Allow client opportunity to manipulate inhaler, canister and spacer device. Explain and demonstrate how canister fits into inhaler.	Client must be familiar with how to use equipment.

STEPS	RATIONALE
11. Explain what metered dose is, and warn client about overuse of inhaler, including medication side effects.	Client must not arbitrarily administer excessive inhalations because of risk of serious side effects. If medication is given in recommended doses, side effects are uncommon.
12. Explain steps for administering inhaled dose of medication (demonstrate steps when possible):	Use of simple, step-by-step explanations allows client to ask questions at any point during procedure.
a. Remove mouthpiece cover from inhaler.	
b. Shake inhaler well.	Ensures fine particles are aerosolised.
c. Have client take a deep breath and exhale.	Prepares the client's airway to receive the medication.
d. Instruct the client to position the inhaler in one of two ways. (1) Open lips and place inhaler in mouth with opening towards back of throat (see illustration). (2) Position the device 2.5–5 cm from the mouth (see illustration).	Directs aerosol spray towards airway. Positioning the mouthpiece 2.5–5 cm from the mouth is considered the best way to deliver the medication.
e. With the inhaler properly positioned, have client hold inhaler with thumb at the mouthpiece and the index and middle fingers at the top. This is called a three-point or lateral hand position.	MDIs work best when clients use a three-point or lateral hand position to activate canisters.
f. Instruct client to tilt head back slightly, inhale slowly and deeply through mouth and depress medication canister fully.	Medication is distributed to airways during inhalation. Inhalation through mouth rather than nose draws medication more effectively into airways.
g. Hold breath for approximately 10 seconds.	Allows tiny drops of aerosol spray to reach deeper branches of airways.
h. Exhale through pursed lips.	Keeps small airways open during exhalation.

Step 12d(1) Inhaler placed in mouth with opening towards back of throat.

Step 12d(2) Inhaler positioned 2.5–5 cm from the mouth.

STEPS	RATIONALE
13. Explain steps to administer inhaled dose of medication using a spacer such as a Volumatic (demonstrate when possible):	
a. Remove mouthpiece cover from MDI and mouthpiece of spacer.	Inhaler fits into end of spacer.
b. Insert MDI into end of spacer.	Spacer traps medication released from the MDI; the client then inhales the drug from the device. These devices deposit up to 80% more medication in the lungs rather than in the oropharynx.
c. Shake inhaler well.	Ensures fine particles are aerosolised.
d. Place spacer mouthpiece in mouth and close lips. Do not insert beyond raised lip on mouthpiece. Avoid covering small exhalation slots with the lips (see illustration).	Medication should not escape through mouth.
e. Breathe normally through spacer mouthpiece.	Allows client to relax before delivering medication.
f. Depress medication canister, spraying one puff into spacer.	Emits spray that allows finer particles to be inhaled. Large droplets are retained in spacer.
g. Breathe in slowly and fully (for 5 seconds).	Ensures particles of medication are distributed to deeper airways.
h. Hold full breath for 5–10 seconds.	Ensures full medication distribution.
14. Instruct client to wait 2–5 minutes between inhalations or as ordered by prescriber.	Medications must be inhaled sequentially. First inhalation opens airways and reduces inflammation. Second or third inhalation penetrates deeper airways.
15. Instruct client against repeating inhalations before next scheduled dose.	Medications are prescribed at intervals during day to provide constant drug levels and minimise side effects. Beta-adrenergic MDIs are used either on an ‘as needed’ basis or regularly every 4–6 hours.

Step 13d Spacer mouthpiece placed between lips.
Care must be taken not to cover the exhalation slots with the lips.

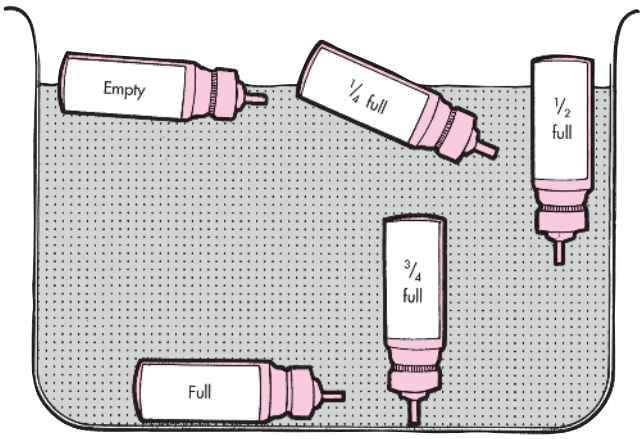
STEPS	RATIONALE
16. Explain that client may feel gagging sensation in throat caused by droplets of medication on pharynx or tongue.	Results when inhalant is sprayed and inhaled incorrectly.
17. Instruct client to rinse mouth with water.	Reduces buccal absorption of medication.
18. Instruct client in removing medication canister and cleaning inhaler in warm water.	Accumulation of spray around mouthpiece can interfere with proper distribution during use. Some medicines can also increase risk of oral candida (thrush) if not washed from mouth.
19. Ask if client has any questions.	Clarifies misconceptions or misunderstanding.
20. Have client explain and demonstrate steps in use of inhaler. Teach client how to check the volume of the inhaler.	Return demonstration provides feedback for measuring client's learning.
21. Ask client to explain medication schedule.	Improves likelihood of compliance with therapy.
22. Ask client to describe side effects of medication and criteria for calling prescriber.	Will allow client to recognise signs of overuse and need to seek medical support when medications are ineffective.
23. After medication instillation, assess client's respirations and auscultate lungs.	Determines status of breathing pattern and adequacy of ventilation.

RECORDING AND REPORTING

- Document in nurses' notes what skills were taught and client's ability to perform skills.
- Record time when client used MDI (number of puffs).
- Report any undesirable effects from medication.

HOME CARE CONSIDERATIONS

- Teach clients how to determine fullness of canisters, using displacement in water (see illustration below).



Determining fullness of canisters.

An MDI delivers a measured dose of medication with each push of a canister – approximately 2–8 kg of hand pressure must be used to activate the aerosol. It is important to assess hand strength and psychomotor skill, as both can diminish with age and from the effects of chronic respiratory disease.

In many cases, a more even absorption of the medication is achieved by the use of a *spacer*, a device that mixes the medication with room air inside the spacer before it is inhaled (see *Research highlight*). Clients should be encouraged to use these devices to improve the action of their medication and reduce absorption of the medicine via the oral mucosa.

Medications administered via the inhalation route exert local and systemic effects; for example, salbutamol relieves bronchospasm via a local effect on the respiratory system but also acts systemically, potentially increasing heart rate and causing headaches. Clients should rinse the mouth after using this type of medication.

Administering medications by irrigation

Medications may be used to irrigate or wash out a body cavity and are delivered in a stream of solution. Irrigation solutions are most commonly sterile water, saline or antiseptic solutions and are used for the eye, ear, throat, vagina and urinary tract. If there is a break in the skin or mucosa, the nurse uses aseptic technique. When the cavity to be irrigated is not sterile, as is the case with the ear canal (see Box 27-12) or vagina, clean technique is acceptable. In healthcare settings, however, use sterile solutions. Irrigations can be used to clean an area, instil a medication or be applied hot or cold to injured tissue.

Parenteral administration of medications

Parenteral administration of medications is the administration of medications by a route that bypasses the GI tract (e.g. topical or injectable routes). The term 'parenteral administration' is often used to refer to injections. This is an invasive procedure that must be performed using aseptic techniques (Box 27-13). After a needle pierces the skin, there is risk of infection. Each type of injection requires certain skills to ensure the medication reaches its target location. The effects of a parenterally administered medication can develop rapidly, depending on the rate of medication absorption. The nurse closely observes the client's response.

Equipment

Various syringes and needles are available, each designed to deliver a certain volume of a medication to a specific type of tissue.

Syringes

Syringes consist of a cylindrical barrel and a close-fitting plunger with a tip designed to fit the hub of a

RESEARCH HIGHLIGHT

Research focus

In acute asthma, inhaled beta-2-agonists have been administered in the past for relief of bronchospasm using wet nebulisation. More recently, clinicians and researchers have argued that metered-dose inhalers with a holding chamber (spacer) are just as effective and easier to use as they do not require a power source or regular maintenance and are less expensive.

Research abstract

A systematic review of the research comparing the effects of holding chambers compared with nebulisers for the delivery of beta-2-agonists for acute asthma was undertaken. 1897 children and 729 adults were included from 39 trials from emergency room and community settings. In addition, six trials on inpatients with acute asthma (207 children and 28 adults) were also reviewed.

Method of delivery of beta-2-agonist did not appear to affect hospital admission rates. In adults, the relative risk of admission for spacer versus nebuliser was 0.94 (95% CI: 0.61–1.43). The relative risk for children was 0.71 (95% CI: 0.47–1.08). In children, length of stay in the emergency department was significantly shorter when the spacer was used, with a mean difference of –70 minutes (95% CI: –0.43 to –0.24 minutes). Length of stay in the emergency department for adults was similar for the two delivery methods.

Peak flow and forced expiratory volume were also similar for the two delivery methods. Pulse rate was lower for spacer in children, mean difference –5% baseline (95% CI: –8 to –2% baseline).

Evidence-based practice

- Metered-dose inhalers with holding chamber produced outcomes that were at least equivalent to nebuliser delivery in children.
- Holding chambers may have some advantages compared with nebulisers for children with acute asthma.

BOX 27-13 Preventing infection during an injection

- To prevent contamination of solution, draw medication from ampoule quickly. Do not allow it to stand open.
- To prevent needle contamination, avoid letting needle touch contaminated surface (e.g. outer edges of ampoule or vial, outer surface of needle cap, nurse's hands, countertop, table surface).
- To prevent syringe contamination, avoid touching length of plunger or inner part of barrel. Keep tip of syringe covered with cap or needle.
- To prepare skin, wash skin soiled with dirt, drainage or faeces with soap and water and dry. Use friction and a circular motion while cleaning with an antiseptic swab. Swab from centre of site, and move outwards in a 5 cm radius.

hypodermic needle. In general, syringes are classified as being Luer-lock or non-Luer-lock, based on the design of the syringe tip. Luer-lock syringes require needles that are twisted onto the tip and automatically lock in place (Figure 27-13A, B). This design prevents the inadvertent removal of the needle. Non-Luer-lock syringes require needles that slip firmly onto the tip (Figure 27-13C, D).

Most healthcare institutions use disposable single-use plastic syringes, which are inexpensive and easy to manipulate. A syringe is filled by aspiration, pulling the plunger outwards while the needle tip remains immersed in the prepared solution. The nurse may handle the outside of the syringe barrel and the handle of the plunger. To maintain sterility, avoid letting any unsterile object touch the tip or inside of the barrel, the hub, the shaft of the plunger or the needle (Figure 27-14). Syringe sizes range from 0.5 to 60 mL with a scale along the barrel divided into tenths of a millilitre.

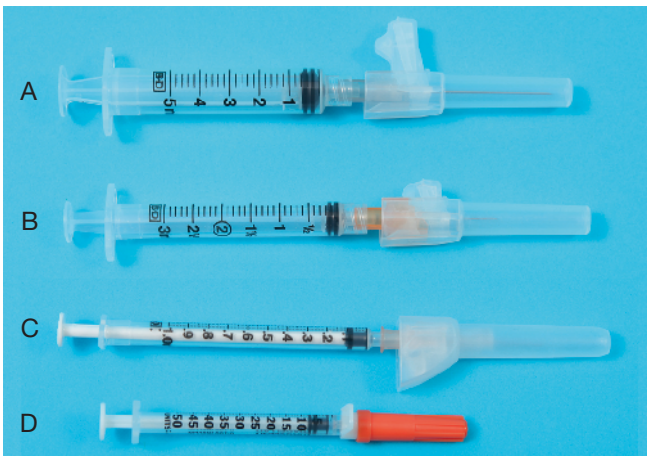

Figure 27-13 Types of syringes.

A, 5 mL syringe (Luer-lock). B, 3 mL syringe (Luer-lock). C, Tuberculin syringe marked in 0.01 mm (hundredths) for doses < 1 mL. D, Insulin syringe marked in units (50).

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Insulin syringes

These are available in sizes that hold 0.3–1 mL (Figure 27-13) and are calibrated in units. Insulin syringes that hold 0.3 mL are known as low-dose syringes. Most insulin syringes are U-100s, designed for use with U-100 strength insulin. Each millilitre of solution contains 100 units of insulin; 1 mL = 100 units.

Needles

Needles come individually packaged to allow flexibility in choosing the right needle for a client. Some needles are pre-attached to standard-sized syringes. Most needles are disposable and have three parts: the *hub*, which fits onto the tip of a syringe; the *shaft*, which connects to the hub; and the *bevel* or slanted tip. When inserted into tissue the bevel creates a narrow incision that quickly closes when the needle is removed, preventing leakage of medication, blood or serum. A short-bevelled tip is best for intravenous injections because it is not easily occluded against the inside of a blood vessel wall. Long-bevelled tips are sharper and narrower; this minimises discomfort when entering subcutaneous or intramuscular tissue. Large-diameter, flat-tip needles are only used for drawing up medications (i.e. not used directly on clients).

The nurse chooses the needle length (Figure 27-15) according to the client's size and weight and the type of tissue into which the medication is to be injected. A child or slender adult generally requires a shorter needle. The nurse uses longer needles (25–38 mm) for intramuscular injections and shorter needles (9–16 mm) for subcutaneous injections.

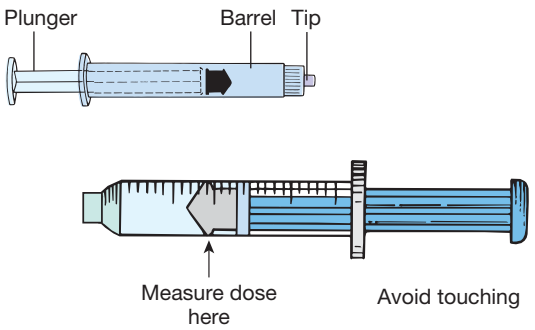

Figure 27-14 Parts of a syringe.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

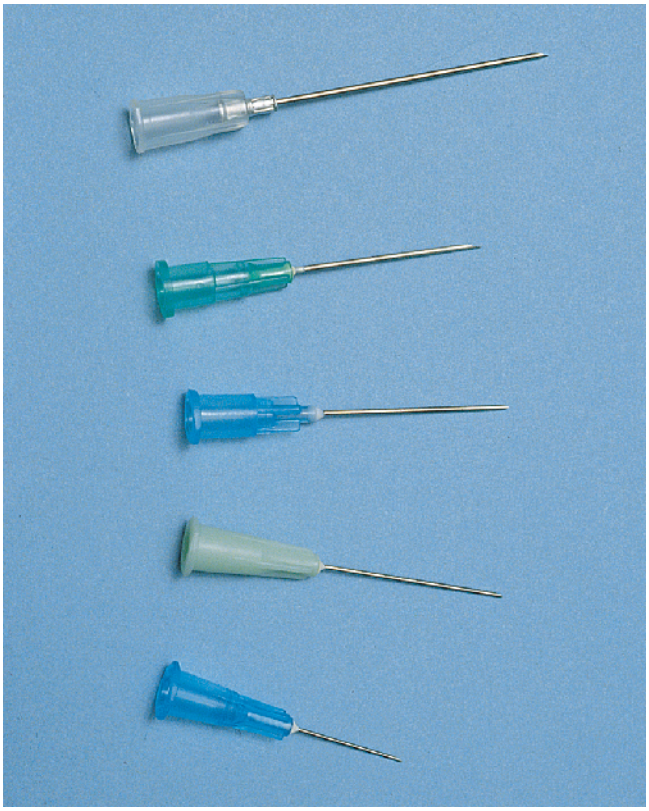

Figure 27-15 Needles.

Top to bottom: 19 gauge, 38 mm length; 20 gauge, 25 mm length; 21 gauge, 25 mm length; 23 gauge, 25 mm length; and 25 gauge, 16 mm length.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

The smaller the needle gauge, the larger the needle diameter (Figure 27-15). The selection of a gauge depends on the viscosity of fluid to be injected or infused. An intramuscular injection requires a 23 or 24 gauge needle. Subcutaneous injections require smaller diameter needles such as a 25 or 26 gauge needle. A 26 gauge needle is used for an intradermal injection.

Disposable injection units

Disposable single-dose, pre-filled syringes are available for some medications. The nurse must be careful to check the medication and concentration because all pre-filled syringes appear very similar. With these syringes, the nurse does not have to prepare medication dosages except to expel portions of unneeded medication. Another type of injection system involves screwing a plunger-like device into the end of a pre-filled vial containing a needle. The nurse advances the plunger to expel excess medication as in a regular syringe. After the medication is given, the entire unit is disposed of in an appropriate receptacle (sharps container). This system is designed to reduce the risk of needle-stick injuries.

Preparing an injection from an ampoule

Ampoules contain single doses of medication in a liquid. Ampoules are available in several sizes, from 1 mL to 10 mL or more. An ampoule may be made of glass or plastic with a constricted neck that must be snapped off to allow access to the medication (Figure 27-16A). A colour ring or a large dot is sometimes placed on the neck to indicate where the ampoule is pre-scored to be broken easily. Aspiration of the medication into a syringe is completed using a drawing-up needle (usually an 18 or 19 gauge needle), which is discarded and replaced by the injection needle (Skill 27-7). A filter needle may be used instead of a drawing-up needle (if required by institutional policy).

Preparing an injection from a vial

A vial is a single-dose or multidose container with a rubber seal at the top (Figure 27-16B). A metal or plastic cap protects the seal until it is ready for use. Vials can contain liquid or dry forms of medications; those that are unstable in solution are packaged dry. The vial label or package insert specifies the solvent or diluent used to dissolve the medication and the amount of diluent needed to prepare a desired medication concentration. Normal saline and sterile distilled water are commonly used to dissolve medications. Unlike the ampoule, the vial is a closed system, and air must be injected into it to permit easy withdrawal of the solution. Failure to inject air before drawing up creates a vacuum within the vial that makes withdrawal difficult (Skill 27-7).

Mixing medications

If two medications are compatible, it is possible to mix them in one injection as long as the final volume is within accepted limits for the site to be used. A client will then receive just one injection at a time. Most nursing units have

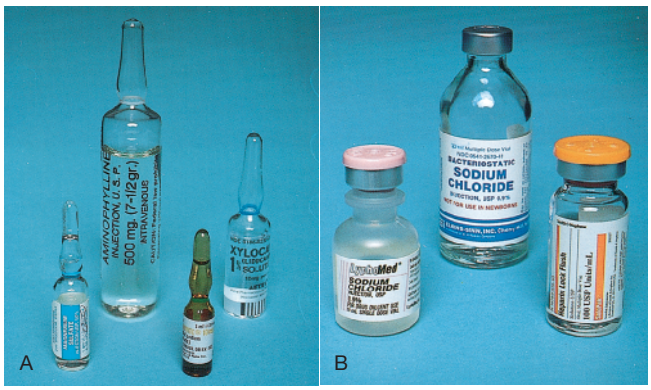

Figure 27-16 Ampoules and vials

A, Medication in ampoules. **B**, Medication in vials.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

SKILL 27-7

Preparing injections

Delegation considerations

Preparing injections from ampoules and vials requires the problem-solving and knowledge-application abilities of professional nurses. In some states of Australia and New Zealand, client care attendants or enrolled nurses may legally be able to administer medications via this route. For this procedure, client assessment by the registered nurse is required as delegation may not be appropriate.

Equipment

Medication in an ampoule:

- Syringe and two needles (filter needle optional)
- Small gauze pad or alcohol swab

Medication in a vial:

- Syringe and two needles (filter needle optional)
- Small gauze pad or alcohol swab
- Diluent (e.g. Normal saline or sterile water)

Both:

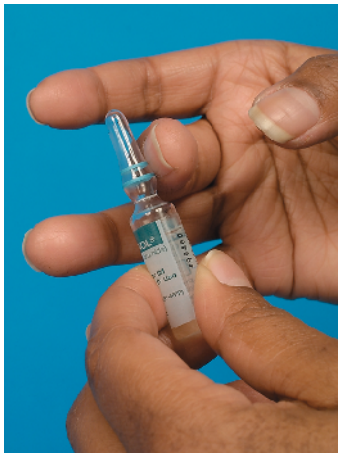
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

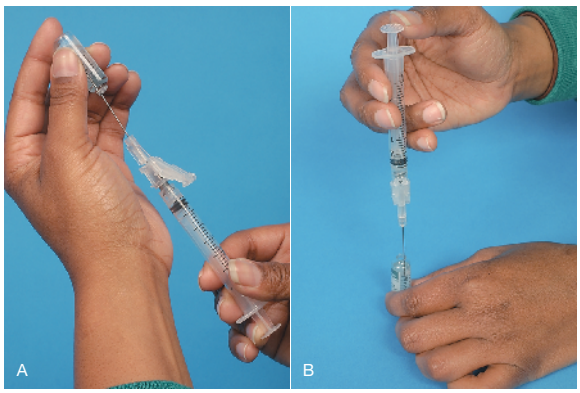
STEPS	RATIONALE
1. Review order, including name and medication name, dose, route of administration and time of administration.	Ensures correct administration of medication.
2. Review pertinent information related to medication, including action, purpose, side effects and nursing implications.	Allows nurse to administer medication properly and to monitor client's response.
3. Check date of expiration of medication vial or ampoule.	Medication potency may increase or decrease when outdated.
4. Assess client's body build, muscle size and weight.	Determines type and size of syringe and needles for injection.
5. Perform hand hygiene.	Reduces transmission of microorganisms.
6. Prepare medication.	
A. Ampoule preparation	
(1) Tap top of ampoule lightly and quickly with finger until fluid moves from neck of ampoule (see illustration).	Dislodges any fluid that collects above neck of ampoule. All solution moves into lower chamber.

STEPS	RATIONALE
(2) Place small gauze pad around neck of ampoule.	Placing pad around neck of ampoule protects nurse's fingers from trauma as glass tip is broken off.
(3) Snap neck of ampoule quickly and firmly away from hands (see illustration).	Protects nurse's fingers and face from shattering glass.
(4) Draw up medication quickly.	System is open to airborne contaminants.
(5) Hold ampoule upside down, or set it on a flat surface. Insert syringe or filter needle (see agency policy) into centre of ampoule opening. Do not allow needle tip or shaft to touch rim of ampoule.	Broken rim of ampoule is considered contaminated. When ampoule is inverted, solution will dribble out if needle tip or shaft touches rim of ampoule.



Step 6A(1) Tapping ampoule to move fluid down neck.

Step 6A(3) Snapping neck away from hands.



Step 6A(6) Medication aspirated with (A) ampoule inverted and (B) ampoule on flat surface.

(6) Aspirate medication into syringe by gently pulling back on plunger (see illustration).	Withdrawal of plunger creates negative pressure within syringe barrel, which pulls fluid into syringe.
(7) Keep needle tip under surface of liquid. Tip ampoule to bring all fluid within reach of the needle.	Prevents aspiration of air bubbles.
(8) If air bubbles are aspirated, do not expel air into ampoule.	Air pressure may force fluid out of ampoule and medication will be lost.

STEPS	RATIONALE
(9) To expel excess air bubbles, remove needle from ampoule. Hold syringe with needle pointing up. Tap side of syringe to cause bubbles to rise towards needle. Draw back slightly on plunger, and then push plunger upwards to eject air. Do not eject medication.	Withdrawing plunger too far will remove it from barrel. Holding syringe vertically allows fluid to settle in bottom of barrel. Pulling back on plunger allows fluid within needle to enter barrel so fluid is not expelled. Air at top of barrel and within needle is then expelled.
(10) If syringe contains excess medication, use sink for disposal. Hold syringe vertically with needle tip up and slanted slightly towards sink. Slowly eject excess medication into sink. Recheck medication level in syringe by holding it vertically.	Medication is safely dispersed into sink. Position of needle allows medication to be expelled without flowing down needle shaft. Rechecking fluid level ensures proper dose.
(11) Change needle on syringe.	New needle prevents tracking medication through skin and subcutaneous tissues. New needle is sharp and correct gauge and length.
B. Vial containing a solution	
(1) Remove cap covering top of unused vial to expose sterile rubber seal, keeping rubber seal sterile. If reusing multi-dose vial, firmly and briskly wipe surface of rubber seal with alcohol swab and allow it to dry.	Vial comes packaged with cap to prevent contamination of rubber seal. Cap cannot be replaced after seal removal. Allowing alcohol to dry prevents needle from being coated with alcohol and mixing with medication.
(2) Pick up syringe and remove needle cap. Pull back on plunger to draw amount of air into syringe equivalent to volume of medication to be aspirated from vial.	Air must first be injected into vial to prevent build-up of negative pressure in vial when aspirating medication.
(3) With vial on flat surface, insert tip of needle with bevelled tip entering first through centre of rubber seal (see illustration). Apply pressure to tip of needle during insertion.	Centre of seal is thinner and easier to penetrate. Injecting bevelled tip first and using firm pressure prevent coring of rubber seal, which could enter vial or needle.

Step 6B(3) Inserting needle through centre of rubber seal with vial on flat surface.

Step 6B(5) Vial inverted to allow fluid to be withdrawn.

Step 6B(10) Tapping barrel of syringe to dislodge air bubbles.

STEPS	RATIONALE
(4) Inject air into the vial's airspace, holding on to plunger. Hold plunger with firm pressure; plunger may be forced backwards by air pressure within the vial.	Air must be injected before aspirating fluid. Injecting into vial's airspace prevents formation of bubbles and inaccuracy in dose.
(5) Invert vial while keeping firm hold on syringe and plunger (see illustration). Hold vial between thumb and middle fingers of non-dominant hand. Grasp end of syringe barrel and plunger with thumb and forefinger of dominant hand to counteract pressure in vial.	Inverting vial allows fluid to settle in lower half of container. Position of hands prevents forceful movement of plunger and permits easy manipulation of syringe.
(6) Keep tip of needle below fluid level.	Prevents aspiration of air.
(7) Allow air pressure from the vial to fill syringe gradually with medication. If necessary, pull back slightly on plunger to obtain correct amount of solution.	Positive pressure within vial forces fluid into syringe (unless vial has been used several times).
(8) When desired volume has been obtained, position needle into vial's airspace; tap side of syringe barrel carefully to dislodge any air bubbles. Eject any air remaining at top of syringe into vial.	Forcefully striking barrel while needle is inserted in vial may bend needle. Accumulation of air displaces medication and causes dose errors.
(9) Remove needle from vial by pulling back on barrel of syringe.	Pulling plunger rather than barrel causes plunger to separate from barrel, resulting in loss of medication.
(10) Hold syringe at eye level, at 90-degree angle, to ensure correct volume and absence of air bubbles. Remove any remaining air by tapping barrel to dislodge any air bubbles (see illustration). Draw back slightly on plunger; then push plunger upwards to eject air. Do not eject fluid.	Holding syringe vertically allows fluid to settle in bottom of barrel. Pulling back on plunger allows fluid within needle to enter barrel so fluid is not expelled. Air at top of barrel and within needle is then expelled.
(11) Change needle to appropriate gauge and length according to route of medication.	Inserting needle through a rubber stopper may dull bevelled tip. New needle is sharper. Because no fluid is along shaft, needle will not track medication through tissues.
(12) For multi-dose vial, make label that includes date of mixing, concentration of medication per millilitre and nurse's initials.	Ensures that future doses will be prepared correctly. Some medications must be discarded after certain number of days after mixing of vial.
C. Vial containing a powder (reconstituting medications)	
(1) Remove cap covering vial of powdered medication.	Cap prevents contamination of rubber seal.
(2) Draw up diluent into syringe following Steps 5B(2) to 5B(10).	Prepares diluent for injection into vial containing powdered medication.

STEPS	RATIONALE
(3) Insert tip of needle through centre of rubber seal of vial of powdered medication. Inject diluent into vial. Remove needle.	Diluent begins to dissolve and reconstitute medication.
(4) Mix medication thoroughly. Roll in palms. Do not shake.	Ensures proper dispersal of medication throughout solution. Shaking produces bubbles.
(5) Draw up the prescribed volume of reconstituted medication into syringe.	Once diluent has been added, concentration of medication (mg/mL) determines dose to be given.
7. Dispose of soiled supplies. Place broken ampoule and/or used vials and used needle in puncture-proof and leakproof sharps container. Clean work area and perform hand hygiene.	Correct disposal of glass and needle prevents accidental injury to staff. Controls transmission of infection.

charts that list common compatible medications, as do the manufacturers' instructions. If there is any uncertainty about medication compatibility, consult a pharmacist.

Mixing medications from two vials

It is no longer best practice (or common) that multiuse vials are used, except sometimes in vaccination programs or in some areas of anaesthetics. However, if multidose vials are used and a client requires one injection drawn from two different multiuse vials, the nurse applies the following principles when mixing the medications:

- Do not contaminate the contents of one vial with those of another.
- Ensure the final dosage is accurate.
- Maintain aseptic technique.

Only one syringe is needed to mix medications from two vials, assuming both medicines are compatible (Figure 27-17). The nurse takes an appropriately sized syringe with a needle attached and aspirates the volume of air equivalent to the dose of the first medication (vial A). The nurse injects the air into vial A, making sure the needle does not touch the solution. The nurse withdraws the needle, aspirates air equivalent to the dose of the second medication (vial B), and then injects the volume of air into vial B. The nurse immediately withdraws the medication from vial B into the syringe. At this point the medication from vial A has not contaminated vial B. The nurse applies a new sterile needle to the syringe and inserts it into vial A, being careful not to push the plunger and expel the medication within the syringe into the vial. The nurse then withdraws the desired amount of medication from vial A into the syringe. If a vial has excess positive pressure, the plunger may move before the nurse is ready, causing an accidental withdrawal of too much of the medication. If excess medication is withdrawn, the whole solution in the syringe must be discarded; under no circumstances is the excess fluid returned to the vial. After withdrawing the necessary amount, the nurse withdraws the needle and applies a new needle for administration to the client. The process of mixing two medications in one syringe is complex, and should be done only by experienced nurses.

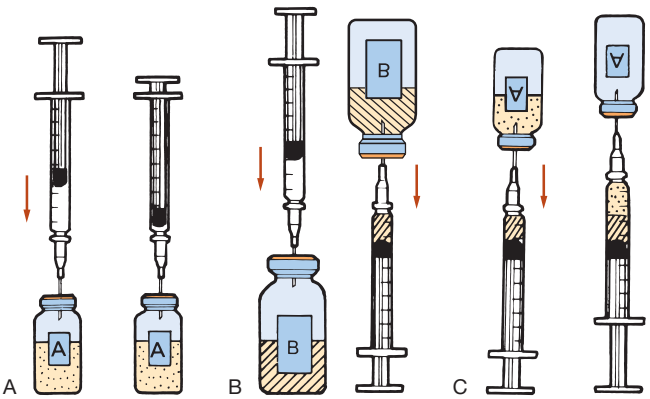


Figure 27-17 Steps in mixing medications from two vials.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Mixing medications from one vial and one ampoule

Mixing medications from a vial and an ampoule is simple because it is not necessary to add air to withdraw medication from an ampoule. The nurse prepares medication from the vial first and, using the same syringe and needle, withdraws medication from the ampoule. This

technique prevents contamination of the solution in the vial and the needle.

Mixing and preparing insulin

Insulin is the hormone used to treat diabetes mellitus as well as some other medical disorders. It must be administered by injection because it is a protein and therefore would be broken down and destroyed in the GI tract. Most diabetic clients requiring insulin learn to self-administer injections. The medication is available in 100 units per mL of solution. When preparing insulin, an insulin 'pen' is most commonly used; however, sometimes in acute care, the insulin may also be administered using an appropriately sized 'insulin syringe'. A 100-unit scaled syringe is commonly used to prepare 100-unit insulin (see Figure 27-13C).

Insulin is classified by rate of action, including *rapid*, *intermediate* and *long-acting*. Each type has a different onset, peak and duration of action. A client with diabetes may require more than one type of insulin. For example, by receiving a rapid-acting (regular) and an intermediate-acting insulin, a client receives more-sustained control of blood glucose over 24 hours.

Regular insulin is a clear solution that acts rapidly and can be given either subcutaneously or intravenously. Other types of insulin are also mostly clear, although some older and less commonly used types are cloudy (because of the addition of a protein, which slows absorption). The slower-acting insulin can be given only subcutaneously.

Insulin is ordered by specific dosage at select times, or by a sliding scale. A sliding scale dictates a certain dosage based on the client's blood-glucose level (BGL) (Box 27-14). Only regular insulin is used for sliding scales. If more than one type of insulin is required to manage the client's diabetes, the client will usually have these administered by separate insulin injecting pens. Rarely, the nurse can mix two different types of insulin into one syringe, provided the volume of the injection is not too large (see Box 27-15). This minimises the discomfort associated with multiple injections. The mixing of insulin, however, is less common today because stable pre-mixed insulin (70% intermediate and 30% regular, or 50% of each) is available.

Before withdrawing insulin from a vial, the vial should be rotated for at least 1 minute between both hands. This re-suspends the modified insulin preparations and helps to warm the medication. Insulin vials should not be shaken. Shaking causes bubbles to form, which take up space and alter the dosage.

BOX 27-14 Example of sliding scale insulin order (in units of insulin)

Give regular insulin subcut:
2 units for glucose 5.1–7.0 mmol/L
4 units for glucose 7.1–10 mmol/L
6 units for glucose 10.1–13 mmol/L
For glucose > 13.1 mmol/L, call prescriber

BOX 27-15 Procedural guidelines for mixing two kinds of insulin in one syringe

Mixing insulins in a syringe is not common in practice anymore, but for some clients this may be required (especially in children). In general, advice should be sought from a diabetes nurse educator and the long-acting insulin is drawn up into the syringe before the short-acting insulin. In the past this used to be known as 'Cloudy before Clear' whereby the cloudy insulin (most long-acting insulins were cloudy, i.e. Protaphane, which is not commonly used today) was drawn up before the clear insulin (the short-acting insulins were clear). This statement is now misleading and shouldn't be used as most insulins are clear now, irrespective of whether they are short- or long-acting.

Modified from White JR, Campbell RK 1996 In Haire-Joshu D (ed) Management of diabetes mellitus: perspectives of care across the life span, 2nd edn, Mosby, St Louis.

Administering injections

Each injection route is unique with regard to the type of tissue into which the medication is to be injected. The characteristics of the tissue involved influence the rate of medication absorption and thus the onset of medication action. Before injecting a medication, the nurse should know the volume of the medication to administer, the medication's characteristics, including viscosity, and the location of anatomical structures underlying injection sites (Skill 27-8).

Inability to administer injections correctly can have negative consequences. Failure to select an injection site in relation to anatomical landmarks can result in nerve or bone damage during needle insertion. It can also result in failure to administer the medicine into the correct tissue, for example, intramuscularly instead of subcutaneously. Inability to maintain stability of the needle and syringe unit could result in pain for the client and possibly tissue damage. If the nurse fails to aspirate the syringe before injecting an intramuscular medication, the medication may accidentally be injected directly into an artery or vein. Injecting too large a volume of medication for the

SKILL 27-8

Administering injections

Delegation considerations

Administering injections requires the problem-solving and knowledge-application abilities of professional nurses. For this procedure, delegation to nurse assistants is inappropriate. In some states of Australia and New Zealand, client care attendants or enrolled nurses may legally be able to administer medications via this route. For this procedure, client assessment by the registered nurse is required as delegation may not be appropriate.

Equipment

- Proper size syringe and needle:
  - Subcutaneous (subcut): Syringe (1–3 mL) and needle (25 to 26 gauge)
  - Intramuscular (IM): Syringe 2–3 mL for adult, 0.5–1 mL for infants and small children. Two needles: 21 to 24 gauge
  - Intradermal (ID): 1 mL tuberculin syringe with pre-attached 26 or 27 gauge needle
- Small gauze pad and/or alcohol swab
- Vial or ampoule of medication or skin test solution
- Disposable gloves
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
For all injections	
1. Review prescriber's medication order for client's name, medication name, dose, time and route of administration.	Ensures safe and correct administration of medication.
2. Assess client's history of and known response to allergies.	Certain substances have similar compositions; nurse should not administer any substance with known allergic response.
3. Observe verbal and non-verbal responses towards receiving injection.	Injections can be painful. Anxiety can increase pain.
4. Assess for contraindications.	
A. For subcutaneous injections Assess for factors such as circulatory shock or reduced local tissue perfusion. Assess adequacy of client's adipose tissue.	Reduced tissue perfusion interferes with medication absorption and distribution. Physiological changes of ageing or client illness may influence the amount of SC tissue a client possesses. This influences methods of administering injections.
B. For intramuscular injections Assess for factors such as muscle atrophy, reduced blood flow or circulatory shock.	Atrophied muscle absorbs medication poorly. Factors interfering with blood flow to muscles impair medication absorption.

STEPS	RATIONALE
5. Prepare correct medication dose from ampoule or vial (see Skill 27-7). Check carefully. Be sure all air is expelled.	Ensures that medication is sterile. Preparation techniques differ for ampoule and vial.
6. Identify client; check identification bracelet with MAR and ask client's name.	Ensures correct client receives ordered medication.
7. Explain steps of procedure and tell client injection will cause a slight burning or sting.	Helps minimise client's anxiety.
8. Close room curtain or door.	Provides privacy.
9. Wash hands thoroughly; apply disposable gloves.	Reduces transfer of microorganisms.
10. Keep sheet or gown draped over body parts not requiring exposure.	Selection of correct injection site may require exposure of body parts.
11. Select appropriate injection site. Inspect skin surface over sites for bruises, inflammation or oedema. a. subcut: Palpate sites for masses or tenderness. Avoid these areas. For daily insulin, rotate site daily. Be sure needle is correct size by grasping skinfold at site with thumb and forefinger. Measure fold from top to bottom; needle should be half length. b. IM: Note integrity and size of muscle and palpate for tenderness or hardness. Avoid these areas. If injections are given frequently, rotate sites. c. ID: Note lesions or discolourations of forearm. Select site three to four finger widths below antecubital space and a hand width above wrist.	

■ **Critical decision point: Injection sites should be free of abnormalities that may interfere with medication absorption. Sites used repeatedly can become hardened from lipohypertrophy (increased growth in fatty tissue). An ID site should be clear so that results of skin test can be seen and interpreted correctly.**

12. Help client to comfortable position:	
a. subcut: Have client relax arm, leg or abdomen, depending on site chosen for injection.	Relaxation of site minimises discomfort.
b. IM: Have client lie flat, on side or prone, depending on site chosen.	Reduces strain on muscle and minimises discomfort of injections.
c. ID: Have client extend elbow and support it and forearm on flat surface.	Stabilises injection site for easiest accessibility.
d. Talk with client about subject of interest.	Distraction reduces anxiety.

■ **Critical decision point: Ensure that client's position is not contraindicated by medical condition.**

13. Relocate site using anatomical landmarks.	Injection into correct anatomical site prevents injury to nerves, bones and blood vessels.

STEPS	RATIONALE
14. Clean site with an antiseptic swab. Apply swab at centre of the site and rotate outwards in a circular direction for about 5 cm (see illustration). Note: Some agencies may not require the use of alcohol swabs before giving an injection, but the evidence for this is not clear so many agencies will still require this step.	Mechanical action of swab removes secretions containing microorganisms.
15. Hold swab or gauze between third and fourth fingers of non-dominant hand.	Gauze or swab remains readily accessible when needle is withdrawn.
16. Remove needle cap from needle by pulling it straight off.	Prevents needle from touching and contaminating sides of cap.
17. Hold syringe between thumb and forefinger of dominant hand:	
a. subcut: Hold as dart, palm down (see illustration) or hold syringe across tops of fingertips. b. IM: Hold as dart, palm down.	Quick, smooth needle insertion minimises discomfort.
c. ID: Hold bevel of needle pointing up.	With bevel up, medication is less likely to be deposited into tissues below dermis.
18. Administer injection **A. Subcutaneous**	
(1) For average-size client, spread skin tightly across injection site or pinch skin with non-dominant hand.	Needle penetrates tight skin more easily than loose skin. Pinching skin elevates subcutaneous tissue and may desensitise area.
(2) Inject needle quickly and firmly at 45- to 90-degree angle. Then release skin, if pinched.	Injecting medication into compressed tissue irritates nerve fibres.
(3) For obese client, pinch skin at site and inject needle at 90-degree angle below tissue fold.	Obese clients have fatty layer of tissue above subcutaneous layer.
(4) Inject medication slowly.	Aspiration of heparin injection may cause the needle to move, creating tissue damage and bleeding (haematoma).

STEPS	RATIONALE

Step 14 Cleaning site using circular motion.

Step 17a Holding syringe as a dart.

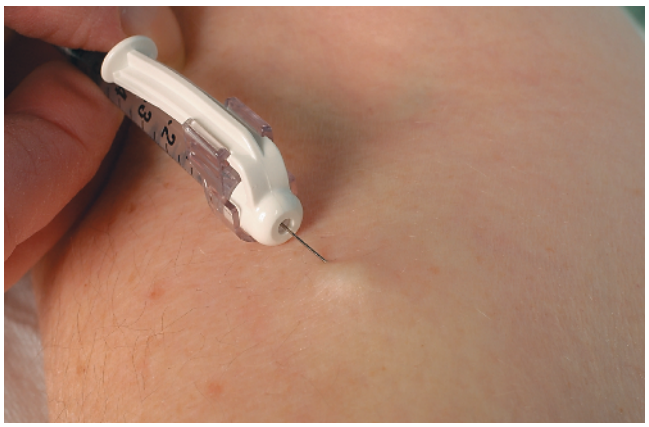
Step 18B(3) Pulling back on plunger to aspirate drug.

B. Intramuscular	
(1) Position non-dominant hand at proper anatomical landmarks and pull skin down to administer in a Z-track.	Speeds insertion and reduces discomfort. Creates zigzag path through tissues that seals needle track to avoid leaking of medication into subcutaneous tissue.
(2) If client's muscle mass is small, grasp body of muscle between thumb and fingers.	Ensures that medication reaches muscle mass.
(3) Insert needle quickly at 90-degree angle into muscle. After needle enters site, grasp lower end of syringe barrel with non-dominant hand. Move dominant hand to end of plunger. Avoid moving syringe while slowly pulling back on plunger to aspirate drug (see illustration). If blood appears in syringe, remove needle, discard medication and syringe and repeat procedure.	Properly performed injection requires smooth manipulation of syringe parts. Movement of syringe may displace needle and cause discomfort. Aspiration of blood into syringe indicates IV placement of needle; subcut and IM injections are not for IV use (dermis is relatively vascular).

■ **Critical decision point: If blood appears in syringe (indicating needle is in the bloodstream rather than into the muscle), remove needle and dispose of medication and syringe correctly. Repeat preparation procedure.**

(4) Inject medication slowly.	Slow injection reduces pain and tissue trauma.
(5) Smoothly and steadily withdraw needle and release skin.	Support of tissues around infection site minimises discomfort during needle withdrawal. Some advocate use of dry gauze to minimise client discomfort associated with alcohol on non-intact skin.
C. Intradermal	
(1) With non-dominant hand, stretch skin over site with forefinger or thumb.	Needle pierces tight skin more easily.

STEPS	RATIONALE
(2) With needle almost against client's skin, insert it slowly at a 5- to 15-degree angle until resistance is felt. Then advance needle through epidermis to approximately 3 mm below skin surface. Needle tip can be seen through skin.	Ensures needle tip is in dermis.
(3) Inject medication slowly. Normally, resistance is felt. If not, needle is too deep; remove and begin again.	Slow injection minimises discomfort at site. Dermal layer is tight and does not expand easily when solution is injected.
(4) While injecting medication, notice that small bleb approximately 6 mm resembling mosquito bite appears on skin's surface (see illustration).	Bleb indicates medication is deposited in dermis.



Step 18C(4) Injection creates a small bleb.

19. Withdraw needle while applying alcohol swab or gauze gently over site. Support of tissue around injection site minimises discomfort during needle withdrawal.	Some advocate the use of dry gauze to minimise client discomfort associated with alcohol on non-intact skin.
20. Do not massage site after subcut injection of heparin or insulin or after IM or ID injection.	Massage of site after heparin injection may cause bleeding; massage after insulin injection may increase absorption of insulin. Massage of IM site may cause underlying tissue damage. Massage of ID site may disperse medication into underlying tissue and alter test results.
21. Help client to comfortable position.	Gives client sense of wellbeing.
22. Discard uncapped needle or needle enclosed in safety shield and attached syringe into puncture and leakproof receptacle.	Needles should not be recapped before disposal. Safety shields prevent needle-stick injuries.
23. Remove disposable gloves and perform hand hygiene.	Reduces transmission of microorganisms.

STEPS	RATIONALE
24. Stay with client for 3–5 minutes and observe for any adverse reactions.	Severe anaphylactic reaction is characterised by dyspnoea, wheezing and circulatory collapse.
25. Ask whether client feels any acute pain, burning, numbness or tingling at injection site.	Continued discomfort may indicate injury to underlying bones or nerves.
26. Inspect site, noting any bruising or induration.	Bruising or induration indicates complication associated with injection. Notify nurse in charge or medical officer. Provide warm compress to site.
27. Return to evaluate client's response to medication in 10–30 minutes. IM medications absorb quickly; undesired effects may also develop rapidly.	Nurse's observations determine efficacy of medication action.
28. Ask client to explain purpose and effects of medication.	Evaluates client's understanding of information taught.
29. For ID injections, use skin pencil and draw circle around perimeter of injection site. Read site within 48–72 hours of injection.	Site must be read at various intervals to determine test results. Pencil mark makes site easy to find.

RECORDING AND REPORTING

- Chart medication dose, route, site, time and date given in medication record.
- Report any undesirable effects from medication to nurse in charge or medical officer.
- Record client's response to medications in nurses' notes.

HOME CARE CONSIDERATIONS

- Clients with hypertrophy of the skin from repeated insulin injections (common with beef or pork formulations) should be taught not to use the site for 6 months.

site selected causes extreme pain and may result in local tissue damage.

Many clients, particularly children, fear injections. Clients with serious or chronic illness are often given several injections daily. The nurse may be able to minimise a client's discomfort in the following ways:

- Use topical anaesthetic creams or patches to reduce the sensation of the injection.
- Use a sharp-bevelled needle in the smallest suitable length and gauge.
- Position the client as comfortably as possible to reduce muscular tension.
- Select the proper injection site, using anatomical landmarks.
- Divert the client's attention from the injection through conversation.
- Insert the needle quickly and smoothly to minimise tissue pulling.
- Hold the syringe steady while the needle remains in tissues.
- Inject the medication slowly and steadily.
- Massage the injected area gently for several seconds (unless contraindicated, e.g. anticoagulants).

There are several different types of injections: subcutaneous, intramuscular and intradermal.

Subcutaneous injections

These involve placing medications into the loose connective tissue under the dermis (Skill 27-8). Because subcutaneous tissue is not as richly supplied with blood, absorption of the medication is somewhat slower than with intramuscular injections. Because subcutaneous tissue contains pain receptors, the client may experience some discomfort. The best subcutaneous injection sites are the outer posterior aspect of the upper arms, the abdomen from below the costal margins to the iliac crests, and the anterior aspects of the thighs (Figure 27-18). The site most

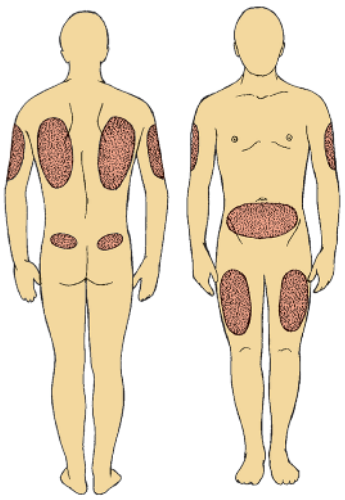


Figure 27-18 **Sites recommended for subcutaneous injections.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Figure 27-19 **Giving subcutaneous heparin in the abdomen.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

often recommended for heparin and insulin injection is the abdomen (Figure 27-19). Other sites include the scapular areas of the upper back and the upper ventral or dorsal gluteal areas.

The injection site chosen should be free of skin lesions, bony prominences and large underlying muscles or nerves. Clients with diabetes should practise intra-site rotation of insulin injections. Use of the same part of the body (e.g. abdomen) for a sequence of injections provides more consistency in the absorption of the insulin; the injections should be given at least 2.5 cm away from the previous site. Rotation of sites within an anatomical region ensures more consistent absorption times. Repeated injection into the same site causes a natural immune response, resulting in lipodystrophy.

Only small doses (0.5–1 mL) of water-soluble medications should be given subcutaneously, because the tissue is sensitive to irritating solutions and large volumes of medications. Collection of medications within the tissues can cause a sterile abscess, which appears as a hard, painful lump under the skin.

A client's bodyweight indicates the depth of the subcutaneous layer, so the nurse must choose the needle length and angle of insertion based on weight. Generally, a 25 gauge 26 mm needle inserted at a 45-degree angle (Figure 27-20) or a 13 mm needle inserted at a 90-degree angle deposits medications into the subcutaneous tissue of a normal-sized client. A child may require only a 13 mm needle. If the client is obese, pinch the tissue and use a needle that is long enough to insert through fatty tissue at the base of the skin fold. The preferred needle length is half the width of the skin fold. Thin clients may have insufficient tissue for subcutaneous injections; the upper abdomen is the best site for injection with thin clients.

To ensure the medication reaches the subcutaneous tissue, the nurse follows this rule: if 5 cm of tissue can be grasped, the needle should be inserted at a 90-degree angle; if 2.5 cm of tissue can be grasped, the needle should be inserted at a 45-degree angle.

Intramuscular injections

The intramuscular (IM) route provides faster medication absorption than the subcutaneous, because of the greater vascularity of muscle. Muscle is less sensitive to irritating and viscous medications. There is less danger of causing tissue damage when medications enter deep muscle. There is, however, a risk of inadvertently injecting medications directly into blood vessels. The nurse uses a longer and heavier-gauge needle to pass through subcutaneous tissue and penetrate deep muscle tissue. Bodyweight and the amount of adipose tissue can influence needle size selection. For example, an obese client may require a needle 77 mm long, and a thin client may require a needle only 12–25 mm long.

The angle of insertion for an intramuscular injection is 90 degrees (Figure 27-20). A normal, well-developed client can tolerate 3–4 mL of medication into a larger muscle without severe muscle discomfort. A larger volume of medication is unlikely to be absorbed properly. Children, older adults and thin clients can tolerate only 2 mL of an intramuscular injection, and no more than 1 mL is recommended for small children and older infants.

Repeated injections into the same muscle can cause severe discomfort. With the client relaxed, palpate the muscle to rule out any hardened lesions. Discomfort is minimised by helping the client assume a position which reduces muscle strain.

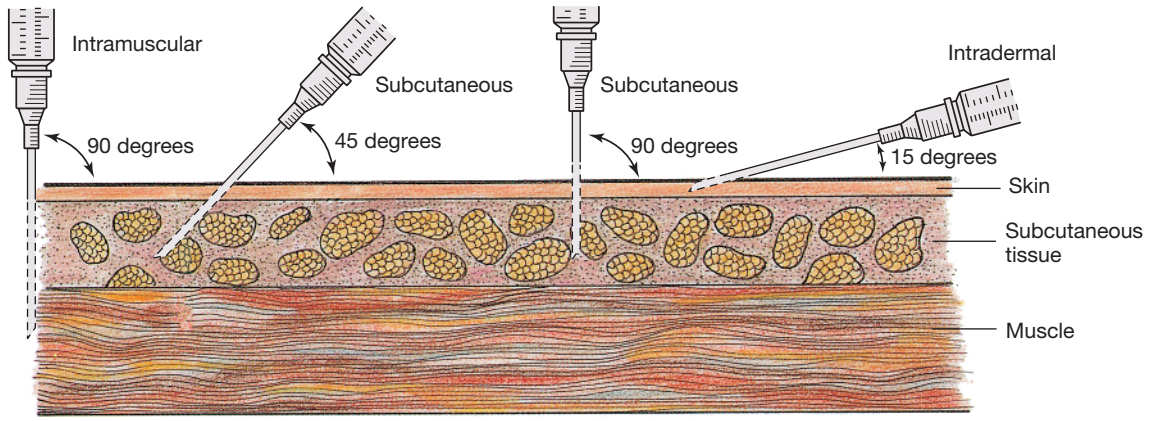

Figure 27-20 Comparison of angles of insertion for intramuscular (90 degrees), subcutaneous (45 degrees) and intradermal (15 degrees) injections.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Intramuscular sites

When selecting an intramuscular site (Box 27-16), consider whether the area is free from infection or necrosis; the presence of localised areas of bruising or abrasions or tenderness; the location of underlying bones, nerves and major blood vessels; and the volume of medication to be administered.

Ventrogluteal

The ventrogluteal muscle is a safe site for all clients, with a maximum dose of 4 mL. The gluteus medius and minimus are situated deep and away from major nerves and blood vessels. Injuries such as fibrosis, nerve damage, abscess, tissue necrosis, muscle contraction, gangrene and pain are rare.

Locate the muscle by placing the heel of the hand over the greater trochanter of the client's hip, with the wrist perpendicular to the femur. The right hand is used for the left hip, and the left hand is used for the right hip. Point the thumb towards the client's groin and the fingers towards the client's head, point the index finger to the anterosuperior iliac spine and extend the middle finger back along the iliac crest towards the buttock. The index finger, the middle finger and the iliac crest form a triangle, and the injection site is the centre of the triangle (Figure 27-21). The client may lie on the side or the back. Flexing of the knee and hip helps the client relax this muscle.

BOX 27-16 Characteristics of intramuscular sites

Vastus lateralis

- Lacks major nerves and blood vessels.
- Rapid drug absorption.

Ventrogluteal

- A deep site, situated away from major nerves and blood vessels.
- Less chance of contamination in incontinent adults or infants.
- Easily identified by any prominent bony landmark.

Deltoid

- Easily accessible but muscle not well developed in most people.
- Used for small amounts of medications.
- Not used in infants or children with underdeveloped muscles.
- Potential for injury to radial and ulnar nerves or brachial artery.

Vastus lateralis

The vastus lateralis muscle is normally used in adult clients, for volumes up to 5 mL. The muscle is thick and well developed, is located on the anterior lateral aspect of the thigh and extends in an adult from a hand width above the knee to a hand width below the greater trochanter of the femur (Figure 27-22). The middle third of the muscle is the suggested site for injection. The width of the muscle usually extends from the midline of the thigh to the midline of the thigh's outer side. With young children or cachetic (wasted) clients, it helps to grasp the body of the muscle during injection to be sure that the medication is deposited in muscle tissue. To help relax the muscle, ask the client to lie flat with the knee slightly flexed. The injection can also be given while the client is in the sitting position.

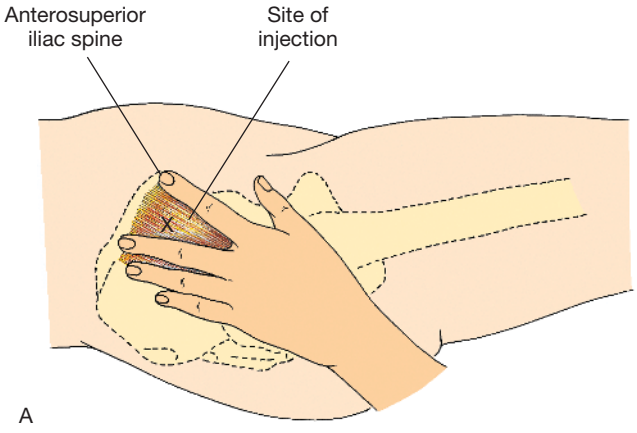

Figure 27-21

A, Landmarks for ventrogluteal site. B, Locating IM injection for ventrogluteal site.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

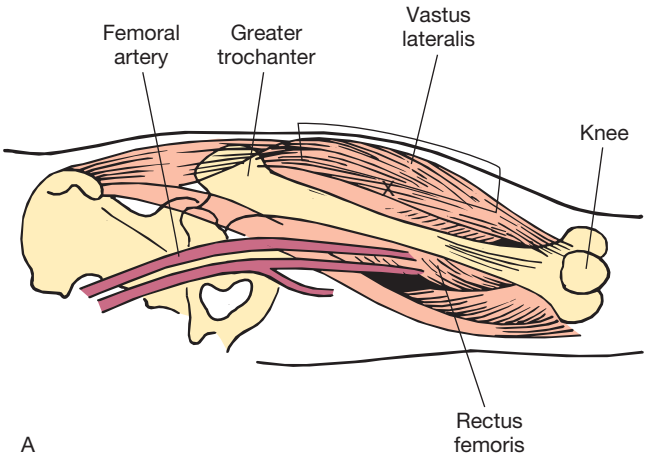

Figure 27-22

A, Landmarks for vastus lateralis site. B, Giving IM injection in vastus lateralis site.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Dorsogluteal

The dorsogluteal muscle has been a traditional site for intramuscular injections for volumes of 1–4 mL. Because of the risk of striking major blood vessels or the underlying sciatic nerve and the risk of causing permanent or partial paralysis of the involved leg, this site is not recommended by this text.

Deltoid

Although the deltoid muscle is easily accessible, this muscle is often not well developed and is not recommended for injection volumes over 2 mL. The radial and ulnar nerves and brachial artery lie within the upper arm along the humerus (Figure 27-23). This site should only be used for small volumes of medication, or when other sites are inaccessible. To locate the deltoid muscle, fully expose the client's upper arm and shoulder (a tight-fitting sleeve should not be rolled up). Ask the client to relax the arm by flexing the elbow. The client may sit, stand or lie down. Palpate the lower edge of the acromion process, which forms the base of a triangle in line with the midpoint of the lateral aspect of the upper arm. The injection site is in the centre of the triangle, about 2.5–5 cm below the acromion process. The site may also be located by placing four fingers across the deltoid muscle, with the top finger along the acromion process. The injection site is then three finger widths below the acromion process.

• CRITICAL REFLECTION POINT

The volume of an ordered IM injection is 4 mL. Identify the muscles you could use to administer this volume, and select the length of needle required for an obese client in this situation.

Special techniques for IM injections

Air-lock technique

Intramuscular injections using the air-lock technique are less irritating to subcutaneous tissues during needle

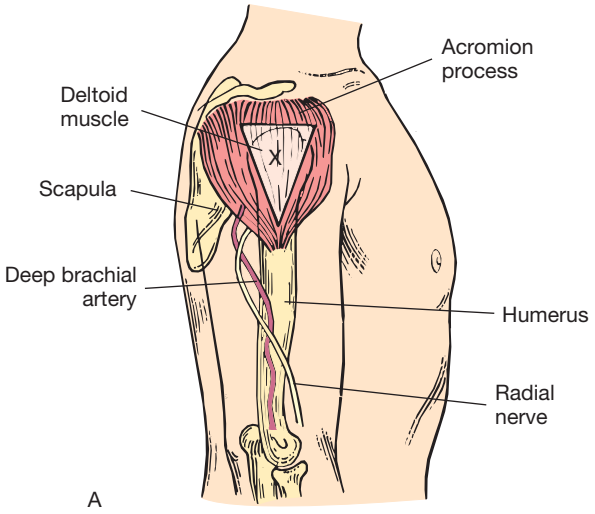

Figure 27-23

A, Landmark for deltoid site. B, Giving IM injection in deltoid muscle.
Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

withdrawal. A small volume of air injected behind a bolus of medication clears the needle of medication, preventing it from leaking through subcutaneous tissues. This technique is not used commonly and should be used only when recommended in the medication information insert. Examples include Wyeth's vaccines prepared with aluminium adjuvant, diphtheria and tetanus toxoid and the pertussis vaccine. After preparing the proper dose, draw up 0.2 mL of air. The needle is then injected downwards at a 90-degree angle so that the air rises to the top of the medication towards the plunger. As the medication is injected into the muscle, the air follows the medication, creating an air lock (Figure 27-24). Administering the medication with the needle at an

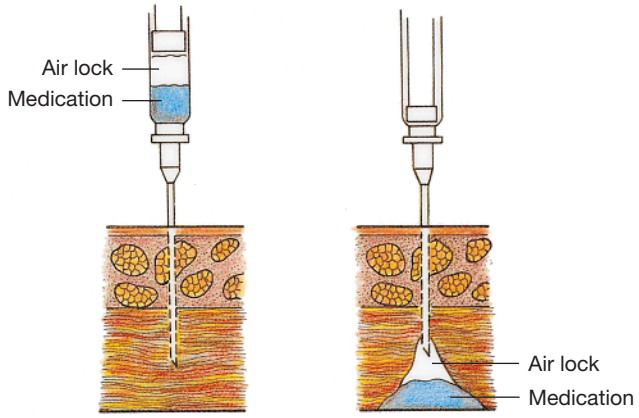

Figure 27-24 Administering IM injection by the air-lock technique prevents tracking of caustic medications through subcutaneous tissue.

angle of less than 90 degrees allows the air to collect along the barrel of the syringe and enter the muscle too soon, causing medication to leak into subcutaneous tissues.

Z-track method

When irritating preparations such as iron are given intramuscularly, the **Z-track method of injection** minimises irritation and staining by sealing the medication in muscle tissue. Select an IM site, preferably in larger, deeper muscles such as the ventrogluteal muscle. A new needle must be applied to the syringe after preparing the medication so that no solution remains on the outside needle shaft. After preparing the site with an antiseptic swab, pull the overlying skin and subcutaneous tissues approximately 2.5–3.5 cm to the side. Holding the skin taut with the non-dominant hand, inject the needle deep into the muscle. If there is no blood return on aspiration, the nurse injects the medication slowly. The needle remains inserted for 10 seconds to allow the medication to disperse evenly. Withdraw the needle and then release the skin. This leaves a zigzag path that seals the needle track where tissue planes slide across one another (Figure 27-25). The medication cannot escape from the muscle tissue. Massage of the site is contraindicated as it could force medication into subcutaneous tissues.

Intradermal injections

The nurse typically gives intradermal injections for skin testing, for example, tuberculin screening and allergy tests. These medications are potent, so they are injected into the dermis, where blood supply is reduced and medication absorption occurs slowly. A client may have

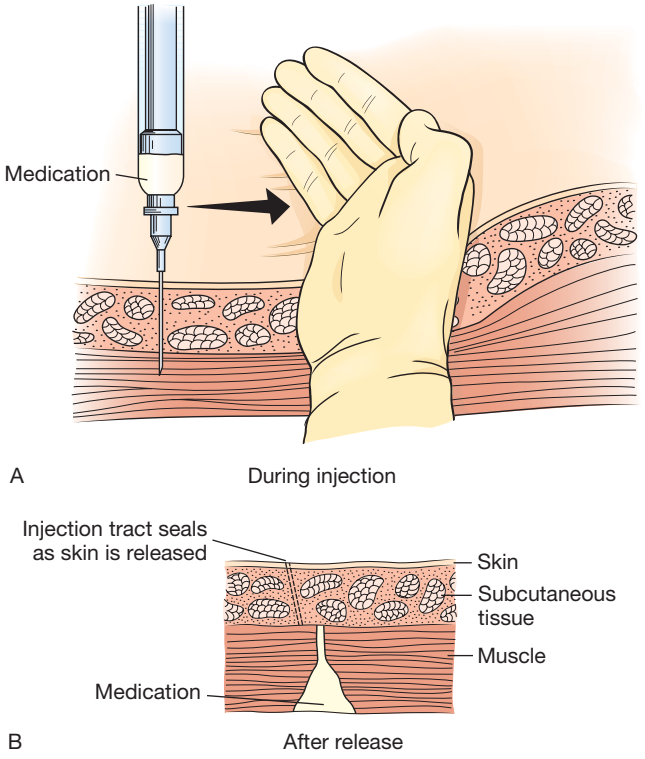

Figure 27-25

A, Pulling on overlying skin during IM injection moves tissue to prevent later tracking. B, The Z-track left after injection prevents the deposit of medication through sensitive tissue.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

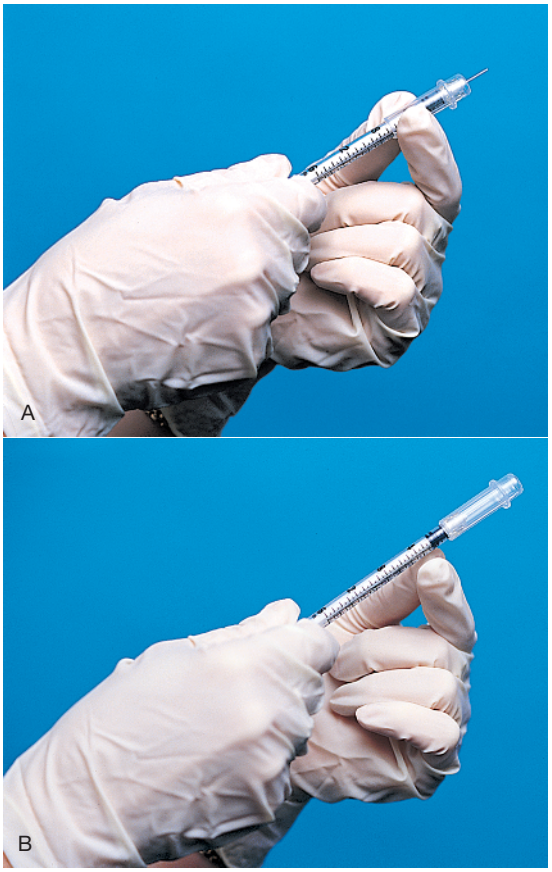

Figure 27-26 Needle with plastic guard to prevent needle-sticks.

A, Position of guard before injection. B, After injection the guard locks in place, covering the needle.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

a severe anaphylactic reaction if the medication enters the circulation too rapidly.

Skin testing requires the nurse to be able to clearly see the injection sites for changes in colour and tissue integrity. Intradermal sites should be lightly pigmented, free of lesions and relatively hairless. The inner forearm and upper back are ideal locations.

The nurse uses a small hypodermic syringe for skin testing. The angle of insertion for an intradermal injection is 5–15 degrees (see Figure 27-20). As the nurse injects the medication, a small bleb (bubble) resembling a mosquito bite should appear on the skin's surface. If a bleb does not appear or if the site bleeds after needle withdrawal, there is a good chance that the medication entered subcutaneous tissues. In this case, test results will be invalid.

Safety in administering medications by injection

Needleless devices

A large number of needle-stick injuries occur in healthcare settings each year. These injuries commonly occur when nurses forget to recap needles, mishandle intravenous lines and needles or contact stray needles left at a client's bedside. The risk of exposure of health workers to blood-borne pathogens has led to the development of 'needleless devices' or special needle safety devices. Special syringes designed with a sheath or guard that covers the needle after it is withdrawn from the skin are available (Figure 27-26). The needle is immediately covered, eliminating the chance of a needle-stick injury. The syringe and sheath are disposed of together in a sharps receptacle. 'Needleless' syringes (e.g. Interlink system) for use with needleless injection ports on intravenous lines are widely used.

Needles and other instruments considered 'sharps' are always disposed of into clearly marked sharps containers (Figure 27-27). Containers should be puncture- and leak-proof. A needle should never be forced into a full receptacle.

Needle recapping

The practice of recapping contaminated needles is not recommended and is against institutional policy.

Figure 27-27 **Sharps disposal using only one hand.**

Intravenous administration

The nurse administers medications intravenously by the following methods:

- as mixtures, within large volumes of IV fluids
- by injection of a bolus, or small volume, of medication through an existing intravenous infusion line or intermittent venous access (referred to as a *heparin* or *medication lock*)
- by '**piggyback**' infusion of a solution containing the prescribed medication and a small volume of IV fluid through an existing IV line
- direct intravenous injection into the vein via a 21–25 gauge needle and syringe.

In the first three methods, the client has either an existing IV infusion line or an access site, such as an intermittent infusion. The IV route is often used in emergencies when a fast-acting medication must be delivered quickly (Skill 27-9).

When using any method of IV medication administration, clients must be closely observed for symptoms of adverse reactions; this includes assessing vital signs before, during and after infusion. After a medication enters the bloodstream, it begins to act immediately and there is no way to stop its action. Special care must be taken to avoid errors in dose calculation and preparation. The seven rights of safe medication administration should be double-checked and the desired action and side effects known. The known antidote should be available during administration. The nurse uses the principles of aseptic non-touch technique when preparing and administering IV medications (see Chapter 29).

The IV route is best when it is necessary to establish constant therapeutic blood levels. Medications which are highly alkaline and irritating to muscle and subcutaneous tissue cause less discomfort when given intravenously.

Large-volume infusions

Of the methods of administering IV medications, mixing medications in large volumes of fluids is the safest

SKILL 27-9

Adding medications to intravenous fluid containers

Delegation considerations

Adding medications to IV fluid containers requires the problem-solving and knowledge-application abilities of professional nurses. For this procedure, delegation to nurse assistants is inappropriate. (In some institutions the pharmacist may add medications to primary containers of IV solutions.)

Equipment

- Vial or ampoule of prescribed medication
- Syringe of appropriate size (5–20 mL)
- Sterile Interlink cannula or needle (19 to 21 gauge) with special filters (optional)
- Correct diluent (e.g. sterile water, Normal saline)
- Sterile IV fluid container of ordered fluid volume
- Alcohol or antiseptic swab
- Label to attach to IV bag or bottle
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

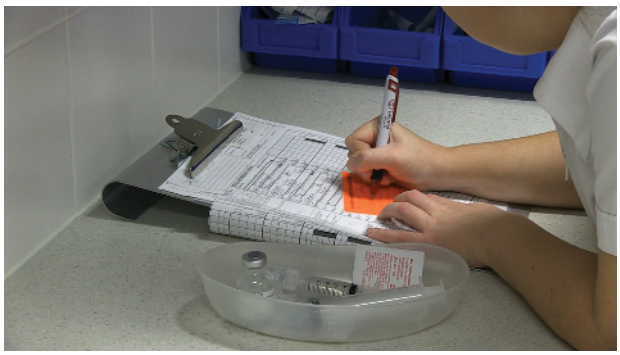
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Check prescriber's order to determine type of IV solution to use and type of medication and dosage.	Client's overall physical condition dictates type of IV solution used. Ensures safe and accurate medication administration.
2. Collect information necessary to administer drug safely, including action, purpose, side effects, normal dose, time of peak onset and nursing implications.	Allows nurse to give medication safely and to monitor client's response to therapy.
3. When more than one medication is to be added to IV solution, assess for compatibility of medications.	Medications are often incompatible when mixed together. Chemical reactions that occur result in clouding or crystallisation of IV fluids. Check clinical agency policy for approved medication compatibility list.
4. Assess client's systemic fluid balance, as reflected by skin hydration and turgor, bodyweight, pulse, blood pressure and urine output.	Danger of continuous IV infusions is that fluids may infuse too rapidly, causing circulatory overload.
5. Assess client's history of medication allergies.	IV administration of medications causes rapid effects. Allergic response can be immediate.
6. Assess IV insertion site for signs of infiltration or phlebitis.	An intact, properly functioning site ensures medication is given safely.
7. Perform hand hygiene and use gloves if this is agency policy (i.e. for cytotoxic or antibiotic medicines).	Reduces transfer of microorganisms.
8. Assemble supplies in medication room (or other area as designated by clinical agency).	Ensures orderly procedure, with less likelihood of contaminating supplies.
9. Prepare prescribed medication from vial or ampoule (see Skill 27-7).	Ensures accurate delivery of medication.
10. Identify client by reading identification band and asking name. Compare with MAR.	Ensures correct client receives medication.
11. Assess client's understanding of purpose of medication therapy.	May reveal need for education.
12. Add medication to new container (usually done in medication room):	
a. Solution in a bag: locate medication injection port on plastic IV solution bag. Port has small stopper at end. Do not select port for the IV tubing insertion or air vent.	Medication injection port is self-sealing to prevent introduction of microorganisms after repeated use.
b. Solution in a bottle: locate injection site on IV solution bottle, which is often covered by a cap.	Accidental injection of medication through main tubing port or air vent can alter pressure within bottle and cause fluid leaks through air vent. Cap seals bottle to maintain its sterility.

STEPS	RATIONALE
c. Wipe off port or injection site with alcohol/antiseptic swab (see illustration).	Reduces risk of introducing microorganisms.
d. Remove needle cap or sheath from syringe and insert needle of syringe or needleless device through centre of injection port or site; inject medication (see illustration).	Injection of needle into sides of port may produce leak and lead to fluid contamination.
e. Withdraw syringe from bag or bottle.	
f. Mix medication and IV solution by holding bag or bottle and turning it gently end to end.	Allows even distribution of medication.
g. Complete medication label with name and dose of medication, date, time and nurse's initials and attach to bottle or bag (see illustration). Optional (check agency policy): Apply a flow strip that identifies the time the solution was hung and intervals indicating fluid levels. Spike bag or bottle with IV tubing and prime the tubing with the fluid.	Label can be easily read during infusion of solution. Informs nurses and other healthcare workers of contents of bag or bottle. Priming the line removes the air within the tubing which reduces risk of air embolism.

Step 12c Wiping port with alcohol/antiseptic swab.

Step 12d Injecting medicine through centre of port.



Step 12g Completing medication label.

■ **Critical decision point: Do not use felt-tip markers on plastic surfaces. The ink can penetrate the plastic and leak into the IV solution.**

13. Bring assembled items to client's bedside and check client's name against the prescriber's orders.	Ensures correct client receives ordered medication.

STEPS	RATIONALE
14. Prepare client by explaining that medication is to be given through existing IV line or one to be started. Explain that no discomfort should be felt during medication infusion. Encourage client to report symptoms of discomfort.	Most IV medications do not cause discomfort when diluted. Pain at insertion site may be early indication of infiltration.
15. Regulate infusion at prescribed rate.	Prevents rapid infusion of fluid.
16. Add medication to existing container:	
a. Prepare vented IV bottle or plastic bag:	
(1) Check volume of solution remaining in bottle or bag.	Ensures the appropriate minimal volume is available to dilute medication adequately.
(2) Close off IV infusion clamp.	Prevents medication from directly entering circulation as it is injected into bag or bottle.
(3) Wipe off medication port with an alcohol or antiseptic swab.	Mechanically removes microorganisms that could enter container during needle insertion.
(4) Insert syringe needle or needleless device through injection port and inject medication.	Injection port is self-sealing and prevents fluid leaks.
(5) Lower bag or bottle from IV pole and gently mix. Rehang bag.	Ensures medication is evenly distributed.
b. Complete medication label and attach it to bag or bottle.	Informs nurses and doctors of contents of bag or bottle.
c. Regulate infusion to desired rate.	Prevents rapid infusion of fluid.
17. Properly dispose of equipment and supplies. Do not cap needle on syringe. Specially sheathed needles are discarded as a unit with needle covered.	Proper disposal of needle prevents injury to nurse and client. Capping of needles increases risk of needle-stick injuries.
18. Perform hand hygiene.	Reduces transmission of microorganisms.
19. Observe client for signs or symptoms of adverse reaction.	IV medications can cause rapid effects.
20. Observe for signs and symptoms of fluid volume excess.	Rapid uncontrolled infusion can cause circulatory overload.
21. Periodically return to client's room to assess IV insertion site and rate of infusion.	Over time IV site may become infiltrated or cannula may become malpositioned. Flow rate may change according to client's position or volume left in container.
22. Observe for signs or symptoms of IV infiltration.	Infiltrated medications can injure tissue.

RECORDING AND REPORTING

- Record solution and medication added to parenteral fluid on appropriate form.
- Report any adverse reactions to nurse in charge or prescriber.

and easiest. Medications are diluted in large volumes (500 mL or 1000 mL) of compatible IV fluids, such as Normal saline or dextrose solution. In some agencies the pharmacist adds medications to the primary container of IV solution to ensure asepsis. Because the medication is not in a concentrated form, the risk of side effects or fatal reactions is reduced when infused over the prescribed timeframe. Vitamins and potassium chloride are two types of medications commonly added to IV fluids.

Intravenous infusions which contain medicines should be administered via a volume-controlled system to ensure the medication is given at the ordered rate. If the volume is given too quickly, the risk of adverse reactions or side effects (e.g. fluid overload, drug overdose or cardiac arrest) is increased; slow administration, however, may not allow the medication to reach therapeutic levels.

Intravenous bolus

An IV bolus involves introducing a concentrated dose of a medication directly into the systemic circulation via the side-arm of the IV giving set or directly into an IV cannula (Skill 27-10). The use of a bolus which requires only a small amount of fluid to deliver the medication is an advantage when the client's daily fluid intake is restricted.

The IV bolus is the most dangerous method of administering medications, because there is no time to correct errors. In addition, a bolus may cause direct irritation to the lining of blood vessels.

Before administering a bolus, the nurse confirms placement and patency of the IV line (Box 27-17). Accidental injection of a medication into the tissues around a vein can cause pain, sloughing of tissues, abscesses and even tissue necrosis, depending on the medication's composition. The rate of administration of an IV bolus medication is usually determined by the amount of medication that can be given each minute. The rate of infusion is critical and the nurse must resist the temptation to hurry the procedure. The nurse should determine the recommended concentration and rate of administration, the purpose for which a medication is prescribed and any potential adverse effects related to the rate or route of administration. It is important that the rate of infusion is slowed if the client complains of pain. The bolus should be stopped immediately if the client shows any signs of adverse effects of the medication.

Patient-controlled analgesia (PCA) is one form of bolus administration (see Chapter 41). A small-volume infusion pump or syringe pump/syringe-driver (Figure 27-29) is equipped with a handheld button, which, when pressed by the client, delivers a pre-set dose of the medication as a bolus. PCA allows clients to assess and treat their pain on a continuous basis. For a PCA to be effective, the client must be well informed on how the device works and have the coordination to use the handset.

BOX 27-17 Procedural guidelines for checking the patency of an intravenous cannula

Flushing – not always a reliable indicator, as little resistance may be experienced even when cannula has tissued.

Lack of pain around the IV site – problematic, as infiltration of isotonic solutions generally does not produce discomfort.

Oedema and coolness of IV site – a medication should never be given intravenously if the insertion site appears puffy or oedematous or the IV fluid cannot flow at the proper rate. This is not always descriptive of extravasation, for it depends on the site and previous status of tissues.

Checking for blood return – the inability to obtain a blood return may suggest that the needle or catheter is in the client's tissues or is resting against the vein wall. Unreliable, as blood may flow freely with seepage of solution into tissues around the cannula.

Obstructing the venous flow above the cannula by the application of a tourniquet or occlusion by finger pressure – may be advised in determining patency. If the IV cannula is in the vein, the flow rate will decrease or stop with obstruction of venous flow; whereas with infiltration, the flow rate will continue unchanged.

Volume-controlled infusions

Control of the volume of fluid or medication administered via an intravenous infusion is very important, especially if the client is young or elderly, or if the medication in the infusion has serious side effects or is given in small doses. Using volume-controlled infusions has several advantages:

- It reduces the risk of rapid-dose infusion by IV push. Medications are diluted and infused over a longer time, for example, 30–60 minutes.
- It allows administration of medications while they are still in a stable condition (e.g. antibiotics are stable for a limited time in solution).
- It allows control of IV fluid intake.
- It may be used to allow clients to control their own medication use (i.e. PCA).

One way of administering a medication IV is to mix it with a small amount (50–100 mL) of compatible IV fluid. The fluid is within a secondary fluid container separate from the primary infusion. The secondary infusion connects directly to the primary IV line or to separate tubing that inserts into the primary line.

SKILL 27-10

Administering medications by intravenous bolus

Delegation considerations

Administering medications by intravenous bolus requires the problem-solving and knowledge-application abilities of professional nurses. For this procedure, delegation to nurse assistants is inappropriate.

Definitions

Bolus: method of rapid IV medication administration; refers to the concentration or amount of medication.

Flush: solution (usually 5–10 mL Normal saline) is slowly administered to check patency of cannula; to flush medication from cannula or to create a lock (saline or heparin).

Equipment

IV medication (existing infusion):

- Disposable gloves
- Medication in vial or ampoule
- Syringe
- Needleless device or sterile needles (21 and 25 gauge)
- Antiseptic swab
- Watch with second-hand or digital readout
- Medication administration record (MAR)

IV flush (IV lock):

- Disposable gloves
- Medication in vial or ampoule
- Syringe
- Vial of appropriate flush solution (5–10 mL saline most common, but heparin may also be used; if heparin is used, most common concentration is 10–100 units; check agency policy)
- Needleless device or sterile needles (21 and 25 gauge)
- Alcohol or antiseptic swab
- Watch with second-hand or digital readout
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Check the prescriber's order for type, dosage, route and time of medication.	Ensures safe and accurate medication administration.
2. Assess IV insertion site for signs of infiltration or phlebitis.	Confirming the placement of the IV catheter and the integrity of the surrounding tissue ensures that the medication is administered safely.
3. If medication is to be pushed into an IV line, assess the patency of the line.	The IV line must be patent for medication to reach venous circulation effectively.
4. Prepare ordered medication from vial or ampoule (see Skill 27-7). Read directions carefully for proper IV dilution of medications.	Directions can be found in Australian Injectable Handbook, from package instructions or in MIMS Annual.
5. After drawing up medications, remove the needle (for needleless system) otherwise apply a small-gauge needle to the syringe (this system is rarely used).	Used to insert through IV line with needle system only.

STEPS	RATIONALE
6. Perform hand hygiene. Put on gloves.	During IV bolus administration, risk of blood exposure is low. However, nurse may manipulate IV dressing or expose site while completing other activities. Gloves reduce exposure.
7. Check client's identification by looking at identification bracelet and asking name and any known allergies.	Ensures that medication is administered to correct client.
8. **Administer medications by IV medication (existing infusion)**	
a. Select injection port of IV tubing closest to client. (Circle on port may indicate site for needle insertion.) If add-on 0.22 micrometre filter is used, give medication below filter next to client.	Allows for easier fluid aspiration to obtain blood return. Injection ports are self-sealing and will not leak.
b. Clean injection port with antiseptic swab. Allow to dry.	Prevents introduction of microorganisms during needle insertion.
c. Connect syringe to IV line (needleless) or insert needle of syringe containing prepared drug through centre of injection port (see illustration).	Prevents damage to port's diaphragm and subsequent leakage.
d. Check patency (Box 27-17) to ensure safe and adequate medication administration.	Final check that medication is being delivered into the bloodstream.
e. Leave concurrent compatible infusion running and inject medication slowly over several minutes as per directions on medication package. Use watch to time administration (see illustration).	Ensures safe medication infusion. Rapid injection of IV medication can prove fatal.
f. After injecting medication, withdraw syringe, and recheck fluid infusion rate.	Injection of bolus may alter rate of fluid infusion. Rapid fluid infusion can cause circulatory overload.

Step 8c Connecting syringe to needleless IV line.

Step 8e Using a watch to time administration of medication.

9. **Administer medications into IV cannula (non-concurrent infusion) (IV lock or a needleless system)**	

STEPS	RATIONALE
A. Prepare flushing solutions (1) Flushing with heparin: (a) Prepare syringe with heparin flush solution as per prescriber's orders. (b) Prepare 2 syringes with 5–10 mL of Normal saline. (2) Flushing with saline only: (a) Prepare 2 syringes with 5–10 mL of Normal saline each.	Flush solution keeps heparin lock patent after medication is administered.
B. IV lock	
(1) Clean lock's rubber diaphragm with antiseptic swab.	Prevents introduction of microorganisms during needle insertion.
(2) Insert needle of syringe containing Normal saline through centre of diaphragm (only for needle-based systems).	
(3) Pull back gently on syringe plunger and look for blood return.	Determines whether IV needle or catheter is positioned in vein.
Critical decision point: At times a heparin lock will not yield a blood return even though the lock is patent.	
(4) Flush reservoir with saline by pushing slowly on plunger.	Clears needle and reservoir of blood.
Critical decision point: Observe closely the area of skin above the IV catheter. Note any puffiness or swelling as the reservoir is flushed, which could indicate infiltration into the tissues, requiring removal of the catheter.	
(5) Remove needle and syringe.	
(6) Clean lock's diaphragm with antiseptic swab.	Prevents transmission of infection.
(7) Insert needle of syringe containing prepared medication through centre of diaphragm (see illustration).	Using centre of diaphragm prevents leakage.

Step 9B(7) Inserting needle of syringe through centre of lock diaphragm.

STEPS	RATIONALE
(8) Inject medication bolus slowly over several minutes. (Each medication has recommended rate for bolus administration. Check package directions.) Use watch to time administration.	Rapid injection of IV medication can result in death.
(9) After administering bolus, withdraw syringe.	
(10) Clean lock's diaphragm with antiseptic swab.	Prevents transmission of microorganisms.
(11) Repeat injection of Normal saline.	Flushes reservoir and needle of medication.
(12) Heparin flush: insert needle of syringe containing heparin through diaphragm. Inject heparin slowly, and remove syringe.	Maintains patency of needle by inhibiting clot formation.
C. IV needleless valve cap (1) Insert syringe (without a needle) containing Normal saline into the valve.	
(2) Flush reservoir with saline by pushing slowly on plunger.	Clears reservoir of any blood.
(3) Remove the syringe.	
(4) Insert syringe containing prepared medication into the valve.	
(5) Inject medication slowly over several minutes. Follow precautions in Step 9B(8).	Rapid injection of IV drug can result in death.
(6) After administering bolus, withdraw syringe.	
(7) Repeat injection of 5–10 mL of Normal saline.	Unless patient is a child or on a strict fluid restriction.
(8) See Step 9B(12).	
(9) Replace sterile cap over valve.	

RECORDING AND REPORTING

- Record medication, dose, time and route on appropriate form.
- Report any side effects immediately to prescriber and pharmacy, because they could be life-threatening.

Three volume-control infusion methods are commonly used in Australasia: a secondary small-volume drip chamber or burette placed between the client and the primary infusion, a piggyback and/or tandem set and mechanical 'pumps'.

Volume-control administration sets

Volume-control administration sets (burettes) are small (50–150 mL) containers that attach just below the primary infusion bag or bottle. The set is attached and filled in a manner similar to that used with a regular IV infusion. The priming filling of the set varies, however, depending on the type of filter (floating valve or membrane) within the set. Follow package directions for priming sets.

Large volume-controlled system

This system is a mains-power or battery-operated pump which controls the rate at which the infusion is delivered,

and supplies a history of how much fluid has been delivered, the rate of delivery and any problems (alarms) which may have been encountered. There are many pumps available and the nurse must be careful to set up and run the device according to the manufacturer's instructions. An example of a volume-controlled system is shown in Skill 27-11.

SKILL 27-11

Administering intravenous medications by piggyback/tandem set-up, intermittent intravenous infusion sets and mini-infusion pumps

Delegation considerations

Administering medications by IV fluid by piggyback/tandem set-up, intermittent intravenous infusion sets and mini-infusion pumps requires the problem-solving and knowledge-application abilities of professional nurses. For this procedure, delegation is inappropriate.

Equipment

Piggyback, tandem or mini-infusion pump

- Gloves (for connecting IV tubing)
- Medication prepared in 5–150 mL labelled infusion bag or syringe
- Short microdrip or macrodrip tubing set for piggyback/tandem
- Needleless device
- Needles (21 or 23 gauge, only if stopcocks or other needleless methods are not available)
- Stopcocks
- Mini-infusion pump
- Adhesive tape (optional)
- Alcohol or antiseptic swab
- IV pole or rack
- Medication administration record (MAR)

Volume-control administration set

- Gloves (for connecting IV tubing)
- Burette
- Infusion tubing (may have needleless system attachment)
- Syringe (5–20 mL)
- Vial or ampoule of ordered medication
- Medication label
- Medication administration record (MAR)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Check prescriber's order to determine type of IV solution to be used, type of medication, dose, route and time of administration.	Client's overall physical condition dictates type of IV solution used. Ensures safe and accurate medication administration.
2. Collect information necessary to administer medication safely, including action, purpose, side effects, normal dose, time of peak onset and nursing implications.	Allows nurse to give medication safely and to monitor client's response to therapy.
3. Assess patency of client's existing IV infusion line (Box 27-17).	IV line must be patent for medication to reach venous circulation effectively.

STEPS	RATIONALE
4. Assess IV insertion site for signs of infiltration or phlebitis: redness, pallor, swelling, tenderness on palpation.	Confirmation of placement of IV needle or catheter and integrity of surrounding tissues ensures medication is administered safely.
5. Assess client's history of medication allergies.	Effects of medications can develop rapidly after IV infusion. Nurse should be aware of clients at risk.
6. Assemble supplies at bedside. Inform client that medication will be given through IV equipment.	Medication preparation is not usually required. Nurse may assemble infusion tubing and bag of medication in medication room or client's room. Allows client to understand procedure and minimises anxiety.
7. Perform hand hygiene and put on gloves.	Reduces transmission of infection. During handling of IV tubing there is some risk of blood exposure.
8. Check name on MAR with client's identification bracelet and ask client's name and any known allergies.	Ensures medication is administered to correct client.
9. Assess client's understanding of purpose of medication therapy.	May reveal need for education.
10. Explain purpose of medication and side effects to client and explain that medication is to be given through existing IV line. Encourage client to report symptoms of discomfort at site.	Keeps client informed of planned therapies.
11. **Administer infusion**	
A. Piggyback or tandem infusion	
(1) Connect infusion tubing to medication bag. Allow solution to fill tubing by opening regulator flow clamp (priming).	Infusion tubing should be filled/primed with solution and free of air bubbles to prevent air embolus.
(2) Hang piggyback medication bag above level of primary fluid bag. (Hook may be used to lower main bag.) Hang tandem infusion at same level as primary fluid bag (see illustration).	Height of fluid bag affects rate of flow.
(3) Connect tubing of piggyback or tandem infusion to appropriate connector on primary infusion line:	
(a) Stopcock: Wipe off stopcock port with alcohol swab and connect tubing. Turn stopcock to open position.	Stopcock eliminates need for needle.
(b) Needleless system: Wipe off needleless port, and insert tip of piggyback or tandem infusion tubing (see illustration).	Establishes route for IV medication to enter main IV line.

STEPS	RATIONALE
(4) Regulate flow rate of medication solution by adjusting regulator clamp. (Usually medication should infuse within 20–90 minutes.) Make your client comfortable and stay with them for 3–5 minutes to watch for signs of allergic reaction.	Provides slow, intermittent infusion of medication in 20–90 minutes; maintains therapeutic blood levels. Read medication package insert for specific information on how long to infuse the medication.
(5) After medication has infused, check flow regulator on primary infusion. Back-check valve on piggyback stops flow of the primary infusion until second medication infuses. The tandem and primary infusions flow together until the tandem set empties.	Valve prevents backup of medication into main infusion line. Checking flow rate ensures proper administration of IV fluids.
(6) Regulate main infusion line to desired rate, if necessary.	Infusion of piggyback may interfere with the main line infusion rate.
(7) Leave secondary bag and tubing in place for future medication administration or discard in appropriate containers.	Establishment of secondary line produces route for microorganisms to enter main line. Repeated changes in tubing increase risk of infection transmission (check clinical agency policy).

Step 11A(2) Position of tandem infusion bag.

Step 11A(3)(b) Needleless system: inserting tip of piggyback infusion tubing into port.

B. Volume-control administration set (e.g. burette)	
(1) Assemble supplies in medication room.	Controls risk of contaminating IV solution.
(2) Prepare medication from vial or ampoule (see Skill 27-7).	Ensures medication is sterile.
(3) Explain procedure to client. Encourage client to report symptoms of discomfort at site. Check client's name against prescriber's orders and assess client's condition to ascertain if it is appropriate to administer medication.	Keeps client informed of planned therapies.

STEPS	RATIONALE
(4) Fill burette chamber with desired amount of fluid (50–100 mL) by opening clamp between chamber and main IV bag (see illustration).	Small volume of fluid dilutes IV medication and reduces risk of too-rapid infusion.
(5) Close clamp and check to be sure clamp on air vent of chamber is open.	Prevents additional leakage of fluid into chamber. Air vent allows fluid in chamber to exit at regulated rate.
(6) Clean injection port on top of chamber with antiseptic swab.	Prevents introduction of microorganisms during medication insertion.
(7) Remove needle cap or sheath and insert syringe needle through port, then inject medication (see illustration). Gently rotate chamber between hands. If burette has a needleless valve then inject medication directly into the burette with the syringe only.	Rotating mixes medication with solution in chamber to ensure equal distribution.

Step 11B(4) Filling burette chamber with fluid from main IV bag.

Step 11B(7) Injecting medication into burette chamber.

(8) Regulate IV infusion rate to allow medication to infuse at the required rate.	For optimal therapeutic effect, medication should infuse in prescribed time interval.
(9) Label chamber with name of medication, dosage, total volume including diluent and time of administration.	Alerts nurses to medication being infused. Prevents other medications from being added to chamber.
(10) Dispose of uncapped needle or needle enclosed in safety shield and syringe in proper container. Remove gloves and wash your hands.	Prevents accidental needle-stick injuries and transfer of microorganisms.
(11) Make your client comfortable and stay with them for 3–5 minutes to ensure that they have not had any adverse reactions. During the infusion ensure you check the infusion rate and condition of the IV site.	Ensures timely intervention can occur in the case of allergy or infiltrated IV site.
(12) After the medicine has infused, check and regulate the flow of the primary infusion. Leave secondary bag and tubing in place for future medicine administration or discard according to agency policy.	

STEPS	RATIONALE
C. Mini-infuser/syringe driver administration	
(1) Connect pre-filled syringe to mini-infusion tubing.	Special tubing designed to fit syringe delivers medication to main IV line.
(2) Carefully apply pressure to syringe plunger, allowing tubing to fill with medication.	Ensures tubing is free of air bubbles to prevent air embolus.
(3) Place syringe into mini-infuser/syringe driver pump (follow product directions). Be sure syringe is secure.	
(4) Connect mini-infusion tubing to main IV line.	
(a) Stopcock: Wipe off stopcock port with alcohol swab and connect tubing. Turn stopcock to open position.	Stopcock reduces risk of needle-stick injuries.
(b) Needleless system: Wipe off needleless port and insert tip of mini-infuser tubing.	Needleless system reduces risk of needle-stick injuries.
(5) Explain purpose of medication and side effects to client and explain that medication is to be given through existing IV line. Ask client to report symptoms of discomfort at site. Check client's name against prescriber's orders and assess client's condition to ascertain if it is appropriate to administer medication.	Informs client of planned therapies and assesses if medicine is given to the correct client.
(6) Hang infusion pump with syringe on IV pole alongside main IV bag. Press button on pump to begin infusion. Optional: set alarm.	Pump automatically delivers medication at safe, constant rate based on volume in syringe. (Alarm is used if medication is delivered into heparin/saline lock.)
(7) Remove disposable gloves. Wash hands.	Reduces transmission of infection.
12. Observe client for signs of adverse reactions.	IV medications act rapidly.
13. During infusion, periodically check infusion rate and condition of IV site.	IV must remain patent for proper medication administration. Development of infiltration necessitates discontinuing infusion.

RECORDING AND REPORTING

- Record medication, dose, route and time administered on MAR.
- Record volume of fluid in medication bag or chamber on intake and output form.
- Report any adverse reactions to nurse in charge or prescriber.

HOME CARE CONSIDERATIONS

- Ensure that all needles contaminated by blood are disposed of in puncture-resistant containers (e.g. small sharps container, or if not available a coffee tin while a sharps container is being organised).
- Piggyback tubing and intravenous container should be disposed of in non-puncture container or according to agency policy.

Mini-infuser or syringe-pump

A mini-infuser pump is mains-powered or battery-operated and allows medications to be given in very small amounts (5–60 mL) within controlled infusion times, often using standard syringes (Figure 27-28). It is important that the infusion site is checked regularly for signs of puffiness, redness or pain (signs that IV has 'tissued'). Mechanical devices may continue the infusion without problems even if the site is damaged.

Piggyback infusion

A piggyback is a small IV bag or bottle (25–100 mL) connected to short tubing lines, which in turn connect to the upper port of a primary infusion line, or to an intermittent venous access. The set is called a piggyback because the small bag or bottle is set higher than the primary infusion bag or bottle. In the piggyback set-up, the main line does not infuse when the piggybacked medication is infusing. The port of the primary IV line contains a back-check valve that automatically stops flow of the primary infusion once the piggyback infusion flows. After the piggyback solution infuses and the solution within the tubing falls below the level of the primary infusion drip chamber, the back-check valve opens and the primary infusion again flows. The term 'piggyback line' is often used for the tandem infusion method described below.

A **tandem infusion** set-up is a small IV bag or bottle (25–100 mL) connected to a short tubing line in the lower port of a primary infusion line, or to an intermittent venous access line. The tandem set is placed at the same height as the primary infusion bag or bottle. In the tandem set-up, the tandem and the main line infuse simultaneously. The nurse must monitor the tandem set-up closely. If the tandem set-up is not immediately clamped when the medication is infused, the IV solution from the primary line will back up into the tandem line.

Figure 27-28 **Small-volume infusion pump.**

Dreamstime/Linqong.

Intermittent venous access

An intermittent venous access is an IV catheter not connected to an infusion, and is used for medication administration at designated intervals (Figure 27-29). If it is inserted peripherally it is often called an 'IV bung'; other devices may be inserted centrally (Portacath or peripherally inserted central catheter (PICC line) which may also give intermittent venous access).

The advantages of intermittent venous access include:

- cost savings resulting from the omission of continuous IV therapy
- convenience to the nurse by eliminating constant monitoring of flow rates
- increased mobility, safety and comfort for the client.

Prior to medication administration the cannula must be checked for patency (see Box 27-17). After an IV bolus or piggyback medication has been administered through an intermittent venous access, the access must be flushed with a solution to maintain patency and to ensure that all of the medication is administered into the vein. It is now widely accepted that Normal saline is as effective as the traditionally used heparin flush solution for peripheral catheters.

Figure 27-29 **Intermittently accessed peripheral intravenous catheter. Here a medication is being administered from a syringe, known as a 'bolus' dose.**

Wikimedia/Calleamanecer.

Key concepts

- Learning medication classifications improves understanding of nursing implications for administering medications with similar characteristics.
- Medication legislation regulates the production, distribution, prescription and administration of medications.
- All controlled substances are handled according to strict procedures that account for each medication.
- The nurse applies understanding of the physiology of medication action when timing administration, selecting routes, initiating actions to promote medication efficacy and observing responses to medications.
- The older person's body undergoes structural and functional changes that alter actions of medication and influence the manner in which nurses provide medication therapy.
- Children's medication doses are calculated on the basis of body surface area and/or weight.
- Each medication order should include the client's name, the order date, the medication name, dosage, route and time of administration and the prescriber's signature.
- A medication history should reveal allergies, medications a client is taking and client's compliance with therapy.
- Nurses should involve clients in the planning of medication administration.
- The seven rights of medication administration ensure accurate preparation and administration of medication doses: right medication, right dose, right client, right route, right time, right reason and right documentation.
- Nurses should administer only medications they prepare, and prepared medications are never left unattended.
- Medications should be charted immediately after administration.
- A nurse uses clinical judgement in determining the best time to administer prn medications.
- The nurse reports a medication error immediately.
- When preparing medications, the nurse checks the medication container label against the medication administration record three times.
- Air locks prevent leaking of medication through subcutaneous tissues and localise the medication in muscle tissue.
- The Z-track method for intramuscular injections protects subcutaneous tissues from irritating parenteral fluids.
- Failure to select injection sites by anatomical landmarks may lead to tissue, bone or nerve damage.
- Application of the principles of quality use of medications (QUM) improves client outcomes.

Learning outcomes

Mastery of content will enable you to:

- demonstrate a comprehensive understanding of the concepts of mobility and immobility
- describe the physiological and pathological influences on body alignment and joint mobility
- identify key changes in physiological and psychosocial function associated with immobility
- perform a comprehensive mobility and activity assessment and advocate for appropriate patient-centred care
- identify the key complication for each body system in relation to immobility
- develop nursing and collaborative interventions for preventing and treating immobility
- perform safe positioning and transfer techniques of the patient with impaired mobility
- describe the key active and passive range-of-motion exercises
- describe they key concepts of safe mobilisation and using aids for walking
- engage in a clinical reasoning process for immobility nursing management following a systematic approach.

Promoting mobility and preventing immobility

One of the fundamental aims of nursing practice is to assist the patient to maintain or regain independence. Individuals experiencing health breakdown often develop problems with mobility and movement which make it difficult to get into and out of beds and chairs, stand up, sit down and walk. Losing the ability to move purposefully and easily impinges on the individual's ability to remain physically independent in daily activities and invariably reduces quality of life.

Nurses use a range of interventions aimed at promoting mobility and movement. These typically include methods of helping patients walk, positioning of limbs, physical exercises, supportive equipment and techniques to help patients transfer from one place to another (Kneafsey 2007). When working in acute care settings, encouraging patients to mobilise may be a low priority compared with meeting their other needs. Yet, for the patient with impaired physical mobility, the resultant inactivity may lead to life-threatening complications, such as a pressure injury, deep vein thrombosis or pulmonary infection, as well as longer-term decreased functional ability.

This chapter will briefly review anatomy and physiology relating to body mechanics that are relevant to both the nurse's own body mechanics as well as the patient's activity–exercise pattern. Nursing practice will be outlined in relation to mobility, including nursing interventions to promote mobility and movement and prevent complications of immobility.

Overview of body mechanics, exercise and activity

The coordinated efforts of the musculoskeletal and nervous systems to maintain balance, posture and body alignment provide the foundation for safe and effective movement of the body during normal physical activity. Therefore the use of proper body mechanics is important for the safety and wellbeing of nurses and patients (see Table 28-1).

Body alignment

Body alignment refers to the relationship of one body part to another along a horizontal or vertical line. Correct alignment reduces strain on musculoskeletal structures, maintains adequate muscle tone and contributes to balance.

Body balance

Body balance is achieved when a relatively low centre of gravity is balanced over a wide, stable base of support and a vertical line falls from the centre of gravity through the base of support. The base of support is the foundation and the nervous system is responsible for muscle tone regulating and coordinating the amount of pull exerted by the individual muscles. When the vertical line from the centre of gravity does not fall through the base of support, the body loses balance. Body balance is also enhanced by proper **posture** – the body position that most favours function, requires the least muscular work to maintain and places the least strain on muscles, ligaments, cartilage and bones.

TABLE 28-1 Body mechanics for healthcare workers

Action	Rationale
When planning to move a patient, arrange for adequate help. Use mechanical aids	Two workers lifting together divide the workload by 50%. Mechanical aids reduce worker and patient injury
Encourage patient to help as much as possible	Promotes patient's independence and strength while minimising workload
Keep back, neck, pelvis and feet aligned. Avoid twisting	Reduces risk of injury to lumbar vertebrae and muscle groups. Twisting increases risk of injury
Flex knees; keep feet wide apart	A broad base of support increases stability
Position self close to patient (or object being lifted)	The force is minimised. 5 kg at waist height close to body is equal to 50 kg at arm's length
Use arms and legs (not back)	The leg muscles are stronger, larger muscles capable of greater work without injury
Slide patient towards yourself using a slide sheet	Sliding requires less effort than lifting. Slide sheet minimises shearing forces, which can damage patient's skin
Set (tighten) abdominal and gluteal muscles in preparation for move	Preparing muscles for the load minimises strain and stabilises the trunk

The maintenance of proper body alignment and posture is achieved by using two simple techniques:

- By separating the feet to a comfortable distance, the base of support can then easily be widened.
- Bending the knees and flexing the hips until the person is squatting and still maintaining proper back alignment by keeping the trunk erect will increase balance by bringing the centre of gravity closer to the base of support.

Coordinated body movement

Coordinated body movement is a result of weight, centre of gravity and balance. *Weight* is the force exerted on the body mass by gravity. When an object is lifted the lifter must overcome the object's weight and be aware of its centre of gravity; in symmetrical objects, the *centre of gravity* is located at the exact centre of the object. *Balance* is the even distribution of weight allowing an object to remain upright. The force of weight is always directed downwards. An object that is unbalanced has its centre of gravity away from the midline and falls without support. Because people are not geometrically perfect, their centres of gravity are usually at 55–57% of standing height and located in the midline. Like unbalanced objects, patients who fail to maintain a balance with their centre of gravity are unsteady, which places them at risk of falling.

Friction

Friction is a force that occurs in a direction opposing that of movement. As the nurse turns, transfers or moves a patient up in bed, friction must be minimised or prevented. The greater the surface area of an object, the greater the friction. This can present some issues when moving a patient. However, by following some basic principles, including using patient-movement devices such as a slide sheet, friction can be reduced.

A passive or immobilised patient has the potential to produce greater friction when moved. Thus, when possible, nurses should use the patient's strength and mobility in association with the appropriate lifting aid when transferring or moving the patient up in bed. This can be done by explaining the procedure and telling patients when to move. The use of a slide sheet reduces friction because the patient is more easily moved along the bed's surface.

Exercise and activity

Exercise is physical activity for the purpose of conditioning the body, improving health and maintaining fitness. It may also be used as a therapeutic measure. The exercise program chosen and developed for a patient depends heavily on the individual's **activity tolerance**, the kind and amount of exercise or activity that the person is able to perform. Physiological, emotional and developmental factors influence the patient's activity tolerance.

A program of regular physical activity and exercise promotes physical and psychological health (Department of Health 2014). An active lifestyle is important for maintaining and promoting health; it is also an essential treatment modality for many chronic diseases. A program of regular physical activity and exercise enhances functioning of all body systems, including cardiopulmonary functioning (endurance), musculoskeletal fitness (flexibility and bone integrity), weight control and maintenance (body image) and psychological wellbeing. For example, Cooney and colleagues' (2014) review of the evidence suggests that exercise and physical activity have significant effects on depression symptoms.

The best program of physical activity includes a combination of exercises that produce different physiological and psychological benefits. Isotonic, isometric and resistive isometric are three categories of exercise classified according to the type of muscle contraction involved. *Isotonic exercises* cause muscle contraction and changes in muscle length (isotonic contraction) – examples are walking, swimming, dance aerobics, jogging, bicycling, and moving arms and legs with light resistance. The benefits of isotonic exercises are increased circulation and respiratory functioning; increased osteoblastic activity (activity by bone-forming cells which maintain bone strength); and increased muscle tone, mass and strength.

Isometric exercises involve tightening or tensing of muscles without moving body parts (isometric contraction) – examples are quadriceps static exercises and contraction of the gluteal muscles. This form of exercise is ideal for patients who are unable to tolerate the increase in activity that is expected during isotonic exercises. An immobilised patient in bed easily accomplishes isometric exercises. The benefits are increased muscle mass, tone and strength (thus decreasing the potential for muscle wasting); and increased circulation to the involved body part.

Isometric exercises may also be resistive. *Resistive isometric exercises* are those where the person contracts the muscle while pushing against a stationary object or resisting the movement of an object. A gradual increase in the amount of resistance and length of time that the muscle contraction is held will increase muscle strength and endurance. Examples of resistive isometric exercises are push-ups, pushing against a footboard to move up in bed, and hip lifting. In hip lifting, the patient, who is in a sitting position, pushes with the hands against a surface such as the seat of a chair and raises the hips. Resistive isometric exercises help to promote muscle strength

and provide sufficient stress against bone to promote osteoblastic activity.

Regulation of movement

Coordinated body movement involves integrated functioning of the skeletal, muscular and nervous body systems. Because of the integrative nature of these three systems in mechanical support of the body, they are often considered as a single functional unit.

Musculoskeletal system

Bones perform five major functions in the body: support, protection, movement, mineral and fat storage and haematopoiesis (blood-cell formation) (Marieb & Hoehn 2015). In the discussion of body mechanics, two of these functions – support and movement – are most important. In *support*, bones serve as the framework and contribute to the shape, alignment and positioning of the body parts. In *movement*, bones together with their joints constitute levers for muscle attachment. As muscles contract and shorten, they pull on bones, producing joint movement.

Joints

An articulation, or *joint*, is the connection between bones. Each joint is classified according to its structure and degree of mobility. On the basis of connective structures, joints are classified as fibrous, cartilaginous or synovial. *Fibrous joints* fit closely together and are fixed, permitting little, if any, movement (i.e. the skull). *Cartilaginous joints* have little movement but are elastic and use cartilage to unite separate body surfaces (i.e. spinal joints). *Synovial joints*, or true joints, are freely movable and are the most mobile, numerous and anatomically complex of the body's joints (i.e. the elbow, the knee, etc.).

Ligaments, tendons and cartilage

These are structures that support the skeletal system. *Ligaments* are white, shiny, flexible bands of fibrous tissue that bind joints and connect bones and cartilage. Ligaments are elastic and aid joint flexibility and support. In some areas of the body, ligaments also have a protective function. *Tendons* are white, glistening, fibrous bands of tissue that connect muscle to bone. *Cartilage* is avascular, supporting connective tissue with the flexibility of a firm, plastic material. The characteristics of cartilage permit it to sustain weight and serve as a shock-absorber between articulating bones.

Skeletal muscle

When we walk, talk, run, breathe or participate in physical activity, we do so by contracting skeletal muscles. There are over 600 skeletal muscles in the body. In addition to facilitating movement, these muscles determine the form and contour of our bodies. Most of our muscles span at least one joint and attach to both articulating bones. When contraction occurs, one bone is fixed while the other moves. The *origin* is the point of attachment that remains still; the *insertion* is the point that moves when the muscle contracts (Marieb & Hoehn 2015).

The muscles of movement are located near the skeletal region, where movement is caused by a lever system. The lever system makes the work of moving a weight or load easier. It occurs when specific bones, such as the humerus, ulna and radius, and the associated joints, such as the elbow, act as a lever. Thus, the force applied to one end of the bone to lift a weight at another point tends to rotate the bone in the direction opposite to that of the applied force. Muscles that attach to bones of leverage provide the necessary strength to move the object.

Gravity is constantly pulling on parts of the body. The only way the body can be held in position is for muscles to exert a force on bones in the opposite direction. Muscles accomplish this counterforce by maintaining a low level of sustained contraction. Poor posture places more work on muscles to counteract the force of gravity. This leads to fatigue and can eventually interfere with bodily functions and cause deformities.

The antagonistic, synergistic and antigravity muscle groups are coordinated by the nervous system and maintain posture and initiate movement.

- *Antagonistic muscles* bring about movement at the joint. During movement, the active mover muscle contracts while its antagonist relaxes. For example, during flexion of the arm the active mover, the biceps brachii, contracts and its antagonist, the triceps brachii, relaxes. During extension of the arm the active mover, now the triceps brachii, contracts and the new antagonist, the biceps brachii, relaxes.
- *Synergistic muscles* contract to accomplish the same movement. When the arm is flexed, the strength of the contraction of the biceps brachii is increased by contraction of the synergistic muscle, the brachialis. Thus with synergistic muscle activity there are now two active movers – the biceps brachii and the brachialis – which contract while the antagonistic muscle, the triceps brachii, relaxes.
- *Antigravity muscles* are involved with joint stabilisation. These muscles continuously oppose the effect of gravity on the body and permit a person to maintain an upright or sitting posture. In an adult, the antigravity muscles are the extensors of the leg, the gluteus maximus, the quadriceps femoris, the soleus muscles and the muscles of the back.

Skeletal muscles support posture and carry out voluntary movement. The muscles are attached to the skeleton by tendons, which provide strength and permit motion. The movement of the extremities is voluntary and requires coordination from the nervous system.

Nervous system

Movement and posture are regulated by the nervous system. The major voluntary motor area, located in the cerebral cortex, is the precentral gyrus. A majority of motor fibres descend (via pyramidal pathways) from the motor cortex and cross at the level of the medulla. Thus the motor fibres from the right motor cortex initiate voluntary movement for the left side of the body, and vice versa. The cerebellum and basal ganglia integrate information from the motor cortex as well as sensory input to plan and coordinate complex motor activities (Marieb & Hoehn 2015).

Transmission of impulses from the nervous system to the musculoskeletal system is an electrochemical event. The neurotransmitter acetylcholine transfers the electric impulse from the nerve across the neuromuscular junction to stimulate the muscle, causing contraction.

Proprioception

Proprioception is the awareness of the position of the body and its parts. Proprioceptors are specialised receptors located in skeletal muscles, tendons, joints, ligaments and connective-tissue coverings of bones and muscles (Marieb & Hoehn 2015). During daily activities, proprioceptors constantly advise the brain of our body movements and position by monitoring how much the tissues containing the receptors are stretched.

Balance

Balance centres in the central nervous system (i.e. vestibular nuclei in the brainstem and cerebellum) respond to information from three main sources about the body's position in space. The vestibular apparatus in the inner ear (receptors in the semicircular canals and vestibule) respond to changes in body position and send signals to the brain. Balance centres also receive input through vision as well as somatic receptors, such as proprioceptors (Marieb & Hoehn 2015). These centres initiate reflexes that fix the eyes on objects and activate muscles to maintain balance.

Pathological influences on mobility

Many pathological conditions affect mobility. Although a complete description of each is beyond the scope of this chapter, an overview of four pathological influences is presented here: postural abnormalities, impaired muscle development, damage to the central nervous system and direct trauma to the musculoskeletal system. Common abnormal assessment findings of the musculoskeletal system are presented in Table 28-2.

Postural abnormalities

Congenital or acquired postural abnormalities affect the efficiency of the musculoskeletal system, as well as body alignment, balance and appearance. During the nursing assessment, body alignment and range of motion (ROM) are observed. Postural abnormalities can cause pain and impair alignment and mobility. Some postural abnormalities may limit ROM. Nurses intervene to maintain maximum ROM in unaffected joints and then may design interventions to strengthen affected muscles and joints, improve the patient's posture and adequately use affected and unaffected muscle groups. Referral to and/or collaboration with a physiotherapist may enhance nursing interventions for a patient with a postural abnormality.

Impaired muscle development

Injury and disease can lead to numerous alterations in musculoskeletal function. The *muscular dystrophies* are a group of familial disorders that cause degeneration of skeletal muscle fibres. The most prevalent of the muscle diseases in childhood, the muscular dystrophies are characterised by progressive, symmetrical weakness and wasting of skeletal muscle groups, with increasing disability and deformity (Nash 2014).

Damage to the central nervous system

Damage to any component of the central nervous system that regulates voluntary movement results in impaired body alignment and mobility. Neurological diseases, such as multiple sclerosis and Parkinson's disease, can cause progressive mobility problems. The motor cortex can be damaged by trauma such as a head injury, stroke or meningitis. Motor impairment is directly related to the location and amount of destruction of the motor cortex. For example, a person with a right-sided cerebral haemorrhage with complete necrosis is likely to have destruction of the right motor cortex and left-sided hemiplegia.

Trauma to the descending pathways in the spinal cord involved in motor control, such as the pyramidal (corticospinal) tracts, also impairs mobility. The most common trauma is transection of the spinal cord in which motor fibres are damaged. If the injury is complete, it is likely to cause a complete bilateral loss of voluntary motor control below the level of the trauma. Spinal cord trauma frequently results from motor vehicle accidents, gunshot or knife wounds to the neck and back.

TABLE 28-2 Common assessment abnormalities of the musculoskeletal system

Finding	Description	Possible aetiology and significance
Ankylosis	Scarring within a joint leading to stiffness or fixation	Chronic joint inflammation
Atrophy	Wasting of muscle, characterised by decreased circumference and flabby appearance leading to decreased function and tone	Muscle denervation, contracture, prolonged disuse as a result of immobilisation
Contracture	Resistance of movement of muscle or joint as a result of fibrosis of supporting soft tissues	Shortening of muscle or ligaments, tightness of soft tissue, incorrect positioning of immobilised extremity
Crepitation (crepitus)	Crackling sound or grating sensation as a result of friction or broken bone or cartilage bits in joint	Fracture, dislocation, chronic inflammation, osteoarthritis
Effusion	Fluid in joint, possibly with swelling and pain	Trauma, especially to knees; inflammation
Ganglion	Small fluid-filled synovial cyst usually on dorsal surface of wrist or foot	Degeneration of connective tissue close to tendons and joints leading to formation of small cysts
Hypertrophy	Increase in size of muscle as a result of enlargement of existing cells	Exercise or other increased stimulation, increased androgens
Kyphosis (dowager's hump)	Anteroposterior or forward bending of thoracic spine with convexity of curve in posterior direction	Poor posture, tuberculosis, arthritis, osteoporosis, growth disturbance of vertebral epiphyses
Lordosis	Lumbar spinal deformity resulting in anteroposterior curvature with concavity in posterior direction	Secondary to other spinal deformities, muscular dystrophy, obesity, flexion contracture of hip, congenital dislocation of hip
Pesplanus	Flatfoot	Congenital condition, muscle paralysis, mild cerebral palsy, early muscular dystrophy
Scoliosis	Deformity resulting in lateral curvature of thoracic spine	Idiopathic or congenital condition, fracture or dislocation, osteomalacia
Subluxation	Partial dislocation of joint	Instability of joint capsule and supporting ligaments (e.g. from trauma, arthritis)
Valgus (bow legs)	Angulation of bone away from midline	Alteration in gait, pain, arthritis
Varus (knock-knees)	Angulation of bone towards midline	Alteration in gait, pain, arthritis

Brown D, Edwards H (eds) 2012 Lewis's Medical–surgical nursing: assessment and management of clinical problems, 3rd edn. Mosby, Sydney.

Direct trauma to the musculoskeletal system

Direct trauma to the musculoskeletal system can result in contusions, sprains and fractures. A **fracture** is a disruption of bone tissue continuity. Fractures most commonly result from direct external trauma, but they can also occur as a consequence of some deformity of the bone (e.g. pathological fractures of osteoporosis, Paget's disease or osteogenesis imperfecta). As the fracture heals, bone begins to repair. The fractured bone initiates a cellular process that results in bone formation. Young children are able to form new bone more easily than adults and, as a result, have few complications after a bone fracture. Treatment includes positioning the fractured bone in proper alignment and immobilising it to promote healing and restore function. Immobilisation results in some muscle atrophy, loss of tone and joint stiffness.

Acquired or congenital conditions that affect the structure of the musculoskeletal or nervous system impair body alignment or joint mobility. Impairment can be temporary or permanent. Regardless of the duration of the impairment, the nursing care plan includes interventions that maintain the present level of alignment and joint mobility and/or increase the patient's level of motor function.

Complications of immobility

Fully understanding mobility requires more than an overview of normal body mechanics and the regulation of movement by the musculoskeletal and nervous systems. Having knowledge of how **immobility** affects physical and psychosocial functioning can help you prevent, assess for and manage complications caused by impaired mobility. Putting this nursing knowledge and skill into practice

can mean the difference between patient recovery and independence, and costly and life-threatening complications, functional decline and disability.

Nurses have always been concerned with the clinical problems caused by immobility and have developed a body of knowledge over time. It is instructive to read a collection of classic articles published almost half a century ago in the *American Journal of Nursing*, entitled 'The hazards of immobility', which summarised the physiological changes that occur in healthy, ill and injured people who undergo bed rest (Olson 1967). The articles described the detrimental effects of immobility on cardiovascular, respiratory, gastrointestinal, musculoskeletal, urinary, metabolic and psychosocial health, with implications for nursing practice. Today there is a large and growing body of nursing research that examines the effectiveness of interventions to prevent and manage the complications of immobility.

Mobility refers to a person's ability to move about freely, whereas *immobility* refers to the inability to move about freely. Mobility and immobility are best understood as the end points on a continuum. Some patients move back and forth on this continuum, but for other patients immobility is absolute and continues indefinitely. The terms 'bed rest' and 'impaired physical mobility' are frequently used when discussing patients on the mobility–immobility continuum.

Bed rest is an intervention that restricts patients to bed for therapeutic reasons. Bed rest is most often prescribed by nursing and medical staff and may have different interpretations among healthcare professionals. For example, in some settings bed rest may mean strict confinement to the bed or 'complete bed rest', while in others patients on bed rest may be assisted to use a bedside commode or go to the bathroom. Patients with a wide variety of conditions are placed on bed rest, and the duration of bed rest depends on the illness or injury and the patient's prior state of health.

Impaired physical mobility is defined as a 'limitation in independent, purposeful movement of the body or of one or more extremities' (Carpenito-Moyet 2013:390). Alterations in the level of physical mobility can result from prescribed restriction of movement in the form of bed rest, physical restriction of movement because of external devices (e.g. a cast or skeletal traction), voluntary restriction of movement or impairment of motor or skeletal function.

The deleterious effects of muscular deconditioning associated with lack of physical activity may be apparent within days. The normal individual on complete bed rest loses muscle strength from baseline levels at a rate of 3% a day (Nash 2014). Bed rest is also associated with other systemic complications. The term 'disuse atrophy' has been used to describe the pathological reduction in the normal size of muscle fibres after prolonged inactivity from bed rest, trauma, casting, or local nerve damage (Nash 2014).

Periods of immobility or prolonged bed rest can cause major physiological and psychological effects. These effects can be gradual or immediate, and vary from patient to patient. The greater the extent and the longer the duration of immobility, the more pronounced the consequences. A sedentary lifestyle will increase the risks of associated immobility complications. In society today many people lead relatively sedentary lives, working at computers, watching television for long periods of time and with overall decreasing levels of activity. When these people require nursing care their levels of activity need to be identified in order to assess increased potential for immobility complications. The patient with complete mobility restrictions is continually at risk of complications.

Systemic effects of immobility

All body systems work more efficiently with some form of movement. Exercise has been shown to have positive outcomes for all major systems of the body. Therefore, when there is an alteration in mobility, each body system is at risk of impairment. The severity of the impairment depends on the patient's overall health, degree and length of immobility, and age. For example, older adults with chronic illnesses develop pronounced effects of immobility more quickly than do younger patients with the same degree of immobility.

Metabolic changes

Immobility disrupts normal metabolic functioning, including decreasing the metabolic rate; altering the metabolism of carbohydrates, fats and proteins; causing fluid, electrolyte and calcium imbalances; and causing gastrointestinal disturbances such as decreased appetite and slowing of peristalsis. However, in the presence of an infectious process, immobilised patients may have an increased basal metabolic rate as a result of fever or wound healing because these increase cellular oxygen requirements.

A deficiency in kilojoules and protein is characteristic of patients with a decreased appetite secondary to immobility. Proteins are constantly being synthesised and broken down into amino acids in the body to be re-formed into other proteins. Amino acids that are not used are excreted. The body can synthesise certain non-essential amino acids, but depends on ingested proteins to supply the eight essential amino acids. When more nitrogen (the

end-product of amino-acid breakdown) is excreted than is ingested in proteins, the body is said to have a negative nitrogen balance, and weight loss, decreased muscle mass and weakness result from tissue catabolism (tissue breakdown). Protein loss leads to muscle loss.

Another metabolic change is increased calcium loss from bones, resulting in *hypercalcaemia*. As a result, urinary excretion of calcium increases because immobility causes the release of calcium into the circulation.

Decreased gastrointestinal motility that develops from immobility can lead to various impairments of gastrointestinal functioning. Constipation is a common problem, although diarrhoea may result from a faecal impaction (accumulation of hardened faeces). This finding is not normal diarrhoea but rather liquid stool passing around the area of impaction (see Chapter 32). Left untreated, faecal impaction can result in a mechanical bowel obstruction that may partially or completely occlude the intestinal lumen, blocking normal propulsion of liquid and gas. The resulting fluid in the intestine produces distension and increases intraluminal pressure. Over time, intestinal function becomes depressed, dehydration occurs, absorption ceases and fluid and electrolyte disturbances worsen.

Respiratory changes

Regular aerobic exercise is known to enhance respiratory functioning. Lack of movement and exercise places patients at higher risk of respiratory complications. Postoperative and immobile patients are at high risk of developing pulmonary complications. The most common respiratory complications are **atelectasis** (collapse of alveoli) and **hypostatic pneumonia** (inflammation of the lung from stasis or pooling of secretions). In atelectasis, secretions block a bronchiole or a bronchus and the distal lung tissue (alveoli) collapses as the existing gas is absorbed, producing hypoventilation. The site of the blockage determines the extent of atelectasis. A lung lobe or even a whole lung may be collapsed. Pooling secretions and decreased ability to cough productively increase the collection of mucous in the bronchi, particularly when the patient is in the supine, prone or lateral position (Figure 28-1). Secretions accumulate in the dependent regions of the airways (Figure 28-2). Because mucous is an excellent medium for bacterial growth, hypostatic pneumonia may result.

Cardiovascular changes

Orthostatic (or postural) hypotension is defined as a reduction in systolic blood pressure of at least 20 mmHg or diastolic blood pressure of at least 10 mmHg within 3 minutes of standing from a lying position (Consensus Committee of the American Autonomic Society and the American Academy of Neurology 1996). Patients with orthostatic hypotension may present with lightheadedness, blurred vision, dizziness, weakness and fatigue, or with syncope. In the immobilised patient, decreased circulating fluid volume, pooling of blood in the lower extremities and decreased autonomic response occur. These factors result in decreased venous return, followed by a decrease in cardiac output, which is reflected by a decline in blood pressure.

As the workload of the heart increases, so does oxygen consumption. The heart therefore works harder and less efficiently during periods of prolonged rest. As immobilisation increases, cardiac output falls, further decreasing cardiac efficiency and increasing workload.

Patients are also at risk of *thrombus formation*, such as a deep-vein thrombosis (DVT) (Figure 28-3). A *thrombus*

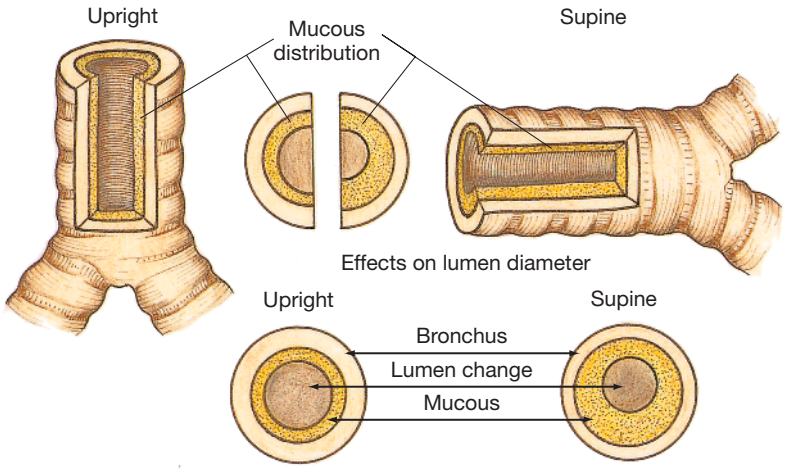

Figure 28-1 Effect of recumbency and gravity on distribution of respiratory tract and diameter of bronchiolar lumen.

Nobel SI, Shelley MD, Coles B et al 2008 Management of venous thromboembolism in patients with advanced cancer: a systematic review and meta-analysis. Lancet Oncology 9(6):577–84. © 2008 Elsevier Ltd.

is an accumulation of platelets, fibrin, clotting factors and the cellular elements of the blood attached to the interior wall of a vein or artery, sometimes occluding the lumen of the vessel. There are three factors that contribute to venous thrombus formation (known as Virchow's triad):

1. Venous stasis (e.g. poor venous return associated with bed rest and immobility)
2. Damage to the endothelium (inner lining of the vein), and
3. Hypercoagulability of the blood (Soars 2015).

A dislodged thrombus, called an **embolus**, may travel through the circulatory system to the lungs (called a pulmonary embolism or PE) or brain, where they are life-threatening.

Musculoskeletal changes

The effects of immobility on the musculoskeletal system can include permanent impairment of mobility. Restricted mobility may result in loss of endurance, strength and muscle mass. Other effects of restricted mobility affecting the skeletal system are impaired calcium metabolism and impaired joint mobility.

Decreased mobility and muscle atrophy – loss of muscle tissue – may occur with immobility. Pathological atrophy is a phenomenon widely observed in response to illness, decreased **activities of daily living (ADLs)**, and immobilisation (Craft et al 2014). Because of protein breakdown, the patient loses lean body mass, which is composed partially of muscle. Therefore, the reduced muscle mass is unable to sustain activity without increased fatigue. The muscle mass is decreased from metabolic causes and disuse. As immobility continues and the muscles are not exercised, there is continued decrease in mass. Loss of endurance, decreased muscle mass and strength, and joint instability subsequent to immobility put patients at risk of falls (see Chapter 12).

Immobilisation causes two skeletal changes: impaired calcium metabolism and joint abnormalities. Because immobilisation results in bone reabsorption, the bone tissue is less dense, or is atrophied and disused and can result in *osteoporosis*. When osteoporosis occurs, the patient is at risk of pathological fractures. Immobilisation and non-weightbearing activities increase the rate of bone reabsorption. Bone reabsorption also causes calcium to be released in the blood, and hypercalcaemia results.

Based on a recent study measuring bone density in a population sample, the prevalence of osteoporosis among those aged 50 and over was estimated to be 23% of women and 6% of men. This estimate includes both diagnosed and undiagnosed cases of osteoporosis (AIHW 2014).

More women are affected because of the postmenopausal rapid decline of oestrogen, a hormone that plays a central role in the maintenance of bone mass balance. Osteoporosis increases the risk of fractures. In 2011–12 over 19,000 people were hospitalised due to hip fractures (AIHW 2014). It is imperative for nurses to recognise that immobilised patients may be at high risk of accelerated bone loss if they have primary osteoporosis. Early patient evaluation and consultation and referral to nutritionists and physiotherapists are important interventions for

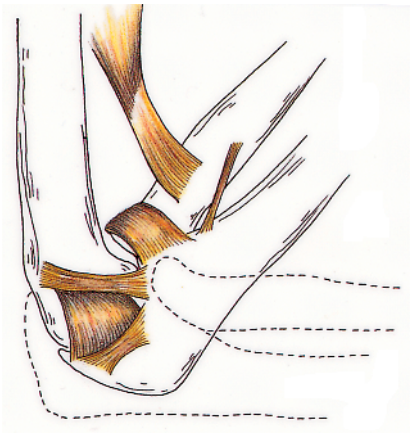

Figure 28-4 **Contracture of the elbow: inability to extend to a 90-degree angle (dotted line) and to a 180-degree angle (not illustrated).**

preventing disability in patients with primary osteoporosis who become immobilised.

Immobility can lead to joint contractures. A **joint contracture** is an abnormal and possibly permanent condition characterised by fixation of the joint (Figure 28-4). It is caused by disuse, atrophy and shortening of the muscle fibres. When a contracture occurs, the joint cannot obtain full range of motion. Contractures may leave a joint in a non-functional position.

One common and debilitating contracture is **footdrop** (Figure 28-5). When footdrop occurs, the foot is permanently fixed in plantar flexion. Walking is difficult with the foot in this position, since the person cannot dorsiflex the foot. The patient with footdrop is therefore unable to lift the toes off the ground. Patients who have suffered strokes with resulting left- or right-sided paralysis (hemiplegia) are susceptible to footdrop.

Urinary elimination changes

The patient's urinary elimination is altered by immobility. In the upright position, urine flows out of the renal pelvis and into the ureters and bladder because of gravitational forces. When the patient is recumbent or flat, the kidneys and the ureters move towards a more level plane. Urine formed by the kidney must enter the bladder unaided by gravity. Because the peristaltic contractions of the ureters are insufficient to overcome gravity, the renal pelvis may fill before urine enters the ureters (Figure 28-6). This condition is called urinary stasis and increases the risk of urinary tract infection (UTI) and renal calculi (see Chapter 33).

Renal calculi are calcium stones that lodge in the renal pelvis and pass through the ureters (Figure 28-7). Immobilised patients are at risk of calculi because of altered calcium metabolism and the resulting hypercalcaemia.

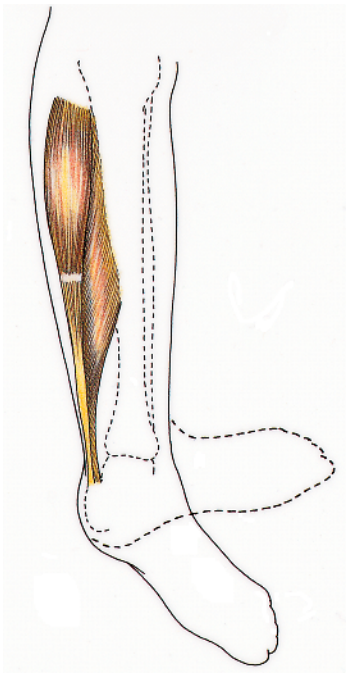

Figure 28-5 **Footdrop. Ankle is fixed in a plantar flexion. Normally the ankle is able to flex (dotted line), which eases walking.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

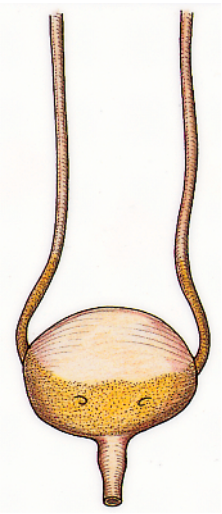

Figure 28-6 **Stasis of urine with reflux to ureters.**

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

As the period of immobility continues, fluid intake can diminish; other causes, such as fever, increase the risk of dehydration. As a result, urinary output declines and urine is usually highly concentrated. This concentrated urine increases the risk of calculi formation and infection. Poor perineal care after bowel movements, particularly in women, increases the risk of urinary tract contamination by *Escherichia coli bacteria*. Another cause of UTIs in

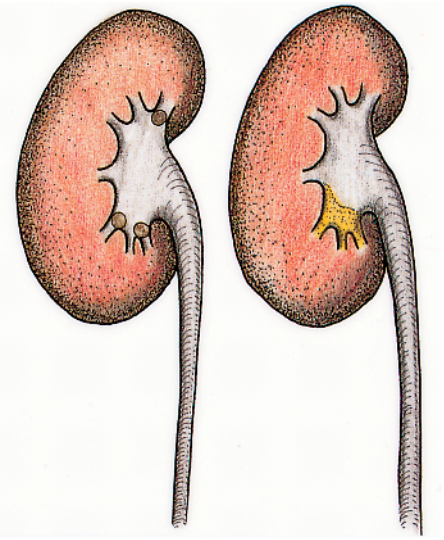

Figure 28-7 **Types of renal calculi in the renal pelvis.**

immobilised patients is the use of an indwelling urinary catheter.

Integumentary changes

The direct effect of pressure on the skin is compounded by the changes in metabolism that accompany immobility. Older adults and patients with paralysis also have a greater risk of developing pressure ulcers. Any break in the skin's integrity is difficult to heal in the immobilised patient.

A *pressure ulcer* is an impairment of the skin as a result of prolonged ischaemia to tissues (see Chapter 26). The ulcer is characterised initially by inflammation and usually forms over a bony prominence. Ischaemia develops when the pressure on the skin is greater than the pressure inside the small peripheral blood vessels supplying blood to the skin.

Tissue metabolism depends on the body's receipt of oxygen and nutrients from the blood supply and the elimination of metabolic wastes. Any factor that interferes with perfusion will affect cellular metabolism and, as a result, the function of the cell. Pressure affects cellular metabolism by decreasing or obliterating tissue circulation. When a patient lies in bed or sits in a chair, the weight of the body is on bony prominences. The longer the pressure is applied, the longer the period of ischaemia and therefore the greater the risk of skin breakdown.

Psychosocial effects

Immobilisation may lead to emotional and behavioural responses, sensory alterations and changes in coping. These changes are individualised to each patient. In addition, immobilised patients may also have social and family difficulties.

The most common emotional changes are depression, behavioural changes, sleep–wake disturbances and impaired coping. The immobilised patient can become depressed because of changes in role, self-concept and other factors. *Depression* is an affective disorder characterised by extreme feelings of sadness, melancholy, dejection, worthlessness, emptiness and hopelessness out of proportion to reality. Depression can result from worrying about present and future levels of health, finances and family needs. Because immobilisation removes patients from their daily routine, they have more time to worry about disability. Worrying can quickly increase depression, causing withdrawal. Assessing behavioural changes throughout restricted mobility helps to identify changes in self-concept, recognise early signs of depression and develop nursing interventions (see Chapter 40).

Behavioural changes resulting from immobilisation vary widely, depending on the patient. Common behavioural changes include hostility, fear and anxiety. Early in the clinical reasoning process nurses will interview the patient and the patient's family and friends about normal behavioural patterns to gain baseline data. If unexpected behaviours are observed later, nurses can intervene to reduce the effects of immobilisation on the patient's behavioural patterns.

The immobilised patient requires frequent and regular nursing care. Because of physiological hazards, the patient cannot be allowed to sleep for 8 hours without a change of position or other nursing care. *Disruption of normal sleeping patterns* can further cause behavioural changes. Nursing interventions should be used to ensure that the patient receives sufficient sleep (see Chapter 30). The patient who is on bed rest and able to change position during sleep does not require continuous physical nursing care directed at reducing the hazards of immobility. Unless other treatment activities are required during the night, the care plan for the physiologically stable patient on bed rest should provide for uninterrupted sleep.

Long-term immobility or bed rest can affect usual *coping patterns*. Such a patient may withdraw and become passive. The passive patient allows nurses to provide care but is not interested in increasing independence or being involved in care. Early in the care of an immobilised patient, the patient's normal coping mechanisms should be assessed. A nursing care plan is then developed that will enable the patient to continue to use these coping abilities or help the patient develop new ones.

Developmental changes

Developmental changes tend to be associated more with immobility in the very young and in older adults.

The immobilised young or middle-aged adult who has been healthy may experience few, if any, developmental changes. However, there are exceptions and patients must be fully assessed for developmental implications. One exception might be permanent immobilisation as the result of a spinal cord injury.

Infants, toddlers and preschoolers

The newborn infant's spine is flexed and lacks the anteroposterior curves of the adult (see Chapter 16). As the baby grows, musculoskeletal development permits support of weight for standing and walking. Posture is awkward because the head and upper trunk are carried forward. Because bodyweight is not evenly distributed along a line of gravity, posture is off-balance, and falls occur often. When the infant, toddler or preschooler is immobilised, it is usually because of trauma or the need to correct a congenital skeletal abnormality. Prolonged immobilisation can delay the child's gross motor skills and intellectual development. Nurses caring for immobilised children should plan activities that provide physical and psychosocial stimulation.

Adolescents

The adolescence stage is usually initiated by a tremendous growth spurt (see Chapter 16) where growth is frequently uneven. Prolonged immobilisation may alter adolescent growth patterns, causing the adolescent to lag behind peers in gaining independence. When immobilisation occurs, social isolation is often a major concern for this age group.

Adults

An adult who has correct posture and body alignment feels good and generally appears self-confident. The healthy adult also has the necessary musculoskeletal development and coordination to carry out ADLs (see Chapter 17). When periods of prolonged immobility occur, all physiological systems are at risk. In addition, the role of the adult may change with regard to the family or social structure, such as loss of identity associated with a job.

Older adults

A progressive loss of total bone mass occurs with the older adult. Some of the possible causes of this loss include decreased physical activity, hormonal changes and actual bone reabsorption. The effect of bone loss is weaker bones and, as a result, older adults may walk more slowly, walk bent over, take smaller steps and appear less coordinated. When balance is impaired, they are at greater risk of falls and injuries (see Chapter 18). Falls in older adults are associated with immediate serious consequences such as fractures and head injuries, as well as longer-term functional decline (Grealish & Chaboyer 2015).

Older adults are also at risk of decreased functional status and impaired mobility secondary to hospitalisation (see Box 28-1). Immobilisation of older adults may increase their physical dependence on others, which accelerates functional losses. Immobilisation of some older adults can result from degenerative diseases, trauma or chronic illness. For some older adults, immobilisation occurs gradually and progressively; whereas for others, especially those who have had a stroke, immobilisation is sudden. When providing nursing care for an older adult, the plan of care developed should be one that encourages the patient to perform as many self-care activities as possible, thereby maintaining the highest level of mobility (see *Research highlight*).

BOX 28-1 Hazards of hospitalisation of the older adult

- For many older people, hospitalisation results in functional decline despite cure or repair of the condition for which they were admitted. Hospitalisation can result in complications unrelated to the problem that caused admission or to its specific treatment, and for reasons that are explainable and avoidable.
- Usual ageing is often associated with functional change, such as a decline in muscle strength and aerobic capacity; vasomotor instability; reduced bone density; diminished pulmonary ventilation; altered sensory continence, appetite and thirst; and a tendency towards urinary incontinence. Hospitalisation and bed rest superimpose factors such as enforced immobilisation, reduction of plasma volume, accelerated bone loss, increased closing volume and sensory deprivation. Any of these factors may thrust vulnerable older people into a state of irreversible functional decline.
- The factors that contribute to a cascade to dependency are identifiable and can be avoided by modification of the usual acute hospital environment by de-emphasising bed rest, removing the hazard of the high hospital bed with rails and actively facilitating ambulation and socialisation.

Creditor MC 1993 Hazards of hospitalization of the elderly. Ann Intern Med 118(3):219.

• CRITICAL REFLECTION POINT

Critical thinking and sound clinical judgement when caring for patients with impaired mobility requires nurses to draw on their knowledge of mobility and immobility and on previous experience, and apply evidence-based practices

RESEARCH HIGHLIGHT

Research focus

In older patients, acute medical illness that requires hospitalisation is a sentinel event that often precipitates disability. This results in the subsequent inability to live independently and complete basic activities of daily living (ADLs). This nursing research examined the association between mobility levels of older adults during hospitalisation and functional outcomes at discharge and 1-month follow-up.

Research abstract

Design: Prospective cohort study.

Setting: A 900-bed teaching hospital in Israel.

Participants: 525 older (≥ 70 years) acute medical patients hospitalised for a non-disabling condition.

Measurements

In-hospital mobility was assessed using a previously validated scale. The main outcomes were decline from premorbid baseline functional status at discharge (ADLs) and at 1-month follow-up (ADLs and instrumental ADLs). Hospital mobility levels and functional outcomes were assessed according to prehospitalisation functional trajectories. Logistic regressions were modelled for each outcome, controlling for functional status, morbidity and demographic characteristics.

Results

Forty-six per cent of participants had declined in ADLs at discharge and 49% at follow-up; 57% had declined in IADLs at follow-up. Mobility during hospitalisation was twice as high in participants with no pre-admission functional decline.

Low versus high in-hospital mobility was associated with worse basic functional status at discharge (adjusted odds ratio (AOR) = 18.03; 95% confidence interval (CI) = 7.68–42.28) and at follow-up (AOR = 4.72; 95% CI = 1.98–11.28) and worse IADLs at follow-up (AOR = 2.00; 95% CI = 1.05–3.78). The association with poorer discharge functional outcomes was present in participants with pre-admission functional decline (AOR for low vs high mobility = 15.26; 95% CI = 4.80–48.42) and in those who were functionally stable (AOR for low vs high mobility = 10.12; 95% CI = 2.28–44.92).

Evidence-based practice

- The results of this study show that low levels of in-hospital mobility were associated with functional decline of older adults at discharge and, even more so, at follow-up.
- In-hospital mobility, unlike personal and disease-related risk factors, is a potentially modifiable care aspect that has important implications for in-hospital care regimens.
- Level of mobility was significantly related to functional outcomes of patients whether or not they had functional decline before their hospitalisation, indicating the value of developing and evaluating a policy for the early and effective mobilisation of all older hospitalised patients in general medical units.

and professional standards. Patients with impaired mobility often have multiple needs, which must be prioritised. To understand the impact of immobility on the patient and family, nurses integrate knowledge from nursing and other disciplines, previous experiences and information gathered from patients.

CLINICAL EXAMPLE

You are a student nurse caring for Albert Devereaux, an alert and oriented 81-year-old man, admitted to hospital after a fall with complaints of dizziness and syncope. His blood pressure (BP) on admission was 80/40 mmHg. At the aged care nursing facility where he lives, he ambulated with a walker independently but, since a recent episode of syncope, he has complained of weakness and needs another person to assist him while walking as a fall precaution.

Nursing staff found Mr Devereaux lying on the floor on his right hip, and he explained, 'I had to go to the bathroom. I know I should have called for help, but the nurses are so busy. I figured I could go myself. Only two more steps and I could have reached my walker. I just slipped.' He reports pain in his right hip that is a 5 on a 0–10 numerical pain rating scale, which he describes as an 'ache' that is worse with movement of his right leg.

An X-ray of his right hip is taken, which is negative for a fracture. You take a set of orthostatic vital signs: lying BP = 110/80 mmHg, heart rate = 73 beats per minute; standing BP = 90/50 mmHg, heart rate = 92 beats per minute. His other vital signs are temperature 36.8°C, respiratory rate 16 breaths per minute, oxygen saturation (SpO_2) 99% on room air.

No injuries are noted on inspection and palpation of his head and neck. Pupils are equal and react briskly to light. His chest is clear to auscultation, heart sounds are irregular. There is full range of motion in the upper extremities and handgrip strength is bilaterally equal. His abdomen is soft and non-tender. There is no physical deformity of the right hip or other injuries apparent, but a moderate amount of

continued

ecchymosis is visible over his right hip that extends around to his lower back and right upper buttock. He demonstrates normal movement and sensation in both feet. He has requested the urinal once for 200 mL of clear yellow urine. An electrocardiogram confirms his known history of atrial fibrillation.

Mr Devereaux is admitted, and his plan of care includes assessment of orthostatic vital signs every shift and fall precautions. You explain to him how to use the call light and he remains on bed rest with side rails up. Later in the shift Mr Devereaux tells you he is worried about the consequences of this fall for his mobility and independence.

Adapted from Douglas C 2001 Pulling it all together. In Lewis P, Foley D (eds) Weber & Kelley's Health assessment in nursing. Lippincott Williams & Wilkins, Philadelphia.

• CRITICAL REFLECTION POINT

1. **Based on the *Clinical example* above, construct a concept map which demonstrates all the significant assessment data from the case study and the relationships or links among this data.**
2. **What priority nursing interventions would you implement for Mr Devereaux to maintain his safety and promote normal movement and mobility?**
3. **How will you assess for and prevent the complications of immobility while Mr Devereaux remains on bed rest?**
4. **How would you further explore the psychosocial impact of this fall on Mr Devereaux and his fears about loss of mobility and independence?**

CLINICAL REASONING PROCESS

Using the clinical reasoning process discussed in Chapter 5, the critical application of anatomy and physiology knowledge, and experience with patients enables nurses to develop individualised care plans for patients with mobility impairments and for those who are at risk. A care plan is designed to improve the patient's functional status, promote self-care, maintain psychological wellbeing and prevent the complications of immobility.

GATHERING RELEVANT INFORMATION AND DATA

Mobility

Collecting patient data around mobility focuses on range of motion, gait, exercise and activity tolerance and body alignment (Figure 28-8). When unsure of the patient's abilities, the nurse should begin assessment of mobility with the patient in the most supportive position and move to higher levels of mobility according to the patient's tolerance. Generally, assessment of movement is commenced while the patient is lying down, and then proceeds to assessing sitting positions in bed, transfers to chair and finally gait by watching the patient walk. This helps to protect the patient's safety.

Range of motion

Range of motion (ROM) is the maximum amount of movement available at a joint in one of the three planes of the body: sagittal, frontal or transverse (Figure 28-9). Ligaments, muscles and the nature of the joint limit joint mobility in each of the planes. However, some joint movements are specific to each plane. In the *sagittal plane*, movements are flexion and extension (fingers and elbows), dorsiflexion and plantar flexion

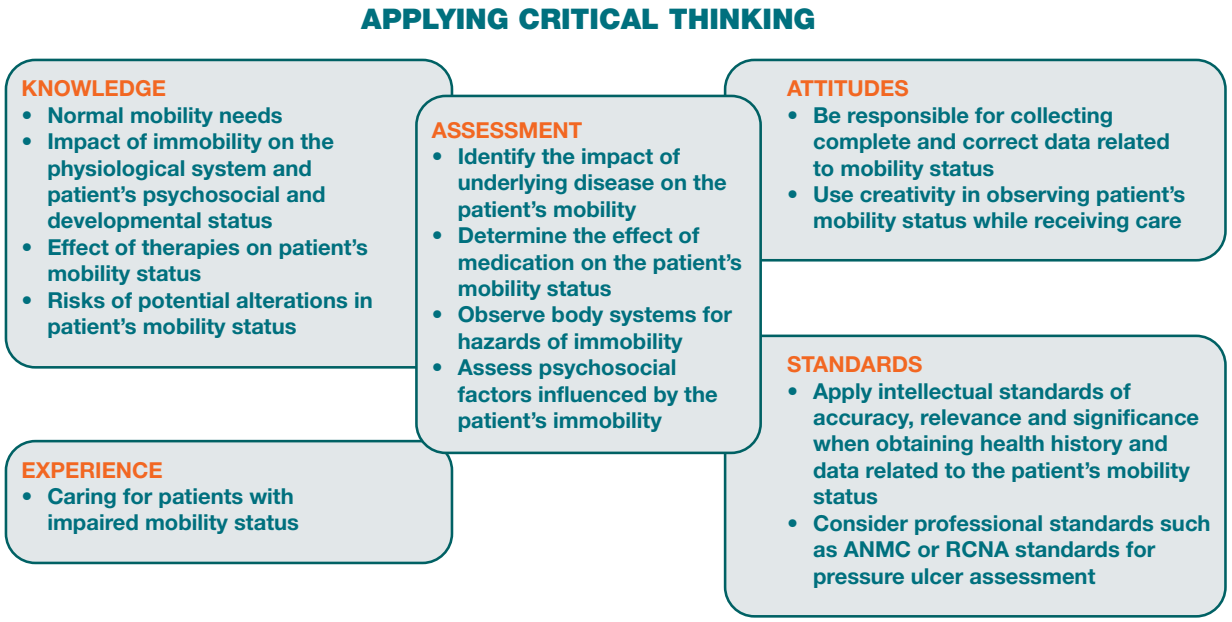

Figure 28-8 Critical thinking associated with the assessment phase for immobility.

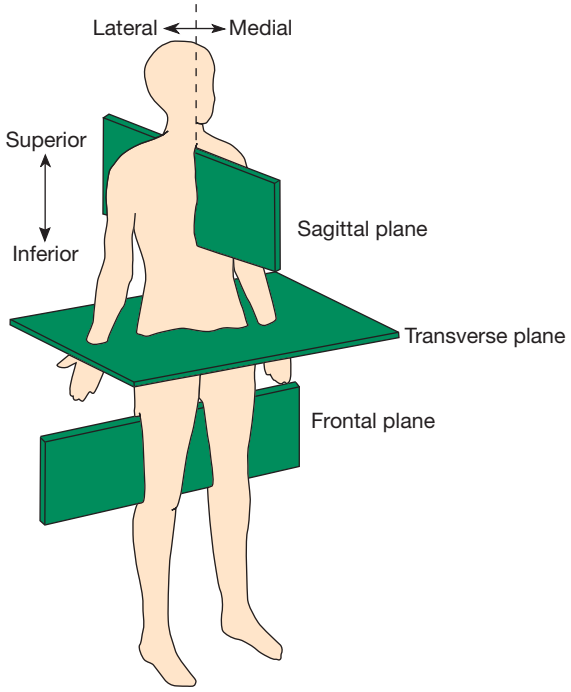

Figure 28-9 Planes of the body.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

(feet) and extension (hip). In the *frontal plane*, movements are abduction and adduction (arms and legs) and eversion and inversion (feet). In the *transverse plane*, movements are pronation and supination (hands) and internal and external rotation (hips).

To assess ROM, the patient is questioned about and physically examined for stiffness, swelling, pain, limited movement and unequal movement. This data is then documented in the appropriate nursing documentation. Table 28-3 presents the normal ROM ranges for each joint.

Patients whose mobility is restricted because of illness, disability or trauma require ROM exercises to reduce the hazards of immobility. ROM exercises may be *active* (patients are able to move all joints through their ROM unassisted) or *passive* (patients are unable to move independently, and the nurse moves each joint through its ROM), or somewhere in between. With a weak patient, for example, the nurse may merely provide support while the patient performs most of the movement, or the patient may be able to move some joints actively while the nurse passively moves others. Nurses first assess the patient's ability to engage in active ROM exercises and the need for assistance, teaching or reinforcement. In general, exercises should be as active as health and mobility allow. Contractures may develop in joints not moved periodically through their full ROM.

Gait

Gait is the manner or style of walking, including rhythm, measure of beat, cadence and speed. Assessing gait allows for conclusions to be made about the patient's balance, posture and the ability to walk without assistance.

Gait can easily be assessed as the patient walks into the room, by asking the patient to walk a short distance or while assisting the patient to mobilise. A normal gait should demonstrate:

- a regular, smooth rhythm
- symmetry in the length of leg swing
- smooth transition from stance through the swing phases
- smooth, symmetrical opposite arm swing.

TABLE 28-3 Range-of-motion exercises

Body part	Type of joint	Type of movement	Range (degrees)	Muscles involved
Neck, cervical spine	Pivotal			
		*Flexion:* Bring chin to rest on chest	45	Sternocleidomastoid
		Extension: Bend head back as far as possible	10	Trapezius
		*Lateral flexion:* Tilt head as far as possible towards each shoulder	40–45	Sternocleidomastoid
		*Rotation:* Turn head as far as possible in circular movement	180	Sternocleidomastoid, trapezius

continued

TABLE 28-3 *continued*

Body part	Type of joint	Type of movement	Range (degrees)	Muscles involved
Shoulder	*Ball and socket*			
		*Flexion:* Raise arm from side position forwards to position above head	170–180	Coracobrachialis, deltoid
		Extension: Move arm behind body, keeping elbow straight	45–60	Latissimus dorsi, teres major, deltoid
		*Abduction:* Raise arm to side to position above head with palm away from head *Adduction:* Lower arm sideways and across body as far as possible	170–180	Deltoid, supraspinatus Pectoralis major
		*Internal rotation:* With elbow flexed, rotate shoulder by moving arm until thumb is turned inwards and towards back	70–80	Pectoralis major, latissimus dorsi, teres major, subscapularis
		External rotation: With elbow in full circle, move arm until thumb is upwards and lateral to head	81–90	Infraspinatus, teres major
		*Circumduction:* Move arm in full circle (circumduction is combination of all movements of ball-and-socket joint)	360	Deltoid, coracobrachialis, latissimus dorsi, teres major

continued

TABLE 28-3 ***continued***

Body part	Type of joint	Type of movement	Range (degrees)	Muscles involved
Elbow	*Hinge*			
		*Flexion:* Bend elbow so that lower arm moves towards its shoulder joint and hand is level with shoulder	150	Biceps brachii, brachialis, brachioradialis
		Extension: Straighten elbow by lowering hand	150	Triceps brachii
Forearm	*Pivotal*			
		*Supination:* Turn lower arm and hand so that palm is up	70–90	Supinator, biceps brachii
		Pronation: Turn lower arm so that palm is down	70–90	Pronator teres, pronator quadratus
Wrist	*Condyloid*			
		*Flexion:* Move palm towards inner aspect of forearm	80–90	Flexor carpi ulnaris, flexor carpi radialis
		Extension: Bring dorsal surface of hand back as far as possible	89–90	Extensor carpi radialis brevis, extensor carpi radialis longus, extensor carpi ulnaris
		*Abduction (radial deviation):* Bend wrist medially towards thumb	Up to 30	Flexor carpi radialis, extensor carpiradialis brevis, extensor carpiradialis longus
		Adduction (ulnar deviation): Bend wrist laterally towards fifth finger	30–50	Flexor carpi ulnaris, extensor carpi ulnaris
Fingers	*Condyloid hinge*			
		*Flexion:* Make fist	90	Lumbricales, interosseus volaris, interosseus dorsalis
		*Extension:* Bend fingers back as far as possible	30–60	Extensor digiti quinti proprius, extensor digitorum communis, extensor indicis proprius
		*Abduction:* Spread fingers apart	30	Interosseus dorsalis
		Adduction: Bring fingers together	30	Interosseus volaris

TABLE 28-3 ***continued***

Body part	Type of joint	Type of movement	Range (degrees)	Muscles involved
Thumb	*Saddle*			
		*Flexion:* Move thumb across palmar surface of hand *Extension:* Move thumb straight away from hand	70–80	Flexor pollicis brevis Extensor pollicis longus, extensor pollicis brevis
		Abduction: Extend thumb laterally (usually done when placing fingers in abduction and adduction) *Adduction:* Move thumb back towards hand	70–80	Abductor pollicis brevis and longus Adductor pollicis obliquus, adductor pollicis transversus
		*Opposition:* Touch thumb to each finger of same hand		Opponeus pollicis, opponeus digiti minimi
Hip	*Ball and socket*			
		*Flexion:* Move leg forwards and up	120–130	Psoas major, iliacus, sartorius
		Extension: Move back beside other leg	120–130	Gluteus maximus, semitendinosus, semimembranosus
		*Hyperextension:* Move leg behind body	10–20	Gluteus maximus, semitendinosus, semimembranosus
		*Abduction:* Move leg laterally away from body	30–50	Gluteus medius, gluteus minimus
		Adduction: Move leg back towards medial position and beyond if possible	20–30	Adductor longus, adductor brevis, adductor magnus

continued

TABLE 28-3 ***continued***

Body part	Type of joint	Type of movement	Range (degrees)	Muscles involved
		*Internal rotation:* Turn foot and leg towards other leg	35–40	Gluteus medius, gluteus minimus, tensor fasciae latae
		External rotation: Turn foot and leg away from other leg	40–50	Obturatorius internus, obturatorius externus, quadratus femoris, piriformis, gemellus superior and inferior, gluteus maximus
		*Circumduction:* Move leg in circle		Psoas major, gluteus maximus, gluteus medius, adductor magnus
Knee	*Hinge*			
		*Flexion:* Bring heel back towards back of thigh	135–145	Biceps femoris, semitendinosus, semimembranosus, sartorius
		Extension: Return leg to floor	0	Rectus femoris, vastus lateralis, vastus medialis, vastus intermedius
Ankle	*Hinge*			
		*Dorsal flexion:* Move foot so that toes are pointed upwards	20–30	Tibialis anterior
		Plantar flexion: Move foot so that toes are pointed downwards	45–50	Gastrocnemius, soleus
Foot	*Gliding*			
		*Inversion:* Turn sole of foot medially	30–40	Tibialis anterior, tibialis posterior
		Eversion: Turn sole of foot laterally	15–25	Peroneus longus, peroneus brevis
Toes	*Condyloid*			
		*Flexion:* Curl toes downwards	30–60	Flexor digitorum, lumbricalis pedis, flexor hallucis brevis
		Extension: Straighten toes	30–60	Extensor digitorum longus, extensor digitorum brevis, extensor hallucis longus

		*Adduction:* Bring toes together	15 or less	Adductor hallucis, interosseus plantaris

Exercise and activity tolerance

Exercise and activity tolerance is the kind and amount of exercise or work that a person is able to perform. Assessment of activity tolerance is necessary when planning activity such as walking, ROM exercises or ADLs such as bathing, for patients with acute or chronic illness. Activity-tolerance assessment includes data from physiological, emotional and developmental domains. This assessment is applicable in all clinical settings and is completed by nurses.

As activity is begun, patients should be monitored for symptoms such as dyspnoea, fatigue or chest pain and/or a change in vital signs from baseline. The weak or deconditioned patient is unable to sustain activity because the greater energy needed to complete the activity creates fatigue and generalised weakness. Even seemingly simple tasks such as eating and moving in bed may need to be monitored. When decreased activity tolerance is noted, assessment is made of the time needed by the patient to recover. Decreasing recovery time may indicate improving activity tolerance.

People who are depressed, worried or anxious are frequently unable to tolerate exercise. Depressed patients are usually not motivated to participate. Patients who are worried or anxious tire easily because they expend a great deal of energy in worry and anxiety. Thus they may experience physical and emotional exhaustion.

Developmental changes also affect activity tolerance. As the infant enters the toddler stage, the activity level increases and the need for sleep declines. The school-aged child expends mental energy in learning and may require more rest after school or before strenuous play. The adolescent going through puberty may require more rest because much of the body's energy is expended on growth and hormone changes.

Changes may still occur through the adult years, but many of these changes are related to work and lifestyle choices. Pregnancy may cause fluctuations in a woman's energy tolerance, especially during the first and third trimesters when she may have increased fatigue. Hormonal changes and fetal development use body energy, and the woman may be unable or unmotivated to carry out physical activities. During the last trimester, fetal development consumes a great deal of the mother's energy and the size and location of the fetus may limit the ability to take a deep breath, resulting in less oxygen being available for physical activities.

As a person grows older, activity tolerance changes. Muscle mass is reduced, posture changes and the composition of bones is altered. There are often changes in the cardiorespiratory system, such as decreased maximum heart rate and decreased lung compliance, which affect the intensity of exercise. As age progresses, the older individual may still exercise, but will do so at a reduced intensity.

There is an overall improvement of physiological functioning as a result of exercise. All systems become stronger and function more efficiently. Nurses may therefore plan interventions directed at increasing exercise. However, nurses in rehabilitation and acute care settings often care for patients with impaired mobility, and therefore develop nursing therapies designed to minimise the hazards of immobility.

Body alignment

Assessment of body alignment can be carried out with the patient standing, sitting or lying down. The first step in assessing body alignment is to put patients at ease so that unnatural or rigid positions are not assumed. When the body alignment of an immobilised or unconscious patient is assessed, pillows and positioning supports should be removed from the bed and the patient placed in the supine position.

STANDING Assessment of the patient's body alignment when the standing patient is focused on the following points:

- The head is erect and midline.
- When observed posteriorly, the shoulders and hips are straight and parallel.
- When observed posteriorly, the vertebral column is straight.
- When the patient is observed laterally, the head is erect and the spinal curves are aligned in a reversed S pattern. The cervical vertebrae are anteriorly convex, the thoracic vertebrae are posteriorly convex and the lumbar vertebrae are anteriorly convex.
- When observed laterally, the abdomen is comfortably tucked in and the knees and ankles are slightly flexed. The person appears comfortable and does not seem conscious of the flexion of knees or ankles.
- The arms hang comfortably at the sides.
- The feet are placed slightly apart to achieve a base of support, and the toes are pointed forwards.
- When the patient is viewed anteriorly, the centre of gravity is in the midline, and the line of gravity is from the middle of the forehead to a midpoint between the feet. Laterally the line of gravity runs vertically from the middle of the skull to the posterior third of the foot (Figure 28-10).

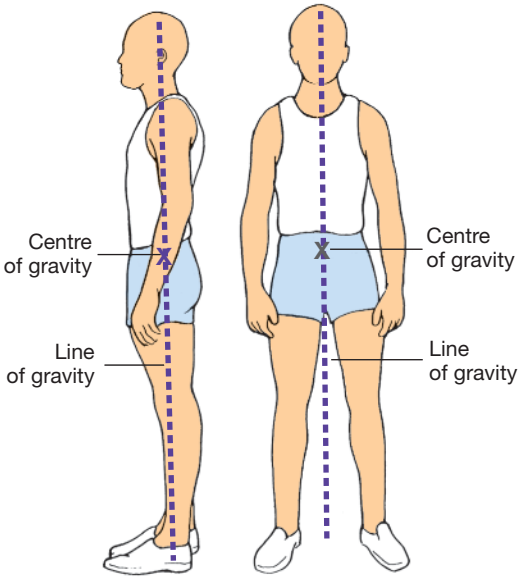

Figure 28-10 Correct body alignment when standing.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

SITTING Assessment of body alignment of the sitting patient (Figure 28-11) is undertaken by observations of the following:

- The head is erect, and the neck and vertebral column are in straight alignment.
- The bodyweight is evenly distributed on the buttocks and thighs.
- The thighs are parallel and in a horizontal plane.
- Both feet are supported on the floor. With patients of short stature, a footstool is used and the ankles are comfortably flexed.
- A 2–4 cm space is maintained between the edge of the seat and the popliteal space on the posterior surface of the knee. This space ensures that there is no pressure on the popliteal artery or nerve to decrease circulation or impair nerve function.
- The patient's forearms are supported on the armrest, in the lap or on a table in front of the chair.

It is particularly important to assess alignment when sitting if the patient has muscle weakness, muscle paralysis or nerve damage. Because of these alterations, the patient has diminished sensation in the affected area and is unable to perceive pressure or decreased circulation. Proper alignment while sitting reduces the risk of musculoskeletal system damage in such a patient. The patient with severe respiratory disease may assume a posture of leaning on the table in front of the chair in an attempt to breathe more easily.

LYING People who are conscious and healthy have voluntary muscle control and normal perception of pressure. As a result, they usually assume a position of comfort when lying down. Because their ROM, sensation and circulation are within normal limits, they change positions when they perceive muscle strain and decreased circulation.

Assessment of body alignment with the patient in the lateral position (Figure 28-12) is best done when the patient is

Figure 28-11 Correct body alignment when sitting.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

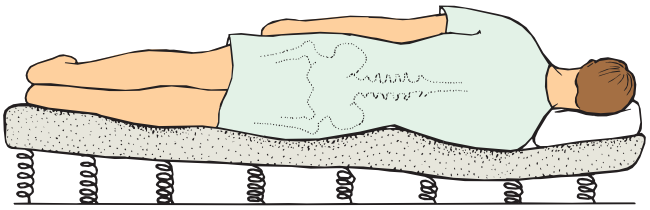

Figure 28-12 Correct body alignment when lying down.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

restricted to bed and not able to move well. All positioning supports should be removed from the bed except for the pillow under the head, and an adequate mattress should support the body. This position allows for full view of the spine and back and will help provide other baseline body alignment data, such as whether the patient can remain positioned without aid. The vertebrae should be in straight alignment without observable curves. The position should not cause discomfort. Conditions that create a risk of damage to the musculoskeletal system when lying down include patients with impaired mobility (e.g. in traction or with arthritis), decreased sensation (e.g. sensory deficits after stroke), impaired circulation (e.g. diabetes) or lack of voluntary muscle control (e.g. spinal cord injuries).

Impaired mobility

Assessment of the patient with impaired mobility is undertaken by performing a head-to-toe body systems physical assessment (refer to Chapter 23 for normal findings). In addition, gathering nursing data should also focus on the psychosocial and developmental impact of immobility. Common abnormal assessment findings associated with immobility for each body system are presented in Table 28-4.

Assessment of passive and active ROM is important as a baseline against which later measurements can be compared to evaluate whether a loss in joint mobility has occurred. Objective data about the degree of joint ROM can be measured with

TABLE 28-4 Body systems assessment for complications of immobility

System	Assessment techniques	Abnormal findings
Metabolic	Inspection	Slowed wound healing, abnormal laboratory data
		Muscle atrophy, decreased amount of subcutaneous fat
Respiratory	Inspection	Increased respiratory rate, asymmetrical chest wall movement, dyspnoea
	Auscultation	Crackles, wheezes
Cardiovascular	Palpation	Increased heart rate, weak peripheral pulses, peripheral oedema
	Auscultation	Orthostatic hypotension, third heart sound
Musculoskeletal	Inspection, palpation	Erythema, increased diameter in calf or thigh, muscle atrophy
	Palpation	Decreased ROM, joint contracture
Skin	Inspection	Break in skin integrity
Elimination	Inspection	Decreased urine output, cloudy or concentrated urine, decreased frequency of bowel movements
	Palpation	Distended bladder and abdomen
	Auscultation	Decreased bowel sounds

WORKING WITH DIVERSITY

Focus on cultural care

Dairy products are key sources of the calcium necessary to prevent osteoporosis. However, people's ability to tolerate the lactose in dairy products is thought to be related to their ethnic background. People with an Asian background often have lactose intolerance, but research has shown that they may be able to tolerate small amounts of dairy products. Australian Aboriginal peoples and those of Greek and Mediterranean origin are also reported to experience lactose intolerance more than Caucasians. To ensure bone health, education is needed about sources of calcium, both dairy and non-dairy. Although generally in lower amounts per serving than dairy foods, the non-dairy sources of calcium include green leafy vegetables, legumes and cereals. Calcium-fortified foods and calcium supplements are another option for people who cannot meet their calcium needs from foods naturally containing this mineral.

Implications for practice

- For all patients, be aware of their normal dietary habits.
- When assessing a person's nutritional intake, note the sources of calcium.
- Offer alternatives to dairy products for people with suspected or actual lactose intolerance.
- Provide education to patients about sources of calcium.
- Consider lactose intolerance as a cause of diarrhoea, gaseous distension and abdominal cramping.

a goniometer, although this is rarely done in the acute care setting (see Figure 28-13).

Psychosocial assessment

Common reactions to immobilisation include boredom, feelings of isolation, depression and anger. Changes in the patient's emotional status should be identified. Examples of change that may indicate psychosocial concerns are a cooperative patient who becomes less cooperative or an independent patient who asks for more help than is usual. The reasons for such alterations should be determined. Identifying how the patient usually copes with loss is vital (see Chapter 22). A change in mobility status, whether permanent or not, may cause a grief reaction. Families are a key resource for information about behaviour changes.

Unexplained changes in the sleep–wake cycle must be identified and corrected. Most can be prevented or minimised, such as those occurring because of nursing activities, a noisy environment or discomfort. They may also occur because of medications such as analgesics or sleep medications (see Chapter 36).

Because psychosocial changes usually occur gradually, nurses should observe the patient's behaviour on a daily basis. If behavioural changes occur, the nurse should determine the causes and evaluate the changes as short-term or long-term. Identifying the cause helps nurses to design appropriate nursing interventions.

Developmental assessment

Assessment of the immobilised patient should include developmental considerations to ensure that the patient's needs are identified. The nurse determines whether the young child can meet developmental tasks and is progressing normally. The child's development may regress or be slowed because of immobilisation. By identifying a child's overall developmental needs, nursing therapies can be designed to maintain normal development. The parents should also be reassured that developmental delays are usually temporary.

Immobilisation of a family member affects normal role-relationship patterns and the family's functioning. The family's response to this change may lead to problems, stress and anxieties. Children seeing parents who are immobile may have difficulty understanding what is happening.

Assessing for hospitalisation-associated immobility

As discussed above, hospitalisation of the older adult commonly leads to reduced mobility and functional status, even when the acute illness that necessitated hospitalisation is successfully treated. Nursing assessment at admission and over the course of hospitalisation is important to identify changes in functional status. Covinsky et al (2011) suggest that the key domains that should be documented include baseline ADL function, mobility and cognition. These are simple and brief assessments that nurses can make during daily patient care. A decline in function needs prompt investigation to determine why the change occurred and what can be done to return the patient to an optimal level of functioning as soon as possible.

Immobility may also directly lead to complications, such as pulmonary emboli or pneumonia. If these conditions develop, the primary nurse will collaborate with the medical or nurse practitioner for prescribed therapy to intervene. Nurses need to be alert for these potential complications and work to prevent them.

CLINICAL EXAMPLE

You are a student nurse caring for Abby O'Brien, a 31-year-old woman on an orthopaedic ward. During your initial shift assessment you elicit the following data.

Interview data

Abby states, 'I fell off my horse while riding. The horse stepped on my leg and crushed the bone in my upper leg.' She reports pain in her right leg of severity 6 (on a 0–10 numerical pain rating scale) and says the prescribed analgesia only helps a little. She wants to move but cannot because of the traction. Abby states, 'My bottom hurts because I can't move around.' She tells you, 'I haven't had a bowel movement for 3 days now; the last time I did it was hard to pass. Normally at home I go every day.' Abby hasn't been hungry either. She says, 'The food is horrible.' She states that she is so bored she cannot stand it. 'I am used to being active – being stuck in bed is driving me crazy. TV shows aren't worth watching.'

Physical examination data

- Vital signs: temperature 36.7°C, heart rate 88 beats per minute, respiratory rate 16 breaths per minute, blood pressure 108/72 mmHg; height 165 cm, weight 61 kg.
- Medication: oxycodone (an opioid analgesic) 5 mg by mouth every 6 hours for pain relief. She has taken these regularly for the last several days.
- Diet: regular diet. Has eaten, on average, 30% of meals. Fluid intake has averaged 1000 mL/day.
- Activity: patient is on complete bed rest.
- Respiratory: breathing even and unlaboured. Lungs are clear to auscultation.
- Cardiovascular: all distal pulses palpable. Heart rate and rhythm regular. No peripheral oedema.
- Abdomen: slightly distended. Hypoactive bowel sounds throughout abdomen.
- Musculoskeletal: right leg in skeletal traction. Normal sensation to foot/toes, capillary refill < 2 seconds. Other extremities: full range of motion. No pain over joints and muscles.
- Integument: skin warm and dry. Pin sites for traction without redness or drainage. 5 cm diameter redness over sacrum. Skin intact.

Adapted from Wilson SF, Giddens JF 2009 Health assessment for nursing practice, 4th edn. Mosby, St Louis.

• CRITICAL REFLECTION POINT

1. **Identify the significant or abnormal assessment data in the *Clinical example*. Explain how and why this data is abnormal given the patient's presenting problem.**
2. **Construct a concept map that demonstrates all the significant assessment data from the clinical scenario and the relationships or links among this data.**
3. **Identify three nursing problems from the clinical scenario and list all the supporting assessment data for each problem identified.**
4. **How would you develop a nursing care plan to manage each of the identified problems?**

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

After collecting the data from the patient in relation to mobility or immobility, nurses synthesis this information and make informed clinical judgements about the person's needs,

concerns and health problems. Critical thinking ensures that a decision relating to the patient's plan of care integrates all that the nurse knows about the individual whilst also drawing on past experiences with immobilised patients. Evidence-based clinical guidelines are similarly important to consider when developing a plan of care.

Together, the nurse and patient set realistic expectations for care, and goals are set that are individualised and measurable. Therapeutic interventions are planned for patients with actual problems with or risks to body alignment and mobility. Therapies are planned according to severity of risks to the patient, and the plan is individualised according to the patient's developmental stage, level of health and lifestyle. Care planning must take the patient's own goal-setting into consideration. The immediacy of any problem is determined by the effect the problem has on the patient's mental and physical health.

It can be easy to overlook the potential complications of immobility until they occur. Nurses must therefore be vigilant in monitoring patients, reinforcing prevention techniques and supervising appropriate others in carrying out activities aimed at preventing immobility complications. Maintaining body alignment is especially important for patients with actual or potential limitations in mobility. Turning and positioning of a comatose patient must be done correctly and the position must be changed frequently to reduce the risk of poor alignment and future injury to the skin and musculoskeletal system. The frequency of turning is based on patient assessment of the risk of pressure injury.

The nurse frequently collaborates with others in the healthcare team, such as a physiotherapist or occupational therapist, when considering mobility needs. For example, physiotherapists are a resource for planning ROM or strengthening exercises and occupational therapists are a resource for planning ADLs that patients need to modify or relearn. Discharge planning is begun when a patient enters the healthcare system. In anticipation of the patient's discharge from an institution, a referral may be made to help the patient remain mobile or regain mobility at home. Therefore, consideration must be given to the patient's home environment when planning therapies to maintain or improve body alignment and mobility.

SETTING PRIORITIES AND ESTABLISHING GOALS

Priorities of care

When developing a plan of care, you need to establish priorities and goals based on the patient's level of mobility/immobility (see Figure 28-14). For patients who are mobile it is imperative that they are encouraged to mobilise safely. Patients should also be involved in setting their priorities for their care whenever possible. For example, the nurse should encourage the patient to help determine care routines. The patient should provide as much self-care as possible. Hygiene and grooming articles should be kept within easy reach. Patients should be encouraged to wear their glasses or dentures and to shave or apply make-up, if this is their normal routine. These are activities through which people maintain their body image. Maintenance of body image can help improve the patient's ability to mobilise. Nursing care should provide mental and physical stimulation in all patients.

Goals and outcomes

Nursing care should provide mental and physical stimulation, particularly for a young child. Play activities can be incorporated into the care plan. Completing games and puzzles, for example, helps a child develop fine motor skills, and reading helps the child develop cognitively. An immobilised child should be placed with children of the same age who are not immobilised, unless a contagious disease is present. Nursing activities, such as dressing changes, cast care and care of traction, can be designed to require the child's participation. The nurse must recognise significant changes from normal behavioural patterns. If these continue, the nurse should consult a clinical nurse, counsellor or other healthcare professional whose specialty is children.

APPLYING CRITICAL THINKING

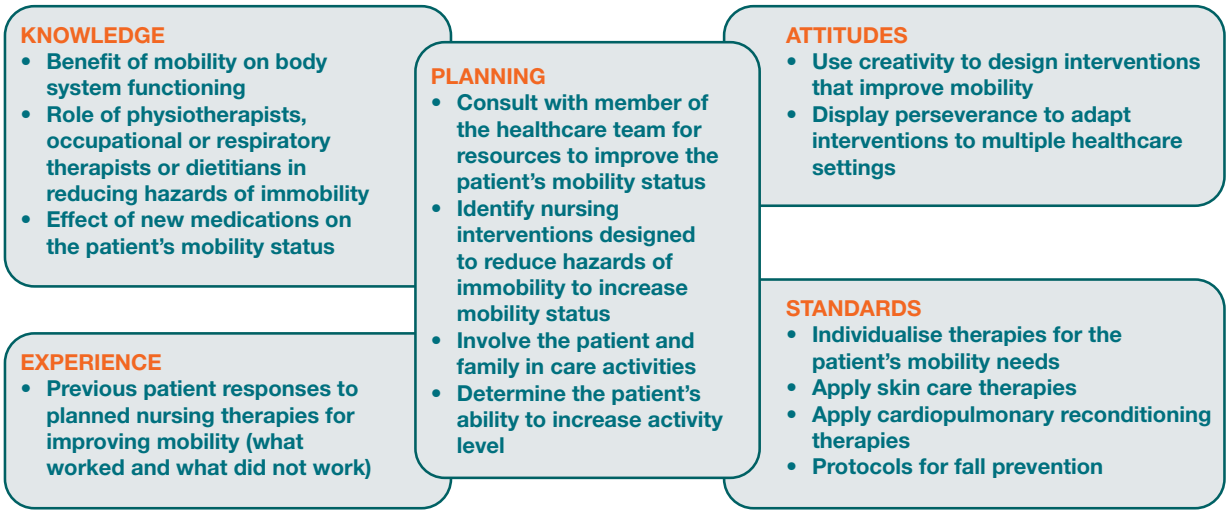

Figure 28-14 **Critical thinking associated with the planning phase for immobility.**

Nursing care should provide mental and physical stimulation in all patients. Restricted mobility of older patients presents unique nursing problems. Older patients who are frail or have chronic illnesses may have an increased risk of the psychosocial hazards of immobility. Having a calendar and a clock with a large dial, conversing about current events and family members and encouraging visits from significant others may reduce the risk of social isolation. Nursing care should encourage older patients to perform as many ADLs as independently as possible.

The nurse should also observe the patient's failure to cope with restricted mobility. If the nursing care plan is not improving coping patterns, an advanced practice nurse, counsellor, social worker, spiritual adviser or other consultant may be needed. Their recommendations should be incorporated into the care plan.

Time should be made to assist patients to walk, encourage exercise if the patient is able and encourage patients to ambulate from bed to the chair as much as possible. This should include removing any unnecessary tethers such as oxygen, bladder catheters and intravenous catheters, creating hospital norms that patients are expected to walk regularly.

PREPARING FOR AND TAKING ACTION

When preparing to care for the patient with impaired mobility the nurse must also prepare himself or herself. This requires an understanding of their own body mechanics and the requirements of moving a patient with impaired mobility.

Body mechanics

Mao (Mao et al 2015) identified that a healthcare worker's quality of working life is impacted significantly if human factors and ergonomics (HFE) are not given the appropriate attention, this includes **body mechanics**, which can lead to pain and injury to both staff and patients. The number of injuries in occupational settings has increased over the years, and back pain is the most common and expensive injury. Back injuries are often the direct result of improper lifting and bending. The most common back injury is strain on the lumbar muscle group, which includes the muscles around the lumbar vertebrae.

Nurses are especially at risk of injury to lumbar muscles when lifting, transferring or positioning immobilised patients. Because of this, most facilities in Australia have adopted a manual handling policy where the concept of no lifting is central, as well as providing training to staff on the use of devices and mechanical aids that are alternatives to lifting when transferring, moving and repositioning patients. It is important to assess the weight and obtain assistance when moving objects or patients that would be hazardous to your health or the patient's health.

Nurses need to adopt good manual handling techniques to protect themselves, those they supervise and the patients for whom they care. When assisting to mobilise patients, the nurse should assess the patient's mobility care plan, weight to be mobilised and what assistance (if any) is needed. Another consideration is the condition of the patient and whether they can provide help while being moved. If help is needed, the nurse should determine the number of persons required and equipment needed to safely transfer the patient. The manual handling protocols of the healthcare agency should be checked before transferring or mobilising patients (Commonwealth of Australia 2007).

While nurses should adhere to a no-lift approach in their workplace, you may encounter situations where it is necessary to transfer patients under less than ideal circumstances (Kay et al 2013). In these extreme circumstances you should adopt proper body mechanics to minimise the risk of injury:

- Keep the weight to be lifted as close to the body as possible; this action places the object in the same plane as the lifter and close to the centre of gravity for balance.
- Bend at the knees; this helps to maintain the centre of gravity and uses the stronger leg muscles to do the lifting (Figure 28-15).
- Avoid twisting. Twisting can overload the spine and lead to serious injury.
- Tighten abdominal muscles and tuck the pelvis; this provides balance and helps protect the back.
- Maintain the trunk erect and knees bent so that muscle groups work together in a coordinated manner.

Exercise

Although many health problems can cause or contribute to immobility, it is important to remember that exercise programs can enhance wellness. Exercise is known to reduce the risk of many health problems, such as cardiovascular disease, diabetes and osteoporosis. Thus, exercise should be incorporated into the care plan. Functional decline from disuse is a major concern as ageing occurs. Nurses can contribute to promoting health for many patients by encouraging or starting managed exercise programs. Older adults can enjoy and benefit from exercises other than traditional Western exercises such as walking or swimming. Hospitalised patients should be encouraged to do stretching, ROM exercises and ambulate within the limits of their condition.

A sedentary lifestyle contributes to the development of health-related problems. Nurses promote health by encouraging patients to engage in a regular exercise program (Box 28-2). Low-to-moderate levels of exercise are associated with a range of health benefits. A holistic approach is taken to develop and implement a plan to enhance the patient's overall physical fitness. The recommendations for physical activity and fitness should be discussed with the patient, and a program of exercise designed in collaboration with the patient. The national physical activity guidelines for Australians (Department of Health 2014) outline the minimum levels of physical activity required to gain a health benefit and ways to incorporate incidental physical activity into everyday life (see Box 28-3).

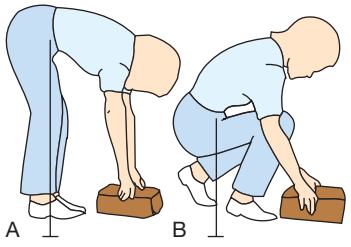

Figure 28-15 Incorrect (A) and correct (B) body position for lifting.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

BOX 28-2 Procedural guidelines for helping patients to exercise

1. Be aware of any medical limitations (e.g. weightbearing status, untreated fracture, cardiovascular disease).
2. Teach patients breathing skills to help reduce anxiety and to fully oxygenate tissues and expand lungs.
3. Always know the patient's limitations.
4. Do not force a muscle or a joint during exercise.
5. Let each patient move at their own pace.
6. Posture, body alignment and good body mechanics should be maintained during exercise.
7. Monitor vital signs before, during and after exercise.
8. Stop exercising if the patient has pain, shortness of breath or a change in vital signs.
9. Patients should wear shoes and comfortable clothing.
10. Know what the patient's mobility skills were before hospitalisation.
11. Keep a record of the patient's progress and provide feedback as the patient exercises.

• CRITICAL REFLECTION POINT

Your clinical rotation is in extended care and you are working in assisted living. The registered nurse working in the assisted-living wing asks you to help her with a program entitled 'Lifestyle choices: living life to its fullest'. She asks you to participate and discuss how regular exercise can improve overall health and to show how exercise can be incorporated into activities of daily living. Develop a content outline and justify the teaching strategies you intend to use.

Acute care

In the acute care setting, specific interventions are designed to reduce the impact of immobility on the patient and to position and transfer patients correctly.

Metabolic system interventions

The immobilised patient requires a high-protein, high-kilojoule diet with vitamin B and C supplements. Protein is needed to repair injured tissue and rebuild depleted protein stores. A high-kilojoule intake provides sufficient fuel to meet metabolic needs and to replace subcutaneous tissue. Supplementation with vitamin C is necessary to replace protein stores. Vitamin B complex is needed for skin integrity and wound healing.

If the patient is unable to eat, nutrition must be provided parenterally or enterally. Enteral feedings include delivery through a nasogastric or gastrostomy tube of high-protein, high-kilojoule solutions with complete requirements of vitamins, minerals and electrolytes (see Chapter 31).

Respiratory system interventions

Nursing interventions for the respiratory system are aimed at maintaining a patent airway, promoting expansion of the chest and lungs, preventing stasis of pulmonary secretions and promoting adequate exchange of respiratory gases.

BOX 28-3 Australian National Physical Activity Guidelines

Physical activity recommendations for children 0–5 years

- Being physically active every day is important for the healthy growth and development of infants, toddlers and preschoolers.
- **Infants (birth to 1 year):** For healthy development in infants, physical activity – particularly supervised floor-based play in safe environments – should be encouraged from birth.
  - Before infants begin to crawl, physical activity includes reaching and grasping, pulling and pushing, moving their head, body and limbs during daily routines and supervised floor play, including tummy time. Once your infant is mobile, encourage them to be as active as possible in a safe, supervised and nurturing play environment.
- **Toddlers (1–3 years) and preschoolers (3–5 years):** Toddlers and preschoolers should be physically active every day for at least 3 hours, spread throughout the day.
  - You'd be surprised by how many opportunities there are throughout the day for toddlers and preschoolers to be active. Remember that kids don't need to do their 3 hours of physical activity all at once. It can be accumulated throughout the day and can include light activity like standing up, moving around and playing.
  - Children younger than 2 years of age should not spend any time watching television or using other electronic

continued

media (DVDs, computer and other electronic games). For children 2–5 years of age, sitting and watching television and the use of other electronic media (DVDs, computer and other electronic games) should be limited to less than 1 hour per day.

- Infants, toddlers and preschoolers should not be sedentary, restrained or kept inactive for more than 1 hour at a time, with the exception of sleeping.
- 'Sedentary behaviour' refers to time spent being physically inactive. All children need some 'down time' but they are not naturally inactive for long periods of time. Sitting in strollers, highchairs and car seats (being restrained) for long periods isn't good for children's health and development and goes against their natural tendency to be active and play.

Physical activity recommendations for 5- to 12-year-olds

- For health benefits, children aged 5–12 years should accumulate at least 60 minutes of moderate to vigorous intensity physical activity every day.
- Children's physical activity should include a variety of aerobic activities, including some vigorous intensity activity.
- On at least 3 days per week, children should engage in activities that strengthen muscle and bone.
- To achieve additional health benefits, children should engage in more activity – up to several hours per day.
- To reduce health risks, children aged 5–12 years should minimise the time they spend being sedentary every day. To achieve this:
  - Limit use of electronic media for entertainment (e.g. television, seated electronic games and computer use) to no more than 2 hours a day – lower levels are associated with reduced health risks.
  - Break up long periods of sitting as often as possible.

Physical activity recommendations for 13- to 17-year-olds

- For health benefits, young people aged 13–17 years should accumulate at least 60 minutes of moderate to vigorous intensity physical activity every day.
- Young people's physical activity should include a variety of aerobic activities, including some vigorous intensity activity.
- On at least 3 days per week, young people should engage in activities that strengthen muscle and bone.
- To achieve additional health benefits, young people should engage in more activity – up to several hours per day.
- Limit use of electronic media for entertainment (e.g. television, seated electronic games and computer use) to no more than 2 hours a day – lower levels are associated with reduced health risks.
- Break up long periods of sitting as often as possible.

Physical activity guidelines for adults (18–64 years)

- Being physically active and limiting your sedentary behaviour every day is essential for health and wellbeing.
- Doing any physical activity is better than doing none. If you currently do no physical activity, start by doing some, and gradually build up to the recommended amount.
- Be active on most, preferably all, days every week.
- Accumulate 150–300 minutes (2.5–5 hours) of moderate intensity physical activity or 75–150 minutes (1.25–2.5 hours) of vigorous intensity physical activity, or an equivalent combination of both moderate and vigorous activities, each week.
- Do muscle strengthening activities on at least 2 days each week.
- Minimise the amount of time spent in prolonged sitting.
- Break up long periods of sitting as often as possible.

Physical activity recommendations for older Australians (65 years and older)

Being physically active and staying fit and healthy will help you get the most out of life, whatever your age. Being physically active for 30 minutes every day is achievable and even a slight increase in activity can make a difference to your health and wellbeing.

There are five physical activity recommendations for older Australians.

1. Older people should do some form of physical activity, no matter what their age, weight, health problems or abilities.
2. Older people should be active every day in as many ways as possible, doing a range of physical activities that incorporate fitness, strength, balance and flexibility.
3. Older people should accumulate at least 30 minutes of moderate intensity physical activity on most, preferably all, days.
4. Older people who have stopped physical activity, or who are starting a new physical activity, should start at a level that is easily manageable and gradually build up to the recommended amount, type and frequency of activity.
5. Older people who continue to enjoy a lifetime of vigorous physical activity should carry on doing so in a manner suited to their capability into later life, provided recommended safety procedures and guidelines are adhered to.

Australian National Physical Activity Guidelines © 2014 Commonwealth of Australia as represented by the Department of Health.

MAINTAINING A PATENT AIRWAY Immobilised patients and those on bed rest are generally weakened. If weakness progresses, the cough reflex gradually becomes inefficient. The stasis of secretions in the lungs may be life-threatening for an immobilised patient because hypostatic pneumonia can easily develop. Dislodging and mobilising the stagnant secretions reduces the risk of pneumonia. Assessment findings that indicate this condition include productive cough with greenish-yellow sputum, fever, pain on breathing, crackles and/or wheezes and dyspnoea. The nurse should actively work with the patient to deep-breathe and cough every 1–2 hours as described in promoting chest expansion, below.

In the immobilised patient, an obstructed airway is usually the result of a mucous plug. The nurse can implement several therapies, such as chest physiotherapy, to reduce the risk of mucous plugs and to maintain a patent airway. Nasotracheal or orotracheal suction techniques may be used to remove secretions in the upper airways of a patient who is unable to cough productively. This procedure must be performed aseptically. The nurse places a suction catheter in the patient's nose or through the mouth and applies suction. The nurse can also suction secretions from an artificial airway, such as an endotracheal or tracheal tube. The nurse inserts a catheter into the artificial airway in a sterile procedure. This removes pulmonary secretions from the upper and lower airways (see Chapter 35 for suctioning techniques).

PROMOTING EXPANSION OF THE CHEST AND LUNGS The nurse promotes chest expansion with several interventions. Changing the position of the patient at least every 2 hours allows the dependent lung regions to re-expand. Re-expansion maintains the elastic recoil property of the lungs and clears the dependent lung regions of pulmonary secretions.

The nurse should encourage the patient to deep-breathe and cough every 1–2 hours. Alert patients can be taught to deep-breathe or yawn every hour or to use an incentive spirometer (see Chapter 35). The nurse teaches the patient to take in three deep breaths and cough with the third exhalation. This technique produces a more forceful, productive cough without excessive fatigue. These respiratory interventions will aid alveolar expansion and prevent atelectasis. Coughing reduces the stasis of pulmonary secretions.

PREVENTING STASIS OF PULMONARY SECRETIONS Stagnant secretions accumulating in the bronchi and lungs may lead to growth of bacteria and subsequent development of pneumonia. Changing the patient's position every 2 hours can reduce stagnation of secretions. This change helps mobilise secretions.

The immobile patient should maintain hydration, taking into consideration any requirements to limit fluid intake. Hydration helps keep mucociliary clearance normal. In patients free from infection and with adequate hydration, pulmonary secretions will appear thin, watery and clear. The patient can easily remove the secretions with coughing. Without adequate hydration the secretions are thick and tenacious and difficult to remove. Encouraging fluids also benefits in helping with bowel and urine elimination and aids in maintaining circulation and skin integrity.

Chest physiotherapy, including percussion and positioning, is an effective method of preventing pulmonary secretion stasis. These techniques help the patient to drain secretions from specific segments of the bronchi and lungs into the trachea so that the patient can cough and expel the secretions. Respiratory assessment findings identify areas of the lungs requiring chest physiotherapy (see Chapter 35).

Cardiovascular system interventions

The effects of bed rest or immobilisation on the cardiovascular system include orthostatic hypotension, increased cardiac workload and thrombus formation. Nursing therapies are designed to minimise or prevent these alterations.

REDUCING ORTHOSTATIC HYPOTENSION After bed rest, patients usually have an increased pulse rate, a decrease in pulse pressure and an increase in fainting in response to a tilting or an erect posture. Interventions should be directed towards reducing or eliminating the effects of orthostatic hypotension. The nurse attempts to get the patient moving as soon as the physical condition allows, even if this only involves dangling legs from the bed or moving to a chair. This activity maintains muscle tone and increases venous return. Isometric exercises, those activities that involve muscle tension without muscle shortening, do not have any beneficial effect on preventing orthostatic hypotension but may improve activity tolerance. When getting an immobile patient up for the first time, the nurse should usually be assisted with at least one other person. This is a precautionary step. The patient will still be expected to do as much of the transfer as the condition allows.

REDUCING CARDIAC WORKLOAD The nurse designs interventions to reduce cardiac workload, which is increased by immobility. A primary intervention is to discourage the patient from using the Valsalva manoeuvre. When using this manoeuvre the patient holds their breath, which increases

BOX 28-4 Procedural guidelines for application of sequential compression devices (SCDs)

1. Measure patient for proper-size stocking by measuring around the largest part of the patient's thigh.
2. Place a protective stocking over the patient's leg.
3. Wrap the stocking around the leg, starting at the ankle, with the opening over the patella (see illustration).
4. Attach the stockings to the insufflator and verify that the intermittent pressure is between 35 and 45 mmHg.

Application of sequential compression stockings.

intrathoracic pressure. This decreases venous return and cardiac output. When the strain is released, venous return and cardiac output immediately increase and systolic blood pressure and pulse pressure rise. These pressure changes produce a reflex bradycardia and a possible decrease in blood pressure that may cause sudden cardiac death in patients with heart disease. The nurse teaches the patient to breathe out while moving or being lifted up in bed.

PREVENTING THROMBUS FORMATION Prevention of **venous thromboembolism** is the goal of care through an aggressive program of prophylaxis. The National Health and Medical Research Council's National Institute of Clinical Studies (NICS) has developed an evidence-based clinical practice guideline for the prevention of venous thromboembolism in patients admitted to Australian hospitals (NICS 2009, see *Online resources*).

Prevention begins with identification of patients at risk and continues throughout the time patients are immobile or otherwise at risk. Many interventions reduce the risk of thrombus formation in the immobilised patient. Leg exercises, position changes, fluids and teaching should begin when the patient becomes immobile. Preoperative patients should be given this information before surgery (see Chapter 39).

Elastic compression stockings and the sequential compression device also help maintain external pressure on the muscles of the lower extremities and thus may promote venous return (Skill 28-1 and Skill 28-2). When considering applying graded compression stockings, the nurse first needs to assess the

SKILL 28-1

Applying sequential compression devices (SCDs)

Delegation and other considerations

Applying SCDs can be delegated to nurse assistants. The following information should be given when delegating this task:

- Avoid activities that promote venous stasis (e.g. crossing legs, wearing garters or placing pillows under the knees).
- When possible, elevate legs to improve venous return.
- Do not massage legs.

Equipment

- Disposable leg wraps (knee or thigh length or foot)
- Tubing set
- Pump controller

Therapeutic relationship and patient considerations

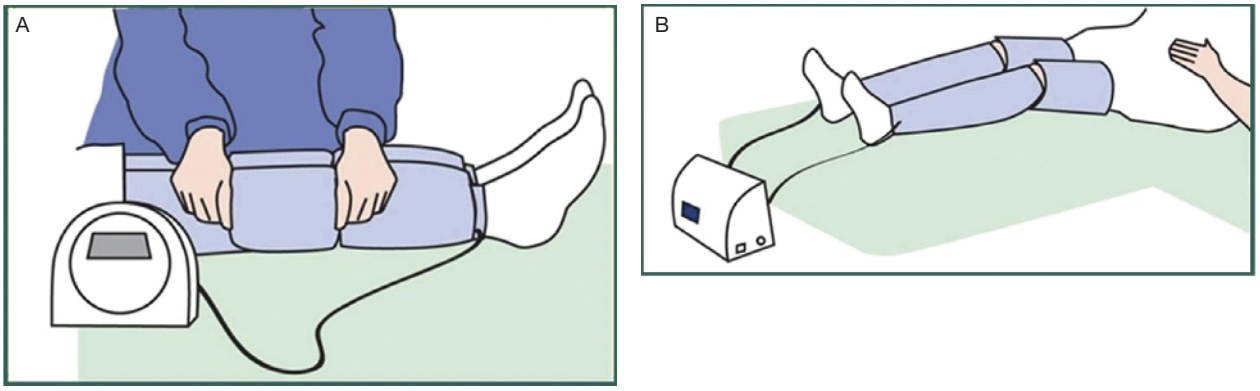
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
PREPARATION	
1. Assess patient for risk factors for venous thromboembolism to determine need for SCD.	
2. Review medical prescription for type/length of SCD.	
3. Observe for signs, symptoms and conditions that might contraindicate the use of SCD.	
4. Review product information for application and use.	
5. Gather equipment.	
6. Assess patient's or caregiver's understanding of application of SCD.	Identifies potential educational needs of patient or caregiver.

STEPS	RATIONALE
7. Assess and document condition of patient's skin and circulation to legs (i.e. neurovascular assessment and for presence of pedal pulses, oedema, discolouration of skin, temperature, lesions or cuts).	Identifies a baseline for skin integrity and quality of peripheral pulses in lower extremities after SCD in place.
8. Explain procedure and reasons for applying SCD.	
9. Perform hand hygiene.	
10. Plug the SCD pump into the wall socket, but leave turned off.	

■ **Critical decision point: Follow policy of the clinical facility for the amount of time alternating pneumatic compression devices are removed during the day.**

11. Remove wraps from packaging.	
12. Connect tubing set to the pump, noting the connecting click is heard.	
13. Unfold wrap and place the inflatable bladder directly behind the patient's calf.	



(A) Application of intermittent pneumatic compression device. (B) Intermittent pneumatic compression device.

14. Wrap the device around the patient's leg and ensure the fastener tabs are secured. Repeat the process for the other leg.	
15. Check the wrap is not too tight by slipping two fingers beneath it.	To prevent wraps from constricting circulation distally.
16. Attach the wraps to the tubing set-up; be alert for a clicking connecting sound to indicate connection.	
17. Adjust the pump pressure regulator to product recommended pressure according to the physician's request.	Intermittent compression and relaxation reduces venous stasis and therefore improves the natural fibronolytic activity of the body.
18. Ensure there are no kinks in the tubing.	Kinks can restrict airflow through the system.
19. Turn the pump on. Note illumination of the light that indicates it is operational.	

STEPS	RATIONALE
20. Position the patient comfortably, with the nurse call bell at reach.	
21. Advise the patient to notify nurse of any tingling, numbness or discomfort.	
22. Perform hand hygiene.	
23. Regularly remove wraps for inspection of the skin and neurovascular assessment.	Wraps should be removed accordingly.

(C) Sequential compression devices are placed on the patient's legs prior to the induction of anesthesia.

(D) Intermittent compression devices can be used in conjunction with graduated compression stockings.

Critical decision point: The effectiveness of the mechanical device in preventing clot formation is dependent on appropriate fitting and being consistently applied with minimal interruptions.

RECORDING AND REPORTING

- Record baseline neurovascular assessment data.
- Record neurovascular assessment data after application.
- Record condition of skin.
- Record type of sleeve used; thigh high, knee high.
- Record date and time of SCD application.

HOME CONSIDERATIONS

- The use of SCDs is not appropriate in the home.

patient's suitability for wearing them. The stockings should not be applied if there is any local condition affecting the leg (e.g. any skin lesion, gangrenous condition or recent vein ligation), as application may compromise circulation. The stockings must be applied properly, and they must be removed and reapplied at least twice a day (Box 28-4). In addition, the stockings should always be clean and dry. It may be useful for the patient to have two pairs.

Positioning techniques help reduce compression of the leg veins. Proper positioning used with other therapies (e.g. heparin or elastic stockings) helps reduce the patient's risk of thrombus formation (see Positioning patients in bed, Skill 28-3). When positioning patients, the nurse must be careful to prevent pressure on the posterior knee and deep veins in the lower extremities. Patient teaching should include avoiding crossing the legs, not sitting for prolonged periods of time, not wearing

SKILL 28-2

Applying elastic stockings

Delegation considerations

Applying elastic stockings can be delegated to nurse assistants. The following information should be given when delegating this task:

- Avoid activities that promote venous stasis (e.g. crossing legs, wearing garters or placing pillows under the knees).
- When possible, elevate legs to improve venous return.
- Do not massage legs.
- Elevate legs before applying stockings.
- Avoid wrinkles in the stockings.
- Observe for allergic reactions, skin irritation and thrombophlebitis.

Equipment

- Tape measure
- Talcum powder
- Elastic support stockings (proper size)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess patient for risk factors for venous thromboembolism to determine need for elastic stockings.	Potential candidates for elastic stockings are patients who have an alteration in one of the elements of Virchow's triad.
2. Observe for signs, symptoms and conditions that might contraindicate the use of elastic stockings:	
• Dermatitis or open skin lesion	Elastic stockings may aggravate a skin condition or cause it to spread. Also, medication and dressings may need to be applied to lesion.
• Recent skin graft	Continuous pressure is necessary to keep graft adherent to recipient bed, but pressure should not be so firm as to cause death of graft.
• Disproportionately large thighs	Elastic stockings may not fit correctly, causing excessive pressure and constriction around thighs, thereby reducing venous return.
• Decreased circulation in lower extremities (e.g. peripheral vascular disease) as evidenced by cyanotic, cool extremities	Elastic stockings may further impede circulation.
3. Obtain medical prescription.	May be needed for legal or reimbursement reasons.
4. Assess patient's or caregiver's understanding of application of elastic stockings.	Identifies potential educational needs of patient or caregiver.

STEPS	RATIONALE
5. Assess and document condition of patient's skin and circulation to legs (i.e. presence of pedal pulses, oedema, discolouration of skin, temperature, lesions or cuts).	Identifies a baseline for skin integrity and quality of peripheral pulses in lower extremities.
6. Explain procedure and reasons for applying stockings.	Reduces anxiety and encourages patient cooperation.
7. Use tape measure to measure patient's legs to determine proper stocking size.	Stockings must be measured according to manufacturer's directions. Elastic stockings come in two lengths: knee length and thigh length. The choice of length depends on the prescription.

■ **Critical decision point: Compare patient's measurements with the manufacturer's sizing chart. If too large, stockings will not adequately support extremities. If too small, stockings may impede circulation. The optimum stocking pressure is 20–30 mmHg at the ankle, decreasing to 8 mmHg at the middle to upper thigh. This change in pressure produces the greatest increase in venous flow velocity that is both safe and practical.**

8. Perform hand hygiene.	Reduces transmission of microorganisms.
9. Position patient in supine position. Elevate head of bed to comfortable level.	Promotes good body mechanics for nurse. Patient position eases application. Also, the stockings should be applied before standing to prevent stagnation of blood in lower extremities. If patient has been standing, patient should sit in chair or lie in bed for 15 minutes with legs elevated before applying elastic stockings.
10. After legs are cleaned, apply small amount of talcum powder to legs and feet, provided that patient does not have sensitivity to talcum powder.	Talcum powder reduces friction and allows for easier application of stockings.
11. Apply stockings.	
a. Turn elastic stocking inside out by placing one hand into sock, holding toe of sock with other hand, and pulling (see illustration). Leave the toe of the stocking tucked inside to form a pocket.	Allows easier application of stocking.
b. Place patient's toes into foot of elastic stocking, making sure that sock is smooth (see illustration).	Wrinkles in sock can impede circulation to lower region of extremity.

Step 11a Turning stocking inside out.

Step 11b Placing foot into sock.

STEPS	RATIONALE
c. Slide remaining portion of sock over patient's foot, being sure that the toes are covered. Make sure the foot fits into the toe and heel position of the sock. Sock will now be right side out (see illustration).	If toes remain uncovered, they will become constricted by elastic and their circulation can be reduced.
d. Slide sock up over patient's calf until sock is completely extended. Be sure sock is smooth and no ridges are present (see illustration).	Ridges impede venous return and can counteract overall purpose of elastic stocking.
e. Instruct patient not to roll socks partially down.	Rolling sock partially down has a constricting effect and can impede venous return.

Step 11c Sliding stocking over foot.

Step 11d Applying stocking over calf.

12. Reposition patient to position of comfort and wash hands.	Maintains proper body alignment and promotes comfort. Reduces transmission of microorganisms.
13. Inspect stocking to make sure there are no wrinkles or binding at top of stocking.	Wrinkles lead to increased pressure and alter circulation.
14. Observe patient's reaction to stockings.	Ensures patient is adapting to stockings and is not experiencing any discomfort from stockings.
15. Observe patient or caregiver applying stockings.	Determines ability to perform skill accurately.
16. Remove stockings at least once a shift, and assess skin and circulatory status.	Stockings may shift or be too tight, and this step ensures skin and circulation are intact.
17. Ensure shoes/slippers are available for patient.	Wearing shoes/slippers decreases risk of patient slipping.

RECORDING AND REPORTING

- Record date and time of stocking application and stocking length and size in nurses' notes (flow sheet may be used).
- Record condition of skin and circulatory assessment, including pulses, temperature, sensation, movement, capillary refill and calf circumference at application and each shift.
- Report changes indicating a decline in circulation.

HOME CARE CONSIDERATIONS

- Instruct patients to have two pairs of stockings – one pair to wear, the other to wash.
- Instruct patients that if there are bodyweight changes greater than 4.5 kg, stockings should be remeasured.
- Remind patients to put on stockings before getting up for the morning or sitting for prolonged periods. As the day progresses, leg swelling may increase and may make stocking application difficult. (It may be helpful to remind patients that they may have noticed this swelling when wearing shoes.)

clothing that constricts the legs or waist, not putting pillows under the knees and avoiding massaging the legs.

ROM exercises are designed to reduce the risk of contractures but may also aid in preventing thrombi. Activity causes contraction of the skeletal muscles, which in turn exerts pressure on the veins to promote venous return, thereby reducing venous stasis. Specific exercises that help prevent thrombophlebitis are ankle pumps, foot circles and knee flexion. Ankle pumps, sometimes called calf pumps, include alternating plantar flexion and dorsiflexion. Foot circles require the patient to rotate the ankle. Knee flexion involves alternately extending and flexing the knee. These exercises are sometimes referred to as *anti-embolic exercises* and should be done hourly while awake.

When DVT is suspected, the nurse should report it immediately for further investigation. The legs should be elevated with no pressure on the thrombus to reduce swelling and pain. Elastic compression stockings are applied to both legs to above the thighs. Drug therapy includes intravenous heparin or subcutaneous low-molecular-weight heparin, with overlap with an oral anticoagulant (warfarin) until it becomes effective. The family, patient and all healthcare personnel should be instructed not to massage the area because of the danger of dislodging the thrombus.

Musculoskeletal system interventions

The immobilised patient must receive some exercise to prevent excessive **muscle atrophy** and joint contractures. If the patient is unable to move part or all of the body, the nurse must perform passive ROM exercises for all immobilised joints while bathing the patient and at least two or three further times a day. If one extremity is paralysed, the patient can be taught to put each joint independently through its ROM. Patients on bed rest should have active ROM exercises incorporated into their daily schedules. Nurses can teach patients to integrate exercises during ADLs.

Some orthopaedic conditions require more frequent passive ROM exercises to restore the injured joint's function after surgery. Patients with such conditions may use automatic equipment for passive ROM exercises (Figure 28-16). The equipment moves an extremity to a prescribed angle for a prescribed period. This is beneficial when the patient must gradually increase the degree and duration of flexion and extension.

Figure 28-16 Continuous passive range-of-motion machine.

Potter PA, Perry AG 2004 Fundamentals of nursing, 6th edn. Mosby, St Louis.

Active ROM exercises maintain function of the musculoskeletal system. The nurse should also plan interventions for the gradual return of mobility for patients who will be able to resume normal activity. The best nursing intervention is establishing an individualised progressive exercise program. A progressive exercise program gradually increases the patient's physical activity to reverse the deconditioning associated with immobility. Progressive exercise programs are used for patients with musculoskeletal, neurological, cardiopulmonary, renal and other chronic diseases. When working with older adults, the nurse should consider gerontological principles that enhance the effectiveness of exercise programs and limit injuries (see *Working with diversity*, Focus on older adults).

Teaching, referral and interdisciplinary collaboration are important for patients with limited mobility. Depending on the setting and resources available, the nurse may want to refer the patient for physiotherapy. The therapist sets up the specific exercise program and the nurse plays an important role in reinforcing it.

WORKING WITH DIVERSITY

Focus on older adults

- Ensure low exercise intensity of 40–70% maximum predicted heart rate (maximum predicted heart rate = age in years subtracted from 220) and very gentle exercise progression.
- Use perceived exertion versus exercise heart rate to monitor exercise intensity.
- Perform a gradual, extended exercise warm-up and cool-down to decrease risk of postural hypotension and cardiac dysrhythmias.
- Use correct body mechanics, appropriate clothing, exercise-specific shoes and sufficient hydration.
- Avoid sudden twisting movements, rapid movements and rapid transitions from one movement to the next.
- Avoid exercises that tax vision and balance.
- Avoid sustained isometric contractions of more than 10 seconds.
- Avoid exercise during acute viral infections.
- Stop exercising if angina, premature ventricular contractions or excessive breathlessness occurs.
- Seek a physical examination and written instructions for specific exercise restrictions before onset of an exercise program.
- Engage in brisk walking for 10–15 minutes to tone the extremities and provide aerobic activity for older adults.
- Older adults may perform both strenuous and less strenuous activities. Activities may range from gardening to chair-based exercises and Tai Chi.

Integumentary system interventions

The major risk to the skin from restricted mobility is the formation of pressure ulcers (Coleman et al 2013). Nursing interventions therefore focus on preventing or treating these ulcers (see Chapter 26). Early identification of high-risk patients and their risk factors helps the nurse prevent pressure ulcers. Interventions aimed at prevention are positioning, skin care and the use of therapeutic devices to relieve pressure. The immobilised patient's position should be changed according to the patient's activity level, perceptual ability, treatment protocols and daily routines. Although turning every 1–2 hours is recommended for preventing ulcers, it may also be necessary to use devices for relieving pressure. The time that a patient sits uninterrupted in a chair should be limited to 1 hour or less, but this time interval is individualised. The patient should be repositioned frequently because uninterrupted pressure will cause skin breakdown.

Elimination system interventions

The nursing interventions for maintaining optimal urinary functioning are directed at keeping the patient well hydrated and preventing urinary stasis, calculi and infections without causing bladder distension.

Adequate hydration helps prevent **renal calculi** and UTIs. The well-hydrated patient should void a large amount of dilute urine that is approximately equal to fluid intake. If the patient is incontinent, the nurse should modify the care plan to include toileting aids and a hygiene schedule so that the increased urinary output does not cause skin breakdown.

To prevent bladder distension, nurses assess the frequency and amount of urinary output. A patient who continually dribbles urine and whose bladder is distended may have reflex incontinence. If the immobilised patient does not have voluntary control of bladder elimination, bladder re-training may be necessary. If the patient experiences bladder distension, the nurse may be required to insert a straight catheter or an indwelling Foley catheter (see Chapter 33).

Nurses can also record the frequency and consistency of bowel movements; constipation is common in immobile patients. A diet rich in fluids, fruits, vegetables and fibre can facilitate normal peristalsis. If a patient is unable to maintain regular bowel patterns, a medical prescription for stool softeners, cathartics or enemas may be indicated (see Chapter 32).

Psychosocial changes

Assessment can identify effects of prolonged immobilisation on the patient's psychosocial dimension. People who have a tendency towards depression or mood swings are at greater risk of developing psychosocial effects during bed rest or immobilisation. There are many nursing interventions to meet the patient's psychosocial needs.

Nurses should anticipate changes in the patient's psychosocial status. They must also provide stimuli to maintain orientation. A daily newspaper helps the patient keep track of events and time. Diversional activities such as reading, music, television and DVDs can be used to provide stimulation and help pass the time.

Positioning techniques

Patients with impaired nervous, skeletal or muscular system functioning and increased weakness often require help from the nurse to attain proper body alignment while in bed or sitting. Several positioning devices are available for maintaining good body alignment for patients (summarised in Table 28-5).

TABLE 28-5 Devices used for proper positioning

Devices	Uses and descriptions
Abduction or wedge pillow	Triangular-shaped pillows made of heavy foam Used following total hip replacement surgery to ensure the new hip joint remains in abduction and flexion (Figure 28-19)
Bed boards	Plywood boards placed under the entire surface area of the mattress Useful for increasing back support and alignment, especially with a soft mattress
Hand rolls	Foam-filled rolls of various shapes/sizes Maintain the thumb slightly adducted and in opposition to the fingers; maintain fingers in a slightly flexed position. The nurse evaluates the position of the hand roll to make certain the hand is indeed in a functional position
Hand–wrist splints	Individually moulded splints; should be used only for the patient for whom the splint was made Maintain proper alignment of the thumb in slight adduction and the wrist in slight dorsiflexion
Footboard	Board placed perpendicular to mattress, parallel to and touching plantar surfaces of patient's feet Used to prevent footdrop by maintaining feet in dorsiflexion
Foot boots	Boots made of rigid plastic or heavy foam which keep the foot flexed at the proper angle Used to maintain feet in dorsiflexion Foot boots should be removed two or three times a day to assess skin integrity and joint mobility
Pillows	Readily available in most healthcare facilities, including the home Should be of appropriate size for the body part to be positioned Pillows provide support, elevate body parts and can splint incisional areas, reducing postoperative pain during activity or coughing and deep-breathing

continued

TABLE 28-5 ***continued***

Devices	Uses and descriptions
Sandbags	Filled plastic tubes that can be shaped to body contours; can be used in place of, or in addition to, trochanter rolls Provide support and shape to body contours, immobilise extremities and maintain specific body alignment
Side rails	Bars positioned along the sides of the length of the bed Ensure patient safety and are useful for increasing mobility. In addition, they provide assistance in rolling from side to side or sitting up in bed
Trapeze bar	Bar descending from a securely fastened overhead bar attached to the bed frame (Figure 28-18) Allows patient to use upper extremities to raise the trunk off the bed, to assist in transfer from bed to wheelchair or to perform upper-arm strengthening exercises
Trochanter rolls	A cotton bath blanket or a sheet folded lengthwise to a width extending from the greater trochanter of the femur to the lower border of the popliteal space (Figure 28-17). The blanket is placed under the buttocks and then rolled away from the patient until the thigh is in the neutral position or an inward position with the patella facing upwards Used to prevent external rotation of legs when patients are in the supine position

Pillows are a positioning aid that may or may not be readily available. Before using a pillow it should be assessed to determine whether it is the proper size. A thick pillow under the patient's head increases cervical flexion. A thin pillow under body prominences may be inadequate to protect skin and tissue from damage caused by pressure. When additional pillows are unavailable, or if they are an incorrect size, folded sheets, blankets or towels can be used as positioning aids. The 30-degree lateral position is recommended for patients at risk of pressure ulcer development.

A footboard is placed perpendicular to the mattress, parallel to and touching the plantar surfaces of the patient's feet. The footboard prevents footdrop by maintaining the feet in dorsiflexion. After placing it on the bed, the nurse needs to determine that it is correctly placed, with the patient's feet placed firmly against the board. Another common technique is the use of high-top tennis shoes or an ankle–foot orthotic to help maintain dorsiflexion.

A trochanter roll prevents external rotation of the hips when the patient is in a supine position. To form a trochanter roll, a cotton bath blanket is folded lengthwise to a width that will extend from the greater trochanter of the femur to the lower border of the popliteal space (see Figure 28-17). The blanket is placed under the buttocks and then rolled counter-clockwise until the thigh is in neutral position or in inward rotation. When correct alignment of the hip is achieved, the patella faces directly upwards. Sandbags are sand-filled plastic tubes or bags that can be shaped to body contours. Sandbags can be used in place of or in addition to trochanter rolls. They immobilise an extremity or maintain body alignment.

Hand rolls maintain the thumb in slight adduction and in opposition to the fingers. A hand roll maintains the hand, thumb and fingers in a functional position. Nursing assessment will include evaluating the hand roll to make sure that the hand is indeed in a functional position. Hand rolls are most often used for patients whose arms are paralysed or who are unconscious. Rolled washcloths should not be used as hand rolls, since they do not keep the thumb well abducted, especially in patients who have a spastic paralysis.

Figure 28-17 Trochanter roll.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Hand–wrist splints are individually moulded for the patient to maintain proper alignment of the thumb (slight adduction) and the wrist (slight dorsiflexion). These splints should be used only by the patient for whom the splint was made.

The trapeze bar is a triangular device that descends from a securely fastened overhead bar that is attached to the bed frame. It allows the patient to pull with the upper extremities to raise the trunk off the bed, to assist in transfer from bed to wheelchair or to perform upper-arm exercises (see Figure 28-18). It is a useful device for helping to increase independence, maintain upper body strength and decrease the shearing action from sliding across or up and down in bed.

Although each procedure for positioning has specific guidelines, there are some universal steps that best nursing practice should follow for patients who require positioning

Figure 28-18 Patient using a trapeze bar.

Hoffman-Wold G 2008 Basic Geriatric nursing. Mosby, St Louis.

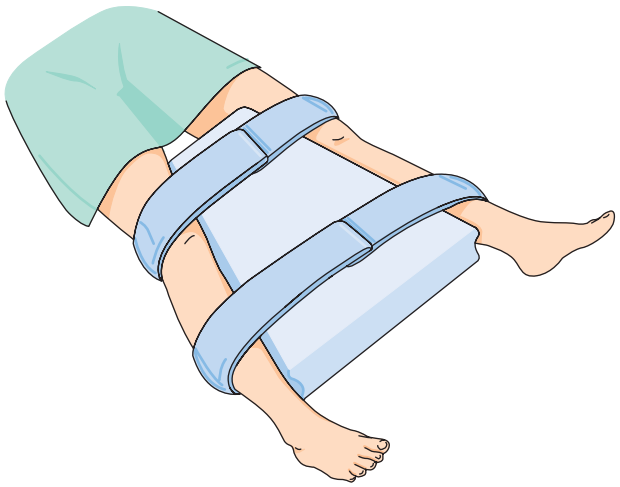


Figure 28-19 Abduction pillow used after total hip replacement.

Beare PG, Myers JL 1998 Adult health nursing, 3rd edn. Mosby, St Louis.

assistance (Skill 28-3). Following the guidelines reduces the risk of injury to the musculoskeletal system when the patient is sitting or lying. When joints are unsupported, their alignment is impaired. Likewise, if joints are not positioned in a slightly flexed position, their mobility is decreased. During positioning, the nurse also assesses for pressure points. When actual or potential pressure areas exist, nursing interventions involve removal of the pressure, thus decreasing the risk of development of pressure ulcers and further trauma to the musculoskeletal system. In these patients the 30-degree lateral position should be used when possible. A further consideration is maintaining the optimum position of the patient. Once the nurse has positioned the patient consideration needs to be given to the potential of the patient compromising the position, such as through slouching. Although at all times the nurse needs to encourage the patient to move where possible, the nurse also needs to consider the possible impact on the patient if the patient compromises their positioning. An example of this is the patient sliding down the bed after being positioned in a supported Fowler's position. This could result in slouching, which can restrict the lungs and breathing, and ultimately result in a decrease in tissue oxygenation.

SUPPORTED FOWLER'S POSITION In the supported Fowler's position the head of the bed is elevated 45–60 degrees and

SKILL 28-3

Positioning patients in bed

Delegation considerations

The task of moving and positioning patients in bed can be delegated to assistants. A risk assessment should be conducted on all patients requiring assistance with positioning. A 'no-lift' policy has been implemented in most facilities. Equipment such as lifting machines should be used whenever repositioning poses a risk to the patient and to the staff.

Equipment

- Slide sheets
- Pillows
- Other support devices as necessary (e.g. hand splints, sandbags, wedge pillows, trochanter rolls)
- Lifting devices if required

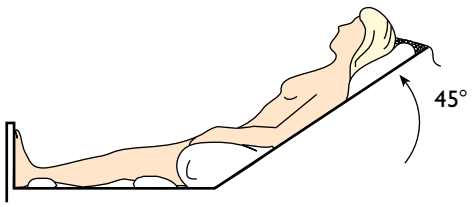
Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess patient's body alignment and comfort level while patient is lying down.	Provides baseline data for later comparisons. Determines ways to improve position and alignment.
2. Assess for risk factors that may contribute to complications of immobility:	Increased risk factors require patient to be repositioned more frequently.
• Paralysis: hemiparesis resulting from stroke; decreased sensation	Paralysis impairs movement; muscle tone changes; sensation is affected. Because of difficulty in moving and poor awareness of involved body part, patient is unable to protect and position body part for self.
• Impaired mobility: traction or arthritis or other contributing disease processes	Traction or arthritic changes of affected extremity result in decreased range of joint motion.
• Impaired circulation	Decreased circulation predisposes patient to pressure injury.
• Age: very young, older adults	Premature and young infants require frequent turning because their skin is fragile. Normal physiological changes associated with ageing predispose older adults to greater risks of developing complications of immobility.
• Patient's level of consciousness	Determines need for special aids or devices. Patients with altered levels of consciousness may not understand instructions and may be unable to help.
3. Assess patient's physical ability to help with moving and positioning.	Enables nurse to use patient's mobility and strength. Determines need for additional help. Ensures patient and nurse safety.
4. Explain procedure to patient.	Helps to decrease anxiety and increase cooperation.
5. Adjust the bed height to between mid-thigh and hip height.	Raises level of work towards nurse's centre of gravity.
6. Remove all pillows and devices used in previous position.	Reduces interference from bedding during positioning procedure.
7. Get extra help as needed.	Provides for patient and nurse safety.
8. Position patient in bed.	
A. Patient-assisted bed slide (one nurse):	
(1) Place patient supine with head of bed flat.	Enables nurse to assess body alignment. Reduces gravity's pull on patient's upper body.
(2) Remove pillow from under head and shoulders and place pillow at head of bed.	Prevents striking patient's head against head of bed.
(3) Ask or assist the patient to fold his or her arms across the chest.	

STEPS	RATIONALE
(4) Fold a slide sheet in half and tuck under the patient's shoulders and hips with the fold facing towards the patient's feet.	Slide sheets reduce friction and reduce the force required to move the patient.
(5) Ask or assist the patient to roll to the side to pull the slide sheet into position.	
(6) Have the patient roll back to supine position and bend their knees.	
(7) Stand at the end of the bed and support the patient's feet.	
(8) Ask the patient to extend the legs while holding the feet against the mattress. The patient will push himself or herself up the bed.	Where possible, patients should be encouraged to move themselves.
B. Bed slide (two nurses):	
(1) Place patient supine with head of bed flat.	Enables nurse to assess body alignment. Reduces gravity's pull on patient's upper body.
(2) Remove pillow from under head and shoulders and place pillow at head of bed.	Prevents striking patient's head against head of bed.
(3) Ask or assist the patient to fold his or her arms across the chest.	
(4) Tuck two slide sheets (on top of each other) under the length of the patient's body.	Slide sheets reduce friction and reduce the force required to move the patient.
(5) Ask or assist the patient to cross their legs (i.e. if rolling to the left, cross right over left). Roll the patient to the side and pull the slide sheet into position over the mattress.	
(6) Roll the patient back to a supine position.	
(7) Stand at the top end of the bed corners and gather the ends of the top slide sheet with palms down.	Face in the direction of movement to prevent spinal twisting.
(8) In a controlled manner and with arms straight, both nurses should lunge backwards on the count of three, transferring weight from the front foot to the back foot, moving the patient towards the head of the bed.	Assuming a broad stance increases stability and balance. Use of large muscle groups and shifting weight reduces the force needed to move load.
(9) Tuck the slide sheets under the patient and pull them out from beneath the patient. Replace pillows and position the patient to a position of comfort and safety.	

STEPS	RATIONALE
C. Position patient in supported semi-Fowler's position (see illustration):	
(1) Elevate head of bed 45–60 degrees.	Increases comfort, improves ventilation and increases patient's opportunity to socialise or relax.
(2) Rest head against mattress or on small pillow.	Prevents flexion contractures of cervical vertebrae.
(3) Use pillows to support arms and hand if patient does not have voluntary control or use of hands and arms.	Prevents shoulder dislocation from effect of downward pull of unsupported arms, promotes circulation by preventing venous pooling and prevents flexion contractures of arms and wrists.
(4) Position pillow at lower back.	Supports lumbar vertebrae and decreases flexion of vertebrae.
(5) Place small pillow or roll under thigh.	Prevents hyperextension of knee and occlusion of popliteal artery from pressure from bodyweight.
(6) Place small pillow or roll under ankles.	Prevents prolonged pressure of mattress on heels.

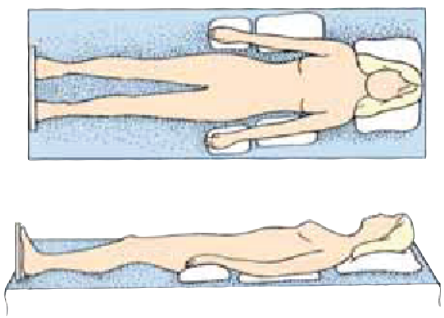


Step 8C(6) Supported semi-Fowler's position.

■ **Critical decision point: To keep feet in proper alignment, place footboard at bottom of patient's feet.**

D. Position hemiplegic patient in supported semi-Fowler's position:	
(1) Elevate head of bed 45–60 degrees.	Increases comfort, improves ventilation and increases patient's opportunity to relax.
(2) Position patient in sitting position as straight as possible, with support for affected shoulder.	Counteracts tendency to slump towards affected side. Improves ventilation and cardiac output; decreases intracranial pressure. Improves patient's ability to swallow and helps to prevent aspiration of food, liquids and gastric secretions.
(3) Position head on small pillow with chin slightly forwards. If patient is totally unable to control head movement, hyperextension of the neck must be avoided.	Prevents hyperextension of neck. Too many pillows under head may cause or worsen neck flexion contracture.
(4) Provide support for involved arm and hand on overbed table in front of patient. If transfer is to wheelchair, arms of chair can provide support. Place arm away from patient's side and support elbow with pillow.	Paralysed muscles do not automatically resist pull of gravity as they do normally. As a result, shoulder subluxation, pain and oedema may occur.

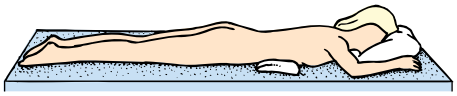
STEPS	RATIONALE
(a) Position flaccid hand in normal resting position with wrist slightly extended, arches of hand maintained and fingers partially flexed; may use section of rubber ball cut in half; clasp patient's hands together.	Maintains hand in functional position. Prevents contractures.
(b) Position spastic hand with wrist in neutral position or slightly extended; fingers should be extended with palm down or may be left in relaxed position with palm up.	Maintains hand in functional position. Inhibits flexor spasticity.
(5) Flex knees and hips by using pillow or folded blanket under knees.	Ensures proper alignment. Flexion prevents prolonged hyperextension, which could impair joint mobility.
(6) Support feet in dorsiflexion with firm pillow or footboard.	Prevents footdrop. Stimulation of ball of foot by hard surface has tendency to increase muscle tone in patient with extensor spasticity of lower extremity.
E. Position patient in supine position:	
(1) Place patient on back with head of bed flat.	Necessary for placing patient in supine position.
(2) Place small rolled towel under lumbar area of back.	Provides support for lumbar spine.
(3) Place pillow under upper shoulders, neck or head.	Maintains correct alignment and prevents flexion contractures of cervical lumbar spine.
(4) Place trochanter rolls or sandbags parallel to lateral surface of patient's thighs.	Reduces external rotation of hip.
(5) Place small pillow or roll under ankle to elevate heels.	Reduces pressure on heels, helping to prevent pressure sores.
(6) Support feet in dorsiflexion with firm pillow or footboard.	Prevents footdrop.
(7) Place pillows under pronated forearms, keeping upper arms parallel to patient's body (see illustrations).	Reduces internal rotation of shoulder and prevents extension of elbows. Maintains correct body alignment.



Step 8E(7) Supine position with supporting pillows.

STEPS	RATIONALE
(8) Place hand rolls in patient's hands. Consider physical therapy referral for use of hand splints.	Reduces extension of fingers and abduction of thumb. Maintains thumb slightly adducted and in opposition to fingers.
F. Position hemiplegic patient in supine position:	
(1) Place head of bed flat.	Necessary for positioning in supine position.
(2) Place folded towel or small pillow under shoulder or affected side.	Decreases possibility of pain, joint contracture and subluxation. Maintains mobility in muscles around shoulder to permit normal movement patterns.
(3) Keep affected arm away from body with elbow extended and palm up. (Alternative is to place arm out to side, with elbow bent and hand towards head of bed.)	Maintains mobility in arm, joints and shoulder to permit normal movement patterns. (Alternative position counteracts limitation of ability of arm to rotate outwards at shoulder (external rotation). External rotation must be present to raise arm overhead without pain.)
(4) Place folded towel under hip of involved side.	Diminishes effect of spasticity in entire leg by controlling hip position. Slight flexion breaks up abnormal extension pattern of leg. Extensor spasticity is most severe when patient is supine.
(5) Support feet with soft pillows at right-angle to leg, and keep heels off bed or use heel protectors.	Maintains foot in dorsiflexion and prevents footdrop. Pillows prevent stimulation to ball of foot by hard surface, which has tendency to increase muscle tone in patient with extensor spasticity extremity.
G. Position patient in prone position:	
(1) Roll patient over arm positioned close to body, with elbow straight and hand under hip. Position on abdomen in centre of bed.	Positions patient correctly so alignment can be maintained.
(2) Turn patient's head to one side and support head with small pillow (see illustration).	Reduces flexion or hyperextension of cervical vertebrae.
(3) Place small pillow under patient's abdomen below level of diaphragm (see illustration).	Reduces pressure on breasts of some female patients and decreases hyperextension of lumbar vertebrae and strain on lower back. Improves breathing by reducing mattress pressure on diaphragm.
(4) Support arms in flexed position level at shoulders.	Maintains proper body alignment. Support reduces risk of joint dislocation.
(5) Support lower legs with pillow to elevate toes (see illustration).	Reduces external rotation of legs and mattress pressure on toes.

STEPS	RATIONALE

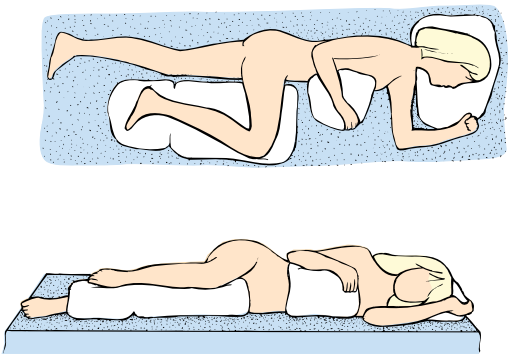


Step 8G(2 & 3) Placement of pillows under head and abdomen.

Step 8G(5) Placement of pillows to support lower legs.

H. Position hemiplegic patient in prone position:	
(1) Move patient towards unaffected side.	Ensures proper patient alignment in centre of bed when patient is rolled onto abdomen.
(2) Roll patient onto side.	
(3) Place pillow on patient's abdomen.	Prevents sagging of abdomen when patient is rolled over; decreases hyperextension of lumbar vertebrae and strain on lower back.
(4) Roll patient onto abdomen by positioning involved arm close to patient's body, with elbow straight and hand under hip. Roll patient carefully over arm.	Prevents injury to affected side.
(5) Turn head towards involved side.	Promotes development of neck and trunk extension, which is necessary for standing and walking.
(6) Position involved arm out to side, with elbow bent, hand towards head of bed and fingers extended (if possible).	Counteracts limitation of arm's ability to rotate outwards at shoulder (external rotation). External rotation must be present to raise arm over head without pain.
(7) Flex knees slightly by placing pillow under legs from knees to ankles.	Flexion prevents prolonged hyperextension, which could impair joint mobility.
(8) Keep feet at right-angle to legs by using pillow high enough to keep toes off mattress.	Maintains feet in dorsiflexion.
I. Position patient in lateral (side-lying) position:	
(1) Lower head of bed completely or as low as patient can tolerate.	Provides position of comfort for patient and removes pressure from bony prominence on back.
(2) Position patient supine towards side of bed.	Provides room for patient to turn to side.

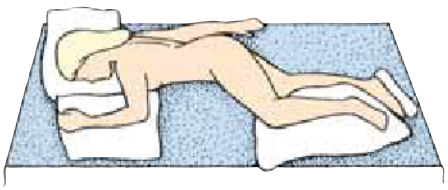
STEPS	RATIONALE
Critical decision point: Patients at risk of pressure ulcer development require the 30-degree lateral position.	
(3) Roll patient onto side towards nurse by flexing patient's knees and placing one hand on patient's hip and one hand on patient's shoulder.	Client is positioned so leverage on hip makes turning easy. Rolling patient towards nurse lessens trauma to tissues.
(4) Place pillow under patient's head and neck.	Maintains alignment. Reduces lateral neck flexion. Decreases strain on sternocleidomastoid muscle.
(5) Bring shoulder blade forward.	Prevents patient's weight from resting directly on shoulder joint.
(6) Position both arms in slightly flexed position. Upper arm is supported by pillow level with shoulder; other arm, by mattress.	Decreases internal rotation and adduction of shoulder. Supporting both arms in slightly flexed position protects joint. Ventilation is improved because chest is able to expand more easily.
(7) Place tuck-back pillow behind patient's back. (Make by folding pillow lengthwise. Smooth area is slightly tucked under patient's back.)	Provides support to maintain patient on side.
(8) Place pillow under semiflexed upper leg level at hip from groin to foot (see illustrations).	Flexion prevents hyperextension of leg. Maintains leg in correct alignment. Prevents pressure on bony prominence.
(9) Place sandbag parallel to plantar surface of dependent foot.	Maintains dorsiflexion of foot. Prevents footdrop.



Step 8I(8) Side-lying patient with pillows in place.

J. Position patient in Sims' (semi-prone) position:	
(1) Lower head of bed completely.	Provides for proper body alignment while patient is lying down.
(2) Place patient in supine position.	Prepares patient for position.

STEPS	RATIONALE
(3) Position patient in lateral position, lying partially on abdomen.	Patient is rolled only partially on abdomen.
(4) Place small pillow under patient's head.	Maintains proper alignment and prevents lateral neck flexion.
(5) Place pillow under flexed upper arm, supporting arm level with shoulder.	Prevents internal rotation of shoulder. Maintains alignment.



Step 8J(7) Sims' (semi-prone) position with pillows and sandbag in place.

(6) Place pillow under flexed upper legs, supporting leg level with hip.	Prevents internal rotation of hip and adduction of leg. Flexion prevents hyperextension of leg. Reduces mattress pressure on knees and ankles.
(7) Place sandbags parallel to plantar surface of foot (see illustration).	
9. Perform hand hygiene.	Reduces transmission of infection.
10. Lower bed and raise side rails.	Provides for patient safety.
11. Observe patient's body alignment, position and level of comfort.	Determines effectiveness of positioning. Additional supports (e.g. pillows, bath blankets) may be added or removed to promote comfort and correct body alignment.
12. Assess for areas of erythema or breakdown involving skin.	Provides ongoing observation regarding patient's skin and musculoskeletal systems. Indicates complications of immobility or improper positioning of body part.

RECORDING AND REPORTING

- Record each position change, including amount of assistance needed and patient's response and tolerance.
- Record and report any signs of pressure injury in areas such as over bony prominences.

HOME CARE CONSIDERATIONS

- For patients who need positioning at home, teach family the importance of body mechanics for themselves and the patient.
- Teach family about the signs of skin breakdown and the importance of safety during positioning for patients with decreased sensation.

the patient's knees are slightly elevated without pressure to restrict circulation in the lower legs. The angle of head and knee elevation and the length of time that the patient should remain in the supported Fowler's position are influenced by the patient's illness and overall condition. Supports must permit flexion of the hips and knees and proper alignment of the normal curves in the cervical, thoracic and lumbar vertebrae.

SUPINE POSITION The supine position, in which the patient rests on the back, is also called the dorsal recumbent position. In the supine position the relationship of body parts is essentially the same as in good standing alignment, except that the body is in the horizontal plane. Pillows, trochanter rolls and hand rolls or arm splints are used to increase comfort and reduce injury to the skin or musculoskeletal system. The mattress should be firm enough to support the cervical, thoracic and lumbar vertebrae. Shoulders are supported, and the elbows are slightly flexed to control shoulder rotation. A foot support is used to prevent footdrop and maintain proper alignment.

PRONE POSITION The prone position is lying face or chest down. Often the patient's head is turned to the side, but if a pillow is under the head it should be thin enough to prevent cervical flexion or extension and maintain alignment of the lumbar spine. Placing a pillow under the lower leg permits dorsiflexion of the ankles and some knee flexion, which promotes relaxation. If a pillow is unavailable, the ankles should be in dorsiflexion over the end of the mattress.

SIDE-LYING POSITION In the side-lying (or lateral) position, the patient is resting on the side with the major portion of bodyweight on the dependent hip and shoulder. Therefore, in patients at risk of pressure ulcers, a 30-degree lateral position may be used (see Chapter 26). Trunk alignment should be the same as in standing. For example, the structural curves of the spine should be maintained, the head should be supported in line with the midline of the trunk, and rotation of the spine should be avoided.

SIMS' POSITION Sims' position differs from the side-lying position in the distribution of the patient's weight. In Sims' position the weight is placed on the anterior ilium, humerus and clavicle.

Transfer techniques

Nurses often provide care for immobilised patients whose position must be changed, who must be moved up in bed or who must be transferred from a bed to a chair or from a bed to a stretcher. Use of proper body mechanics enables nurses to move or transfer patients safely and also minimises risk of injury. Although nurses use many transfer techniques, the following general guidelines should be followed in any transfer procedure:

- Raise the side rail on the side of the bed opposite to the nurse to prevent the patient from falling out of bed.
- Elevate the level of the bed to a comfortable height.
- Assess the patient's mobility and strength to determine what help the patient can offer during transfer.
- Determine the need for assistance.
- Explain the procedure and describe what is expected of the patient.
- Assess for correct body alignment and pressure areas after each transfer.

Moving a completely immobilised patient alone is difficult and dangerous. The nurse who is attempting transfer or moving techniques for the first time should request help to reduce the risk of injury to the patient and nurse. It is important to be aware of lifting and transferring policies in different states and healthcare agencies – Victoria, for example, has manual handling principles and the Australian Nursing Federation has a no-lift policy.

MOVING PATIENTS Patients require various levels of assistance to move up in bed, move to the side-lying position or sit up at the side of the bed. For example, a young, healthy woman may need only a little support as she sits at the side of the bed for the first time after childbirth, whereas an older man may need help from one or more nurses to do the same task 1 day after abdominal surgery. Nurses should always enlist the patient's help to the fullest extent possible. To determine what the patient is able to do alone and how many people are needed to help move the patient in bed, a nursing assessment of the patient is done to determine whether the illness contradicts exertion (e.g. cardiovascular disease). Next, it is important to determine whether the patient comprehends what is expected of them. For example, a patient recently medicated for postoperative pain may be too lethargic to understand instruction, so to ensure safety two nurses are needed to move the patient in bed. Best nursing practice determines the comfort level of the patient, and also evaluates the patient's personal strength and knowledge of the procedure. Finally, as a part of the nursing assessment, a clinical decision is made about whether the patient is too heavy or immobile for a nurse to complete the procedure alone. In doubtful cases nurses should always request assistance from another person. Always use lifting aids. Skills 28-3 and 28-4 describe the steps commonly used in moving patients in bed and transferring them to a sitting position at the side of the bed.

TRANSFERRING A PATIENT FROM A BED TO A CHAIR Transfer of a patient from a bed to a chair by one nurse requires assistance from the patient and should not be attempted with a patient who cannot help (see Skill 28-4).

The procedure is explained to the patient before the transfer. Moving obstacles out of the way also prepares the environment. The chair is placed next to the bed with the chair back in the same plane as the head of the bed. Placement of the chair allows the nurse to pivot with the patient and to transfer the patient's weight quickly. A safe transfer is the first priority. The nurse who is doubtful about personal strength or the patient's ability to help should request assistance. Often a hydraulic lift can be used to transfer patients (see Skill 28-4). The patient should sit and dangle the feet over the side of the bed for a minute before standing. The patient should then stand at the side of the bed for another minute, so that the patient can quickly be lowered back into bed in case of dizziness or fainting.

When moving an immobilised patient from a bed to a wheelchair, nurses must use proper body mechanics. If a patient has an immobile lower extremity from a cast or paralysis, the transfer should be towards the unaffected leg. A lifting device should be used.

TRANSFERRING A PATIENT FROM A BED TO A STRETCHER An immobilised patient who must be transferred from a bed to a stretcher or from a bed to another bed requires the use of a transfer board and slide

SKILL 28-4

Transfer techniques

Delegation considerations

The task of moving and positioning patients in bed can be delegated to assistants. A risk assessment should be conducted on all patients requiring assistance with positioning. A 'no-lift' policy has been implemented in most facilities. Equipment such as lifting machines should be used whenever repositioning poses a risk to the patient and to the staff.

Equipment

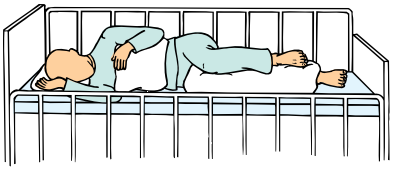
- Transfer belt (if needed), sling or lap board (as needed), non-skid shoes, bath blankets, pillows, lifting equipment when necessary
- Wheelchair: position chair at 45-degree angle to bed, lock brakes, remove footrests, lock bed brakes
- Stretcher: position at right-angle (90 degrees) to bed, lock brakes on stretcher, lock brakes on bed
- Mechanical/hydraulic lift: use frame, canvas strips or chains, and hammock or canvas strips

Therapeutic relationship and patient considerations

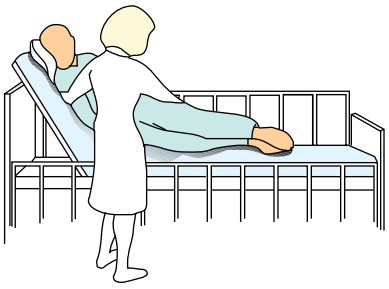
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess the patient for the following: • Muscle strength • Joint mobility • Presence of paralysis or paresis • Orthostatic hypotension • Activity tolerance • Level of consciousness • Level of comfort • Ability to follow instructions	Provides information relative to patient's abilities, physical status, ability to comprehend, and the number of people needed to provide safe transferral.
2. Identify patients at greatest risk of problems with transferral.	Provides information relative to patients who may require intervention beyond the care provider (e.g. physiotherapy department).
3. Explain procedure to patient.	Promotes cooperation, encourages assistance and enhances understanding of procedure.
4. Close door or curtain.	Maintains privacy.
5. Perform hand hygiene.	Reduces transfer of microorganisms.
6. **Transfer patient**	
A. Assisting patient into sitting position on side of bed:	
(1) With patient in supine position, raise head of bed 30 degrees.	Decreases amount of work needed by patient and nurse to raise patient to sitting position.

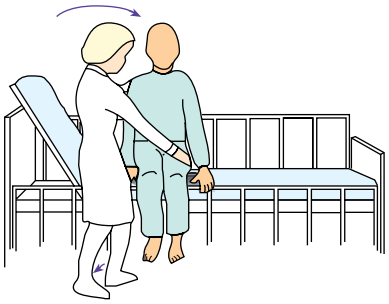
STEPS	RATIONALE
(2) Where possible, patients should be encouraged to move themselves into position or assist as much as possible.	
(3) Turn patient to side, facing nurse on side of bed on which patient will be sitting (see illustration).	Prepares patient to move to side of bed and protects patient from falling.
(4) Stand opposite patient's hips. Turn diagonally so that nurse faces patient and far corner of foot of bed.	Places nurse's centre of gravity nearer patient. Reduces twisting of nurse's body because nurse is facing direction of movement.
(5) Place feet apart with foot closer to head of bed in front of other foot.	Increases balance and allows nurse to transfer weight as patient is brought to sitting position on side of bed.
(6) Place arm nearer head of bed under patient's shoulder, supporting head and neck.	Maintains alignment of head and neck as nurse brings patient to sitting position.
(7) Place other arm over patient's thighs (see illustration).	Supports hip and prevents patient from falling backwards during procedure.
(8) Move patient's lower legs and feet over side of bed. Pivot towards rear leg, allowing patient's upper legs to swing downwards.	Decreases friction and resistance. Weight of patient's legs when off bed provides gravity to lower legs, and weight of legs helps pull upper body into sitting position.
(9) At same time, shift weight to rear leg and elevate patient (see illustration).	Allows nurse to transfer weight in direction of motion.
(10) Remain in front of patient until patient regains balance.	Reduces risk of falling.



Step 6A(3) Patient lying on side, facing nurse.



Step 6A(7) Placement of nurse's arms to support patient.



Step 6A(9) Nurse shifting weight to rear leg to elevate patient safely.

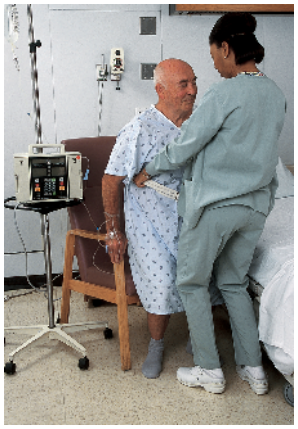
B. Transfer patient from bed to chair:	
(1) Adjust the bed slightly higher than the chair. Assist patient to sitting position on side of bed. Have chair in position at 45-degree angle to bed and ensure brakes are on.	Positions chair within easy access for transfer.

STEPS	RATIONALE
(2) Apply transfer belt or other transfer aids, if needed.	Transfer belt allows nurse to maintain stability of patient during transfer and reduces risk of falling. Patient's arm should be in sling if flaccid paralysis is present.
Critical decision point: If patient has immobile lower leg (i.e. cast, paralysis), transfer towards the stronger leg.	
(3) Ensure that patient has stable, non-skid shoes. Weightbearing, or stronger, leg is placed forwards, with weaker foot back.	Non-skid soles decrease risk of slipping during transfer. Always have patients wear shoes during transfer; bare feet increase risk of falls. Patient will stand on weightbearing, or stronger, leg.
(4) Spread feet apart.	Ensures balance with wide base of support.
(5) Flex hips and knees, aligning feet and knees with patient's feet (see illustration).	Flexion of knees and hips lowers nurse's centre of gravity to object to be raised; aligning knees with patient's allows for stabilisation of knees when patient stands.
(6) Grasp transfer belt from underneath, if used, or reach through patient's axillae and place hands on patient's scapulae.	Transferring patient with hands on scapulae reduces pressure on axillae and maintains patient stability. Patients with upper-extremity paralysis or paresis should never be lifted by or under arms. Transfer belt is grasped at each side to provide movement of patient at centre of gravity.
(7) Rock patient up to standing position on count of three while straightening hips and legs and keeping knees slightly flexed (see illustration). Patient is instructed to use hands to push up if possible.	Rocking motion gives patient's body momentum and requires less muscular effort to transfer patient.
(8) Maintain stability of patient's weak or paralysed leg with knee.	Ability to stand can often be maintained in paralysed or weak limb with support of knee to stabilise.
(9) Pivot on foot further from chair.	Maintains support of patient while allowing adequate space for patient to move.
(10) Instruct patient to use armrests on chair for support and ease themselves into chair (see illustration).	Increases patient stability.
(11) Flex hips and knees while lowering patient into chair (see illustration).	Prevents injury to nurse from poor body mechanics.
(12) Assess patient for proper alignment for sitting position. Provide support for paralysed extremities. Lap board or sling will support flaccid arm. Stabilise leg with bath blanket or pillow.	Prevents injury to patient from poor body alignment.

STEPS	RATIONALE

Step 6B(5) Position of flexed hips and knees.

Step 6B(7) Rock patient up to standing position.



Step 6B(10) Patient uses armrests for support while being lowered.

Step 6B(11) Flexion of hips and knees to lower patient.

(13) Praise patient's progress, effort, performance.	Continued support and encouragement provide incentive for patient perseverance.
C. Use mechanical/hydraulic lift to transfer patient from bed to chair (two nurses):	
(1) Bring lift to bedside. Before using lift, be thoroughly familiar with its operation.	
(2) Position chair near bed and allow adequate space to manoeuvre hoist.	Prepares environment for safe use of lift and subsequent transfer.
(3) Raise bed to safe working height with mattress flat. Lower side rails.	Allows nurse to use proper body mechanics.

■ **Critical decision point: Assess all tubes, making sure that they will not be inadvertently pulled, tangled or strained during transfer.**

(4) Roll patient laterally towards one nurse.	Positions patient for use of lift sling.
(5) Place sling evenly under patient's back (follow manufacturer's guidelines for correct positioning of the sling) and then roll patient to opposite side to position sling.	Place sling under patient's centre of gravity and greatest portion of bodyweight.
(6) Roll patient supine on sling and position hoist over patient. Lower boom and attach sling to frame with the head end attached first. Raise patient's knees and feed the leg sections of the sling under the thighs and attach to frame.	Sling should extend from shoulders to knees to support patient's bodyweight equally.
(7) Elevate head of bed.	Positions patient in sitting position.
(8) Ask or assist patient to fold their arms over the chest.	To prevent injury during transfer.

STEPS	RATIONALE
(9) Pump hydraulic handle using long, slow, even strokes, or activate electronic hoist until patient is raised off bed ensuring the head is supported (see illustration).	
(10) Use steering handle to pull lift from bed and manoeuvre to chair.	Moves patient from bed to chair.
(11) Slowly lower patient into chair (see illustration).	
(12) Detach sling from frame and remove hoist. Pull leg straps to the side, tilt patient forward to slide out the sling.	Safely guides patient into back of chair as seat descends.
(13) Reposition the patient to a position of comfort and safety.	
7. Perform hand hygiene.	
8. With each transfer, assess patient's tolerance and level of tiredness.	
9. With each transfer, evaluate patient's alignment.	

Step 6C(9) Using mechanical lift to raise patient off bed.

Step 6C(11) Lowering patient into chair.

RECORDING AND REPORTING

- Record each transfer and position change, including amount of assistance needed and patient's response.
- Record and report any signs of pressure injury over areas such as bony prominences.

HOME CARE CONSIDERATIONS

- Teach family the importance of body mechanics for safety of themselves and the patient.

sheet beneath the patient (Figure 28-20). In this technique, nurses need to be on opposite sides of the bed and holding on to the slide sheet when transferring the patient to the stretcher. The stretcher and the bed are placed side by side so that the patient can be transferred quickly and easily using the slide sheet. As with all procedures, safety is the priority. Safety is increased if the team works together in a coordinated way. Therefore one person should assume the leadership role.

Caution is used when the patient has or is suspected of having spinal cord trauma. If the patient must be moved, a transfer board should be placed under them to maintain spinal alignment before transferring the patient to a stretcher (see Figure 28-20). The patient should be prepared for the transfer and asked to help when possible (e.g. by folding arms over the chest). The environment should be free from obstacles, and unnecessary equipment should be removed from the bed.

Restorative care

The goal of restorative care for the patient who is immobile is to maximise functional mobility and independence and reduce residual functional deficits such as impaired gait and decreased endurance. The focus in restorative care is not only on ADLs that relate to physical self-care, but also on *instrumental activities of daily living (IADLs)*. IADLs are activities that are necessary to be independent in society beyond eating, grooming, transferring and toileting, and include such skills as shopping, preparing meals, banking and taking medications.

Many of the same nursing interventions as described in the acute care section above are used, but the emphasis with restorative care is on working collaboratively with patients and their significant others and with other healthcare professionals. The aim is to facilitate the patient's return to maximal functional ability in both ADLs and IADLs so that quality of life is enhanced.

Intensive specialised therapy such as occupational or physiotherapy is common. The patient, if in a restorative or rehabilitation institution, is likely to go to the therapy department two to three times a day. The nurse's role is to work collaboratively with these professionals and reinforce exercises and teaching. For example, after a stroke, a patient is likely to receive gait training from a physiotherapist, speech rehabilitation from a speech therapist and training from an occupational therapist on food preparation or other household chores. The therapy may not be able to restore total functional health, but may help the patient adapt to the mobility limitations or complications.

Restorative care is carried out in a variety of settings for the patient who has mobility limitations. The site of the care depends on the level of care needed, the amount and frequency of care required and the types of care that are available in a geographical area. Extended care refers to a variety of supportive care services provided to patients who have lost the ability for some aspect of self-care. The term 'extended care' is somewhat misnamed, however, since the timeframe for restorative care services that a patient requires may range from several weeks to years. After a total knee replacement, for example, it is not unusual for a patient to move from the acute care setting to a restorative care setting such as a nursing home or a rehabilitation facility, or to a rehabilitative unit at the same hospital where acute care was provided. Restorative care may also take place at home. The patient may go from hospital to nursing home to home, or go directly home from a hospital. The patient may receive care in the home from professionals or make outpatient visits to therapists' offices.

Common restorative interventions focus on regaining mobility. Performing exercises to maintain or regain joint mobility and teaching the use of aids for walking are common restorative nursing interventions. Items frequently used to help adapt to mobility limitations include walkers, walking sticks, wheelchairs, and aids such as toilet seat extenders, reaching sticks, special eating utensils and clothing with Velcro closures.

Range-of-motion exercises

To ensure adequate joint mobility, the nurse can teach the patient about active ROM exercises. When the patient does not have voluntary motor control, the nurse institutes passive ROM exercises. Walking also increases joint mobility. Occasionally patients need to use aids such as crutches or walkers to help them walk.

Figure 28-20

A, Transfer board is placed under a slide sheet beneath the patient. B, Patient is transferred from bed to stretcher using slide sheet and board.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Patients with restricted mobility are unable to perform some or all ROM exercises independently. This limitation can be identified in patients in whom one extremity has limited movement or in completely immobilised patients. When caring for patients with actual or potential impaired mobility, the nurse designs interventions directed at maintaining maximum joint mobility. One such nursing intervention is ROM exercises.

To ensure that patients routinely receive these exercises the nurse should schedule them at specific times, perhaps with another nursing activity, such as during the patient's hygiene care. This enables the nurse to systematically assess and improve the patient's ROM. In addition, bathing usually requires that extremities and joints be put through complete ROM. The nurse first assesses the patient's ability to engage in active ROM exercises and the need for assistance. In general, exercises should be as active as health and mobility allow. Contractures may develop in joints not moved periodically through their full ROM.

Unless contraindicated, the care plan should include moving the patient's extremities through the fullest ROM possible. Passive ROM exercises should begin as soon as the patient's ability to move the extremity or joint is lost. Movements are carried out slowly and smoothly, just to the point of resistance, and should not cause pain. A joint should never be forced beyond its capacity. Each movement should be repeated at least five times during the session.

When performing passive ROM exercises, the nurse stands at the side of the bed closest to the joint being exercised. If an extremity is to be moved or lifted, the nurse places a cupped hand under the joint to support it (Figure 28-21), supports the joint by holding the adjacent distal and proximal areas (Figure 28-22) or supports the joint with one hand and cradles the distal portion of the extremity with the remaining arm (Figure 28-23).

Helping a patient to walk

In the normal walking posture the head is erect; the cervical, thoracic and lumbar vertebrae are aligned; the hips and knees have appropriate flexion; and the arms swing freely with the legs. Illness or trauma can reduce activity tolerance so that assistance in walking is required. In addition, temporary or permanent damage to the musculoskeletal and nervous systems may necessitate use of an aid for walking.

Like other procedures, helping a patient to walk requires preparation. When a patient's mobility has been restricted, the nurse must assess the patient's activity tolerance, tolerance of the upright position (orthostatic hypotension), strength, presence of pain, coordination and balance to determine the amount of help needed.

The patient is given an indication of the distance they should try to walk, who is going to help, when the walk will take place and why walking is important. In addition, the nurse and patient determine how much independence the patient can assume.

The environment is also checked to be sure that there are no obstacles in the patient's path. Chairs, overbed tables and wheelchairs are cleared out of the way so that the patient has ample room to walk safely. Before starting, rest points should be established in case activity tolerance is less than estimated or the patient becomes dizzy. For example, a chair might be placed in the hall for the patient to rest if needed.

Potter PA, Perry AG 2004 Fundamentals of nursing, 6th edn. Mosby, St Louis.

Figure 28-23 Cradling the distal portion of an extremity.

Potter PA, Perry AG 2004 Fundamentals of nursing, 6th edn. Mosby, St Louis.

To prevent orthostatic hypotension, the patient should be helped to a position of sitting at the side of the bed and should rest for 1–2 minutes before standing. Likewise, after standing, the patient should remain stationary for 1–2 minutes before moving. The patient's balance must stabilise before walking. A dizzy patient is quickly assisted back to bed. It is important to remember that the longer the period of immobility, the greater the risk of hypotension when the patient stands.

The nurse should provide support at the waist so that the patient's centre of gravity remains midline. This can be achieved when the nurse places both hands at the patient's waist or uses a gait belt; a gait belt encircles the waist and has handles attached for the nurse to hold. While walking, the patient should not lean to one side because this alters the centre of gravity, distorts balance and increases the risk of falling.

A patient who at any point appears unsteady or complains of dizziness should be helped to a nearby bed or chair. If the patient faints or begins to fall, the nurse should assume a wide base of support with one foot in front of the other, thus supporting the bodyweight. Then the nurse should gently lower the patient to the floor, protecting the head. Although lowering a patient to the floor is not difficult, the student should practise this technique with a friend or classmate before attempting it in a clinical setting.

Patients with **hemiplegia** (one-sided paralysis) or **hemiparesis** (one-sided weakness) often need assistance to walk. The nurse always stands on the patient's affected side and supports the patient by holding one arm around the patient's waist (or uses a gait belt once the patient's stability is ensured), with the other arm around the inferior aspect of the patient's upper arm so that the nurse's hand is under the patient's axilla. Providing support by holding the patient's arm is incorrect because the nurse cannot easily support the weight to lower the patient to the floor if the patient faints or falls. In addition, if the patient falls with the nurse holding an arm, a shoulder joint may be dislocated. A two-nurse method helps distribute the patient's weight evenly. The two nurses stand on either side of the patient. Each nurse's near arm is around the patient's waist, and the other arm is around the inferior aspect of the patient's arm, so that both nurses' hands are supporting the patient's axillae.

Using aids for walking

Patients who are recovering from a lengthy illness that has required bed rest and whose mobility is impaired often require walking aids. These include walking sticks, walkers and crutches; the patient and family may need to be taught how to use these aids.

WALKERS Walkers are extremely light, movable devices about waist-high and made of metal tubing (Figure 28-24). They have four widely placed, sturdy legs. The patient holds the handgrips on the upper bars, takes a step, moves the walker forwards and takes another step. There are many variations on this theme.

WALKING STICKS Walking sticks are lightweight, easily movable devices that are about waist high and made of wood or metal. Two common types of walking stick are the single straight-legged walking stick and the four-pronged walking stick. The single straight-legged stick is more common and is used to support and balance a patient with decreased leg strength. This stick should be kept on the stronger side of the body. For maximum support when walking, the patient places the stick forward 15–25 cm, keeping bodyweight on both legs. The weaker leg is moved forwards to the stick so that bodyweight is divided between the stick and the stronger leg. The stronger leg is then advanced past the stick so that the weaker leg and the bodyweight are supported by the stick and weaker leg. The patient must be taught that two points of support, such as both feet or one foot and the stick, are present at all times.

Figure 28-24 Patient using a walker.

Dreamstime/Monkey Business Images.

Figure 28-25 Four-pronged stick.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

The four-pronged stick provides the most support and is used when there is partial or complete leg paralysis or some hemiplegia (Figure 28-25). The same three steps that are used with the straight-legged stick are taught to the patient.

CRUTCHES Crutches are often needed to increase mobility. The nurse begins crutch instruction with guidelines for safe use (Box 28-5). The use of crutches may be temporary, such as after ligament damage to the knee. However, a patient with paralysis of the lower extremities may need crutches permanently. A crutch is a wooden or metal staff. The two types of crutches are the double adjustable Lofstrand, or forearm, crutch (Figure 28-26) and the axillary wooden or metal crutch.

BOX 28-5 Patient teaching for crutch safety

Objective

- Patient will state and demonstrate safe crutch walking.

Teaching strategies

- Teach patient with axillary crutches about the dangers of pressure on the axillae, which occurs when leaning on the crutches to support bodyweight.
- Explain why patient must use crutches that were measured for him or her.
- Show patient how to routinely inspect crutch tips. Rubber tips should be securely attached to the crutches. When tips are worn, they should be replaced. Rubber crutch tips increase surface friction and help prevent slipping.
- Explain that the crutch tips should remain dry. Water decreases surface friction and increases the risk of slipping.
- Show patient how to inspect the structure of the crutches. Cracks in a wooden crutch decrease its ability to support weight. Bends in aluminium crutches can alter body alignment.
- Provide patient with a list of pharmacies or medical supply companies in the community for obtaining repairs, new rubber tips, handgrips and crutch pads.

Evaluation

Patient states and demonstrates principles of crutch safety.

The forearm crutch has a handgrip and a metal band that fits around the patient's forearm. The metal band and the handgrip are adjusted to fit the patient's height. The axillary crutch has a padded curved surface at the top, which fits under the axilla. A handgrip in the form of a crossbar is held at the level of the palms to support the body.

It is important that crutches be measured for the appropriate length and that patients be taught to use their crutches safely, to achieve a stable gait, to ascend and descend stairs and to rise from a sitting position.

MEASURING FOR CRUTCHES The axillary crutch is the more common crutch used. Measurements include the patient's height, the angle of elbow flexion and the distance between the crutch pad and the axilla. When crutches are fitted, the length of the crutch should be 5 cm from the axilla to a point 15 cm lateral to the patient's heel (Figure 28-27).

The handgrips should be positioned so that the patient's bodyweight is not supported by the axillae. Pressure on the axillae increases risk to underlying nerves, which could result in partial paralysis of the arm (crutch palsy). Correct position of the handgrips is determined with the patient upright, supporting weight by the handgrips with the elbows slightly flexed (20–25 degrees). When the height and placement of the handgrips have been determined, the nurse should again verify that the distance between the crutch pad and the patient's axilla is 3–4 finger-widths (Figure 28-28).

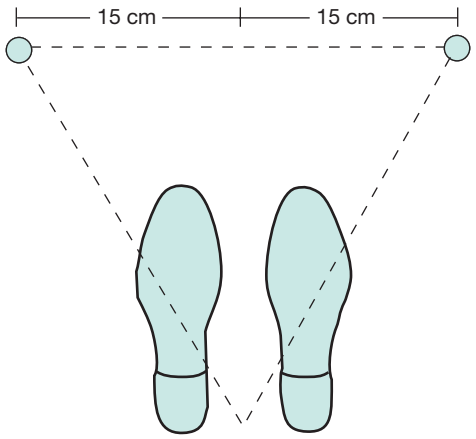

Figure 28-29 Tripod position, basic crutch stance.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

CRUTCH GAIT Crutch gait is assumed by alternately bearing weight on one or both legs and on the crutches. The gait selected by the doctor is determined by assessing the patient's physical and functional abilities and the disease or injury that resulted in the need for crutches.

This section summarises the basic crutch stance and the four standard gaits: four-point alternating gait, three-point alternating gait, two-point gait and swing-through gait.

The *basic crutch stance* is the tripod position, formed when the crutches are placed 15 cm in front of and 15 cm to the side of each foot (Figure 28-29). This position improves the patient's balance by providing a wider base of support. The body alignment of the patient in the tripod position includes an erect head and neck, straight vertebrae and extended hips and knees. No weight should be borne by the axillae. The tripod position is assumed before crutch walking.

Four-point alternating, or *four-point gait* gives stability to the patient but requires weightbearing on both legs. Each leg is moved alternately with each opposing crutch so that three points of support are on the floor at all times (Figure 28-30A).

Three-point alternating, or *three-point gait* requires the patient to bear all of the weight on one foot. In three-point gait, weight is borne on both crutches and then on the uninvolved leg, and the sequence is repeated (Figure 28-30B). The affected leg does not touch the ground during the early phase of the three-point gait. Gradually the patient progresses to touchdown and full weightbearing on the affected leg as the doctor orders.

The *two-point gait* requires at least partial weightbearing on each foot (Figure 28-30C). The patient moves a crutch at the same time as the opposing leg, so that the crutch movements are similar to arm motion during normal walking.

The *swing-through gait* is often used by paraplegics who wear weight-supporting braces on their legs. With weight placed on the supported legs, the patient places the crutches one stride in front and then swings to or through the crutches while they support the patient's weight.

CRUTCH WALKING ON STAIRS When ascending stairs on crutches, the patient usually uses a modified three-point gait (Figure 28-31). The patient stands at the bottom of the stairs and transfers bodyweight to the crutches. The unaffected leg is advanced between the crutches onto the stairs. The patient then shifts weight from the crutches to the unaffected leg. Finally, the patient aligns both crutches on the stairs. This sequence is repeated until the patient reaches the top of the stairs.

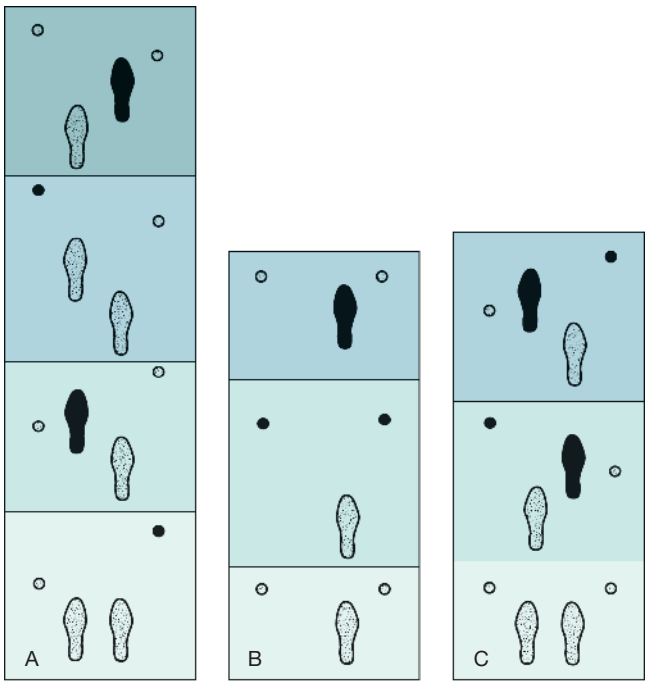

Figure 28-30 (Read each diagram from bottom to top.)

A, Four-point alternating gait. Solid feet and crutch tips show foot and crutch tip moved in each of the four phases. B, Three-point gait with weight borne on unaffected leg. Solid foot and crutch tips show weightbearing in each phase. C, Two-point gait with weight borne partially on each foot and each crutch advancing with opposing leg. Solid areas indicate leg and crutch tips bearing weight.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

To descend the stairs (Figure 28-32), a three-phase sequence is also used. The patient transfers bodyweight to the unaffected leg. The crutches are placed on the stairs, and the patient transfers bodyweight to the crutches, moving the affected leg forwards. Finally, the unaffected leg is moved to the stairs with the crutches. Again, the patient repeats the sequence until reaching the bottom of the stairs.

Because in most cases patients will need to use crutches for some time, they should be adequately taught to use crutches on stairs before discharge. This instruction applies to all crutch-dependent patients, not only those who have stairs in their homes.

SITTING IN A CHAIR WITH CRUTCHES As with crutch-walking and crutch-walking up and down stairs, the procedure for sitting in a chair involves phases and requires the patient to transfer weight (Figure 28-33). First, the patient gets positioned at the centre front of the chair with the posterior aspect of the legs touching the chair. Then the patient holds both crutches in the hand opposite the affected leg. If both legs are affected, as with a paraplegic person who wears weight-supporting braces, the crutches are held in the hand on the patient's stronger side. With both crutches in one hand, the patient supports

Figure 28-31 Ascending stairs.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

bodyweight on the unaffected leg and the crutches. While still holding the crutches, the patient grasps the arm of the chair with the remaining hand and lowers the body into the chair. To stand, the procedure is reversed, and the patient, when fully erect, should assume the tripod position before beginning to walk.

Activity and exercise for patients with chronic disease

The nurse is also involved in implementing a plan of care designed to increase activity and exercise in patients with chronic diseases such as heart disease, hypertension, chronic obstructive pulmonary disease (COPD) and diabetes mellitus which require specific considerations.

Figure 28-33 Sitting in a chair.

A, Both crutches are held by one hand. Patient transfers weight to crutches and unaffected leg. B, Patient grasps arm of chair with free hand and begins to lower herself into chair. C, Patient completely lowers herself into chair.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

CORONARY HEART DISEASE Activity and exercise have been shown to play a role in secondary prevention or recurrence of coronary heart disease (CHD). Cardiac rehabilitation has become an integral part of comprehensive care of patients who have been diagnosed with CHD. Nurses are involved in many aspects of cardiac rehabilitation and may help patients develop a program of exercise that fits their needs and level of functioning. Exercise-based cardiac rehabilitation is effective in reducing overall and cardiovascular mortality and appears to reduce the risk of hospital admissions in the shorter term (< 12 months follow-up) in patients with CHD (Heran et al 2011). Basic exercise guidelines for patients following an acute coronary syndrome are based on the FITT formula (frequency, intensity, type of exercise, time) and are presented in Box 28-6.

HYPERTENSION Regular physical activity is an important lifestyle modification for people with prehypertension and hypertension to control BP and reduce overall cardiovascular risk. Moderate-intensity aerobic exercise such as brisk walking, cycling and swimming, can lower BP, promote relaxation and decrease or control bodyweight.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE A reduction in exercise tolerance is one of the main complaints of people with chronic lung disease. Pulmonary rehabilitation – of which exercise training is an essential component – is a beneficial therapeutic tool in helping patients reach an optimal level of functioning (Lacasse et al 2006). Some patients are fearful of participating in exercise because of the potential of worsening dyspnoea. This aversion to physical activity sets up a progressive deconditioning in which minimal physical exertion results in dyspnoea. Pulmonary rehabilitation provides a safe environment with nurses and other healthcare professionals

BOX 28-6 FITT exercise guidelines after acute coronary syndrome

Warm-up/cool-down

Mild stretching for 3–5 minutes before the exercise activity and 5 minutes after the activity is important. Activity should not be started or stopped abruptly.

Frequency

The patient should exercise 5 or more times a week.

Intensity

Exercise intensity should be determined by the patient's heart rate (HR). If a treadmill test has not been performed, the patient recovering from a myocardial infarction should not exceed 20 beats/minute over the resting HR.

Type of exercise

Exercise should be regular, rhythmic and repetitive, using large muscles to build up endurance (e.g. walking, cycling, swimming, rowing).

Time

Exercise for 20–30 minutes. It is important to begin slowly at personal tolerance (perhaps only 5–10 minutes) and build up to 30 minutes.

Brown D, Edwards H (eds) Lewis's Medical–surgical nursing: assessment and management of clinical problems, 3rd edn. Mosby, Sydney.

monitoring the progress of the patient, thus providing encouragement and support to increase activity and exercise. In some situations pulmonary rehabilitation is not an option and patients are advised to exercise on their own. Walking is the best physical exercise for COPD patients, and they should be encouraged to walk for 15–20 minutes a day by building up gradually (Kent 2012).

DIABETES MELLITUS Along with diet, glucose monitoring and medication, exercise is considered an essential component in diabetes management. People with diabetes are also encouraged to exercise because it leads to improved cardiovascular fitness and psychological wellbeing. The nurse educates the person with diabetes about certain risks and precautions regarding exercise (see Box 28-7). Instruction for patients with type 1 diabetes should include the need for a pre-exercise physical examination and precautions to monitor blood glucose before, during and after exercise, to avoid injecting insulin into muscles that will be active during exercise, to perform low- to moderate-intensity exercises, to carry a concentrated form of carbohydrates (boiled sweets or jelly beans) and to wear a medical-alert bracelet.

• CRITICAL REFLECTION POINT

Willie Portman is a 65-year-old man who has enrolled in a cardiac rehabilitation program following a myocardial infarction (MI). What factors do you consider in developing an exercise program for Mr Portman? What interventions could be incorporated to help motivate this patient to exercise on a daily basis?

BOX 28-7 Exercise for patients with diabetes mellitus

1. Exercise does not have to be vigorous to be effective. The blood-glucose-reducing effects of exercise can be attained with mild exercise, such as brisk walking. The exercises selected should be enjoyable to foster regularity.
2. Exercise is best done after meals, when the blood glucose level is rising.
3. Exercise plans should be individualised for each patient and monitored by the healthcare provider.
4. It is important to self-monitor blood glucose levels before, during and after exercise to determine the effect exercise has on the blood glucose level at particular times of the day.
5. Be alert to the possibility of delayed exercise-induced hypoglycaemia, which may occur several hours after the completion of exercise.
6. Taking a glucose-lowering medication does not mean that planned or spontaneous exercise cannot occur.
7. It is important to compensate for extensive planned and spontaneous activity by monitoring the blood glucose level to make adjustments in the insulin dose (if taken) and food intake.

Brown D, Edwards H (eds) Lewis's Medical–surgical nursing: assessment and management of clinical problems, 3rd edn. Mosby, Sydney.

EVALUATING IMPACTS AND OUTCOMES

Patient care

To evaluate outcomes and review the processes of nursing care, nurses measure the effectiveness of all interventions. Patient assessment data are compared with the selected evaluation criteria and expected outcomes, such as the patient's ability to maintain or improve body alignment, joint mobility, walking, moving or transferring, or the absence of complications of immobility. The effectiveness of patient and family teaching to prevent future risks to mobility are also evaluated (Figure 28-34). Evaluation is cumulative and continuous. The continuous or formative nature of evaluation allows the nurse to determine whether new or revised therapies are required and if new nursing diagnoses have developed.

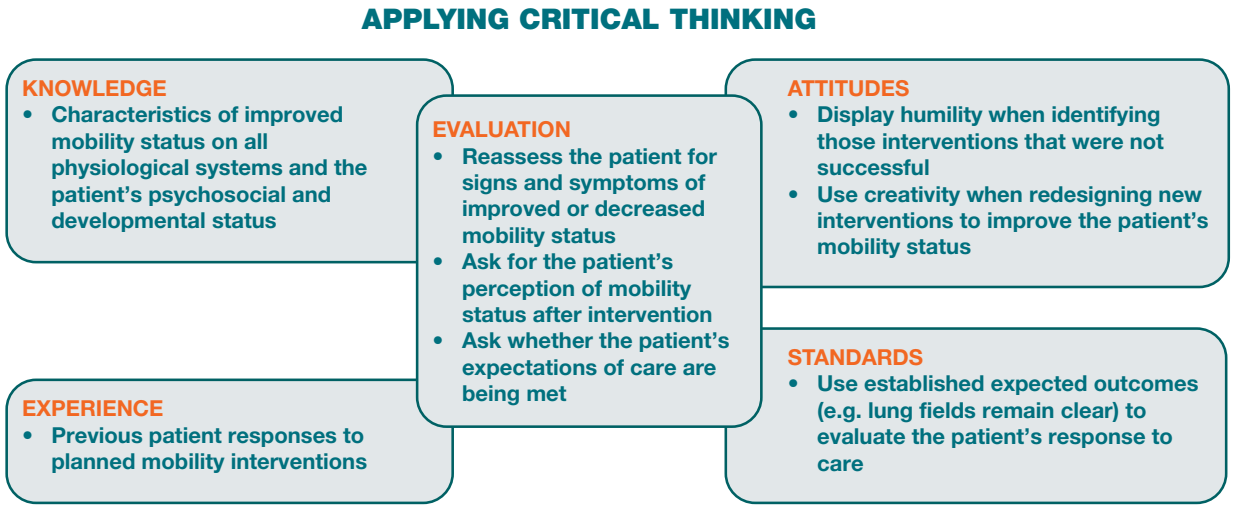

Figure 28-34 **Critical thinking associated with the evaluation phase for immobility.**

Patient expectations

Patients who are immobile and dependent on others for some or all of their needs can become overly dependent or try to do too much for themselves too early. Finding the balance between independence and dependence is a difficult task. Patients will want control over their mobility that is personally satisfactory. In the patient who is completely dependent on others for care, control over how and when things are done may be very important. Do patients feel they are treated with dignity? Do caregivers treat them as adults? Are they given opportunities to make meaningful choices? Patients who are dependent on others for care may see their demands as the only control they have over their life. Empathy is an important attitude in critical thinking when assessing patients' expectations; it helps the nurse to identify modifications that may be needed in care planning.

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant data and information*

Evelyn Brown is an 84-year-old woman admitted for a right-sided **total hip replacement (THR) for osteoarthritis**. It is day 4 postoperatively. Mrs Brown is afebrile and her wound is clean, dry and intact. Observations are within normal limits. During the shift you find that she is **not able to transfer from chair to bed without assistance**. She states that she is '**afraid of falling**' and **frequently refuses to get out of bed**. She rates her pain as a 1 on a scale of 0–10. She states that she needs analgesia to help her sleep during the night but does not need any during the day.

**Important data to cluster in setting priorities in bold.*

Priority problem(s)

Immobility

Making appropriate judgements and decisions

Judgements and decisions on Mrs Brown's nursing care plan will require synthesis of the data and information collected from the patient and relevant others. This will include synthesis of mobility assessment including ROM; exercise and activity tolerance; body alignment; ability to transfer; full head-to-toe systems assessment and potential immobility complications. Decisions and judgements about Mrs Brown's care will also be determined by the patient's own expectations and the dependence or independence Mrs Brown experienced prior to hospital admission.

Setting priorities and establishing goals	Expected outcomes
The overall priority for Mrs Brown is to maintain mobility Goals: • Return Mrs Brown to previous level or improved level of mobility prior to surgery • Involve Mrs Brown in all decisions of her care plan • Prevent development of immobility complications	Patient demonstrates ability to transfer independently, walk with assistive devices and move with ease within 2 days. Patient will state fear of falling is less within 2 days. Patient's calves non-tender, without redness or oedema. Patient's skin will remain intact.
Preparing for and taking action†	**Rationale**
Circulatory care	
• Administer low-molecular-weight heparin (LMWH) for thromboprophylaxis as prescribed.	Patients are at high risk of venous thromboembolism (VTE) following total hip replacement. Evidence-based clinical guidelines recommend LMWH as an effective therapy to prevent VTE after hip replacement (National Health and Medical Research Council 2009).
• Use graduated compression stockings, intermittent pneumatic compression (SCDs) or a foot pump following total hip replacement until the patient is fully mobile; remove each shift for hygiene. • Reinforce antiembolic exercises (e.g. leg exercises) while awake.	Application increases venous tone, improving venous return and reducing venous stasis. Evidence-based clinical guidelines recommend these interventions after hip replacement whether or not pharmacological thromboprophylaxis is used (National Health and Medical Research Council 2009).
• Assist Mrs Brown to sit on the side of the bed before transferring to chair.	Moving slowly will decrease the likelihood of orthostatic hypotension. Moving the patient slowly will also avoid the perception by the patient of being rushed, which may cause the patient to become more fearful.

Preparing for and taking action†	Rationale
Skin surveillance	
• Perform skin integrity assessment (e.g. check for any non-blanchable redness, localised heat, oedema and induration).	To monitor for pressure areas and plan appropriate intervention.
• Encourage Mrs Brown to shift position at least every hour while awake.	
• Use pressure-relieving devices, keeping Mrs Brown's heels off the bed by placing a pad under the lower legs.	Reducing the pressure on the heels so that tissue blood flow is maintained to prevent pressure areas.
Positioning	
• Explain transfer procedure to Mrs Brown and ensure understanding of hip precautions.	Reduces anxiety.
• Collaborate with physiotherapist in developing and executing an exercise program.	Helps to strengthen muscles used in transfer.
• Encourage Mrs Brown to assist as much as possible in transfer and positioning.	

† Intervention classification labels from McCloskey JC, Bulechek GM 2000 Nursing interventions classification (NIC), 3rd edn. Mosby, St Louis.

Evaluating impacts and outcomes

- Assess calves daily.
- Perform neurovascular assessment of extremities every shift.
- Observe skin integrity each shift.
- Observe patient transfer from bed to chair.
- Ask Mrs Brown to rate her fear of falling on a scale of 0–10.
- Ask Mrs Brown to rate her mobility against her expectations.

Key concepts

- Coordinated body movement requires integrated functioning of the muscular, skeletal and nervous systems.
- Developmental stages influence body alignment and mobility; the greatest impact of physiological changes on the musculoskeletal system is observed in children and older adults.
- Immobility may result from illness or be prescribed for therapeutic reasons and presents hazards to physiological and psychosocial health.
- Nursing assessment of mobility focuses on range of motion, gait, exercise and activity tolerance, and body alignment.
- Exercise and activity are essential components for maintaining and regaining health. Nurses are well placed to improve health by encouraging physical activity and working with patients to develop individualised exercise programs.
- In the acute care setting, specific interventions are designed to reduce the impact of immobility on the patient and by positioning and transferring patients safely.
- Nurses use a range of interventions aimed at promoting mobility and movement, including range-of-motion exercises, helping patients walk and using supportive equipment and techniques to help patients mobilise.

Learning outcomes

Mastery of content will enable you to:

- describe factors that influence personal hygiene practices
- discuss the role critical thinking plays in the provision of hygiene care
- conduct a comprehensive assessment of a person's total hygiene needs
- discuss conditions that place a person at risk of impaired skin integrity
- discuss factors that influence the condition of the nails and feet
- explain the importance of foot care for the person with diabetes
- discuss conditions that place the person at risk of impaired oral mucous membranes
- list common hair and scalp problems and their related interventions
- describe how hygiene care for the older adult may differ from that for the younger person
- discuss the different approaches used in maintaining a person's comfort during hygiene care
- successfully perform hygiene procedures for the care of the eyes, ears, nose, mouth, skin, perineum, feet and nails.

Introduction

Maintenance of personal hygiene is necessary for a person's comfort, safety and wellbeing. Well people are capable of meeting their own hygiene needs, but ill or physically challenged people may require assistance. A variety of personal and sociocultural factors influence the person's hygiene practices. Nurses determine a person's ability to perform self-care, and provide hygiene care according to the person's needs and preferences. In the home setting, nurses help the person and family adapt hygiene techniques.

Because hygiene care requires close contact with the person, nurses uses communication skills (see Chapter 12) to promote a caring therapeutic relationship and to use the time with the person for teaching and counselling. Nurses can integrate other nursing activities into hygiene care, including person assessment and interventions such as range-of-motion exercises, inspection of pressure points or inspection and care of intravenous sites. While providing hygiene, nurses must preserve as much of the person's independence as possible, ensure privacy, convey respect and foster physical comfort as well as dignity.

Proper hygiene care requires an understanding of the anatomy and physiology of the integument, oral cavity, eyes, ears, nose and perineal area. While administering hygiene, nurses are able to apply this knowledge in recognising abnormalities and taking appropriate action to prevent further injury to sensitive tissues. The skin and mucosa cells exchange oxygen, nutrients and fluids with underlying blood vessels. The cells require adequate nutrition, hydration and circulation to resist injury and disease. Good hygiene techniques promote the normal structure and function of body tissues.

In addition to anatomy and physiology, nurses apply knowledge of pathophysiology to provide good preventive hygiene care. Nurses learn to recognise those disease states that create changes in the integument, oral cavity and sensory organs. For example, diabetes mellitus may result in chronic vascular changes that impair healing of the skin and mucosa. In the early stages of acquired immune deficiency syndrome (AIDS), fungal infections of the oral cavity are common. As a result of a cerebral vascular accident, paralysis of the trigeminal nerve eliminates the blink reflex, causing corneal drying. In the presence of conditions such as these and in people with sensory impairment, nurses adapt practices to anticipate hygiene needs and minimise any injurious effects (Huskinson & Lloyd 2009).

The skin

The skin is an active organ with the functions of protection, secretion, excretion, temperature regulation and sensation (Table 29-1). The skin has three main layers: epidermis, dermis and subcutaneous. The **epidermis** (outer layer) is composed of several thin layers of cells undergoing different stages of maturation. It shields underlying tissue against water loss and injury and prevents entry of disease-producing microorganisms. The innermost layer of the epidermis generates new cells to replace the dead cells that are continuously shed from the skin's outer surface. The epidermis also contains melanocytes, special cells that produce melanin or dark pigment of the skin. Bacteria commonly reside on the outer epidermis. These resident bacteria are normal flora (see Chapter 25) that do not cause disease, but instead inhibit the multiplication of disease-causing microorganisms.

The **dermis** is a thicker skin layer containing bundles of collagen and elastic fibres to support the epidermis. Nerve fibres, blood vessels, sweat glands, sebaceous glands and hair follicles course through the dermal layers. Sebaceous glands secrete *sebum*, an oily, odorous fluid, into the hair follicles. Sebum lubricates the skin and hair and acts as an antibacterial layer. There are two types of sweat glands: eccrine and apocrine. The **eccrine glands** are distributed throughout the skin. Sweat excreted from the eccrine glands assists in temperature control through evaporation. The **apocrine glands** can be found in the axillary and genital areas. The bacterial decomposition of sweat from these areas is responsible for body odour. In the ears, *ceruminous glands* secrete **cerumen** (earwax) into the external ear canal. This heavy, oily substance traps foreign material entering the ear.

The *subcutaneous tissue layer* contains blood vessels, nerves, lymph tissue and loose connective tissue filled with fat cells. The fatty tissue is a heat insulator for the body. Subcutaneous tissue also supports upper skin layers to withstand stresses and pressure without injury. Very little subcutaneous tissue underlies the oral mucosa.

The skin often reflects a change in physical condition by alterations in colour, thickness, texture, turgor, temperature and hydration (see Chapter 26). As long as the skin is intact and healthy, its physiological function remains good.

The feet, hands and nails

The feet and hands are important to physical health. The structure of the *foot* is similar to that of the hand, with certain differences that adapt it for supporting weight (Thibodeau & Patton 2013). The tarsals and metatarsals play the major role in the functioning of the foot as a

TABLE 29-1 Functions of the skin and implications for care

Function/description	Implications for care
Protection	
The epidermis is a relatively impermeable layer that prevents entrance of microorganisms Although microorganisms reside on the skin surface and in hair follicles, relative dryness of the skin's surface inhibits bacterial growth Sebum removes bacteria from hair follicles Acidic pH of skin further retards bacterial growth	Weakening of epidermis occurs by scraping or stripping its surface (e.g. use of dry razors, tape removal or improper turning or positioning techniques) Excessive dryness causes cracks and breaks in skin and mucosa that allow bacteria to enter. Emollients soften skin and prevent moisture loss, soaking of skin improves moisture retention and hydration of mucosa prevents dryness However, constant exposure of skin to moisture causes maceration or softening, which interrupts dermal integrity and promotes ulcer formation and bacterial growth. Sheets and clothing should be kept dry Misuse of soap, detergents, cosmetics, deodorant and depilatories can cause chemical irritation. Alkaline soaps neutralise the protective acid condition of skin Cleaning of skin removes excess oil, sweat, dead skin cells and dirt that can promote bacterial growth.
Sensation	
Skin contains sensory organs for touch, pain, heat, cold and pressure	Friction should be minimised to avoid loss of stratum corneum, which can result in development of pressure ulcers Smoothing bedclothes removes sources of mechanical irritation Removing rings from fingers prevents nurse from accidentally injuring person's skin Bathwater should not be excessively hot or cold
Temperature regulation	
Body temperature is controlled by radiation, evaporation, conduction and convection	Factors that interfere with heat loss can alter temperature control Wet bedclothes or gowns interfere with convection and conduction Too many blankets or bed coverings can interfere with heat loss through radiation and conduction Coverings can promote heat conservation
Excretion and secretion	
Sweat promotes heat loss by evaporation Sebum lubricates skin and hair	Perspiration and oil can harbour microorganisms. Bathing removes excess body secretions, although too much bathing can cause drying of skin

supporting structure. Any injury or deformity to the foot, including any growths or injuries to the overlying skin, can be painful and thus interfere with a person's normal ability to walk and bear weight.

The *hand*, in contrast to the foot, is constructed largely for manipulation rather than support. A wide range of dexterity exists in the hand because of the wide range of movement between the thumb and fingers. Any condition that interferes with movement of the hand (e.g. superficial or deep pain, joint inflammation) can impair a person's self-help abilities.

The *nails* are epithelial tissues that grow from the root of the *nail bed*, located in a groove hidden by the fold of skin called the **cuticle**. The visible part of the nail is the nail body. It has a crescent-shaped white area known as the **lunula**. Under the nail lies a layer of epithelium called the nail bed (Figure 29-1). The abundance of blood vessels in the nail bed creates its pink or light tan appearance (depending on race). Normally the nails grow about 0.5 mm a week, with fingernails growing faster than toenails (Thibodeau & Patton 2013).

The oral cavity

The oral cavity is lined with mucous membranes continuous with the skin. The *oral* or *buccal cavity* consists of the lips surrounding the opening of the mouth, the cheeks running along the side walls of the cavity, the tongue and its muscles, and the hard and soft palates. The oral mucosa is normally light pink and moist. The floor of the mouth and the undersurface of the tongue are richly supplied with blood vessels. Any type of ulceration or trauma can result in significant bleeding. There are three pairs of salivary glands that secrete about 1 L of saliva a day. The **buccal glands**, found in the mucosa lining the cheeks and mouth, secrete less than 5% of the total saliva; however, buccal gland secretion maintains the hygiene and comfort of oral tissues. Salivary secretion in the mouth

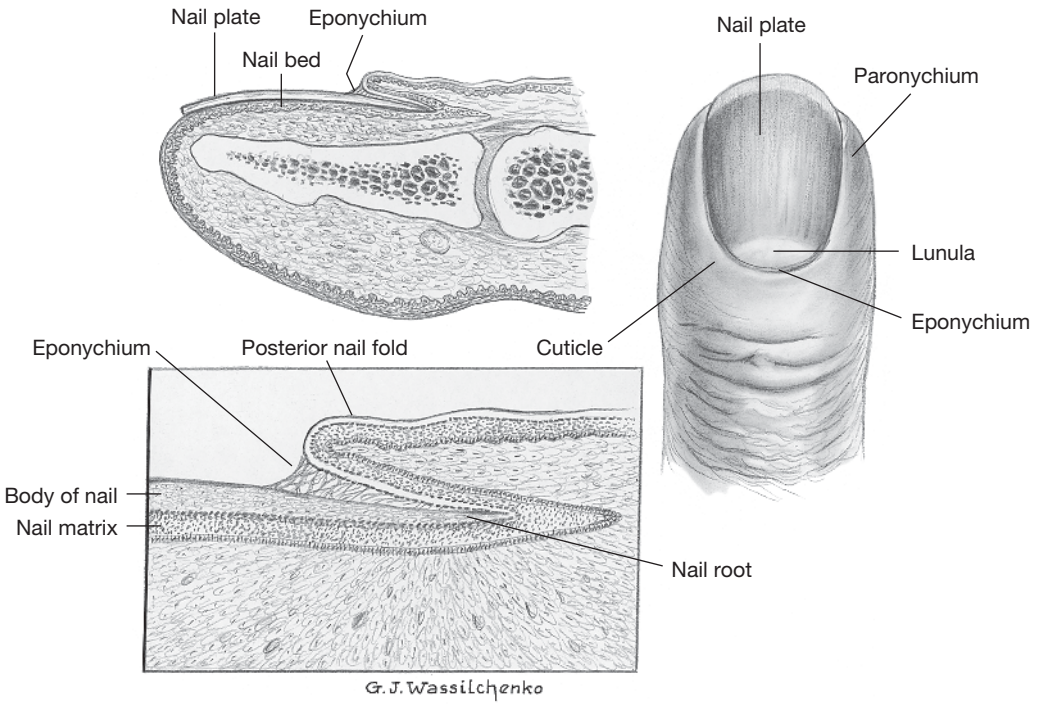

Figure 29-1 **Anatomical structure of a normal nail.**

Thompson J et al 2002 Clinical nursing, 5th edn. Mosby, St Louis.

can be impaired through dehydration, mouth breathing, the effects of medications and exposure to radiation.

The *teeth* are the organs of chewing, or **mastication**. They are designed to cut, tear and grind food so it can be mixed with saliva and swallowed (Thibodeau & Patton 2013). A normal tooth consists of the crown, neck and root (Figure 29-2). The periodontal membrane lies just below the gum margins, surrounds a tooth and holds it firmly in place. Healthy teeth appear white, smooth, shiny and properly aligned. Difficulty in chewing can develop when surrounding gum tissues become inflamed or infected, or when teeth are lost or become loosened. Regular oral hygiene is necessary to maintain the integrity of tooth surfaces and thus prevent dental caries and **gingivitis** (gum inflammation).

The hair

Hair growth, distribution and pattern can indicate a person's general health status. Hormonal changes, emotional and physical stress, medications, ageing, infection and certain illnesses can affect hair characteristics. The hair shaft itself is inert and cannot be directly affected by physiological factors. However, changes in its colour or condition are caused by hormonal and nutrient deficiencies of the hair follicle. The hair follicle contains live cells and a rich capillary blood supply (Figure 29-3).

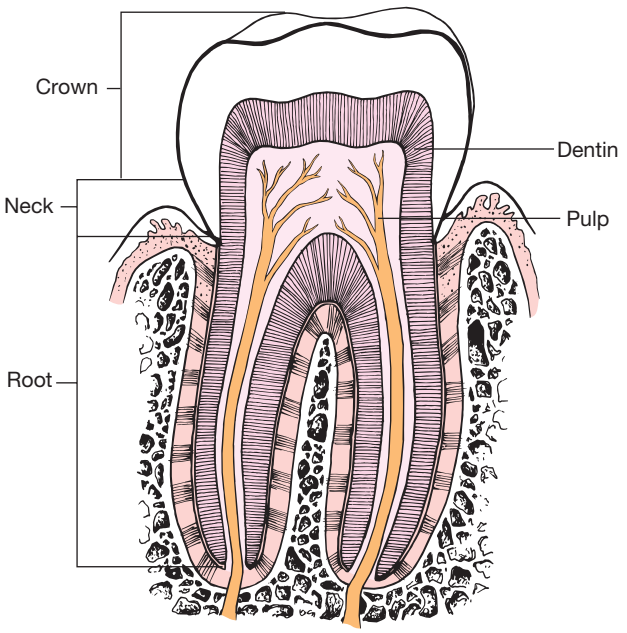

Figure 29-2 **A normal tooth.**

The eyes, ears and nose

When nurses provide hygiene care, the eyes, ears and nose require careful attention. Chapter 27 describes the structure and function of these organs. Cleaning of the

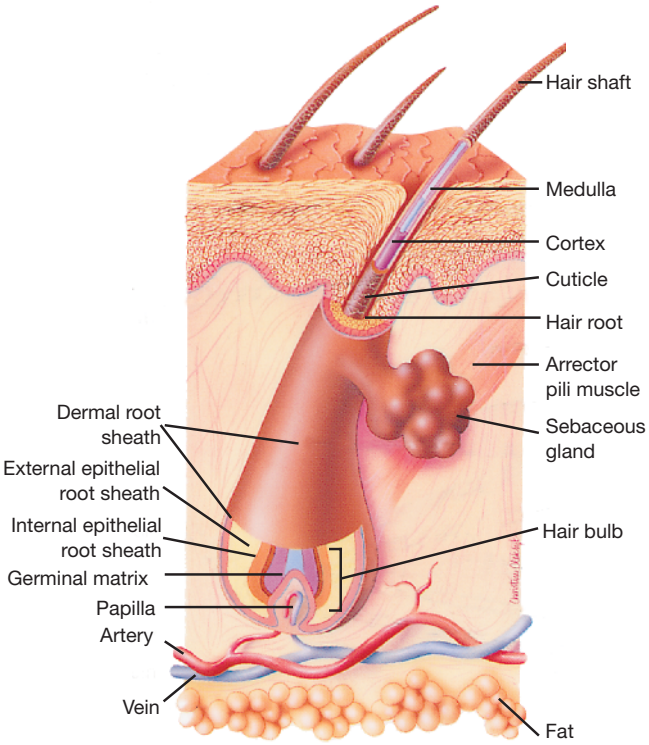

Figure 29-3 Hair follicle, relationship of a follicle and related structures to the epidermal and dermal layers of the skin.

Thibodeau GA, Patton KT 2013 Anatomy and physiology, 8th edn. Mosby, St Louis.

sensitive sensory tissues should be done in a way that prevents injury and discomfort for the person.

The perineal area

Provision of hygiene care to the perineal area requires tact and appreciation of the person's dignity, culture, emotions and physical safety as well as privacy. Maintaining a clean and dry perineal area helps to prevent breakdown and maceration of these sensitive tissues. Soiling with urine, faecal material and perspiration causes irritation and discomfort. Care of the perineal area of a person with a retention catheter is performed more frequently than daily hygiene (see Skill 29-2, on p. 936).

Nurses view people's healthcare needs from a holistic perspective. In the case of hygiene, it is important to consider the knowledge that is available regarding the numerous sociocultural, economic and developmental factors that influence hygiene practices. Application of this knowledge base allows nurses to provide individualised hygiene care. As healthcare professionals, nurses must be conscious of their own hygiene, as they are considered a role model by the person.

Social practices

Social groups influence hygiene preferences and practices, including the type of hygiene products used and the nature and frequency of personal care. During childhood, hygiene is influenced by family customs. This may include, for example, the frequency of bathing, the time of day bathing is performed and the type of oral hygiene practised. As children enter their adolescent years, personal hygiene may be influenced by peer-group behaviour. Young girls, for example, may become more interested in their personal appearance and begin to wear make-up. During the adult years, involvement with friends and work groups shape the expectations people have about their personal appearance. Older adults' hygiene practices may change because of living conditions and available resources.

Personal preferences

Each person has individual desires and preferences about when to bathe, shave and perform hair care. People select different products according to personal preferences, needs and financial resources. These desires should help nurses deliver individualised care. Nurses need to be aware of these, and respect the person's preferences. In addition, nurses should help the person develop new hygiene practices when indicated by an illness or condition.

Body image

A person's general appearance may reflect the importance hygiene holds for that person. Body image is a person's subjective concept of their physical appearance (see Chapter 20). These images can change frequently. Body image affects the way hygiene is maintained. If a person is neatly groomed, nurses should consider the details of grooming when planning care and consult the person before making decisions about how hygiene care is to be provided. People who appear unkempt or uninterested in hygiene may require education about its importance, and nurses should assess the contributing factors. Culturally, maintaining cleanliness may not hold the same importance for some ethnic groups as it does for others. Nurses should be sensitive in considering that the person's economic status may influence the ability to regularly maintain hygiene, and never convey feelings of disapproval when caring for people whose hygiene practices are different from theirs.

When a person undergoes surgery, illness or a change in functional status, body image can change dramatically. For this reason, nurses needs to make an extra effort to promote the person's hygiene, comfort and appearance.

Socioeconomic status

A person's economic resources influence the type and extent of hygiene practices used. Nurses determine whether people can afford necessary supplies such as deodorant, shampoo, toothpaste and cosmetics. When basic care items are not affordable, nurses try to find alternatives. It is also important to learn whether use of these products is a part of the social habits practised by the person's social group. For example, not all people may choose to use shampoos, deodorant or cosmetics. Access to a reliable water supply in some isolated communities alters hygiene practices.

When a nurse cares for a person it is important to learn about the individual's routine adherence to hygiene practices and whether the person values those practices. Health promotion focuses on equity of access to resources while enabling people to increase control over the determinants of their health (Ridde 2007). Thus, health promotion represents combining personal choice with social responsibility for health. When people have the added problem of a lack of socioeconomic resources, it becomes difficult to participate and take a responsible role in health-promotion activities such as basic hygiene.

Cultural variables

A person's cultural beliefs and personal values influence hygiene care. People from diverse cultural backgrounds follow different self-care practices (see Chapter 14). In many cultural groups in Australia, it is common to bathe or shower daily, whereas in some other cultural groups it is customary to bathe completely only once a week (see *Working with diversity*).

WORKING WITH DIVERSITY

Focus on cultural care

For Hindus, personal hygiene is an important part of each day. A daily bath is part of their religious duty. Bathing needs to take place at correct times and in the correct way. For example, bathing after a meal is believed by some Hindus to be injurious. Similarly, a bath that is too hot may injure the eyes. Hot water may be added to cold water, but cold water is not to be added to hot water when one is preparing a bath. Once a bath is completed, the body is dried thoroughly with a towel.

Reference

Adapted from Giger JN, Davidhizar RE 2008 Transcultural nursing: assessment and intervention, 5th edn. Mosby, St Louis.

Health beliefs and motivation

Knowledge about the importance of hygiene and its implications for wellbeing influence hygiene practices. However, knowledge alone is not enough. The person also must be motivated to maintain self-care. Health motivation is part of an individual's health beliefs or attitudes that influence health-related behaviours. The health belief model includes four variables that influence the individual's motivation towards health promotion: (1) the likelihood of experiencing a harmful condition in response to behaviours; (2) perceived seriousness or threat of the condition; (3) perceived effectiveness of modifying behaviours to reduce a threat; and (4) negative aspects of the behaviour (Gillibrand & Stevenson 2006). In regard to a person's hygiene practices, it is important for nurses to know whether, for example, a person perceives being at risk of dental disease, thinks dental disease to be serious, thinks brushing and flossing to be effective in reducing risk and believes there are any negative implications from following recommended hygiene practices. When people recognise there is a risk and reasonable action can be taken with no negative consequence, they will be more receptive to the nurses' counselling and teaching efforts.

Physical condition

People with certain types of physical limitations or disabilities often lack the physical energy and dexterity to perform hygiene care. A person in traction or a cast or who has an intravenous line or other device connected to the body will need assistance with hygiene. Illnesses that cause pain may limit the dexterity and range of motion needed to perform certain measures. People still under the effects of sedation will not have the mental clarity or coordination to perform self-care. Chronic illnesses, such as cardiac disease, cancer, neurological disorders and certain mental health conditions, may exhaust or incapacitate a person. A weakened grasp resulting from arthritis, cerebrovascular accident or muscular disorders can prevent a person from using a toothbrush, washcloth or comb.

CLINICAL REASONING PROCESS

Because hygiene care is so important for a person to feel comfortable, refreshed and renewed, avoid making hygiene care a simple routine. Instead, synthesise knowledge, previous experience with patients, critical-thinking attitudes and standards in judging the most effective way to provide effective hygiene. A middle-aged woman with abdominal

pain who has had major surgery only 24 hours previously will require a different approach to hygiene compared to an older adult who has left-sided paralysis. During the nurses' assessment (Figure 29-4), all critical-thinking elements are considered in understanding the person's needs and in making appropriate nursing diagnoses. In addition, while hygiene is being administered, nurses make important observations (e.g. condition of person's skin, ability of person to move and initiate activities) and use them when making clinical judgements about the person's overall nursing care.

GATHERING RELEVANT INFORMATION AND DATA

Nursing assessment is an ongoing process. Nurses may not have assessed all body regions before administering hygiene; however, they routinely assess the person's condition whenever care is given. For example, during oral care the condition of the teeth and mucosa can be inspected. When a person has had an ongoing problem (e.g. dry skin, inflamed oral mucosa), then it is important to conduct an assessment before care is administered because variations in technique may be necessary. Hygiene care allows nurses to make assessment findings for a variety of healthcare problems and thus helps set healthcare priorities.

Physical examination

While assisting a person with personal hygiene, nurses assess the integument, oral cavity structures, and the eyes, ears and nose (see Chapter 23). Using the skills of inspection and palpation, nurses looks for alterations in the integrity and function of tissues. The assessment also reveals the type and extent of hygiene care required. Special attention is given to the characteristics most influenced by hygiene measures. Is the skin dry from too much bathing? Are there calluses on the feet that may benefit from soaking and moisturising lotion? Is there a coating of the tongue that requires frequent brushing and hydration? Over time, nurses' assessment provides the baseline for determining whether hygiene measures maintain or improve the person's condition.

Skin

While inspecting the skin, nurses thoroughly examines its colour, texture, thickness, turgor, temperature and hydration. The skin should be smooth, warm and supple with good turgor. Pay special attention to the presence and condition of any lesions (see Chapter 26). Certain common skin problems affect how hygiene is administered (Table 29-2). Special care is also given to assess less-obvious or difficult-to-reach skin surfaces, such as under the female's breasts, under the male's scrotum or around the female's perineal tissues (see Chapter 33). Nurses who observe skin problems should explain proper skin care and specific hygiene techniques to the person.

Certain conditions place people at risk of impaired skin integrity (Box 29-1). Nurses must be particularly alert when assessing people with reduced sensation, vascular insufficiency and immobility. Be sure to assess extremities and help turn a person so that a skin surface can be fully viewed. The development of pressure ulcers is a common complication that can extend hospital stays and threaten the wellbeing of the extended-care person (Bluestein & Javaheri 2008).

Feet and nails

Assessment of the feet involves a thorough examination of all *skin surfaces*, including areas between the toes and over the soles of the feet. The heels, soles and sides of the feet are prone to irritation from poorly fitting shoes. In addition, nurses inspect the *shape* and size of toes and the shape of the foot. The toes are normally straight and flat. The feet should be in straight alignment with the ankle and tibia. Inspection of the feet for *lesions* includes noting areas of dryness, inflammation or cracking.

Assess the person's *gait*. Painful foot disorders or decreased sensation can cause limping or an unnatural gait. Nurses ask whether the person has foot discomfort and determines factors

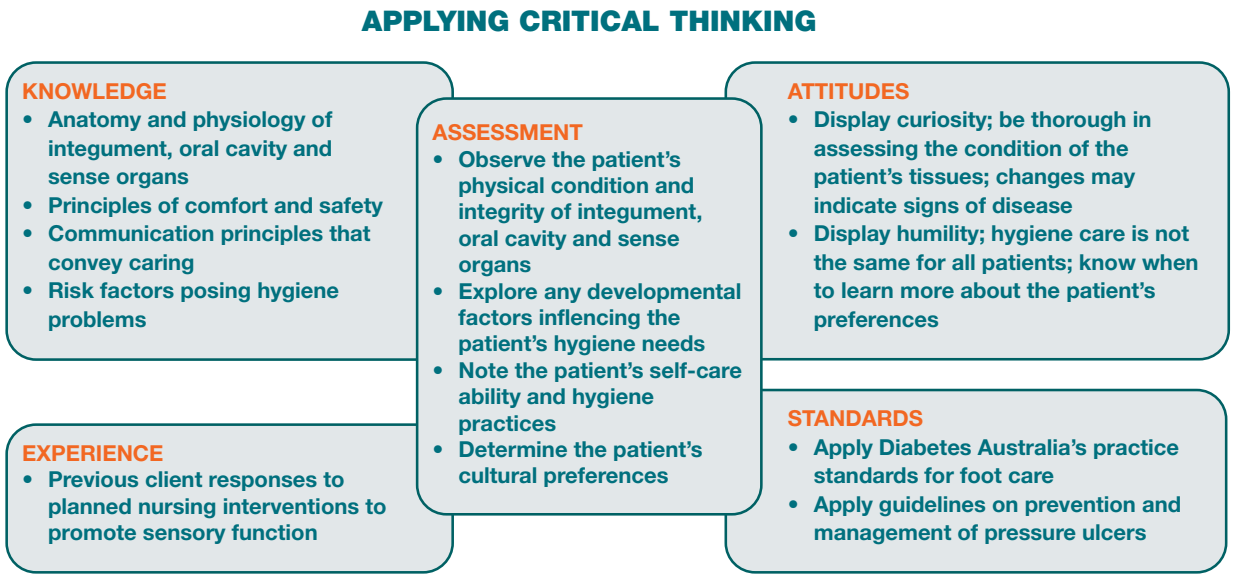

Figure 29-4 **Critical thinking associated with the assessment phase for hygiene.**

TABLE 29-2 Common skin problems

Characteristics	Implications	Interventions
Dry skin		
Flaky, rough texture on exposed areas such as hands, arms, legs or face	Skin may become infected if epidermal layer is allowed to crack	Have person bathe less frequently and rinse body of all soap because residue left on skin can cause irritation and breakdown Where possible, using non-soap products Add moisture to air through use of humidifier Increase fluid intake when skin is dry Use moisturising cream to aid healing. (Cream forms protective barrier and helps maintain fluid within skin.) Use cream such as Sorbolene Use creams to clean skin that is dry or allergic to soaps and detergents
Acne		
Inflammatory, papulopustular skin eruption, usually involving bacterial breakdown of sebum; appears on face, neck, shoulders and back	Infected material within pustule can spread if area is squeezed or picked; permanent scarring can result	Wash hair and skin thoroughly each day with hot water and soap to remove oil Use cosmetics sparingly because oily cosmetics or creams accumulate in pores and tend to make condition worse Implement dietary restrictions, if necessary (foods that aggravate condition should be eliminated from diet) Inform person that exposure to ultraviolet rays, either from sunshine or from heat lamp, may help control acne (caution should be used to prevent burning of skin) Use prescribed topical antibiotics for severe forms of acne
Hirsutism		
Excessive growth of body and facial hair, especially in women	Hirsutism may cause negative body image by giving women a male appearance	Use the following to remove unwanted hair: depilatories (can cause infection, rashes, dermatitis), shaving (safest method), electrolysis (permanently removes hair by destroying hair follicles), tweezers (lasts only temporarily), bleaching of hair (lasts only temporarily), waxing (can cause ingrown hair)
Skin rashes		
Skin eruption that may result from overexposure to sun or moisture or from allergic reaction (may be flat or raised, localised or systemic, pruritic or non-pruritic)	If skin is continually scratched, inflammation and infection may occur. Rashes can also cause discomfort	Wash area thoroughly and apply antiseptic spray or lotion to prevent further itching and help the healing process Apply warm or cold soaks to relieve inflammation, if indicated
Contact dermatitis		
Inflammation of skin characterised by abrupt onset with erythema, pruritus, pain and appearance of scaly oozing lesions (seen on face, neck, hands, forearms and genitalia)	Dermatitis is often difficult to eliminate because person is usually in continual contact with substance causing skin reaction. Substance may be hard to identify	Avoid causative agents (e.g. cleansers and soaps) Do not wash hands with hot water
Abrasion		
Scraping or rubbing away of epidermis that may result in localised bleeding and later weeping of serous fluid	Infection occurs easily because of loss of protective skin layer	Be careful not to scratch person with jewellery or fingernails Wash abrasions with mild soap and water; dry thoroughly and gently Observe dressing or bandage for retained moisture because it could increase risk of infection

BOX 29-1 Risk factors for skin impairment

Immobilisation

When restricted from moving freely, dependent body parts are exposed to pressure, reducing circulation to affected body parts. Nurses should know which people need help to turn and change positions.

Reduced sensation

People with paralysis, circulatory insufficiency or local nerve damage are unable to sense an injury to the skin. During a bath, assess the status of sensory nerve function by checking for pain, tactile sensation and temperature sensation.

Nutrition and hydration alterations

People with limited kilojoule and protein intake can develop thinner, less-elastic skin, with loss of subcutaneous tissue. This can result in impaired or delayed wound healing.

Secretions and excretions on the skin

Moisture on the skin's surface serves as a medium for bacterial growth and can cause irritation, soften epidermal cells and lead to skin maceration. Presence of perspiration, urine, watery faecal material and wound drainage on the skin can result in breakdown and infection.

Vascular insufficiency

Inadequate arterial supply to tissues and impaired venous return decrease circulation to the extremities. Inadequate blood flow can cause ischaemia and breakdown. Risk of infection also exists because delivery of nutrients, oxygen and white blood cells to injured tissues is inadequate.

External devices

An external device applied to or around the skin exerts pressure or friction on the skin. Nurses assesses all surfaces exposed to casts, cloth restraints, bandages and dressings, tubing or orthopaedic braces.

that aggravate the pain. Foot problems may result from bone or muscular alterations rather than skin disorders.

People with peripheral vascular disease, such as those with diabetes mellitus, should be assessed for the adequacy of *circulation* to the feet (see Chapter 23). Palpation of the dorsal pedis and posterior tibial pulses indicates whether adequate blood flow is reaching peripheral tissues. Oedema and changes in skin colour, texture and temperature can indicate whether the person requires special hygiene care.

People with diabetes mellitus should also be checked for **neuropathy**, degeneration of the peripheral nerves characterised by a loss of sensation. Nurses assess the person's sensation to light touch and temperature.

Inspect the condition of the *fingernails and toenails*, looking for lesions, dryness, inflammation or cracking (Table 29-3). The nail is surrounded by a cuticle, which slowly grows over the nail and must be regularly pushed back. The skin around the nail beds and cuticles should be smooth and without inflammation. Nurses should ask women whether they frequently polish their nails and use polish remover, because chemicals in these products can cause excessive nail dryness. Disease can change the shape and curvature of the nails (see Chapter 23).

Inflammatory lesions and fungus of the nail bed can cause thickened, horny nails, which can separate from the nail bed. Reduced circulation to the feet can cause thickening and brittleness of the toenails.

Oral cavity

Chapter 23 describes in detail nurses' assessment of the person's lips, teeth, buccal mucosa, gums, palate and tongue. Inspect all areas carefully for *colour*, *hydration*, *texture* and *lesions*. People who do not follow regular oral hygiene practices may have receding gum tissue, inflamed gums, a coated tongue, discoloured teeth (particularly along gum margins), dental **caries** (chalky white discolouration of tooth or presence of brown or black discolouration), missing teeth and **halitosis** (bad breath). Note that halitosis can also arise from conditions in other parts of the gastrointestinal (GI) tract. Localised pain is a common symptom of gum disease and certain tooth disorders. An infection of the mouth may involve organisms such as *Treponema pallidum*, *Neisseria gonorrhoeae* and herpesvirus hominis.

It is especially important to examine the oral cavity of the patient receiving radiation or chemotherapy. Both treatments can cause serious changes in salivary gland function and mucosal integrity. Nurses' assessment serves as a basis for preventive care for people as they undergo treatment (Harris et al 2008).

Hair

Before performing hair care, assess the condition of the hair and scalp. Normally the hair is clean, shiny and untangled, and the scalp is clear of lesions. The hair of a dark-skinned person is usually thicker, drier and curlier than that of lighter-skinned people. Table 29-4 summarises hair and scalp problems that nurses may identify. In the community health and home-care settings, it is particularly important to inspect the hair for lice so that appropriate hygiene treatment can be provided. If *Pediculosis capitis* (head lice) is suspected, nurses guards against self-infestations by handwashing and using gloves or tongue blades to inspect the person's hair. The loss of hair (**alopecia**) can result from the effects of chemotherapy medications, hormonal changes or unsuitable hair care practices. People at risk of scalp problems are those who have experienced head trauma and those who practise poor hygiene.

Eyes, ears and nose

Nurses examine and assess the condition and function of the eyes, ears and nose (see Chapter 23). Normally the *eyes* are free of infection and irritation. The sclerae are visible anteriorly as the white portion of the eye. The conjunctivae (linings of the eyelids) are clear, pink and without inflammation. The eyelid margins are in close approximation with the eyeball, and the lashes are turned outwards. The lid margins are without inflammation, drainage or lesions. The eyebrows should be symmetrical.

Another important aspect of an eye examination is to determine whether the person wears contact lenses. This is especially significant for people who enter hospitals or other agencies in an unresponsive or a confused state. An undetected lens can cause severe corneal injury when left in place too long.

TABLE 29-3 Common foot and nail problems

Characteristics	Implications	Interventions
Callus		
Thickened portion of epidermis consists of mass of horny, keratotic cells Callus is usually flat, painless and found on undersurface of foot or on palm of hand Problem is caused by local friction or pressure	Condition may cause discomfort when wearing tight shoes	Nurse advises person to wear gloves when using tools or objects that may create friction on palmar surfaces Soft-sole shoes with inner soles are recommended Nurse soaks callus in warm water and Epsom salts to soften cell layers Applications of creams or lotions can reduce reformation Encourage person to see podiatrist
Corns		
Keratosis is caused by friction and pressure from ill-fitting or loose shoes. It is seen mainly on or between toes, over bony prominence Corn is usually cone-shaped, round and raised. Soft corns are macerated	Conical shape compresses underlying dermis, making it thin and tender. Pain is aggravated when tight shoes are worn Tissue can become attached to bone if allowed to grow Person may suffer alteration in gait resulting from pain	Surgical removal may be necessary, depending on severity of pain and size of corn Nurse avoids use of oval corn pads, which increase pressure on toes and reduce circulation Warm water soaks can soften corns before gentle rubbing with a callus file or pumice stone (consult doctor) Wider and softer shoes are suggested
Plantar warts		
Fungating lesion appears on sole of foot and is caused by papillomavirus	Warts may be contagious. They are painful and make walking difficult	Treatment ordered by doctor may include applications of salicylic acid, electrodessication (burning with electrical spark) or freezing with solid carbon dioxide
*Athlete's foot (*Tinea pedis*)*		
Athlete's foot is fungal infection of foot; scaliness and cracking of skin occurs between toes and on soles of feet. Small blister containing fluid may appear Problem is apparently induced by wearing of constricting footwear	Athlete's foot can spread to other body parts, especially hands. It is contagious and frequently recurs	Feet should be well ventilated Drying feet well after bathing and applying powder help prevent infection Wearing clean socks or stockings reduces incidence Doctor may order application of griseofulvin, miconazole or tolnaftate
Ingrown nails		
Toenail or fingernail grows inwards into soft tissue around nail; often results from improper nail trimming	Ingrown nails can cause localised pain when pressure is applied	Treatment is frequent hot soaks in antiseptic solution and removal of portion of nail that has grown into skin Instruct person on proper nail-trimming techniques and refer to podiatrist
Ram's horn nails		
Ram's horn nails are usually long, curved nails	Attempt by nurse to cut nails may result in damage to nail bed with risk of infection	Nurse refers person to podiatrist
Paronychia		
Inflammation of tissue surrounding nail occurs after hangnail or other injury; occurs in people who frequently have their hands in water and is common in diabetic people	Area can become infected	Treatment is hot compresses or soaks and local application of antibiotic ointments Paronychia can be prevented by careful manicuring
Foot odours		
Foot odours are the result of excess perspiration promoting microorganism growth	Condition may cause discomfort because of excess perspiration and embarrassment because of odour	Frequent washing, use of foot deodorants and powders and wearing clean footwear prevent or reduce problem

TABLE 29-4 Hair and scalp problems

Characteristics	Implications	Interventions
Dandruff		
Scaling of scalp is accompanied by itching In severe cases, dandruff is found on eyebrows	Dandruff causes person embarrassment If dandruff enters eyes, conjunctivitis may develop	Shampoo regularly with medicated shampoo. In severe cases, obtain doctor's advice
Ticks		
Small, grey-brown parasites burrow into skin and suck blood	Ticks transmit several diseases to people, including typhoid, Lyme disease, spotted fever and tick paralysis. Some species of tick can cause paralysis	Do not pull the tick from the skin Kill the tick with methylated spirits or insect repellent. Repeat after 1 minute. After 1 hour, brush the tick off. If necessary, lever tick out with open scissor blades
*Lice (*Pediculosis*)*		
Tiny, greyish-white parasite insects which infest mammals		
Head lice (*Pediculosis capitis*) Parasite is found on scalp attached to hair strands Eggs look like oval particles, similar to dandruff Bites or pustules may be observed behind ears and at hairline	Head lice are difficult to remove and may spread to furniture and other people if not treated	Thorough combing can remove lice Doctor may recommend shampooing with a pediculocidal shampoo. Follow directions as to repeating treatment Change bedclothes. Wash bedclothes in hot water to kill lice Caution children not to share hats or towels
Body lice (*Pediculosis corporis*) Parasites tend to cling to clothing, so they may not be easily seen Body lice suck blood and lay eggs on clothing and furniture	Person itches constantly. Scratches seen on skin may become infected Haemorrhagic spots may appear on skin where lice are sucking blood	Bath or shower thoroughly. After skin is dried, apply recommended pediculocidal lotion. After 12–24 hours, have another bath or shower Bag infested clothing or sheets until washed in hot water Vacuum rooms thoroughly and throw away bag after completion
Crab lice (*Pediculosis pubis*) Parasites are found in pubic hair Crab lice are greyish white with red legs	Lice may spread through bed linen, clothing or furniture, or between people via sexual contact	Shave hair off affected area. Clean as for body lice If lice were sexually transmitted, notify partner
Hair loss (alopecia)		
Alopecia occurs in all races Balding patches are seen in periphery of hair line. Hair becomes brittle and broken Condition is caused by use of hair curlers, tight braiding and hot rollers	Patches of uneven hair growth and loss alter person's appearance	Stop hair-care practices that damage hair

Assessment of the external *ear* structures includes inspection of the auricle, external ear canal and tympanic membrane. While performing hygiene measures, note the presence of accumulated cerumen or drainage in the ear canal, local inflammation or pain.

Inspect the *nares* for signs of inflammation, discharge, lesions, oedema and deformity. The nasal mucosa is normally pink and clear and has little or no discharge. A clear, watery discharge may be the result of allergies.

If the person has any form of tubing exiting the nose (e.g. nasogastric), the nurse should look at the nares' surfaces that come in contact with the tubing for tissue sloughing, localised tenderness, inflammation and bleeding.

Developmental changes

The normal process of ageing influences the condition of body tissues and structures and thus the manner in which hygiene measures are performed.

Skin

The *neonate's* skin is relatively immature at birth. The epidermis and dermis are loosely bound together and the skin is very thin. Friction against the skin layers can cause bruising. The neonate

must be handled carefully during bathing. Any break in the skin can easily lead to infection.

A *toddler's* skin layers are more tightly bound together than the neonate's, so the child has a greater resistance to infection and skin irritation. However, because of the child's more-active play and the absence of established hygiene habits, greater attention is needed from parents and caregivers to provide thorough hygiene and to begin teaching good hygiene habits.

During *adolescence* the growth and maturation of the integument increases. In girls, oestrogen secretion causes the skin to become soft, smooth and thicker, with increased vascularity. In boys, male hormones produce an increased thickness of the skin with some darkening in colour. Sebaceous glands become more active, predisposing adolescents to **acne**. Eccrine and apocrine sweat glands become fully functional during puberty. Adolescents usually begin to use antiperspirants. More-frequent bathing and shampooing also become necessary to reduce body odours and eliminate oily hair. Sweating is usually more pronounced in boys in temperate climates.

The condition of the *adult's* skin depends on hygiene practices and exposure to environmental irritants. Normally the skin is elastic, well hydrated, firm and smooth. When an adult bathes frequently or is exposed to an environment with low humidity, the skin can become very dry and flaky. With age, the skin loses its resilience and moisture, and sebaceous and sweat glands become less active. The epithelium thins and elastic collagen fibres shrink, making the skin fragile and subject to bruising and breaking (see *Working with diversity*). These changes warrant caution when turning and repositioning older adults. Typically, the older person's skin is dry and wrinkled. Daily bathing as well as bathing with water that is too hot or soap that is harsh may cause the skin to become excessively dry.

Feet and nails

Changes in the infant's feet occur during infancy and early childhood as locomotion and weightbearing progress. At birth the feet are flat because the arches are protected by fat pads on the soles. As the bones in the arches develop, the pads disappear and the feet begin to assume a mature shape (Hockenberry & Wilson 2011).

The main reason for wearing shoes is protection. Shoes should retain their fit, be made of durable material with a smooth interior and few construction seams to irritate the skin and be soft and flexible, especially in the toes. During weightbearing, there should be at least the space of half the width of the thumbnail, or 1.25 cm, between the end of the longest toe and the shoe (Hockenberry & Wilson 2011). Frequent changes in shoe size are needed to accommodate the infant's rapidly growing feet. Curled toes when shoes are removed and redness and irritation of the skin on the bottom of the toes indicate the need for a larger shoe size. As children grow, it is important that they continue to be fitted with a proper shoe size. The more active a child becomes, the greater the need for sturdy shoes that protect the feet from injury.

During standing, the foot provides body support and absorbs shock. With ageing, the feet begin to show signs of wear and tear. This may occur earlier if a person has not worn comfortable, supportive footwear. The cushioning layer of fat on the soles of the feet becomes thin. Years of walking cause the metatarsal bones to spread and ligaments to stretch, which results in wider feet (Kwan et al 2010).

Chronic foot problems are a common part of ageing. Older adults often have dry feet because of a decrease in sebaceous gland secretion, dehydration of epidermal cells and poor condition of footwear. Fissures that result in itching often develop. The feet of older adults often develop abnormalities over time, which can become disabling if not cared for appropriately (Touhy & Jett 2011). Painful feet can be the result of congenital deformities, weak structure, injuries, and diseases such as diabetes, rheumatoid arthritis and osteoarthritis. Arthritis is generally the cause of changes in the feet after age 55 years. Additional common problems of the feet include hammer and claw toes (flexion contractures); bunions, corns and calluses; heel spurs and gout (Touhy & Jett 2011). Fungal infections occur under toenails, causing yellow streaks or total discolouration. The nails can also become opaque, scaly and hypertrophied. If foot or nail problems stay unresolved, an older adult can easily become disabled. Nurses apply knowledge of typical changes in the feet and nails when anticipating the type of hygiene a person will require.

The mouth

At approximately 6–8 months of age, infants begin teething (Hockenberry & Wilson 2011). The eruption of the deciduous (primary) teeth usually begins with the lower central incisors, followed closely by the upper central incisors (Table 29-5). When the crown of a tooth breaks through the periodontal membrane, some discomfort can be experienced. Drooling, increased finger-sucking or biting on hard objects may be the only signs of discomfort. Some children can become very irritable and have difficulty sleeping and eating. Teething continues to occur until the final molars erupt, at around 27–29 months of age.

The first permanent (secondary) teeth erupt between 5 and 8 years of age (Thibodeau & Patton 2013). Before their appearance they have been developing in the jaw beneath the primary teeth. Meanwhile, the roots of primary teeth are gradually absorbed, so that at the time a deciduous tooth is shed, only the crown remains. The pattern of shedding primary teeth and the eruption of secondary teeth varies widely among

WORKING WITH DIVERSITY

Focus on older adults

With normal ageing the skin decreases in thickness and elasticity. The epidermal cells of the older adult contain less moisture and the skin often has a dry and wrinkled appearance. The connections between the dermis and epidermis are reduced and therefore increase the possibility for skin tears. For many older adults the slightest impact or friction against their fragile skin will cause a skin tear. Nurses play a critical role in maintaining skin integrity of the older adult. Extra care must be taken to protect fragile skin when assisting elders to move and reposition in the bed and to complete hygiene measures, as well as in other activities of daily living.

TABLE 29-5 Physiological development of the mouth

Developmental level	Changes
Infant	Deciduous teeth begin to erupt at about 6 months of age
	Solid food can be taken in mouth at 5–6 months
	Chewing begins by 6–8 months
18 months to 6 years	Twenty deciduous teeth are present
	By age 2, child can begin to brush teeth and learn hygienic practices from parents. Dental caries may become a problem if dental hygiene is neglected
	By age 6, 'baby' teeth begin to fall out and are replaced by permanent teeth
6–12 years	Deciduous teeth are replaced by permanent teeth. Permanent teeth are present by age 12 except second and third molars
	Definite food preferences become apparent
	Dental caries and irregularity in spacing of teeth are significant health problems
12–18 years	All permanent teeth are present
	Dental hygiene practices tend to improve because of increased awareness of body image
18–40 years	Third molars appear
	Good oral hygiene and nutrition practices are needed to avoid problems in later years
40–65 years	Although loss of teeth, usually a result of periodontal disease, is declining, about half of people over age 55 have lost some or all of their teeth because of poor oral care. Root caries and oral cancer occur with higher frequency
65 years and over	Ageing teeth become brittle, drier and darker in colour
	Teeth become uneven, jagged and fractured after years of crushing and grinding
	Gums lose vascularity and tissue elasticity, causing dentures to fit poorly
	Eating habits often change, and malnutrition may be a problem
	Diminished taste sensitivity, thinning of mucosa and decreased mass and strength of muscles of mastication also occur

Adapted from Hockenberry M, Wilson D 2011 Wong's Essentials of pediatric nursing, 9th edn. Mosby, St Louis; Jarvis C 2008 Physical examination and health assessment, 5th edn. Saunders, St Louis.

children. Many of the difficulties created by crowding of teeth become apparent. Since it is during the school-age years that the permanent teeth erupt, good dental hygiene and regular attention to dental caries are a part of health-promotion practices. Children of this age tend to be lax about oral hygiene and are not motivated by improved appearance and odour, as they will be during adolescence. In addition, children prefer sugary sweets and soft drinks for snacks. Parental support is critical for health maintenance.

From adolescence, when all of the permanent teeth are in place, through middle adulthood, the teeth and gums remain healthy if a person follows good eating patterns and good dental care. Avoidance of fermentable carbohydrates and sticky sweets are central to keeping the teeth free of caries. Regular brushing and flossing helps to prevent caries and periodontal disease (Huskinson & Lloyd 2009).

As a person grows older there are numerous factors that can result in poor oral care (see *Research highlight*). These include age-related changes of the mouth, chronic disease such as diabetes, physical disabilities involving hand grasp or strength, lack of attention to oral care, and prescribed medications that have oral side effects. Effects of inadequate care include dental caries and loss of teeth; periodontal disease; systemic infection; and long-term effects on self-esteem, the ability to eat and the maintenance of relationships. Many older people are **edentulous** (without teeth) and wear complete or partial dentures. It is important for nurses to learn whether older adults wear dentures and the condition of underlying supportive gum tissue.

Hair

Throughout life, changes in the growth, distribution and condition of the hair influence the hygiene a person requires (Table 29-6). As males reach adolescence, shaving becomes a part of routine grooming. Young girls who reach puberty may begin to shave or wax their legs and axillae. With ageing, as scalp hair becomes thinner and drier, shampooing is usually done less frequently.

Eyes, ears and nose

Chapter 19 covers the changes in hearing, vision and smell as a result of growth and development.

Self-care ability

A person's self-care abilities determine whether assistance is needed in managing activities of daily living (ADLs), including routine hygiene. Nurses assess a person's physical and cognitive ability to perform basic hygiene measures. The assessment must include measurement of a person's muscle strength, flexibility

RESEARCH HIGHLIGHT

Research focus

Poor oral health in adult life has been linked to socioeconomic status in childhood. Studies have also been conducted linking oral disease to other conditions in adult life. This study reports the lessons learned from an interprofessional education initiative where two or more professions learn about, from and with each other to improve collaboration and the quality of care.

Research abstract

Nursing and dental hygiene students at George Brown College were brought together in an initiative to learn from each other about the overlapping roles they share in oral-health and blood-pressure monitoring. The World Health Organization (WHO) has long advocated for 'multiprofessional' education among undergraduate healthcare students to build 'the skills necessary for solving the priority health problems of individuals and communities that are known to be particularly amenable to team-work'.

There is evidence of a connection between oral health and systemic health, and the increased need for proper daily oral health assessment and care for populations within acute and long-term care. At present, members of the nursing profession whose scope of practice includes providing oral assessment and daily oral care are the frontline caregivers for these populations. The increase in high blood pressure within the general population is also a priority health problem. Dental hygienists are frontline healthcare professionals in oral assessment and oral care education whose scope of practice includes taking blood pressure and pulse.

The results of the Canadian Health Measures Survey show that approximately 70% of the population sees an oral health practitioner on an annual basis. Dental hygienists are in an ideal position to monitor and screen for high blood pressure.

Evidence-based practice

- Promotion of a healthy adult lifestyle and the identification of risk factors, such as smoking, to all sectors of the population.
- Advice regarding oral hygiene throughout the life span.

TABLE 29-6 Physiological development of hair growth

Age	Condition of hair
Infancy	Infants may have little or no scalp hair at birth. Scalp hair grows by first year Fine body hair (lanugo) is present on forehead, cheeks, shoulders and back
Childhood	Scalp hair is lustrous, silky, strong and elastic Hair of dark-skinned child is curlier and coarser
Middle childhood to puberty	Androgenic hormones cause increase in thickening and darkening of scalp hair, growth of hair in axillae and pubic areas in both sexes and growth of facial hair in boys
Adolescence	Boys may acquire additional amounts of distribution of body hair, such as on chest Increase in sebaceous gland activity causes hair to become oily
Adulthood	Men with genetic tendency develop baldness
Older adulthood	Axillary and pubic hair diminish in women Scalp hair becomes thinner and depleted of melanin, causing grey colouring Older women may develop chin and facial hair because of decreased oestrogen production Men may experience balding or receding hairline

and dexterity, balance, coordination, and activity tolerance necessary in performing activities such as bathing, brushing teeth and bending over to inspect the feet (Figure 29-5). For example, observing a person's ability to completely brush the front surfaces of all lower front teeth in 30 seconds and noting the person's ability to pick up and use the brush is a way to assess ability to brush the teeth (Miegel & Watchel 2009). The degree of assistance required by a person during hygiene care may also depend on vision, the ability to sit without support, attached equipment, hand grasp and the range of motion in the person's extremities. Painful conditions of the upper extremities pose special problems. Nurses can assess self-care ability by asking the person to perform activities such as brushing the teeth or combing the hair. Observe the person carefully and

Figure 29-5 **A nurse observes a person brushing their teeth. During such observations the nurse can determine how much help the person may need.**

note not only whether the activity is performed correctly, but also whether the person is thorough and can complete the task without undue fatigue.

When people have self-care limitations, part of nurses' assessment is determining whether family or friends are available to assist. In addition, nurses assess the home environment and its influence on the person's hygiene practices. Are there barriers in the home that may affect the person's self-care abilities? Taps that are too tight to easily adjust, baths with high sides and a bathroom too small to fit a chair in front of a sink are a few examples. Burns to small children and the elderly often occur because the tap-water temperature is set too high. Ideally, the temperature should be no higher than 49°C.

Hygiene practices

Each person has a preferred routine for how to perform hygiene. Nurses should not assume that all people typically bathe and groom early each morning after getting out of bed. Some people may bathe on a weekly basis only. In addition, people vary in the type of hygiene products used and in which hygiene measures they practise. In assessing a person's practices, nurses may ask a person to describe what is typically done to care for the skin, teeth, hair and feet. Nurses also observe the person's appearance. For example, dull, tangled and dirty hair indicates improper care. Unkempt hair may result from lack of interest, depression, lack of grooming resources, a physical inability to care for the hair, or the person's preference. When a person's appearance suggests poor hygiene, nurses must be sensitive in learning what the causes are.

Assessment of hygiene practices reveals the person's preferences for grooming. For example, a person may choose to groom the hair in a certain style or choose to trim their nails in a certain way. When a person has a physical disability, special precautions may be needed to perform grooming without injury. Asking the person to help or teach nurses how to perform preferred grooming practices gives the person a greater sense of independence and helps nurses avoid causing the person any discomfort or injury.

Because of a significant increase in the numbers of older adults and minorities, dental practice is facing new challenges. Immigrant communities may have high levels of untreated dental caries or gingivitis. This pattern suggests deficient hygiene practices, limited access to dental care resources or improper hygiene techniques. Helpful questions to use in assessing dental hygiene practices include the following:

- How often does the person brush the teeth?
- What type of toothbrush and toothpaste are used?
- Does the person have dentures, partials or bridges? When and how are they cleaned?
- Does the person use mouthwash, which can cause excess mucosal drying?
- Does the person floss? If so, how often?
- When was the person's last dental visit? How often are visits to a dentist made? What were the most recent results?
- Does the person drink tap-water that is fluoridated?

Toothbrushes should be discarded every 3 months or after an upper respiratory infection or pharyngitis. This prevents infection or reinfection from microbial colonisation on the toothbrush (Harris et al 2008).

Cultural factors

A person's cultural background is an influential factor when determining hygiene needs. Culture plays a role not only in hygiene practices and preferences, but also in sensitivity to personal space (see Chapter 14). For example, some Chinese people may view tasks associated with closeness and touch as being offensive or impolite (Giger 2013). Nurses should ask the person what would make them feel most comfortable during a bath. Perhaps a person would prefer only a partial instead of a full bath from nurses, with a family member completing the bathing of more-private body parts. The person may also defer part of the hygiene. If, in nurses' judgement, hygiene is critical to prevent or worsen problems, such as skin breakdown, nurses must take the time to understand the person's concerns and then offer an explanation that will help the person accept intervention by nurses.

People at risk of hygiene problems

Some people present risks that require more attentive and rigorous hygiene care (Table 29-7). These risks result from side effects of medications, a lack of knowledge, an inability to perform hygiene or a physical condition that potentially injures the skin, integument or other structures. An immobilised person who has a fever, for example, will require more frequent bathing to minimise sweat on the skin, and more frequent turning and positioning to reduce the chance of skin breakdown. Nurses anticipate whether a person is predisposed to such risks and follow through with a complete assessment. For example, if a person is receiving chemotherapy there is the risk of the medication destroying normal flora in the mouth, allowing for the overgrowth of opportunistic microorganisms, for example, fungal organisms such as *Candida albicans*; therefore, the oral examination should be more thorough and detailed, with all surfaces of the tongue and mucosa examined. If a person is diaphoretic, nurses will give special attention to body areas such as a woman's breasts and perineal area to check where moisture may collect and irritate skin surfaces. Nurses anticipate problems created by these risks so as to provide appropriate preventive care. Their assessment will include a review of the

person's medical and surgical history, medications and the specific risk factors the person is likely to have.

Special considerations in hygiene assessment

Depending on the type of hygiene nurses plan to provide, there are certain focused assessments that need to be conducted. Before giving foot care, nurses assess the type of footwear worn by the person. Children or young adults who often don't wear socks may have excess perspiration that promotes fungal growth. Tight or poorly fitting shoes, socks, garters or knee-high stockings may cause skin irritation and interfere with circulation to the feet. Nurses also assess whether people wear clean footwear daily, because repeated use of soiled footwear can lead to infection. If the person has diabetes mellitus or other peripheral vascular disease, it is extremely important that correct footwear be worn. Extra-wide and

TABLE 29-7 Risk factors for hygiene problems

Problem	Hygiene implications
Oral problems	
People who are unable to use upper extremities due to paralysis, weakness or restriction (e.g. cast or dressing)	Person lacks upper-extremity strength or dexterity needed to brush teeth
Dehydration, inability to take fluids or food by mouth (NBM)	Causes excess drying and fragility of mucosa; increases accumulation of secretions on tongue and gums
Presence of nasogastric or oxygen tubes; mouth breathers	Causes drying of mucosa
Chemotherapeutic drugs	Drugs kill rapidly multiplying cells, including normal cells lining oral cavity; ulcers and inflammation can develop
Lozenges, cough drops, antacids and chewable vitamins over-the-counter (OTC)	Medications contain large amounts of sugar; repeated use increases sugar or acid content in mouth
Radiation therapy to head and neck	Reduces salivary flow and lowers pH of saliva; can lead to stomatitis and tooth decay.
Oral surgery, trauma to mouth, placement of oral airway	Cause trauma to oral cavity with swelling, ulcerations, inflammation and bleeding
Immunosuppression; alters blood clotting	Predisposes to inflammation and bleeding gums
Diabetes mellitus	Prone to dryness of mouth, gingivitis, periodontal disease and loss of teeth
Skin problems	
Immobilisation	Dependent body parts are exposed to pressure from underlying surfaces. The inability to turn or change position increases risk of pressure ulcers
Reduced sensation due to stroke, spinal cord injury, diabetes, local nerve damage	Normal transmission of nerve impulses not received when excessive heat or cold, pressure, friction or chemical irritants are applied to skin
Limited protein or kilojoule intake and reduced hydration (e.g. fever, burns, gastrointestinal alterations, poorly fitting dentures)	Limited kilojoule and protein intake predispose to impaired tissue synthesis: skin becomes thinner, less elastic and smoother with a loss of subcutaneous tissue. Poor wound healing may result Reduced hydration impairs skin turgor
Excessive secretions or excretions on the skin from perspiration, urine, watery faecal material and wound drainage	Moisture is a medium for bacterial growth and can cause local skin irritation, softening of epidermal cells and skin maceration
Presence of external devices (e.g. casts, restraint, bandage, dressing)	Device can exert pressure or friction on skin's surface
Vascular insufficiency	Arterial blood supply to tissues is inadequate, or venous return is impaired, causing decreased circulation to extremities. Tissue ischaemia and breakdown may occur; risk of infection is high
Foot problems	
Person unable to bend over or has reduced visual acuity	Person is unable to fully see entire surface of each foot, impairing ability to adequately assess condition of skin and nails
Eye care problems	
Reduced dexterity and hand coordination	Physical limitations create inability to safely insert or remove contact lens

extra-deep shoes will accommodate bunions or hammer toes. Cushioned inner soles help redistribute pressure on the metatarsal head.

• CRITICAL REFLECTION POINT

Mrs Viera is 62 years old and is being seen in the endocrinology clinic for a follow-up appointment for management of her diabetes mellitus. During the nurse's conversation with Mrs Viera, the patient says, 'You know, last week I found a sore on my left foot; I didn't even know it was there.' What type of assessment should the nurse conduct for Mrs Viera, and what could the findings indicate?

A person's eating patterns need to be assessed prior to oral care. The presence of any problems may help nurses to locate abnormalities. Does the person have any problems associated with chewing, denture fit or swallowing? They may have changed the type of food in their diet as a result of chewing difficulties. The presence of an ulcer or irritation may impair chewing and cause a person to avoid eating. This is common in an older adult with poorly fitting dentures.

According to the Australian Institute of Health and Welfare (2008), people living in rural or remote areas have a greater incidence of poor dental health than city people, and have less access to dental care. Indigenous Australians have twice the level of edentulism or complete tooth loss compared with other Australians. Nurses can play a very important role, particularly when caring for people in rural settings, poor people and older adults, in being able to screen for abnormalities such as dental decay and referring dental problems to a dental professional.

If a person wears glasses, contact lenses, artificial eyes or hearing aids, assess the person's knowledge of methods used to care for the aids, and the presence of any problems. Box 29-2 outlines factors to assess in people who use sensory aids. Findings have implications for patient education and nursing care.

The person's expectations

As is the case in any nursing assessment, it is important to know what a person expects from nursing care. In relation to hygiene care, the person may simply expect to have hygiene preferences and practices applied in the healthcare setting. Nurses can learn a person's expectations by asking questions such as 'To make you most comfortable and feel at home, how can I best perform your bath and personal care?' or 'How can we help you to care for your teeth, nails and hair, now that you are back home?'

Learning a person's expectations and applying them in practice is important in establishing a caring relationship. Truly individualising hygiene care shows respect for the person's needs. As nurses learn what the person expects, this information can be incorporated into goal development.

• CRITICAL REFLECTION POINT

Alison Jakes is 14 years old and visiting the clinic for a vaccination. She mentions to the clinic nurse that she has a toothache. What assessment would be required for Alison? What recommendations might the clinic nurse make about dental care?

BOX 29-2 Assessing person's use of sensory aids

Glasses

- Purpose for wearing glasses (e.g. reading, distance, or both)
- Methods used to clean glasses
- Presence of symptoms (e.g. blurred vision, photophobia, headaches, irritation)

Contact lenses

- Type of lens worn
- Frequency and duration of time lenses are worn (including sleep time)
- Presence of symptoms (e.g. burning, excessive eye-watering, redness, irritation, swelling, sensitivity to light)
- Techniques used to clean, store, insert and remove lenses
- Use of eye drops or ointments
- Use of emergency identification bracelet or card that warns others to remove person's lenses in case of emergency

Artificial eye

- Method used to insert and remove eye
- Method of cleaning eye
- Presence of symptoms (e.g. drainage, inflammation, pain involving the orbit)

Hearing aid

- Type of aid worn
- Methods used to clean aid
- Ability to change battery and adjust hearing-aid volume

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Nurses' assessment will reveal the condition of the skin, oral cavity and other tissues, as well as the person's need for and ability to meet personal hygiene needs. Nurses review all data gathered, consider previous people cared for, review knowledge pertaining to pre-existing conditions and then look for clusters of data suggesting a problem trend. For example, an older adult with degenerative arthritis presents to the home health nurse with pain in the joints, weakness, mobility limitations in the dominant hand and a generally unkempt appearance. Closer review of assessment data reveals defining characteristics of an inability to wash body parts and difficulty turning and regulating a tap. The nursing diagnosis of bathing/hygiene self-care deficit is supported and becomes part of the nursing plan of care. The accurate selection of nursing diagnoses requires critical thinking to identify actual or potential health problems (Box 29-3). Assessment activities must be thorough in revealing all appropriate defining characteristics so that an accurate diagnosis can be made.

BOX 29-3 Priority problems associated with hygiene care

Assessment activities	Defining characteristics	Priority problem
Inspect condition of person's perianal and perineal tissues.	Skin is becoming reddened over perianal area.	Risk of impaired skin integrity related to chemical irritation.
Observe character of person's loose stools.	Stools are diarrhoeal in nature, occurring 5–6 times daily.	
Note frequency of loose stools.		
Observe person attempt to bath self either in bed or at bathroom sink. (Note: be sure positioning does not restrict potential movement.)	Person is unable to wash body or body parts.	Self-care deficit, bathing/hygiene related to upper extremity weakness.
Observe person adjust flow of water.	Person is unable to regulate water flow.	
Assess person's upper extremity strength, range of motion and coordination.	Person has reduced upper extremity movement and strength.	

Whether a person has an actual problem (e.g. impaired tissue integrity) or is at risk (e.g. of infection) determines the focus of nursing interventions. The person with an actual problem will require extensive hygiene care, often more thorough than routine hygiene might involve. For example, if the person has skin breakdown, nurses must initiate care more frequently to keep existing skin surfaces clean and dry and to eliminate factors such as moisture or drainage that can worsen the condition of the skin. Nurses would also provide care to promote healing of injured skin surfaces (see Chapter 26). If the person is at risk of a problem, nurses will institute preventive measures. In the case of risk of impaired oral mucous membranes, nurses will keep the mucosa well hydrated, minimise foods that irritate the membranes and provide cleaning that soothes and reduces tissue inflammation.

The identification of related factors guides nurses in the selection of nursing interventions. Identification of an impaired oral mucous membrane related to malnutrition and one of impaired oral mucous membrane related to chemical trauma require very different interventions. When malnutrition is a causal factor, nurses will obviously confer with a dietitian for appropriate dietary supplements and incorporate patient education into the plan. When mucosa are injured as a result of chemical trauma from chemotherapy, techniques for cleaning and hydrating inflamed tissues and eliminating sources of irritation will be the focus of nursing care. Box 29-4 summarises possible nursing problems that apply to people in need of hygiene care.

BOX 29-4 Priority problems associated with hygiene

Dentition
Fatigue
Risk of infection
Knowledge deficit about hygiene practices
Impaired physical mobility
Altered oral mucous membrane
Powerlessness
Self-care deficit, bathing/hygiene
Self-care deficit, dressing/grooming
Self-esteem disturbance
Impaired skin integrity
Tissue integrity, impaired
Peripheral tissue perfusion, altered

SETTING PRIORITIES AND ESTABLISHING GOALS

During planning, nurses synthesise information from multiple resources (Figure 29-6). Critical thinking ensures that the person's plan of care integrates all that nurses know about the individual person and key critical-thinking elements. Previous experience with other people can be very useful in knowing how to adapt hygiene techniques for special needs. Professional standards are especially important to consider when nurses develop a plan of care. These standards often establish scientifically proven guidelines for effective nursing interventions. For example, Diabetes Australia's guidelines are valuable for preventive foot care in diabetic people (see *Online resources*).

Goals and outcomes

Nurses develop an individualised plan of care for each of the person's potential problems (see *Sample student nursing care plan*). Nurses work together with the person to identify goals and expected outcomes. Goals are established with the person's self-care abilities and resources in mind. Outcomes should be measurable and achievable within the person's limitations. Nurses work further with the person to then select hygiene measures that are appropriate and realistic. For example, a goal for self-care deficit hygiene might be: 'The person will complete his own hygiene care with supervision within 1 week.' The expected outcomes would be 'remains free of body odour, states satisfaction with the ability to use aids in the shower and bathes with minimal assistance in and out of shower'.

APPLYING CRITICAL THINKING

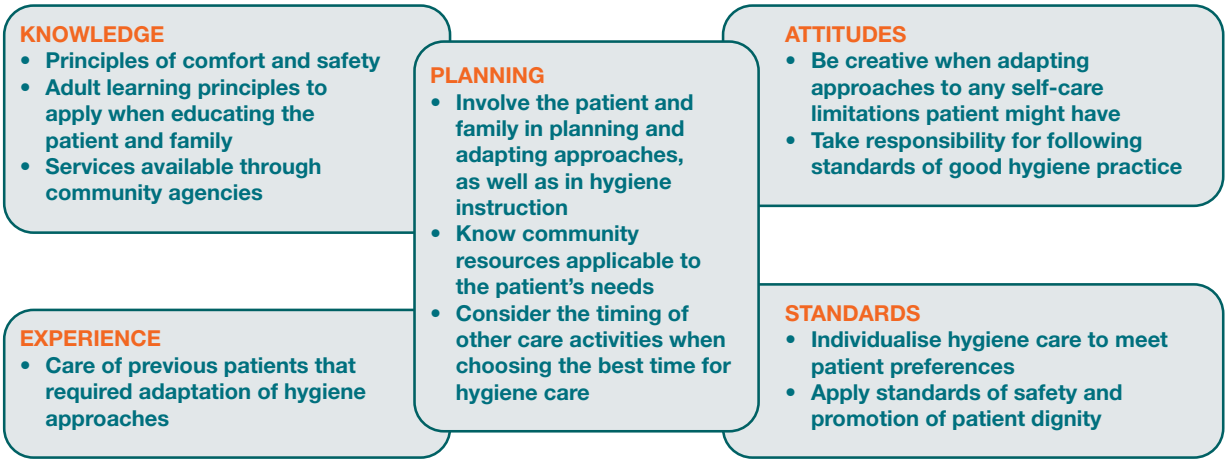

Figure 29-6 **Critical thinking associated with the planning phase for hygiene.**

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant data and information*

Mrs Wyatt is a 57-year-old who has had multiple sclerosis for 10 years. She was recently hospitalised for an acute exacerbation of the disease. Jeannette, the nurse, makes the initial home visit to see Mrs Wyatt. Jeannette's assessment reveals that Mrs Wyatt has reduced hearing, requiring Jeannette to speak clearly and to stand so Mrs Wyatt can see her lip movements. Mrs Wyatt is married, but her husband, Lon, works full-time during the day. Her sister comes over periodically to help with her care and household chores. Mrs Wyatt has **muscular weakness of both upper extremities**, making it **difficult for her to raise her arms above her shoulders**. She has some foot dragging and ataxia (unsteady gait), so she **bathes in a chair placed in front of the bathroom sink**. Recently her sister has helped with bathing. With some spasticity in her right dominant arm, Mrs Wyatt has difficulty grasping objects. Jeannette arranged her assessment in the morning to observe Mrs Wyatt bathe. She had **increased spasticity while bathing and became very fatigued after only about 5 minutes**. Mrs Wyatt continues to be very independent in making decisions about her care. She tells Jeannette, 'It is important for me to be able to bathe myself.'

**Important data to cluster in setting priorities in bold.*

Priority problem(s)

Inability to self-care: bathing/hygiene related to muscle spasticity and fatigue.

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Mrs Wyatt will be able to perform self-bathing without assistance within 1 month.	Mrs Wyatt will experience decreased duration of muscle spasms within 2 weeks. Mrs Wyatt will experience less fatigue during bathing activities within 1 month. Mrs Wyatt will be able to grasp and manipulate bathing equipment.

Preparing for and taking action†	Rationale
Energy management	
• Plan bathing at a time when Mrs Wyatt has most energy.	Will minimise occurrence of fatigue.
Self-care assistance	
• Set up bathing area (with assistance of husband or sister) so that all bathing equipment is at waist level, easy for Mrs Wyatt to reach.	Easy access to equipment will reduce muscle fatigue.
• Instruct Mrs Wyatt's sister to encourage Mrs Wyatt's independence and to intervene only when she is unable to bathe herself.	Multiple sclerosis is a degenerative disease that progresses. People may have remissions along with relapses. Therapy maintains the highest level of independent activity.
• Confer with physical or occupational therapist about the appropriateness of aids to use during bathing.	Decrements in the ability to perform gross motor function over time indicate need for aids and a modified environment to help control symptoms and to make activities of daily living easier to perform.
Exercise promotion: stretching	
• Perform stretching exercises prescribed by physical therapy every 6–8 hours.	Stretching prevents muscle contraction and reduces muscle spasms.

† Preparing for and taking action classification labels from Bulechek GM et al 2008 Nursing interventions classification (NIC), 5th edn. Mosby, St Louis.

Evaluating impacts and outcomes

- Assess the range of motion of upper extremities for presence of spasticity.
- Ask Mrs Wyatt to report if they experience fatigue during bathing.
- Observe Mrs Wyatt bathing at the bathroom sink.

The person's condition influences the plan for delivering hygiene. A seriously ill person usually needs a daily bath because body secretions accumulate and can become a source of infection. An older person at home may require a visit from a home health aide to help with a bath. People who are normally inactive during the day and have skin that tends to be dry may need to bathe only twice a week. Timing is also important in planning hygiene. Being interrupted in the middle of a bath to go to an X-ray examination can frustrate and embarrass a person. Following extensive diagnostic tests (e.g. a stress test), it may be best to delay hygiene and allow a person to rest. In the home, bathing may be planned to refresh the person before daily activities. Nurses should try to plan hygiene around tests, procedures and person needs. This can be difficult in a hospital because tests are often not scheduled for specific times.

• CRITICAL REFLECTION POINT

Mr Wilkes is a 54-year-old man with an advanced stage of lung cancer. The tumour has spread to the bone, causing Mr Wilkes considerable pain and predisposing him to pathological fractures (fractures that result when bone is weakened by tumour growth). He has been experiencing a high fever almost daily. What might you consider in anticipating Mr Wilkes's hygiene needs?

When a person needs assistance as a result of a self-care limitation, the family becomes a valuable resource to nurses. Family members can usually help with hygiene measures, but may need guidance in adapting techniques to fit their limitations. In devising a plan that involves family members, nurses try to match the family's schedule of availability with the person's needs. It is also important to have the family member with whom the person is most comfortable routinely involved (Paquay et al 2010).

Setting priorities

Although hygiene needs are not the top priority for saving lives, for the person these needs are often a higher priority than nurses perceive them to be. The discomfort and lowered self-esteem of knowing that your body odour is offensive or that your teeth feel thick and you have halitosis or that your skin is sweaty and uncomfortable cause hygiene needs to assume a high priority.

Continuity of care

Discharge planning involves alerting the community nurse to the person's needs and functional ability. Information sharing is crucial to people receiving seamless care from hospital to home. Social workers may need to become involved to provide funds for home aids or alterations. Occupational therapists are able to assess the person's home environment and suggest changes that would improve independent living. Nurses must plan for necessary assistance for people who are weakened or possess poor coordination. For example, a partially paralysed person who has had difficulty getting out of a bath should have a bath chair, handrails, a handheld shower or extra people available to help.

Nurses may need various community resources in planning hygiene care. For example, nurses involved in the care of a

homeless person may need to be aware of the location of clothing distribution centres for basic hygiene supplies or a shelter where bathing facilities are available. Frequently nurses will consult with social workers or staff in local churches and schools to be sure people have the resources they need to maintain hygiene.

PREPARING FOR AND TAKING ACTION

Providing hygiene is a very basic but important part of a person's care. Nurses learn to use caring practices that help to alleviate the person's anxiety and promote comfort and relaxation while performing each hygiene measure. For example, while giving a person a bath and changing a gown, nurses use a gentle approach in turning and repositioning. Using a soft, gentle voice while conversing with the person helps to relieve any fears or concerns. For people suffering symptoms such as pain or nausea, administering symptom relief therapies prior to hygiene will better prepare the person for any procedure.

• CRITICAL REFLECTION POINT

Thanos is an 18-year-old man admitted to the intensive care unit following a head injury. He is currently unconscious, responsive only to painful stimulus. What assessment is critical for nurses to perform before providing oral hygiene?

Another important part of nursing interventions are assisting and preparing people so that they are able to administer their own hygiene. This includes educating people in proper hygiene techniques and connecting people with the community resources necessary to enable them to perform hygiene care. People at risk of hygiene problems are the ones in greatest need of understanding their risks, knowing the implications and then having the information they need to make choices about when and how hygiene is performed.

Health promotion

In primary healthcare settings, nurses educate and counsel people and families on proper hygiene techniques. A new mother will need help to learn how to bathe her newborn infant. An older adult will need to be informed about the importance of regular ear care to avoid any hearing deficits resulting from accumulated cerumen. The hygiene skills described throughout this chapter provide standards for excellent physical care. When helping people, nurses try to maintain these standards and incorporate adaptations as needed to the person's lifestyle, living arrangements and preferences. Tips to help nurses educate people about hygiene include the following.

- *Make instructions relevant.* After assessing a person's knowledge, motivation, health beliefs and ability/capacity for self-care, provide information that relates to the person's situation and which will be most useful in resolving the person's problem. For example, when offering foot care instruction to a person with diabetes mellitus, explain how the circulation to the feet can be impaired and when the skin becomes cut or broken this poses a risk for poor healing and infection.
- *Adapt instruction of any techniques to the person's personal bathing facilities.* Not all people will have the ideal situation that exists in a healthcare setting (e.g. easily accessible shower or a bedside table to place over a bed). Use what facilities or equipment the person has so that personal care items are easy to reach, the person's safety is ensured and the person feels comfortable in performing hygiene. For example, a young mother may feel that bathing an infant will be safer (with more room) if she uses her kitchen sink and counter rather than her bathroom sink.
- *Be sure to teach the person steps to take to avoid injury.* Almost any hygiene procedure can pose risks (e.g. cutting a nail too close to the skin, failing to adjust the water temperature of the bath or using tap-water for contact lens care). Any instruction must clearly outline safety risks.
- *Reinforce infection control practices.* Damage to the skin, mucosa, eyes or other tissues creates an immediate risk of infection. Be sure the person understands the relationship between healthy and intact skin and tissues and the prevention of infection.

Acute and restorative care

In healthcare settings where people receive direct nursing care, nurses provide a variety of hygiene measures. Box 29-5

BOX 29-5 Hygiene care schedule in acute care and extended care settings

Early morning care

Nursing personnel on the night shift provide basic hygiene to people getting ready for breakfast, scheduled tests or early-morning surgery. This includes offering a bed pan or urinal if the person is not mobile, washing the person's hands and face and helping with oral care.

Morning, or after-breakfast, care

In care performed after breakfast, nurses help by offering a bed pan or urinal to people confined to bed; providing a bath or shower; providing oral, foot, nail and hair care; giving a back rub, changing the person's gown or pyjamas; changing the bed linen; and straightening the person's bedside unit and room.

Afternoon care

Hospitalised people often undergo many exhausting diagnostic tests or procedures in the morning. In rehabilitation centres, people may participate in physical therapy during the morning. Afternoon hygiene care includes washing the hands and face, helping with oral care, offering a bed pan or urinal and straightening bed linen.

Evening, or hour-before-sleep, care

Before bedtime, nurses offer personal hygiene care that can help a person relax to promote sleep. This may include changing soiled bedclothes, gowns or pyjamas; helping the person wash the face and hands; providing oral hygiene; giving a back massage; and offering a bed pan or urinal to non-mobile people. Some people may enjoy a drink such as juice.

describes the different hygiene care schedules commonly found in acute care and extended-care settings. Times may change because of factors affecting nurses' organisation or scheduling of care, such as personal preferences, planned diagnostic and treatment procedures, the person's need for more hygiene, or nurses' work assignments. In extended-care facilities and nursing homes, the schedule for hygiene may be less frequent.

Bathing and skin care

Bathing and skin care are a part of total hygiene. The extent of a person's bath and the methods used for bathing depend on the person's physical abilities, health problems and the degree of hygiene required. If a person is physically dependent or cognitively impaired, more attention must be given by nurses in providing thorough, preventive skin care.

A **complete bed bath** is for people who are totally dependent and require total hygiene care (Skill 29-1). It can be exhausting for a person, even if nurses provide all of the care. Nurses must assess whether a person is physically able to tolerate a complete bath. Measuring heart rate before, during and after the bath provides a measure of the person's physical tolerance.

SKILL 29-1

Bathing a person

Delegation considerations

Bathing may be undertaken by nurse assistants under the guidance of the registered nurse.

- Inform caregiver about early signs of impaired skin integrity, and tell caregiver to have nurse reassess the skin when changes are noted.
- Warn against massaging reddened areas.
- Review type of bath, person's ability to participate and any safety precautions needed.

Equipment

- Two washcloths
- Two bath towels
- Bath blanket
- Soap and soap dish
- Toiletry items (deodorant, powder, lotion, cologne)
- Clean hospital gown or person's own pyjamas or gown
- Dirty linen bag
- Disposable gloves (when risk of contacting body fluids)

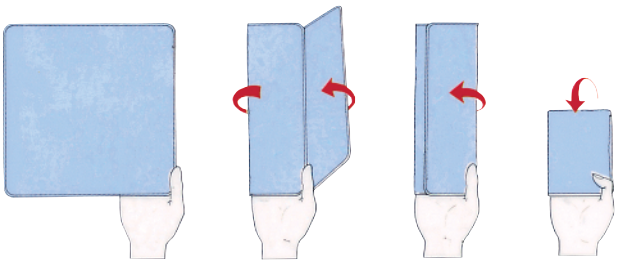
Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

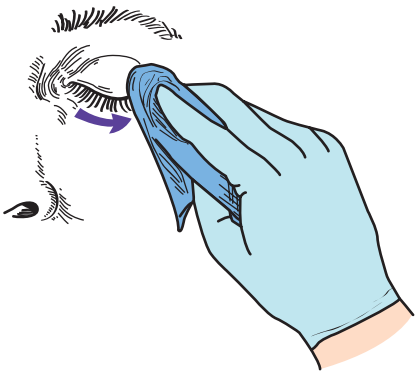
STEPS	RATIONALE
1. Assess person's tolerance for activity, discomfort level, cognitive ability and musculoskeletal function.	Determines person's ability to perform self-care and level of assistance required from nurse. Also determines type of bath to administer (e.g. tub bath or partial bed bath).
2. Review orders for specific precautions concerning person's movement or positioning.	Prevents accidental injury to person during bathing activities. Determines level of assistance required by person.
3. Explain procedure, and ask person for suggestions on how to prepare supplies. If partial bath, ask how much of bath person wishes to complete.	Promotes person's cooperation and participation.
4. Adjust room temperature and ventilation, close room doors and windows and draw room divider curtain.	A warm room that is free of drafts prevents rapid loss of body heat during bathing. Privacy ensures person's mental and physical comfort.

STEPS	RATIONALE
5. Prepare equipment and supplies.	Avoids interrupting procedure or leaving person unattended to retrieve missing equipment.
6. Bathe the person.	
A. Complete or partial bed bath	
(1) Offer the person bed pan or urinal. Provide towel and washcloth.	Person will feel more comfortable after voiding. Prevents interruption of bath.
(2) Wash your hands. If the person's skin is soiled with drainage or body secretions, wear disposable gloves. Ensure the person is not allergic to latex.	Reduces transmission of microorganisms.
(3) Lower side rail closest to you, and help the person into a comfortable position, maintaining body alignment. Bring the person towards the side closest to the nurse. Place hospital bed in high position.	Aids nurse's access to person. Maintains person's comfort throughout procedure. Nurse does not have to reach across bed, thus minimising strain on back muscles.
(4) Loosen top covers at foot of bed. Place bath blanket over top sheet. Fold and remove top sheet from under blanket. If possible, have the person hold the bath blanket while withdrawing the sheet. Optional: Use top sheet when bath blanket is not available.	Removal of top covers prevents them from becoming soiled or moist during bath. Blanket provides warmth and privacy.
(5) If the top sheet is to be reused, fold it for replacement later. If not, place in dirty linen bag, taking care not to allow linen to contact uniform.	Proper disposal prevents transmission of microorganisms.
(6) Remove the person's gown or pyjamas. If an extremity is injured or has reduced mobility, begin removal from unaffected side. If the person has intravenous (IV) tube, remove gown from arm without IV first; then lower IV container or remove from pump and slide gown covering affected arm over tubing and container. Rehang IV container and check flow rate or reset pump rate. Do not disconnect tubing.	Provides full exposure of body parts during bathing. Undressing unaffected side first allows easier manipulation of gown over body part with reduced range of motion (ROM).
(7) Pull side rail up. Fill washbasin two-thirds full with warm water. Have the person place their fingers in the water to test temperature tolerance. Place plastic container of bath lotion in bathwater to warm, if desired.	Raising side rail maintains person's safety as nurse leaves bedside. Warm water promotes comfort, relaxes muscles and prevents unnecessary chilling. Testing temperature prevents accidental burns. Bathwater warms lotion for application to person's skin.

STEPS	RATIONALE
(8) Remove pillow if allowed, and raise head of bed 30–45 degrees. Place bath towel under the person's head. Place second bath towel over the person's chest.	Removal of pillow makes it easier to wash person's ears and neck. Placement of towels prevents soiling of bed linen and bath blanket.
(9) Fold washcloth around fingers of nurse's hand to form mitt (see illustration). Immerse mitt in water and wring thoroughly.	Mitt retains water and heat better than loosely held washcloth; keeps cold edges from brushing against person and prevents splashing.
(10) Wash the person's eyes with plain warm water. Ask whether the person is wearing contact lenses. If so, perform eye care as described in Skill 29-8. Use different section of mitt for each eye. Move mitt from inner to outer canthus (see illustration). Soak any crusts on eyelid for 2–3 minutes with a damp cloth before attempting removal. Dry eye thoroughly but gently.	Soap irritates eyes. Use of separate sections of mitt reduces infection transmission. Bathing eye from inner to outer canthus prevents secretions from entering nasolacrimal duct. Pressure can cause internal injury.



Step 6A(9) Steps for folding washcloth to form a mitt.



Step 6A(10) Wash eye from inner to outer canthus.

Step 6A(13) Washing arms.

(11) Ask whether the person prefers to use soap on face. Wash, rinse and dry well forehead, cheeks, nose, neck and ears. (Men may wish to shave at this point or after bath.)	Soap tends to dry face, which is exposed to air more than other body parts.

STEPS	RATIONALE
(12) Remove bath blanket from the person's arm that is closest to nurse. Place bath towel lengthwise under their arm.	Prevents soiling of bed.
(13) Wash arm with soap and water using long, firm strokes from distal to proximal areas (fingers to axilla; see illustration). Raise and support arm as needed while thoroughly washing axilla.	Soap lowers surface tension and facilitates removal of debris and bacteria when friction is applied during washing. Long, firm strokes stimulate circulation. Movement of arm exposes axilla and exercises joint's normal ROM.
(14) Rinse and dry arm and axilla thoroughly. If person uses deodorant or talcum powder, apply it.	Alkaline residue from soap discourages growth of normal skin bacteria. Excess moisture causes skin maceration or softening. Deodorant controls body odour.
(15) Fold bath towel in half, and lay it on bed beside the person. Place basin on towel. Immerse the person's hand in water. Allow hand to soak for 3–5 minutes before washing hand and fingernails (see Skill 29-5). Remove basin and dry hand well.	Soaking softens cuticles and calluses of hand, loosens debris beneath nails and enhances feeling of cleanliness. Thorough drying removes moisture from between fingers.
(16) Raise side rail, and move to other side of bed. Lower side rail, and repeat Steps 12–15 for other arm.	
(17) Check temperature of bathwater, and change water if necessary.	Warm water maintains person's comfort. Clean water reduces microorganism transmission.
(18) Cover the person's chest with bath towel, and fold bath blanket down to umbilicus. With one hand, lift edge of towel away from chest. With mitted hand, bathe chest using long, firm strokes. Take special care to wash skinfolds under a female's breasts. It may be necessary to lift breast upwards while washing underneath it. Keep person's chest covered between wash and rinse periods. Dry well.	Draping prevents unnecessary exposure of body parts. Towel maintains warmth and privacy. Secretions and dirt collect easily in areas of tight skinfolds. Skinfolds are susceptible to excoriation if breasts are pendulous.
(19) Place bath towel lengthwise over chest and abdomen. (Two towels may be needed.) Fold blanket down to just above pubic region.	Prevents chilling and exposure of body parts.
(20) With one hand, lift bath towel. With mitted hand, bathe abdomen, giving special attention to umbilicus and abdominal folds. Stroke from side to side. Keep abdomen covered between washing and rinsing. Dry well.	Moisture and sediment that collect in skinfolds predispose skin to maceration and irritation.
(21) Dress the person in a clean gown or pyjama top. If one extremity is injured or immobilised, always dress affected side first. This step may be omitted until completion of bath; gown should not become soiled during remainder of bath.	Maintains person's warmth and comfort. Dressing affected side first allows easier manipulation of gown over body part with reduced ROM.

STEPS	RATIONALE
(22) Cover chest and abdomen with top of bath blanket. Expose near leg by folding blanket towards midline. Be sure perineum is draped.	Prevents unnecessary exposure.
(23) Bend the person's knee by positioning nurse's arm under leg. While grasping the person's heel, elevate leg from mattress slightly and slide bath towel lengthwise under leg. Ask the person to hold foot still. Place bath basin on towel on bed and secure its position next to foot to be washed.	Towel prevents soiling of bedclothes. Support of joint and extremity during lifting prevents strain on musculoskeletal structures. Sudden movement by person could spill bathwater. (Omit this step if person is unable to hold leg in basin.)
(24) With one hand supporting the lower leg, raise it and slide the basin under lifted foot. Make sure the foot is firmly placed on bottom of basin. Allow the foot to soak while washing leg. If the person is unable to hold leg, do not immerse it; simply wash with washcloth (see illustration).	Proper positioning of foot prevents pressure being applied from edge of basin against calf. Soaking softens calluses and rough skin.
(25) Unless contraindicated, use long, firm strokes in washing from the ankle to knee and from knee to thigh. Dry well.	Promotes venous return.

■ **Critical decision point: People with history of deep-vein thromboses or hypercoagulation disorders should not have their lower extremities washed with long, firm strokes.**

(26) Clean foot, making sure to wash between toes. Clean and clip nails as needed (see Skill 29-5). Dry well. If skin is dry, apply lotion. Do not massage any reddened area on person's skin.	Secretions and moisture may be present between toes. Lotion helps retain moisture and soften skin.

Step 6A(24) Washing leg of person unable to hold foot in basin.

Step 6A(31) Washing back.

(27) Raise side rail, and move to other side of the bed. Lower side rail, and repeat Steps 22–26 for other leg and foot.	
(28) Cover the person with a bath blanket, raise the side rail for the person's safety and change bathwater.	Decreased bathwater temperature can cause chilling. Clean water reduces microorganism transmission.

STEPS	RATIONALE
(29) Lower side rail. Help person into a prone or side-lying position (as applicable). Place towel lengthwise along the person's side.	Exposes back and buttocks for bathing.
(30) Put on disposable gloves if not done previously.	Prevents contact with microorganisms in body secretions.
(31) Keep the person draped by sliding bath blanket over shoulders and thighs. Wash, rinse and dry back from neck to buttocks using long, firm strokes (see illustration). Clean buttocks and anus (see Skill 29-2). Give a back rub (see Skill 29-4). Change bathwater.	Maintains warmth, and prevents unnecessary exposure. Skinfolds near buttocks and anus may contain faecal secretions that harbour microorganisms. Changing water prevents transfer of microorganisms from anal area to genitalia.
(32) Help the person into a side-lying or supine position. Cover the chest and upper extremities with towel and lower extremities with bath blanket. Expose only genitalia. (If the person can wash, covering entire body with bath blanket may be preferable.) Wash, rinse and dry perineum (see Skill 29-2). Pay special attention to skinfolds. Apply water-repellent ointment to area exposed to moisture.	Maintains person's privacy. People capable of performing partial bath usually prefer to wash their own genitalia. Water-repellent ointments protect skin from moisture.
(33) Dispose of gloves in receptacle.	Prevents transmission of infection.
(34) Apply additional body lotion or oil as desired.	Moisturising lotion prevents dry, chapped skin.
(35) Help the person to dress. Comb person's hair. Women may want to apply make-up.	Promotes person's body image.
(36) Make the person's bed (see Skill 29-9).	Provides clean environment.
(37) Remove soiled linen, and place in dirty linen bag. Clean and replace bathing equipment. Replace call light and personal possessions. Leave room as clean and comfortable as possible.	Prevents transmission of infection. Clean environment promotes person's comfort. Keeping call light and articles of care within reach promotes person's safety.
(38) Wash hands.	Reduces transmission of microorganisms.
B. Bath or whirlpool bath or shower	
(1) Consider the person's condition, and review orders for precautions concerning the person's movement or positioning.	Prevents accidental injury to person during bathing.
(2) Check bath or shower for cleanliness. Use cleaning techniques outlined in agency policy. Place rubber mat on bath or shower bottom. Place disposable bath mat or towel on floor in front of bath or shower.	Cleaning prevents transmission of microorganisms. Mats prevent slipping and falling.

STEPS	RATIONALE
(3) Collect all hygiene aids, toiletry items and linen requested by person. Place within easy reach of the bath or shower.	Placing items close at hand prevents possible falls when person reaches for equipment.
(4) Help the person to the bathroom if necessary. Have the person wear dressing gown and slippers to bathroom.	Assistance prevents accidental falls. Wearing dressing gown and slippers prevents chilling.
(5) Demonstrate how to use call signal for assistance.	Bathrooms are equipped with signalling devices in case person feels faint or weak or needs immediate assistance. People prefer privacy during bath if safety is not jeopardised.
(6) Place 'occupied' sign on bathroom door.	Maintains person's privacy.
(7) Provide shower seat or bath chair if needed (see illustration). Fill bath halfway with warm water. If the person's sensations are normal, ask them to test the water and adjust the temperature if the water is too warm. Explain which tap controls hot water. If the person is taking a shower, turn the shower on and adjust the water temperature before they enter the shower unit.	Adjusting water temperature prevents accidental burns. Older adults and people with neurological alterations (e.g. spinal cord injury) are at high risk of burns as a result of reduced sensation. Use of aids facilitates bathing and minimises physical exertion.

Step 6B(7) Shower seat for personal safety.

(8) Instruct person to use safety bars when getting into and out of bath or shower. Caution person against use of bath oil in bathwater.	Prevents slipping and falling. Oil causes bath surfaces to become slippery.
(9) Instruct the person not to remain in bath longer than 20 minutes. Check on them every 5 minutes.	Prolonged exposure to warm water may cause vasodilation and pooling of blood, leading to lightheadedness or dizziness.
(10) Return to the bathroom when the person signals, and knock before entering.	Provides privacy.

STEPS	RATIONALE
(11) For an unsteady person, drain bath of water before person attempts to get out of it. Place bath towel over the person's shoulders. Help the person get out of bath as needed, and help them with drying. If the person is weak or unstable, have a nurse assistant help.	Prevents accidental falls. Person may become chilled as water drains.
(12) Help the person as needed to don clean gown or pyjamas, slippers and dressing gown. (In a home setting, the person may wear ordinary clothing.)	Maintains warmth to prevent chilling.
(13) Help the person to their room and into a comfortable position in bed or on a chair.	Maintains relaxation gained from bathing.
(14) Clean the bath or shower according to agency policy. Whirlpool baths may require special cleaning. Remove soiled linen and place in a dirty linen bag. Discard disposable equipment in the proper receptacle. Place 'unoccupied' sign on bathroom door. Return supplies to storage area.	Prevents transmission of infection through soiled linen and moisture.
(15) Wash hands.	Reduces transfer of microorganisms.
7. Observe skin, paying particular attention to areas that were previously soiled, reddened or showed early signs of breakdown.	Techniques used during bathing should leave skin clean and clear.
8. Observe ROM during bath.	Measures joint mobility.
9. Ask person to rate level of comfort.	

RECORDING AND REPORTING

- Record bath on flow sheet. Note level of assistance required.
- Record condition of skin and any significant findings (e.g. reddened areas, bruises, naevi or joint or muscle pain).
- Report evidence of alterations in skin integrity to nurse in charge or doctor.

HOME CARE CONSIDERATIONS

- Assess person's bath and shower area – are grab bars, shower chair or handheld shower needed?

A **partial bed bath** involves bathing only body parts that would cause discomfort or odour if left unbathed. An ageing or dependent person in need of only partial hygiene or a self-sufficient bedridden person unable to reach all body parts receive partial bed baths. Carefully assess to determine whether the person can sufficiently bathe other body parts on their own, so as to promote independence.

When administering either a complete or a partial bath, it is important for nurses to assess the condition of the skin in determining whether soap is necessary or whether the person requires daily bathing. People with excessively dry skin are predisposed to skin impairment. Nurses may decide to skip a bath for a day or bathe only badly soiled areas. Using soaps that contain emollients or using bath gels rather than soap are other

options. Lubricating the skin with lotion can also help reduce dryness.

The *bath or shower* gives a more thorough bath than a bed bath. Safety is the main concern because the surface of a bath or shower unit is slippery. In some agencies, showers are equipped with a chair for people with weakness or poor balance. Most extended-care facilities have showers that permit the person to be brought into the shower on a specialised wheeled chair. Both baths and showers should be equipped with grab-bars for people to hold on to during entry, exit and manoeuvring. People vary in how much help they will need.

Regardless of the type of bath the person receives, nurses should use the following guidelines.

- *Provide privacy.* Close the door, or pull room curtains around the bathing area. While bathing the person, expose only the areas being bathed.
- *Maintain dignity.* Keep the approach to the person professional and dignified.
- *Maintain safety.* Keep side rails up while away from the person's bedside. (This is critical for dependent and unconscious people.) Place the call light within the person's reach if leaving the room temporarily.
- *Maintain warmth.* The room should be kept warm because the person is partially uncovered and may easily be chilled. Wet skin causes an excess loss of heat through convection. Control drafts and keep windows closed. Keep the person covered, exposing only the body part being washed.
- *Promote independence.* Encourage the person to participate in as many of the bathing activities as possible. Offer assistance when needed.
- *Anticipate needs.* Help the person to use the toilet before bathing. Bring a new set of clothing and hygiene products to the bedside or bathroom.

BAG BATHS An innovative approach to the traditional bed bath was developed because of concern for people who are predisposed to dry skin and the risk of infection. The advantages of the 'bag bath' include less cross-contamination from one body part to another, less growth of organisms in the bath or basin and reduced residue on the skin from soap, resulting in fewer skin reactions and improved skin integrity. It has also been shown to improve person satisfaction and reduce staff time and costs (Lentz 2003). The 'bag bath' is a specially prepared package containing 10 washcloths that are premoistened in a mixture of water and a non-rinseable cleanser. A bag is warmed in a microwave before use, and then a different cloth is used for each part of the person's body. In this technique the skin is allowed to air-dry, since towel-drying removes the emollient that is left behind after the water/cleanser solution evaporates.

PERINEAL CARE is usually part of the complete bed bath (Skill 29-2). People most in need of **perineal care** are those at greatest risk of acquiring an infection (e.g. uncircumcised males, people who have indwelling urinary catheters, people who are recovering from rectal or genital surgery or childbirth and people who are incontinent of either urine or faeces). In addition, women who are having a menstrual period will require

SKILL 29-2

Perineal care

Delegation considerations

Perineal care can be undertaken by nurse assistants under the guidance of the registered nurse.

- Instruct caregiver in proper way to position male and female people.
- Inform caregiver about proper positioning of indwelling catheter during perineal care.
- Instruct caregiver to inform nurse if any perineal drainage, excoriation or rash is observed.

Equipment

- Washbasin
- Soap dish with soap
- Two or three washcloths
- Bath towel
- Bath blanket
- Waterproof pad or bed pan
- Toilet paper or nappy wipes
- Disposable gloves

Additional supplies are needed when perineal care is given other than during a bath:

- Cotton balls or swabs
- A solution bottle or container filled with warm water or prescribed rinsing solution
- Waterproof bag

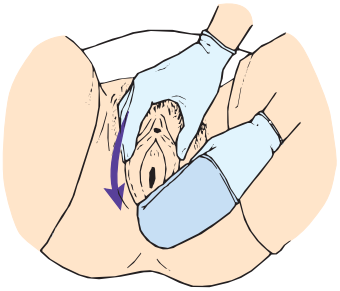
Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Identify people at risk of developing infection of genitalia, urinary tract or reproductive tract (e.g. uncircumcised male, presence of indwelling catheter, faecal incontinence).	Secretions that accumulate on surface of skin surrounding genitalia act as reservoirs for infection. Tissues traumatised by surgery or by presence of foreign object provide route for introduction of infectious organisms.
2. Assess the person's cognitive and musculoskeletal function.	Determines person's ability to perform self-care and determines level of assistance required from nurse.
3. Assess genitalia for signs of inflammation, skin breakdown or infection (see Chapter 29).	Determines extent of perineal care required by person.
4. Assess the person's knowledge of importance of perineal hygiene.	People at risk of infection in perineal area may be unaware of importance of cleanliness. Reflects person's need for education.
5. Explain procedure and its purpose to the person.	Helps minimise anxiety during procedure that is often embarrassing to nurse and person.
6. Prepare necessary equipment and supplies.	As used when administering a bed bath.
7. Pull curtain around the person's bed, or close room door. Assemble supplies at bedside.	Maintains person's privacy and ensures orderly procedure.
8. Raise bed to comfortable working position. Lower side rail, and help the person into a side-lying position, placing towel lengthwise along the person's side and keeping them covered with a bath blanket or top sheet.	Facilitates good body mechanics. Provides easy access to genitalia.
9. Put on disposable gloves.	Eliminates transmission of microorganisms.
10. If faecal material is present, enclose in a fold of underpad or toilet paper, and remove with disposable wipes or toilet paper. Clean buttocks and anus, washing front to back (see illustration). Clean, rinse and dry area thoroughly. If needed, place an absorbent pad under the person's buttocks. Remove and discard underpad and replace with clean one.	Cleaning reduces transmission of microorganisms from anus to urethra or genitalia.  Step 10 Cleanse buttocks (and anus) from front to back.
11. If the person has had urinary or bowel incontinence, apply thin layer of skin barrier containing petrolatum or zinc oxide over anal and perineal skin.	Protects skin from maceration and irritants in urine or stool.
12. Change gloves when they are soiled.	
13. Prepare to undertake perineal care.	

STEPS	RATIONALE
a. Raise side rail. Fill washbasin with warm water.	Prevents person from falling. Proper water temperature prevents burns to perineum.
b. Place washbasin and toilet paper on overbed table. Place washcloths in basin.	Equipment placed within nurse's reach prevents accidental spills.
14. Provide perineal care.	
A. Female perineal care	
(1) Help the person to dorsal recumbent position.	Provides easy access to genitalia.
(2) Lower the side rail, and help the person flex knees and spread legs. Work within restrictions or limitations in the person's ability to assume this position.	Provides full exposure of female genitalia. Minimise degree of abduction in female if position causes pain because of arthritis or reduced joint mobility.
(3) Fold top sheet down towards foot of bed, and raise the person's gown above genital area.	Exposes perineal area for easy accessibility.
(4) 'Diamond' drape the person by placing the bath blanket with one corner between the person's legs, one corner pointing towards each side of bed, and one corner over the person's chest (see illustration). Tuck side corners around the person's legs and under the hips.	Prevents unnecessary exposure of body parts and maintains person's warmth and comfort during procedure.  Step 14A(4) Draping person for perineal care.
(5) Fold lower corner of bath blanket up between the person's legs onto abdomen. Wash and dry the person's upper thighs.	Minimises transmission of microorganisms. Keeping person draped until procedure begins minimises anxiety. Build-up of perineal secretions can soil surrounding skin surfaces.
(6) Wash labia majora. Use non-dominant hand to gently retract labia from thigh; with dominant hand, wash carefully in skinfolds. Wipe in direction from perineum to rectum (front to back). Repeat on opposite side using separate section of washcloth. Rinse and dry area thoroughly.	Skinfolds may contain body secretions that harbour microorganisms. Wiping from perineum to rectum (front to back) reduces chance of transmitting faecal organisms to urinary meatus.

STEPS	RATIONALE
(7) Separate labia with non-dominant hand to expose urethral meatus and vaginal orifice. With dominant hand, wash downwards from pubic area towards rectum in one smooth stroke (see illustration). Use separate section of cloth for each stroke. Clean thoroughly around labia minora, clitoris and vaginal orifice.	Cleaning method reduces transfer of microorganisms to urinary meatus. (For menstruating women or people with indwelling urinary catheters, clean with cotton balls.)
(8) If the person uses bed pan, pour warm water over perineal area. Dry perineal area thoroughly, using front-to-back method.	Rinsing removes soap and microorganisms more effectively than wiping. Retained moisture harbours microorganisms.
(9) Fold lower corner of bath blanket back between the person's legs and over perineum. Ask the person to lower legs and assume comfortable position.	



Step 14A(7) Cleanse from perineum to rectum.

B. Male perineal care

(1) Lower side rails, and help person into supine position. Note restriction in mobility.	Provides full exposure of male genitalia.
(2) Fold top sheet down towards foot of bed, and raise the person's gown above genital area. Drape the person with bath blanket.	Exposes perineal area for easy accessibility. Draping promotes comfort and minimises a person's anxiety.
(3) Fold top half of bath blanket down below the penis. Wash and dry the person's upper thighs.	Minimises transmission of microorganisms. Keeping person draped until procedure begins minimises anxiety. Build-up of perineal secretions can soil surrounding skin surfaces.
(4) Gently raise penis, and place bath towel underneath. Gently grasp the shaft of penis. If the person is uncircumcised, retract foreskin (see illustration). If the person has an erection, defer procedure until later.	Towel prevents moisture from collecting in inguinal area. Gentle but firm handling reduces chance of person having an erection. Secretions capable of harbouring microorganisms collect underneath foreskin.
(5) Wash the tip of the penis at urethral meatus first. Using a circular motion, clean from meatus outwards (see illustration). Discard washcloth, and repeat with clean cloth until the penis is clean. Rinse and dry gently.	Direction of cleaning moves from area of least contamination to area of most contamination, preventing microorganisms from entering urethra.

STEPS	RATIONALE
 Step 14B(4) Retract foreskin.	 Step 14B(5) Use circular motion to cleanse tip of penis.
(6) Return foreskin to its natural position.	Tightening of foreskin around shaft of penis can cause local oedema and discomfort.
(7) Wash shaft of penis with gentle but firm downward strokes. Pay special attention to underlying surface of penis. Rinse and dry penis thoroughly. Instruct the person to spread legs apart slightly.	Vigorous massage of penis can lead to erection, which can embarrass person and nurse. Underlying surface of penis may have greater accumulation of secretions. Abduction of legs provides easier access to scrotal tissues.
(8) Gently clean scrotum. Lift it carefully, and wash underlying skinfolds. Rinse and dry.	Pressure on scrotal tissues can be painful to person. Secretions collect between skinfolds.
(9) Fold bath blanket back over person's perineum, and help the person into side-lying position.	Draping promotes comfort and minimises a person's anxiety. Side-lying position provides access to anal area.
15. Remove disposable gloves, and dispose of in proper receptacle.	Moisture and body secretions on gloves can harbour microorganisms.
16. Help the person into a comfortable position, and cover with sheet.	Person's comfort helps to minimise stress of procedure.
17. Remove bath blanket, and dispose of all soiled bedclothes. Return unused equipment to storage area.	Reduces transmission of microorganisms.
18. Inspect surface of external genitalia and surrounding skin after cleaning.	Thick secretions may cover underlying skin lesions or areas of breakdown. Evaluation determines need for additional hygiene.
19. Ask whether the person feels clean.	Evaluates person's comfort level.
20. Observe for abnormal drainage or discharge from genitalia.	Evaluates presence of infection.

RECORDING AND REPORTING

- Record procedure and presence of any abnormal findings (e.g. character and amount of discharge or condition of genitalia).
- Record appearance of suture line, if present.
- Report any break in suture line or presence of abnormalities to nurse in charge or doctor.

HOME CARE CONSIDERATIONS

- For people who require bathing, assess perineum at every visit because of the risk of infection and skin breakdown. When appropriate, teach caregiver how to make this assessment, and instruct caregiver to do this assessment daily.

BOX 29-6 Menstrual care

Choice of sanitary products depends on the comfort needs of the woman and her menstrual flow. Manufacturers have introduced a wide variety of products. Essentially three types are available: external, internal and re-useable.

- *External:* Commonly known as pads or panty liners; obtainable worldwide. Usually the pad has a cotton-fibre cover with an absorbent inner layer. Pads are available in a range of absorbent capacities (light to heavy blood flow). Most of these pads have an adhesive strip, which attaches to the underwear gusset.
- *Internal:* Tampons are available in a range of absorbencies and permit absorption of menstrual flow within the vaginal canal. The tampon is cylindrical in shape and made of compacted absorbent cotton, approximately 5–8 cm in length and 12–15 mm in diameter. A string-like cord attached to one end enables location and removal of the tampon from the vagina following use. Tampons can be inserted into the vagina with the finger or by using a brand of tampon which provides a cardboard tube applicator to guide appropriate insertion into the vagina.
- *Re-useable:* Washable external pads are an environmentally friendly option for women. Another option is the menstrual cup, which fits around the cervix to collect the blood loss. These cups are available in either silicon or latex and are also washable and re-useable (see www.mooncup.co.uk).

Developed by Laura Robertson and Catherine Ward.

good perineal care (see Box 29-6). Menstrual hygiene can be attended to during perineal care (Skill 29-3). A person able to perform self-care should do so. Nurses can become embarrassed about providing perineal care, particularly to people of the opposite sex. Similarly, the person usually feels embarrassed. This should not result in the person's hygiene needs being overlooked. It may help to have present in the room a nurse of the same sex as the person when providing perineal care. A professional, dignified and sensitive approach can reduce embarrassment and put the person at ease.

If a person performs self-care, various problems such as vaginal and urethral discharge, skin irritation and unpleasant odours may go unnoticed. Ask about or be alert for complaints of burning during urination or localised soreness, excoriation, or pain in the perineum. Also inspect the person's bedclothes for signs of discharge. People most at risk of skin breakdown in the perineal area are those with urinary or faecal incontinence, rectal and perineal surgical dressings, indwelling urinary catheters and the morbidly obese.

SKILL 29-3

Menstrual hygiene

Delegation considerations

The client may wish to perform self-care with partial assistance.

Menstrual hygiene can be undertaken by nurse assistants under the guidance of the registered nurse.

- Registered nurse (RN) should discuss with client preferred products.
- Inform caregiver to report any heavy discharge.

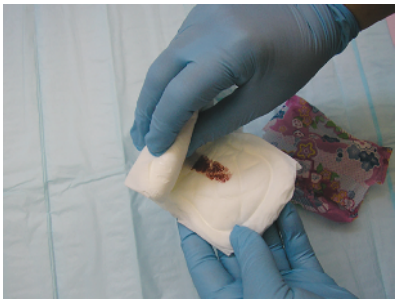
Equipment

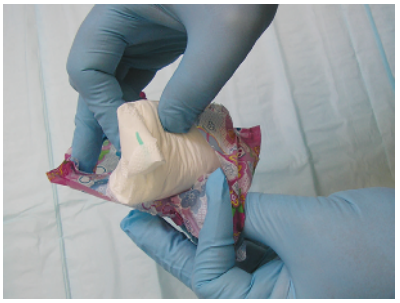
- Disposable gloves
- Sanitary pads or tampons
- Rubbish bag
- Toilet paper
- Washcloth(s) (consider use of disposable washcloth)
- Towel
- Change of underwear
- Waterproof pad
- Wash bowl
- Warm water

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Close curtains or door to room.	Ensures client privacy.
2. Assemble supplies at the bedside. Fold down the top of the rubbish bag to form a cuff.	Ensures orderly procedure and facilitates disposal of contaminated material.
3. Assess client's cognitive and musculoskeletal function.	Determines client's ability to perform self-care and determines level of assistance required from nurse. Pain relief may be required for positioning.
4. Explain procedure and its purpose to client.	Minimises anxiety and embarrassment about need for assistance.
5. Ask client about her normal pattern of menstrual care and whether she would prefer to change sanitary ware herself.	Involves client in own care, gives sense of control over preferences.
6. Position bed to a comfortable working height.	Facilitates good body mechanics, provides good access to the perineal area.
7. Wash hands. Apply disposable gloves.	Reduces transmission of infectious organisms. Gloves prevent contact with microorganisms contained in blood and body fluids.
8. Use of sanitary pads a. Lower or remove underwear. b. Remove used sanitary pad. Assess per vagina (PV) loss and dispose of pad in rubbish bag (see illustrations).	Based on area of pad saturated, time taken to soak pad.

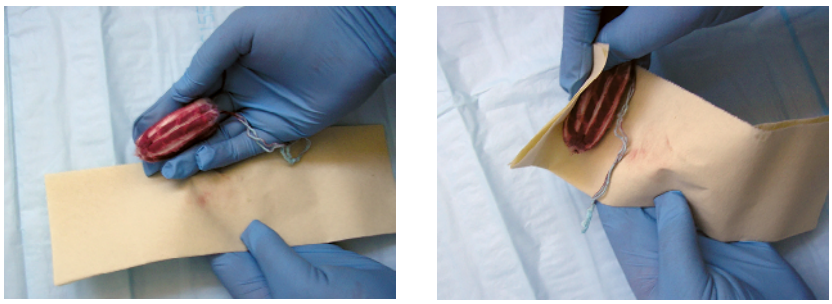




Step 8b Sanitary pad disposal.

c. Assess perineal area for extra perineal care/ washing required.	Determines extent of care required by client.
d. If washing is required, place a waterproof pad under the client, wash perineum with a washcloth and dry with a towel (see Skill 29-2).	
e. Apply clean pad to underwear using self-adhesive strips.	
f. Replace underwear.	

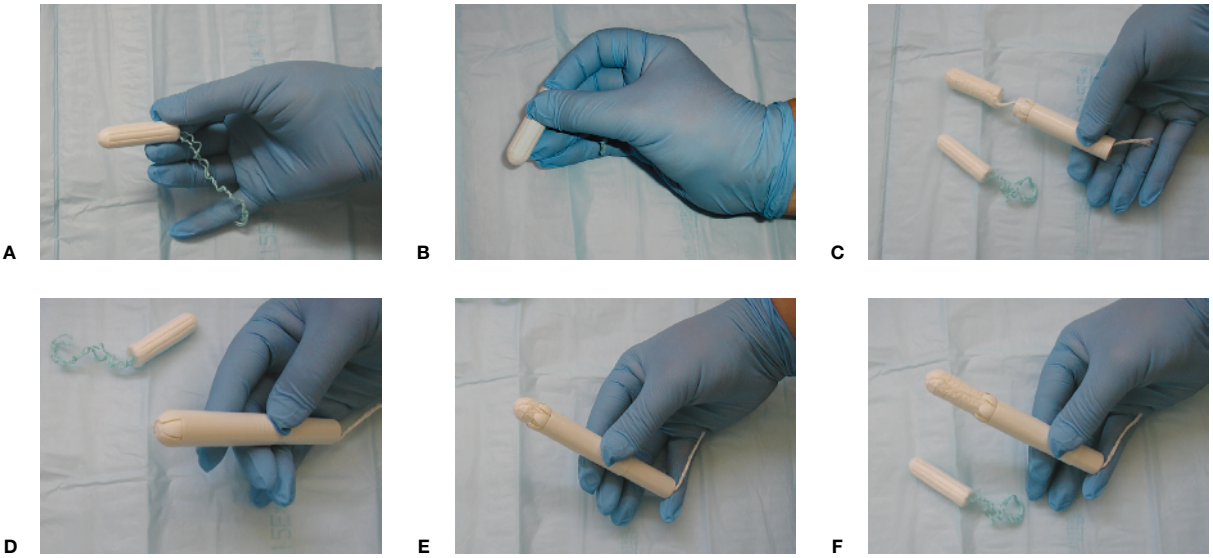
STEPS	RATIONALE
g. Remove gloves and dispose in rubbish bag. Wash hands.	Reduces transmission of infectious organisms.
h. Help client return to a comfortable position.	Promotes comfort and reduces embarrassment.
9. Use of tampons	
a. Lower or remove underwear.	Provides access to perineum.
b. With client lying on her side, part labia with non-dominant hand to view the outlet of the vagina.	
c. Remove used tampon by grasping the cord with fingers of dominant hand. Draw the cord outwards and downwards (towards client's feet) until the tampon emerges.	
d. Assess PV loss. Wrap tampon in toilet paper and dispose of in rubbish bag (see illustrations).	Based on saturation of tampon, time taken to soak tampon.



Step 9d Tampon disposal.

e. Hold the tampon by cord end, with cord across palm of hand and index finger guiding the cord-end dimple of tampon. Illustrations 9fA and 9fB show non-applicator tampons and illustration 9fC compares non-applicator tampon with applicator tampon. Once applicator tampon is inserted into the vagina, gentle finger pressure on sliding cylinder causes tampon to be released into the distal part of the vagina. Cardboard cylinder is then removed and discarded (see illustrations 9fD–F).	

STEPS	RATIONALE



Steps 9e A,B, Non-applicator tampon. C, Comparison of non-applicator tampon to applicator tampon. D–F, Operation of applicator to release tampon.

f. Insert the tampon in the vagina, angling upwards and backwards, following the vaginal canal.	
g. Insert to the length of the index finger or applicator tube.	
h. Cord will emerge externally as a guide to placement and to facilitate removal.	
i. Replace underwear.	
j. Remove gloves and dispose of in rubbish bag. Wash hands.	Reduces transmission of infectious organisms.
k. Help client return to a comfortable position.	Promotes comfort and reduces embarrassment.
10. If client has participated in care, offer her a bowl and washcloth for her own handwashing.	Promotes hygiene and comfort, reduces microorganism transmission from body fluids to linens and furniture.
11. Ask if client feels sense of cleanliness.	Evaluates client's comfort levels.
12. Ask about and observe for any signs of pain, dysfunction or infection in perineal area.	

RECORDING AND REPORTING

- Record PV loss in fluid charts if heavy; estimate volume.
- Adjust the nursing care plan regularly to accommodate the changing need for menstrual care.

SAFETY CONSIDERATIONS

- At night, care should include a pad of extra absorbency to facilitate an undisturbed sleep for the client. Super-absorbent tampons should be avoided due to the link with toxic shock syndrome.

BACK RUB A back rub or back massage usually follows the person's bath (Skill 29-4). It promotes relaxation, relieves muscular tension and stimulates skin circulation. Harris and Richards (2010) evaluated research-based massage studies; slow-stroke back massage had positive effects on the physiological measures of relaxation, with people generally reporting that they were more comfortable following a back rub regardless of the length of the massage. Walton (2009) showed that the long, slow, gliding strokes (**effleurage**) of a massage are associated with a reduction in blood pressure, heart rate, respiratory rate and reported pain level.

When providing a back rub, nurses can enhance relaxation by reducing any noise and ensuring the person is comfortable. It is important to ask whether a person would like a back rub, or if the person prefers gentle instead of heavy massage, because some individuals dislike physical contact. Nurses should consult the medical record for any contraindications to a massage (e.g. fractured ribs, burns of the skin and heart surgery).

SKILL 29-4

Administering a back rub

Delegation considerations

Administering a back rub can be delegated to nurse assistants under the guidance of the registered nurse.

- Registered nurse (RN) should assess for any possible contraindication to back rub.
- Inform caregiver to report any change in vital signs or behaviour during back rub.

Equipment

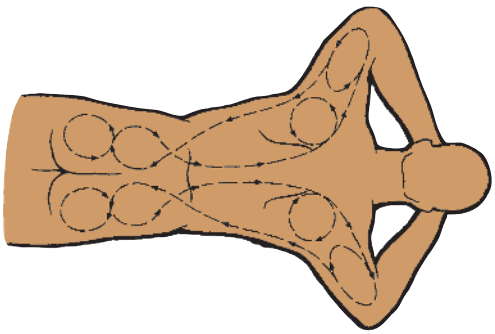
- Moisturising lotion or lubricant
- Sphygmomanometer and stethoscope
- Bath towel
- Bath blanket

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Identify factors or conditions such as rib or vertebral fractures, burns, reddened areas on the skin or open wounds and status post-coronary artery (CA) bypass that contraindicate back rub.	Massage of sensitive tissues might lead to further tissue injury. Massaging reddened areas of skin increases breaks in capillaries in underlying tissues. An increase in heart rate and systolic and diastolic blood pressure occurs in post-CA bypass people.
2. Explain procedure and desired position to person. Determine whether the person is comfortable with heavy massage stroke.	Helps promote relaxation.
3. Adjust bed to high, comfortable position.	Ensures proper body mechanics and prevents strain on back muscles.
4. Adjust light, temperature and sound within room.	Environmental distractions can prevent person from relaxing.
5. Lower side rail and help the person into a prone or side-lying (Sims') position with back towards you. Close curtain around the bed.	Position makes it easier to apply necessary pressure to back muscles. Privacy promotes relaxation.

STEPS	RATIONALE
6. Assess the person's heart rate (HR), respiratory rate (RR) and blood pressure (BP).	Decreased HR, RR and BP are usual following even a 3-minute back rub. Assessment establishes baseline.
7. Expose person's back, shoulders, upper arms and buttocks. Cover remainder of body with bath blanket. Lay towel alongside person's back.	Prevents unnecessary exposure of body parts and prevents excess lotion from touching bedclothes.
8. Wash hands in warm water. Warm lotion in hands or by placing container under warm water. Place small amount of lotion in hands.	Cold causes muscle tension.
9. Explain to person that lotion will feel cool and wet.	Warning person reduces startled response.
10. Apply hands first to sacral area, massaging in circular motion. Stroke upwards from buttocks to shoulders. Massage over scapulae with smooth, firm stroke. Continue in one smooth stroke to upper arms and laterally along sides of back down to iliac crests (see illustration). Do not allow your hands to leave person's skin. Continue massage pattern for at least 3 minutes.	Gentle, firm pressure applied to all muscle groups promotes relaxation. Continuous contact with skin's surface is soothing and stimulates circulation to tissues.



Step 10 Massage pattern; use smooth, firm strokes.

Step 11 Massaging skin.

STEPS	RATIONALE
11. Knead skin by gently grasping tissue between your thumb and fingers. Knead upwards along one side of spine from buttocks to shoulders and around nape of neck. Knead or stroke downwards towards sacrum. Repeat along other side of back.	Kneading increases circulation. Motion is soothing and relieving.
12. End massage with long stroking movements for an additional 3 minutes, and tell the person you are ending the massage.	Long stroking is most soothing.
13. If lying on their side, ask the person to turn to opposite side, and massage other hip.	
14. Wipe excess lubricant from person's back with bath towel. Re-tie gown or help with pyjamas. Help the person to comfortable position. Raise side rails as needed, and open curtain. Lower bed.	Excess lotion can be an irritant. Comfortable position enhances back rub's effects.
15. Dispose of soiled towel and wash hands.	Promotes infection control.
16. Ask person about comfort. Note any areas of muscle pain or tension.	Degree of relief gained depends on length of massage, person's ability to relax and degree of discomfort before massage.
17. Reassess pulse and BP.	Gentle back massage may increase HR and systolic BP.

RECORDING AND REPORTING

- Record response to massage and condition of skin.

HOME CARE CONSIDERATIONS

- Massage is an easy technique to teach a family member to promote person's relaxation at any time of the day.

BATHING AN INFANT An infant can be bathed in much the same order as an adult, by a sponge bath or in a small bathtub. However, there are special precautions. Because an infant's temperature-control mechanisms are still immature, prolonged exposure of body parts may cause cooling. When giving a bath, keep the infant covered as much as possible and work quickly. It is important to be sure the water temperature is warm enough to prevent chilling.

The surface of an infant's skin has a pH of about 5 soon after birth (Hockenberry & Wilson 2011). This acidic covering helps prevent bacterial growth on the skin's surface. Thus only plain warm water is used for the bath. As the infant becomes older and soiling is more common, it is appropriate to use a gentle soap with very little rubbing (Hockenberry & Wilson 2011). Alkaline soaps, oils, powder and lotions are not to be used.

Give the bath in a head-to-toe direction using a clean washcloth. First nurses wash the eyes, face, ears and scalp before removing the infant's shirt and nappy. The eyes are carefully washed from the inner to the outer canthus. The washcloth is used and then turned so that a clean part touches the skin with each stroke. It may be necessary to shampoo the scalp and hair. The infant can be positioned (wrapped with only the head exposed) over a small basin. Lather the scalp with a mild soap, and rinse by pouring water from a small container into the basin. A washcloth can be used to wash and rinse as well. The infant is kept covered during shampooing. A rolled wisp of dampened cotton or the twisted end of the washcloth works well to clean the external ear. Pat dry the scalp gently but well.

After undressing the infant for the remainder of the bath, nurses give special attention to around the neck, where food that has been regurgitated collects, and in skin folds of the axillae and joints. Genitalia of both sexes require careful and gentle cleansing. For a girl, it is important to retract the labia fully to remove the vernix caseosa after it has dried. With successive baths the vernix caseosa will disappear. The vulva is cleaned front to back to prevent the spread of infection. In male infants, wash carefully around the penis and scrotum. To complete the bath, nurses wash the buttocks and anal area thoroughly. After bathing, the infant must be completely rinsed, dried and a clean nappy put on.

Care of the umbilical cord is a special consideration for the newborn. The umbilical stump is a good medium for bacterial growth. Sponge baths are given until the cord falls off and the skin heals. A nappy should be positioned below the cord to avoid wetness and irritation. Give special care to infants who have been circumcised. A small amount of bleeding normally occurs from the penis. The doctor places a ring between the penis and foreskin; the latter remains in situ until it falls off in 7–10 days. Vaseline is applied to the tip of the penis and the nappy liner to decrease irritation. Circumcision is usually carried out between 6 and 8 weeks of age.

Infants can be given a tub bath after the umbilicus has healed. Supplies are the same as those used in the sponge bath. The face, neck, ears, eyes and scalp are washed before the infant is undressed and placed in the baby bath. Lowering the infant slowly into the bath avoids startling. The infant must always be held firmly with one hand (Figure 29-7). Never leave the child unattended. Body creases are much easier to clean and rinse in a bath. After the bath, wrap the infant completely in a towel and gently pat the infant dry.

In hospitals where the infant and mother are in the same room, the infant's bath is an excellent opportunity to involve the parents in the child's care. The parents can examine the infant's body parts and learn about normal variation in skin characteristics. This is also a good time to stress the importance of safety in terms of water temperature and supervision of the infant.

FOOT AND NAIL CARE Foot and nail care should be incorporated into a person's regular hygiene routine. Routine care involves soaking to soften cuticles and layers of horny cells, thorough cleansing, drying and proper nail trimming. The exception involves people with diabetes mellitus, who do not soak their nails due to the risk of infection. When care is being administered, the person may remain in bed or sit in a chair (Skill 29-5).

Figure 29-7 Holding an infant during a bath.

Shutterstock/michaeljung.

Nurses should take time during the procedure to teach the person and family proper techniques for cleaning and nail trimming. Measures to prevent infection and promote good circulation should be stressed. People learn to protect the feet from injury, keep the feet clean and dry and wear footwear that fits properly. Instruct people on the proper way to inspect all

SKILL 29-5

Performing nail and foot care

Delegation considerations

Nail and foot care of the non-diabetic person can be undertaken by nurse assistants under the guidance of the registered nurse. If the person is diabetic, this should not be delegated.

- Instruct caregiver in proper way to use nail clippers.
- Instruct caregiver to report immediately any cuts in skin.

Equipment

- Washbasin
- Emesis basin
- Washcloth
- Bath or face towel
- Nail clippers
- Orange stick
- Emery board or nail file
- Body lotion
- Disposable bath mat
- Paper towels
- Disposable gloves

Therapeutic relationship and patient considerations

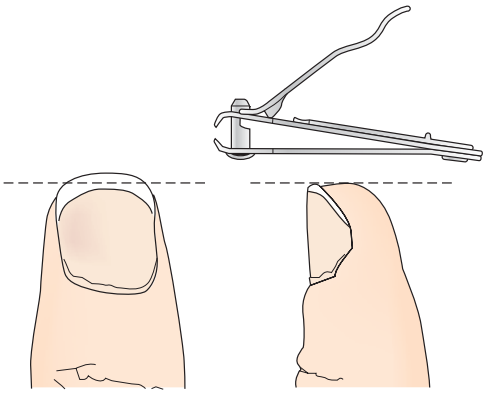
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Inspect all surfaces of fingers, toes, feet and nails. Pay particular attention to areas of dryness, inflammation or cracking. Also inspect areas between toes, heels and soles of feet.	Integrity of feet and nails determines frequency and level of hygiene required. Heels, soles and sides of feet are prone to irritation from ill-fitting shoes.
2. Assess colour and temperature of toes, feet and fingers. Assess capillary refill of nails. Palpate radial and ulnar pulse of each hand and dorsalis pedis pulse of foot; note character of pulses.	Assesses adequacy of blood flow to extremities. Circulatory alterations may change integrity of nails and increase person's chance of localised infection when break in skin integrity occurs.
3. Observe person's gait. Have person walk down hall or walk straight line (if able).	Painful disorders of feet can cause limping or unnatural gait.
4. Ask female people whether they use nail polish and polish remover frequently.	Chemicals in these products can cause excessive dryness.
5. Assess type of footwear worn by people. Are socks worn? Are shoes tight or ill-fitting? Are garters or knee-high stockings worn? Is footwear clean?	Types of shoes and footwear may predispose person to foot and nail problems (e.g. infection, areas of friction, ulcerations).
6. Identify person's risk of foot or nail problems:	Certain conditions increase likelihood of foot or nail problems.
a. Older adult	Poor vision, lack of coordination or inability to bend over contribute to difficulty in performing foot and nail care. Normal physiological changes of ageing also result in nail and foot problems.
b. Diabetes mellitus	Vascular changes associated with diabetes mellitus reduce blood flow to peripheral tissues. Break in skin integrity places diabetic at high risk of skin infection.
c. Heart failure, renal disease	Both conditions can increase tissue oedema, particularly in dependent areas (e.g. feet). Oedema reduces blood flow to neighbouring tissues.
d. Cerebrovascular accident, stroke	Presence of residual foot or leg weakness or paralysis results in altered walking patterns. Altered gait pattern causes increased friction and pressure on feet.
7. Assess type of home remedies person uses for existing foot problems:	Certain preparations or applications may cause more injury to soft tissue than initial foot problem.
a. Over-the-counter liquid preparations to remove corns	Liquid preparations can cause burns and ulcerations.
b. Cutting of corns or calluses with razor blade or scissors	Cutting of corns or calluses may result in infection caused by break in skin integrity.
c. Use of oval corn pads	Oval pads may exert pressure on toes, thereby decreasing circulation to surrounding tissues.

STEPS	RATIONALE
d. Application of adhesive tape	Skin of older adult is thin and delicate and prone to tearing when adhesive tape is removed.
8. Assess person's ability to care for nails or feet: visual alterations, fatigue, musculoskeletal weakness.	Determines person's ability to perform self-care and degree of assistance required from nurse.
9. Assess person's knowledge of foot and nail care practices.	Determines person's need for health teaching.
10. Explain procedure to person, including fact that proper soaking requires several minutes.	Person must be willing to place fingers and feet in basins for 10–20 minutes. Person may become anxious or fatigued.
Critical decision point: Diabetic people do not soak hands and feet. Soaking increases risk of infection in diabetics.	
11. Obtain doctor's order for cutting nails if agency policy requires it.	Person's skin may be accidentally cut. Certain people are more at risk of infection, depending on their medical condition.
12. Wash hands. Arrange equipment on overbed table.	Easy access to equipment prevents delays.
13. Pull curtain around bed or close room door (if desired).	Maintaining a person's privacy reduces anxiety.
14. Help mobile person to sit in bedside chair. Help bed-bound person to supine position with head of bed elevated. Place disposable bath mat on floor under person's feet or place towel on mattress.	Sitting in chair facilitates immersing feet in basin. Bath mat protects feet from exposure to soil or debris.
15. Fill washbasin with warm water. Test water temperature.	Warm water softens nails and thickened epidermal cells, reduces inflammation of skin and promotes local circulation. Proper water temperature prevents burns.
16. Place basin on bath mat or towel, and help person place feet in basin. Place call light within person's reach.	People with muscular weakness or tremors may have difficulty positioning feet. Person's safety is maintained.
17. Adjust overbed table to low position, and place it over person's lap. (Person may sit in chair or lie in bed.)	Easy access prevents accidental spills.
18. Fill emesis basin with warm water, and place basin on paper towels on overbed table.	
19. Instruct person to place fingers in emesis basin and place arms in comfortable position.	Prolonged positioning can cause discomfort unless normal anatomical alignment is maintained.
20. Allow person's feet and fingernails to soak for 10–20 minutes. Rewarm water after 10 minutes.	Softening of corns, calluses and cuticles ensures easy removal of dead cells and easy manipulation of cuticle.

STEPS	RATIONALE
STEPS	**RATIONALE**
21. Clean gently under fingernails with orange stick after fingers have been soaked (see illustration). Remove emesis basin, and dry fingers thoroughly.	Orange stick removes debris under nails that harbours microorganisms. Thorough drying impedes fungal growth and prevents maceration of tissues.
22. With nail clippers, clip fingernails straight across and even with tops of fingers (see illustrations). Shape nails with emery board or file. If person has circulatory problems, do not cut nail; file the nail only.	Cutting straight across prevents splitting of nail margins and formation of sharp nail spikes that can irritate lateral nail margins. Filing prevents cutting nail too close to nail bed.

Step 21 Cleaning under fingernails.



Step 22 Clip nails straight across.

23. Push cuticle back gently with orange stick.	Reduces incidence of inflamed cuticles.
24. Move overbed table away from person.	Provides easier access to feet.
25. Put on disposable gloves, and scrub calloused areas of feet with washcloth.	Gloves prevent transmission of fungal infection. Friction removes dead skin layers.
26. Clean gently under nails with orange stick. Remove feet from basin, and dry thoroughly.	Removal of debris and excess moisture reduces chances of infection.
27. Clean and trim toenails using procedures in Steps 22 and 23. Do not file corners of toenails.	Shaping corners of toenails may damage tissues.
28. Apply lotion to feet and hands, and help person back to bed and into comfortable position.	Lotion lubricates dry skin by helping to retain moisture.
29. Remove disposable gloves and place in receptacle. Clean and return equipment and supplies to proper place. Dispose of soiled linen. Wash hands.	Reduces transmission of infection.
30. Inspect nails and surrounding skin surfaces after soaking and nail trimming.	Evaluates condition of skin and nails. Allows nurse to note any remaining rough nail edges.
31. Ask person to explain or demonstrate nail care.	Evaluates person's level of learning techniques.
32. Observe person's walk after toenail care.	Evaluates level of comfort and mobility achieved.

STEPS	RATIONALE
33. Record procedure and observations (e.g. breaks in skin, inflammation, ulcerations).	Documents procedure, person's response and presence of abnormalities requiring additional therapy.
34. Report any breaks in skin or ulcerations to nurse in charge or doctor.	These abnormalities can seriously increase person's risk of infection and must be carefully observed.

RECORDING AND REPORTING

- Record procedure and observations (e.g. breaks in skin, inflammation, ulcerations).
- Report any breaks in skin or ulcerations to nurse in charge or doctor. These are serious in person with peripheral vascular disease and illnesses in which person's circulation is impaired. Special foot care treatments may be needed.

HOME CARE CONSIDERATIONS

- Alternative therapies: moleskin applied to areas of feet that are under friction is less likely to cause pressure than corn pads; spot adhesive bandages can guard against friction, but they do not have padding to protect against pressure; wrapping small pieces of lamb's wool around toes reduces irritation of soft corns between toes.
- If person is mobile, instruct to soak feet in bathtub. When person's mobility is limited, a large basin or pan can be used.

surfaces of the feet and hands for lesions, dryness or signs of infection. It is important for people to know the appearance of any abnormalities and the importance of reporting these conditions to their caregiver.

A person with diabetes mellitus or peripheral vascular disease is at risk of foot and nail problems as a result of poor peripheral blood supply to the feet. In addition, sensation in the feet can be reduced. These people are especially at risk of developing chronic foot ulcers, which typically heal very slowly and, once present, are difficult to treat. Over time, circulation can become sufficiently compromised to cause ischaemia and sloughing of tissue. Ongoing foot care can help prevent toe amputation, but many people need to be shown proper care. The following risk conditions are associated with an increased risk of amputation: peripheral neuropathy; altered biomechanics; evidence of increased pressure from callus, erythema or haemorrhage under a callus; limited joint mobility, bony deformity or severe nail pathological condition; peripheral vascular disease; a history of ulcers or amputation.

Nurses observe for changes that would indicate peripheral neuropathy or vascular insufficiency. The person must be given information to understand how circulation directly affects the health and integrity of tissues. Nurses advise people to use the following guidelines in a routine foot and nail care program:

- Inspect the feet daily, including the tops and soles of the feet, the heels and the areas between the toes. Use a mirror to help inspect the feet thoroughly, or ask a family member to check daily.
- All people with diabetes mellitus should receive a 12-monthly foot assessment by a podiatrist (Australasian Podiatry Council 2011). People with one or more high-risk foot conditions should be evaluated frequently. People with neuropathy should have a visual inspection of their feet at every visit to a healthcare professional.
- Wash the feet daily using lukewarm water; do not soak. People with reduced sensation may want to use a bath thermometer at home to test water temperature. Thoroughly pat the feet dry, and dry well between toes.
- Do not cut corns or calluses or use commercial removers. Consult a doctor or podiatrist.
- If dryness is noted along the feet or between the toes, apply lanolin or baby oil and rub gently into the skin.
- File the toenails straight across and square; do not use scissors or clippers. Consult a podiatrist as needed.
- Do not use over-the-counter preparations to treat athlete's foot or ingrown toenails. Consult a doctor or podiatrist.
- Avoid wearing elastic stockings, knee-high stockings or constricting garters and do not cross the legs while sitting. These impair circulation to the lower extremities.
- Wear clean cotton socks or stockings daily. Change socks twice a day if feet perspire heavily. Lightly apply an unscented foot powder. Socks should be dry and free of holes or darns that might cause pressure.
- Do not walk barefoot.
- Wear properly fitted shoes. The soles of shoes should be flexible and non-slipping. Small amounts of lamb's wool can be used between toes that rub or overlap. Shoes should be sturdy, closed in and not restrictive to the feet. People with increased plantar pressure (e.g. erythema, callus) should use footwear or orthotics (individualised formed insoles) that cushion and redistribute pressure. People with bony deformity (e.g. bunion or Charcot's joint) may need extra-wide or extra-deep shoes with cushioned or orthotic insoles.
- Do not wear new shoes for an extended time. Wear them for short periods over several days to break them in.

- Exercise regularly to improve circulation to the lower extremities. Elevate, rotate, flex and extend the feet at the ankles. Walking slowly also improves the circulation.
- Avoid applying hot-water bottles or heating pads to the feet; use extra coverings instead.
- Minor cuts should be washed immediately and dried thoroughly. Use only mild antiseptics (e.g. Neosporin ointment). Avoid iodine or mercurochrome. Contact a doctor to treat cuts or lacerations.

Generally, any person who requires regular, thorough foot care should have a family member able to provide care during times when the person is incapacitated. People with visual difficulties, physical constraints preventing movement, or cognitive problems that impair their ability to assess the condition of the feet will need family assistance.

Oral hygiene

Oral hygiene helps maintain the healthy state of the mouth, teeth, gums and lips. Brushing cleans the teeth of food particles, plaque and bacteria. It also massages the gums and relieves discomfort resulting from unpleasant odours and tastes. Flossing further helps remove food particles, plaque and tartar from between teeth to reduce gum inflammation and infection. Complete oral hygiene enhances wellbeing and comfort and stimulates the appetite. People also benefit from a proper diet, which excludes foods promoting plaque formation and tooth decay and promotes healthy periodontal structures. Nurses help people maintain good oral hygiene by teaching the importance of correct techniques and a routine daily schedule. People of all ages, including infants and children (see *Working with diversity* below), should have a dental check-up at least every 6 months. Education about common gum and tooth disorders and methods of prevention can motivate people to follow good oral hygiene practices. Nurses also help perform hygiene for weakened or disabled people. When people have variations in oral mucosal integrity, nurses adapt hygiene techniques to ensure thorough and effective care (see *Working with diversity* below).

WORKING WITH DIVERSITY

Focus on infants and children

- *Oral hygiene* – the parent/caregiver should be instructed to brush the child's teeth thoroughly twice daily (morning and evening) and to floss at least once every day from the time the first tooth erupts.
- *Diet* – the parent/caregiver should be instructed to provide fruit juices only at meals and to avoid all carbonated beverages during the first 30 months of the infant's life.
- *Fluoride* – the parent/caregiver should be instructed to use fluoride toothpaste and rinse every night with an alcohol-free over-the-counter mouth rinse containing 0.05% sodium fluoride. Tap-water should be given (rather than bottled water) in areas where the water supply is fluoridated.
- *Caries removal* – parents/caregivers should be referred to a dentist for an examination and removal of all active decay as soon as feasible.
- *Delay of colonisation* – parents/caregivers should be educated to prevent early colonisation of dental flora in their infants by avoiding sharing spoons or cleaning a dropped dummy with their saliva, and so on.

WORKING WITH DIVERSITY

Focus on older adults

- 50% of people over age 65 are edentulous (without teeth), and teeth that are present are often diseased or decayed.
- The periodontal membrane weakens, making it more prone to infection.
- Partial plates or dentures may not fit properly, causing pain and discomfort.
- Weaker jaw muscles and a shrinkage of the bony structure of the mouth may increase the work of chewing and lead to increased fatigue when eating.
- There is a decrease in saliva, once thought to be associated with ageing, but now considered to be related to medication therapy that may cause mucous membranes to become drier.

Adapted from Touhy TA, Jett KF 2011 Ebersole and Hess' toward healthy aging: human needs and nursing response, 8th edn. Mosby, St Louis.

BRUSHING TEETH Thorough brushing of teeth, ideally four times a day (after meals and at bedtime), is basic to an effective oral hygiene program. A toothbrush should have a straight handle and a brush small enough to reach all areas of the mouth. An even, rounded brushing surface with soft, multi-tufted nylon bristles is best. Rounded soft bristles stimulate the gums without causing abrasion and bleeding. Older adult people with reduced dexterity and grip may require an enlarged handle with an easier grip or an electric toothbrush. Simple ways to devise an enlarged brush handle are to pierce a soft rubber ball and push the brush handle through, or glue a short piece of plastic tubing around the handle. People should be advised to obtain a new toothbrush every 3 months or following a cold or streptococcal infection of the throat to minimise growth of microorganisms on the brush surfaces and subsequent reinfection.

Commercially made foam-rubber toothbrushes are useful for people with sensitive gums. However, swabbing fails to clean teeth adequately because plaque accumulates around the base of the teeth (Huskinson & Lloyd 2009). Foam-rubber swabs should be used in moderation. Electric toothbrushes can be used, but nurses working in an agency setting should check for electrical hazards. All tooth surfaces should be brushed thoroughly using fluoride toothpaste. Whether a brush or sponge is used, thorough rinsing after brushing is important to remove dislodged food particles and excess toothpaste. Some people enjoy using mouthwash for its pleasant taste. Used over a long period, however, mouthwash dries mucosa (Huskinson & Lloyd 2009).

When teaching people about mouth care, nurses should recommend they do not share toothbrushes with family members or drink directly from a bottle of mouthwash. Cross-contamination occurs easily. The use of disclosure tablets or drops to stain the plaque that collects at the gum line can be useful for showing people, and particularly children, how effectively they brush.

The amount of assistance needed by the person when brushing the teeth may vary (Skill 29-6). Many people can perform their own oral care and should be encouraged to do so. Nurses observe the person to be sure proper techniques are used.

People will experience conditions that threaten the integrity of oral mucosa. For example, mucosal changes associated with ageing, use of chemotherapeutic drugs or dehydration require

SKILL 29-6

Providing oral hygiene

Delegation considerations

Brushing teeth can be delegated to nurse assistants under the guidance of the registered nurse (RN).

- Instruct caregiver in proper way to provide toothbrushing.
- Instruct caregiver in how to recognise impaired integrity of oral mucosa.

Equipment

- Soft-bristled toothbrush
- Non-abrasive fluoride toothpaste
- Dental floss
- Glass with cool water
- Normal saline or fluoride mouthwash (optional; follow person's preference)
- Emesis basin
- Face towel
- Paper towels
- Disposable gloves

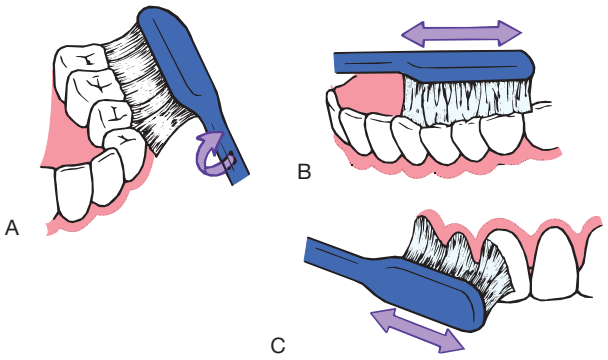
Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

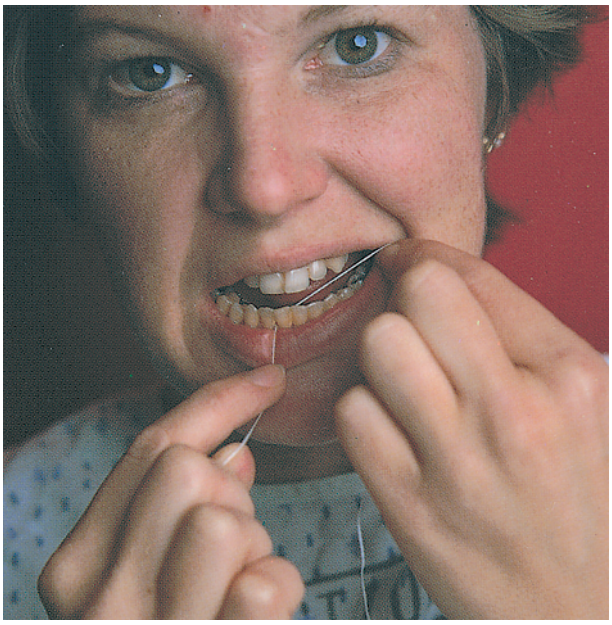
STEPS	RATIONALE
1. Wash hands and put on disposable gloves.	Reduces transmission of microorganisms.
2. Inspect integrity of lips, teeth, buccal mucosa, gums, palate and tongue (see Chapter 27).	Determines status of the person's oral cavity and extent of need for oral hygiene.
3. Identify presence of common oral problems: a. Dental caries – chalky white discolouration of tooth or presence of brown or black discolouration b. Gingivitis – inflammation of gums c. Periodontitis – receding gum lines, inflammation, gaps between teeth d. Halitosis – bad breath e. Cheilosis – cracking of lips f. Stomatitis – inflammation of the mouth	Helps determine type of hygiene the person requires and information they require for self-care.
4. Remove gloves and wash hands.	Prevents spread of microorganisms.

STEPS	RATIONALE
5. Assess risk of oral hygiene problems (see Table 29-7).	Certain conditions increase likelihood of impaired oral cavity integrity and need for preventive care.
6. Determine the person's oral hygiene practices: a. Frequency of toothbrushing and flossing b. Type of toothpaste used c. Last dental visit d. Frequency of dental visits	Allows the nurse to identify errors in technique, deficiencies in preventive oral hygiene and the person's level of knowledge regarding dental care.
e. Type of mouthwash or moistening preparation.	Lemon–glycerin preparations can be detrimental. Glycerin is an astringent that dries and shrinks mucous membranes and gums. Lemon exhausts salivary reflex and can erode tooth enamel. Mouthwash provides pleasant aftertaste but can dry mucosa after extended use if it has an alcohol base.
7. Assess the person's ability to grasp and manipulate toothbrush. (For an older adult, try 30 seconds of toothbrush assessment.)	Determines level of assistance required. Toothbrush test useful in assessing dexterity and strength.
8. Prepare equipment at bedside.	
9. Explain the procedure to the person and discuss preferences regarding use of hygiene aids.	Some people feel uncomfortable about having nurses care for their basic needs. Anxiety is minimised by involving the person in the procedure.
10. Place paper towels on overbed table and arrange other equipment within easy reach.	
11. Raise bed to comfortable working position. Raise head of bed (if allowed) and lower side rail. Move the person, or help them move closer. Side-lying position can be used.	Raising bed and positioning the person prevents the nurse from straining muscles. Semi-Fowler's position helps prevent the person from choking or aspirating.
12. Place towel over the person's chest.	Keeps the person's clothing clean and dry.
13. Apply gloves.	Prevents contact with microorganisms or blood in saliva.
14. Apply toothpaste to the brush, holding brush over emesis basin. Pour small amount of water over toothpaste.	Moisture helps distribute toothpaste over tooth surfaces.
15. The person may help by brushing. Hold toothbrush bristles at 45-degree angle to gum line (see illustration). Be sure tips of bristles rest against and penetrate under gum line. Brush inner and outer surfaces of upper and lower teeth by brushing from gum to crown of each tooth. Clean biting surfaces of teeth by holding top of bristles parallel with teeth and brushing gently back and forth (see illustration). Brush sides of teeth by moving bristles back and forth (see illustration).	Angle allows brush to reach all tooth surfaces and to clean under gum line where plaque and tartar accumulate. Back-and-forth motion dislodges food particles caught between teeth and along chewing surfaces.

STEPS	RATIONALE
16. Have the person hold brush at 45-degree angle and lightly brush over surface and sides of tongue. Avoid initiating gag reflex.	Microorganisms collect and grow on tongue's surface and contribute to bad breath. Gagging may cause aspiration of toothpaste.
17. Allow the person to rinse mouth thoroughly by taking several sips of water, swishing water across all tooth surfaces and spitting into emesis basin.	Irrigation removes food particles.
18. Allow the person to gargle to rinse mouth with mouthwash as desired.	Mouthwash leaves pleasant taste in mouth.
19. Help wipe the person's mouth.	Promotes sense of comfort.
20. Allow the person to floss (see illustration).	Reduces tartar on tooth surfaces.



Step 15 Direction for toothbrush placement.
A, 45-degree angle brushes gum line. B, Parallel position brushes biting surfaces. C, Lateral position brushes sides of teeth.



Step 20 Flossing between front teeth.

21. Allow the person to rinse mouth thoroughly with cool water and spit into emesis basin. Help wipe person's mouth.	Irrigation removes plaque and tartar from oral cavity.
22. Help the person into comfortable position, remove emesis basin and bedside table, raise side rail and lower bed to original position.	Provides for person comfort and safety.
23. Wipe off overbed table, discard soiled linen and paper towels in appropriate containers, remove soiled gloves and return equipment to proper place.	Proper disposal of soiled equipment prevents spread of infection.
24. Wash hands.	Reduces transmission of microorganisms.
25. Ask the person whether any area of oral cavity feels uncomfortable or irritated.	Pain indicates more chronic problem.

STEPS	RATIONALE
26. Put on gloves and inspect condition of oral cavity.	Determines effectiveness of hygiene and rinsing.
27. Ask the person to describe proper hygiene techniques.	Evaluates the person's learning.
28. Observe the person brushing.	Evaluates the person's ability to use correct technique.

RECORDING AND REPORTING

- Record procedure on flow sheet. Note condition of oral cavity in nurses' notes.
- Report bleeding or presence of lesions to nurse in charge or doctor.

HOME CARE CONSIDERATIONS

- Assess oral cavity at each visit to determine the effects of medications on the structures of the oral cavity.

nurses to adapt oral hygiene approaches. More-frequent mouth care and use of anti-infective agents are examples of ways nurses can revise approaches to meet personal needs.

FLOSSING Flossing involves inserting waxed or unwaxed dental floss between the teeth. The seesaw motion used to pull floss between teeth removes plaque and tartar from tooth enamel. To prevent bleeding, people who are receiving chemotherapy or radiation or are on anticoagulant therapy should use unwaxed floss and avoid vigorous flossing near the gum line. If toothpaste is applied to the teeth before flossing, fluoride can come in direct contact with tooth surfaces, aiding in cavity prevention. Flossing once a day is sufficient. Because it is important to clean all teeth surfaces thoroughly, nurses should not rush to complete flossing. Placing a mirror in front of the person will help nurses to demonstrate the proper method for holding the floss and cleaning between the teeth. Floss holders are available for people who have difficulty manipulating the floss.

PEOPLE WITH SPECIAL NEEDS Some people require special oral hygiene methods because of their level of dependence on nurses or the presence of oral mucosa problems. Unconscious people are susceptible to drying of mucous-thickened salivary secretions because they are unable to eat or drink, frequently breathe through the mouth and often receive oxygen therapy. The unconscious person also cannot swallow salivary secretions that accumulate in the mouth. These secretions often contain Gram-negative bacteria that can cause pneumonia if aspirated into the lungs. While providing hygiene to an unconscious person, nurses must protect the person from choking and aspiration. The safest technique is to have two nurses provide the care. One nurse does the actual cleaning, while the other removes secretions with suction equipment.

While cleaning the oral cavity, nurses should never use fingers to hold the person's mouth open. A human bite is highly contaminated. It may be necessary to perform mouth care at least every 2 hours. The nurse explains the steps of mouth care and the sensations the person will feel. The nurse also advises the person when the procedure is completed (Skill 29-7).

SKILL 29-7

Performing mouth care for an unconscious or debilitated person

Delegation considerations

Brushing teeth of an unconscious or debilitated person can be delegated to nurse assistants under the supervision of the registered nurse (RN).

- After RN checks for gag reflex, inform caregiver about proper way to position people for mouth care.
- Instruct caregiver in how to use the oral suction catheter for clearing oral secretions.
- Instruct caregiver in how to recognise impaired integrity of oral mucosa.

Equipment

- Anti-infective solution (e.g. diluted hydrogen peroxide) that loosens crusts
- Small soft-bristled toothbrush
- Sponge toothette or tongue blade wrapped in single layer of gauze
- Padded tongue depressor
- Face towel
- Paper towels
- Emesis basin

- Water glass with cool water
- Water-soluble lip lubricant
- Small-bulb syringe (optional)
- Suction machine equipment (optional)
- Disposable gloves (three pairs)
- Eye shield or goggles

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Wash hands. Put on disposable gloves and goggles or eye shield.	Reduces transmission of microorganisms. Gloves prevent contact with microorganisms in blood or saliva.
2. Test for presence of gag reflex by placing tongue blade on back half of tongue. People with impaired gag reflex require oral care as well. The nurse determines the type of suction apparatus needed at the bedside to protect the person's airway against aspiration.	Reveals whether person is at risk of aspiration.
3. Inspect condition of oral cavity (see Chapter 27).	Determines condition of oral cavity and need for hygiene.
4. Remove gloves. Wash hands.	Prevents spread of infection.
5. Assess the person's risk of oral hygiene problems (see Table 29-7).	Certain conditions increase likelihood of alterations in integrity of oral cavity structures and may require more frequent care.
6. Position person on side (Sims' position) with head turned well towards dependent side and head of bed lowered. Raise side rail.	Allows secretions to drain from mouth instead of collecting in back of pharynx. Prevents aspiration.
7. Explain procedure to the person.	Allows debilitated person to anticipate procedure without anxiety. Unconscious person may retain ability to hear.
8. Wash hands and apply disposable gloves.	Reduces transfer of microorganisms.
9. Place paper towels on overbed table and arrange equipment. If needed, turn on suction machine and connect tubing to suction catheter.	Prevents soiling of table top. Equipment prepared in advance ensures smooth, safe procedure.
10. Pull curtain around bed, or close room door.	Provides privacy.
11. Raise bed to its highest horizontal level; lower side rail.	Use of good body mechanics with bed in high position prevents injury.
12. Position person close to side of bed; turn person's head towards mattress.	Proper positioning of head prevents aspiration.

STEPS	RATIONALE
13. Place towel under the person's head and emesis basin under chin.	Prevents soiling of bedclothes.
14. Carefully separate upper and lower teeth with padded tongue blade by inserting blade, quickly but gently, between back molars. Insert when the person is relaxed, if possible. Do not use force. Never use fingers to separate the person's teeth.	Prevents the person from biting down on nurse's fingers and provides access to oral cavity.
15. Clean mouth using brush or sponge toothettes moistened with peroxide and water (see illustration). Clean chewing and inner tooth surfaces first. Clean outer tooth surfaces. Swab roof of mouth, gums and inside cheeks. Gently swab or brush tongue but avoid stimulating gag reflex (if present). Moisten clean swab or toothette with water to rinse. (Bulb syringe may also be used to rinse.) Repeat rinse several times.	Brushing action removes food particles between teeth and along chewing surfaces. Swabbing helps remove secretions and crusts from mucosa and moistens mucosa. Repeated rinsing removes peroxide that can be irritating to mucosa.

Step 15 Using toothette to clean mouth of person with oral airway.

Step 17 Applying water-soluble moisturiser to lips.

16. Suction secretions as they accumulate, if necessary.	Suction removes secretions and fluid that can collect in posterior pharynx.
17. Apply thin layer of water-soluble jelly to lips (see illustration).	Lubricates lips to prevent drying and cracking.
18. Inform the person that the procedure is completed.	Provides meaningful stimulation to unconscious or less responsive person.
19. Remove gloves and discard in proper receptacle.	Prevents transmission of infection.
20. Reposition the person comfortably, raise side rail and return bed to original position.	Maintains the person's comfort and safety.
21. Clean equipment and return to its proper place. Place soiled linen in proper receptacle.	Proper disposal of soiled equipment prevents spread of infection.
22. Wash hands.	Reduces transmission of microorganisms.

STEPS	RATIONALE
23. Put on gloves, and inspect oral cavity.	Determines efficacy of cleansing. Once thick secretions are removed, underlying inflammation or lesions may be revealed.
24. Ask debilitated person if mouth feels clean.	Evaluates level of comfort.
25. Assess the person's respirations on an ongoing basis.	Ensures early recognition of aspiration.

RECORDING AND REPORTING

- Record procedure, including pertinent observations (e.g. presence of bleeding gums, dry mucosa, ulcerations, crusts on tongue).
- Report any unusual findings to nurse in charge or doctor.

HOME CARE CONSIDERATIONS

- Irrigate cavity with bulb syringe.
- Mouth care should be given at least twice a day. Caregivers can get non-prescription oral care solutions (e.g. carbamide peroxide solutions) at most chemists/pharmacies. Have caregivers demonstrate positioning person to prevent aspiration.

Those who receive chemotherapy, radiation or nasogastric tube intubation or who have an infection of the mouth can suffer from stomatitis. Inflammation of the oral mucosa can cause oral burning, pain and change in food tolerance. Gentle brushing and flossing are important in preventing bleeding of the gums. The person should be advised to avoid alcohol and commercial mouthwash and to stop smoking. Normal saline rinses (approximately 30 mL) on waking in the morning, after each meal and at bedtime can effectively clean the oral cavity. The rinses can be increased to every 2 hours if necessary. The doctor may order a mild oral analgesic for pain control.

People with diabetes mellitus often have periodontal disease. They will need to visit the dentist every 3–4 months. All tissues should be handled gently to minimise further periodontal trauma. A person should learn to follow rigid cleaning schedules, at least four times a day.

DENTURE CARE A person should be encouraged to clean their dentures on a regular basis to avoid gingival infection and irritation. When a person becomes disabled, a nurse or family caregiver can assume responsibility for denture care (Box 29-7).

Dentures are the person's personal property and need to be handled with care because, apart from being easily broken, they are expensive items. Dentures must be removed at night to give the gums a rest and prevent bacterial build-up. To prevent warping, dentures should be kept covered in water when they are not worn, and they should always be stored in an enclosed, labelled cup with the cup placed on the person's bedside stand. Discourage the person from removing their dentures and placing them on a serviette or tissue because they could easily be thrown away.

Hair and scalp care

A person's appearance and feeling of wellbeing often depend on the way the hair looks and feels. Illness or disability may prevent a person from maintaining daily hair care. An immobilised person's hair soon becomes tangled. Dressings may leave sticky blood or antiseptic solutions on the hair. In the clinic and home care settings, nurses will encounter people who have head lice. Proper hair care is important to the person's body image. Brushing, combing and shampooing are basic hygiene measures for all people.

BRUSHING AND COMBING Frequent brushing helps to keep hair clean and distributes oil evenly along hair shafts. Combing prevents hair from tangling. The person should be encouraged to maintain routine hair care. However, people with limited mobility or weakness and those who are confused require help. People in a hospital or extended-care facility appreciate the opportunity to have their hair brushed and combed prior to visiting hours.

When caring for people from different cultures, it is important to learn as much as possible from them or their family about preferred hair care practices. Cultural preferences will also affect how hair is combed and styled.

Long hair can easily become matted after a person is confined to bed, even for a short period. When lacerations or incisions involve the scalp, blood and topical medications can also cause tangling. Frequent brushing and combing keep long hair neatly groomed. Plaiting can help to avoid repeated tangles, but plaits should be unplaited periodically and hair combed to ensure good hygiene. Plaits made too tightly can lead to discomfort and, ultimately, bald patches. Nurses obtain permission from the person before plaiting hair.

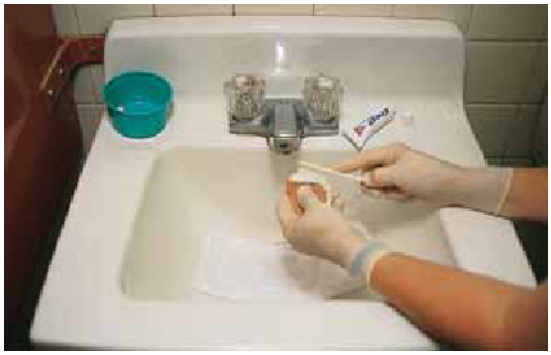
To brush hair, part the hair into several sections. It is easier to brush smaller sections of hair. Brushing from the scalp towards the hair ends minimises pulling. Moistening the hair with water or alcohol frees tangles for easier combing. Never cut a person's hair without written consent.

A person who develops head lice (*Pediculosis capitis*) requires special considerations in the way combing is performed. The lice are small, about the size of a sesame seed. Bright light or natural sunlight is necessary for the lice to be visible. Thorough

BOX 29-7 Procedural guidelines for cleaning dentures

Equipment: Soft-bristled toothbrush, denture toothbrush, emesis basin or sink, denture toothpaste, glass, 10 cm × 10 cm gauze, washcloth, denture cup, disposable gloves.

1. Clean dentures for person during routine mouth care. Dentures need to be cleaned as often as natural teeth.
2. Fill emesis basin with tepid water. (If using sink, place washcloth in bottom of sink and fill sink with approximately 2.5 cm of water.)
3. Remove dentures. If person is unable to do this independently, don gloves, grasp upper plate at front with thumb and index finger wrapped in gauze and pull downwards. Gently lift lower denture from jaw, and rotate one side downwards to remove from person's mouth. Place dentures in emesis basin or sink.
4. Apply toothpaste to dentures, and brush surfaces of dentures (see illustration). Hold dentures close to water. Hold brush horizontally, and use back-and-forth motion to clean biting surfaces. Use short strokes from top of denture to biting surfaces of teeth to clean outer tooth surface. Hold brush vertically, and use short strokes to clean inner tooth surfaces. Hold brush horizontally, and use back-and-forth motion to clean undersurface of dentures.
5. Rinse dentures thoroughly in tepid water.
6. Return dentures to person, or store in tepid water in denture cup. Keep denture cup inside bedside cabinet.



Step 4 Applying toothpaste and brushing the sides of the dentures.

combing is recommended and may be more effective than use of pediculicidal shampoos, which are often toxic and ineffective against resistant lice. Thick white conditioners have been demonstrated to stun lice for sufficient time for them, along with their eggs (nits), to be combed out with a nit comb (Martinez-Diaz & Mancini 2010). Follow these steps:

- Liberally apply a thick, white conditioner.
- Use a grooming comb or hairbrush to remove tangles.
- Divide the person's hair into sections and fasten off hair that is not being combed.
- Comb out from the scalp to the end of the hair (special combs are available in pharmacies).
- Dip the comb in a cup of water or use a paper towel to remove lice between each pass.
- After combing, look through the hair carefully for attached lice.
- Live lice may be caught with tweezers or comb.
- Move to next section of hair after combing thoroughly.
- Rinse hair thoroughly.
- Clean the comb with an old toothbrush and dental floss, and boil the comb (if possible).
- Instruct family to comb and screen for lice daily.

When a person is being treated for head lice, the doctor will often prescribe a pediculicidal shampoo. Have the person consult with the doctor or a pharmacist carefully if they have questions about the toxicity of the shampoo.

SHAMPOOING Frequency of shampooing depends on a person's daily routines and the condition of the hair. Nurses should remind people in hospitals or extended-care facilities that staying in bed, excessive perspiration, or treatments that leave blood or solutions in the hair may necessitate more-frequent shampooing. For those at home, it can be a challenge for nurses to find ways in which the person can shampoo the hair without causing discomfort or even injury.

If the person is able to take a shower or bath, the hair can usually be shampooed without difficulty. A shower or bath chair may be used for the mobile, weightbearing person who becomes tired or faint. Handheld shower nozzles allow a person to easily wash their hair in the bath or shower. The person who can sit in a chair may choose to be shampooed in front of a sink or over a washbasin. However, bending can be limited or contraindicated in certain conditions (e.g. eye surgery or neck injury). In these situations nurses need to teach the person the degree of bending allowed.

If a person is unable to sit but can be moved, they may be transferred to a bath trolley for transport to a sink or shower equipped with a handheld nozzle. Extended-care facilities are commonly equipped with this option. Caution is again needed when the person's head and neck are positioned, particularly in people with any form of head or neck injury.

In some agencies a doctor's order is necessary for shampooing the hair of a totally dependent person. If the person is unable to sit in a chair or be transferred to a trolley, shampooing must be done with the person in bed (Box 29-8). A special shampoo trough can be positioned under the person's head to catch water and suds. This method makes rinsing at the back of the head difficult.

After rinsing, most people like having their hair styled and dried. Most healthcare centres have portable hair dryers. Dry shampoos that reduce the need to wet the person's hair are also available, but are not very effective.

SHAVING Shaving facial hair can be done after the bath or shampoo. Women may prefer to shave their legs or axillae while bathing. When helping a person, nurses should take care to avoid cutting the person with a razor blade. People prone to bleeding (e.g. those receiving anticoagulants or high doses of aspirin, or those with low platelet counts) should use an electric razor. Before using an electric razor, nurses should check for

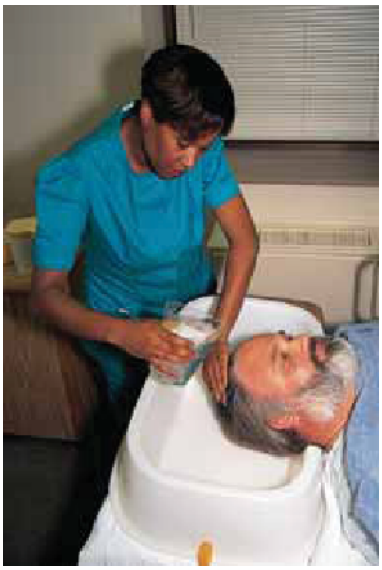
BOX 29-8 Procedural guidelines for shampooing hair of bed-bound person

Equipment

Bath towels, washcloths, shampoo and hair conditioner (optional), water jug, plastic apron, plastic shampoo trough, washbasin, bath blanket, waterproof pad, clean comb and brush, hair dryer (optional).

1. Before washing person's hair, determine that there are no contraindications to this procedure. Certain medical conditions, such as head and neck injuries, spinal cord injuries and arthritis, could place the person at risk of injury during shampooing because of positioning and manipulation of person's head and neck.
2. Inspect the hair and scalp before starting the procedure. This determines the presence of any conditions that may require the use of special shampoos or treatments (e.g. for dandruff or the removal of dried blood).
3. Place waterproof pad under person's shoulders, neck and head. Position person supine, with head and shoulders at top edge of bed. Place plastic trough under person's head and washbasin at end of trough. Be sure trough spout extends beyond edge of mattress (see illustration).

4. Place rolled towel under person's neck and bath towel over person's shoulders.
5. Brush and comb person's hair.
6. Obtain warm water.
7. Offer person the option of holding face towel or washcloth over eyes.
8. Slowly pour water from jug over hair until it is completely wet (see illustration). If hair contains matted blood, don gloves and eye shield, apply peroxide to dissolve clots and then rinse hair with saline. Apply small amount of shampoo.



9. Work up lather with both hands. Start at hairline, and work towards back of neck. Lift head slightly with one hand to wash back of head. Shampoo sides of head. Massage scalp by applying pressure with fingertips.
10. Rinse hair with water. Make sure water drains into basin. Repeat rinsing until hair is free of soap. Take care that hair at back of head is thoroughly rinsed.
11. Apply conditioner or cream rinse if requested, and rinse hair thoroughly.
12. Wrap person's head in bath towel. Dry person's face with cloth used to protect eyes. Dry off any moisture along neck or shoulders.
13. Dry person's hair and scalp. Use second towel if first becomes saturated.
14. Comb hair to remove tangles, and dry with dryer if desired.
15. Apply oil preparation or conditioning product to hair, if desired by person.
16. Help person into comfortable position, and complete styling of hair.

frayed cords or other electrical hazards. Electric razors should be used on only one person because of infection-control considerations.

When a razor blade is used for shaving, the skin must be moisturised to prevent pulling, scraping or cuts; for example, placing a warm washcloth over the male person's face for a few seconds, followed by application of shaving cream/gel/foam or a lathering of mild soap, decreases friction. If the person is unable to shave, a nurses may perform the shave. To avoid causing discomfort or razor cuts, the nurse gently pulls the skin taut and uses short, firm razor strokes in the direction the hair grows (see Figure 29-8). Short downward strokes work best to

Figure 29-8 Shave in the direction of hair growth. Use longer strokes on the larger areas of the face. Use short strokes around the chin and lips.

Sorrentino SA, Remmert LN 2012 Mosby's textbook for nursing assistants, 8th edn. Mosby, St Louis.

remove hair over the upper lip. The man can usually explain to nurses the best way to move the razor across the skin.

MOUSTACHE AND BEARD CARE Men with moustaches or beards require daily grooming. Keeping these areas clean is important because food particles and mucous can easily collect in the hair. If the man is unable to carry out self-care, nurses should do so at their request. Beards can be gently combed out. A shaggy or unkempt moustache or beard can be trimmed. Shaving off a moustache or beard cannot be performed without the person's consent.

HAIR AND SCALP CARE To best promote and restore hair and scalp health, people should be instructed how to keep hair clean, combed and brushed regularly. People may also need to know how to check for and remove parasites (see Table 29-4). Nurses should tell people that they need to notify their primary caregiver of changes in the texture and distribution of hair, which may indicate a serious systemic problem.

Care of the eyes, ears and nose

Special attention is given to cleaning the eyes, ears and nose during a routine bath and when drainage or discharge accumulate. This aspect of hygiene not only makes the person more comfortable, but also improves sensory reception (see Chapter 19). Care focuses on preventing infection and maintaining normal sensory function. In addition, care of the eyes, ears and nose requires approaches that consider the person's special needs (see *Working with diversity*).

BASIC EYE CARE Cleaning the eyes simply involves washing with a clean washcloth moistened in water. Soap or shower gel may cause burning and irritation (see Skill 29-1). Direct pressure should never be applied over the eyeball because it may cause serious injury.

WORKING WITH DIVERSITY

Focus on older adults

- Maintaining and improving eyesight are important aspects of an independent and satisfying life for older adults.
  - Encourage regular eye examinations.
  - Discuss vision changes that occur naturally with ageing.
  - Describe signs and symptoms of major eye diseases associated with ageing.
- 30% of people 65 years of age and 40–50% of those over age 75 years have hearing loss, so speak slowly and articulate carefully. However, do not shout, and do not assume that all older people have difficulty hearing.
- Earwax tends to be drier in older people, impacts more easily and takes longer to soften. Treatment includes a topical emollient instilled in the ear canal once a week, or syringing the ear canal to remove the impacted earwax. This should only be performed by someone who is experienced in this area (Linton & Lach 2007).

References

Linton A, Lach H 2007 Matteson and McConnell's Gerontological nursing: concepts and practice, 3rd edn. Saunders, St Louis.

Unconscious people often require more-frequent eye care. Secretions may collect along the lid margins and inner canthus when the blink reflex is absent or when the eye does not totally close. It may be necessary to place an eye patch over the involved eye to prevent corneal drying and irritation. Lubricating eye drops may be given according to the doctor's orders.

Unconscious people have lost the ability to protect their own corneas. Care must be taken to ensure that the eyelid covers the cornea or that the eyes are properly patched to prevent abrasion from bedclothes.

GLASSES Glasses are made of hardened glass or plastic that is impact-resistant to prevent shattering. Nevertheless, because of the expense, nurses should be careful when cleaning glasses and should protect them from breakage or other damage when they are not worn. Glasses should be put in a case in a drawer of the bedside table when not in use.

Cool water is sufficient for cleaning glass lenses. A soft cloth is best for drying to prevent scratching the lens; paper towels can scratch a lens. Plastic lenses in particular are scratched easily, and special cleaning solutions and drying tissues are available. Use whatever the person's eye-care specialist recommends.

CONTACT LENSES A contact lens is a small, round, transparent and sometimes coloured disk that fits directly over the cornea of the eye. Contact lenses are designed specifically to correct refractive errors of the eye or abnormalities in the cornea's shape. They are relatively easy to apply and remove.

There are three basic types of contact lenses: *rigid* (hard), *soft* and *rigid gas-permeable* (RGP), also known as oxygen-permeable. They differ in size, material, and the amount of oxygen flow they permit to the eye's surface. For example, rigid lenses ride on the tear-film layer of the cornea and are held in place by surface tension. The tear film moves under and over

BOX 29-9 Teaching contact lens care

Objectives

- Person will be able to identify warning signs of corneal irritation and eye infection.
- Person will be able to clean and care for contact lenses correctly.

Teaching strategies

- Encourage person to see a vision care specialist (ophthalmologist or optometrist) regularly: every 3–5 years before age 40, every 2 years after age 40 and yearly after age 65.
- Plastic lenses scratch easily. Special cleaning solutions and drying tissues are recommended.
- Never use fingernail on lens to remove dirt or debris that does not loosen during washing.
- Follow recommendations of lens manufacturer or eye-care practitioner when cleaning and disinfecting lenses.
- Encourage person to remember the mnemonic RSVP: Redness, Sensitivity, Vision problems and Pain. If one of these problems occurs, remove contact lenses immediately. If problems continue, contact vision care specialist.
- Lenses become very slippery once cleaning solution is applied.
- If lens is dropped on a hard surface, moisten finger with cleaning or wetting solution and gently touch lens to pick it up. Then clean, rinse and disinfect lens.
- Lens should be kept moist or wet when not worn.
- Use fresh solution daily when storing and disinfecting lenses.
- Do not wipe lens with tissue or towel.
- Thoroughly wash and rinse lens storage case on a daily basis. Clean periodically with soap or liquid detergent; rinse thoroughly with warm water and air dry.
- To avoid mix-up, always start with the same lens when removing or inserting lenses.
- Disposable or planned replacement lenses should be thrown away after prescribed wearing period.

Evaluation

- Have person identify warning signs of corneal irritation and eye infection.
- Ask person to describe methods of contact lens care that can lead to infection.
- Ask person to describe techniques to use in cleaning and storing contact lens.

the lens during blinking to provide oxygen to the cornea. Soft lenses cover the entire cornea and a small rim of the sclera; they do not ride on the corneal tear film. The cornea receives oxygen through the soft lens, which is oxygen-permeable. RGP lenses are made of plastic that allows oxygen to pass through to the cornea. All three lenses are available as clear (untinted) or tinted.

Contact lenses are available for daily wear or extended wear and may be disposable. In terms of a person's hygiene care, it is important to know that all lenses must be removed periodically to prevent ocular infection and corneal ulcers or abrasions. Common infectious agents are *Pseudomonas aeruginosa* and staphylococci. Education must include a discussion of proper lens care techniques (Box 29-9). *Daily-wear lenses* should be removed overnight for cleaning and disinfection and should not be worn for more than 10–14 hours daily (Lemp & Bielory 2008). Although it is recommended that *extended-wear lenses* be worn no longer than 6 consecutive nights without cleaning and disinfecting, there is a 30-day/night continued-wear lens available. *Disposable lenses* are available for daily wear and extended wear and are usually replaced every 1–2 weeks. Pain, eye-watering, discomfort and redness of the conjunctivae may be symptoms of lens overwear for any type of lens. Persistence of symptoms even after lens removal is abnormal, however, and may indicate serious ocular damage.

As contact lenses are worn, they accumulate secretions and foreign matter. This material deteriorates and then irritates the eye, causing distorted vision and risk of infection. Once removed, contact lenses should be cleaned and thoroughly disinfected. People should be cautioned never to use saliva, homemade saline or tap-water when cleaning lenses, as these solutions may contain microorganisms that can cause serious infection. Skill 29-8 reviews steps for contact lens removal, cleaning and reinsertion.

SKILL 29-8

Caring for the person with contact lenses

Delegation considerations

Caring for eye prostheses can be delegated to nurse assistants.

- Instruct caregiver in proper way to care for eye prostheses.
- Stress to caregiver that careful handling of these devices is of utmost importance to prevent physical injury to the person and damage to the devices.
- Inform caregiver of types of findings to report (e.g. eye pain, eye socket drainage).

Equipment

- Clean lens storage container
- Bath towel
- Suction cup (optional)
- Sterile saline solution
- Sterile lens cleaning solution
- Sterile lens rinsing solution
- Sterile lens disinfectant
- Sterile enzyme solution (depends on care regimen)
- Sterile wetting solution (depends on care regimen)
- Cotton ball or cotton bud
- Emesis basin
- Disposable gloves

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Place towel just below the person's face.	Catches lens if one should accidentally fall from eye.
2. Stand at the person's side. Inspect eye, or ask person whether contact lens is in place. Unconscious or confused people should be carefully assessed; lenses are often difficult to assess if clear (untinted).	Lenses are generally comfortable to wear, and person may forget they are in place. Prolonged wear may cause injury to eye.
3. Ask whether the person feels any eye discomfort, and assess length of time the person normally wears lenses.	Scratched lenses can cause corneal irritation and abrasion. Accumulation of dust or debris between lens and cornea causes irritation. Continuous wearing of certain types of lenses can irritate cornea.
4. Ask whether the person is able to manipulate and hold contact lens.	Determines level of assistance required in care.
5. Assess the person for any unusual visual signs/symptoms (reduced visual acuity, blurred vision, pain, photophobia).	May indicate underlying visual alteration or need to change lens prescription. A reduction in visual acuity calls for referral.
6. Assess types of medications prescribed for person: sedatives, hypnotics, muscle relaxants, antihistamines, anticholinergics and antidepressants.	Sedatives, hypnotics and muscle relaxants reduce blink reflex and thus reduce lubrication of cornea. Antihistamines, anticholinergics and antidepressants can reduce tear production.
7. After lenses are removed (see Step 11), inspect eye for signs of corneal irritation (e.g. redness, pain, swelling of eyelids and conjunctivae, discharge and excess watering). If pain persists or worsens after removal of lenses, an immediate referral to the ophthalmologist should be made.	Signs/symptoms indicate corneal irritation or abrasion. Severe pain may indicate corneal epithelium disruption or infection.
8. Discuss procedure with the person.	Person can help plan by explaining technique that may aid removal and insertion. Person may be anxious as nurse retracts eyelids and manipulates lenses.

STEPS	RATIONALE
9. Have the person assume supine or sitting position in bed or chair.	Provides easy access for nurse while retracting eyelids and manipulating lenses.
10. Assemble supplies at bedside.	Provides easy access to supplies.
11. **Remove lenses.** **A. Soft lenses**	
(1) Wash hands. Put on disposable gloves if there are cuts, scratches or dermatological lesions on nurse's hands.	Reduces transmission of microorganisms.
(2) Add a few drops of sterile saline solution to the person's eye.	Lubricates eye to facilitate lens removal.
(3) Tell the person to look straight ahead.	Eases tipping of lens during removal.
(4) Using middle finger, retract lower eyelid.	Exposes lower edge of lens.
(5) With pad of index finger of same hand, slide lens off cornea onto white of eye.	Positions lens for easy grasping. Use of finger pad (rather than fingernail) prevents injury to cornea and damage to lens.
(6) Pull upper eyelid down gently with thumb of other hand, and compress lens slightly between thumb and index finger.	Causes soft lens to double up. Air enters underneath lens to release suction.
(7) Gently pinch lens, and lift out.	Protects lens from damage. Avoid allowing lens edges to stick together. Soft lenses can be easily torn.

Step 11A(8) Ensure lenses are placed in correct storage compartments.

(8) Clean and rinse lens. Place lens in proper storage case compartment: R for right lens and L for left lens (see illustration).	Ensures proper lens will be reinserted into correct eye. Proper storage prevents cracking or tearing.
(a) After removing one lens from case, apply one or two drops of cleaning solution to lens in palm of hand (use cleaner recommended by lens manufacturer or eye-care practitioner).	Removes tear components, including mucous, lipids and proteins that collect on lens.

STEPS	RATIONALE
(b) Rub lens gently but thoroughly on both sides for 20–30 seconds. Use index finger (soft lenses) or little finger or cotton bud soaked with cleaning solution (rigid lenses) to clean inside lens. Be careful not to turn lens wrong side out or touch or scratch lens with fingernail.	It is easier to manipulate and clean lens using fingertips. Cleans microorganisms from all surfaces.
(c) Holding lens over emesis basin, rinse thoroughly with manufacturer-recommended rinsing solution (soft lenses) or cold tap water (rigid lenses).	Removes debris and cleaning solution from lens surface. Rinsing methods and solutions differ for each type of lens.
(d) Place lens in proper storage case compartment and fill with storage solution recommended by manufacturer or eye-care practitioner.	Disinfects lens, removes residue, enhances wetability of lens and prevents scratches to lens that can be caused by a dry case.
(9) Repeat Steps (2) to (8) for other lens. Secure cover over storage case. Label with person's name and room number.	Proper storage prevents damage to or loss of lenses.
(10) Dispose of towel, remove gloves and wash hands.	Reduces transmission of infection.
B. Rigid lenses	
(1) Wash hands, and put on gloves if needed.	Reduces transmission of microorganisms.
(2) Be sure lens is positioned directly over cornea. If lens is not positioned directly over cornea, have the person close their eyelids, place index and middle fingers of one hand on the eyelid just beside the lens and beneath it and gently but firmly massage lens back into place.	Correct position of lens allows easy removal from eye.
(3) Place index finger on outer corner of the person's eye, and draw skin gently back towards ear.	Tightens eyelid against eyeball.
(4) Tell the person to blink. Do not release pressure on the eyelid until blink is completed.	Manoeuvre should cause lens to dislodge and pop out. Lid margins must clear top and bottom of lens until the blink.
(5) If lens fails to pop out, gently retract eyelid beyond edges of lens. Press lower eyelid gently against lower edge of lens.	Pressure causes upper edge of lens to tip forwards.
(6) Allow both eyelids to close slightly, and grasp lens as it rises from eye. Cup lens in hand.	Manoeuvre causes lens to slide off easily. Protects lens from breakage.

STEPS	RATIONALE
(7) A lens suction cup can be used to remove lenses from the eyes of confused or unconscious people. Gently apply suction cup to lens surface, and lift out.	
(8) Clean and rinse lens (see Step 11A(8)). Place lens in proper storage case compartment: R for right lens and L for left lens. Centre lens in storage case, convex side down.	The lenses may not have the same prescription. Proper storage prevents breaking, scratching, chipping and discolouration.
(9) Repeat Steps (2) to (8) for other lens. Secure cover over storage case. Label with person's name and room number.	Proper storage prevents damage to or loss of lenses.
(10) Dispose of towel, remove gloves and wash hands.	Reduces spread of infection and keeps person's environment neat.
12. Insert lenses.	
A. Soft lenses	
(1) Remove right lens from storage case and rinse with recommended rinsing solution; inspect lens for foreign materials, tears or other damage.	
(2) Check that lens is not inverted (inside out). Apply wetting agent (sterile saline).	Soft lens is inverted if the edge has a lip; it is in proper position if curve is even from base to rim.
(3) Using middle or index finger of opposite hand, retract upper lid until iris is exposed.	
(4) Use middle finger of the hand holding lens to pull down lower lid.	
(5) Tell the person to look straight ahead; gently place lens directly on cornea; release lids slowly, starting with lower lid.	Ensures lens is centred, free of trapped air and comfortable.
(6) Tell the person to close their eyes slowly and roll them towards lens if not on the cornea.	
(7) Tell person to blink a few times.	
(8) Ask the person to open their eyes. Check for blurred vision or discomfort.	
(9) Repeat Steps (1) to (8) for left eye.	
(10) Discard used solution in the storage case.	
(11) Wash lens case with soap and a scrubber. Rinse case in sterile saline or a known disinfectant. Store dry.	Prevents multiplication of amoebae and bacteria.

STEPS	RATIONALE
B. Rigid lenses	
(1) Remove right lens from storage case; attempt to lift lens straight up (see illustration).	Sliding lens out of case can cause scratches on the surface.
(2) Rinse with recommended rinsing solution; inspect lens for foreign material or chips.	Hot water causes lens to warp.
(3) Wet lens on both sides, using prescribed wetting solution.	
(4) Place right lens concave side up on tip of index finger of dominant hand (see illustration).	Inner surface of lens should face up so that it is applied against cornea.
(5) Instruct the person to look straight ahead while retracting both upper and lower lids; place lens gently over centre of cornea (see illustration).	
(6) Ask the person to close their eyes briefly and avoid blinking.	Helps to secure position of lens.
(7) Ask the person to open their eyes. Check for blurred vision or discomfort.	
(8) Repeat Steps (1) to (7) for left eye.	
(9) Discard used solution. See Step 12A(11) for case cleansing.	

Step 12B(1) Rinsing lens lifted from storage case.

Step 12B(4) Placement of rigid lens on index finger of dominant hand.

STEPS	RATIONALE
 Step 12B(5) Person looks straight ahead as lens is placed over centre of cornea.	
13. Ask the person whether the lens feels comfortable after removal and reinsertion of lenses.	Determines if any debris is caught between lens and cornea. Lens should be removed if person experiences discomfort.
14. Inspect the eye (over time) for signs of ocular infection.	
15. Assess the person's visual acuity (see Chapter 27).	Determines improvement in visual perception.
16. Observe the person for signs of eye injury.	

RECORDING AND REPORTING

- Record or report any signs/symptoms of visual alterations or corneal irritation noted during procedure.
- Record on nursing care plan times of lens insertion and removal if person is going to surgery or special procedure.

HOME CARE CONSIDERATIONS

- People must be taught not to wear lenses in presence of noxious or irritating vapours or fumes because these irritants can cause damage to lens surface.

ARTIFICIAL EYES People with artificial eyes have had an **enucleation** of an entire eyeball as a result of tumour growth, severe infection or eye trauma. Some artificial eyes are permanently implanted. Others can be removed for routine cleaning. A person with artificial eyes usually prefers to care for their own eyes. Nurses should respect the person's wishes and help by assembling needed equipment.

A person may at times require assistance in prosthesis removal and cleaning. To remove an artificial eye, the nurse retracts the lower eyelid and exerts slight pressure just below the eye (Figure 29-9). This action causes the artificial eye to rise from the socket because the suction holding the eye in place has been broken. A small, rubber bulb syringe or medicine dropper bulb may also be used to create a suction effect. The suction created by placing the bulb tip directly over the eye and squeezing lifts the eye from the socket.

The artificial eye is usually made of glass or plastic. Warm Normal saline cleans the prosthesis effectively. Also clean the edges of the eye socket and surrounding tissues with soft gauze moistened in saline or clean tap-water. Signs of infection should be reported immediately because bacteria can spread to the neighbouring eye, underlying sinuses or even underlying brain tissue. To reinsert the eye, retract the upper and lower lids and gently slip the eye into the socket, fitting it neatly under the upper eyelid. An artificial eye may be stored in a labelled container filled with tap-water or saline.

Ear care

Routine ear care involves cleaning the ear with the end of a moistened washcloth, rotated gently into the ear canal. When cerumen is visible, gentle, downward retraction at the entrance of the ear canal may cause the wax to loosen and slip out. People must be cautioned never to use sharp objects such as

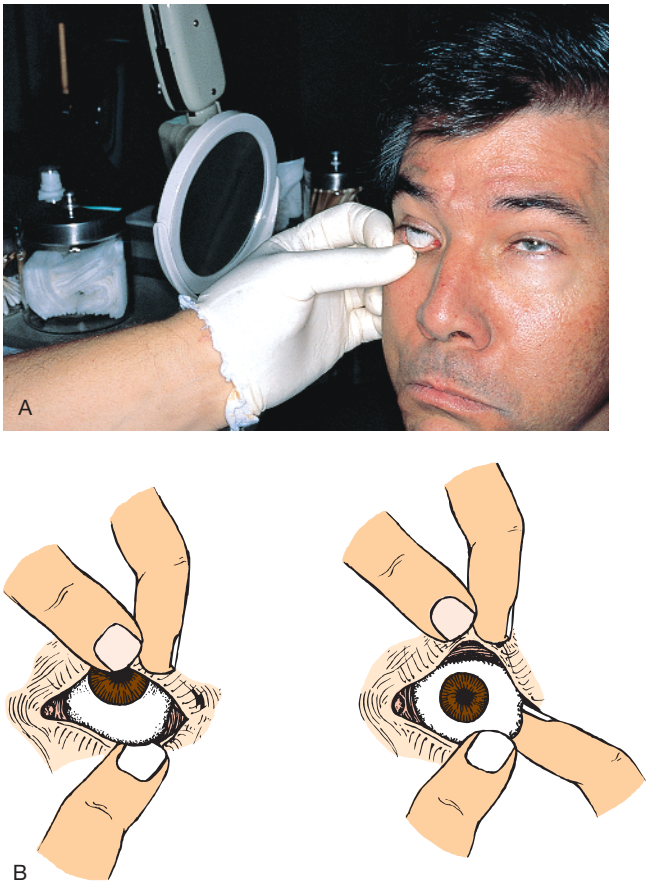


Figure 29-9 Removal of prosthetic eye.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

bobby pins or paper clips to remove earwax. The use of such objects can traumatise the ear canal and rupture the tympanic membrane. Use of cotton-tipped applicators should also be avoided because they can cause earwax to become impacted within the canal.

Children and older adults commonly have impacted cerumen. Excessive or impacted cerumen can usually be removed only by irrigation. If a person has a history of a perforated eardrum or if perforation is discovered during assessment, the procedure is contraindicated. The initial part of the procedure is the administration of prescribed ear drops to soften and loosen the wax, which is commenced 3–5 days before the irrigation component (Stevenson 2010). Then the instillation of approximately 250 mL of warm water (37°C) into the ear canal mechanically washes away loosened wax. Cold or hot water causes nausea or vomiting. The person may sit or lie on the side with the affected ear up. A small curved basin is placed under the affected ear to catch the irrigating solution. A Water Pik (set on No. 2 setting) or a bulb-irrigating syringe can be used to irrigate the ear canal. The tip of the syringe or Water Pik should not occlude the canal, to avoid exerting pressure against the tympanic membrane. Gentle irrigation directed at the top of the canal loosens the cerumen from the sides of the canal. After the canal is clear, nurses wipe off any moisture from the ear and inspects the canal for remaining cerumen.

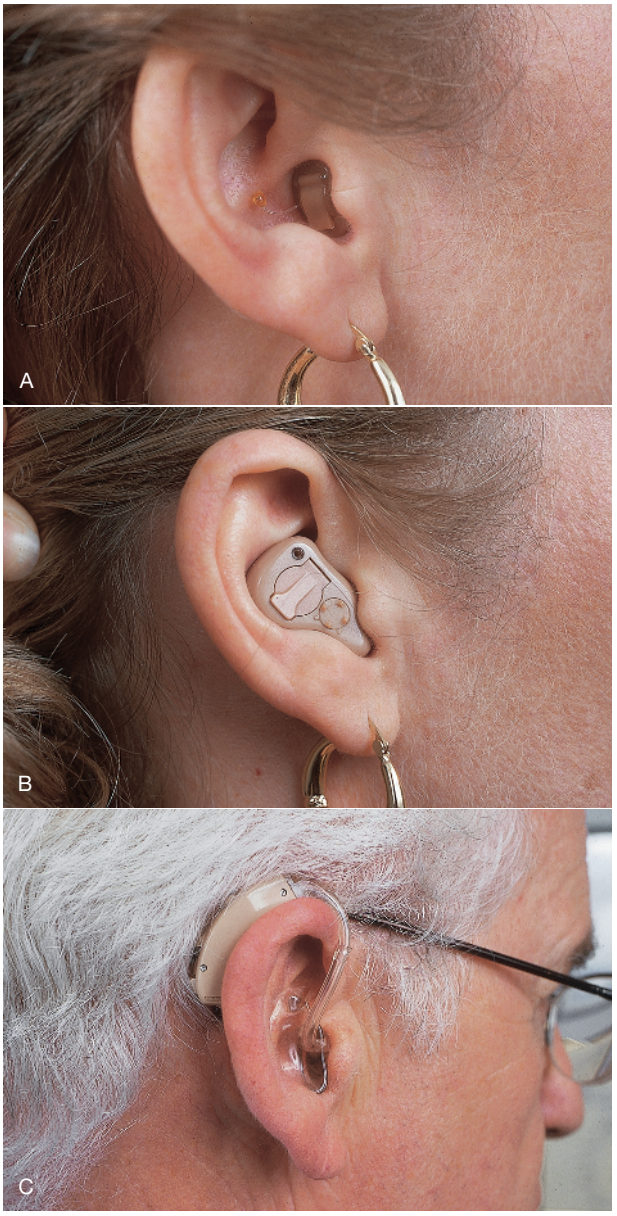

Figure 29-10 Three common types of hearing aids.

A, In-the-canal (ITC). B, In-the-ear (ITE). C, Behind-the-ear (BTE).

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

HEARING-AID CARE Hearing aids are instruments made up of miniature parts working together as a system to amplify sound in a controlled manner. The aid receives normal low-intensity sound inputs and delivers them to the person's ear as louder outputs. Newer classes of hearing aids can reduce background noise interference; computer chips placed in the aids allow for fine adjustments to the specific person's hearing needs. Hearing aids are used by people both hard-of-hearing (slight or moderate hearing loss) and deaf (severe hearing loss).

There are three popular types of hearing aids. An in-the-canal (ITC) aid (see Figure 29-10A) is the newest, smallest and least visible and fits entirely in the ear canal. It has cosmetic appeal, is easy to manipulate and place in the ear, does not interfere with

wearing glasses or using the telephone and can be worn during most types of physical exercise. However, it requires adequate ear diameter and depth for proper fit. It does not accommodate progressive hearing loss, and it requires manual dexterity to operate, insert and remove, and change batteries. Also, cerumen tends to plug this model more than the others.

An in-the-ear (ITE, or intra-aural) aid (see Figure 29-10B) fits into the external auditory canal and allows for more fine-tuning. The auditory augmentation is more powerful and stronger, and it is therefore useful for a wider range of hearing loss than the ITC aid. It is easy to position and adjust and does not interfere with wearing glasses. It is, however, more noticeable than the ITC aid and is not recommended for people with moisture or skin problems in the ear canal.

A behind-the-ear (BTE, or post-aural) aid (see Figure 29-10C) hooks around and behind the ear and is connected by a short, clear, hollow plastic tube to an ear mould inserted into the external auditory canal. It allows for fine-tuning. It is the largest of the three aids and is useful for people with rapidly progressive hearing loss or manual dexterity difficulties, or those who find partial ear occlusion intolerable. Disadvantages are that it is more visible and may interfere with wearing glasses and using a phone and it is more difficult to keep in place during physical exercise.

Box 29-10 reviews guidelines for the care and cleaning of a hearing aid.

BOX 29-10 Hearing aids – care and use

- Initially wear a hearing aid for 15–20 minutes; then gradually increase time up to 10–12 hours.
- Once inserted, turn the aid slowly to one-third or half volume.
  - A whistling sound indicates incorrect ear mould insertion.
  - Adjust volume to a comfortable level for talking at a distance of 1 metre.
- Sit close to speaker in noisy situations. Continue to be observant of non-verbal cues.
- Do not wear aid in bath, under heat lamps or an overhead hair dryer or in very wet, cold weather.
- Batteries last 1 week with daily wearing of 10–12 hours.
  - Remove or disconnect battery when not in use.
  - Routinely check battery compartment: Is it clean? Are batteries inserted properly? Is compartment shut all the way?
- Replace ear moulds every 2–3 years.
- Dials on hearing aid should be clean and easy to rotate, creating no static during adjusting.
- Routinely check cord or tubing (depending on type of aid) for cracking, fraying and poor connections.
- It takes time to adapt to using a hearing aid but, with patience, the wearer will be rewarded.

Modified from Touhy TA, Jett KF 2011 Ebersole and Hess' toward healthy aging: human needs and nursing response, 8th edn. Mosby, St Louis.

Nasal care

The person can usually remove secretions from the nose by gently blowing into a soft tissue. Caution the person against harsh blowing that creates pressure capable of injuring the eardrum, nasal mucosa and even sensitive eye structures. Bleeding from the nares is a sign of harsh blowing.

If the person is unable to remove nasal secretions, nurses assist by using a wet washcloth or a cotton-tipped applicator moistened in water or saline. The applicator should never be inserted beyond the length of the cotton tip. Excessive nasal secretions can also be removed by gentle suctioning.

Oxygen via nasal prongs dries and irritates the nasal tissues. Removing crusted secretions with damp gauze or a fine washcloth should be followed by applying a non-petroleum-based lubricating ointment.

When a person has nasogastric, feeding or endotracheal tubes inserted through the nose, the tape anchoring the tube should be changed by nurses at least once a day.

Person's room environment

Attempting to make a person's room as comfortable as the home is one of the priorities of nurses. The person's room should be comfortable, safe and large enough to allow the person and visitors to move about freely. Nurses can control room temperature, ventilation, noise and odours to create a more comfortable environment. Keeping the room neat and orderly also contributes to the person's sense of wellbeing.

MAINTAINING COMFORT The nature of what constitutes a comfortable environment depends on the person's age, severity of illness and level of normal daily activity. Depending on the person's age and physical condition, the room temperature should be maintained between 20°C and 23°C. Infants, older adults and the acutely ill may need a warmer room. However, certain ill people benefit from cooler room temperatures to lower the body's metabolic demands.

A good ventilation system keeps stale air and odours from lingering in the room. Nurses must protect the acutely ill, infants and older adults from drafts by ensuring that they are adequately dressed and covered with a lightweight blanket.

Good ventilation also reduces lingering odours caused by draining wounds, vomitus, bowel movements and unemptied urinals. Nurses should always empty and rinse bed pans or urinals promptly. Thorough hygiene measures are the best way to control body or breath odours. Healthcare institutions prohibit smoking within the facility. Room deodorisers can help remove many unpleasant odours but should be used with discretion in consideration of the person's possible embarrassment. As well, many people who are ill seem to be more sensitive to odours. Before using room deodorisers nurses should determine that the person is not allergic to or sensitive to the deodoriser itself. Strong personal odours on nurses (perfumes, lingering cigarette odours, halitosis, body odour) are offensive and disturbing to many ill people, and nurses need to practise excellent hygiene as well.

Ill people seem to be more sensitive to common hospital noises (e.g. intravenous pump alarms, suction apparatus or trolleys leaving a lift). Until the person is familiar with hospital noises, nurses should try to control the noise level. This can help the person gain necessary sleep. Explaining the source of any

unfamiliar noise to the person and family members can also be helpful.

Proper lighting is necessary for everyone's safety and comfort. A brightly lit room is usually stimulating, but a darkened room is best for rest and sleep. Room lighting can be adjusted by closing or opening curtains, regulating overbed and floor lights and closing or opening room doors. When entering a person's room at night, refrain from abruptly turning on an overhead light unless necessary.

ROOM EQUIPMENT A typical hospital room contains the following basic pieces of furniture: overbed table, bedside locker, chairs, lamp and bed (Figure 29-11). Extended-care and rehabilitation facilities may have similar equipment. The overbed table rolls on wheels and can be adjusted to various heights over the bed or a chair. Usually two storage areas are under the tabletop. The table provides an ideal working space for nurses performing procedures. It also provides a surface on which to place meal trays, toiletry items and objects frequently used by the person. The bed pan and urinal should not be placed on the overbed table. The bedside locker is used to store the person's personal possessions and hygiene equipment. The telephone, water jug and drinking cup are commonly found on a bedside locker.

Most hospital rooms contain an armless straight-backed chair and an upholstered lounge chair with arms. The lounge chair is used by the person and visitors and is usually placed at the foot of the bed or beside it. Straight-backed chairs are convenient when temporarily transferring the person from the bed, such as during bedmaking.

Each room usually has an overbed light and a floor or table lamp. Movable lights that extend over the bed from the wall should be positioned for easy reach but moved aside when not in use. Gooseneck or special examination lights are portable standing lamps used to provide extra light during bedside procedures.

Other equipment usually found in a person's room includes a call light, a television set, a blood-pressure gauge, oxygen and vacuum wall outlets and personal-care items. Special equipment designed for comfort or positioning people includes foot boots (Figure 29-12) and footboards, special mattresses (see Chapter 26) and bed boards.

Figure 29-11 Typical hospital room.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

BEDS A seriously ill person may remain in bed for a long time. Because a bed is the piece of equipment used most by a hospitalised person, it should be designed for comfort, safety and adaptability for changing positions.

The typical hospital bed has a firm mattress on a metal frame that can be raised and lowered horizontally. More and more hospitals are converting the standard hospital bed to one in which the mattress surface can be electronically adjusted for person comfort. Different bed positions are used to promote person comfort, minimise symptoms, promote lung expansion and improve access during certain procedures (Table 29-8).

The position of a bed is usually changed by electrical controls incorporated into the person's call light and in a panel on the side or foot of the bed. It is important for nurses to become familiar with use of the bed controls. Ease in raising and lowering a bed and in changing position of the head and foot eliminates undue musculoskeletal strain on nurses. Nurses should instruct the person in the proper use of controls and caution them against raising the bed to a position that might cause harm.

Beds contain safety features, such as locks on the wheels or castors. Wheels should be locked when the bed is stationary to prevent accidental movement. Side rails usually protect people

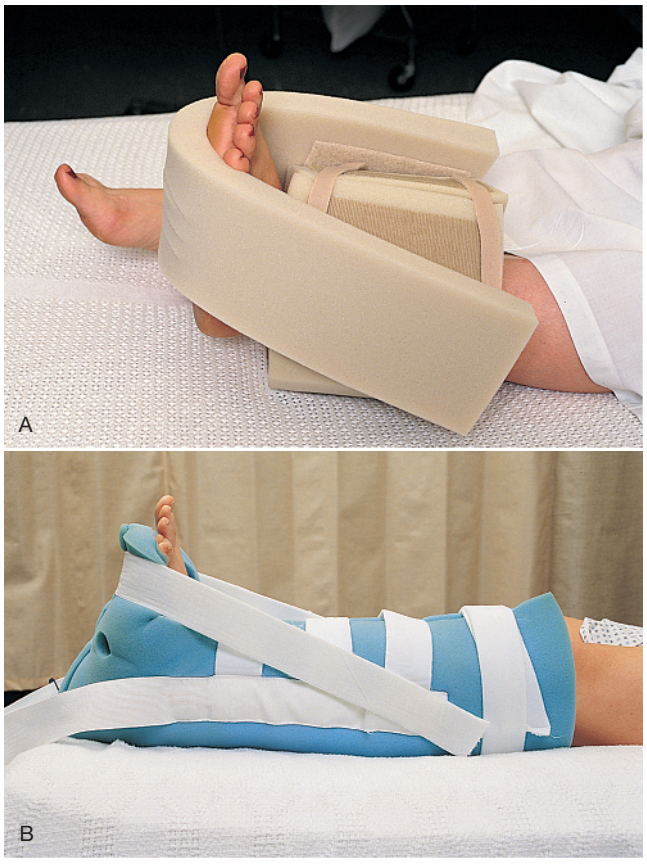

Figure 29-12 Types of foot boot.

A, Foot boot. B, Foot boot with lower leg extension.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

TABLE 29-8 Common bed positions

Fowler's 	Head of bed raised to angle of 45 degrees or more; semi-sitting position; foot of bed may also be raised at knee	Preferred while person eats Used during nasogastric tube insertion and nasotracheal suction Promotes lung expansion
Semi-Fowler's 	Head of bed raised approximately 30 degrees; inclination less than Fowler's position; foot of bed may also be raised at knee	Promotes lung expansion Used when people receive gastric feedings to reduce regurgitation and risk of aspiration
Trendelenburg's 	Entire bed frame tilted with head of bed down	Used for postural drainage Facilitates venous return in people with poor peripheral perfusion
Reverse Trendelenburg's 	Entire bed frame tilted with foot of bed down	Used infrequently Promotes gastric emptying Prevents oesophageal reflux
Flat 	Entire bed frame horizontally parallel with floor	Used for people with vertebral injuries and in cervical traction Used for people who are hypotensive Generally preferred by people for sleeping

from accidental falls, but they may actually cause a confused person to fall (as the person tries to climb over them). The headboard can be removed from most beds – this is important when the medical team needs easy access to the head, such as during cardiopulmonary resuscitation.

BEDMAKING A person's bed should be kept clean and comfortable. This requires frequent inspections to be sure linen is clean, dry and free of wrinkles. When people are diaphoretic, have draining wounds or are incontinent, nurses should check often for soiled bedclothes, and change them accordingly.

Nurses usually make a bed in the morning after the person's bath or while the person is showering, sitting in a chair eating or out of the room for procedures or tests. Throughout the day nurses straighten bedclothes that become loose or wrinkled. The bedclothes should be checked for food particles after meals and for wetness or soiling. Bedclothes that are soiled or wet should be changed.

When changing bedclothes, nurses follow principles of medical asepsis by keeping soiled sheets away from the uniform (Figure 29-13). Soiled linen is placed in special linen bags before discarding in a dirty linen basket. To avoid air currents, which can spread microorganisms, never fan linen. To avoid transmitting infection, do not place soiled linen on the floor. If clean linen touches the floor, it is immediately discarded.

Figure 29-13 Holding sheets away from the uniform prevents contact with microorganisms.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Nurses must use proper body mechanics when making a bed (see Chapter 33). The bed should always be raised to the nurse's hip-level, or if two nurses are making the bed, to the level of the

hip of the shorter of the two nurses. This should be done before changing linen so that the nurses do not have to bend or stretch over the mattress. Nurses move back and forth to opposite sides of the bed when applying new linen. Body mechanics also become important when turning or repositioning the person in bed.

When a person is confined to bed, bedmaking activities should be organised to conserve time and energy (Skill 29-9). The person's privacy, comfort and safety are all-important when making a bed. Using side rails, keeping call lights within the person's reach and maintaining the proper bed position help promote comfort and safety. After making a bed, always return it to the lowest horizontal position to prevent accidental falls should the person get in and out of the bed alone.

When possible, nurses should make the bed while it is unoccupied (Box 29-11 on p. 982). Use judgement in choosing

SKILL 29-9

Making an occupied bed

Delegation considerations

Making an occupied bed can be undertaken by nurse assistants under the guidance of the registered nurse (RN).

- Inform caregiver how to properly position people during occupied bedmaking procedure.
- Tell caregiver what to do if wound drainage, dressing material, drainage tubes or intravenous (IV) tubing becomes dislodged or is found in the bedclothes.
- Instruct caregiver on what to do if person becomes tired.
- Stress safety procedures, e.g. location of call system for easy access in the event that staff assistance is needed.
- Instruct caregiver to report any changes in person's level of consciousness, breathing patterns, level of pain or dizziness.

Equipment

- Dirty linen bag(s)
- Mattress pad (needs to be changed only when soiled)
- Bottom sheet (flat or fitted)
- Drawsheet
- Top sheet
- Blanket
- Bedspread
- Waterproof pads and/or bath blankets (optional)
- Pillowcases
- Bedside chair or table
- Disposable gloves (optional)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine whether person is incontinent or has excess drainage on bedclothes.	Determines need for protective waterproof pads or extra bath blankets on bed.
2. Check chart for orders or specific precautions for movement and positioning.	Ensures safety and use of proper body mechanics for nurse and person.
3. Explain procedure to person, noting that person will be asked to turn on side to roll over bedclothes.	Minimises anxiety and promotes cooperation.
4. Prepare needed equipment and supplies.	
5. Wash hands.	Minimises spread of infection.

STEPS	RATIONALE
6. Assemble and arrange equipment on bedside chair or table. Remove unnecessary equipment.	Provides for smooth procedure and ensures comfort.
7. Draw room curtain around bed or close door.	Maintains privacy, thus promoting emotional and physical comfort.
8. Lower side rail on near side of bed. Remove call light.	Provides easy access to bed and bedclothes.
9. Adjust bed height to comfortable working position.	Minimises strain on nurse's back. It is easier to remove and apply bedclothes evenly to bed in flat position.
10. Loosen top sheet at foot of bed.	Makes bedclothes easier to remove.
11. Remove bedspread and blanket separately by folding them into squares and placing them in dirty linen bag (if not to be reused). Do not allow bedclothes to contact uniform. Do not fan or shake bedclothes.	Reduces transmission of microorganisms.
12. If blanket and bedspread are to be reused, fold by bringing top and bottom edges together. Fold into neat squares and place over back of chair.	Facilitates replacement and prevents wrinkling.
13. Cover person with bath blanket in following manner. Unfold bath blanket over top sheet. Ask person to hold top edge of bath blanket. If person is unable to help, tuck top of bath blanket under shoulder. Grasp top sheet under bath blanket at person's shoulders, and bring down to foot of bed. Remove, and discard it into linen bag. *Optional:* Person may be covered with loosened top sheet if bath blanket is not available.	Bath blanket provides warmth and keeps body parts covered during bedclothes removal.
14. With help from another nurse, slide mattress towards head of bed.	If mattress slides towards foot of bed when head of bed is raised, it is difficult to tuck bedclothes in and is uncomfortable for person.
15. Position person on their side on far side of bed, facing away. Adjust pillow under head. Be sure furthest side rail is up.	Provides space for placement of clean linen. Side rail ensures safety.
16. Loosen bottom sheet, moving from head to foot of bed.	
17. Fanfold first drawsheet and then bottom sheet towards person (see illustration). Tuck edges of linen just under buttocks, back and shoulders. Do not fanfold mattress pad if it is to be reused.	Provides maximum work space for placing clean linen. Later, when person turns to other side, soiled linen can easily be removed.
18. Wipe off moisture on mattress with towel and appropriate disinfectant.	Reduces transmission of microorganisms.
19. Apply clean linen to exposed half of bed:	

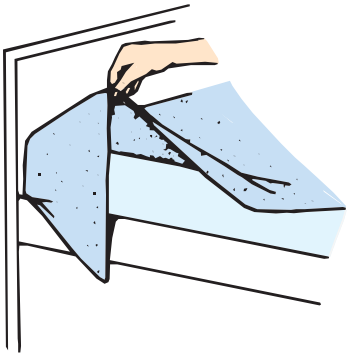
STEPS	RATIONALE
a. Place clean mattress pad on bed by folding it lengthwise with centre crease in middle of bed. Fanfold top layer over mattress. (If pad is reused, simply smooth out wrinkles.)	Applying linen over bed in successive layers minimises energy and time nurse uses in bedmaking.
b. Unfold bottom sheet lengthwise so centre crease is situated lengthwise along centre of bed. Fanfold sheet's top layer towards centre of bed alongside person (see illustration). Smooth bottom layer of sheet over mattress, and bring edge over near side. Allow sheet's edge to hang about 25 cm over mattress edge. Lower hem of bottom sheet should lie seam down and even with bottom edge of mattress.	Proper positioning of linen on one side ensures that adequate linen will be available to cover opposite side of bed. Keeping seam edges down eliminates irritation to person's skin.

Step 17 Fanfold used linen and tuck under person.

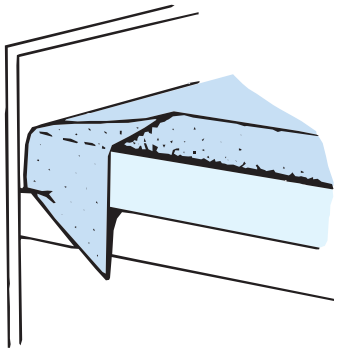
Step 19b Fanfold clean linen towards centre of bed.

20. Mitre bottom sheet at head of bed: a. Face head of bed diagonally. Place hand away from head of bed under top corner of mattress, near mattress edge, and lift. b. With other hand, tuck top edge of bottom sheet smoothly under mattress so side edges of sheet above and below mattress would meet if brought together. c. Face side of bed, and pick up top edge of sheet at approximately 45 cm down from top of mattress (see illustration). d. Lift sheet, and lay it on top of mattress to form neat triangular fold, with lower base of triangle even with mattress side edge (see illustration). e. Tuck lower edge of sheet, which is hanging free below mattress, under mattress (see illustration). Tuck with palms down without pulling triangular fold. f. Hold part of sheet covering side edge of mattress in place with one hand. With other hand, pick up top of triangular linen fold, and bring it down over side of mattress. Tuck this portion of sheet under mattress (see illustrations).	Mitred corner cannot be loosened easily, even if person moves about frequently in bed.

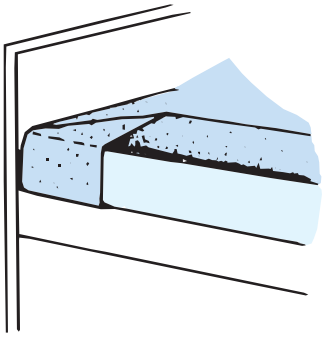
STEPS	RATIONALE



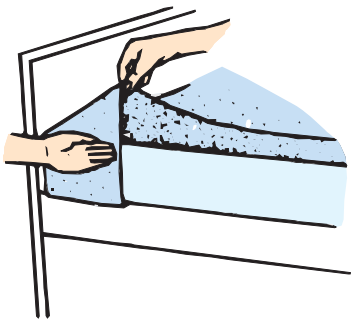
Step 20c Pick up top edge of sheet.

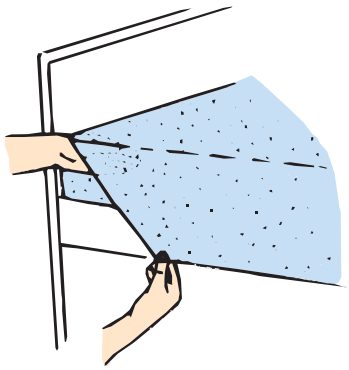


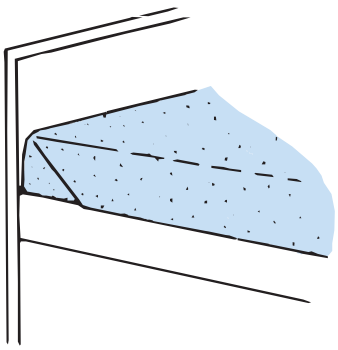
Step 20d Lay sheet over bed to form triangular fold.



Step 20e Tuck free end of sheet under.







Step 20f Bring triangular fold neatly down over side of mattress and tuck in.

21. Tuck remaining part of sheet under mattress, moving towards foot of bed. Keep sheet smooth.	Folds of sheet are a source of irritation.
22. *Optional:* Open drawsheet so it unfolds in half. Lay centre fold along middle of bed lengthwise, and position sheet so it will be under buttocks and torso (see illustration). Fanfold top layer towards person with edge alongside back. Smooth bottom layer out over mattress and tuck excess edge under mattress (keep palms down).	Drawsheet is used to lift and reposition person. Placement distributes most of bodyweight over sheet.
23. Place waterproof pad over drawsheet with centre fold against person's side. Fanfold far half towards person.	Used to protect bedclothes from soiling.
24. Raise side rail on working side, and go to other side.	Maintains safety.
25. Lower side rail. Help person to roll slowly onto other side, over folds of linen (see illustration).	Exposes opposite side of bed for removal of soiled linen and placement of clean linen.

STEPS	RATIONALE
 Step 22 Positioning drawsheet.	 Step 25 Assisting person to roll onto other side to expose folds of clean linen.
26. Loosen edge of soiled linen from underneath mattress.	Makes linen easier to remove.
27. Without allowing dirty linen to touch uniform, remove soiled linen by folding it into a bundle or square, with soiled side turned in. Discard it into linen bag.	Reduces transmission of microorganisms.
28. Spread clean, fanfolded linen smoothly over edge of mattress from head to foot of bed (see illustration).	Smooth linen will not irritate person's skin.
29. Help person roll back into supine position. Reposition pillow.	Person's comfort is maintained.
30. Mitre corner of bottom sheet at foot of bed (see Step 20). When tucking corner, be sure sheet is smooth and free of wrinkles.	Wrinkles and folds can cause mechanical irritation to skin.
31. Facing side of bed, grasp remaining edge of bottom sheet, keep back straight, and pull as excess linen is tucked under mattress. Proceed from head to foot of bed. (Avoid lifting mattress during tucking to ensure fit.) Mitre remaining corners, keeping bottom sheet smooth.	Proper use of body mechanics while tucking linen prevents injury to nurse.
32. Smooth fanfolded drawsheet over bottom sheet. Grasp edge of sheet with palms down, lean back and tuck sheet under mattress. Tuck from middle to top and to bottom.	Tucking first at top or bottom may pull sheet sideways, causing poor fit.
33. Place top sheet over person with centre fold lengthwise down middle of bed. Open sheet from head to foot, and unfold it over person (see illustration).	Sheet should be equally distributed over bed by correctly positioning centre fold.

STEPS	RATIONALE
 Step 28 Spreading out folds of clean linen over other half of bed.	 Step 33 Unfolding top sheet over person
34. Without allowing dirty linen to touch uniform, ask person to hold clean top sheet, or tuck sheet around shoulders. Remove bath blanket, and discard it into linen bag.	Sheet prevents exposure of body parts. Having person hold sheet encourages participation in care.
35. Place blanket on bed, unfolding it so that crease runs lengthwise along middle of bed. Unfold blanket to cover person. Top edge should be parallel with edge of top sheet and 15–20 cm down from top sheet's edge.	Blanket should be placed to cover person completely and provide adequate warmth.
36. Place bedspread over bed according to Step 35. Be sure top edge extends about 2.5 cm above blanket's edge. Tuck top edge over and under top edge of blanket.	Bedspread gives bed neat appearance and provides extra warmth.
37. Make cuff by turning edge of top sheet down over top edge of blanket and bedspread.	Smooth cuff protects person's face from rubbing against blanket or bedspread.
38. Standing on one side at foot of bed, lift mattress corner slightly with one hand, and tuck top bedclothes under mattress. Top sheet and blanket are tucked under together. Be sure they are loose enough to allow for movement of person's feet. Horizontal toe pleat may be made (see illustration).	Tucking all top bedclothes together gives neat appearance. Pressure sores can develop on person's toes and heels from feet rubbing between tight-fitting bed sheets.  Step 38 Optional toe pleat.

STEPS	RATIONALE
39. Make modified mitred corner with top sheet, blanket and bedspread: a. Pick up side edge of top sheet, blanket and bedspread approximately 45 cm up from foot of mattress. Lift to form triangular fold, and lay it on bed. b. Tuck lower edge of sheet, which is hanging free below mattress, under mattress. Do not pull triangular fold. c. Pick up triangular fold, and bring it down over mattress while holding bedclothes in place along side of mattress. Do not tuck tip of triangle.	Modified mitred corner secures top bedclothes but keeps an even edge of blanket and top sheet draped over mattress.
40. Raise side rail. Make other side of bed; spread top sheet, blanket and bedspread out evenly; fold top edge of bedspread over blanket, and make cuff with top sheet (see Step 37); make modified mitred corner at foot of bed (see Step 39).	Side rail protects person from accidental falls.
41. Change pillowcase:	
a. Have person raise head. While supporting neck with one hand, remove pillow.	Prevents injury during flexion and extension of neck.
b. Remove soiled case and discard into linen bag.	
c. Grasp clean pillowcase at centre of closed end. Gather case, turning it inside out over hand holding it. With same hand, pick up middle of one end of pillow. Pull pillowcase down over pillow with other hand and be sure pillow corners fit evenly in corners of pillowcase.	Method makes it easy to slide pillowcase over pillow. Poorly fitting case constricts fluffing and expansion of pillow.
42. Support person's head under neck, and place pillow under head.	Prevents hyperextension of neck muscles.
43. Place call light within person's reach; return bed to comfortable position.	Ensures safety and comfort.
44. Open room curtains. Rearrange furniture. Place personal items within easy reach on overbed table or bedside stand. Return bed to comfortable height.	Promotes sense of wellbeing.
45. Place dirty linen in main dirty linen bag or chute; wash hands.	Prevents transmission of microorganisms.

RECORDING AND REPORTING

- Bedmaking need not be documented. Record the person's vital signs and symptoms only if there are changes.

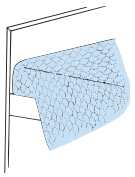
HOME CARE CONSIDERATIONS

- Assess the primary caregiver's ability to safely make an occupied bed.
- Assess the home laundry facilities to plan for the frequency with which the linen can be laundered.
- Assess the amount of linen in the home for the anticipated amount of linen changes needed.

BOX 29-11 Procedural guidelines for making an unoccupied bed

Equipment: Linen bag, mattress pad (change only when soiled), bottom sheet (flat or fitted), drawsheet (optional), top sheet, blanket, bedspread, waterproof pads (optional), pillowcases, bedside chair or table, disposable gloves (if linen is soiled), washcloth and antiseptic cleanser.

1. Determine whether the person has been incontinent or whether excess drainage is on sheets. Gloves will be necessary.
2. Assess activity orders or restrictions in mobility in planning whether person can get out of bed for procedure. Assist to bedside chair or recliner.
3. Lower side rails on both sides of bed and raise bed to comfortable working position.
4. Remove soiled linen and place in laundry bag. Avoid shaking or fanning linen.
5. Reposition mattress and wipe off any moisture using a washcloth moistened in antiseptic solution. Dry thoroughly.
6. Apply all bottom linen on one side of bed before moving to opposite side.
7. Be sure fitted sheet is placed smoothly over mattress. To apply a flat unfitted sheet, allow about 25 cm to hang over mattress edge. Lower hem of sheet should lie seam down, even with bottom edge of mattress. Pull remaining top portion of sheet over top edge of mattress.
8. While standing at head of bed, mitre top corner of bottom sheet (see Skill 33-9, Step 20).
9. Tuck remaining portion of unfitted sheet under mattress.
10. Optional: Apply drawsheet, laying centre fold along middle of bed lengthwise. Smooth drawsheet over mattress and tuck excess edge under mattress, keeping palms down.
11. Move to opposite side of bed and spread bottom sheet smoothly over edge of mattress from head to foot of bed.
12. Apply fitted sheet smoothly over each mattress corner. For an unfitted sheet, mitre top corner of bottom sheet, making sure corner is taut.
13. Grasp remaining edge of unfitted bottom sheet and tuck tightly under mattress while moving from head to foot of bed. Smooth folded drawsheet over bottom sheet and tuck under mattress, first at middle, then at top and then at bottom.
14. If needed, apply waterproof pad over bottom sheet or drawsheet.
15. Place top sheet over bed with vertical centre fold lengthwise down middle of bed. Open sheet out from head to foot, being sure top edge of sheet is even with top edge of mattress.
16. Make horizontal toe pleat: stand at foot of bed and fanfold sheet 5–10 cm across bed. Pull sheet up from bottom to make fold approximately 15 cm from bottom edge of mattress (see Skill 29-9, Step 38).
17. Tuck in remaining part of sheet under foot of mattress. Then place blanket over bed with top edge parallel to top edge of sheet and 15–20 cm down from edge of sheet. (Optional: Place additional blanket over bed.)
18. Make cuff by turning edge of top sheet down over top edge of blanket and bedspread.
19. Standing on one side at foot of bed, lift mattress corner slightly with one hand, and with other hand tuck top sheet, blanket and bedspread under mattress. Be sure toe pleats are not pulled out.
20. Make modified mitred corner with top sheet, blanket and bedspread. After triangular fold is made, do not tuck tip of triangle (see illustration).



21. Go to other side of bed. Spread sheet, blanket and bedspread out evenly. Make cuff with top sheet and blanket. Make modified corner at foot of bed.
22. Apply clean pillowcase.
23. Place call light within the person's reach on bed rail or pillow and return bed to height allowing for person transfer. Help the person into bed.
24. Arrange the person's room. Remove and discard supplies. Wash hands.

the best time to have the person sit up in a chair while the bed is made. When making an unoccupied bed, nurses follow the same basic principles as for when the bed is occupied.

An unoccupied bed can be open or closed. In an *open bed*, the top covers are folded back so that a person can easily get into bed. In a *closed bed*, the top edges of the top sheet, blanket and bedspread are drawn up to the head of the mattress and under the pillows. A closed bed is prepared in a hospital room before a new person is admitted to that room. A surgical, recovery or postoperative bed is a modified version of the open bed. The top bedclothes are arranged for easy transfer of the person from a stretcher to the bed. The top sheets and bedspread are not tucked in or mitred at the corners. Instead, the top sheets are folded to one side or fanfolded to the bottom third of the bed (Figure 29-14). This makes it easier to transfer the person into the bed.

LINEN In any healthcare agency, it is important to have an adequate supply of linen to care appropriately for people. Many agencies have what are called 'nurse servers' either within or just outside a person's room, where a daily supply of linen is

SKILL 29-10

Making a postoperative bed

Delegation considerations

Making a postoperative (post-op) bed can be undertaken by nurse assistants under the direction of the registered nurse (RN).

- Dirty linen bag(s)
- Mattress pad
- Bottom sheet (flat or fitted)
- Drawsheet
- Top sheet
- Blanket
- Bedspread
- Pillowcases

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. The entire bed requires clean linen.	
2. Know the type of surgical procedure the person is having, to determine bedmaking.	
3. Remove soiled linen and place in laundry bag. Avoid shaking or fanning linen.	Minimises spread of infection.
4. Wash hands.	Minimises spread of infection.
5. Assemble and arrange equipment on bedside chair or table. Remove unnecessary equipment.	Provides for smooth procedure and ensures comfort.
6. Adjust bed height to comfortable working position.	Minimises strain on nurse's back. It is easier to remove and apply bedclothes evenly to bed in flat position.
7. Reposition mattress and wipe off any moisture using a washcloth moistened in antiseptic solution. Dry thoroughly.	
8. Apply all bottom linen on one side of bed before moving to opposite side.	
9. Be sure fitted sheet is placed smoothly over mattress. To apply a flat unfitted sheet, allow about 25 cm to hang over mattress edge. Lower hem of sheet should lie seam down, even with bottom edge of mattress. Pull remaining top portion of sheet over top edge of mattress.	

STEPS	RATIONALE
10. While standing at head of bed, mitre top corner of bottom sheet (see Skill 29-9, Step 20).	
11. Tuck remaining portion of unfitted sheet under mattress.	
12. *Optional:* Apply drawsheet, laying centre fold along middle of bed lengthwise. Smooth drawsheet over mattress and tuck excess edge under mattress, keeping palms down.	
13. Move to opposite side of bed and spread bottom sheet smoothly over edge of mattress from head to foot of bed.	
14. Apply fitted sheet smoothly over each mattress corner. For an unfitted sheet, mitre top corner of bottom sheet, making sure corner is taut.	
15. Tuck remaining part of sheet under mattress, moving towards foot of bed. Keep sheet smooth.	Folds of sheet are a source of irritation.
16. Grasp remaining edge of unfitted bottom sheet and tuck tightly under mattress while moving from head to foot of bed. Smooth folded drawsheet over bottom sheet and tuck under mattress, first at middle, then at top and then at bottom.	
17. Place top sheet over bed with vertical centre fold lengthwise down middle of bed. Open sheet out from head to foot, being sure top edge of sheet is even with top edge of mattress.	
18. Place blanket over bed with top edge parallel to top edge of sheet and 15–20 cm down from edge of sheet.	
19. Make cuff by turning edge of top sheet down over top edge of blanket.	Smooth cuff protects person's face from rubbing against blanket or bedspread.
20. Place bedspread over bed with top edge parallel to cuff of sheet.	

■ **Critical decision point: Edges of top bedding are not tucked under the mattress.**

21. The head and foot corners of the untucked top bedding are brought to the centre of bed to form right angles. The right angles are folded vertically and then horizontally, to resemble a package, which is placed in the centre of the bed.	Tucking the top bedding under the mattress may hamper the patient to enter the bed from a trolley.
22. Apply clean pillowcase.	

STEPS	RATIONALE
23. Apply bed brakes.	To prevent moving the bed accidentally when the client is shifted from a stretcher to the bed.
24. When the patient is transferred to the bed post-op, cover the patient by the top bedding immediately. Tuck top bedding and mitre corners at the end of the bed.	To prevent the patient from chilling and/or developing hypothermia.

RECORDING AND REPORTING

- Post-op bedmaking need not be documented. Record the person's vital signs and symptoms immediately following transfer into the post-op bed.

HOME CARE CONSIDERATIONS

- Nil

Figure 29-14 Surgical or recovery bed.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

stored. Because of the importance of cost control in health care, it is important not to bring excess linen into a person's room, because even if it is unused, it must be discarded for washing. This can increase an agency's costs. Excess linen lying around a person's room creates clutter and obstacles for personal care activities.

Before making the bed, it is important to collect the necessary bedclothes and the person's personal items. In this way nurses will have all equipment accessible to prepare the bed and room. Linen is pressed and folded to prevent the spread of microorganisms and to make bedmaking easier. When fitted sheets are not available, flat sheets are usually pressed with a centre crease to be placed down the centre of the bed. The sheets unfold easily to the sides, with creases often fitting over the mattress edge. A complete bedclothes change is not always necessary. Nurses may reuse the mattress pad, sheet, blanket and bedspread for the same person if they are not wet or soiled.

Linen must be disposed of correctly to minimise the spread of infection (see Chapter 25). Agency policies provide guidelines for the proper way to bag and dispose of soiled linen. When a person is discharged, all the bedclothes are sent to the laundry, the mattress and bed are cleaned by housekeeping staff and fresh bedclothes are put on the bed.

EVALUATING IMPACTS AND OUTCOMES

Person care

Evaluation of hygiene measures occurs both during and after performance of each particular skill. For example, as the person is being bathed, closely inspect the skin to see whether drainage or other soiling has been effectively removed from the skin's surface. Once the bath is complete, ask whether the person's comfort and relaxation have improved. When evaluating the effectiveness of hygiene measures, observe for changes in the person's behaviour. Do they assume a more relaxed position? Is the person free of body odour? Is the person able to fall asleep? Does the person's facial expression convey a sense of comfort?

Often it takes time for hygiene care to result in an improvement in the person's condition. The presence of oral lesions, a scalp infestation or skin excoriation will often require repeated measures and a combination of nursing interventions. Nurses will evaluate for improvement in the person's condition over time and determine whether existing therapies are effective.

Throughout evaluation, nurses consider the goals of care and gauge whether expected outcomes are achieved. A critical-thinking approach ensures that nurses consider all factors when evaluating the person's care (Figure 29-15). Nurses' knowledge base and experience provide important perspectives when they analyse observations made about a person. For example, if nurses see how dehydration of the oral mucosa clears with repeated hygiene, this helps in recognising when another person's progress is slow. The standards for evaluation are the expected outcomes established in the planning stage of the person's care. If outcomes are not met, the care plan may need to be revised. Nurses continue to apply critical-thinking attitudes when considering all evaluation findings.

Person expectations

The final part of the evaluation considers whether the person's expectations were met through hygiene care. Nurses might

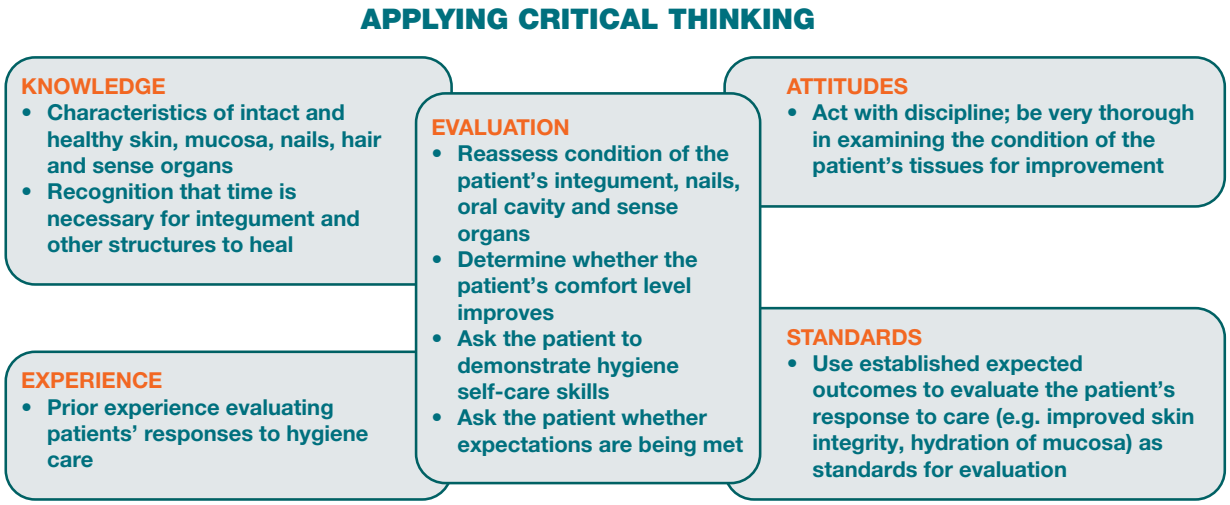


Figure 29-15 **Critical thinking associated with the evaluation phase for hygiene.**

ask: 'How do you feel since your bath and massage?', 'Are there ways you feel we can do a better job with your foot care?', 'What further measures do you think are necessary to keep your mouth clean and refreshed?'

The person's expectations are important guidelines in determining person satisfaction. Nurses must feel comfortable discussing the person's concerns and expectations. A caring approach can help facilitate discussion of these issues.

Key concepts

- Nurses determine a person's ability to perform self-care, and provide hygiene care according to the person's needs and preferences.
- During hygiene, nurses integrate other activities such as physical assessment and range-of-motion exercises.
- While providing daily hygiene needs, nurses use teaching and communication skills in developing a caring relationship with the person.
- Proper hygiene care requires an understanding of anatomy and physiology and sociocultural, economic and developmental factors.
- People's health beliefs indicate the likelihood of assuming health promotion behaviour, such as the maintenance of good hygiene.
- Nurses assess a person's physical and cognitive ability to perform basic hygiene measures, including muscle strength, flexibility and dexterity, balance, coordination, activity tolerance and ability to attend.
- Nurses maintain a person's privacy, comfort and safety when providing hygiene care.
- Culture plays a significant role in hygiene practices and preferences.
- Standard precautions should be observed by nurses during hygiene care when the risk of contacting body fluids is high, and always during perineal care.
- For people suffering symptoms such as pain or nausea, administering symptom relief therapies prior to hygiene will better prepare the person for any procedure.
- People with diabetes mellitus require special hygiene measures such as foot and nail care.
- Family members can usually help with hygiene measures but may need guidance in adapting techniques to fit person limitations.
- The person's room should be comfortable and safe, and large enough to allow the person and visitors to move about freely.
- Evaluation of hygiene care is based on the person's sense of comfort, relaxation, wellbeing and understanding of hygiene techniques.

Fostering sleep

Christopher J Gordon

Learning outcomes

Mastery of content will enable you to:

- characterise circadian rhythms and the 24-hour sleep–wake cycle
- discuss mechanisms that control sleep
- describe normal sleep cycle stages
- explain the functions of sleep
- compare and contrast the sleep requirements of different age groups
- identify factors that promote and disrupt sleep
- discuss characteristics of common sleep disorders, such as insomnia and sleep apnoea
- conduct a sleep history for a client
- identify nursing diagnoses appropriate for clients with sleep alterations
- identify nursing interventions designed to promote sleep for clients across the life span
- describe ways to evaluate sleep therapies.

Sleep is fundamental to life. We spend approximately one-third of our life doing it, yet we do not have a full understanding of the functions of sleep. We do know that sleep is a complex, homeostatic process involved in learning, memory, immunity, hormonal, metabolic and cellular restorative functions. Sleep is a natural component of all people's lives and involves a change in consciousness and reduction in sensory awareness of surroundings. People need different amounts of sleep and rest, but without adequate amounts, people may be vulnerable to poor health and illness. Physical and emotional health depends on the ability to fulfil basic human needs, one of which is sleep. Without adequate amounts of sleep and rest, the ability to maintain biological, psychological and social functions becomes more difficult. Inadequate rest and sleep is known to affect morbidity, and is likely to be contributory to mortality. As such, sleep is a fundamental need of all humans.

Seeking to understand sleep has been recognised for millennia, with the first documented text by the Greek physician Alcmaeon (c. 500 BC) stating that sleep was a loss of consciousness that coincided with blood flow away from the body surface. This description was extended by Hippocrates (c. 300 BC) who further related sleep to health (Kirsch 2011). The essential and unavoidable nature of sleep points to an evolutionary and adaptive role, and there are different theories of sleep which can be broadly classified into adaptation and restoration theories. Achieving optimum sleep quantity and quality is important for the promotion of good health, as well as recovery from illness. Nurses care for clients with a range of sleep problems, such as sleep disturbances, clients with sleep disorders and those who may develop sleep problems as a result of illness or hospitalisation. In addition, people may seek health care because they have a sleep problem that cannot be remediated without intervention. Illness can require people to need more sleep and rest than healthy people. The nature of illness, however, may prevent clients from gaining adequate sleep and recovery. The institutional environment of a hospital or long-term care facility and the activities of healthcare personnel can make sleep difficult and need to be addressed.

Identifying and treating clients' sleep problems is an important goal for nurses. To help clients, nurses need to understand the nature of sleep, the factors influencing sleep, and the clients' sleep habits. Impaired sleep impacts significantly on health and this risk is increased in clients with sleep disorders. Clients require an individualised approach based on their personal habits and patterns of sleep, as well as on the particular problem interrupting their sleep. Nursing interventions can be effective in resolving short- and long-term sleep disturbances.

Physiology of sleep

Sleep is a cyclical physiological process that alternates with longer periods of wakefulness, in an approximately one to two (wake to sleep) ratio. Sleep is a state of lower responsiveness to extrinsic stimuli compared to wakefulness. Sleep is not a passive state but a dynamic biological state characterised by distinct physiological responses over the course of the sleep bout. These are broadly divided into **non-rapid eye movement (NREM) sleep** and **rapid eye movement (REM) sleep** which can be quantified using electrophysiological measurements. In addition, there are changes in cardiovascular, endocrine, renal and respiratory function during sleep, with a general reduction in activity; however, the endocrine system releases several hormones during sleep which are influenced by the sleep state and circadian rhythms.

Sleep–wake cycle

An overarching feature of sleep regulation from a physiological perspective is the sleep–wake cycle. This cycle is regulated by two distinct physiological processes, one that promotes sleep, also called **sleep pressure**, and one that maintains wakefulness, which is controlled by the **circadian rhythm**. These two processes interact to regulate periods of sleep and wake in approximately 24-hour cycles. The two-process model was proposed to explain how the two separate mechanisms (sleep and wake) interact with each other (Borbély 1982). The model was constructed using a homeostatic drive for sleep, known as Process S, which builds up during the day and peaks prior to habitual bedtime (Figure 30-1). This causes an increase in sleep pressure, driving the individual to sleep and is related to the amount of time from the last sleep bout. In other words, the more you stay awake, the greater the Process S and the drive to produce sleep. Following sleep onset, this process dissipates rapidly as we sleep, thereby increasing the likelihood of awakening.

The other side of the equation is Process C, or the drive to awaken, which is regulated by the circadian system. In contrast, Process C builds up during the day such that individuals stay awake and alert (circadian drive for arousal), and declines in the evening when the alertness is decreased (Figure 30-1). At this time, the circadian release of melatonin promotes sleep initiation, which corresponds to peak sleep pressure. In the early morning period, melatonin secretion ceases and the circadian arousal drive is initiated, which eventually overpowers the sleep drive and awakening occurs.

These processes are complex and require other systems to be coordinated, such as the light–dark cycle

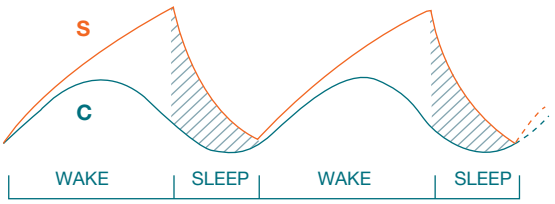

Figure 30-1 Two-process model of sleep regulation.

C is *Process C*, the circadian rhythm drive, which operates over approximately a 24-hour period and is governed by the master body clock. S is *Process S*, the sleep process, which is the change in sleep pressure and regulates sleep–wake homeostasis.

Adapted from Borbély, AA 1982 A two process model of sleep regulation. Hum Neurobiol 1(3):195–204.

of day and night. It should be noted that these processes are also influenced by genetics and external factors, such as shift work, stress, environmental temperature, and medications. When these processes are disturbed, the sleep–wake cycle can be impacted, leading to dysynchrony and potentially sleep disturbance and changes in arousal levels.

Circadian rhythms

People experience cyclical rhythms as part of their everyday life. Biological and psychological rhythms that oscillate around a 24-hour cycle are known as circadian rhythms (derived from Latin: *circa*, 'about', and *dies*, 'day'). The fluctuation and predictability of blood pressure, core body temperature, hormone secretion, sensory acuity and mood are all components of the 24-hour circadian cycle.

A master clock controls the intrinsic pattern of the circadian rhythms of the organs. This is located in the *suprachiasmatic nucleus* (SCN), which is above the optic chiasm behind the hypothalamus in the brain. It is important to note the location as the master clock receives cues from optic input (light–dark cycle) and the hypothalamus, which controls many autonomic nervous system functions. The SCN also controls the release of melatonin (produced by the pineal gland) and is also important in the sleep–wake cycle. In addition to the central master clock, there are a number of peripheral clocks which respond to inputs and are involved in the regulation of circadian rhythms and of the particular tissue where they are located.

As noted above, the circadian system is intricately involved in the sleep–wake cycle that assists with synchronisation of sleep. However, while these patterns may be entrained, the sleep–wake patterns of people vary widely and some people function best at different times of the day and night. This refers to an individual's chronotype, which can range from very early morning, to very late evening types (Roenneberg et al 2007). In extreme examples, an individual's chronotype can cause either an advance or delay in sleep such that the person either wakes too early or goes to sleep very late, and this can impact on their daytime function. These impacts are classified as circadian rhythm disorders and often are linked to melatonin release (Kanterman et al 2015).

Circadian rhythms can be disturbed when individuals are being cared for in healthcare facilities, as traditionally, these facilities fail to adapt care to an individual's sleep–wake cycle preferences. Routine-based nursing care can cause interruptions to sleep, or prevent clients from falling asleep at their usual time. For example, patient bed-bathing in intensive care units often occurs between 2.00 and 6.00 am, with 'freshen up' washes often given at 6.00 am (Coyer et al 2011). This suggests that nursing practice is being influenced by nursing shift times, rather than by patient sleep–wake cycles.

Circadian rhythms can be synchronised with other body functions. For example, changes in core body temperature have an intricate relationship with sleep. Typically, core body temperature peaks in the late afternoon, and decreases gradually in early evening with an accelerated drop prior to sleep onset. As such, nurses need to be aware of circadian rhythms to maximise the cycle rhythmicity of individuals despite their illness or hospitalisation.

Sleep state

Sleep involves a sequence of physiological states maintained by highly integrated central nervous system (CNS) activity that is associated with changes in the peripheral nervous, endocrine, cardiovascular, respiratory and muscular systems. Each sequence can be identified by specific physiological responses and patterns of brain activity. Instruments that measure brain activity and provide information about some structural physiological aspects of sleep are: *electroencephalogram* (EEG), which measures electrical activity in the cerebral cortex; *electromyogram* (EMG), which measures muscle tone; and *electro-oculogram* (EOG), which measures eye movements.

The initiation of sleep is not fully understood, but is thought to involve several discrete sections of the brain. It has been shown that the *ventrolateral preoptic area* (VLPO) in the hypothalamus acts like a 'sleep switch' which induces sleep following a build-up of metabolites during wake periods (Saper et al 2005). The VLPO together with the *reticular activating system* (RAS), located in the upper brainstem, and the other sites in the hypothalamus interact to maintain wakefulness and sleep.

Sleep stages

The quantity of sleep can be measured using self-reported sleep diaries. These provide a subjective assessment of how long the individual was asleep. For a more detailed and objective assessment of sleep, laboratory-based studies measuring several physiological signals are required. This is achieved using EEG, EMG and EOG signals that record brain, muscle and eye activity in the wake and sleep state. The synchronous measurement of cardiac and respiratory signals, including breathing frequency, oxygen saturations and heart rate, are also often included. Collectively, these signals are referred to as **polysomnography** (PSG), or in lay-terms, 'sleep studies'. Formal measurement of these signals is often required to diagnose sleep disorders (see later in the chapter).

The EEG, EMG and EOG signals are used to quantify different stages of sleep. Normal sleep involves two phases: non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep (Box 30-1). The quality of sleep from stage 1 to stage 4 becomes increasingly deep. Lighter sleep is characteristic of stages 1 and 2, and a person is more easily woken. Stages 3 and 4 involve a deeper sleep, called *slow wave sleep*, from which it is more difficult to rouse a person. REM sleep is characteristically at the end of NREM periods and is greater in the latter phases of the entire sleep cycle. It should be noted that sleep stages do not display numerical sequencing from stages 1 to 4 with REM over the course of the sleep episode. Individuals vary as to the sequencing of the stages, and in fact, often have several arousals during the sleep episode (without conscious recognition). However, REM does not occur until 90 minutes following sleep onset, and the NREM and REM cycles generally occur over 90-minute cycles, which means that most adults have about five cycles (90 minutes over 8 hours) (Figure 30-2).

Normally, the routine sleep pattern of an adult begins with a *pre-sleep period*, during which the person is aware only of a gradually developing sleepiness. This period normally lasts less than 15 minutes. Once asleep, the person usually passes through approximately five complete sleep cycles per night, each consisting of NREM sleep and a period of REM sleep. With each successive cycle, stages 3 and 4 shorten and the period of REM lengthens. REM sleep may last up to 60 minutes during the last sleep cycle. Not all people progress consistently through the usual stages of sleep. For example, a sleeper may fluctuate for short intervals between NREM stages 2, 3 and 4 before entering the REM stage. The amount of time spent in each stage varies over the life span (see Figure 30-3). The number of sleep cycles depends on the total amount of time the person spends sleeping.

BOX 30-1 Sleep cycle stages

Stage 1: NREM sleep

- Lightest level of sleep
- Transitional phase from wake to sleep and only lasts up to 7 minutes
- Person is easily aroused by sensory stimuli such as noise
- Awakened, person feels as though daydreaming has occurred

Stage 2: NREM sleep

- Period of sound sleep
- Relaxation progresses
- Arousal is still relatively easy
- Stage lasts 10–25 minutes
- Increasing levels of biological function relaxation

Stage 3: NREM sleep

- Deep sleep
- Sleeper is difficult to arouse and rarely moves
- Muscles are completely relaxed
- Breathing, blood pressure and heart rate decline but remain regular
- Dreaming more common than stage 1 and 2
- Stage lasts 15–30 minutes

Stage 4: NREM sleep

- Deepest stage of sleep
- Very difficult to arouse sleeper
- If sleep loss has occurred, sleeper will spend considerable portion of night in this stage
- Vital signs are significantly lower than during waking hours
- Dreaming more common than stage 1 and 2
- Stage lasts approximately 20–440 minutes

REM sleep

- Usually commences about 90 minutes after sleep has begun
- Typified by autonomic response of rapidly moving eyes, fluctuating heart and respiratory rates and increased or fluctuating blood pressure
- Loss of skeletal muscle tone occurs
- Gastric secretions increase
- Very difficult to arouse sleeper
- Duration of REM sleep increases with each cycle and averages 20 minutes
- Dreaming most often associated with REM
- Dreams can be vivid especially if awoken from REM
- Memory consolidation

KEY: NREM = non-rapid eye movement; REM = rapid eye movement.

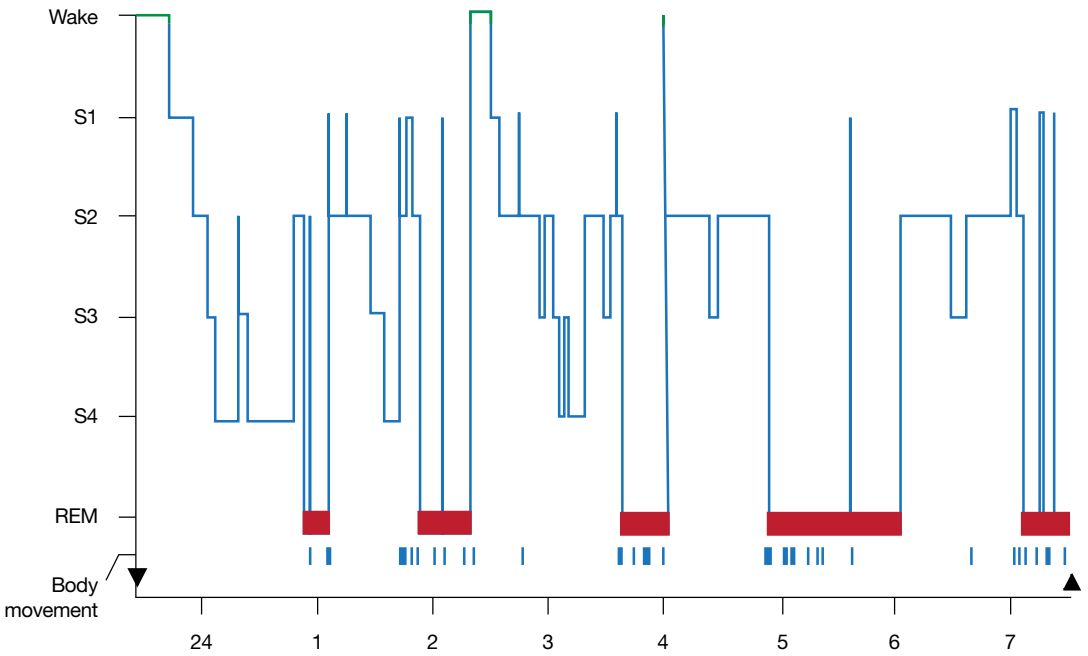

Figure 30-2 Sleep stage progression across an 8-hour sleep period.

This hypnogram displays sleep stages from an overnight in-laboratory polysomnography recording.

Carskadon MA, Dement W 2011 Normal human sleep: an overview. In MH Kryger, T Roth, WC Dement (eds), Principles and practices of sleep medicine, 5th edn. Elsevier Saunders, St Louis.

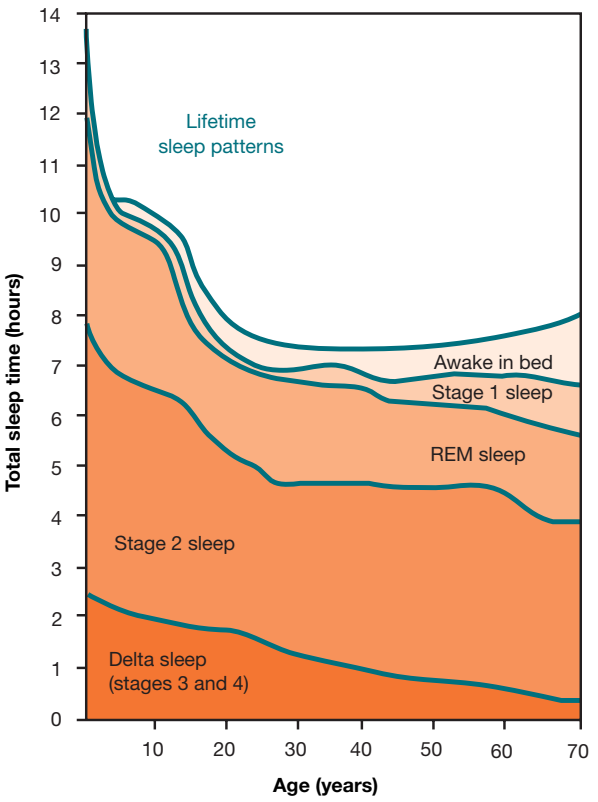

Figure 30-3 Distribution of sleep stages over the life span.

Adapted from Berman et al 1990 Sleep disorders: take them seriously. Patient Care 24:85.

Functions of sleep

Sleep is believed to contribute to physiological and psychological restoration. According to one theory, sleep is a time of restoration and preparation for the next period of wakefulness. During NREM sleep, biological functions slow; for example, a healthy adult's normal heart rate will be slower during sleep than during wakefulness. Clearly, restful sleep may be beneficial in preserving cardiac function.

Sleep appears to be needed to routinely restore biological processes. During deep slow wave (NREM stage 3 and 4) sleep, the body releases human growth hormone for the repair and renewal of epithelial and specialised cells such as neurons. Another theory about the purpose of sleep is that the body conserves energy during sleep. The skeletal muscles relax progressively, and the absence of muscular contraction preserves chemical energy for cellular processes. Lowering of the basal metabolic rate further conserves the body's energy supply.

REM sleep appears to be important for cognitive restoration. REM sleep is associated with changes in cerebral blood flow, increased cortical activity, increased oxygen consumption, and adrenaline release. This association may help with memory storage and learning. During sleep, the brain filters stored information about the day's activities.

The beneficial effects of sleep on behaviour often go unnoticed until a person develops a problem resulting from sleep deprivation. A loss of REM sleep can affect functioning of the CNS, with impacts on thought and behaviour. Some large-scale accidents resulting in significant loss of life, such as the 1986 nuclear accident in Chernobyl, have been attributed to human error associated with sleep deprivation. Traffic, home and work-related accidents caused by falling asleep cost millions of dollars a year – driving licence authorities in Australia and New Zealand require notification of any medical conditions that may affect driving before licences are issued, including conditions that may cause sleepiness.

Dreams

Although dreams occur during both NREM and REM sleep, the dreams of REM sleep are typically more vivid and elaborate. REM dreams may progress in content throughout the night from dreams about current events to emotional dreams of childhood or the past. Personality can influence the quality of dreams. For example, a creative person may have creative dreams, whereas a depressed person may dream of helplessness.

Most people dream about immediate concerns, such as an argument with a spouse, plans for a wedding or worries over work. Sometimes a person is unaware of fears represented in bizarre dreams. The ability to describe a dream and interpret its significance may help resolve personal concerns or fears.

Another theory suggests that dreams erase certain fantasies or nonsensical memories. Since most dreams are forgotten, many people have little dream recall and do not believe they dream at all. To remember a dream, a person must consciously think about it on waking. People who recall dreams vividly have usually woken just after a period of REM sleep.

• CRITICAL REFLECTION POINT

Take a moment to think about your own sleep patterns. What helps the quality and quantity of your sleep?

Effects of illness on sleep

Any illness that causes pain, physical discomfort (e.g. difficulty breathing) or mood problems (e.g. anxiety or depression) can result in sleep problems. People with physical or emotional alterations may have trouble falling or staying asleep. Illnesses may also force people to sleep in positions to which they are unaccustomed. For example, assuming an awkward position when an arm or leg has been immobilised in traction can interfere with sleep.

Respiratory disease often interferes with sleep. Clients with chronic lung diseases such as emphysema are short of breath and frequently cannot sleep without two or three pillows to raise their torso and head. Asthma, bronchitis and allergic rhinitis alter the rhythm of breathing and disturb sleep. A person with a common cold has nasal congestion, sinus drainage and a sore throat, which can all impair breathing and the ability to relax.

Coronary heart disease can be manifested by episodes of chest pain and abnormal heart rhythm which can occur at any time of day, including the early-morning hours. Hypertension often causes early-morning waking and increased fatigue. Hypothyroidism decreases stage 4 sleep, whereas hyperthyroidism causes people to take more time to fall asleep.

Nocturia, or the need to urinate during the night, disrupts sleep and leads to sleep fragmentation. This condition is most common in older adults with reduced bladder tone (see Chapter 18) or people with cardiac disease, diabetes or prostatic disease. After a person wakes repeatedly to urinate, returning to sleep may be difficult.

Older adults may experience restless legs syndrome (RLS), which is a neurological condition exacerbated at rest in which the individual is urged to move. People experience recurrent, rhythmical movements of the feet and legs and have an itching sensation deep in the muscles. Relief comes only from moving the legs, which prevents relaxation and subsequent sleep. RLS usually occurs before sleep onset when the individual is resting. Depending on how severely sleep is disrupted, RLS may be a relatively benign condition; however, it can have a significant impact on daytime functioning. RLS is likely to have a genetic component (Xiong et al 2010) with a consistent finding that people with RLS have iron deficiency anaemia (Kryger et al 2002). In contrast, people who have severe leg cramps during the night may have a problem with dietary imbalances, arterial circulation or spasticity from neurological problems.

Sleep disorders

Sleep disorders are relatively common in the Australian and New Zealand populations. Many adults have significant sleep problems ranging from inadequacy of sleep either in quantity or quality, through to disorders that have a significant health impact in terms of morbidity and mortality. These problems can be classified into six sleep disorders, with conditions related to insomnia, sleep-related breathing disorders, disorders of hypersomnolence, circadian rhythm disorders, parasomnias, and sleep-related movement disorders refer to Cleveland Clinic in *Online resources*.

Insomnia is a subjective report of a lack of sleep or non-restorative sleep and includes both short-term and chronic types. *Sleep-related breathing disorders* are those caused by obstruction of the upper airway, or are of central origin, such as sleep-related hypoventilation due to lung disease, other medical conditions or medication. *Disorders of hypersomnolence* refer to those disorders that cause daytime sleepiness, but cannot be attributed to problems with night-time sleep or circadian rhythm misalignment. Examples are narcolepsy and hypersomnia associated with psychiatric disorder, a medical condition or substance misuse.

Circadian rhythm sleep disorders arise from a misalignment between the timing of sleep and what is desired by the individual or as a societal norm; jet lag is a common example. The **parasomnias** are undesirable behaviours that occur predominantly during sleep: arousal disorders, partial arousals or disorders during transitions in the sleep cycle or from sleep to wakefulness. Common parasomnias are sleep walking, night terrors, tooth grinding (bruxism) or enuresis (Sateia 2014). The *sleep-related movement disorders* are those that cause simple, repetitive movement during sleep or wakefulness that causes sleep disturbance or affects bed partners. Finally, there are many medical and psychiatric sleep disorders that are associated with sleep and wake disturbances. These sleep disturbances are divided into those associated with psychiatric, neurological or other medical specialty disorders.

The total societal costs of the two most common sleep disorders, obstructive sleep apnoea (OSA) (see below) and insomnia, are substantial, with conservative estimates at more than $32 billion annually for Australian adults (Sleep Health Foundation 2011). As such, the nursing management of these clients, be it specifically for their sleep disorder or for another condition affecting sleep, needs to be focused and client-specific.

Insomnia

Insomnia is a complex, heterogeneous sleep disorder (Morin et al 2009, Vgontzas et al 2013) and is the most prevalent sleep disorder in Australia. Approximately 30% of Australians will be affected by the symptoms of insomnia, with 10% developing chronic insomnia (Bartlett et al 2008). Insomnia is described as a complaint of difficulty falling asleep, maintaining sleep, or having early-morning awakenings – or a combination of all three – with individuals reporting significant daytime impairment without any physical, mental or substance-related cause. Insomnia can be an acute (1 month) or chronic (greater than 3 months) condition. Insomnia may signal an underlying physical or psychological disorder and is more common in women (Zhang & Wing 2006).

People may experience transient insomnia as a result of situational stresses such as family, work or school problems, jet lag, illness, or loss of a loved one. Insomnia may recur, but between episodes the person is able to sleep well. An acute period of insomnia due to stressful situations may lead to chronic insomnia, which is often more difficult to treat.

Insomnia is also often associated with poor **sleep hygiene** habits and practices, such as eating large meals or drinking alcohol before going to bed. If the condition continues, the fear of not being able to sleep can be enough to cause wakefulness, and thus a cycle develops. During the day, people with chronic insomnia may have poor daytime performance, increased sleepiness, fatigue, anxiety and depression.

Due to the numerous aetiologies of insomnia, treatment is challenging and can involve several approaches (Unbehaun et al 2010). The ancient Egyptians recognised insomnia as a problem and used natural remedies to treat it (Kirsch 2011). It is important to identify any underlying physical or emotional problems that may be causing the night-time sleep problem and to offer appropriate solutions or treatment for these in the first instance. The most effective treatment regimen involves a 'stepped care' approach, whereby people with insomnia are provided a non-pharmacological approach using cognitive behavioural therapy (CBT). This focuses on assisting the individual to recognise and change behaviours and thoughts that may influence their sleep habits (Espie 2009). If this treatment is unsuccessful, individuals may then progress to more one-on-one individualised treatments prescribed by a sleep clinician. Treatment can also be symptomatic, including improving sleep hygiene measures, biofeedback and relaxation techniques. For individuals with acute insomnia, a short-term course of sedative–hypnotics in combination with CBT may be required (Schutte-Rodin et al 2005).

Sleep apnoea

Sleep apnoea is a disorder characterised by partial or complete upper-airway obstruction causing apnoea for periods of 10 seconds or longer with an associated oxygen desaturation during sleep. There are three types of sleep apnoea: central, obstructive and mixed apnoea (which has both a central and an obstructive component).

Obstructive sleep apnoea (OSA) is the second most prevalent sleep disorder in the middle-aged population (Punjabi 2008) with the moderate–severe form of OSA independently associated with an increase in morbidity

and mortality (Marshall et al 2014). OSA causes a serious decline in arterial oxygen level. People with OSA are at increased risk of cardiac dysrhythmia, right heart failure, pulmonary hypertension, angina, stroke and hypertension. Middle-aged men are usually thought to be more frequently affected; however, obesity-related hypertension and the metabolic syndrome (which can occur in both children and adults) can be associated with impaired respiratory mechanics and depressed respiratory control during sleep and with severe morbidity and high mortality.

OSA occurs when the muscles or structures of the oral cavity or throat relax during sleep. The upper airway becomes partially or completely blocked, and nasal airflow is diminished (hypopnoea) or stopped (apnoea). The severity of the disorder is characterised by the number of apnoeas and hypopnoeas per hour, with a threshold of 15 events per hour considered the gold standard for diagnosis of OSA (Balk et al 2011). The person still attempts to breathe because chest and abdominal movement continues, which often results in loud snoring and snorting sounds. When breathing is partially or completely diminished, each successive diaphragmatic movement becomes stronger until the obstruction is relieved.

Structural abnormalities, such as a deviated septum, nasal polyps, certain jaw configurations or enlarged tonsils, predispose a client to obstructive apnoea. The effort to breathe during sleep results in arousals from deep sleep, often to the stage 2 cycle. In serious cases, hundreds of hypopnoea/apnoea episodes can occur every hour, resulting in severe interference with deep sleep. Excessive daytime sleepiness (EDS) is the most common complaint of people with OSA. Those with severe OSA may report taking daytime naps and experiencing a disruption in their daily activities because of sleepiness, and in some cases the condition may predispose the client to accidents and injury.

Central sleep apnoea involves dysfunction in the brain's respiratory control centre. The impulse to breathe temporarily fails, and nasal airflow and chest wall movement cease. The oxygen saturation of the blood falls. This condition is seen in people with brainstem injury, muscular dystrophy and encephalitis and in people who breathe normally during the day. Less than 10% of sleep apnoea is predominantly central in origin. People with central sleep apnoea tend to wake during sleep and therefore complain of insomnia and EDS. Mild and intermittent snoring is also present.

The client with sleep apnoea is often significantly deprived of restorative sleep. In addition to complaints of EDS, sleep attacks, fatigue, car accidents and poor work performance are common (Basoglu & Tasbakan 2014). In Australia, private and commercial drivers who have sleep disorders require medical clearance to retain a driver's licence (Austroads 2014). Sleep apnoeas are a significant health problem and nurses need to be aware of the treatment options best suited to individual patients and clients. Treatment includes therapy for underlying cardiac or respiratory complications, and any emotional or other problems that may arise as a result of the symptoms of this disorder. Management usually begins with lifestyle changes and a weight-loss program. One of the most effective therapies for sleep apnoea is the use of a **continuous positive airway pressure** (CPAP) device, which requires the client to wear a mask over the nose or mouth during sleep. Room air is delivered through the mask at a high pressure to prevent upper-airway collapse and therefore prevents periods of hypopnoea and apnoea. The CPAP device is portable and is particularly effective for obstructive apnoea. In cases of severe sleep apnoea, the tonsils, uvula or portions of the soft palate may be surgically removed. However, the majority of patients do not need surgery and CPAP plays a key role in their management of sleep.

Narcolepsy
