Narcolepsy is a dysfunction of the mechanisms that regulate the sleep and wake states. EDS is the most common complaint associated with this disorder. During the day a person may suddenly feel an overwhelming wave of sleepiness and fall asleep. REM sleep can occur within 15 minutes of falling asleep. Cataplexy, or sudden muscle weakness during intense emotions such as anger, sadness or laughter, may occur at any time during the day. If the cataplectic attack is severe, the client may lose voluntary muscle control and fall to the floor. A person with narcolepsy may have dreams that occur as the person is falling asleep and are difficult to distinguish from reality (called hypnagogic hallucinations). Sleep paralysis, or the feeling of being unable to move or talk just before waking or falling asleep, is another symptom of narcolepsy. Some studies suggest a genetic link for narcolepsy (Longstreth et al 2007).

A significant problem for the person with narcolepsy is that they fall asleep uncontrollably at inappropriate times. Unless this disorder is understood, a sleep attack can easily be mistaken for laziness, lack of interest in activities or drunkenness. Typically, the symptoms first begin to arise in adolescence and may be confused with the EDS that is thought to commonly occur in teens. Narcoleptics are treated with stimulants that may only partially increase wakefulness and reduce sleep attacks, and medications

that suppress cataplexy and the other REM-related symptoms. Brief daytime naps no longer than 20 minutes may help reduce subjective feelings of sleepiness. Factors that increase a narcoleptic's drowsiness should be avoided, for example, alcohol, heavy meals, exhausting activities, long-distance driving, long periods of sitting, hot stuffy rooms.

Parasomnias

The parasomnias are sleep problems that are more common in children than in adults. Parasomnias that occur among older children include somnambulism (sleepwalking), night terrors, nightmares, nocturnal enuresis (bed-wetting) and teeth grinding (bruxism). If an adult has any of these problems, they may be an indicator of a more serious disorder. Specific treatment for parasomnias varies; however, in all cases it is important to support clients and maintain their safety. For example, sleepwalkers are unaware of their surroundings and are slow to react, so the risk of falls is high.

Normal sleep requirements and patterns

As we saw in Figure 30-3, sleep is different across the life span and there are characteristic changes that occur both in sleep duration and the type of sleep. The sleep and rest patterns of people entering healthcare facilities, such as hospitals, can easily be affected by their illness, the unfamiliar surroundings and healthcare routines. The extent of change in usual sleep and rest patterns experienced by a patient or client in a healthcare facility depends on the client's physiological and psychological states and the physical environment, such as background noise and the work patterns of caregivers. Bed rest is considered different from sleep, but may also be a component of a client's health condition or treatment. Some critical care and acute care settings have introduced policies to restrict visiting and allow rest periods for patients in the afternoon to improve sleep. An Australian study investigating the effectiveness of a scheduled 'quiet time' intervention in acute wards found that it reduced perceived noise by half, and patients were more than twice as likely to be asleep during the quiet-time period compared with patients in the control ward (Gardner et al 2009).

Neonates

The neonate up to the age of 3 months averages about 16 hours of sleep a day with continuous sleep periods of up to 4 hours. The neonate experiences both non-REM and REM sleep but with a marked difference from adults. Neonates' sleep commences with REM, and this is related to the lack of entrainment of circadian rhythms (Davis et al 2004). Neonates wake often and become overly responsive to stimuli, such as hunger, pain or cold. For the first week of life, the neonate sleeps almost constantly.

Infants

Infants usually develop a night-time pattern of sleep by 3 months of age. By 3 months, circadian rhythms have been established leading to sleep concentration and sleep onset aligned with NREM sleep. The infant may take several naps during the day, but usually sleeps an average of 9–11 hours during the night for a total daily sleep time of 15 hours. About 30% of sleep time is spent in the REM cycle. Awakening commonly occurs early in the morning, although it is not unusual for an infant to wake during the night. If waking during the night becomes routine, the problem may be with diet because hunger frequently wakes a child. A breastfed infant usually sleeps for shorter periods, with more frequent awakenings than a bottle-fed infant. A large infant sleeps longer than a smaller one because of greater stomach capacity. Compared with older children, REM sleep makes up a larger proportion of infant sleep. In contrast with newborns in whom sleep and wakefulness alternate throughout a 24-hour period, by 3 months of age the longest sleep period is at night.

Toddlers

By the age of 2 years children are usually sleeping through the night and taking daily naps. Total sleep averages 12 hours a day and the percentage of REM sleep continues to fall. Children over 3 years of age often give up daytime naps and it is common for toddlers to wake during the night. Toddlers may be unwilling to go to bed at night. This unwillingness may be due to a need for autonomy or a fear of separation from parents. Toddlers have a need to explore and satisfy their curiosity, which may explain why some of them try to delay bedtime (see Chapter 16).

Preschoolers

On average, a preschooler sleeps about 12 hours a night (about 20% is REM). By the age of 5 years, the preschooler rarely takes daytime naps as social factors begin to influence their daytime activity (Jenni & O'Connor 2005). The preschooler usually has difficulty relaxing or quietening down after long, active days. A preschooler may also have problems with bedtime fears, waking up, nightmares or sleep terrors. Parents are most successful in getting a preschooler to bed by establishing a consistent ritual that includes some quiet activity before bedtime. Ordinarily,

experts do not recommend that a child be allowed to sleep with parents. However, in some cultures sharing a bed or room with parents is an accepted sleeping practice.

School-age children

The amount of sleep needed during the school years varies according to levels of activity, cultural and family norms and states of health. The school-age child enters a wakeful time in life and usually does not require a nap during the day. Sleep times are highly individualised, depending on activity levels, growth, age and state of health. The 7-year-old can usually be persuaded to go to bed by encouraging quiet activities, whereas an older child often resists sleeping because of unawareness of fatigue or their increasing need to be independent.

Adolescents

Pre-adolescence and adolescence is a time of substantial change in sleep patterns. At a time when sleep needs increase, the typical pre-adolescent (approx. 10–12 years) and adolescent (approx. 12–19 years) is subject to a number of social changes that often reduce the amount of time spent sleeping (Gradisar et al 2011). School and peer demands, after-school social activities, social media engagement and part-time jobs may result in compressed time available for sleep. Adolescents often go to bed later and rise earlier during the secondary school years. A common societal expectation is that adolescents require less sleep than pre-adolescents; however, epidemiological data indicate that many adolescents are not receiving adequate sleep (Gamble et al 2014). Because of lifestyle demands that shorten the time available for sleep and probable physiological need, teenagers often experience **excessive daytime sleepiness**. Performance in school, vulnerability to accidents, and behaviour and mood problems can be often be directly attributed to insufficient sleep. Parents, teachers and teens themselves often lack knowledge about what is adequate sleep, and may need education to improve what can become a significant health problem for teens.

WORKING WITH DIVERSITY

Focus on children

Snoring is relatively common in children and obstructive sleep apnoea is related to snoring. Obstructive sleep apnoea can have serious consequences in adults and also may affect children negatively. Studies have shown a strong link between childhood obesity and paediatric obstructive sleep apnoea. However, it is not known if obstructive sleep apnoea affects non-obese children's development. A recent study found that in non-obese twins (one with obstructive sleep apnoea and one without) that treatment with adeno-tonsillectomy improved growth and development. This means that obstructive sleep apnoea in non-obese children can impact on growth and development.

Reference

Zhang XM et al 2015 The effect of obstructive sleep apnoea syndrome on growth and development in nonobese children: a parallel study of twins. J Pediatr 166 (3):646–50.

• CRITICAL REFLECTION POINT

Anh is a 14-year-old who regularly engages with friends by social media after 11.00 pm. Some nights, especially over the weekend, he games or chats to friends – sometimes until 2.00 am. Anh is the captain of the school hockey team but is experiencing great difficulty getting up for early training and weekend games. Sometimes he arrives late for training. What sleep hygiene practices could you recommend to Anh?

Young adults

Most young adults (approximately 20–39 years) average 6–8½ hours of sleep a night, but this can vary widely. Young adults rarely take regular naps. Approximately 20% of sleep time is spent in REM sleep, a pattern which remains consistent through to middle adulthood. Healthy young adults require adequate sleep to participate in daily activities. However, it is common for lifestyle demands to interrupt usual sleep patterns. The stresses of jobs, family relationships and social activities may lead to insomnia (i.e. difficulties initiating and/or maintaining sleep) and the use of medication for sleep. Long-term use of such medications can disrupt sleep patterns and make the insomnia problem worse. Daytime sleepiness contributes to an increased number of accidents, decreased productivity and interpersonal problems in this age group. Obesity, depression and subjective sleep estimation are common risk factors for sleep problems in this age group (Bixler et al 2005).

Middle-aged adults

During middle adulthood (approx. 40–59 years) the total time spent sleeping at night begins to decline. The amount of **slow wave sleep** begins to fall – a decline that continues with advancing age. Sleep disturbances are often initially diagnosed among people in this age group, even when the symptoms of a disorder have been present for several years. Insomnia is particularly common, probably because of the physiological changes and stresses of middle age. Sleep disturbances can be caused by anxiety, depression or certain physical ailments. Women experiencing menopausal symptoms may have insomnia and increased sleep disturbances.

Older adults

The total amount of sleep decreases and the quality of sleep appears to deteriorate for many older adults. Episodes of REM sleep tend to shorten. There is a progressive decrease in slow wave sleep, and some older adults have almost no deep sleep at all. Older adults often wake earlier and fall asleep during the daytime, which is also thought to affect the quality of their night-time sleep.

Changes in an older person's sleep pattern may be due to changes in the central nervous system that affect sleep regulation. Sensory impairment, which is common with ageing, may also reduce an older person's sensitivity to time cues that maintain circadian rhythms. Variability in the sleep behaviours of older adults is common.

Factors affecting sleep

A number of factors affect the quantity and quality of sleep. Often a single factor may not be the only cause of a sleep problem. Physiological, psychological and environmental factors can alter the quality and quantity of sleep.

Sleep deprivation

Sleep deprivation is a problem many people experience as it is often related to sleep disturbances. Sleep deprivation involves decreases in the quantity and quality of sleep and inconsistency in the timing of sleep. When sleep becomes interrupted or fragmented, changes in the normal sequencing of the sleep cycles occur.

Families with a new baby will experience temporary sleep deprivation, for example. Healthcare workers may be particularly prone to sleep deprivation due to long work schedules and rotating shifts. Other causes may include illness (e.g. fever, difficulty breathing, pain), emotional stress, medications, environmental disturbances (e.g. noise, comfort, temperature) and variability in the timing of sleep due to caring roles or shift work. A cumulative sleep deprivation can develop even in patients who are sedated.

People's responses to sleep deprivation are highly variable. Clients may experience a variety of physiological and psychological symptoms (Box 30-2) with the severity of symptoms often related to the duration of sleep deprivation. The most effective treatment for sleep deprivation is elimination or correction of factors that disrupt the sleep pattern. Hospitalisation makes clients particularly vulnerable to sleep fragmentation and sleep deprivation leading to daytime drowsiness. Nurses can play an important role in identifying treatable sleep deprivation problems and planning care to improve the quality and quantity of sleep.

BOX 30-2 Sleep deprivation symptoms

Physiological symptoms

Ptosis, blurred vision
Fine motor clumsiness
Decreased reflexes
Slowed response time
Decreased reasoning and judgement
Decreased auditory and visual alertness
Cardiac arrhythmias

Psychological symptoms

Confusion and disorientation
Increased sensitivity to pain
Irritable, withdrawn, apathetic
Excessive sleepiness
Agitation
Hyperactivity
Decreased motivation

Drugs and other substances

Sleepiness and sleep deprivation are common side effects of some commonly prescribed medications (Box 30-3). These medications may alter sleep and impair daytime alertness (Bryant & Knight 2014). Sometimes, medications prescribed for sleep may cause more problems than benefits by locking the person into a cycle of dependence. Older adults often take a variety of drugs to control or treat chronic illness, and the combined effects of several drugs can also seriously disrupt sleep. Alcohol, caffeine, recreational drugs and the timing and type of food intake will also affect the quality of sleep in most people.

Lifestyle

A person's daily routine may influence their sleep patterns. Those who are inactive or nap frequently during the day may have difficulty sleeping at night. Similarly, other alterations in routine that can disrupt sleep patterns include performing unaccustomed heavy work, engaging in late-night social activities and changing evening mealtimes. A person working a rotating shift (e.g. 2 weeks of day shifts followed by a week of night shifts) often has difficulty adjusting to the altered sleep schedule. The body's internal clock might be set at 11.00 pm, but the work schedule forces sleep at 9.00 am instead. The person may be able to sleep only 3 or 4 hours because the body's clock perceives that it is time to be awake and active. Difficulties with maintaining alertness during work time can result in decreased and even hazardous performance

BOX 30-3 Drugs and their effects on sleep

Hypnotics
- Interfere with reaching deeper sleep stages
- Provide only temporary (1 week) increase in quantity of sleep
- Eventually cause 'hangover' during day: excessive drowsiness, confusion, decreased energy
- May worsen sleep apnoea in older adults

Diuretics
- Cause nocturia

Antidepressants and stimulants
- Suppress rapid eye movement (REM) sleep
- Decrease total sleep time

Alcohol
- Speeds onset of sleep
- Disrupts REM sleep
- Awakens person during night and causes difficulty returning to sleep

Caffeine
- Prevents person from falling asleep
- May cause person to awaken during night

Beta-adrenergic blockers
- Cause nightmares
- Cause insomnia
- Cause awakening from sleep

Benzodiazepines
- Increase sleep time
- Increase daytime sleepiness

Steroids
- Can affect circadian rhythm regulation
- Exacerbate existing sleep disorders

Narcotics
- Suppress REM sleep
- Cause increased daytime drowsiness

Anticonvulsants
- Decrease REM sleep time
- May cause daytime drowsiness

but after several weeks of working a night shift, a person's biological clock usually does adjust.

Usual sleep patterns and excessive daytime sleepiness

As noted above, EDS often results in impairment of waking function, poor work or school performance, accidents while driving or using equipment, and behavioural or emotional problems. Feelings of sleepiness are usually most intense on waking from sleep, or just before going to sleep, and about 12 hours after the mid-sleep period.

Sleepiness becomes pathological when it occurs at times when people need or want to be awake. People who experience temporary sleep deprivation as a result of an active social evening or lengthened work schedule usually feel sleepy the next day. However, they may be able to overcome these feelings even though they have difficulty performing tasks and remaining attentive. Chronic lack of sleep is much more serious than temporary sleep deprivation, and can cause serious alterations in the ability to perform daily functions. EDS tends to be most difficult to overcome during sedentary tasks.

Emotional stress

Worry over personal problems or situations can disrupt sleep. Emotional stress or distress causes a person to be tense and often leads to frustration when sleep does not come. Stress may also cause a person to try too hard to fall asleep, to wake frequently during the sleep cycle, or to oversleep. Continued stress may cause poor sleep habits.

Environment

The physical environment in which a person sleeps has a significant influence on their ability to fall asleep and remain asleep. Good ventilation is essential for restful sleep. The size, firmness and position of the bed can affect the quality of sleep. Hospital beds are often smaller and harder than those at home. If a person usually sleeps with another individual, sleeping alone can cause wakefulness. On the other hand, sleeping with a restless or snoring bed partner can also disrupt sleep.

Light levels may affect the ability to fall asleep. Some people may prefer a dark room, whereas others, such as children or older adults, may prefer keeping a soft light on during sleep. People may have trouble sleeping because of the temperature of a room – a room that is too warm or too cold often causes restlessness.

Sound also influences sleep. The level of noise needed to wake people depends on the stage of sleep. Low noises are more likely to arouse a person from stage 1 sleep, whereas louder noises wake people in stage 3 or 4 sleep. Some people require silence to fall asleep, whereas others prefer background noise such as soft music or television.

In hospitals and other inpatient facilities, noise creates a problem for clients. Noise in hospitals is usually new or strange, so clients are prone to waking up. This problem is greatest the first night of hospitalisation, when clients often experience increased total wake time, increased

awakenings and decreased REM sleep and total sleep time. The level of noise in hospitals can be very high. Normal conversation measures about 50 decibels. Sound becomes noise at 35–40 decibels. Noise from people (e.g. health professionals, patients, families, service areas) are all sources of increased sound levels. Intensive care units and other acute care environments have high noise levels. Close proximity of clients and families, noise from confused and ill clients, the ringing of alarm systems and telephones, and disturbances caused by emergencies make the environment loud and unpleasant. Noise is also related to the subjective quality of sleep.

Exercise and fatigue

A person who is moderately fatigued usually achieves restful sleep, especially if the fatigue is the result of enjoyable work or exercise. Exercise should be completed 2 hours or more before bedtime to allow the body to relax and cool down and maintain a state of fatigue. However, excess fatigue resulting from exhausting or stressful work can make falling asleep difficult. This can be a common problem for primary school children and adolescents.

Food and kilojoule intake

Following good eating habits is important for health and people sleep better when they are healthy. Eating a large, heavy and/or spicy meal late at night may result in indigestion that interferes with sleep. Caffeine and alcohol consumed in the evening have insomnia-producing effects. A reduction or avoidance of these substances, especially late at night, is an important strategy that people can use to improve sleep.

Food allergies may cause insomnia. In infants, night-time waking and crying (or colic) may be caused by a milk allergy, requiring that breast milk or a non-milk formula be used. Besides milk, some foods that often result in an insomnia-producing allergy among both children and adults include corn, wheat, nuts, chocolate, eggs, seafood, red and yellow food dyes and yeast. Restoration of normal sleep may take up to 2 weeks when the particular food that is causing the difficulty has been eliminated from the diet.

Weight loss or gain influences sleep patterns. When a person gains weight, sleep periods become longer with fewer interruptions. Weight loss can cause short and fragmented sleep. Certain sleep disorders may be the result of the semi-starvation diets popular in a weight-conscious society. Conversely, some research suggests that sleeping problems may contribute to the development of weight gain (Knutson 2007).

CLINICAL REASONING PROCESS

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from clients and/or their families, critical-thinking attitudes and intellectual and professional standards. Clinical reasoning and judgements require the nurse to anticipate the information necessary, gather relevant information and data, analyse the data and make decisions regarding client care. Critical thinking is always changing in response to the needs and wishes of the client and their family, and the evidence available. During the process of gathering relevant information and data from the client or family (Figure 30-4), the nurse must consider all elements that build towards identifying priority problems in order to make appropriate judgements and decisions with the client.

In the case of sleep, the nurse integrates knowledge from many disciplines, previous experiences, and information gathered from clients to understand the client's sleep problem and its effect on the client and family.

CLINICAL EXAMPLE

Dudley is a 54-year-old truck driver who presents after a recent driving accident at work, which he attributes to difficulty with concentrating and excessive daytime sleepiness. Dudley's wife also convinced him to discuss his sleeping problems. His wife has commented on his loud snoring, and Dudley sleeps in a separate room due to the noise. On assessment, Dudley is centrally obese with a body mass index (BMI) of 39. He is a non-smoker and drinks about a 6-pack of beer per night.

• CRITICAL REFLECTION POINT

1. **What is the likely sleep disorder that Dudley has? What are the implications for his health if it is left untreated?**
2. **In undertaking a focused sleep assessment, what other information and data not given in the *Clinical example* above would you want to collect? How would you assess these data – that is, what questions would you ask or what physical assessments would you conduct?**

GATHERING RELEVANT INFORMATION AND DATA

Sleep is essentially a subjective experience. Only the client can report whether they believe it is sufficient and restorative. If the client is satisfied with the quantity and quality of sleep received, it may be considered normal. If a client identifies a sleep problem or the nurse suspects it, a more detailed history is needed (Figure 30-4). To promote normal sleep for clients, the first step is to gather relevant information and data about factors that usually influence sleep for the client. If the client perceives that sleep is adequate, the nursing history can be brief.

Assessing sleep

Most people can provide a reasonably accurate estimate of their sleep patterns, particularly if any recent changes have

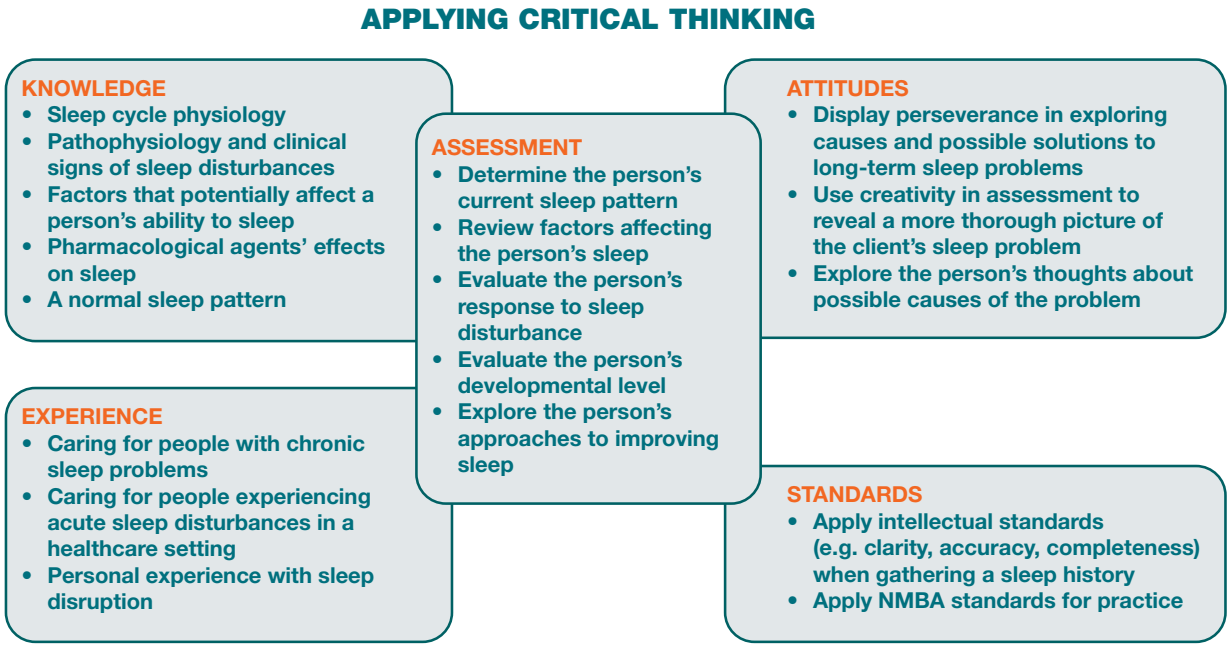

Figure 30-4 **Critical thinking associated with the assessment phase for fostering sleep.**

occurred. The nursing assessment is aimed at understanding the characteristics of any sleep problem and the client's usual sleep habits so that the client's priority problem can be identified and ways of promoting sleep can be incorporated into care. For example, if the nursing history reveals that a client always reads before falling asleep, it makes sense to offer reading material at bedtime.

Sources of sleep assessment

Usually clients are the best resource for describing a sleep problem and the extent to which a problem represents a change from their usual sleep and waking patterns. It is important to note that age affects the time and requirements for sleeping. For example, it has been shown that older women living in the community who have more sleep disturbances (waking after sleep onset and spend longer time in bed without sleep) are more likely to be placed in a nursing home (Spira et al 2012) (see *Research highlight*).

Often the client knows the cause of sleep problems, such as a noisy environment or anxiety due to financial stress. Additionally, bed partners may be able to provide information on the client's patterns that may reveal the nature of certain sleep disorders. For example, partners of clients with obstructive sleep apnoea often note that their sleep is disturbed by their partner's snoring. Often the partners report sleeping in different beds or rooms to obtain adequate sleep. It is useful to ask bed partners whether the client has pauses in their breathing during sleep and how frequently these apnoeic attacks occur. Some partners mention becoming fearful when clients apparently stop breathing for periods during sleep.

Information about the sleep patterns of children should also be sought from parents. However, some parents may not realise that there is a wide variability in the sleeping patterns of infants and may need reassurance if their infant seems to sleep less than others but is otherwise healthy and thriving (Matricciani et al 2012). Hunger, excessive warmth and separation anxiety are factors that may contribute to an infant's difficulty in going to sleep or frequent awakening during the night. Older children are usually able to relate fears or worries that inhibit their ability to fall asleep. If children frequently wake in the middle of bad dreams, parents can identify the problem but perhaps may not understand the meaning of the dreams. Parents can usually describe the typical behaviour patterns that foster or impair sleep in their child, such as excessive stimulation from active play or visiting friends. With chronic sleep problems, parents can relate the duration of the problem, its progression and their child's responses to intervention. Parents of infants may need to keep a 24-hour log of their infant's waking and sleeping behaviour for several days to determine what may be causing the problem. The infant's eating pattern and sleeping environment also need to be described, since these may influence sleeping behaviour.

Tools for sleep assessment

There are several subjective and objective sleep assessment tools available. *Subjective sleep assessment tools* include the visual analogue scale, and subjective rating scales where clients are asked to place a mark on a horizontal line, marked 0–10 or 0–100, at the point corresponding to their perceptions of the previous night's sleep. These scales can be administered repeatedly to determine if there is change over time. Such scales are useful for assessing an individual client, but not for comparing clients. Other validated sleep assessment tools are brief and simple enough to be administered in the clinical setting, such as the Epworth Sleepiness Scale (ESS) (freely available at http://epworthsleepinessscale.com). Other commonly used scales include the Insomnia Severity Index (ISI), which is used to detect insomnia cases and to determine treatment effectiveness (Morin et al 2011) and the Pittsburgh Sleep Quality Index (PSQI), which ascertains sleep quality in

RESEARCH HIGHLIGHT

Research focus

Disturbed sleep is common among older people and has been linked to an increase in disability and impairment of activities of daily living in older adults. While the reasons are multifactorial, older adults placed in long-term care facilities, such as nursing homes, are likely to have changes in their sleep habits with increasing amounts of disturbed sleep. Older adults are often moved to nursing homes because of the amount of nocturnal care personal carers are required to perform. This is usually poorly tolerated by carers and necessitates more permanent sources of support for the older adult.

Research abstract

The focus of this prospective cohort study was to determine if sleep measured in community settings was predictive of subsequent placement in a nursing home. The study was conducted on 1664 community-dwelling women (average age 83 years) whose objective sleep was measured at baseline and followed up 5 years later. Sleep was measured using an actigraphy, a wrist-based device that measures activity and light, thereby allowing quantification of total sleep time, time in bed and the amount of waking after sleep commencement. Sleep was measured over three consecutive nights. Additional measures determined whether the participants lived alone, with a spouse, were a new resident in a nursing home, or required personal home care. Reports of disability and mobility were also included.

It was shown that older women at baseline who had more waking after sleep commencement were three times more likely to be placed in a nursing home or require personal home care support. Those women who spent more time in bed without sleep also had a three times greater risk of being admitted to a nursing home within the next five years.

These data demonstrate clearly that sleep disturbances in older women expose them to greater risk of placement in a nursing home or requiring greater personal home care support.

Evidence-based practice

- Sleep disturbances in older people are common. Older women who are independently living but have more sleep disturbance are at greater risk of requiring extra carer support, such as nursing home care.
- Sleep education should be provided to older people to lower risk of increased carer support.

Spira A, Covinsky K, Rebok GW et al 2012 Objectively measured sleep quality and nursing home placement in older women. J Am Geriatr Soc 60(7):1237–43.

clinical populations (Buysee et al 1989). Despite being reliable and valid tools used extensively in sleep assessment, these tools are not always effective and more objective measures may be required.

Objective sleep assessment tools most commonly include wrist-based **actigraphy** and polysomnography. A wrist actigraphy assessment is a monitoring device attached to the client's non-dominant wrist, which measures body movements (using accelerometry) at regular short intervals. Some wrist actigraphy devices also measure environmental factors such as light, as well as having the ability to record the client's input about sleep, for example, when they tried to go to sleep. Wrist actigraphy is considered an objective tool which is non-invasive and can be used in the client's normal sleep environment. Polysomnography records brain and muscle activity via electrodes attached to the client's body. Although polysomnography is considered to be the gold standard in objective sleep assessment tools, its main disadvantage is that usually it is performed in a sleep laboratory, which removes clients from their normal sleep environment. There is now a trend to undertake home-sleep assessment using a modified polysomnography; however, evidence about effectiveness in clinical populations is lacking.

Sleep history

If clients report that they enjoy adequate sleep, the sleep history can be brief (Box 30-4). A determination of usual bedtime, normal bedtime rituals, preferred environment for sleeping and what time the client usually rises gives the nurse information for collaboratively setting priorities and establishing goals for planning care conducive to sleep. When a sleep problem is suspected, the quality and characteristics of sleep are explored in greater depth.

BOX 30-4 Components of a sleep history

- Satisfaction with quality and quantity of sleep
- Description of client's sleep problem
- Usual sleep pattern prior to sleep problem
- Recent changes in sleep pattern
- Bedtime routines and sleeping environment
- Use of sleep and other prescription medications and over-the-counter drugs
- Pattern of dietary intake and amount of substances (e.g. alcohol, caffeine) that influence sleep
- Symptoms experienced during waking hours
- Concurrent physical illness
- Recent life events
- Current emotional and mental status

Description of sleeping problems

When a sleep problem is identified, the nursing history must be sufficiently detailed so that appropriate judgements and decisions about therapeutic care can be made. Open-ended questions help a client describe a problem more fully. A general description of the problem followed by more-focused questions usually reveals specific characteristics that can be used in planning therapies.

To begin, the nurse needs to understand the nature of the sleep problem, its signs and symptoms, its onset and duration, its severity, any predisposing factors or causes and the overall effect on the client. Questions might include the following:

- *Nature of the problem:* What type of problem do you have with your sleep? Why do you think your sleep is inadequate? Describe a recent typical night's sleep. How is this sleep different from what you are used to?
- *Signs and symptoms:* Do you have difficulty falling asleep, staying asleep or waking up? Have you been told that you snore loudly? Do you have headaches when waking? Does your child wake from nightmares?
- *Onset and duration:* When did you notice the problem? How long has this problem lasted?
- *Severity:* How long does it take you to fall asleep? How often during the week do you have trouble falling asleep? How many hours of sleep a night did you get this week? Compare that with what is usual for you. What do you do when you wake during the night or too early in the morning?
- *Quality of sleep:* Do you wake up refreshed?
- *Predisposing factors:* What do you do just before going to bed? Have you recently had any changes at work or at home? How is your mood, and have you noticed any changes recently? What medications or recreational drugs do you take on a regular basis? Are you taking any new prescription or over-the-counter medications? How long have you been taking medications? Do you eat spicy or greasy foods or drink alcohol or caffeine that could be interfering with your sleep? Do you have a physical illness that might be interfering with your sleep? Does anyone in your family have a history of sleep problems?
- *Effect on client:* How has the loss of sleep affected you? (Ask a partner or friend whether they have noticed any changes in behaviour since the sleep problem started.) Do you feel excessively sleepy, irritable or have trouble concentrating during waking hours? Do you have trouble staying awake or have you fallen asleep at inappropriate times, such as while driving, sitting quietly in a meeting or watching TV?

Proper questioning helps the nurse and their client to determine the type of sleep disturbance and the nature of the problem. Table 30-1 gives examples of some other questions to ask when specific sleep disorders are suspected.

As an adjunct to the sleep history, a client and bed partner may be asked to keep a sleep–wake diary for a specified period of

TABLE 30-1 Questions to ask to assess for sleep disorders

Assessment questions	Rationale
Insomnia	
How easily do you fall asleep?	Determine nature and severity of insomnia
Do you fall asleep and have difficulty staying asleep? How many times do you wake up?	Help in selection of sleep therapies
Do you wake early from sleep?	
What time do you wake up for good? What causes you to wake early?	
What do you do to prepare for sleep? to improve your sleep?	
What do you think about as you try to fall asleep?	
How often do you have trouble sleeping?	
Sleep apnoea	
Do you snore?	Reveal presence of sleep apnoea
Has anyone ever told you that you often stop breathing for short periods during sleep? (Spouse or bed partner/room-mate may report this)	
Do you experience headaches after waking?	
Do you have difficulty staying awake during the day?	
Does anyone else in your family snore or stop breathing during sleep?	
Narcolepsy	
Are you tired during the day?	Help diagnose narcolepsy and influence on daily activities
Do you fall asleep at inopportune times? (Friends or relatives may report this)	
Do you have episodes of losing muscle control or falling to the floor?	
Have you ever had the feeling of being unable to move or talk just before falling asleep?	
Do you have vivid, lifelike dreams when going to sleep or waking up?	

time, usually 1–2 weeks (Carney et al 2012). The sleep–wake diary is completed daily to provide information on day-to-day variations in sleep–wake patterns over extended periods. Diary entries often include 24-hour information about various waking and sleeping health behaviours, such as physical activities, meal-times, type and amount of intake (alcohol and caffeine), time and length of daytime naps, evening and bedtime routines, the time the client tries to fall asleep, night-time waking and the time of waking up in the morning. A partner can help record the estimated times the client falls asleep or wakes. Although the log is helpful, the client must be motivated to participate in its completion. Ordinarily it is not used with acutely ill clients who have short hospital stays.

Usual sleep pattern

Normal sleep is difficult to define because people vary in the quantity and quality of sleep that they perceive as adequate for them. It is important, however, to have clients describe their usual sleep pattern to determine the significance of the changes created by a sleep disorder. Knowing a client's usual, preferred sleep pattern allows a nurse to try to match sleeping conditions in a healthcare setting with those in the home. To determine the client's sleep pattern, the nurse might ask the following questions:

1. What time do you usually go to bed each night?
2. What time do you usually fall asleep? Do you do anything special to help you fall asleep?
3. How many times do you wake at night? Why?
4. What time do you typically wake up in the morning?
5. What time do you get out of bed for good once you have woken?
6. What is the average number of hours you sleep each night?

Comparing these data with the predominant pattern found for other clients of the same age, the nurse can begin to recognise identifiable patterns such as those of insomnia. Clients with sleep problems may show patterns that are drastically different from their usual, or the change may be relatively minor. Hospitalised clients usually need or want more sleep as a result of illness. However, some may require less sleep because they are less active. Clients who are ill may think that it is important to try to sleep more than is usual for them, eventually making sleeping difficult.

Illness

Determining whether the client has any pre-existing health problems that might interfere with sleep is an important part of information gathering. For example, a client with bipolar disorder sleeps more when depressed than when manic. A depressed client often experiences fragmented sleep that is inadequate. Chronic diseases, such as chronic obstructive pulmonary disease and chronic pain problems, interfere with sleep. If a client takes medications to aid sleep, the nurse gathers information about the type and amount of medication that is being used, as well as daily caffeine intake.

If the client has recently undergone surgery, the nurse can expect the client to experience some disturbance in sleep due to discomfort. Clients may wake frequently during the first night after surgery and receive little deep or REM sleep. Depending on the type of surgery, it may take several days for a normal sleep cycle to return.

Current life events

Recent changes in lifestyle may be disrupting sleep or a person's occupation may offer a clue to the nature of the sleep problem. Changes in job responsibilities, rotating shifts or long hours can contribute to a sleep disturbance. Questions about social activities, recent travel or meal-time schedules help clarify the sleep assessment.

Emotional and mental health

If a client is anxious, excitable or angry, mental preoccupations can seriously disrupt sleep. The client may be experiencing emotional stress related to illness or situational crises such as loss of job or a loved one. Thus the client's emotions may affect the ability to sleep.

Bedtime routines

Many people have a routine to prepare for sleep. For example, the client may drink a glass of milk, take a sleeping tablet, eat a snack or watch television. Health professionals can assess and advise on habits that are beneficial and those that have been found to disturb sleep. Not all clients are alike. Watching television may promote sleep for one person, whereas another person may be stimulated to stay awake. Sometimes pointing out that a particular habit may be interfering with sleep can help clients find ways to change or eliminate habits that may be disrupting sleep. Special attention should be given to a child's bedtime rituals, especially if the child is hospitalised. Parents can report whether it is necessary, for example, to read the child a bedtime story, rock the child to sleep or engage in quiet play. Some young children need a special blanket or stuffed animal when going to sleep.

Bedtime environment

The nurse can ask the client to describe their preferred bedroom conditions. The bedroom may be dark or light, and the door to the room may be open or closed. The client may listen to the radio or watch television, or prefer a quiet environment. In addition, a child may require the company of a parent to fall asleep. The nurse may learn that changes in the home or institutional environment will be necessary to promote sleep. In a healthcare environment there may be environmental distractions, such as a room-mate's television, an electronic monitor in the hallway, a noisy nurses' station or another client who cries out at night. The nurse identifies factors that can be reduced or controlled.

Behaviours of sleep deprivation

Some clients may be unaware of how their sleep problems affect their behaviour. Behaviours such as irritability, disorientation, frequent yawning and slurred speech may be indicators of sleep deprivation. If sleep deprivation has lasted a long time, psychotic behaviour such as delusions and paranoia may develop (see Box 30-5). For example, a client may report seeing strange objects or colours in the room, or may seem afraid when the nurse enters the room.

Clients hospitalised in ICUs for an extended time may experience sensory overload (Lusk & Lash 2005). Constant environmental stimuli within the ICU, such as strange noises from equipment, the frequent monitoring and care given by nurses and doctors, ever-present lights and lack of colour stimulation, confuse clients. Repeated environmental stimuli and the client's poor physical status lead to sleep deprivation. Nurses can attempt to cluster episodes of care, particularly at

BOX 30-5 Symptoms of long-term sleep disturbance

night, to reduce the frequency of disturbance and minimise sleep deprivation (Kamdar et al 2012).

Client expectations

It is important to understand clients' expectations regarding their sleep pattern. People who suffer from insomnia often focus their pre-sleep thinking on negative thoughts, including the inability to sleep, causing a vicious circle of sleeplessness. A skilled and caring approach should be used to assess clients' sleep needs. It is useful to ask what practices clients currently use to get to sleep and how successful they are. The nurse can also ask clients what other ways of promoting sleep they prefer and how they might be implemented.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Gathering relevant information reveals clusters of data that include defining characteristics for a sleep problem that results from disturbed sleep (Ackley & Ladwig 2013). If a sleep pattern disturbance is identified as a priority problem for the client, appropriate judgements can be made to specify the nature of the sleep disturbance and to design more-effective interventions. For example, different therapies are used for clients who are unable to fall asleep from those for clients with obstructive sleep apnoea. Box 30-6 demonstrates how to use clinical reasoning to identify and cluster defining characteristics to identify a priority problem with the client.

CLINICAL EXAMPLE

Dudley is diagnosed with obstructive sleep apnoea (OSA) after referral to a sleep specialist who ordered an overnight sleep study which demonstrated significant periods of apnoea accompanied by oxygen desaturation to 78%. As part of his medical management, Dudley is prescribed continuous positive airway pressure (CPAP).

Assessment and clinical reasoning should also identify the related factors or probable causes of the sleep disturbance, such as a noisy environment, a high intake of caffeinated drinks in the evening, or stress involving a marital relationship. These causes become the focus of interventions for minimising or eliminating the problem. For example, if a client is experiencing sleep disturbance due to a noisy healthcare environment, the nurse could offer some recommendations for helping sleep, such as controlling the noise of hospital equipment, reducing interruptions or keeping doors closed. If the sleep disturbance is related to worry over a threatened marital separation, the nurse's actions may involve introduction of coping strategies and creation of an environment for sleep. If the probable cause or related factors are incorrectly defined, the client may not benefit from care.

Sleep problems may affect clients in other ways. For example, a nurse may find that a client with sleep apnoea has problems with a spouse who is tired and frustrated over the client's snoring. In addition, the spouse is concerned that the client is breathing improperly and thus is in danger. The priority problem in this scenario is one of family coping and relationships. Appropriate decisions would include providing support to the client and spouse so that they can understand sleep apnoea and obtain the medical treatment needed.

CRITICAL REFLECTION POINT

1. **What other interventions will you need to plan with Dudley as part of the management of his OSA?**
2. **What lifestyle modifications will help improve sleep (think about obesity and alcohol consumption in this case)?**
3. **What relationship and body image concerns relating to CPAP may need to be addressed?**

BOX 30-6 Identifying priority problem(s)

Assessment activities	Defining characteristics	Priority problem(s)
Ask client to explain nature of sleep problem. Use prompts to refine assessment.	Client reports difficulty in falling asleep, taking up to an hour. Client reports waking up 2–3 times nightly, with difficulty returning to sleep.	Sleep pattern disturbance, difficulty falling and/or remaining asleep related to worry over job loss.
Observe client's behaviour and ask bed partner if behaviour changes have been noted.	Client admits to not feeling well rested. Partner describes episodes of client being lethargic and irritable.	
Determine whether client has had recent lifestyle changes.	Partner reports client recently lost job, has concern over finding new position.	

SETTING PRIORITIES AND ESTABLISHING GOALS

The synthesis of information from multiple resources enables the setting of priorities and goals for intervention or treatment (Figure 30-5). From this, an individualised plan of care can be developed with the client (see *Sample student nursing care plan* as an example).

Setting priorities

In a healthcare setting the nurse should attempt to plan treatments or routines so that the client is able to rest. For example, in the ICU, nurses can check available electronic monitors to track trends in vital signs without waking a client each hour. Other staff and family should be aware of the care plan so that they can cluster activities at certain times to reduce awakenings. In a nursing home setting, the focus of the plan may involve better planning of rest periods around the activities of the other residents. Often the schedule of one room-mate may not coincide with that of another.

Goals and outcomes

Goals should be individualised and realistic with measurable outcomes (e.g. achieving a sleep pattern normal for the client). The success of sleep therapy depends on an approach that fits the client's lifestyle and the nature of the sleep disorder. The goals of any care plan for a client needing sleep or rest include elements of the following:

- a sense of restfulness and renewed energy following sleep
- a healthy sleep pattern
- understanding of factors that promote or disrupt sleep
- development of self-care behaviours to eliminate factors contributing to the sleep disturbance.

Outcomes for the goal of establishing a healthy sleep pattern involve evaluating the client's knowledge of sleep hygiene and their ability to implement these practices, and discussion with the client and partner about their effectiveness. It is important for the plan of care to include strategies that are appropriate for the client's living environment and lifestyle. An effective plan includes outcomes established over a realistic time that focus on the goal of improving the quantity and quality of sleep in the home. This type of plan may require many weeks to accomplish. Working closely with the client and their significant others ensures that any therapies, such as a change in the sleep schedule or changes to the bedroom environment, are realistic and achievable.

Continuity of care

The nature of the sleep disturbance determines whether referrals to additional healthcare providers are necessary. For example, if a sleep problem is related to a situational crisis or emotional problem, the client may be referred to a mental health nurse or clinical psychologist for counselling. When chronic insomnia is the problem, a medical referral or referral to a sleep centre may be beneficial. In an inpatient setting, the client may benefit from a referral from the home health nurse or general practitioner for continued care for their sleep problem after discharge.

PREPARING FOR AND TAKING ACTION

Interventions designed to improve the quality of a person's rest and sleep focus largely on promoting health and wellbeing. Clients need adequate sleep and rest to maintain active and productive lifestyles. During times of illness, rest and sleep are important for recovery. An acute care, restorative care or continuing care setting will differ from the environment in a client's home. The main differences are in the environment and the nurse's ability to support normal rest and sleep habits within this environment. The client's age also influences the types of therapies that are most effective. The *Working with diversity* box provides principles for promoting sleep in older clients.

APPLYING CRITICAL THINKING

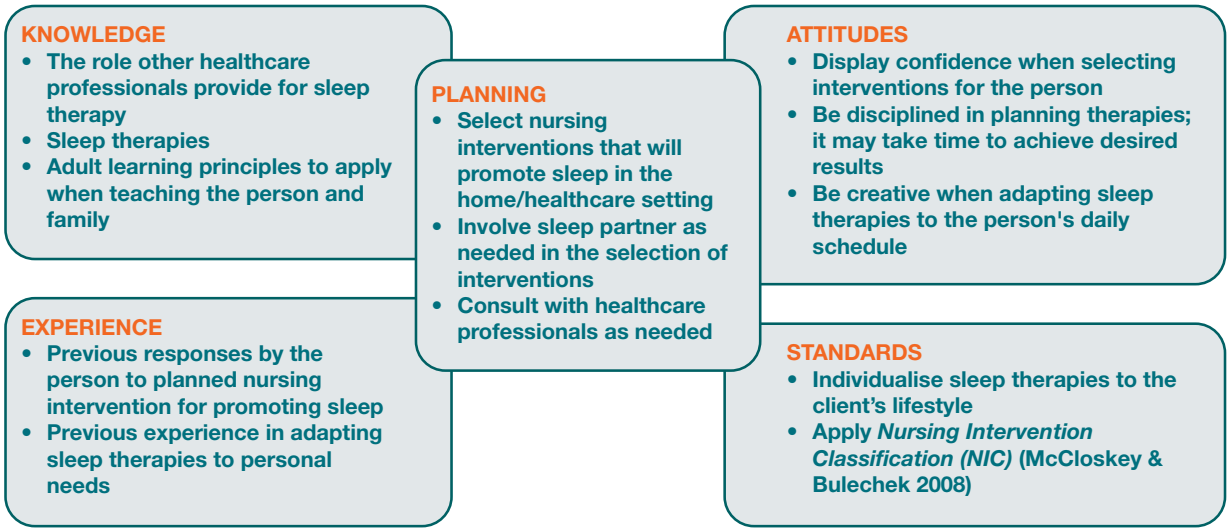

Figure 30-5 **Critical thinking associated with the planning phase for fostering sleep.**

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data*

Julie Arnold, a 42-year-old solicitor, is the first client of the morning at the neighbourhood health clinic where you work. When you ask her how she is, she tells you she is having difficulty sleeping. She tells you this started several days after she began **feeling pressured at work** to complete an important case. On further questioning you find out she is **going to bed between midnight and 1.00 am**, which is 2 hours **later than her normal bedtime** and it **takes her almost an hour to fall asleep**. Julie normally gets 7 hours of sleep a night. Because she is having trouble falling asleep, Julie has been **drinking a glass of wine before bedtime**. She has **2–3 cups of coffee after dinner** to stay awake while working on her case before bedtime. Julie also reports that she wakes up at least once during the night. Julie states, '**I feel tired when I wake up**, and sometimes I have **trouble concentrating in the afternoon** at work. I have **stopped my routine of walking a kilometre a day**.' As you observe Julie, you notice she has dark circles under her eyes, shifts her position in the chair multiple times and yawns frequently. Julie also says she seems to have less patience with her children at home.

** Important data to cluster in setting priorities in bold.*

Priority problem(s)

Sleep pattern disturbance related to psychological stress from job pressures.

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Julie Arnold will achieve an improved sense of adequate sleep. Julie will achieve a more normal sleep pattern.	Julie will report waking up less frequently during the night and feeling rested. Julie will state adherence to a regular bedtime routine. Julie will fall asleep within 30 minutes of going to bed. Julie will report sleeping 7 hours nightly.
Preparing for and taking action	**Rationale**
Sleep enhancement • Encourage Julie to establish a bedtime routine and a regular sleep pattern. • Instruct Julie to limit caffeine, nicotine and alcohol before bedtime. • Help Julie identify ways to eliminate stressful concerns about work before bedtime (e.g. taking time before actual sleep time to read a light novel). • Adjust environment; have Julie control noise, temperature and light in the bedroom. *Exercise promotion* • Encourage Julie to reinstitute walking routinely during the day, but not 2–3 hours before bedtime. *Simple relaxation therapy* • Instruct Julie on how to perform muscle relaxation before bedtime.	A consistent routine promotes sleep. Caffeine and nicotine are stimulants and cause difficulty in falling asleep. Alcohol lightens and fragments sleep. Excess worry and intense activities before bedtime may stimulate client and prevent sleep. A quiet, comfortable environment fosters sleep. Exercise can increase activity levels and the need for sleep. Exercise just before bedtime is a stimulant that prevents sleep. Relaxation therapy can help reduce anxiety and block arousing thoughts which interfere with sleep.

Evaluating impacts and outcomes

- Ask whether Julie is successful in falling and staying asleep.
- Ask Julie to describe waking behaviours at work or home during the day.
- Observe the waking non-verbal expressions and behaviour of Julie.

WORKING WITH DIVERSITY

Focus on older adults

Sleep–wake pattern

- Keep a regular schedule for bedtime and rising the following morning.
- Eliminate naps unless they are a routine part of the schedule.
- If naps are used, limit to 20 minutes or less twice a day.
- Go to bed when sleepy.
- Use relaxation techniques to promote sleep.
- If unable to sleep in 15–30 minutes, get out of bed.

Environment

- Maintain usual patterns and rituals when preparing to sleep.
- Sleep where you sleep best.
- Keep noise to minimum; use soft music to mask noise if necessary.
- Use night-light and keep path to bathroom free of obstacles.
- Set room temperature to preference; wear socks to promote warmth.

Medications

- Use sedatives and hypnotics as last resort and then only short term if absolutely necessary.
- Adjust medications being taken for other conditions and look for drug interactions that may cause insomnia or excessive daytime sleeping.

Diet

- Restrict stimulants such as alcohol, caffeine and nicotine in late afternoon and evening.
- Consume carbohydrates or milk as a light snack before bedtime.
- Try to reduce the need for urinary elimination during the night by decreasing fluids 2–4 hours before sleep.

Physiological/illness factors

- Elevate head of bed and provide extra pillows as preferred.
- Ensure the client's position in the bed promotes comfort.
- Offer complementary therapies that are recognised in promoting sleep, such as aromatherapy.
- Pain relief for chronic or acute conditions is given 30 minutes prior to the client settling for the night.

Mezey M, Kobayashi M, Grossman S 2004 Nurses improving care to healthsystem elders (NICHE): implementation of best practice models. J Nurs Admin 34(10):451–7.

• CRITICAL REFLECTION POINT

Mr Kanaris, aged 55, is recovering on your ward following cardiac surgery. You find him awake at 2.00 am, and he tells you he has been having trouble sleeping since surgery 3 days ago. Develop a plan of care for Mr Kanaris to promote sleep while he is in hospital.

Promoting health and wellbeing

Many factors affect the ability to gain adequate rest and sleep. In community health and home settings, helping clients to develop behaviours conducive to rest and relaxation may include suggesting changes in their environment or certain lifestyle habits. To develop good sleep habits at home, clients and their bed partners can learn techniques that promote sleep and note conditions that interfere with sleep (Ackley & Ladwig 2013) (Box 30-7). Parents can also learn how to promote good sleep habits in their children. Clients benefit most from instructions based on information that is relevant to their homes, culture and lifestyles. Similarly, they are more likely to apply information that is useful and valued.

Environmental controls

All clients require a sleeping environment with a comfortable room temperature and proper ventilation, minimal sources of noise, a comfortable bed and proper lighting. Cots should be positioned away from open windows or drafts. The infant is covered with a light, warm blanket. Children and adults vary widely in regard to comfortable room temperature; however, bedding temperatures are best when slightly above average skin temperature (34–35°C) (van Someren 2006). Older adults often require extra blankets or covers due to changes in skin blood flow as people age. Many older clients sleep wearing socks to keep extremities warm (Raymann et al 2008).

Distracting noise needs to be eliminated so that the bedroom is as quiet as possible. In the home the television, telephone, mobile phone, or the intermittent chiming of a clock may disrupt a client's sleep. The family is an important part of the care plan, especially if there are several family members with different schedules for going to sleep and waking. At home it may require the cooperation of several people living with the client to reduce noise. It is also important to remember that some clients are used to sleeping with familiar inside noises, such as the hum of a fan.

The bed and mattress should provide support and comfortable firmness. Sometimes extra pillows are important to help a person position comfortably in bed. The position of the bed in the room may also make a difference for some clients. Infants' beds must be safe. To reduce the chance of suffocation, pillows, stuffed toys or the ends of loose blankets should not be placed in cots. Loose-fitting plastic mattress covers should not be used because infants might pull them over their faces and suffocate. Infants are usually placed on their backs to prevent suffocation or on their sides to prevent aspiration of stomach contents.

For a client prone to confusion or falls, safety is critical. In the home, a small night-light might help the client orientate to the room environment before rising to go to the bathroom. Beds set lower to the floor may lessen the chance of a person falling when first standing. Clutter and rugs should always be

BOX 30-7 Promoting sleep hygiene

Objective

- Improve home sleep hygiene habits.

Education strategies

- Suggest client tries to exercise daily, preferably in morning or afternoon, and to avoid vigorous exercise in the evening within 3 hours of bedtime.
- Caution client against sleeping long hours during weekends or holidays to prevent disturbance of normal sleep–wake cycle.
- Advise client to avoid daytime naps of longer than 1 hour or after 3.00 pm.
- Make aware of adverse effects of sleeping medications. Caution client not to take sleeping medications unless prescribed and for the shortest possible time.
- Advise client to go to bed and get up at the same time each day.
- Explain that, if possible, the bedroom should not be used for intensive studying, eating, watching TV or other non-sleep activity, besides sex.
- Explain that client should try to avoid thinking about problems when going to bed and should use relaxation exercises.
- Advise client to get out of bed and do some quiet activity until feeling sleepy enough to go back to bed if client does not fall asleep within 30 minutes of going to bed.
- Recommend client limit caffeine to morning coffee and limit alcohol intake (more than 1–2 drinks a day can interrupt sleep cycle).
- Ask client to examine environment: keep room dark, well ventilated, quiet and at a comfortable temperature. Use of earplugs and eyeshades may be helpful.
- Instruct client to avoid heavy meals for 3 hours before bedtime; a light snack may help.

Evaluation

- Ask the client to complete sleep–wake log for 1 week, and compare it with previous sleep–wake log.
- Ask client to periodically complete sleep rating scale for perceptions of quality of sleep.

removed from the path a client uses to walk from the bed to the bathroom. If a client needs help going from a bed to the bathroom, a small bell at the bedside can be used to call family members.

Clients vary in regard to the amount of light that they prefer at night. Infants and older adults sleep best in softly lit rooms. Light should not shine directly on their eyes. Small table lamps prevent total darkness. For older adults this reduces the chance of confusion and prevents falls enroute to the bathroom. If street lights shine through windows, heavy curtains or venetian blinds are helpful.

Promoting bedtime routines

Bedtime routines relax people in preparation for sleep and it is important for people to go to sleep when they feel tired or sleepy, but clearly this is not always possible. Going to bed while fully awake and thinking about other things can cause insomnia. Newborns and infants sleep through so much of the day that a specific routine is hardly necessary. However, quieting activities, such as holding them snugly in blankets, singing or talking softly and gentle rocking, help infants fall asleep. A bedtime routine (e.g. same hour for bedtime, snack or quiet activity) used consistently helps young children avoid delaying sleep. Toddlers and preschoolers may be too excited and full of energy to go to bed. Patterns of preparing for bedtime need to be reinforced. Reading stories or allowing children to sit in a parent's lap while listening to music are routines that can be associated with preparing for bed. Quiet activities such as colouring and reading work well with school-age children.

Adults should try to avoid excessive mental stimulation just before bedtime. Reading a light novel, watching a relaxing television program or listening to music helps a person relax. Relaxation exercises can be useful at bedtime. Slow, deep breathing for 1 or 2 minutes induces calm, and guided imagery and meditation may also promote sleep. At home, a client should not try to finish office work or resolve family problems before bedtime. The bedroom should not be used as a place to work and should always be associated with rest and sleep. Working towards a consistent time for sleep and waking helps most clients gain a healthy sleep pattern and strengthen the rhythm of the sleep–wake cycle.

Promoting comfort

People fall asleep only after feeling comfortable and relaxed. Minor irritations can keep people awake. Soft cotton nightclothes keep infants or small children warm and comfortable. An extra blanket may be all that is needed to prevent a person from feeling chilled and being unable to fall asleep. Clients should be instructed to wear loose-fitting nightwear, and to void before retiring so they are not kept awake by a full bladder.

Establishing periods of rest and sleep

In the home it may help to encourage clients to stay physically active during the day so that they are more likely to sleep at night. Increasing daytime activity lessens problems with falling asleep. Rigorous exercise should always occur at least several hours before bedtime so as not to stimulate the sympathetic nervous system prior to bedtime.

Although older adults get less deep night-time sleep, some often take short naps during the day. This change in pattern associated with ageing may not represent a decrease in need for sleep, but rather a redistribution of sleeping behaviour during a 24-hour period. Naps should be taken at the same time each day to maintain a consistent schedule. For clients with chronic illness, the care plan might include setting aside afternoons for rest to promote optimal health. The nurse can help with adjusting medication schedules and instructing clients to turn off mobile phones and void regularly, so that rest periods are uninterrupted.

Stress reduction

The inability to sleep because of emotional stress or distress can also make a person feel irritable and tense. When clients

are emotionally upset, they should be encouraged not to force sleep, otherwise insomnia may develop and soon bedtime is associated with the inability to relax. A client who has difficulty falling asleep can be helped by getting up and pursuing a relaxing activity, such as sewing or reading, rather than staying in bed and thinking about sleep.

Many preschoolers have bedtime fears (fear of the dark or strange noises), wake during the night or have nightmares. After nightmares, parents should go into the child's room immediately and talk briefly about fears to provide a cooling-down period. One approach is to comfort children but leave them in their own beds so that their fears are not used as excuses to delay bedtime or to sleep with parents. Keeping a light on in the room may also help. Cultural traditions among families will dictate different approaches to sleep practices (see *Working with diversity*).

Bedtime snacks

Some people enjoy bedtime snacks, whereas others cannot sleep after eating. A dairy-product snack such as warm milk that contains L-tryptophan may be helpful in promoting sleep. A full meal before bedtime can often cause gastrointestinal upset and interfere with the ability to fall asleep. Generally, clients should be encouraged to refrain from drinking or ingesting caffeine before bedtime. Coffee, tea, cola, chocolate and alcohol act as stimulants or diuretics, causing a person to stay awake or wake up during the night. Alcohol can also interrupt sleep cycles and reduce the amount of deep sleep.

Infants require special measures to minimise night-time awakenings for feeding. It is common for children to need a middle-of-the-night bottle or breastfeed. It is recommended to offer the last feeding as late as possible and to seek advice on when to introduce solid food. Infants should not be given bottles in bed.

Pharmacological approaches

The liberal use of drugs to manage the symptoms of sleep problems is quite common in Western culture. In sleep, the main use of medications is in the short-term treatment of insomnia. Central nervous system (CNS) stimulants such as amphetamines, caffeine, nicotine, terbutaline and theophylline should be used sparingly under medical management (Bryant & Knight 2014). In addition, withdrawal from CNS depressants such as alcohol, barbiturates, tricyclic antidepressants and benzodiazepines can exacerbate insomnia and must be managed carefully.

Medications used to induce sleep are typically called **hypnotics**, or sedative hypnotics. These medications produce a calming, soothing effect and somnolence. A client who takes sleep medications should know about their proper use as well as the risks and possible side effects. However, extended use of sedative hypnotic agents can disrupt sleep architecture and lead to more serious problems. The main use of short-term medication is for the treatment of chronic insomnia. There are a number of drug groups that are used (Table 30-2). Traditionally, benzodiazepines were used to induce sleep as they work by enhancing the effect of gamma-aminobutyric acid (GABA) in the brain which causes relaxation, anti-anxiety and hypnotic effects, thereby inducing sleep (Riemann & Perlis 2009). They are usually prescribed for short-term use; however,

WORKING WITH DIVERSITY

Focus on cultural care

Practices and patterns of sleep and rest vary among cultures. Co-sleeping, in which infants and children sleep with their parents and later with their siblings, is the expected practice in many cultures. For example:

1. Cross-cultural differences exist in the sleep habits of children around the world. For example, it was found that Asian children had later bedtimes and shorter night-time sleep compared to children from Caucasian countries (Mindell et al 2013). In addition, parental perception of sleep problems was greater in Asian countries. However, Asian children tended to have more daytime nap opportunities, resulting in similar total sleep time over 24 hours in Asian and Caucasian children.
2. Farming communities in developing countries (e.g. Cameroon) adopt co-sleeping practices with their children, while those who work for a wage have taken on the Western cultural values of separateness and individuality in their sleeping behaviours (Yovsi & Keller 2007).

Nortriptyline	Allergon	8–24	75–150
Melatonin			
Melatonin	Circadin	0.5–2	2–5

they can impair cognition and cause a hangover effect and in some cases rebound insomnia, which exacerbates insomnia when weaning off the medication. The other main problem with benzodiazepines is the client can develop dependence and great care needs to be taken in their prescription. Benzodiazepines are used cautiously with children under 12 years of age and are contraindicated in infants less than 6 months. Pregnant clients should avoid benzodiazepines because their use is associated with risk of congenital anomalies. Nursing mothers should not receive the drugs because they will be excreted in breast milk. Older adults are susceptible to side effects of any anti-anxiety or sedative agent because of physiological changes in metabolism. Initial doses of benzodiazepines should be small, and increments are added gradually, based on client response, for a limited period of time. Clients should be warned not to take more than the prescribed dose, especially if the medication seems to become less effective after initial use. If older clients who were recently continent, mobile and alert become incontinent, confused and/or demonstrate impaired mobility, the use of benzodiazepines should be considered a possible cause.

A newer group of drugs are the non-benzodiazepines or commonly called Z drugs (Table 30-2). These drugs are quick-acting by acting on the same benzodiazepine receptor to induce sleep without the anti-anxiety effect. While they appear to have a lower dependence risk than benzodiazepines, they are not without side effects and need to be taken only for short periods of time. Clients need to be aware of the added risks of taking sedative hypnotics which can cause disorientation, amnesia and dependence. Antidepressant medication can also be used to treat insomnia and manage anxiety and depression, which is common in clients with insomnia. Melatonin, a naturally occurring hormone, can also be taken exogenously for treating insomnia.

Regular use of any sleep medication can lead to tolerance, and rebound insomnia can occur after stopping the medication. Immediately administering a sleeping medication when a hospitalised client complains of being unable to sleep may have longer term consequences that may do the client more harm than good. Alternative approaches to promoting sleep must be considered. Routine monitoring of client response to sleeping medications is important.

The use of non-prescription sleeping medications is not advisable. Clients should be made aware of the risks of such drugs as, over the long term, they can lead to further sleep disruption even when they initially seem to be effective. There are an increasing number of behavioural and environmental sleep hygiene options to establish sleep patterns that do not require the use of drugs.

• CRITICAL REFLECTION POINT

You are asked to help develop a health promotion brochure for senior citizens that includes information on how to promote sleep. The brochure will be available in clinics and senior citizens centres. What general information should be included in the brochure for sleep enhancement in this group?

Acute care

Clients in an acute care setting will have their normal rest and sleep routine disrupted; therefore, nursing interventions should focus on controlling factors in the environment that disrupt sleep, relieving physiological or psychological disruptions to sleep, and providing for uninterrupted rest and sleep periods. The nurse should also consider iatrogenic causes of sleep disturbance, such as diuretics prescribed to be given at night.

Environmental controls

A nurse can control the environment in a hospital in several ways. Nurses can close the curtains between clients in shared rooms. Lights in a hospital nursing unit can be dimmed at night. Noise can be reduced by conducting conversations and reports in a private area away from clients' rooms and keeping necessary conversation to a minimum, especially at night. Box 30-8 lists additional ways to control noise in the hospital.

Promoting sleep in healthcare facilities

Compared with beds at home, hospital beds are often harder and of a different height, length or width. Keeping beds clean and dry and in a comfortable position may help clients relax. Some clients suffer painful illnesses, requiring special comfort measures such as application of dry or moist heat, use of supportive dressings or splints and proper positioning before retiring. Pain is a frequent symptom that requires control using both non-pharmacological and pharmacological measures (see Chapter 36).

• CRITICAL REFLECTION POINT

Jo is a registered nurse working on night duty. What are some of the methods Jo could use to control noise and other environmental factors in the ward to make the area more conducive to good quality sleep?

Establishing sleep

In a hospital it is often difficult to provide clients with the time needed to rest and facilitate sleep. However, care can be planned to avoid waking clients for non-essential tasks.

BOX 30-8 Control of noise in the hospital

- Close doors to client's room when possible.
- Keep doors to work areas on unit closed when in use.
- Reduce volume of nearby telephone and paging equipment.
- Wear rubber-soled shoes. Avoid noisy shoes.
- Turn off bedside oxygen and other equipment that is not in use.
- Turn down alarms and beeps on bedside monitoring equipment.
- Turn off room TV and radio unless client prefers soft music.
- Avoid abrupt loud noise such as flushing a toilet or moving a bed.
- Keep necessary conversations at low levels, particularly at night.
- Conduct conversations and reports in a private area away from client rooms.

The nurse can help by scheduling assessments, treatments, procedures and routines for times when clients are awake. For example, if a client's physical condition has been stable, the nurse should avoid waking the client to check vital signs. Rest can be promoted by allowing clients to determine the timing and methods of delivery of basic care measures. Baths and routine hygiene measures should not be given during the night for nursing convenience. Ideally, non-urgent blood samples should be drawn at a time when the client is awake. Unless maintaining a drug's therapeutic blood level is essential, medications should be given during waking hours.

When a client's condition demands more-frequent monitoring, the nurse can plan activities to allow extended rest periods. This means planning activities so that instead of a nurse or other health professional returning to the room every few minutes, the client may have up to an hour or more to rest quietly. For example, if a client needs frequent dressing changes, is receiving physiotherapy and intravenous therapy and has drainage tubes from several sites, the nurse and physiotherapist should try to avoid making separate entries into the room to check or deliver care for each problem. Instead, the nurse should use a single visit to change the dressing, regulate the intravenous system and empty the drainage tubes, communicating with the physiotherapist about when this care will be given. Because of their constant presence, nurses can become the client's advocate for promoting sleep, which may occasionally mean becoming a gatekeeper by monitoring and controlling disturbances.

Stress reduction

Clients who are hospitalised often have difficulty resting or sleeping because of physical and psychological stress. If time permits, a nurse on the night shift should take time to sit and talk with clients who unable to sleep to help determine the factors keeping the client awake. Back rubs or hand massage can also help clients relax. If a sedative is indicated, the nurse will generally administer the lowest dose initially. Discontinuing a sedative as soon as possible prevents creating a dependence that may seriously disrupt the normal sleep cycle. Older adults can be vulnerable to the side effects of **sedatives**, hypnotics or analgesics because the medications are metabolised slowly.

Restorative or continuing care

Nursing interventions to promote sleep in the acute care setting can also be used in the restorative or continuing care environment. Controlling the environment, especially noise, establishing periods of rest and sleep and promoting comfort are important considerations. Nursing interventions related to stress reduction and controlling physiological disturbances are also implemented in these settings.

Promoting comfort

Providing for personal hygiene often improves a client's sense of comfort. A warm bath or shower before bedtime can be relaxing. Clients restricted to bed should be offered the opportunity to void and wash their face and hands. Brushing teeth and taking care of dentures also help to prepare the client for sleep. The nurse can recommend and use several additional measures to promote comfort in these clients (Box 30-9).

BOX 30-9 Comfort measures in restorative care

- Administer hygiene measures for clients on bed rest.
- Encourage client to wear loose-fitting nightwear.
- Remove or change any irritants against the client's skin, such as moist dressings or drainage tubing.
- Position and support dependent body parts to protect pressure points and aid muscle relaxation.
- Provide caps and socks for older adults and those prone to feeling cold.
- Encourage client to void before going to sleep.
- Administer analgesics or sedatives about 30 minutes before bedtime.

Controlling physiological disturbances

For clients with physical illness, the nurse can help control symptoms that disrupt sleep. For example, a client with respiratory abnormalities should sleep with two pillows or in a semi-sitting position to ease the effort to breathe. The client may benefit from taking prescribed bronchodilators before sleep to prevent airway obstruction. A client with a hiatus hernia also needs special care. After meals, the client may experience a burning sensation as a result of gastric reflux. To prevent sleep disturbances, the client should eat a small meal several hours before bedtime and sleep in a semi-sitting position. Clients with pain, nausea or other recurrent symptoms should receive any symptom-relieving medication timed so that the drug takes effect at bedtime.

• CRITICAL REFLECTION POINT

Jo has been experiencing some difficulty sleeping during the day following night duties. Outline some strategies she could use to help her sleep.

EVALUATING IMPACTS AND OUTCOMES

With regard to problems with sleep, the client is the best source for evaluating outcomes as each client has a unique and personal need for sleep and rest. The client is the only one who will know whether their sleep problems are improved and which interventions or therapies are most successful in promoting sleep (Figure 30-6). To determine whether expected outcomes of nursing interventions have been met, however, it is possible to make comparisons with baseline sleep assessment data to see whether evaluative measures of sleep have improved.

Evaluative measures may be used shortly after a therapy has been tried (e.g. observing whether a client falls asleep after reducing noise and darkening a room). Other evaluative measures may be used after a client wakes (e.g. asking how many times the client woke during the previous night). The client and bed partner can usually provide accurate evaluative information. Over longer periods, the nurse may use assessment tools such as the visual analogue scale or sleep rating scale to determine whether sleep has progressively improved or changed.

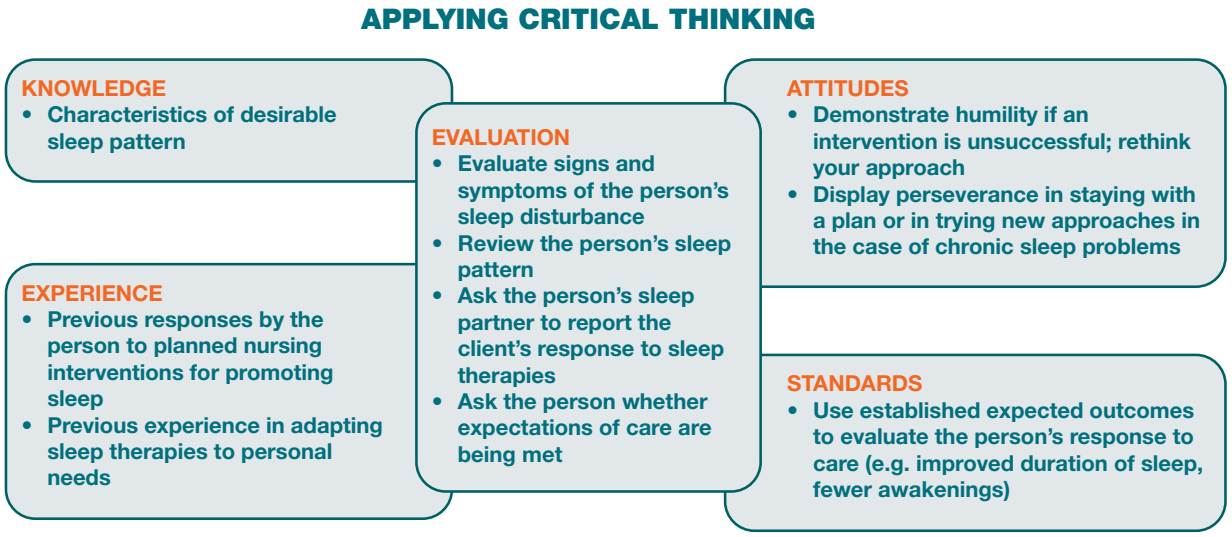

Figure 30-6 Critical thinking associated with the evaluation phase for fostering sleep.

An important part of outcome assessment is to assess the level of understanding that clients or family members have gained after receiving instruction and discussion of sleep habits. Compliance with new sleep practices may best be measured during a home visit, when the environment can be observed. When expected outcomes are not met or the client's situation changes, the nurse and client work together to revise expected outcomes based on the client's needs or preferences.

Client expectations

If the nurse has successfully developed a good relationship with a client and has devised a therapeutic plan of care, subtle behaviours often indicate the level of the client's satisfaction. The nurse may note the absence of signs of sleep problems, such as lethargy, frequent yawning or position changes, in the client. It is important for the nurse to ask the client if sleep needs have been met. For example, ask 'Are you feeling more rested?' or 'Do you feel we have done all we can to help improve your sleep?' If the client's expectations have not been met, the nurse needs to spend more time trying to understand the client's needs and preferences. Working closely with the client and bed partner will ensure that expectations can be realistically met within the limits of the client's condition and treatment.

Key concepts

- Sleep is an essential component of humans' biology and provides physiological and psychological restoration.
- Circadian rhythms are biological processes that oscillate approximately around a 24-hour cycle. They are regulated by a circadian clock and control the sleep–wake cycle.
- The total number of hours of sleep needed by individuals is variable.
- Sleep can be restorative or non-restorative depending on a range of factors (physiological and behavioural). Only the client can report whether sleep is restful.
- Neonates, infants, children and adolescents require more sleep than adults.
- A large number of conditions and diseases, such as anxiety, cancer and pain, can disrupt sleep.
- The most common type of sleep disorder is insomnia, which can be characterised by the inability to fall asleep, maintain sleep or frequently waking during the night or go back to sleep after waking earlier than desired.
- Sleep problems are considered a disorder when they produce significant anxiety or distress, or daytime impairment.
- Diagnosing sleep problems depends on identifying factors that impact or change sleep patterns.
- When planning interventions to promote sleep, the healthcare team should consider the usual characteristics of the client's home environment and normal lifestyle.
- One of the most important nursing interventions for promoting sleep in the hospitalised client is establishing prescribed periods for uninterrupted sleep and rest.
- Noise and pain control is essential to promote sleep.
- Long-term use of sleeping pills, mainly sedative hypnotics, may lead to difficulty in initiating and maintaining sleep.

Sustaining nutrition

Andrea Marshall and Shelley Roberts

Learning outcomes

Mastery of content will enable you to:

- explain why each nutrient is necessary for health
- understand the importance of balancing energy intake and energy output
- describe the role of macronutrients (carbohydrate, protein, fat) and their different types
- understand the different micronutrients and their roles in the body
- describe the digestive system and how nutrients are digested, absorbed, metabolised and stored in the body
- be aware of Australian and New Zealand dietary guidelines
- understand the importance of nutrition throughout different stages of the life cycle
- explain steps of the nutrition care process, including nutritional screening, assessment, intervention and monitoring
- describe the different types of nutrition support, including oral, enteral and parenteral nutrition
- describe the procedure for initiating and maintaining enteral nutrition
- discuss nutrition therapy specific to different disease processes

Nutrition: the basics

Food provides essential sustenance for life. Humans require many nutrients from the diet to provide energy, maintain life and stimulate growth and repair. Adequate nutrition is important for general health and wellbeing, as well as for the prevention and treatment of many diseases. A healthy diet can reduce the risks of diet-related conditions, such as high cholesterol, insulin resistance and obesity, and of chronic diseases such as type 2 diabetes, cardiovascular disease and some types of cancers (NHMRC 2006). Most of these conditions are the result of over-nutrition or obesity. Most chronic diseases and acute illnesses require medical nutrition therapy to help in their management or treatment. For example, diet is often used to manage blood glucose and blood lipids in patients with type 2 diabetes and cardiovascular disease, respectively. Also, acute illness or injury often requires extra nutrition (i.e. high energy/high protein diet) for recovery. In the hospital setting, under-nutrition (i.e. protein energy malnutrition) is a major problem, due to increased needs and decreased intakes of patients during acute illness. This section will describe the nutrients required by the body and how they are digested, absorbed and utilised; the *Australian Dietary Guidelines*; nutrition throughout the life cycle; and nutrition care for hospitalised patients.

Units of nutrition

Energy

The human body requires fuel, or energy, for cellular metabolism and repair, organ function, growth and body movement. Energy provided to and expended by the body is measured in kilocalories (kcal), commonly called calories, or kilojoules (kJ). While both measure energy, they are different units; one kcal is equivalent to 4.18 kJ. In Australia and New Zealand, kJ is the common unit used to describe energy. A variety of terms are used to describe individual energy expenditure, which is influenced by many factors (see Table 31-1).

In healthy individuals, a neutral energy balance (i.e. energy output = energy input) is recommended to maintain normal bodyweight. In this case, our energy requirements are equal to our **total energy expenditure** (TEE). If a positive energy balance exists (i.e. energy input > energy output), weight gain will result, except during times of growth, pregnancy or lactation, when a positive energy balance is needed. A negative energy balance (i.e. energy input < energy output) results in weight loss.

Energy requirements

Estimated energy requirement (EER) is the dietary energy intake predicted to maintain a neutral energy balance in healthy adults; hence, should directly reflect TEE. Many factors affect energy requirements, such as age, gender, body mass and composition, acute and chronic illness, injury, fever, infection, pregnancy and lactation, starvation and activity level. EER calculations should therefore account for such factors.

In hospital, energy requirements may be estimated (usually by dietitians) using predictive equations or indirect calorimetry. The Harris-Benedict, Schofield or Mifflin-St Jeor equations are examples of predictive equations that account for different patient-related factors such as age, gender, weight, height, temperature or activity. Static equations may also be used, which only account for bodyweight and disease state. While relatively quick and easy to use, the accuracy of predictive equations in estimating individual energy requirements is generally poor due to large individual variation in requirements, even between seemingly similar individuals (NHMRC 2006). For certain patient groups, such as the elderly, acutely and critically ill, and overweight and obese, these equations become even less accurate. Alternatively, **resting energy expenditure** (REE) or TEE can be determined through indirect calorimetry, a process that measures oxygen consumption and carbon dioxide production (using a metabolic cart) to calculate energy expenditure. While highly accurate, this method requires expensive and

TABLE 31-1 Measures of energy expenditure

Measure	Description
Basal metabolic rate (BMR)	The **basal metabolic rate** is the energy expenditure of a person at rest. This is the energy needed to maintain life-sustaining activities (breathing, circulation, heart rate and temperature) for a specific period of time and accounts for around 45–70% of total daily energy expenditure.
Resting energy expenditure (REE)	REE accounts for BMR plus energy needed to digest meals and perform mild activity. This is a baseline energy requirement that accounts for approximately 60–75% of our daily needs.
Total energy expenditure (TEE)	TEE is the measure of total daily energy usage. It encompasses BMR, REE and all other physical activities or bodily processes that require energy. TEE accounts for 100% of our energy output.

specialised equipment and trained operators; hence is used mainly for seriously-to-critically-ill patients in the hospital setting.

• CRITICAL REFLECTION POINT

Many clinicians believe that obese patients require fewer calories because they are overweight. All patients, regardless of BMI, can have increased energy requirements associated with illness. Determining resting energy expenditure in this patient population is challenging and should involve an interdisciplinary discussion (Kee et al 2012).

Energy is provided to the body through consumption of food and drink, and can be sourced from three macronutrients: carbohydrates, proteins and fats. Each macronutrient provides a different amount of energy (kJ) per gram and is absorbed, metabolised and used in the body in different ways. Alcohol also provides energy; however, due to the well-documented acute and chronic health consequences associated with its use, alcohol consumption is recommended to be kept to a minimum.

Macronutrients

Carbohydrate

Carbohydrates are the main source of energy in the diet, providing fuel for the brain, nervous system, skeletal muscles and cellular processes. Carbohydrates yield around 17 kJ per gram and in foods, are present as sugars, starches or fibre. Carbohydrates are classified according to their chemical units, called **saccharides** or sugars, and the most basic form of carbohydrate is often referred to as simple or complex (Gropper & Smith 2012). The types of carbohydrates consumed are very important for health outcomes (NHMRC 2006).

Simple carbohydrates

Simple carbohydrates are those that contain one or two sugars. *Monosaccharides* are the most basic unit of carbohydrate, containing only one molecule. They include fructose, galactose and glucose, which are absorbed directly from the gut into the bloodstream and used by the body for energy. Besides fructose (fruit sugar), monosaccharides are rarely found in foods on their own but are the products of broken-down chains of larger carbohydrates.

Disaccharides consist of two molecules, and include:

- Lactose: glucose + galactose (the sugar found in milk)
- Maltose: glucose + glucose (found in beer and some vegetables)
- Sucrose: glucose + fructose (common table sugar).

Complex carbohydrates

Complex carbohydrates, also called *polysaccharides*, contain three or more sugars. In the body, carbohydrate is stored as glycogen, a long-chain polysaccharide found in skeletal muscle and the liver. In food, complex carbohydrates include starches, which are found in breads, cereals, rice, and vegetables. Starches are digested to varying degrees and some, such as fibre, cannot be digested because humans do not have the enzymes capable of breaking them down.

Fibre is found in plant-based foods and is essential for proper functioning of the gastrointestinal tract by promoting regular bowel habits and preventing constipation. Fibre intake is also associated with reduced risk of chronic diseases such as heart disease, certain cancers and diabetes. **Insoluble fibres** are not digestible and include cellulose, hemicellulose and lignin. These aid in adding bulk to faeces for easier bowel movements. **Soluble fibres** include pectins, gums and mucilage. Soluble fibre is beneficial for the digestive system and also reduces cholesterol by binding to it and carrying it out of the body.

Protein

Proteins can be metabolised to release energy, yielding 17 kJ per gram. However, their main purpose is for synthesis (building) of body tissue in growth, maintenance and repair. Collagen, hormones, enzymes, immune cells, DNA and RNA are all composed of protein. In addition, blood clotting, fluid regulation and acid–base balance require proteins. Nutrients and many pharmacological substances are transported in the blood by proteins (Gropper & Smith 2012).

The simplest form of protein is the **amino acid**. There are 20 amino acids that constitute proteins (Box 31-1). Of these, some can be synthesised in the body from other substrates (**non-essential amino acids**). Others cannot be synthesised and therefore must be provided from the diet (**essential amino acids**). Conditionally essential amino acids are needed by the body in special situations when the body has undergone stress, trauma or illness. Amino acids can be linked together to form dipeptides, tripeptides and oligopeptides. Albumin and insulin are **simple proteins** because they contain only amino acids or their derivatives. The combination of a simple protein with a non-protein substance produces a **complex protein**, such as lipoprotein, formed by a combination of a lipid and a simple protein (Gropper & Smith 2012).

Protein is 16% nitrogen and serves as the only source of nitrogen for the body. Nitrogen balance is achieved when the intake and output of nitrogen are equal. When nitrogen intake is greater than nitrogen output, the body

BOX 31-1 Amino acids required in nutrition

Essential amino acids

Histidine
Isoleucine
Leucine
Lysine
Methionine
Phenylalanine
Threonine
Tryptophan
Valine

Non-essential amino acids

Alanine
Asparagine
Aspartic acid
Glutamic acid
Serine

Conditionally essential amino acids

Arginine
Cysteine
Glutamine
Glycine
Proline
Tyrosine

Adapted from Lutz C, Przytulski K 2011 Nutrition and diet therapy: evidence-based applications, 5th edn. FA Davis, Philadelphia.

is in a positive nitrogen balance and hence there is an increase in total body protein. This is normally observed during periods of growth, pregnancy or healing. The nitrogen retained by the body is used for building, repair and replacement of body tissues. Negative nitrogen balance (i.e. nitrogen intake < nitrogen output) indicates a total loss of body protein, which is not normal, but may occur during acute illness, trauma, infection or malnutrition. The increased nitrogen loss is the result of body-tissue destruction or loss of nitrogen-containing body fluids. Nutrition during this period must provide protein to put patients into positive balance for healing.

In the diet, there are different types and quality of proteins:

- A **complete protein** contains all essential amino acids in sufficient quantity for protein synthesis in the body, to allow growth and maintain **nitrogen balance**. Complete proteins are also referred to as high-quality proteins and are mostly sourced from animal-based foods such as meat, poultry, fish, eggs and dairy. This is because the amino acid profiles of animal foods are closer to that of humans; however, some plant-based foods, such as soy, are also considered complete proteins.
- **Incomplete proteins** lack one or more of the nine essential amino acids and include those found in plant-based foods, such as cereals, grains, nuts, legumes (beans, peas) and vegetables. All essential amino acids can be provided from plant sources, given they are adequately complemented in the diet.
- **Complementary proteins** are pairs of incomplete proteins, which, when combined, supply adequate amounts of amino acids for protein synthesis.

Protein can be used to provide energy, but because of protein's essential role in growth, maintenance and repair, adequate kilojoules should be provided in the diet from non-protein sources. Protein is spared as an energy source when there is sufficient carbohydrate in the diet to meet the energy needs of the body. When there is insufficient energy from other sources, the body metabolises dietary protein and body protein (such as skeletal muscle) for energy, leading to muscle wasting. This is commonly seen in protein-energy malnutrition. Protein requirements are higher during growth, healing, pregnancy, lactation and certain disease states.

Fat

Fats (**lipids**) are the most concentrated source of energy, yielding 38 kJ per gram. Most fats in foods are **triglycerides**, comprised of a glycerol and three fatty acids. The combinations of fatty acids, which may be three of the same or different fatty acids, usually determine the type of triglyceride. Fatty acids are composed of chains of carbon and hydrogen atoms with an acid group at one end, and a methyl group at the other end of the chain. The main types of fatty acids are saturated, monounsaturated and polyunsaturated (Gropper & Smith 2012).

Saturated fatty acids are saturated with hydrogen; so each carbon atom in the chain is linked by a single bond and has two hydrogen atoms attached. These fats are more rigid and are therefore solid at room temperature (e.g. butter, lard, coconut oil). As saturated fats can be synthesised by the body, they are not required in the diet.

Unsaturated fatty acids contain double bonds between the carbon atoms and hence have fewer hydrogen atoms in the chain. These fatty acid chains are more fluid, hence are liquid at room temperature (e.g. most oils). *Monounsaturated fats* have one double bond, while *polyunsaturated fats* contain two or more double bonds. The main monounsaturated fatty acid is oleic acid, which is found in olive, canola and peanut oils. The most common

polyunsaturated fat is linoleic acid (omega 6), which can be manufactured in the body or sourced from sunflower, safflower and corn oils. Omega 3 fatty acids cannot be produced by the body and therefore must be provided by the diet. They are found in legumes, canola oils and margarines, linseed oil and walnuts (alpha-linoleic acid) and oily fish such as mackerel, herrings, sardines, salmon and tuna (long-chain omega 3 acids).

Fats are needed in the diet for the absorption of fat-soluble vitamins and have numerous physiological and structural functions in the body. Some fats have beneficial properties for health; for example, high intakes of polyunsaturated fats are associated with reduced risk of heart disease and improved blood lipid profiles. These fats help to reduce total cholesterol and 'bad' low-density lipoprotein (LDL) cholesterol, as well as increase 'good' high-density lipoprotein (HDL) cholesterol in the blood. However, other types of fats may be detrimental when consumed in large quantities, such as saturated fats and trans fats. Trans fats are formed by partial hydrogenation of polyunsaturated fats during cooking and mimic saturated fats in the body. These types of fats can increase total and LDL cholesterol and lower HDL cholesterol, increasing the risk of heart disease. Also, because fat contributes a significant amount of energy per gram, a high total fat intake can lead to overconsumption of energy (or kilojoules), which over time leads to weight gain. Hence, the amount and types of dietary fats are extremely important to consider for general health and disease prevention (NHMRC 2006).

Water

Water is considered an essential nutrient as it is required in greater amounts than can be produced by the body. Water constitutes 50–80% of total bodyweight, depending on age, gender and lean body mass. The percentage of total body water decreases with age and is higher in men due to their higher proportion of lean body mass. All cell functions and biochemical reactions in the body depend on a fluid environment, and water is required for digestion, absorption and transportation of nutrients, elimination of waste and thermoregulation. Unlike all other nutrients, a person cannot survive for more than a few days without water. Fluid needs differ depending on age, gender, physical activity level and individual metabolism and health. Water is provided in the diet from the ingestion of liquids such as free water and/or other fluids, which account for around 80% of fluid intake. The remainder is provided by solid foods that contain water, such as fruits, vegetables and dairy foods. Water is also produced during digestion when food is oxidised, although in inadequate amounts to meet the body's needs (Gropper & Smith 2012).

Dehydration can be caused from high water losses and/or low fluid intake (see Chapter 34). Normal water losses occur from the lungs and skin (i.e. breathing and sweating) and are highly dependent on environmental factors. Water is also lost through urine and faeces, and these losses may be higher in some disease states or with certain medications (e.g. diarrhoea, diuretics). Inadequate fluid intake may occur due to a poor thirst mechanism, difficulty swallowing or dislike of the taste of water. These are particularly common problems among elderly people, who are at higher risk of dehydration. Depending on the degree of water loss and the length of time in negative fluid balance, dehydration can be a very serious condition that can result in acute impairments in physiological and cognitive function, and in chronic diseases or problems such as kidney stones and constipation.

People can also become fluid overloaded, which is usually due to a decreased ability to excrete fluid (e.g. in patients with congestive cardiac failure or renal disease). This often results in the need to restrict fluid intake to avoid high blood pressure, oedema and potentially fatal changes in blood electrolyte concentrations. Maintaining fluid balance is extremely important in a range of clinical conditions.

Vitamins

Vitamins are organic compounds that are required in small amounts for metabolic and physiological processes. As the body is unable to synthesise vitamins in sufficient amounts, humans depend on their dietary intake for vitamins. Vitamins are affected by processing, storage and preparation; hence vitamin content is usually highest in fresh foods that are used quickly after minimal exposure to heat, air or water. Vitamins are classified as either fat-soluble or water-soluble (Gropper & Smith 2012).

Fat-soluble vitamins

The fat-soluble vitamins (A, D, E and K) are mostly provided by the diet and require the ingestion of dietary fat for absorption; however, some can be synthesised in the body. Fat-soluble vitamins are stored in the body (in the liver and adipose/fat tissue) and are not readily excreted; therefore, daily consumption is not necessary but megadoses (usually due to overconsumption of supplemental vitamins or fortified foods) can result in toxicity. Fat-soluble vitamins have a variety of roles and functions in the body and can be sourced from a range of foods.

Vitamin A is essential for reproduction, vision and immune function in the body. It helps to maintain the integrity of epithelial and retinal cells, regulate gene expression and plays an integral role in embryonic development. Sources of vitamin A in the diet include

retinol (true vitamin A), found in animal foods such as eggs, meat, liver, dairy and fish; and also dietary precursors to retinol such as beta-carotene, found in plant foods such as pumpkin, sweet potato, carrots, spinach, apricots and mangoes.

Vitamin D plays an important role in maintaining serum calcium concentrations in the body by enhancing calcium absorption in the small intestine. Vitamin D maintains blood calcium at high concentrations so calcium is deposited into the bone; and when dietary calcium intake is inadequate it assists with mobilising calcium stores from the bone. Vitamin D is mostly produced by the action of sunlight on the skin. While limited amounts are also provided by the diet, in oily fish such as herring, salmon and sardines and milk and dairy products, it is almost impossible to obtain enough vitamin D from food alone.

Vitamin E acts as an antioxidant in the body by protecting polyunsaturated fatty acids from oxidation and free radical damage in the lipid phase of cell membranes. The main source of vitamin E is fats and oils such as sunflower, safflower, canola, olive and soybean oils. It is also found in the fats of meat, poultry and fish, some vegetables, and dairy foods.

Vitamin K is important for normal blood coagulation due to its requirement for the synthesis of coagulant and anticoagulant proteins. Most vitamin K needed by the body is produced by bacteria in the gut, but some is provided from dietary sources such as green leafy vegetables (i.e. spinach, broccoli, cabbage) and fats such as soybean and canola oils and margarines made from these oils.

• CRITICAL REFLECTION POINT

Parents often augment their children's diet with dietary supplements such as multivitamins. A recent review of over-the-counter paediatric multivitamin supplements identified that more than two-thirds of those available exceeded the recommended daily amount of vitamin A. Vitamins D and E were also above the recommended daily amount for children and toddlers. These increased amounts pose a risk of toxicity, particularly if overconsumption is encouraged. A balanced diet should be the main source of micronutrients (Samuel et al 2015).

Water-soluble vitamins

The water-soluble vitamins are the B-complex, which consists of eight vitamins, and vitamin C. Being water-soluble they are easily absorbed (by simple diffusion). Most water-soluble vitamins are not stored in the body in sufficient amounts so must be consumed on a regular basis, although toxicity may still occur. B-complex vitamins have important roles in energy metabolism in the body, as they are used to form a number of co-enzymes for metabolic reactions such as carbohydrate, fat and protein metabolism. Folate and vitamin B_{12} are also vital for DNA synthesis.

Vitamin C is an antioxidant and acts as an electron donor for a number of enzymes involved in collagen synthesis and is required for the growth and repair of tissues such as skin, tendons, ligaments, blood vessels and bone. It also promotes iron and copper absorption in the intestine and protects against infection due to its immunologic roles. Table 31-2 describes common food sources of each of the water-soluble vitamins.

TABLE 31-2 Water-soluble vitamins

Vitamin	Sources
Thiamine (vitamin B_1)	Wholegrains[a]
Riboflavin (vitamin B_2)	Milk and dairy products, fortified breads and cereals
Niacin (vitamin B_3)	Lean meats, poultry, fish, eggs, milk, wholegrains
Pantothenic acid (vitamin B_5)	Meats (particularly organ meats), poultry, egg yolks, potato, tomato products
Vitamin B_6	Meats (muscle and organ meats), wholegrain cereals, vegetables, fruits, nuts
Biotin (vitamin B_7)	Liver, eggs, dairy, nuts, soy
Folate (vitamin B_9)	Cereals and cereal products, green leafy vegetables, liver, lean beef, legumes
Vitamin B_{12}	Milk and dairy products, eggs, fish, meats (muscle and organ meats)[b]
Vitamin C	Fruits and vegetables (berries, citrus and kiwifruit; green leafy vegetables)

a Thiamine is lost in milling and refining of flours, therefore Australia introduced mandatory enrichment of baking flour in 1991 to prevent deficiency.

b Humans must obtain vitamin B_{12} from animal sources.

National Health and Medical Research Council, Australian Government Department of Health and Ageing, New Zealand Ministry of Health 2006 Nutrient Reference Values for Australia and New Zealand. Canberra, ACT.

Minerals

Minerals are inorganic elements essential to the body as catalysts in biochemical reactions. Minerals are classified as macrominerals (daily requirement 100 mg or more) or microminerals (daily requirement < 100 mg). The function and sources of common dietary minerals are summarised in Table 31-3.

TABLE 31-3 Minerals

Mineral	Function	Sources
Trace minerals (macro and microminerals)		
Calcium	Structural component of bones and teeth, cellular and extracellular functions (cell membrane transport, nerve transmission, skeletal and cardiac muscle signalling)	Milk and dairy products, edible bones of fish (i.e. sardines and canned salmon), legumes, green leafy vegetables
Copper	Component of many enzymes involved in oxidising iron before it is transported in the plasma, cross-linking collagen and elastin for connective tissue, electron transport, and antioxidants	Meats (especially organ meats), seafood, nuts, seeds, wholegrains, legumes
Iron	Component of haemoglobin (needed to transport oxygen around the body), myoglobin (oxygen reservoir within muscle) and enzymes involved in redox reactions. Also required for red blood cell and DNA synthesis and immune system function	Meats (especially liver), poultry, seafood, fortified cereals, legumes, green leafy vegetables
Magnesium	Contained in bone, muscle, soft tissues and body fluids. Cofactor for >300 enzyme systems and important for energy production and metabolism	Legumes, nuts, seeds, wholegrains, green leafy vegetables, some shellfish
Phosphorous	Present in the skeleton (as calcium phosphate), soft tissues, in cells (as phospholipids in every cell membrane) and in extracellular fluids. Used in DNA and RNA, ADP, acid–base balance, energy storage and transport, and catalytic proteins	Meat, poultry, fish, eggs, milk and dairy products, nuts, legumes, cereals, grains
Potassium	Essential for osmotic balance between cells and interstitial fluid; and for electrical communication of nerve and muscle cells	Fruits and vegetables (green vegetables, tomatoes, pumpkin, apples, oranges, bananas), milk and dairy products, meats
Sodium	Maintenance of extracellular volume, serum osmolality and membrane potential of cells; and active transport across cell membranes	Found widely in foods as sodium chloride (salt)[a]
Zinc	Component of >300 enzymes involved in synthesis or degradation of carbohydrates, fats, proteins and alcohol; regulation of gene expression; and maintaining structural integrity of proteins	Meat, poultry, seafood, fortified cereals, milk and dairy products
Ultratrace minerals (microminerals)		
Chromium	Potentiates insulin action and influences carbohydrate, protein and fat metabolism	Yeast, seafood, potatoes, wholegrains, meat, poultry
Fluoride	Mineralisation of bones and teeth, protection against dental caries	Fluoridised water, tea, coffee, rice, soybeans, some fish
Iodine	Synthesis of thyroid hormones, which are important for growth, metabolism and cellular processes	Iodised salt, seafood (clams, lobsters, oysters, sardines and other saltwater fish), milk, eggs[b]
Manganese	Formation of bone and tissues; carbohydrate, protein and fat metabolism	Wholegrains, legumes, nuts, tea, vegetables
Molybdenum	Cofactor for several enzymes that catalyse redox reactions and catabolise amino acids	Legumes, wholegrains, milk and dairy products, nuts, green leafy vegetables[b]
Selenium	Antioxidant, redox reactions and thyroid metabolism	Brazil nuts, seafood, poultry, eggs, meats[b]

a Usually overconsumed due to high intakes of packaged and fast foods.

b Amounts of the mineral in foods depend on soil content of the mineral and/or the animal's diet (except seafood).

National Health and Medical Research Council, Australian Government Department of Health and Ageing, New Zealand Ministry of Health 2006 Nutrient Reference Values for Australia and New Zealand. Canberra, ACT.

Anatomy and physiology of the digestive system

The main role of the digestive system is to extract macro- and micronutrients from ingested food and fluids for use in the body. The digestive system also acts as a physical and immunological barrier to ingested microorganisms, antigens or other foreign materials. The digestive system (Figure 31-1) is made up of the gastrointestinal (GI) tract, which runs from the mouth to the anus and includes the oropharangeal structures, oesophagus, stomach and small and large intestine; and accessory organs, including the liver, gallbladder and pancreas. All of these organs have a vital role in processing food and fluids, which occurs in several steps: digestion, absorption, transport and utilisation or storage (Gropper & Smith 2012).

Digestion

Digestion consists of mechanical, chemical and hormonal activities that are interdependent. Mechanical breakdown of food results from chewing, churning and mixing and is required to increase the surface area of food for chemical action. Chemical reactions by which food is reduced to its simplest form are facilitated by **enzymes** – protein-based molecules that act as catalysts to speed up these reactions (see Table 31-4). Hormones regulate digestive processes locally or distally by affecting GI motility, secretions and blood flow and are signalled by the GI tract itself or from the central nervous system (see Table 31-5).

Digestion begins in the mouth, where food is mechanically broken down by chewing. The food is mixed with saliva, which contains ptyalin (salivary amylase), an enzyme that starts to break down starches into shorter chain polysaccharides. The longer food is chewed, the more starch digestion occurs in the mouth. Proteins and fats are broken down physically by chewing, but remain unchanged chemically because enzymes in the mouth do not react with these nutrients. Chewing allows food to be broken down into smaller particles and saliva provides lubrication, both of which assist swallowing.

The epiglottis is a flap of skin that closes over the trachea to prevent aspiration (i.e. food going into the lungs) as swallowing occurs. Difficulty with swallowing is referred to as **dysphagia** and is common among certain patients, such as those who have had a stroke, those experiencing dementia or with a neurodegenerative disease such as Parkinson's disease. Swallowed food enters the oesophagus and is moved along by wavelike muscular contractions (*peristalsis*) to the base of the oesophagus, above the lower oesophageal (cardiac) sphincter. Pressure from a bolus of food at the lower oesophageal sphincter causes it to relax, allowing the food to enter the fundus, or uppermost portion, of the stomach. The lower oesophageal sphincter also prevents the reflux of gastric contents into the oesophagus. Around 9% of Australians suffer from gastro-oesophageal reflux disease (GORD), in which gastric reflux causes symptoms or complications that impact on a person's wellbeing, such as heartburn, regurgitation, oesophageal ulcers or Barrett's oesophagus.

TABLE 31-4 Summary of enzymatic digestion of macronutrients

Place of digestion	Nutrient	Enzyme: action
Mouth	Carbohydrate	Salivary amylase: starch → shorter chain polysaccharides
Stomach	Protein	Pepsin: protein (peptide bonds) → polypeptides and amino acids
	Fat	Gastric lipase: fat → free fatty acids
Small intestine (pancreatic secretions)	Carbohydrate	a-Amylase: starch → dextrins and maltose
	Protein	Trypsin, chymotrypsin, carboxypepsidase and elastase: proteins, peptides and polypeptides → polypeptides and amino acids
	Fat	Pancreatic lipase: fat → monoglycerides and fatty acids
		Cholesterol esterase: cholesterol → cholesterol esters and fatty acids
Small intestine (primarily brush border enzymes)	Protein	Peptidases[a]: peptides → amino acids
	Carbohydrate	Sucrase: sucrose → glucose and fructose
		Maltase: maltose → glucose
		Lactase: lactose → glucose and galactose
		a-Dextrinase (isomaltase): dextrin → glucose

→ hydrolysed to

a carboxypeptidase, aminopeptidase and dipeptidase

TABLE 31-5 Major gastrointestinal hormones and their functions

Hormone (site of release)	Stimulants for release	Effects
Gastrin (stomach, duodenum)	Ingestion of proteins, caffeine, some alcoholic beverages	Stimulates secretion of hydrochloric acid (HCl) and pepsinogen in the stomach; increases gastric motility and lower oesophageal sphincter tone
Secretin (duodenal mucosa)	Acid in small intestine	Increases output of water, bicarbonate, insulin and some enzymes from the pancreas; decreases duodenal motility and increases duodenal mucous output
Cholecystokinin (proximal small intestine)	Ingestion of proteins, fats and presence of HCl	Stimulates secretion of pancreatic enzymes; contraction of gallbladder; slows gastric emptying; increases colon motility
Glucose-dependent insulinotropic polypeptide (small intestine)	Ingestion of glucose, fat	Stimulates insulin release from the pancreas
Glucagon-like peptide (small intestine)	Ingestions of glucose, fat	Slows gastric emptying; inhibits glucagon release; stimulates insulin release
Motilin (stomach, small and large intestine)	Biliary and pancreatic secretions	Promotes gastric emptying and GI motility

In the stomach (Figure 31-1), food is mixed and churned with gastric secretions by wavelike contractions. Gastric secretions contain hydrochloric acid (HCl), mucous, intrinsic factor, the hormone gastrin (see Table 31-5) and a number of enzymes (see Table 31-4). These components act in different ways to chemically break down food or assist with absorption. For example, HCl is important for activating pepsin and killing ingested microorganisms; mucous protects the stomach lining from autodigestion; and intrinsic factor is required for downstream absorption of vitamin B_{12}. The stomach acts as a reservoir for ingested food and slowly releases the mixture of partially digested food and gastric secretions (i.e. chyme) into the small intestine in tiny amounts. Most of a solid meal is emptied from the stomach within 3 hours; however, this can range from 1 to 7 hours depending on the amount and types of foods/fluids consumed. In a mixed meal, liquids are emptied from the stomach the fastest, followed by carbohydrate, protein, fat and lastly, fibre. Large food particles empty more slowly than smaller particles, and concentrated sources of energy empty more slowly than low-calorie meals. These factors tend to have an effect on an individual's satiety (i.e. feeling of fullness after a meal).

Chyme leaves the antrum, or distal stomach, via the pyloric sphincter and enters the duodenum (Figure 31-1). Peristalsis continues in the small intestine, mixing the acidic chyme with bile, intestinal juices and pancreatic secretions. The majority of digestion occurs in the small intestine. Bicarbonate-containing secretions from the pancreas raise the pH of chyme to become more neutral, inhibiting the action of gastric enzymes and promoting the action of duodenal secretions. Bile is manufactured in the liver and stored in the gallbladder, and acts as a detergent by emulsifying fat to permit enzyme action. Pancreatic secretions contain a number of enzymes that act to break down carbohydrates, proteins and fats (see Table 31-4). Intestinal contents are moved slowly along the small intestine by peristalsis and may take between 3–8 hours to reach the ileocaecal valve, where they pass from the small intestine into the colon (Gropper & Smith 2012).

Absorption

The small intestine is the primary absorption site for nutrients. It is lined with finger-like projections called *villi*, which are themselves covered with even smaller projections called *microvilli*, also known as the brush border (see Figure 31-1). The purpose of the villi and microvilli is to create a large surface area (around 200–300 m^2) within the small intestine to facilitate nutrient absorption. Nutrients are absorbed by means of passive diffusion, osmosis, active transport and pinocytosis. Diffusion involves the movement of nutrients through mucosal cell membranes and may be simple (using channel proteins) or facilitated (using carrier proteins). Active transport requires energy (i.e. ATP) to move substances across cell membranes. Pinocytosis allows larger particles such as whole proteins to be absorbed by the epithelial cell membrane engulfing them. Figure 31-1 describes the site, means and route of absorption of major nutrients.

The small intestine reabsorbs the majority of fluids secreted from the GI tract and around 95% of bile salts for recycling. The small intestine also absorbs most of the fluids

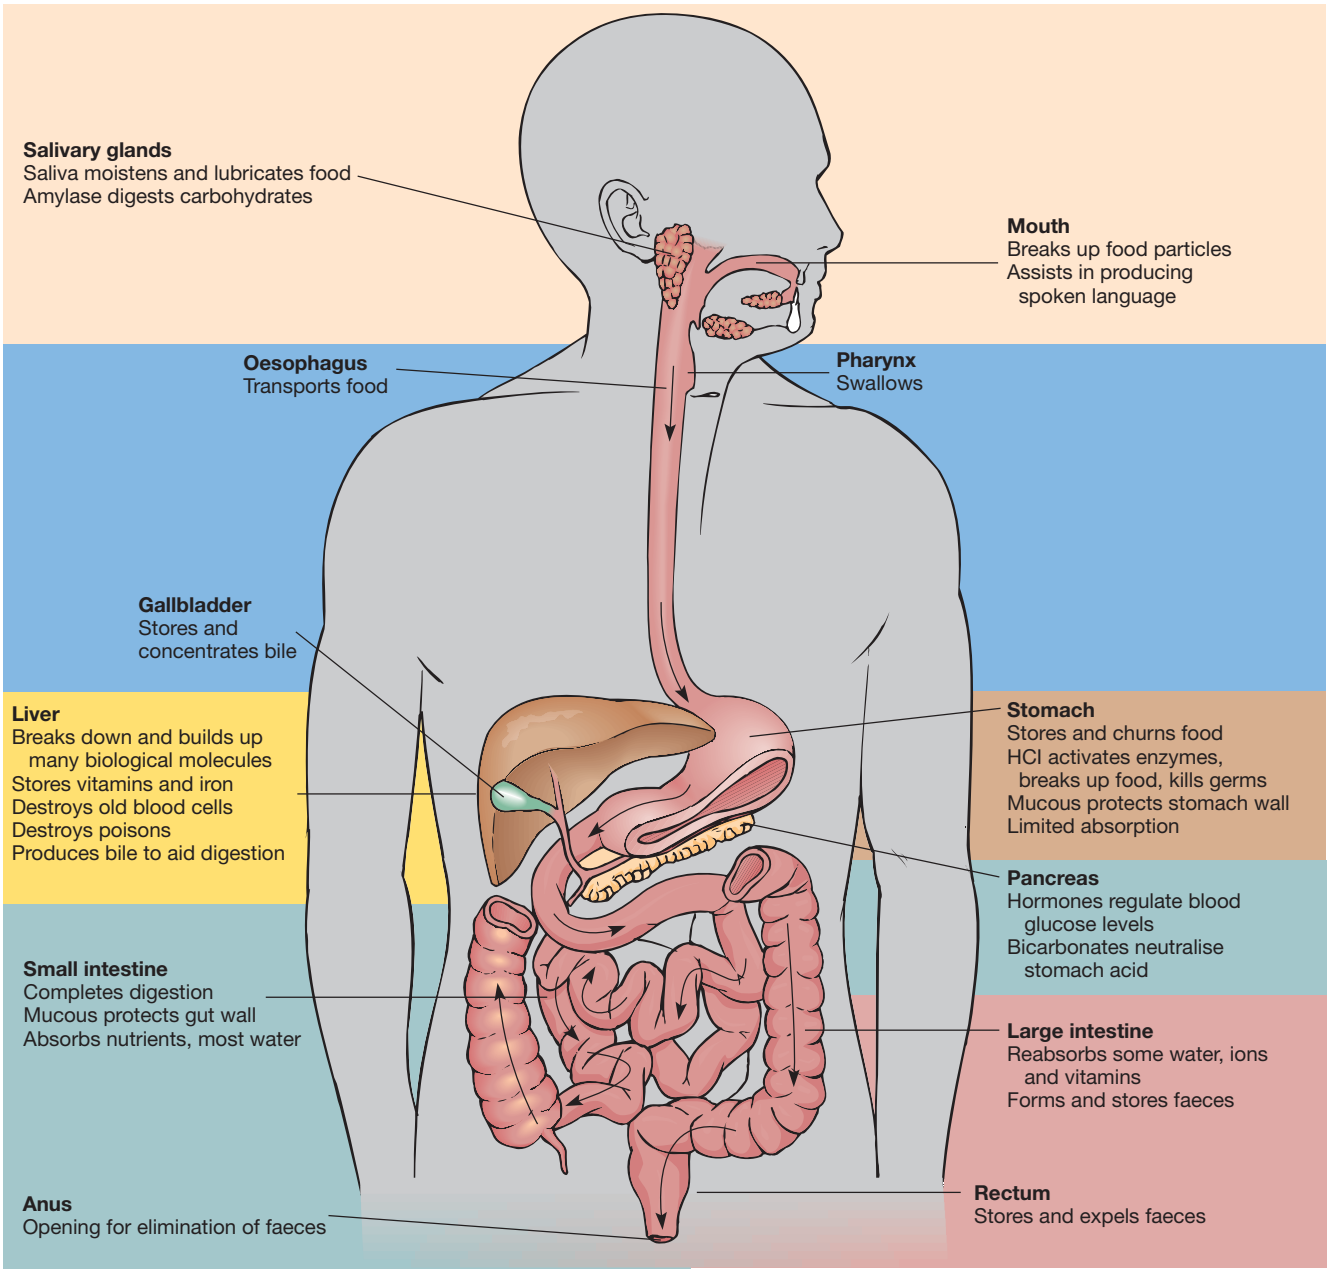

Figure 31-1 Summary of digestive system anatomy/organ function.

Drawn by Rolin Graphics.

ingested through the diet and the large intestine absorbs the remaining water and some electrolytes (sodium and potassium) in the process of producing faeces. In the large intestine, bacterial fermentation and production of vitamin K also occurs. Faeces are the waste product of ingested foods and fluids and are expelled at the anus, the end of the GI tract (Gropper & Smith 2012).

• CRITICAL REFLECTION POINT

Patients who have had surgical resection, a congenital defect or loss of absorption related to acute or chronic illnesses are unable to maintain protein-energy, micronutrient and fluid/electrolyte balance. Typically these patients are managed with intravenous artificial nutrition, although development of advanced medical therapies, such as small bowel transplantation, holds potential for allowing these patients to become nutritionally independent.

Metabolism and storage of nutrients

Metabolism refers to all the biochemical reactions within the cells of the body. Metabolic processes can

be anabolic (building) or catabolic (breaking down). **Anabolism** is the building of more complex biochemical substances by synthesis of nutrients; for example, when lean muscle mass is built or body tissues are repaired. Amino acids are anabolised into tissues, hormones and enzymes. **Catabolism** is the breakdown of biochemical substances such as carbohydrates, proteins and fats into simpler substances to be used for energy. Starvation is an example of catabolism, when wasting of body fat and muscle mass occurs. Normal metabolism and anabolism are physiologically possible when the body is in positive nitrogen balance, whereas catabolism occurs during physiological states of negative nitrogen balance (Gropper & Smith 2012).

Nutrients absorbed in the intestines, including water, are transported through the circulatory system to body tissues. Through the chemical changes of metabolism, nutrients are converted into a number of substances required by the body. Carbohydrates, protein and fat undergo metabolism to produce chemical energy and to maintain a balance between anabolism and catabolism. Chemical energy is converted to other types of energy by different tissues to be used for various body processes. For example, muscle contraction involves mechanical energy, nervous system function involves electrical energy and heat production involves thermal energy. All these forms of energy originate in metabolism.

Some of the nutrients absorbed by the body are not utilised immediately and are stored in tissues. When excesses of macronutrients (i.e. carbohydrate, protein and fat, providing energy) are consumed, they are stored in the body for energy reserves. The body's major form of energy reserve is fat, stored as adipose tissue. To a certain extent, excess protein is stored in muscle mass and excess carbohydrate is stored as glycogen in small amounts in skeletal muscle and the liver. However, most excess energy consumed (regardless of its source) is eventually stored as fat if it is not used (i.e. positive energy balance), leading to weight gain.

Nutrient metabolism consists of three main processes:

- Catabolism of glycogen into glucose, carbon dioxide and water (**glycogenolysis**)
- Anabolism of glucose into glycogen for storage (**glycogenesis**)
- Catabolism of amino acids and glycerol into glucose for energy (**gluconeogenesis**).

When the body's energy expenditure exceeds energy intake (i.e. negative energy balance), stored energy is utilised. Monoglycerides from the digested portion of fats can be converted to glucose by gluconeogenesis. Amino acids can be converted to fat and stored or catabolised into energy via gluconeogenesis. All body cells, except red blood cells and neurons, can oxidise fatty acids into ketones for energy in the absence of dietary carbohydrates. Glycogen (stored carbohydrate) provides energy during brief periods of fasting, maintaining blood glucose levels during sleep.

Dietary guidelines

Nutrient reference values

In Australia the National Health and Medical Research Council (NHMRC) developed *nutrient reference values (NRV)* to provide recommendations for nutritional intake based on the best available scientific knowledge (NHMRC 2006). NRVs are presented in a number of ways, depending on the nutrient and the evidence available for its requirement (see Table 31-6).

For macronutrients, the acceptable macronutrient distribution range (AMDR) is used to suggest levels of intakes and is presented as the percentage of each macronutrient's contribution to total daily energy intake (see Table 31-7). So, if the intake of one nutrient (e.g. protein) is increased, the relative proportions of the other nutrients that contribute to energy intake (e.g. carbohydrate and fat) will decrease. AMDRs were developed based on the best evidence for minimising chronic disease risk and ensuring adequate micronutrient intakes. They are recommendations for healthy people aiming to maintain their current bodyweight.

To calculate the contribution of a macronutrient to total daily energy intake, divide the daily energy provided by that nutrient by the total daily energy intake. For example, if an individual consumes a total of 9000 kJ on a given day, which includes a total of 85 g of fat, the total energy contribution of fat is calculated as:

Total daily grams of fat (85 g) multiplied by its energy content per gram (i.e. 38 kJ per gram):

$$85\ \text{g} \times 38\ \text{kJ/g} = 3230\ \text{kJ provided by fat}$$

Then, divide this number by the total daily energy intake for the percentage of energy coming from fat:

$$3230\ \text{kJ} \div 9000\ \text{kJ} = 35.9\%\ \text{of total energy is provided by fat}$$

As you can see, this falls just outside of the AMDR for fat. For some macronutrients, **recommended daily intake (RDI)** or adequate intake (AI) is age- and gender-dependent (see Table 31-8). Tables 31-9 to 31-11 show the NRVs for fat and water-soluble vitamins and minerals.

TABLE 31-6 Nutrient reference values

Nutrient reference value	Description
RDI (Recommended Dietary Intake)	The average daily level of intake considered adequate to meet the nutrient requirements of practically all (97–98%) healthy people in a particular life stage and gender group. RDIs exceed the actual nutrition requirement of most healthy persons
EAR (Estimated Average Requirement)	The daily level of intake estimated to meet the requirements of half the healthy individuals in a particular life stage and gender group
AI (Adequate Intake)	Used when RDI cannot be determined. This is the average daily level of nutrient intake based on observed or experimentally determined approximations or estimates of nutrient intake by a group or groups of apparently healthy people that are assured to be adequate
UL (Upper Level of intake)	The highest average daily level of nutrient intake likely to pose no adverse health effects to almost all individuals in the general population. As intake increases above the UL, the risk of adverse health effects increases
AMDR (Acceptable Macronutrient Distribution Range)	An estimate of the range of intake for each macronutrient (i.e. carbohydrate, protein, fat), expressed as a percentage of contribution to total energy intake, which would allow for an adequate intake of all other nutrients while maximising general health outcome
SDT (Suggested Dietary Target)	A daily average intake from food and beverages for certain nutrients that may help in the prevention of chronic disease

National Health and Medical Research Council, Australian Government Department of Health and Ageing, New Zealand Ministry of Health 2006 Nutrient Reference Values for Australia and New Zealand. Canberra, ACT.

TABLE 31-7 Acceptable macronutrient distribution ranges

Australian Dietary Guidelines

The *Australian Dietary Guidelines* have been developed by the NHMRC based on the best available scientific evidence (NHMRC 2013). They give advice on dietary habits to promote health and wellbeing and reduce the risk of dietary-related conditions and chronic diseases. The guidelines are aimed at health professionals, researchers, policy-makers and food manufacturers, in order to promote healthy eating among Australians. See Box 31-2 for the general *Australian Dietary Guidelines*.

The *Australian Guide to Healthy Eating* is a visual guide representing the proportion of the five food groups recommended to be consumed each day (see Figure 31-2). The guide was developed using a modelling system to translate the NRVs into dietary models – that is, it describes the amounts of foods within each food group required to meet the estimated nutrient requirements of

TABLE 31-9 Recommended dietary intakes: fat soluble vitamins

Group/Age		Vitamin A (µg)	Vitamin D (µg)[a]	Vitamin E (mg)	Vitamin K(µg)
Infants[b]	0–6 months	250	5	4	2.0
	7–12 months	430	5	5	2.5

BOX 31-2 General dietary guidelines

- To achieve and maintain a healthy weight, be physically active and choose amounts of nutritious foods and drinks to meet your energy needs
- Enjoy a wide variety of nutritious foods from the five food groups every day
- Limit intake of foods containing saturated fat, added salt, added sugars and alcohol
- Encourage, support and promote breastfeeding
- Care for your food; prepare and store it safely

National Health and Medical Research Council (NHMRC) 2013 Australian Dietary Guidelines. Canberra.

groups of individuals, based on age, gender, activity etc using the best available evidence. The number of serves within each food group for individuals based on age and gender are shown in Table 31-12. Definitions of what constitutes a serve for each food group follow.

A serve of grains/cereals is around 500 kJ and is equivalent to:

- 1 slice of bread, ½ a medium roll or flat bread (40 g)
- ½ cup cooked rice, pasta, noodles or other grains (75–120 g)
- ½ cup cooked porridge (120 g), ⅔ cup wheat cereal flakes (30 g) or ¼ cup muesli (30 g)
- 1 crumpet (60 g) or 1 small English muffin or scone (35 g)
- 3 crispbreads (35 g) or ¼ cup flour (30 g)

A serve of vegetables or legumes is around 100–350 kJ and is equivalent to:

- ½ cup (75 g) cooked vegetables (i.e. carrots, broccoli, cauliflower)
- ½ cup (75 g) cooked dried or canned legumes (e.g. beans, chickpeas or lentils)
- 1 cup (75 g) raw green leafy vegetables
- 75 g starchy vegetables (e.g. ½ medium potato, or equivalent of sweet potato or corn)
- 75 g other vegetables (e.g. 1 medium tomato)

To eat a healthy diet:

1. Eat enough food from each of the five food groups every day.
2. Choose different varieties of foods from within each of the five food groups from day to day, week to week and at different times of the year.
3. Eat:
   - plenty of plant foods (bread, cereal, rice, pasta, noodles, vegetables, legumes and fruit)
   - moderate amounts of animal foods (milk, yoghurt, cheese, meat, fish, poultry, eggs) in the proportions shown in the *Guide*
   - small amounts of the extra foods, and margarines and oils.
4. Drink plenty of water.

The five food groups are:
- bread, cereals, rice, pasta, noodles
- vegetables, legumes
- fruit
- milk, yoghurt, cheese
- meat, fish, poultry, eggs, nuts, legumes.

These foods provide the important nutrients the body needs.

Figure 31-2 Australian Guide to Health Eating.

National Health and Medical Research Council.

A serve of fruit is around 100–350 kJ and is equivalent to:
- 1 piece (150 g) of medium-sized fruit (e.g. apple, banana, orange, pear)
- 2 pieces (150 g) of small fruit (e.g. apricot, kiwi fruit, plum)
- 1 cup (150 g) diced, cooked or canned fruit
- ½ cup (125 mL) 100% fruit juice
- 30 g dried fruit (only to be substituted for fresh fruit occasionally)

A serve of protein foods is around 500–600 kJ and is equivalent to:
- 65 g cooked lean red meat, ½ cup lean mince, 2 small chops or 2 slices roast meat
- 80 g cooked poultry
- 100 g cooked fish or 1 small can of fish
- 2 large eggs (120 g)
- 1 cup (150 g) cooked dried or canned legumes (e.g. beans, chickpeas or lentils)
- 170 g tofu
- 30 g nuts or seeds or nut/seed paste

A serve of dairy is around 500–600 kJ and is equivalent to:
- 1 cup (250 mL) milk or ½ cup (120 mL) evaporated unsweetened milk
- ¾ cup (200 g) yoghurt
- 2 slices (40 g) hard cheese (e.g. cheddar) or ½ cup (120 g) ricotta cheese
- 1 cup (250 mL) soy, rice or other cereal drink with added calcium

TABLE 31-12 Recommended average daily food groups and servings

Group/age		Grains (cereals)	Vegetables & legumes	Fruit	Dairy[a]	Protein[b]	Extras[c]
Children	2–3 years	4	2.5	1	1.5	1	1–2

a Includes milk, yoghurt, cheese and/or alternatives (mostly reduced fat recommended)

b Includes lean meats, poultry, fish, eggs, tofu, nuts and seeds, and legumes/beans

c Includes high energy, low nutrient foods such as biscuits, cake, confectionary, crisps, fats (butter, oil, cream), pastries, processed meats, soft drinks, etc

d Upper end of range for boys, lower end of range for girls

e Upper end of range for girls, lower end of range for boys

National Health and Medical Research Council (NHMRC) 2013 Australian Dietary Guidelines. Canberra.

Food labels

In Australia and New Zealand, food labelling is mandatory and is controlled by Food Standards Australia New Zealand (FSANZ). Information provided on a food label must be accurate and in a standard format, helping consumers to understand the food's origin, ingredients and nutritional content. Most foods in Australia require country of origin labelling, which may relate to where the food was made, produced or grown; or where the food was manufactured or packaged (which may contain a mix of local and/or imported ingredients). The label must show all the ingredients contained in the food, arranged in descending order of content (by weight). Food colours and preservatives must be identified by reference to the International Numbering System for food additives (Food Standards Australia New Zealand 2015). The nutrition information panel must state the normal serving size and express the nutritional information per serve and per 100 g of the food. This usually includes the energy (kJ), protein, fat (including saturated fat), carbohydrate (including sugar) and sodium content of the food. Other nutrients, such as fibre, vitamins and minerals, may also be reported. If the food packaging makes a claim about the food (i.e. 'source of fibre'), the fibre content of the food must be reported. Vitamins and minerals may also be expressed as a percentage of the RDI. Figure 31-3 shows an example of a nutrition information panel.

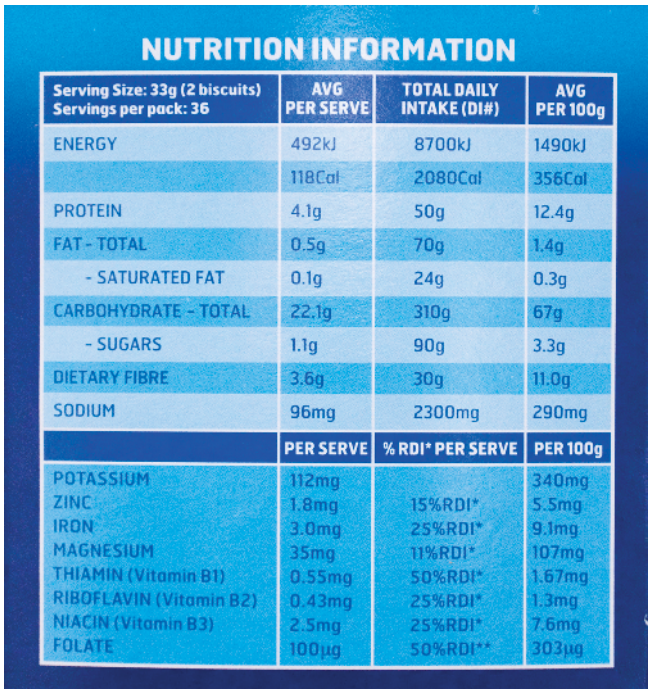

Figure 31-3 Nutrition information panel.

National Measurement Institute.

Nutrition during the life cycle

Infants

Infancy is marked by rapid growth and high nutrient requirements. The average birthweight of an Australian baby is 3370 g (ABS 2007), which doubles by 6 months and increases by 2.5 times by 1 year (NHMRC 2012). Normal weight gain is between 150–200 g per week for the first 3 months; 100–150 g per week from 3–6 months; and 70–90 g per week from 6–12 months. Adequate nutrition during infancy is vital for optimal growth and development. The *NHMRC Infant Feeding Guidelines* contain information for health workers to guide practice when educating or supporting families around infant feeding (NHMRC 2012).

Breastfeeding

Breastfeeding is recognised as the safest, most effective and best source of nutrition for babies. The World Health Organization (2011) states that 'breastfeeding is an unequalled way of providing ideal food for the healthy growth and development of infants' and to 'encourage, support and promote breastfeeding' is one of the *Australian Dietary Guidelines*. There are many benefits of breastfeeding for both the infant and mother (see Table 31-13).

Australian and New Zealand guidelines recommend exclusive breastfeeding for the first 6 months of age. Introduction of solids is recommended at 6 months, with continued breastfeeding to up to 12 months of age. While initiation rates of breastfeeding are high in Australia (over 90%), rates decline to around 50% at 6 months and 25% at 12 months (NHMRC 2012). Similarly, in New Zealand, breastfeeding rates at six weeks are 86% but decline to 66% by 6 months (Plunket 2015). The *Australian National Breastfeeding Strategy 2010–2015* was developed by the Australian Government as a framework to protect, promote and support breastfeeding (Australian Health Ministers' Conference 2009). That is, mothers should be protected and enabled to breastfeed anywhere with confidence and safety and without harassment; breastfeeding should be promoted through education and social marketing; and mothers should be supported in the initiation and maintenance of breastfeeding. In addition, non-government organisations such as the Australian Breastfeeding Association and the New Zealand Breastfeeding Authority provide information and support for breastfeeding mothers (see *Online resources*) and many hospitals now have nurse lactation consultants to support mothers in successful breastfeeding.

There are few contraindications to breastfeeding; even when the mother is a smoker, has a moderate alcohol intake

WORKING WITH DIVERSITY

Focus on breastfeeding

Breastfeeding is recommended solely for the first 6 months of life and encouraged to be continued for 2 years. There are different cultural beliefs about breastfeeding. In a study of over 120 cultures more than half of infants were not breastfed for the first 48 hours because it was believed that colostrum was 'dirty' or 'not real milk'. The reluctance to breastfeed in the first 48 hours is not necessarily a contraindication to further successful breastfeeding.

TABLE 31-13 Benefits of breastfeeding

Infant	Mother
Breast milk: • provides optimal nutrition and is uniquely formulated to adapt to baby's needs • nutrients are easily digested and absorbed • contains important substances for infant's immune system development • is hygienic and readily available Breastfeeding results in: • improved visual, psychomotor and cognitive development • protection against allergies, asthma and infections (gastrointestinal, respiratory and urinary tract) • reduces risks of reflux, sudden infant death syndrome (SIDS) and some childhood cancers • reduces risk of chronic diseases later in life, including obesity, diabetes, cardiovascular disease, bowel disease	Breastfeeding is associated with decreased risks of: • ovarian and breast cancer • type 2 diabetes • postpartum haemorrhage Breastfeeding: • prolongs amenorrhea and hence results in improved fertility control and iron status • may help mothers return to pre-pregnancy bodyweight • has economic benefits, being the most cost-effective and time efficient way of feeding an infant

National Health and Medical Research Council (NHMRC) 2012 Infant feeding guidelines: information for health workers. Eat for Health. Canberra, ACT.

or takes prescription medications, breastfeeding is still usually considered the best option. However, caution should be taken in these instances and smoking and drinking should be minimised. An appropriate health professional should also individually assess the safety of prescription medications in breastfeeding. Infection with hepatitis C, human immunodeficiency virus (HIV) or cytomegalovirus (CMV) are true contraindications to breastfeeding, as these viruses have been isolated in breast milk, increasing the chance of infectious transmission to the infant.

Infant formula

According to the *Australian Infant Feeding Guidelines*, health professionals must always promote breastfeeding first, given the known benefits to both mother and infant. However, if a mother is unable to breastfeed or makes an informed decision not to breastfeed, this should be respected, and education and support around the use of infant formula should be provided. Infant formulas are designed to contain the approximate nutrient composition of human milk. While formula is considered to contain adequate nutrients for infants, it lacks many components of human milk such as living cells, enzymes and bioactive substances. Protein in formula is usually provided as casein or whey, but soy-based formulas are also available. Cow's milk should not be used as infant formula in the first year of life as it may cause GI bleeding or kidney damage.

Health professionals can educate parents on the safe preparation of infant formula, including using safe/clean water for mixing; using an accurate ratio of formula to water; sterilisation of equipment; hygiene in preparation; and effective refrigeration and storage. Other factors to consider are teats and flow rates and how much formula to give an infant at each feed and over each day. Specific information for health workers around these issues is detailed in *Australia's Infant Feeding Guidelines: Information for Health Workers* (NHMRC 2012).

Introduction to solid food

The NHMRC's *Infant Feeding Guidelines* (NHMRC 2012) recommend the following:

- Solids (of appropriate texture and consistency for infant's developmental stage) should be introduced from around 6 months. This includes cooked cereals (i.e. rice, oats), cooked, mashed vegetables and pureed meats from around 6 months; and the introduction of cooked or raw vegetables, fruits, eggs, cereals, bread, pasta, cheese, custards and yoghurts up to 12 months.
- Early on, foods should be iron-rich (such as iron-fortified cereals; pureed meats, poultry and fish; or cooked tofu and legumes) and the variety and quantity of foods should be increased over time, so that by 12 months the infant is consuming a wide range of family foods including vegetables, fruits, and dairy products (such as full-fat yoghurt, cheese and custard).
- Breast milk or infant formula should be continued until 12 months old, alongside solids, and other drinks (except cooled, boiled tap water) should be avoided during the first 12 months.

The introduction of solids at 6 months is based on evidence suggesting that at this age, appetite and requirements are not met with breast milk or infant formula alone and developmentally, infants are able to bite, chew and digest more complex nutrients. Despite these guidelines, research shows that the introduction of solids tends to occur early in Australia, with the median age for introducing solids being 4.7 months (AIHW 2011). Introducing solids too early or too late can be detrimental to nutritional status, growth and development, and risk of allergies. A wide range of foods from the five food groups (cereals/grains, vegetables, fruits, dairy/alternatives and meat/alternatives) should be offered on a regular basis by the age of 12 months. However, some foods should be avoided due to choking risk (e.g. nuts or other hard, small foods) or other risks (e.g. honey should not be fed to infants less than 12 months in order to prevent botulism from spores contained in some honey). In addition, cow's milk should not be given as a main drink to infants under 12 months due to the high renal solute load and risk of iron deficiency.

Toddlers and preschoolers

From around 12 months of age, toddlers should be eating a variety of family foods as per the *Australian Dietary Guidelines*. From this age, water and pasteurised full-cream milk are recommended as drinks, and complementary milks or formulas are not required for healthy children. However, mothers are encouraged to breastfeed as often as the child requires and the mother is able to maximise the benefits of breastfeeding for the infant up to 24 months of age. While cow's milk is an excellent source of protein, calcium and other nutrients and is recommended as a drink from 12 months of age onwards, it can impede iron absorption and may displace other foods; hence, too much milk can lead to iron deficiency in toddlers. For this reason, milk should be limited to 500 mL per day and iron-fortified foods and meats, poultry and fish (or iron-rich alternatives) should continue to be offered regularly. Consumption of low nutrient, energy dense foods such as cakes, biscuits, confectionary and potato chips should be avoided or limited. In addition, whole nuts and similar hard foods that may be a choking hazard should be avoided

until three years of age. See Table 31-8 for a summary of recommended dietary intakes for young children.

School-age children and adolescents

Children and adolescents require adequate nutrition for normal growth and development (see Chapters 16 and 17). Relative to their bodyweight, children have higher energy and nutrient requirements than adults, and need to be in a positive energy balance in order to grow. Growth rate is rapid up until around the age of 5, after which it becomes slower and steadier. Requirements for specific nutrients are shown in Tables 31-7 to 31-11 and for food groups in Table 31-12. Childhood and adolescence is an integral time to establish eating behaviours that may persist throughout the child's life. Therefore, education around nutrition and modelling of healthy eating behaviours are extremely important for the development of good nutrition practices for life. Parents have a significant influence on their child's diet through food access (i.e. foods that are provided at home); parents' food and nutrition beliefs, perceptions and values; and their own dietary behaviours. Both over- and under-nutrition are serious problems that can occur among children and adolescents as a result of poor dietary intakes.

In Australia, 21–25% of children and adolescents are overweight or obese (ABS 2009). In New Zealand, 23% of children aged 2–14 years are overweight and a further 10% are obese (Ministry of Health 2014). Over the past 20 years this number has significantly increased and is causing major implications for individuals, healthcare systems and economies in terms of chronic disease burden and mortality. Overweight children and adolescents are more likely to develop sleep apnoea, breathlessness and reduced exercise tolerance, hypertension, hyperinsulinaemia, hypertriglyceridaemia and type 2 diabetes. Importantly, overweight children are more likely to be overweight or obese in adult life, increasing their risks of a number of chronic diseases and premature death. Besides over-nutrition syndromes (i.e. overweight and obesity), under-nutrition (also called failure to thrive) is a problem in this age group, with 2–5% of Australian children and adolescents remaining underweight. This is often due to socioeconomic factors, but can also be caused by dietary restriction or unhealthy eating behaviours. Purposeful and severe dietary restriction with associated weight loss may be an indication of an eating disorder, which can occur among adolescents.

Young and middle-aged adults

Once growth is complete, adult energy and nutrient needs plateau. During this stage of life, nutrition is important for the maintenance and repair of body tissues and functions. Instances where nutrition needs are higher include increased physical activity, pregnancy, lactation, illness or injury.

The most common nutritional disorder among adults is overweight and obesity. Australian data showed that in 2007–08, 2% of adults were underweight; 37% were healthy weight; 37% were overweight; and 25% were obese (ABS 2009). Overweight and obesity are associated with increased risks of a number of chronic diseases such as type 2 diabetes, cardiovascular diseases, some cancers, respiratory and musculoskeletal conditions, reproductive and gastrointestinal disorders and mental illness, many of which are preventable and some of which are partially reversible with weight loss and healthy eating (NHMRC 2013). Adults should focus on achieving a nutritious diet and being physically active, in line with the *Australian Guide to Healthy Eating*.

Pregnancy

Nutrition during pregnancy is extremely important to ensure the adequate growth and normal development of the fetus. Poor nutrition can cause low birthweight and decreased chances of survival in infants. Generally, the fetus's needs are met at the expense of the mother; however, if nutrients are not available, both can be affected. Appropriate and steady maternal weight gain is important for the short- and long-term health of the mother and infant. For a healthy weight woman, recommended weight gain during pregnancy is between 11–16 kg. Underweight women need to gain more weight (12–18 kg) and overweight or obese women need to gain less weight (7–12 kg and 5–9 kg, respectively). Insufficient weight gain can increase the risk of low birthweight and too much weight gain can increase risks of gestational diabetes for the mother and obesity and metabolic syndrome for the infant later in life.

Requirements for energy and most nutrients and food groups are increased during pregnancy (see Tables 31-8 to 31-12). Energy/macronutrient requirements increase from the second trimester onwards, where there is a significant increase in bodyweight. During second and third trimesters, women need an additional 1400 kJ and 1900 kJ per day, respectively. Fluid needs are increased by around 300 mL per day, due to higher extracellular fluid space, amniotic fluid and fetal needs. Fat-soluble vitamin requirements are not increased, except vitamin A (minimally); but note that overconsumption of vitamin A during pregnancy can lead to birth defects. Most water-soluble vitamin requirements are increased during pregnancy based on maternal and fetal growth and increased energy use. Folate is a particularly important

nutrient before and during pregnancy as insufficiency during the first trimester can cause neural tube defects. As the neural tube is formed before most women are aware they are pregnant, ideally folate should be supplemented prior to conception and during the first trimester. Some mineral requirements are increased, such as iron for increased maternal and fetal blood volumes and to build iron stores for blood loss during delivery, iodine for thyroid activity, and zinc for increased tissue mass. While calcium is very important, especially during the third trimester when fetal bones are mineralised, calcium requirements are not increased as calcium absorption is increased during pregnancy.

Lactation

Similar to pregnancy, energy and nutrient requirements are higher during lactation. A breastfeeding mother needs an additional 2000–2100 kJ per day for milk production, provided by increased macronutrient intake (i.e. protein, carbohydrate and fat, all of which are also components of breast milk). Most vitamins and many minerals are needed in higher amounts (see Tables 31-9 to 31-11) due to their secretion in breast milk and many of the B vitamins are also needed for energy production during lactation. Fluid intake must be sufficient to replace fluid lost during breastfeeding (average water loss ~700 mL per day).

Older adults

Older adults face different nutritional challenges to other age groups. Generally, metabolic rate slows with age, so energy requirements are decreased from around 70 years. However, after this age, protein requirements are increased and vitamin and mineral requirements remain unchanged from adulthood. Older adults need more protein in order to maintain muscle mass and prevent *sarcopenia*, the gradual loss of skeletal muscle that occurs from around 50 years of age. Older adults are also at risk of protein energy malnutrition, due to a complex mix of personal, environmental and social factors (see *Working with diversity*). Prevention or correction of malnutrition in this age group is vital to optimise mobility and function and to avoid complications, such as skin breakdown, impaired immunity and poor healing and recovery from illness (see Chapter 18).

In the hospital setting, a person- and family-centred approach to nutrition care is important to ensure patients' nutritional goals, barriers or enablers to eating adequately, dietary needs or restrictions, and food preferences are considered in the patient's overall nutrition plan.

• CRITICAL REFLECTION POINT

Nurses play an important role in assisting older adults to maintain nutrition while in hospital. Lack of mobility, decreased vision, confusion and lack of dexterity can mean that some older adults may find it difficult to manage independently at mealtimes. Ensuring trays are within reach and packaging is opened assists patients to access and consume their meals. Adequate staffing during mealtimes can also help promote the intake of nutritionally at-risk patients, as some may need assistance to eat.

Alternative food patterns

Long before dietary guidelines were developed, people, groups and communities have followed special patterns of

WORKING WITH DIVERSITY

Focus on older adults

Factors affecting dietary intake	Underlying causes
Physical and physiological factors	
Poor appetite (anorexia)	Age, disease, drugs/treatments, stress, pain, physical inactivity
Loss of taste / taste changes	Age, disease, drugs/treatments
Chewing or swallowing problems	Dry mouth (xerostomia), oral conditions, poor dentition, respiratory problems, swallowing disorders
Depression or anxiety	Chronic illness, loss of a spouse, social isolation
Eating problems	Cognitive function, getting food to mouth, neurodegenerative disorders
Decreased nutrient absorption	Decreased function of gastrointestinal system
Social factors	
Poor food access	Decreased independence/function (i.e. affecting ability to cook and shop), inadequate income to purchase food, social isolation
Poor food choices	Inability to read/understand nutrition labels, lack of nutrition knowledge, institutionalisation

WORKING WITH DIVERSITY

Focus on cultural care

Religious dietary requirements

Christianity

Minimal or no alcohol

Holy day observances may restrict meat

Hinduism

No meats

Islam

No pork

No alcohol

No caffeine

Ramadan fasting sunrise to sunset for month

Ritualised methods of animal slaughter required for meat ingestion (halal)

Judaism

No pork

No predatory fowl

No shellfish (eat only fish with scales)

No rare meats

No blood (blood sausage, etc)

No mixing of milk or dairy products with meat dishes

Must adhere to kosher food preparation methods

24 hours of fasting on Yom Kippur, a day of atonement

No leavened bread eaten during Passover (8 days)

No cooking on the Sabbath (Saturday)

food intake based on religion, cultural background, ethics, health or environmental beliefs, or personal preference (see *Working with diversity*). Alternative diets are not necessarily more or less nutritious than diets based on standard nutritional guidelines as good nutrition depends on a balanced intake of all required nutrients. However, caution must be taken when following some alternative food patterns. In recent years many 'fad diets' have emerged, some of which may actually be detrimental to health, particularly among patients with underlying health conditions. Some common alternative food patterns are described below.

Vegetarianism is the consumption of a diet without meat (i.e. red meat, poultry, seafood and any other animal flesh). This food pattern may be chosen due to religious beliefs, concerns with animal rights or other personal reasons. There are a number of different types of vegetarianism, including ovolacto-vegetarian (eats eggs and dairy but avoids meat, fish and poultry), ovo-vegetarian (eats eggs but not dairy), lacto-vegetarian (eats dairy but not eggs) and vegan (excludes all animal products including eggs, dairy and honey). As long as adequate meat and dairy alternatives are consumed, vegetarian diets are usually adequate to meet most people's nutrient requirements. One exception is the vegan diet, which contains no vitamin B_{12} (as this is only available from animal sources), so this vitamin must be supplemented.

Complementary therapies are increasingly accepted as adjuncts to Western medicine, and many involve nutrition. There is limited research on the use of complementary therapies and while most seem relatively harmless, others may interact with medical treatments. For this reason, patients wishing to try complementary therapies are

WORKING WITH DIVERSITY

Focus on cultural care

Lactose intolerance

The incidence of lactose intolerance around the world occurs from highest to lowest in the following ethnic or racial groups: Asian-Pacific, African, Mexican, Middle Eastern, followed by white Caucasian. This condition affects nutrient absorption, and calcium deficiency results. Calcium is necessary for maintaining bone mass density. Alternative sources of calcium with low lactose are aged cheddar or Swiss cheese, green leafy vegetables, legumes, tofu, sardines, nuts and low-lactose milk products.

'Hot' and 'cold' foods

The theory of hot and cold foods predominates in many cultures. The origin appears to be from Hippocratic beliefs concerning health and the four humours. Arabs were keepers of this knowledge during the Dark Ages and later influenced the Spanish to adopt this belief system in the later Middle Ages. The foundation is keeping harmony with nature by balancing 'cold', 'hot', 'wet' and 'dry'. Some cultures may plan their meals based on these beliefs. Food classification as hot or cold varies slightly from one culture to another.

Classification has nothing to do with spiciness, but is a symbolic representation of temperature. Hot foods include rice, grain, cereals, alcohol, beef, lamb, chillies, chocolate, cheese, temperate-zone fruits, eggs, peas, goat's milk, oils, onions, pork and radishes. In contrast, cold foods encompass beans, citrus fruits, tropical fruits, dairy products, most vegetables, honey, raisins, chicken, fish and goat. Foods can be made hot or cold through methods of preparation. A blending of hot and cold balances food. Menstruation, cancer, pneumonia, earache, colds, paralysis, headache and rheumatism are cold illnesses requiring hot foods. Pregnancy, fever, infections, diarrhoea, rashes, ulcers, liver problems, constipation, kidney problems and sore throats are believed to be hot conditions; thus cold foods may be eaten during these times.

advised to discuss this with their healthcare professional or team. Oncology is an area where complementary therapies and diets are particularly prevalent; and their popularity is increasing due to media coverage of individuals who self-proclaim being 'cured' using such therapies. A major problem with some 'cancer' diets is that they suggest consumption of raw fruits and vegetables only, which can result in severe protein energy malnutrition due to poor energy and macronutrient intake. Caution must be taken when considering following a complementary diet to ensure that it is nutritionally adequate for the individual and especially for those experiencing major illness. More information on complementary therapies in cancer can be found in *Online resources*.

So-called 'fad' diets are becoming increasingly popular in today's society due to their promise of a 'quick fix' and endorsement by high-profile celebrities or other individuals who claim extreme health benefits. Fad diets are usually not based on evidence from scientific research and often contain nutrition misinformation. Any diet that makes dramatic health statements (i.e. claims to cure disease, improve bodily function or result in fast weight loss), recommends omission of whole food groups, or requires purchase of additional dietary supplements, should be considered with extreme caution.

Recently we have seen the emergence of numerous so-called 'nutrition experts' who write books, develop diets or make health claims, usually with little or no formal nutrition education or training. Dietary advice should always be sought from a nutrition expert such as an accredited practising dietitian or nutritionist, or other qualified health professionals.

Alcohol

Alcoholic beverages are consumed on a regular basis by 42% of adult men and 24% of adult women in Australia. Alcohol contributes approximately 5% of the energy intake of adult Australians. The consumption of alcohol declines with age, as does the safe limit of consumption. Ethyl alcohol is a nutrient, but is also a drug affecting the brain, and if consumed in amounts above the recommendations in the NHMRC's *Australian guidelines to reduce health risks from drinking alcohol*, becomes a toxin to many organs in the body. As well, alcohol can be morbidly or even mortally incompatible with many medications and over-the-counter drugs. The effects of alcohol on the brain combined with the toxic effects make it responsible for 1 death in every 34 in Australia (Lobo et al 2010). Alcohol may have health benefits if consumed in small amounts (1–2 standard drinks/day on most days), but the evidence remains contradictory.

CLINICAL REASONING PROCESS

Nurses are in an excellent position to recognise signs of poor nutrition, prevent hospital-acquired malnutrition and take steps to promote optimal nutrition intake. In collaboration with patients and their families, nurses are able to observe changes in physical status, food intake, weight changes and response to therapy. As malnutrition is a common problem in the hospital setting, affecting 20–50% of all patients and resulting in significant harm to patients and a burden to healthcare systems (Barkert et al 2011), its prevention and management is extremely important.

GATHERING RELEVANT INFORMATION AND DATA

There are a number of steps involved in nutrition care: identifying patients at risk of malnutrition, optimising nutrition therapy, and monitoring nutritional outcomes, all of which are supported by a team approach to nutrition care, good communication and documentation.

Nutrition risk screening in hospital and community settings is pivotal for the identification of at-risk patients and referral to appropriate health professionals for nutrition care, such as dietitians. Validated screening tools include the Malnutrition Screening Tool (MST), Malnutrition Universal Screening Tool (MUST) and Nutrition Risk Screening (NRS) (Guaitoli et al 2014). The MST (see Box 31-3) is commonly used in Australian hospitals, and contains two simple questions. A score of two or more warrants referral to a dietitian.

Evidence-based guidelines for the management of malnutrition recommend routine nutrition screening in the acute care setting to identify malnutrition risk and initiate nutrition care. Early recognition of malnourished or at-risk patients has a strong positive influence on both short- and long-term health

RESEARCH HIGHLIGHT

Research focus

Malnutrition is the most common nutrition-related problem in the hospital setting, affecting up to 50% of patients and resulting in severe consequences for patients and the healthcare system. One serious complication of malnutrition is the development of pressure ulcers. The link between malnutrition and pressure ulcer development has been well established and a number of studies have investigated nutritional intervention for pressure ulcer prevention. The aim of this study was to investigate the nutritional intakes of hospitalised patients deemed 'at risk' of developing a pressure ulcer, due to reduced mobility.

Research abstract

The oral intakes of 184 patients with reduced mobility were observed by researchers over a 24-hour period by assessing the amount of each meal component consumed at each meal occasion. Total energy and protein intakes were calculated for each patient and, on average, patients consumed around 5900 kJ and 54 g of protein over 24 hours. For 93 patients, disease-specific energy and protein requirements were calculated individually and compared with energy and protein intakes. Only 45% and 53% of patients ate enough to meet ≥ 75% of their energy and protein requirements, respectively. This is concerning, as intakes of < 75% of requirements has been shown to result in weight loss during hospitalisation, an indicator for malnutrition.

As malnutrition is a risk factor for pressure ulcers, these patients (who were already at risk of developing a pressure ulcer due to restricted mobility) were placed at further risk of pressure ulcer through poor nutritional status. Furthermore, poor nutritional status is linked with reduced mobility, highlighting the complex cycle of malnutrition and its complications. Patients who consumed any amount of nutrition support during the 24-hour study period were 5 and 15 times more likely to meet ≥ 75% of their energy and protein requirements, respectively. This suggests nutrition support may be an important strategy to enable patients with reduced mobility to meet their requirements.

Evidence-based practice

- Adequate nutritional intake is important amongst all patients, but particularly amongst those at risk of pressure ulcer (i.e. with reduced mobility).
- Around half of patients with reduced mobility fail to meet ≥ 75% of their energy and protein requirements.
- Oral nutrition support is a predictor of eating adequately in terms of energy and protein and may be utilised by nurses to increase nutritional intake amongst these patients.

outcomes. Despite this, nutrition screening practices in the community and hospital are often suboptimal (Green & James 2013, Green et al 2014).

In addition to formal nutrition screening, it is also important for the nurse to recognise those patients who might be at risk of developing malnutrition during hospitalisation or while under the care of health professionals in other settings. Decreased nutritional intake related to the presenting illness may place the patient at increased risk of malnutrition. The most common nutrition-impacting symptom among hospitalised patients is poor appetite. This can occur for a number of reasons related to the patient (age, disease, treatments) or the hospital environment (unpleasant smells, aromas, dislike of the food etc). Other common nutrition-impacting symptoms include nausea, vomiting, diarrhoea, constipation, chewing or swallowing difficulties and taste or smell changes due to illness.

Increased nutritional requirements associated with illness severity also have the potential to contribute to the development of protein-calorie malnutrition. For example, nutrition requirements are elevated during infection and sepsis and can also remain increased following recovery from critical illness (Weimann 2013). The increased risk for development of iatrogenic malnutrition highlights the need to closely monitor nutrition intake of patients who are receiving care, particularly those who are acutely unwell and require hospitalisation.

Intake of less than 75% of protein-energy requirements is associated with poorer outcomes, increased length or stay and higher healthcare costs (Feldblum, German et al 2011, Starke, Schneider et al 2011). Nurses are an important part of the multidisciplinary healthcare team and are best positioned to monitor nutrition intake for hospitalised patients. Functional problems with reaching meal trays, opening food packages, using cutlery or getting food to the mouth are also common among hospitalised patients. In addition, behavioural or cognitive problems can affect patients' intakes. It is important to: 1) individually assess patients' nutrition-impacting symptoms and any other barriers to food intake; 2) ensure they are clearly documented in nursing notes; and 3) address these issues by involving appropriate healthcare professionals (i.e. speech pathologist for chewing/swallowing difficulties; occupational therapist for functional problems with eating; doctor or pharmacist for symptoms such as nausea, vomiting, constipation, diarrhoea; or dietitian for provision of extra nutrition) and/or providing feeding assistance and encouragement to patients who are eating poorly.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Nutrition assessment involves evaluating a patient's nutritional status and is usually performed by a dietitian. A formal assessment is extremely important for determining whether a patient is malnourished, and if so, the extent to which the patient is malnourished. There are a number of approaches to nutrition assessment including using tools such as the Subjective Global Assessment, which assesses nutritional status based on weight loss, dietary intake, gastrointestinal symptoms, functional capacity and physical assessment of muscle and fat stores.

Clinical observations can be among the most important aspects of a nutritional assessment. Clinical indicators of nutritional status provide guidelines for observations during physical assessment. An assessment of nutrition can also be made using **anthropometry**, which is the measurement of size, weight and body composition. Other anthropometric measurements that may be used in nutrition assessment include mid-upper-arm circumference, triceps skinfold and mid-upper-arm muscle circumference; however, significant variation is likely between examiners depending on their training and equipment.

Accurate measurement of height and weight is important and height should be measured with the patient standing if possible. Alternatively, the British Association of Parenteral and Enteral Nutrition (BAPEN) ulna measurement can be used (see *Online resources*). Weight should be measured on admission and weekly thereafter. More frequent weight measurement may be required to assess fluid status, such as in patients with cardiac or renal failure. Weight is most accurately measured in the morning, before breakfast and after urinating, in light clothes or hospital gown. Patients should be weighed at the same time each day, on the same scale, with similar clothing. Height and weight are used to calculate **body mass index (BMI)**, a measure of body composition describing our weight relative to height. BMI is used to classify individuals' weight ranges (see Table 31-14) and is calculated using the equation: BMI = weight (kg) ÷ height (m^2).

Common laboratory tests used to study nutritional status include measures of plasma proteins such as albumin, prealbumin, transferrin, total iron-binding capacity and haemoglobin. While this may assist with the clinical assessment of a patient, plasma protein measures are not specific to malnutrition as plasma protein levels can be influenced by fluid balance, liver function, kidney function and the presence of disease. After feeding, the response time for changes in these proteins ranges from hours to weeks. The metabolic half-life of albumin is 21 days, of transferrin 8 days and of prealbumin 2 days; so most serum proteins are not accurate short-term indicators of serum protein status. Furthermore, serum albumin level is affected by inflammation; hydration; haemorrhage; renal or hepatic disease; high-output drainage of wounds, burns or the gut; steroids; age; and trauma, stress or surgery. Therefore, serum plasma protein measurement is not considered an accurate marker of nutritional status.

TABLE 31-14 Classification of adults according to BMI

Classification	BMI	Risk of comorbidities
Underweight	< 18.50	Low (but risk of other clinical problems increased)
Normal range	18.50–24.99	Average
Overweight:	> 25.00	
Pre-obese	25.00–29.99	Increased
Obese class 1	30.00–34.99	Moderate
Obese class 2	35.00–39.99	Severe
Obese class 3	> 40.00	Very severe

Obesity: Preventing and Managing the Global Epidemic, 2000, WHO, Geneva.

CLINICAL EXAMPLE

Thomas, aged 69, has had an elective total hip replacement. Thomas undertook preoperative preparation (including fasting) three times, as his surgery was cancelled three times due to other emergency procedures causing last minute changes to the surgical list. His medical history includes unstable angina and asthma. Thomas's admission weight was 59 kg. Five days postoperatively he now weighs 52.0 kg. His height is 174 cm.

1. What is Thomas's body mass index?
2. What is his percentage weight loss?
3. What processes could have been put in place to prevent preoperative weight loss?

• CRITICAL REFLECTION POINT

If a patient has had negligible oral intake for 5 or more days they may be at risk of developing refeeding syndrome. Refeeding syndrome is a potentially life-threatening change in serum electrolytes, which can occur after rapid refeeding (particularly of carbohydrate) in patients who are malnourished or who have had negligible intakes for 5 or more days. On resumption of oral intake, significant drops in magnesium, phosphate and potassium can occur and may be life-threatening, so must be carefully monitored and supplemented as required. Refeeding syndrome is managed by slow introduction of feeding (starting at around 4000 kJ per day).

SETTING PRIORITIES AND ESTABLISHING GOALS

Nutrition therapy and interventions

Usually, a dietitian will assess the patient's nutritional status and determine the patient's priority problem(s). Priority nutrition problems should be clearly documented in the patient's medical record so the rest of the healthcare team are aware of the patient's nutritional status or condition. With the client and members of the healthcare team, the dietitian will then set priorities and establish goals for a plan or intervention to address the patient's specific nutritional needs and underlying disease (Table 31-15). Depending on the patient's condition, intake and requirements, this may include provision of

TABLE 31-15 Nutrition therapy for specific clinical presentations

Disease	Nutrition therapy
Inflammatory bowel disease	Elemental diets, which are where the nutrients are available in their simplest form, or PN may be used for patients experiencing diarrhoea and weight loss In the chronic stage of disease a regular highly nourishing diet is appropriate Low-fibre diet is recommended during acute exacerbation of inflammatory bowel disease to reduce irritation; high-fibre diet is recommended during the chronic phase to avoid constipation
Malabsorption syndrome	For coeliac disease a gluten-free diet is necessary Short bowel syndrome results in malabsorption which requires ongoing use of elemental formulas or PN
Diverticulitis	Use a moderate or low-residual diet until the infection subsides With chronic diverticulosis a high-fibre diet is recommended
Diabetes mellitus	Type 1 diabetes requires insulin and dietary restrictions Type 2 diabetes mellitus can be controlled through exercise and diet
Cardiovascular disease	Magnesium, folic acid and vitamin B_6 appear to be important for primary prevention of coronary heart disease. Increases in folic acid are associated with a decrease in homocysteine, which is associated with greater risk of coronary artery disease Weight loss may be important to decrease cardiovascular risk
Pulmonary disease	Patients with pulmonary disease may require a high energy high protein diet to meet increased requirements associated with respiratory disease or decreased intake associated with shortness of breath or reduced appetite
Renal disease	In acute renal failure fluid management is important and fluctuates depending on the stage of renal failure. Protein is restricted to 0.8 g–1.0 g/kg/day In chronic renal failure a diet that restricts protein, potassium, phosphate, sodium and fluid is usually required until commencement of dialysis when energy and protein requirements are increased
Cancer and cancer treatment	Cancer and cancer treatment is associated with a high rate of nutrition-impacting symptoms so nutrition management focuses on maximising intake of nutrients and fluids

nutritional therapy or dietary education or counselling. Nutrition therapy may be provided orally, with oral nutrition supplement or high energy high protein foods; or may be invasive, such as enteral or parenteral nutrition (PN). Whether specific nutrition therapy is required or not, it is important for the healthcare team to consider potential drug–nutrient interactions. For example, some medications such as phenytoin need to be given on an empty stomach so drug absorption is maximised. Table 31-16 provides an overview of potential drug–nutrient interactions.

Oral nutrition support

Oral nutrition support is a non-invasive method of providing additional nutrition to patients. In the hospital setting, oral nutrition support has been shown to be effective in improving nutritional intake and associated outcomes (such as reducing risk of mortality, infections, pressure ulcers and unintentional weight loss) among patients, and is associated with fewer complications compared to invasive methods of nutrition support (Stratton & Elia 2007). Oral nutrition support consists of commercially available supplement drinks such as Sustagen, Resource (Nestlé), Ensure (Abbott) and Fortisip (Nutricia). These oral supplements are specially formulated to contain all the essential nutrients required to support life, including macronutrients, micronutrients and fluid in the correct ratios to enable patients to meet their requirements even in the absence of any dietary intake. However, the term 'supplement' means that these drinks should be used to support food intake by making up for a lack of consumption of energy or other nutrients, which may occur due to illness or disease.

Besides standard nutrition support, specialised supplements for specific dietary conditions also exist, such as Resource Diabetic, Novasource Renal and clear fluid supplements for surgical preparation. Oral nutrition support is commonly used in the hospital setting and is usually prescribed by a dietitian. Individuals may also use oral nutrition support at home to supplement their oral intake if it is inadequate. Supplements can be purchased at most pharmacies or directly from companies (some even provide delivery services) and come in ready-to-drink tetra packs or as powders that require mixing with water or milk. While barriers to oral nutrition support include flavour fatigue or dislike, generally they are well tolerated and have been found not to suppress appetite or food intake in patients (Stratton & Elia 2007).

Enteral nutrition

If swallowing function is impaired or patients are unable to take nutrition orally, **enteral nutrition** is the preferred method of meeting long-term nutritional needs if the patient's GI tract is functioning. Enteral nutrition refers to nutrition provided to patients through a feeding device inserted into the GI tract. The enteral route is mostly used when patients are unable to chew or swallow, or when oral intake is inadequate to meet nutritional goals. Enteral nutrition can be delivered continuously, intermittently or by bolus. The benefits of enteral nutrition for

TABLE 31-16 Potential drug–nutrient interactions*

Drug class	Drug	Effect
Analgesic/narcotic	Aspirin	Absorbed directly through stomach; decreased drug absorption with food; decreased folic acid, vitamins C and K and iron absorption
	Opiates	Decreased peristalsis; constipation
	Paracetamol	Decreased drug absorption with food; overdose associated with liver failure
Antacid	Aluminium hydroxide	Decreased phosphate absorption
	Sodium bicarbonate	Decreased folic acid absorption
Antiarrhythmic	Amiodarone	Taste alteration
	Digoxin	Anorexia, decreased renal clearance in older persons
	Propranolol	Increased drug absorption with food
Antiarthritic	Methotrexate	Decreased drug absorption with food, decreased folic acid
	Penicillamine	Taste alteration
Antibiotic	Amoxicillin	Decreased drug absorption with food
	Ampicillin	Taste alteration, decreased drug absorption with food
	Cephalosporin	Decreased vitamin K
	Clarithromycin	Taste alteration
	Doxycycline	Decreased drug absorption with food
	Gentamicin	Anorexia, decreased renal excretion in older persons
	Metronidazole	Anorexia
	Neomycin	Decreased fat, nitrogen, vitamin B_{12}, lactose, sucrose, sodium, potassium, iron, calcium
	Nitrofurantoin	Increased drug absorption with food
	Penicillin	Decreased drug absorption with food
	Rifampicin	Decreased vitamin B_6, niacin, vitamin D
	Tetracycline	Decreased drug absorption with milk and antacids, decreased nutrient absorption of calcium, riboflavin, vitamin C due to binding
	Trimethoprim/sulfamethoxazole	Decreased folic acid
Anticoagulant	Warfarin	Acts as antagonist to vitamin K
Anticonvulsant	Carbamazepine	Increased drug absorption with food
	Phenobarbitone	Decreased drug absorption with food, decreased vitamin D
	Phenytoin	Decreased drug absorption with food so needs to be taken on an empty stomach – enteral feeds should be discontinued before administration; decreased calcium absorption; decreased vitamins D and K and folic acid; taste alteration
	Primidone	Decreased calcium absorption, increased metabolism of vitamins D and K
Antidepressant	Amitriptyline	Appetite stimulant
	Clomipramine	Taste alteration, appetite stimulant
	Fluoxetine (selective serotonin re-uptake inhibitors [SSRIs])	Taste alteration, anorexia
Antifungal	Amphotericin B	Anorexia
	Griseofulvin	Taste alteration, enhanced absorption with food

continued

TABLE 31-16 ***continued***

Drug class	Drug	Effect
Antigout	Allopurinol	Taste alteration
	Colchicine	Decreased vitamin B_{12}, vitamin A (carotene), lactose, sodium, potassium
Antihistamine	Astemizole	Increased appetite, decreased drug absorption with food
	Cyproheptadine	Increased appetite
Antihypertensive	Atenolol	Taste alteration (weight gain for all beta-blockers)
	Captopril	Taste alteration, anorexia
	Hydralazine	Enhanced drug absorption with food, decreased vitamin B_6
	Methyldopa	Decreased vitamin B_{12}, folic acid, iron
Anti-inflammatory	All steroids	Increased appetite and weight, increased folic acid, decreased calcium (osteoporosis with long-term use), promotes gluconeogenesis of protein
	Indomethacin	Decreased iron absorption
	Sulphasalazine	Decreased folic acid
Antimanic	Lithium carbonate	Anorexia, nausea, vomiting, diarrhoea, mucositis, decreased folic acid
Antiparkinson	Levodopa	Taste alteration, decreased vitamin B_6 and drug absorption with food
Antipsychotic	Chlorpromazine	Increased appetite
	Thiothixene	Decreased riboflavin, increased need
Antituberculosis	Isoniazid	Decreased calcium, niacin, vitamins B_6 and D
Bronchodilator	Albuterol sulfate	Appetite stimulant
	Theophylline	Anorexia
Cholesterol-lowering	Cholestyramine	Decreased fat-soluble vitamins (A, D, E, K), vitamin B_{12}, iron
Diuretic	Furosemide	Decreased drug absorption with food
	Spironolactone	Increased drug absorption with food
	Thiazides	Decreased magnesium, zinc and potassium
	Triamterene	Decreased folic acid
Oestrogen/ progestin	Oral contraceptive	Decreased vitamin B_6, B_{12}, folic acid, zinc; increased transferrin
	Hormone replacement therapy (HRT)	
Laxative	Mineral oil	Decreased absorption of fat-soluble vitamins (A, D, E, K), carotene
	Phenolphthalein	Decreased calcium, potassium, vitamin D
Muscle relaxant	Baclofen	Taste alteration
	Dantrolene	Taste alteration, anorexia
Platelet aggregate inhibitor	Dipyridamole	Decreased drug absorption with food
Potassium replacement	Potassium chloride	Decreased vitamin B_{12}
Stimulant	Dexamphetamine	Taste alteration, anorexia
	Methylphenidate	Anorexia, decreased weight, decreased growth
Tranquilliser	Benzodiazepines	Increased appetite

* Not intended to be an exhaustive or all-inclusive list. Always check pharmacology references before administering medications.

those patients who require nutrition therapy are considerable. Adequate nutrition through administration of enteral nutrition can improve wound healing (Cox & Rasmussen 2014), reduce the incidence of pressure injury (Stratton et al 2005), decrease infectious complications and shorten the length of stay among certain patient groups (Elke et al 2014).

While current evidence suggests that there are only a few contraindications to enteral nutrition, traditionally there have been a number of clinical presentations where enteral nutrition has been avoided. For example, patients with bowel obstruction, severe and protracted ileus, major upper gastrointestinal bleeding, intractable vomiting or diarrhoea, severe hemodynamic instability, gastrointestinal ischemia, and a high output fistula should have enteral nutrition withheld or commenced with caution. Patients with pancreatitis are able to be fed by the enteral route (McClave et al 2006). Similarly, patients in the immediate postoperative period can receive enteral nutrition if required (Osland et al 2011), and in some patients this approach may reduce postoperative ileus (Boelens et al 2014).

Effective management of enteral nutrition by nurses is important to ensure optimal nutrition outcomes. Protocols for the delivery of enteral nutrition have been shown to improve clinical outcomes (Friesecke et al 2014); however, many feeding protocols differ in their approach. Tube feedings are typically started at full strength, but the rate at which enteral feeds are commenced differs between and within institutions (Marshall & West 2006). In some institutions, enteral feeding is commenced at lower rates and then gradually increased, while in others, enteral nutrition is commenced at the goal rate. Individual patient assessment should guide which approach is most appropriate. If enteral nutrition is commenced at lower than the goal rate, then increases in the hourly rate should be made every 4 hours until the goal rate is achieved, or as tolerated by the patient.

CLINICAL EXAMPLE

Mrs Caine is 85 years old and has been hospitalised for a urinary tract infection that resulted in sepsis. She required treatment in ICU for six days and is now recovering on the ward.

What factors place Mrs Caine at increased risk of malnutrition? What strategies can be implemented to help promote optimal nutrition and functional recovery?

While the enteral delivery of nutrition has many positive benefits to patients it is not without risks. The potential for complications requires careful assessment and monitoring of the patient (Table 31-17). During enteral feeding, gastric emptying can be assessed by regularly aspirating the feeding tube. This is typically done in acute care settings where patients are more susceptible to reduced gastric emptying. Measuring gastric aspirates does not necessarily provide a clear picture of gastric emptying and is dependent on technique, tube type and the location of the tube within the stomach. Measurement of gastric residual volume is thought to provide an estimate of feeding tolerance and identify patients who might be at risk of aspiration, although there is no evidence to suggest that high gastric residual volumes predict aspiration (Reignier et al 2013). The amount of gastric residual volume that is considered 'high' also varies from 200–500 mL.

TABLE 31-17 Complications of enteral nutrition

Problem	Possible cause	Intervention
Abdominal cramping, nausea/vomiting	High osmolality of formula Rapid increase in rate/volume Delayed gastric emptying Lactose intolerance Intestinal obstruction High-fat formula used Cold formula used	Suggest use of lactose-free formula Lower rate of delivery to increase tolerance Stop feeding with GI obstruction Use greater proportion of carbohydrate Warm formula to room temperature
Delayed gastric emptying	Diabetic gastroparesis Prematurity Serious illnesses Inactivity	Consult with doctor regarding medication for increasing gastric motility (e.g. metoclopramide or erythromycin) Monitor gastric residual volume Minimise medications that may affect GI motility Consider small bowel feeding Assess for pathological conditions that may reduce GI motility
Pulmonary aspiration	Regurgitation of formula Feeding tube displaced Patient in supine position Deficient gag reflex Gastro-oesophageal reflux disease (GORD)	Check tube placement before feeding (every 4–8 hours during continuous feeding before feeds for intermittent or bolus feeding) Elevate head of bed 30–45 degrees during feedings and for 2 hours afterwards

continued

TABLE 31-17 ***continued***

Problem	Possible cause	Intervention
Diarrhoea	Hyperosmolar formula or medications	Antibiotics may destroy normal intestinal flora and can be a primary cause of diarrhoea
	Allergy to elixir ingredients (sorbitol)	Use closed enteral nutrition bags where possible. If open bags are used, follow manufacturer's recommendations for use
	Malnutrition	Avoid bolus feeding; deliver formula continuously
	Hypoalbuminaemia	Consult pharmacist to review medications and eliminate sorbitol containing medications, if possible
	Antibiotic therapy	Monitor albumin 25 g/L lessens oncotic pressure equilibrium
	Bacterial contamination	Check for pancreatic insufficiency, use low-fat, lactose-free formula and continuous feedings
	Malabsorption	
Constipation	Lack of fibre	Select a formula containing fibre
	Lack of free water	Add water as needed*
	Medications	Evaluate side effects; suggest stool softener or bulk-forming laxative
	Inactivity	Monitor patient's mobility; collaborate with doctor for activity order or physiotherapy
Serum electrolyte imbalance	Excess GI losses	Monitor serum electrolyte levels daily
	Dehydration	Know of links with specific pathological condition
	Cirrhosis	Monitor blood glucose level in diabetics or patients receiving insulin
	Renal insufficiency	
	Congestive heart failure, oedema	
	Diabetes mellitus	
Fluid overload	Refeeding syndrome in malnutrition	Restrict fluids if necessary and use either a specialised formula or a diluted enteral formula at first
	Excess free water or diluted (hypotonic) formula	Monitor levels of serum proteins and electrolytes
		Use a more concentrated formula with fluid volume excess without risk of refeeding syndrome
Hyperosmolar dehydration	Hypertonic formula with insufficient free water	Slow rate of delivery, dilute or change to isotonic formula
Tube occlusion	Pulverised medications given per tube	Irrigate with 20 mL water before and after each medication per tube*
	Insufficient tube irrigation	Dilute crushed medications if not liquid
	Sedimentation of formula	Avoid crushed medications, if liquid available
	Reaction of incompatible medications or formula	Shake cans well before administering (read label)
		Read pharmacological information on compatibility of drugs and formula
Tube displacement	Coughing, vomiting	Replace tube and confirm placement before restarting tube feeding
	Not taped securely	With placement verification, check that tape is secure (nasoenteric)

* Check first for fluid-restricted conditions that would affect volume of water given.

Provided there are no contraindications, patients receiving enteral feeding should be positioned with the head of the bed elevated 30–45° to minimise the risk of aspiration. If gastric emptying is reduced, then prokinetic agents, such as erythromycin and metoclopramide, can be administered. Regular assessment of the patient is imperative to monitor for signs of pulmonary aspiration; however, some traditional methods such as using blue dye and testing secretions for glucose are not recommended (Maloney et al 2002).

Diarrhoea may occur in enterally fed patients and is often the reason enteral nutrition is stopped or reduced. Enteral feeding should not necessarily be considered the primary cause of diarrhoea as the underlying illness or disease, use of antibiotics, hypoalbuminaemia, use of histamine-2 receptor antagonists and contamination of enteral feeding solutions can all contribute to the development of diarrhoea.

Enteral access tubes

Enteral tube feeding is indicated when a patient is unable to ingest food or maintain an adequate oral intake, but is still able to digest and absorb nutrients through the GI tract. Feeding tubes can be inserted through the *nose* (nasogastric

or nasojejunal), *surgically* (gastrostomy or jejunostomy) or *endoscopically* (percutaneous endoscopic gastrostomy (PEG) or *jejun-ostomy* (PEJ)).

If enteral therapy is for a period of less than 4 weeks in total, nasogastric or nasojejunal feeding tubes may be used (Figure 31-4). Small-bore nasogastic feeding tubes may be used after feeding is established and if prolonged feeding is anticipated, as this is more comfortable for the patient. Surgical or endoscopically placed tubes are preferred for long-term feeding (more than 4 weeks) to reduce the discomfort of a nasal tube and to provide a more secure, reliable access. Patients with gastroparesis (decreased or absent innervation to the stomach that results in delayed gastric emptying), or with oesophageal reflux, high risk of aspiration or a history of aspiration pneumonia, require placement of enteral feeding tubes beyond the stomach into the intestine.

Skills 31-1, 31-2 and 31-3 describe the procedures for inserting a small-bore nasoenteric tube and initiating enteral feedings.

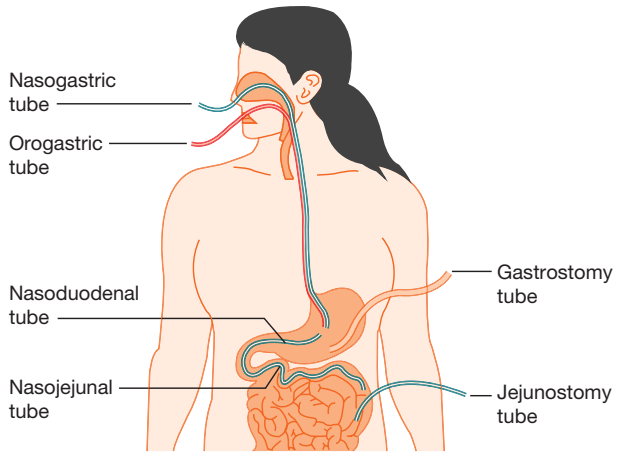

Figure 31-4 Routes of administration in enteral nutrition.

SKILL 31-1

Inserting a small-bore nasoenteric tube for enteral feedings

Delegation considerations

This task requires the problem-solving and knowledge-application skills of professional nurses. For this reason, delegation of this task to nurse assistants is inappropriate.

Equipment

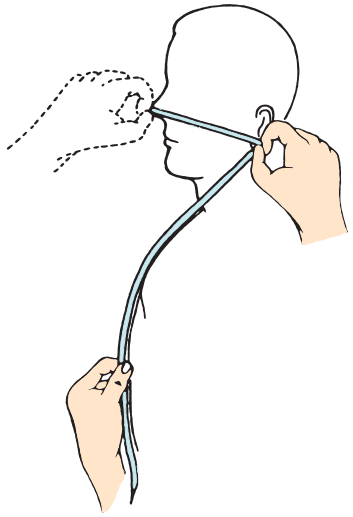
- Nasogastric or nasointestinal tube (8–12 Fr) with guide wire or stylet
- 60 mL or larger Luer-lock syringe
- Hypoallergenic tape and tincture of benzoin
- pH indicator strip
- Glass of water and straw
- Emesis basin
- Safety pin
- Rubber band
- Towel
- Facial tissues
- Clean gloves
- Suction equipment in case of aspiration
- Penlight to check placement in nasopharynx
- Tongue blade

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess patient for the need for enteral tube feeding: NBM or insufficient intake for more than 5 days, functional GI tract, unable to ingest sufficient nutrients.	Identifying patients who need tube feedings before they become nutritionally depleted may help to prevent complications related to malnutrition.
2. Assess patient for appropriate route of administration:	Evaluates nares for patency.

STEPS	RATIONALE
a. Close each nostril alternately, and ask patient to breathe.	Nares may be obstructed. Assessment determines which nostril to use.
b. Assess for gag reflex.	Identifies ability to swallow and risk of aspiration.
c. Inspect nares for any irritation or obstruction.	
d. Review patient's medical history for nasal problems and risk of aspiration.	Nurse may seek doctor's order to change route of nutritional support or to place tube past the stomach into the intestine if there is an increased risk of aspiration.
3. Review doctor's order for type of tube and enteral feeding schedule.	Procedure and tube feedings require a doctor's order.
4. Wash hands.	Reduces transfer of microorganisms.
5. Explain procedure to patient.	Reduces anxiety and helps patient to assist in insertion.
6. Stand on same side of bed as nostril for insertion, and help patient into high-Fowler's position unless contraindicated. Place pillow behind head and shoulders.	Allows easier manipulation of tube. Fowler's position reduces risk of aspiration and promotes effective swallowing.
7. Place bath towel over chest. Keep tissues within reach.	Prevents soiling of gown. Insertion of tube may produce tears.
8. Determine length of tube to be inserted and mark with tape: measure distance from tip of nose to earlobe to xiphoid process of sternum (see illustration).	Length approximates distance from nose to stomach in 98% of patients. For duodenal or jejunal placement, an additional 20–30 cm is required.



Step 8 Determining length of tube to be inserted.

9. Prepare nasogastric or nasointestinal tube for intubation:	
a. Plastic tubes should not be iced.	Tubes will become stiff and inflexible, causing trauma to mucous membranes.

STEPS	RATIONALE
b. Inject 10 mL of water from 30 mL or larger Luer-lock or catheter-tip syringe into the tube.	Aids in guide wire or stylet insertion.
c. Make certain that guide wire is securely positioned against weighted tip and that both Luer-lock connections are snugly fitted together.	Promotes smooth passage of tube into GI tract. Improperly positioned stylet can induce serious trauma.
10. Cut tape 10 cm long.	
11. Put on clean gloves.	Reduces transmission of microorganisms.
12. If the feeding tube is impregnated with surface lubricant, dip tube into glass of water. If there is no surface lubricant, ensure the tube is adequately lubricated before insertion.	Activates lubricant to facilitate passage of tube into nostril to GI tract.
13. Insert tube through nostril to back of throat (posterior nasopharynx). Aim back and down towards ear.	Natural contours facilitate passage of tube into GI tract; reduces gagging by patient.
14. Flex patient's head towards chest after tube has passed through nasopharynx.	Closes off glottis and reduces risk of tube entering trachea.
■ Critical decision point: Encourage patient to swallow by giving small sips of water or ice chips when possible. Advance tube as patient swallows. Rotate tube 180 degrees while inserting.	
15. Emphasise need to mouth-breathe and swallow during the procedure.	Helps facilitate passage of tube and alleviates patient's fears during the procedure.
16. Advance tube each time patient swallows until desired length has been passed. Do not force tube. If resistance is met or patient starts to cough, choke or become cyanotic, stop advancing the tube and pull tube back.	Reduces discomfort and trauma to patient.
17. Check for position of tube in back of throat with penlight and tongue blade.	Tube may be coiled, kinked or entering trachea.
18. Perform measures to verify placement of tube:	
a. Inject 30 mL of air into the tube, and aspirate GI contents with a syringe. b. Measure pH of aspirated GI contents (see illustration).	Gastric contents are usually cloudy and grassy green or tan to off-white; in contrast, intestinal fluid is usually deep golden yellow and is clearer than gastric fluid (see Figure 36-11). Fasting gastric pH is usually in a range of 1–4; gastric pH may be increased if the patient is receiving histamine-2 receptor antagonists or proton pump inhibitors. Intestinal sites usually have a pH of 7 or greater.
c. X-ray verification of placement may be necessary.	X-ray verification is considered gold standard and should be used to assess feeding tube placement except where radiography is unavailable.

STEPS	RATIONALE

Step 18b Comparing pH strip with colour chart.

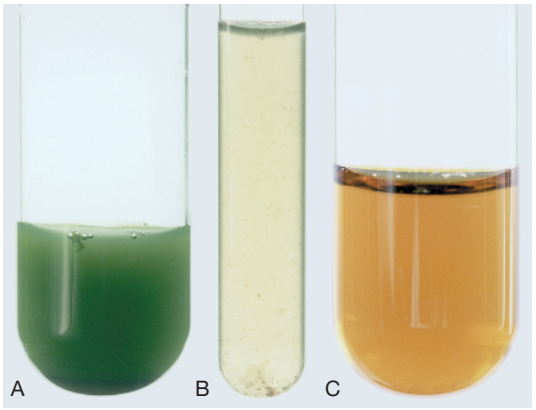


Figure 31-5 Gastric contents.
A, Stomach. B, Stomach. C, Intestinal.
Courtesy Dr Norma Metheny, St Louis University School of Nursing.

■ **Critical decision point: Auscultation is no longer considered a reliable method for verification of tube placement because a tube inadvertently placed in the lungs, pharynx or oesophagus can transmit a sound similar to that of air entering the stomach.**

19. Apply tincture of benzoin or other skin adhesive to tip of patient's nose and tube. Allow to dry.	Helps tape adhere better. Protects skin.
20. Remove gloves, and secure tube with tape, avoiding pressure on nostril.	A properly secured tube allows the patient more mobility and prevents trauma to nasal mucosa.
a. Split one end of tape lengthwise 5 cm. Place the intact end of tape over bridge of patient's nose. Wrap each of the 5 cm strips around tube as it exits nose (see illustration).	Securing tape to nares prevents tissue necrosis.
b. Fasten end of nasogastric tube to patient's gown by looping rubber band around tube in slip knot. Pin rubber band to gown (see illustration).	Reduces traction on the nostril if tube moves.

Step 20a Wrapping tape to anchor nasogastric tube.

Step 20b Pinning tube to gown.

STEPS	RATIONALE
21. For intestinal placement, position patient on right side when possible until radiological confirmation of correct placement has been verified. Otherwise, help patient into a comfortable position.	Promotes passage of the tube into the small intestine (duodenum or jejunum).

■ **Critical decision point: Leave guide wire or stylet in place until correct position is ensured by X-ray. Never attempt to reinsert partially or fully removed guide wire or stylet while feeding tube is in place.**

22. Obtain X-ray of abdomen.	Placement of tube is verified by X-ray examination.
23. Put on gloves, and administer oral hygiene. Clean tubing at nostril.	Promotes patient comfort and integrity of oral mucous membranes.
24. Remove gloves, dispose of equipment and wash hands.	Reduces transmission of microorganisms.
25. Inspect nostril and oropharynx for any irritation after insertion.	If insertion was difficult, irritation of nostril or oropharynx may have occurred.
26. Ask whether patient feels comfortable.	Evaluates patient's level of comfort.
27. Observe patient for any difficulty breathing or gagging.	Malposition of the tube may cause these symptoms.

RECORDING AND REPORTING

- Record and report type and size of tube placed, location of distal tip of tube, patient's tolerance of procedure, pH value and confirmation of tube position by X-ray.

HOME CARE CONSIDERATIONS

- Placement may be verified on the basis of pH recordings. A small amount of water may be instilled via the feeding tube while the patient is carefully observed for coughing or gagging.
- The patient and care provider should be instructed to report pH values that fall outside an established range and to report any difficulties that occur during the feeding.

SKILL 31-2

Administering enteral feeding via nasoenteric tube

Delegation considerations

This task requires the problem-solving and knowledge-application skills of professional nurses. For this reason, delegation of this task to nurse assistants is inappropriate.

Equipment

- Disposable feeding bag and tubing or ready-to-hang system
- 30 mL or larger Luer-lock or catheter-tip syringe
- Stethoscope
- pH indicator strip
- Infusion pump (required for intestinal feedings): use pump designed for tube feedings
- Prescribed enteral feedings
- Gloves
- Equipment to obtain blood glucose by finger-stick

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

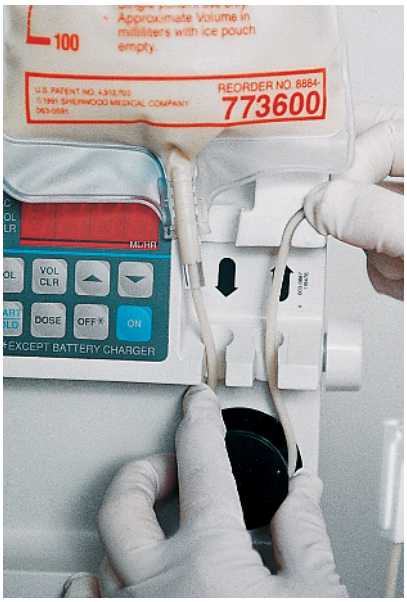
STEPS	RATIONALE
1. Assess patient's need for enteral tube feedings: impaired swallowing, decreased level of consciousness, head or neck surgery, facial trauma, surgeries of upper alimentary canal.	Identify patients who need tube feedings before they become nutritionally depleted.
2. Auscultate for bowel sounds before feeding.	Absent bowel sounds may indicate decreased ability of GI tract to digest or absorb nutrients but are not a contraindication to enteral feeding.
3. Obtain baseline weight and laboratory values. Assess patient for fluid volume excess or deficit, electrolyte abnormalities and metabolic abnormalities such as hyperglycaemia.	Enteral feedings are to restore or maintain a patient's nutritional status. Provides objective data to measure effectiveness of feedings.
4. Verify the order for formula, rate, route and frequency. Laboratory data and bedside assessments, such as finger-stick blood glucose measurement, may also be required.	Tube feedings can be prescribed by a dietitian or doctor. In some institutions feeding protocols provide guidance for nurses to commence enteral nutrition. Laboratory tests and bedside tests must be ordered by doctor.
5. Explain procedure to patient.	Well-informed patient is more cooperative and at ease.
6. Wash hands.	Reduces transmission of microorganisms.
7. Prepare feeding container to administer formula:	
a. Have tube feeding at room temperature.	Cold formula may cause gastric cramping and discomfort because the liquid is not warmed by mouth and oesophagus.
b. Connect tubing to container as needed or prepare ready-to-hang container.	Tubing must be free of contamination to prevent bacterial growth.
c. Shake formula container well, and fill container and tubing with formula (see illustration).	Filling the tubing with formula prevents excess air from entering GI tract.
8. Place patient in high-Fowler's position, or elevate head of bed 30 degrees.	Elevated head helps prevent aspiration.
9. Determine tube placement:	
a. Aspirate gastric contents to check for gastric residual (see illustration). Return aspirated contents to stomach unless the volume exceeds 250 mL.	Presence of gastric secretions indicates that the distal end of the tube is in the stomach. Residual volume indicates whether gastric emptying is delayed. Patients with delayed gastric emptying may have high gastric residual volumes (e.g. more than 400–500 mL).

STEPS	RATIONALE
 Step 7c Pouring formula into container.	 Step 9a Checking for gastric residual.
b. Measure pH of aspirated gastric contents.	Fasting gastric pH is usually equal to or less than 4. pH greater than 6 may occur if patients are receiving acid suppression or if there is undigested feed aspirated. In contrast, intestinal aspirates usually have a pH equal to or greater than 7.
c. Observe the aspirate's appearance.	Gastric fluid is usually cloudy and grassy green or tan to off-white in colour; in contrast, intestinal fluid is usually deep golden yellow and is clearer than gastric contents (see Figure 31-5).
d. Consider the results from pH testing, the aspirate's appearance and compare the insertion length of the feeding tube to what was originally verified on insertion.	An aspirate with a low pH and a typical gastric fluid colour indicates a high probability of gastric placement; in contrast, a golden-coloured aspirate with a high pH indicates a high probability of intestinal placement. Visualisation of gastric contents alone is not a reliable indicator of feeding tube position.

■ **Critical decision point: Auscultation is no longer considered a reliable method for verification of placement of tube because air in tube inadvertently placed in lungs, pharynx or oesophagus can transmit sound similar to that of air entering stomach.**

10. Initiate feeding:	
A. Bolus or intermittent feeding	
(1) Pinch proximal end of the feeding tube. (2) Remove plunger from syringe and attach barrel of syringe to end of tube.	Prevents air from entering patient's stomach.

STEPS	RATIONALE
(3) Fill syringe with measured amount of formula. Release tube and hold syringe high enough to allow it to empty gradually by gravity, refill; repeat until prescribed amount has been delivered to the patient. (4) If feeding bag is used, hang feeding bag on a pole. Fill bag with prescribed amount of formula, and allow bag to empty gradually over at least 30 minutes.	Gradual emptying of tube feeding by gravity from syringe or feeding bag reduces risk of abdominal discomfort, vomiting or diarrhoea induced by bolus or too-rapid infusion of tube feedings.
B. Continuous-drip method (1) Hang feeding bag and tubing on a pole. (2) Connect distal end of tubing to the proximal end of the feeding tube. (3) Connect tubing through infusion pump (see illustration) and set rate.	Continuous feeding method is designed to deliver prescribed hourly rate of feeding. This method reduces risk of abdominal discomfort. Patients who receive continuous drip feedings should have residuals checked every 4–6 hours and tube placement verified. When feeding is well established there is no need to monitor gastric residual volumes regularly.



Step 10B Connecting tubing through infusion pump.

11. Advance tube feeding as recommended by the dietitian or doctor.	Tube feedings can be started at goal rate for many patients. If a more conservative approach to reaching goal rate is required, discuss this with the dietitian or doctor to develop a tailored plan for the patient.
12. When feeding is complete, flush the tubing with 30 mL water. Chart the amount of water on the fluid balance chart.	Reduces the risk of sediment forming and blocking the tubing.
13. When tube feedings are not being administered, cap or clamp the proximal end of the feeding tube.	Prevents air from entering stomach between feedings.
14. Administer water via feeding tube as ordered with diluted formula.	Provides patient with source of water to help maintain fluid and electrolyte balance.

STEPS	RATIONALE
15. Rinse bag and tubing with warm water whenever feedings are interrupted for prolonged periods. Follow the manufacturer's recommendations as some feeding bags are recommended as single-use only.	Rinsing bag and tubing with warm water clears old tube feedings and reduces bacterial growth.
16. Measure amount of aspirate (residual) every 4–6 hours, if required.	Evaluates tolerance of tube feeding.
17. Monitor finger-stick blood glucose every 6 hours until maximum administration rate is reached and maintained for 24 hours. Monitor blood glucose level (BGL). Obtain medical direction for reportable BGL.	Alerts nurse to patient's tolerance of glucose.
18. Monitor intake and output every 24 hours.	Intake and output are indications of fluid balance or fluid volume excess or deficit.
19. Weigh patients weekly after admission unless otherwise indicated.	Weight gain is indicator of improved nutritional status; however, sudden gain of more than 900 g in 24 hours usually indicates fluid retention.

RECORDING AND REPORTING

- Record amount and type of feeding, patient's response to tube feeding, patency of tube and any side effects. Report patient's tolerance and adverse effects.

HOME CARE CONSIDERATIONS

- Ask patient or care provider about any symptoms or discomfort during enteral feedings. Reinforce instruction to contact nurse if symptoms or discomfort occur.

SKILL 31-3

Administering enteral feeding via gastrostomy or jejunostomy tube

Delegation considerations

This task requires the problem-solving and knowledge-application skills of professional nurses. For this reason, delegation to nurse assistants is inappropriate.

Equipment

- Disposable feeding container or ready-to-hang bag
- 30 mL or larger Luer-lock or catheter-tip syringe
- Formula
- Infusion pump: use pump designed for tube feedings
- pH indicator strips
- Stethoscope
- Gloves
- Equipment to obtain blood glucose by finger-stick

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess patient's need for enteral tube feedings (see Skill 31-2): impaired swallowing, decreased level of consciousness, surgeries of upper alimentary tract, need for long-term enteral nutrition.	Identifies patients who need tube feedings before they become nutritionally depleted. Enteral feeding preserves the function and mass of the gut, promotes wound healing, diminishes hypermetabolism in burn injuries and may decrease infection in critically ill patients.
2. Auscultate for bowel sounds for at least 60 seconds before feeding. Consult doctor if bowel sounds are absent.	Absence of bowel sounds may indicate decreased or absent peristalsis and increased risk of aspiration or abdominal distension. Absent or diminished bowel sounds are not absolute contraindications to enteral feeding.
3. Obtain baseline weight and laboratory values.	Enteral feedings are to restore or maintain nutritional status. Provides objective data to measure effectiveness of feedings.
4. Verify doctor or dietitian's order for formula, rate, route and frequency.	Tube feedings are ordered by doctors or dietitians and may be administered by nurses in accordance with local nutrition care protocols.
5. Explain procedure to patient.	Well-informed patient is more cooperative and feels more at ease.
6. Prepare feeding container to administer formula:	
a. Have tube feeding at room temperature.	Cold formula may cause gastric cramping and discomfort because the liquid is not warmed by mouth and oesophagus.
b. Connect tubing to container as needed, or prepare ready-to-hang bag.	Tubing must be free of contamination to prevent bacterial growth.
c. Fill container and tubing with formula.	Placement of formula through tubing prevents excess air from entering gastrointestinal tract.
7. Elevate head of bed 30–45 degrees.	Elevating patient's head helps prevent chance of aspiration.
8. Verify tube placement:	
A. Gastrostomy tube Aspirate gastric secretions; observe their appearance and check pH; return aspirated contents to stomach unless the volume exceeds 150 mL.	Gastric fluid is usually cloudy and grassy green or tan to off-white in colour; in contrast, intestinal fluid is usually deep golden yellow and more clear than gastric fluid (see Figure 31-5).
B. Jejunostomy tube Aspirate intestinal secretions, observe their appearance and check pH.	Presence of intestinal fluid indicates that the end of the tube is in the small intestine (i.e. duodenum or jejunum). Generally the intestinal residual is very small (10 mL or less). If fluid tests acidic on pH test, looks like gastric fluid or the residual volume is large (more than 10 mL), displacement of the tube into the stomach may have occurred.

STEPS	RATIONALE
9. Flush with 30 mL of water.	
10. Initiate feedings:	
A. Syringe feedings (1) Pinch proximal end of gastrostomy tube. (2) Remove plunger and attach barrel of syringe to end of tube, then fill syringe with formula. (3) Allow syringe to empty gradually. Refill until prescribed amount has been delivered to patient.	Usually gastrostomy and jejunostomy feedings are given continuously to ensure proper absorption. However, initial feedings may be given by bolus to assess patient's tolerance to formula. See Skill 31-2 for guidelines to advance enteral feedings.
B. Continuous drip method	
(1) Fill feeding container with enough formula for 4 hours of feeding. In summer, unless air-conditioning is available, this is reduced to 2-hourly to reduce the risk of contamination. (2) Hang container on a pole, and clear tubing of air. (3) Thread tubing on pump according to manufacturer's directions. (4) Connect tubing to end of feeding tube. (5) Begin infusion at prescribed rate.	
11. Following completion of feeding, flush the tube with 30 mL water. Chart additional water on fluid balance chart.	This reduces the risk of sediment forming and blocking the tube.
12. Assess skin around tube exit site. The skin around the tube should be cleaned daily with warm water and mild soap. Dressings around the exit site are not recommended.	Report any drainage, redness, swelling or displacement of the tube to the doctor.
13. Dispose of supplies, and wash hands.	Prevents transmission of microorganisms.
14. Measure the amount of aspirate (residual) every 4–6 hours, if required.	Evaluates tolerance of tube feeding.
15. Monitor finger-stick blood glucose every 6 hours until maximum administration rate is reached and maintained for 24 hours.	Alerts nurse to patient's tolerance of glucose.
16. Monitor intake and output every 24 hours.	Intake and output are indications of fluid balance or fluid volume excess.
17. Weigh patient weekly unless otherwise indicated.	Weight gain is indicator of improved nutritional status; however, a sudden gain of more than 900 g in 24 hours usually indicates fluid retention.
18. Inspect site for signs of pressure.	Enteral tubes can cause uncomfortable pressure areas on patient's nares.

RECORDING AND REPORTING

- Record amount and type of feeding and patient's response to tube feeding, patency of tube and any side effects.
- Report to oncoming nursing staff: type of feeding, status of feeding tube, patient's tolerance, adverse effects.

HOME CARE CONSIDERATIONS

- Ask patient or care provider about any symptoms or discomfort during enteral feeding. Reinforce instruction to contact nurse if symptoms or discomfort occur.
- Instruct patient or care provider in how to care for gastrostomy or jejunostomy tube site and symptoms to report.

CLINICAL EXAMPLE

Sandra White is a 36-year-old who sustained a closed head injury 3 days ago and remains unconscious. Sandra is to be started on enteral tube feeds. What are the potential complications of enteral tube feeding and the nursing interventions to minimise the occurrence of these? What strategies will need to be used to transition Sandra from enteral nutrition to oral intake?

On insertion, the placement of small-bore feeding tubes is ideally verified by X-ray examination. The tube should then be marked where it exits the nose and taped securely. Historically, feeding-tube placement was checked by injecting air through the tube while auscultating the stomach for a gurgling or bubbling sound, or asking the patient to speak (Tho et al 2011). These methods have a high degree of inaccuracy. While radiographic verification is the most reliable method for checking tube placement, this is cost-prohibitive for ongoing placement verification and is not possible in facilities without radiography, such as in nursing homes or remote locations. Where radiography is unavailable, the current most reliable and combined method of assessing tube placement (Metheny et al 2005) is measuring:

1. the length of the tubing extending from the insertion site
2. the volume of aspirate from the feeding tube
3. the appearance of the aspirate, and
4. the pH of the aspirate (acid or alkaline).

These methods must be used in combination as each has its own limitations. For example, assessing gastric aspirate pH can be misleading if the patient is simultaneously receiving acid-inhibitor medications which increase gastric pH.

Parenteral nutrition

Parenteral nutrition (PN) – also called *total parenteral nutrition* (TPN) if it is the sole source of nutrition – is a specialised method of nutrition support in which nutrients are provided directly into the bloodstream, intravenously. Because of the high osmolality of the PN solution, administration requires central access to the superior vena cava via a central venous catheter (CVC) or peripherally inserted central catheter (PICC) (Figure 31-6). Peripheral venous access may be used for limited time periods and lower osmolarity solutions (Pittiruti et al 2009); however,

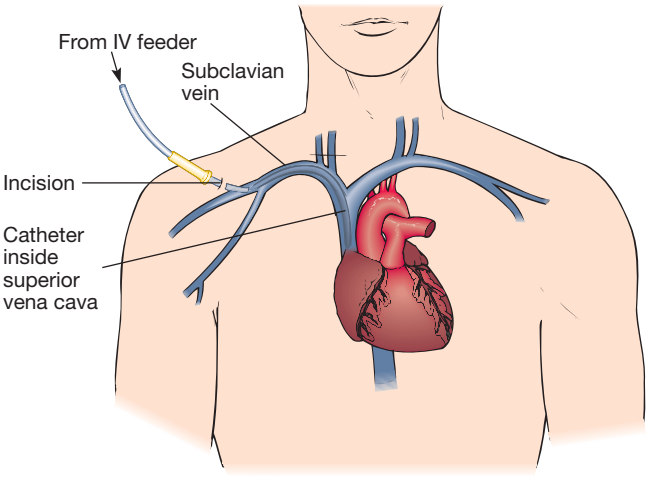


Figure 31-6 Central venous catheter insertion site.

Drawn by Rolin Graphics.

this route is not commonly used for PN in Australian hospitals (Dietitians Association of Australia 2011). PN is indicated in patients whose gut is either not functional or not accessible.

A multidisciplinary team approach is important for the initiation and management of PN. The dietitian is responsible for nutritional assessment and monitoring, calculating requirements and selecting appropriate PN solutions and infusion rates. The nurse oversees care of the vascular access site and PN equipment, prepares and administers the PN infusion and provides education and training for home use of PN to the patient if required. Doctors oversee the patient's medical management and pharmacists consult on the formulation, additives and interactions with other medications.

There are a number of commercially available PN formulas/solutions used in Australia. Standard formulas prepared in 'ready-to-hang' bags are normally used in the home and hospital setting, but specialised formulas may also be developed or compounded for patients with special needs. Standard formulas typically contain between 0.6–1.2 kcal/ mL, with 10–15% of energy provided by protein, 30–45% of energy from fat and 35–55% from carbohydrate (depending on whether the PN is a lower- or higher-carbohydrate solution). Macronutrients in PN are provided in their basic forms: proteins as free amino acids; carbohydrates as dextrose (D-glucose); and fats as water-soluble **lipid emulsions** which can be infused safely into the blood. The lipid emulsion consists of oil (soybean or mixture of olive,

soybean or fish oils) stabilised with egg yolk lecithin, and contains essential fatty acids. PN solutions generally contain electrolytes, but micronutrients such as vitamins and minerals need to be added to the solution. When prescribing an enteral nutrition formula, dietitians or doctors must ensure they have included an appropriate vitamin and mineral supplement to the prescription. Vitamin K cannot be added to the PN solution as it affects the stability of the lipid emulsion; therefore it must be given separately (i.e. IV). The dose and frequency of vitamin K will depend on the hospital's PN policy but is generally around 0.5–1 mg per day (American Society for Parenteral and Enteral Nutrition 2015).

Parenteral solutions

There are many different PN formulas available through different companies, although health services may select only one or two products for use. The most appropriate formula is selected by the dietitian or doctor following a comprehensive nutrition assessment. PN is usually available in a ready-to-hang bag, commonly provided as two-in-one or three-in-one solutions. Two-in-one solutions contain amino acids and dextrose in one bag. Lipids are given separately. Three-in-one solutions allow amino acids, dextrose and lipids to be given in one bag. The hang time for solutions differs, with lipid-only solutions recommended to hang for no more than 12 hours. The hang time for two-in-one and three-in-one solutions is 24 hours.

For some patients, individualised PN solutions are required and must be compounded in a hospital pharmacy or by the manufacturer. If micronutrients need to be added to the PN solution it is recommended that this is done under special sterile conditions by a pharmacy service using a laminar flow hood. This strategy minimises risk such as contamination, solution instability and compounding errors but may not be possible in facilities where such a service is unavailable (Dietitians Association of Australia 2011).

• CRITICAL REFLECTION POINT

TPN solutions have a high concentration of glucose and are an excellent medium for the growth of bacteria. Addition of medications to these solutions has the potential to introduce bacteria into the TPN solution, which is then administered directly into the patient's bloodstream and can cause life-threatening complications. Sterile conditions must be adhered to when adding medications to these solutions.

Beginning an infusion

Administering PN is similar to any other medication. Before beginning an infusion, the nurse must check the doctor's order with the solution prepared by the pharmacy. Checking the solution for particulate matter or a break in the lipid emulsion is also important.

Infusion flow rate

An infusion pump should always be used to administer PN. PN infusion rates vary from 40–150 mL/hour. Patients initially receive PN solutions at a moderate rate, such as 40–60 mL/h. The rate is gradually increased until the target energy needs are being supplied. Too-rapid administration of hypertonic dextrose can result in an osmotic diuresis and dehydration (see Chapter 34). Unlike enteral nutrition administration, if an infusion falls behind schedule, the nurse should not increase the rate in an attempt to catch up. Similarly, sudden discontinuation of the solution can cause hypoglycaemia. Usually, 5–10% dextrose is infused when PN solution is suddenly discontinued to prevent rebound hypoglycaemia.

In hospital, PN is delivered continuously over a 24-hour period. Patients who receive PN at home on a long-term basis are frequently acclimatised to a system of delivering 1–3 L of PN over 12 hours at night. The CVC is flushed and bunged (plugged with a sterile 'bung' or stopper) each morning for independent mobility during daytime hours. Nocturnal administration of PN is achieved by tapering the flow rate up at the beginning and down when ending. This individualised routine is tested during hospitalisation for tolerance and achievement of nutritional outcome.

Preventing complications

Complications most often arise because of the need for central venous access to deliver PN. Infection is the most common complication. To avoid infection, the infusion tubing should be changed every 24 hours for a lipid infusion. If lipids are not infused, CVC administration sets should be changed no more frequently than every 96 hours and should be changed at least every 7 days (O'Grady et al 2011). Clear CVC dressings should be changed every 7 days unless soiled, dampened or loosened. If gauze dressings are used, dressings should be changed every 2 days, unless required earlier.

During CVC insertion, pneumothorax may result from a puncture insult to the pulmonary system and culminates in accumulation of air in the pleural cavity. Pneumothorax is usually accompanied by symptoms of sudden sharp chest pain, dyspnoea and coughing. Other complications of CVC insertion are cardiac dysrhythmias and, infrequently, rupture of major vessels. Air embolus can also occur during insertion of the catheter or when changing the tubing or cap. Having the patient perform a Valsalva manoeuvre (holding one's breath and 'bearing down') while assuming a left lateral position can prevent air embolus. Metabolic complications can also occur as a result of PN administration and are described in Table 31-18.

Transitioning to oral intake

A goal of nutrition care is to move patients from parenteral to enteral and/or oral feeding. Once patients are meeting one-third to one-half their kilojoule needs per day enterally, TPN is usually decreased to half the original volume. Enteral feedings should then be increased to meet needs. When 75% of daily energy needs are consistently met with tube feeding, parenteral feeding may be discontinued.

Patients who make the transition from PN to oral feedings typically have early satiety and decreased appetite. PN should be gradually decreased in response to increased oral intake. If oral intake is inadequate, small, frequent meals may be better tolerated. Kilojoule/protein counts are recommended when patients begin taking soft foods. When 75% of needs are being met by reliable oral dietary intake, PN therapy may be discontinued.

Dietary education and counselling

Dietary education and counselling is a key aspect of nutrition care. This may involve providing general nutrition advice, such

TABLE 31-18 Short-term metabolic complications associated with total parenteral nutrition

Complication	Cause	Detection and treatment
Hyperosmolar coma	Occurs acutely if a rapid infusion of hypertonic fluid is administered. Infusion can cause severe osmotic diuresis, resulting in electrolyte abnormalities, dehydration and malfunction of the central nervous system	Daily blood samples, accurate measurements of fluid balance, routine blood samples. Reduce infusion rate, correct electrolyte imbalances
Electrolyte imbalance	Disturbances in serum electrolytes, particularly sodium potassium, urea and creatinine, may occur early in the treatment of TPN. Electrolyte imbalances can be caused by the patient's underlying medical condition; requirements vary with individual patients' needs. Can be caused by inadequate or excessive administration of intravenous fluids	Daily blood samples taken early in treatment to detect abnormalities. Replacement fluid as required, extra intravenous fluids may be required during the stabilisation period
Hyperglycaemia	Critically ill patients may be resistant to insulin because of the secretion of adrenocorticotropic hormone and adrenaline. This promotes the secretion of glycogen, which inhibits the insulin response to hyperglycaemia	Monitor the patient's blood sugar 4-hourly after commencement of treatment or as required. Monitor daily urinalysis for glucose and ketones. An insulin infusion may be required to keep blood sugar levels within prescribed limits
Rebound hypoglycaemia	May occur on discontinuation of TPN because hyperinsulinism may occur after prolonged intravenous nutrition. A rise in serum insulin occurs with infusion, and thus sudden cessation of infusion can result in hypoglycaemia	Glucose infusion rate should be gradually reduced over the final hour of infusion before discontinuing. Some patients may receive a 10% glucose solution after cessation of TPN
Hypophosphataemia	Glucose infusion results in the continuous release of insulin, stimulating anabolism and resulting in rapid influx of phosphorus into muscle cells. The greatest risk is to malnourished patients with overzealous administration of feeding. Patients who are hyperglycaemic, who require insulin therapy during TPN or who have a history of alcoholism or chronic weight loss may require extra phosphate in the early stages of treatment	Monitor phosphate levels daily. Hypophosphataemia will usually appear after 24–48 hours of feeding. Reduce the carbohydrate load and give phosphate supplementation
Lipid clearance	Lipids are broken down in the bloodstream with the aid of lipoprotein lipase found in the epithelium of capillaries in many tissues. A syndrome known as fat overload syndrome can occur when infusion of lipid is administered that is beyond the patient's clearing capacity, resulting in lipid deposits in the capillaries	Blood samples should be taken after the first infusion commences (within 6 hours) to observe for lipid in the blood
Side effects of lipid infusion	Some patients suffer symptoms either during or after an infusion of lipid mix parenteral nutrition. The exact cause is unknown. The patient may complain of headache, nausea or vomiting, and generally feels unwell	Treat mild symptoms. If tolerated, the TPN solution of non-protein calories can be given in the form of glucose. However, it is essential that the regimen includes some fat to prevent the development of fatty acid deficiency
Anaphylactic shock	This is a rare complication but may occur as a reaction to the administration of a lipid	It may be necessary to administer adrenaline and/or steroids, and to provide supportive therapy as required
Glucose intolerance	TPN using glucose as the main source of calories is associated with a rise in oxygen consumption and CO_2 production. The workload imposed by the high CO_2 production may precipitate respiratory distress in susceptible patients, particularly those requiring mechanical ventilation	Observe patients for signs of respiratory distress. Provide non-protein calories in the form of glucose lipid mix. Slow initial rate of infusion
Liver function	Abnormalities with liver function can be associated with TPN. May be attributable to hepatic stenosis with moderate hepatomegaly; patient may also develop jaundice. Liver function tests often return to normal after cessation of therapy; however, TPN can lead to severe hepatic dysfunction in neonates	Monitor liver function tests twice weekly. There are several factors that may contribute to development of abnormal liver function tests. These most often occur after a period of time and appear to be more of a problem when there is an excess calorie intake or in glucose-based regimens

Marshall AP, Williams T. 2015 Nutrition Assessment and Therapeutic Management. In Aitken L, Marshall A, Chaboyer W ACCCN's Critical Care Nursing, 3rd edn. Elsevier Australia, Sydney.

as that from the *Australian Guide to Healthy Eating*; or may be more specific disease-related dietary education (see Table 31-15 for common dietary modifications for certain disease states). Usually, dietitians will provide in-depth dietary education and counselling, but nurses are also in a good position to encourage healthy eating habits in patients and their families. It is important for nurses to understand key aspects of therapeutic diets in order to reinforce this information to patients or answer any patient queries. Assessing patients' health literacy and providing information appropriate to their level of understanding is a vital aspect of any dietary education and is in line with a person-centred approach to care.

PREPARING FOR AND TAKING ACTION

Person-centred and interdisciplinary nutrition care

The plan for nutritional care should involve the patient and/or their family and reflect achievable, patient-centred goals. Patient-centred care, patient engagement or patient participation in their care are terms that are often used interchangeably. However, all encompass aspects of a trusting relationship between the patient and nurse; surrendering of some power or control by the nurse; meaningful exchange of information and knowledge between patient and nurse; and active mutual agreement in intellectual and/or physical activities (Sahlsten et al 2008) to allow patients and clients to have input into decisions about their own health care.

Patient engagement

Patient engagement in care is one of Australia's National Safety and Quality Health Service Standards (ACSQHC 2011) and has been shown to improve patient outcomes such as reduce symptoms and improve function and patient satisfaction with health care (Arnetz et al 2010, Weingart et al 2011). Research has also shown that when hospitalised patients participate in their nutrition care, by self-monitoring their intake and setting nutritional goals, their energy and protein intakes are improved (Pedersen 2005, Roberts et al 2015). Ultimately, patients should have input into how they manage nutritional concerns. Depending on their level of engagement, some patients may lead their nutrition care and decision-making, while others may be more passive and require significant direction in regards to their nutritional plan. However, all patients should be given the opportunity to participate in their nutrition care.

Interdisciplinary approach

An interdisciplinary approach is essential to ensure high quality nutrition care (Holst et al 2015). Members of the interdisciplinary team will differ depending on the type of organisation or institution – but typically would include dietitians, nurses, speech therapists, occupational therapists, pharmacists and doctors. The dietitian monitors the patient's nutritional status and intake and makes recommendations for changes, based mainly on data documented in the patient's chart. Dietitians are expert in the choice of enteral formulas and dietary modifications required for specific disease states. Nurses monitor and assess patients 24 hours a day and are well positioned to note decreased nutrition intake. They are also responsible for delivering enteral and parenteral nutrition to ensure delivery most closely matches prescription. Speech therapists assist with swallowing assessment and ensuring patients at risk of dysphagia are able to safely consume oral foods and fluids. Occupational therapists work with patients and families to identify devices that help patients eat, or to rearrange food preparation areas in an effort to maximise the patient's functional capacity. The pharmacist is expert in drug–nutrient interactions and mixture of total parenteral nutrition. This team may be supported by nutrition assistants and food service staff who may have responsibility to assist patients with their nutrition care in the hospital setting.

Strong team communication with clear nutritional goals is necessary to ensure optimal nutrition care is delivered and risks of malnutrition are identified. Changes in nutritional status, whether they are improvements or deterioration, do not usually happen quickly. The insidious nature of changes to nutritional status highlights the need for patient and family involvement, as the healthcare team may change throughout a patient's admission and following discharge. During transitions in care, communicating the long-term nutritional goals for a patient is imperative so that nutritional gains are maintained. Involvement of the patient's family may be helpful, particularly if they are assisting with purchasing food and meal preparation after discharge. Family education is crucial to the success of implementing nutritional changes. In both the Aboriginal Australian and the New Zealand Māori populations, poor nutrition is recognised as a contributing factor for both communicable and non-communicable diseases.

EVALUATING IMPACTS AND OUTCOMES: ENSURING CONTINUITY OF CARE

Nutrition care should be consistent across the continuum of health care. This relies on appropriate documentation, monitoring and follow-up, as well as good communication between health professionals, the patient and their family. Documentation is important in all stages of nutrition care; it provides a means of communicating nutritional risk, comparing nutritional assessments over time, and monitoring the effectiveness of interventions. Accurate and complete documentation also enables nutritional care to continue when the patient is transferred between wards, facilities or discharged to the community.

Monitoring and follow-up should include timely re-screening of nutritional risk; regular assessment of nutritional parameters such as weight, dietary intake and nutrition-impacting symptoms; tailoring of nutritional interventions depending on the patient's medical and nutritional conditions; and monitoring of the tolerance of or adherence to nutritional interventions to achieve nutritional goals and priorities for the maintenance of health and wellbeing. All of these aspects of monitoring and follow-up should be clearly documented and communicated with appropriate members of the healthcare team and the patient (See *Sample student nursing care plan* for an example).

The nurse's role in nutrition care

Nutrition is vital for all aspects of life: health, growth, maintenance and repair. Requirements for specific nutrients differ across the life span, and are influenced

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data*

Mrs Cooper's vital signs were all within normal limits. Three months had passed since Mrs Cooper had been started on sertraline for depression related to the loss of her husband 6 months ago. This was an initial episode of depression. Mrs Cooper had also been referred for counselling 3 months ago for help with grief and depression through a local senior service agency. After checking Mrs Cooper's weight and reviewing her chart, Marie realised her client was 20% **below her IBW** (ideal bodyweight) and had a **low BMI of 17**. This weight loss had occurred in **6 months, down 11 kg**. Mrs Cooper said, 'I'm **just not interested in food.** It has no taste.' Mrs Cooper also said she **gets full quickly**. Marie observed **dull, thinning hair, dry scaling skin, pale conjunctivae and mucous membranes** in addition to 12 **pitting oedema bilaterally in the ankles**. Mrs Cooper complained of chronic constipation and said she tires easily. Marie noted generalised poor muscle tone and a stooped posture. Laboratory data revealed a serum albumin 26 g/L; total lymphocyte count (TLC) 2×10^9/L. Laboratory values also suggested dehydration. Mrs Cooper said she drinks some juice in the morning and two or three cups of coffee. Mrs Cooper complained of loneliness, and said she does not get out much, although her psychologist recommended more socialising. She said she likes her counsellor and that she feels better but has not returned to her old self. Her friends at church call her to come back to meetings, but she is just not ready. When Marie inquired as to her financial situation, Mrs Cooper responded that it was tight living on the pension, but she was able to manage. She thanked Marie for finding a psychologist that she could afford.

**Important data to cluster in setting priorities in bold.*

Priority problem(s)

Altered nutrition: less than body requirements related to an inability to ingest food as a result of psychological depression.

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Mrs Cooper will progressively gain weight.	Mrs Cooper will gain 500 g to 1 kg a month until a goal of 60 kg is reached.
Mrs Cooper will learn key nutritional concepts.	Mrs Cooper will demonstrate an understanding of dietary guidelines.
Mrs Cooper will consume adequate nourishment each day.	Mrs Cooper will ingest 8000 kJ/day, including 50 g of protein per day.
Mrs Cooper will exhibit no signs of malnutrition.	Physical assessment and laboratory values will be within normal limits.
Preparing for and taking action†	**Rationale**
Nutritional counselling	
• Coordinate plan of care with doctor, psychologist, patient and dietitian.	Successful nutrition care planning is a multidisciplinary approach throughout the continuum of care.
• Individualise menu plans.	Individualised meal planning is more useful to the patient.
• Have frequent small meals.	Frequent small meals offset early satiety.
• Review healthy eating strategies.	NHMRC recommendations for optimal nutrition.
• Review dietary guidelines.	
Nutritional monitoring	
• Monitor patient monthly for weight gain.	Weight gain should be slow and progressive.
• Perform physical assessment of hair, eyes, mouth, skin and muscle tone.	

Preparing for and taking action†	Rationale
Nutritional management	
• Promote optimal oral hygiene before and after meals.	Consistent oral hygiene promotes taste sensation.
• Alternate rest with activity, resting before meals and after for 30 minutes.	Adequate rest allows for necessary energy for eating and digestion.
• Consider medication (sertraline)-induced anorexia and diminished taste.	SSRIs diminish taste and appetite.
• Encourage fluid intake.	Older adults need eight 250-mL servings per day of fluid. Concentrating intake in morning and early afternoon is acceptable to prevent nocturia.
• Encourage fibre intake.	Adequate fluid, fibre and exercise deter constipation.
• Consult with Mrs Cooper about referral for lunch at senior citizens centre 5 times per week.	Meal participation would encourage good nutrition and promote socialisation with peers.

† Intervention classification labels from Bulechek GM et al 2008 Nursing interventions classification (NIC), 5th edn. Mosby, St Louis.

Evaluating impacts and outcomes

- Ask Mrs Cooper to re-state number of servings from each group necessary for her optimal nutrition.
- Ask Mrs Cooper to state amount of kilojoules and protein she needs each day.
- Observe and monitor physical nutritional status (weight, biochemical indicators).
- Ask Mrs Cooper about appetite and taste status.

by disease states. Comprehensive nutrition assessment is required to determine an individual's nutrition needs and ensure adequate nutrition provision. As part of an interdisciplinary healthcare team, nurses have an important role in screening patients for nutrition risk and contributing to nutrition assessment.

Some patients may be at increased nutrition risk or influenced by pre-existing malnutrition associated with illness, disease or decreased nutrition intake. For hospitalised patients, nurses can ensure that nutrition intake is maintained or enhanced, and that nutrition-impacting symptoms are minimised so the full benefits of nutrition can be realised. Nurses can promote optimal nutrition intake by assisting patients with oral intake, and ensuring adherence to diet prescription and delivery of artificial nutrition such as enteral and parenteral nutrition. As nutrition requirements for individual patients vary, it is essential that a patient-centred approach is adopted and that patients and their families can contribute to strategies targeting adequate nutritional intake.

Key concepts

- There are many nutrients that are required by the body for normal health, growth and functioning, which are supplied by dietary intake.
- Through digestion, food is broken down into its simplest form for absorption. Digestion and absorption occur mainly in the small intestine.
- Australian dietary guidelines provide a range of values that cover the needs of groups (estimated average requirement) and individuals (adequate intakes, recommended dietary intakes and upper limit of intake).
- Guidelines for dietary change advocate reduced fat, saturated fat, sodium, refined sugar and cholesterol and increased intake of complex carbohydrates and fibre.
- Age affects the requirements for essential nutrients, e.g. periods of rapid growth increase the need for protein, vitamins and minerals.
- Because poor nutrition can affect all body systems, assessing patients' nutrition status is extremely important in the hospital setting.
- Multidisciplinary collaboration is essential to maintaining optimal nutrition in patients or clients.
- Nurses can improve food intake of patients by thoughtful attention to the preparation of the person and environment before meals are served.
- Nasogastric and enteral tube feeding can be used for patients who are unable to ingest food but are able to digest and absorb food.
- Total parenteral nutrition (TPN) supplies essential nutrients in appropriate amounts to support life through

the introduction of a concentrated nutrient solution into the superior vena cava near the right atrium of the heart.

- Medical nutrition therapy is a recognised treatment for both acute and chronic disease states.
- Special diets alter the composition, texture, digestibility and residue of foods to suit the patient's particular needs.
- Evaluation of the outcomes of nutrition support is essential to revise, update or continue nursing activities.
- Nutritional research is a dynamic process. Results of studies and new recommendations by expert sources need to be followed for future changes in practice standards.

CHAPTER

32

Maintaining bowel elimination

Elizabeth Watt

Learning outcomes

Mastery of content will enable you to:

- discuss the role of gastrointestinal organs in digestion and elimination
- describe the functions of the large intestine
- explain the physiology of normal defecation
- discuss psychological and physiological factors that influence the elimination process
- describe common health issues related to elimination
- assess a person's elimination pattern
- list nursing diagnoses related to common health issues related to elimination
- describe nursing implications for common diagnostic examinations of the gastrointestinal tract
- describe nursing interventions that promote normal bowel function
- discuss the relationship between the structure and function of bowel diversions and the nursing assessment and care that is required
- use clinical reasoning and best practice evidence in the provision of care to patients with alterations in bowel elimination.

Regular elimination of bowel waste products is essential for normal body functioning. Alterations in elimination are often early signs or symptoms of problems within the gastrointestinal or other body systems. Because bowel function depends on the balance of several factors, elimination patterns and habits vary among individuals.

People who are hospitalised have additional risk factors for bowel problems, such as immobility, bed rest, altered diet, surgery and narcotic-type pain medications. To promote normal function and manage the person's elimination problems, an understanding of normal elimination and factors that promote or cause alterations in elimination is required.

The gastrointestinal (GI) tract is a series of hollow, mucous-membrane-lined muscular organs. The purposes of these organs are to absorb fluid and nutrients, prepare food for absorption and use by the body's cells, and provide for temporary storage of faeces (Figure 32-1). The volume of fluids absorbed by the GI tract is high, making fluid balance a key function of the GI system. In addition to ingested fluids and foods, the GI tract receives digestive secretions from organs such as the gallbladder and the pancreas. Any condition that seriously impairs normal absorption of GI fluids could cause fluid imbalance.

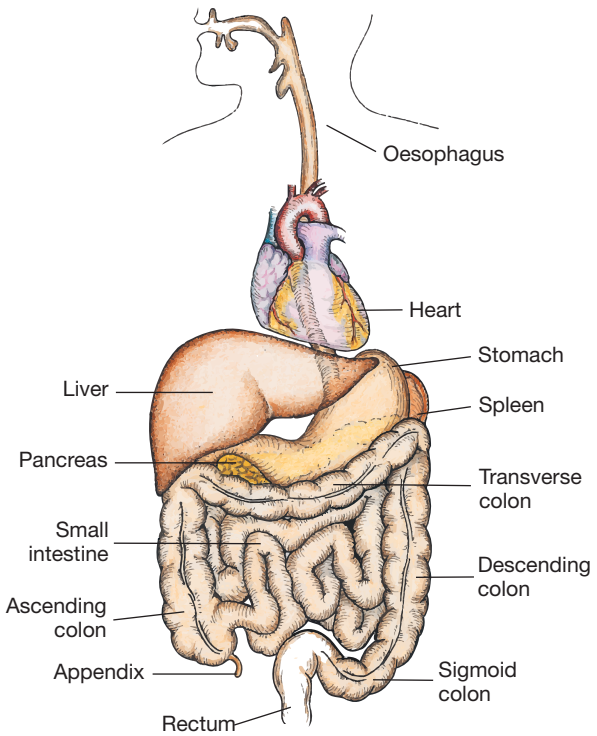

Figure 32-1 Organs of the gastrointestinal tract (with the heart as a reference point).

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Mouth

Digestion begins in the mouth, where mechanical and chemical breakdown of nutrients occurs. The teeth **masticate** (chew) food, breaking it down to a suitable size for swallowing. Saliva secreted from the salivary glands contains enzymes that initiate digestion of dietary starches and fats. Saliva also softens the **bolus** of food in the mouth for easier swallowing and keeps the mucous membranes of the mouth moist.

Oesophagus

As food enters the upper oesophagus, it passes through the *upper oesophageal sphincter*, which is a circular muscle that prevents air from entering the oesophagus and food from **refluxing** (moving backwards) into the throat. The bolus of food travels approximately 25 cm down the oesophagus. Food is pushed along by slow **peristalsis** produced by alternating involuntary contractions and relaxations of smooth muscle. As a portion of the oesophagus contracts above the food bolus, the circular muscle below (or in front) of the bolus relaxes. This alternate contraction–relaxation of smooth muscle propels food towards the next wave (Figure 32-2).

In 15 seconds the bolus of food moves down the oesophagus and reaches the *lower oesophageal sphincter*. The lower oesophageal (or cardiac) sphincter lies between the oesophagus and stomach and prevents backward movement of fluids from the stomach to the oesophagus. Factors influencing cardiac sphincter efficacy include antacids, which minimise reflux, and fatty foods and nicotine, which increase reflux.

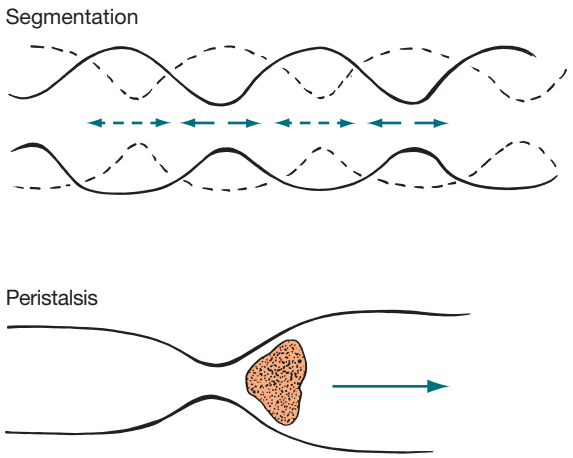

Figure 32-2 Segmented and peristaltic waves.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Stomach

In the stomach, food is temporarily stored and mechanically and chemically broken down for digestion and absorption (see Chapter 31). The stomach consists of four main regions: the cardia, the fundus, the body and the pylorus. When empty, the stomach has *rugaeor* folds which allow it to distend when food is ingested (Marieb & Hoehn 2014). The stomach secretes hydrochloric acid (HCl), mucous, the enzyme pepsin and intrinsic factor. The concentration of *hydrochloric acid* influences stomach acidity and the body's acid–base balance (see Chapter 34), and helps mix and break down food. Prostaglandins assist in the formation of *mucous*, which protects the stomach mucosa from acidity and enzyme activity. *Pepsin* digests proteins, although not much digestion occurs in the stomach. *Intrinsic factor* is the essential component needed for vitamin B_{12} absorption in the intestine and subsequent normal red blood cell formation. Lack of this intrinsic factor results in a condition called pernicious anaemia. Before food leaves the stomach, it is changed into a semifluid material called **chyme**. Chyme is more easily digested and absorbed than solid food.

Small intestine

During normal digestion, chyme leaves the stomach and enters the small intestine via the pyloric sphincter. The small intestine is a tube about 2.5 cm in diameter and 6 m long. It contains three divisions: *duodenum*, *jejunum* and *ileum*. Chyme mixes with digestive enzymes (e.g. bile and amylase) while travelling through the small intestine. Segmentation (alternating contraction and relaxation of smooth muscle) churns the chyme, further breaking down food for digestion (see Figure 32-2). These alternating contractions occur approximately 12 times a minute. As chyme mixes, forward peristaltic movement temporarily ceases, permitting absorption. Chyme travels slowly through the small intestine to allow absorption of nutrients and electrolytes.

Enzymes from the pancreas (e.g. amylase) and bile from the gallbladder are released into the duodenum. The enzymes in the small intestine break down fats, proteins and carbohydrates into basic elements (see Chapter 36). Nutrients are almost entirely absorbed by the duodenum and jejunum, although the ileum absorbs certain vitamins, iron and bile salts. If the function of the small intestine is impaired, the digestive process is greatly altered. For example, inflammation, surgical resection or obstruction can disrupt peristalsis, reduce the area of absorption or block the passage of chyme.

Large intestine

The lower GI tract is called the large intestine because it is larger in diameter than the small intestine. However, its length of 1.5–1.8 m is much shorter. The large intestine is divided into the *caecum*, *colon* and *rectum* (Figure 32-3). It is responsible for the absorption of water and is the primary organ of bowel elimination.

Caecum

Unabsorbed chyme enters the large intestine at the caecum through the *ileocaecal valve*. This valve is a circular muscle layer that prevents colon contents from **regurgitating** and returning to the small intestine. Located at the end of the caecum is the *vermiform appendix*. Inflammation of this area can result in blockage of the appendix, leading to appendicitis.

Colon

Although watery chyme enters the colon, the volume of water lessens as chyme moves along it. The **colon** is divided into the *ascending*, *transverse*, *descending* and

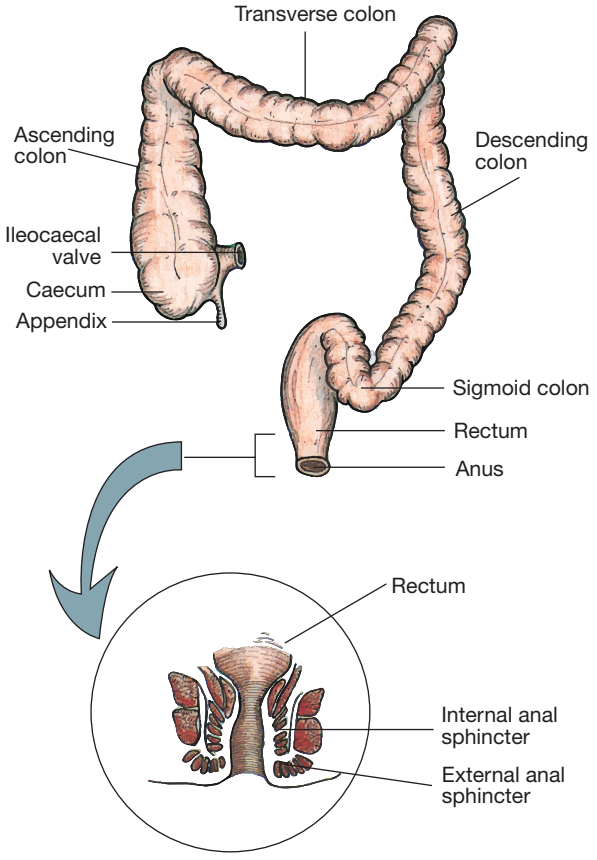

Figure 32-3 Divisions of the large intestine.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

sigmoid colon. The colon is made of muscular tissue, which allows it to accommodate and thus eliminate large quantities of waste.

The colon has four interrelated functions: absorption, protection, secretion and elimination. The colon absorbs a large volume of water and significant amounts of sodium and chloride daily. As food passes through the colon, **haustral contractions** occur. These are similar to segmental contractions of the small intestine but last longer, up to 5 minutes. The contractions produce large sacs in the colon's wall, providing a large surface area for absorption.

The colon can absorb as much as 2.5 L of water in 24 hours. On average, 55 mmol of sodium and 23 mmol of chloride are absorbed daily. The amount of water absorbed from chyme depends on the speed at which colonic contents move. Chyme is normally a soft, formed mass. If the speed of peristaltic contractions is abnormally fast, there is less time for water to be absorbed and the stool will be more liquid. If peristaltic contractions significantly slow down, water continues to be absorbed and a hard mass of stool forms, resulting in **constipation**.

The colon protects itself by secreting a supply of mucous. Mucous is normally clear to opaque, with a stringy consistency. Mucous lubricates the colon, preventing trauma to its inner walls. Lubrication is especially important near the distal end of the colon, where contents become drier and harder. The secretory function of the colon aids in electrolyte balance. Bicarbonate is secreted in exchange for chloride. About 4–9 mmol of potassium is released each day by the large intestine. Serious alterations in colon function, such as diarrhoea, can cause electrolyte imbalance due to loss of potassium and chloride.

Finally, the colon eliminates waste products (**faeces**) and gas (flatus). **Flatus** results from air swallowing, diffusion of gas from the bloodstream into the intestine, and bacterial action on non-absorbable carbohydrates. Fermentation of carbohydrates (such as in cabbage and onions) produces intestinal gas, which can stimulate peristalsis. An adult normally forms 400–700 mL of flatus daily.

Slow peristaltic contractions move contents through the colon. The intestinal content is the main stimulus for peristaltic contraction. Waste products and gas exert pressure against the walls of the colon. The muscle layer stretches, stimulating the reflex that initiates contraction. Mass peristaltic movements push the faecal bolus towards the rectum. These movements occur only three or four times daily, unlike the frequent peristaltic waves in the small intestine (usually heard during auscultation). When these mass peristaltic movements occur, large segments of the colon contract as a result of gastrocolic reflex and duodenocolic reflex responses. These occur when the stomach or duodenum is filled with food and fluid. Filling initiates nerve impulses that stimulate the colon's muscular walls. This reflex eristalsis is strongest during the hour after a meal.

Rectum

Waste products that reach the sigmoid portion of the colon are called faeces. The sigmoid stores faeces until just before defecation. The rectum is the final part of the GI tract. Its length varies according to age:

Infant	2.5–4 cm
Toddler	5 cm
Preschooler	7.5 cm
School-age child	10 cm
Adult	15–20 cm

Normally the rectum is empty of faeces until defecation. It contains vertical and transverse folds of tissue. Each vertical fold contains an artery and veins. If the veins become distended from pressure during excessive straining, **haemorrhoids** can form. Haemorrhoids can make defecation painful if they are swollen and inflamed.

When the faecal mass moves into the rectum and the rectal walls distend, **defecation** begins. The process involves involuntary and voluntary control. The *internal sphincter* is a smooth muscle innervated by the autonomic nervous system. As the rectum distends, sensory nerves are stimulated and carry impulses that cause the internal sphincter to relax, allowing more faeces to enter the rectum. At the same time, impulses travel to the brain to create conscious awareness of the need to defecate.

As the internal sphincter relaxes, so does the *external sphincter*. Adults and toilet-trained children can voluntarily control the external sphincter. If the time for defecation is not right, constriction of the levatorani muscles closes the anus and defecation is delayed. At the time of defecation, the external sphincter relaxes. Pressure can be exerted to expel faeces through an increase in intra-abdominal pressure, or a **Valsalva manoeuvre**. A Valsalva manoeuvre is voluntary contraction of abdominal muscles during forced expiration with a closed glottis (holding one's breath while straining).

Factors affecting bowel elimination

Many factors influence the process of bowel elimination. Knowledge of these factors enables identification of people at risk and the selection of appropriate intervention(s) to prevent or alleviate the symptoms of altered bowel elimination.

Age

Developmental changes that affect elimination occur throughout life. An infant has a small stomach capacity and less secretion of digestive enzymes. Some foods, such as complex starches, are tolerated poorly. Food passes quickly through an infant's intestinal tract because of rapid peristalsis. The infant is unable to control defecation because of a lack of neuromuscular development (see *Working with diversity*). This development usually does not take place until 2–3 years of age.

WORKING WITH DIVERSITY

Focus on infants and children

- Normally, a healthy newborn infant has a bowel motion within 24–36 hours of birth. This first stool is called meconium and is a thick greenish-black material.
- The frequency of bowel movements in babies can be affected by their feeding regimen. Breastfed babies tend to have more frequent bowel actions than those fed with formula. They may have an average of three bowel actions per day.
- The stools of infants are a yellow colour, gradually assuming more adult characteristics as solid food is introduced into the diet after 6 months of age. By the age of 3 years, a child will normally have one soft bowel movement each day.

Reference

Adapted from Hockenberry M, Wilson D 2015 Wong's nursing care of infants and children, 10th edn. Elsevier, Mosby.

During adolescence, there is rapid growth of the large intestine. The secretion of gastric acid increases, particularly in boys. Adolescents typically eat more.

Older adults experience normal changes to the GI tract that occur with ageing (see Table 32-1). While there is degeneration of the enteric nervous system with age, gut transit time and colonic motility tend to be consistent throughout life (Marieb & Hoehn 2014). Therefore, the majority of older adults maintain the same frequency of bowel movements that they had in their younger years. However, bowel function can be influenced by other factors, such as chronic disease, immobility and the various treatments for these health problems. Older adults, particularly women, may have decreased tone in the pelvic floor muscles and anal sphincter, increasing the risk of faecal incontinence.

Diet

The food that a person eats influences elimination. Regular daily food intake helps maintain a regular pattern of peristalsis in the colon. **Fibre**, the indigestible residue in the diet, provides the bulk in faecal material. Bulk-forming foods absorb fluids, thereby increasing stool mass. The bowel walls are stretched, creating peristalsis and initiating the defecation reflex. The following foods contain a high amount of fibre (see Chapter 31):

- raw fruits (apples, bananas, oranges)
- cooked fruits (prunes, apricots)
- greens (spinach, cabbage)
- raw vegetables (celery, green beans, zucchini)
- whole grains (cereal, bran flakes, breads) (National Health and Medical Research Council (NHMRC) 2013).

Ingestion of a high-fibre diet improves the likelihood of a normal elimination pattern if other factors are normal. Gas-producing foods such as onions, cauliflower and beans also stimulate peristalsis. The gas formed distends the intestinal walls, increasing colon motility. Some spicy foods can increase peristalsis but can also cause indigestion and watery stools.

Some foods, such as milk and milk products, are difficult or impossible for some people to digest. These people are known as lactose intolerant. Lactose-intolerant people are unable to digest lactose (milk sugar) due to an inadequate production of the enzyme lactase. Intolerance to lactose-containing foods results in **diarrhoea**, abdominal cramping and gaseous distension. Some people with **lactose intolerance** can tolerate small amounts of milk, cheese and yoghurt (NHMRC 2013).

Fluid intake

An inadequate intake of fluids affects the character of faeces. Fluid liquefies the intestinal contents, easing its passage through the colon. Inadequate fluid intake may slow passage of food through the intestine and can result in hardening of stool contents.

Physical activity

Physical activity promotes peristalsis. Therefore, it is important to encourage people to move around as quickly as possible following surgery or serious illness. Additionally, weakened abdominal and pelvic floor muscles impair the ability to increase intra-abdominal pressure and to control the external sphincter.

Personal habits

Personal elimination habits influence bowel function. Most people benefit from being able to use their own toilet facilities at a time that is most effective and convenient for them. A busy work schedule may prevent the individual from responding appropriately to the urge to defecate,

TABLE 32-1 Normal changes in the gastrointestinal tract from ageing

Portion of GI tract	Changes	Causes
Mouth	Decreased chewing due to reduction in facial muscle bulk and decreased salivation, including oral dryness	Degeneration of cells, use of some medications
	Changes to taste, including increased tolerance to saltiness and bitterness	
Oesophagus	Reduced peristalsis, especially in lower third in late older age (85+ years)	Degeneration of neural cells
Stomach	Decrease in acid secretions	Degeneration of gastric mucosa and increased risk of infection with *Helicobacter pylori* in older people
		Alkaline gastric medium contributes to malabsorption of iron. Although digestive enzymes are decreased, enough remain available for digestion
	Decrease in motor activity	Delayed gastric emptying and fewer hunger contractions
	Decrease in mucosal thickness	Loss of parietal cells also leads to loss of intrinsic factor, which is needed for vitamin B_{12} absorption
Small intestine	Fewer absorbing cells	Absorption of most nutrients and minerals not significantly affected
	Absorption of vitamin A, vitamin D, zinc and calcium declines with age	
Large intestine	Weakened musculature including in the anus and rectum	Increased collagen deposition, atrophy of the muscularispropria with increasing amount of fibrosis and elastin
	Duller nerve sensations	Increase in pouches on the weakened intestinal wall, called diverticulosis
		Decreased resting anal sphincter pressure, rectal wall elasticity
Liver	Size decreased and number of hepatocytes decreased	Reduced storage capacity and ability to synthesise protein and medications
	Reduced hepatic blood flow	
	Altered clearance of certain drugs	
	Reduced ability of the liver to regenerate after injury	

Feldstein RC, Tepper RE, Katz S 2010 Geriatric gastroenterology – an overview. In Fillit HM, Rockwood K, Woodhouse A (eds) Brocklehurst's textbook of geriatric medicine and gerontology, 7th edn. Saunders, Philadelphia, pp. 106–10; Welford, C 2014 Gerontological care. Taylor and Francis, Hoboken.

disrupting regular habits and causing possible alterations such as constipation.

Hospitalised patients can rarely maintain privacy during defecation. Bathroom facilities are often shared with another person whose hygiene habits might be quite different. The patient's illness often limits physical activity and requires the use of a bed pan or bedside commode. The sights, sounds and odours associated with sharing toilet facilities or using bed pans are often embarrassing. Embarrassment prompts patients to ignore the urge to defecate, which can begin a vicious circle of constipation and discomfort.

Position during defecation

Squatting is the normal position during defecation. Modern toilets are designed to facilitate this posture, allowing the person to lean forward, exert intra-abdominal pressure and contract the thigh muscles. For the patient immobilised in bed, defecation is often difficult. In a supine position it is impossible to contract the muscles used during defecation. If allowable within the patient's condition, raise the head of the bed; this helps the patient to a more normal sitting position on a bed pan, enhancing the ability to defecate. The hospitalised patient should be encouraged to get out of bed as soon as possible so they can use the toilet rather than a bed pan. If getting to the toilet is impossible, the person may be able to use a commode chair with a bed pan underneath to simulate as normal as possible position for defecation.

Psychological factors

The function of almost all body systems can be impaired by prolonged emotional stress (see Chapter 37). If an

individual becomes anxious, afraid or angry, the stress response is initiated, allowing the body to restore defences. The digestive process is accelerated, and peristalsis is increased to provide nutrients needed for defence. Side effects of increased peristalsis are diarrhoea and gaseous distension.

Pain

Normally the act of defecation is painless. However, a number of conditions, including haemorrhoids, rectal surgery, rectal fistulas and abdominal surgery, can result in discomfort. In these instances the patient often suppresses the urge to defecate to avoid pain. Constipation is a common consequence for people who experience pain during defecation.

Pregnancy

As pregnancy advances and the size of the fetus increases, pressure is exerted on the rectum. A temporary obstruction created by the fetus impairs the passage of faeces. Slowing of peristalsis during the third trimester often leads to constipation.

Surgery and anaesthesia

Some general anaesthetic agents used during surgery cause temporary cessation of peristalsis (see Chapter 39). The patient who receives local or regional anaesthesia is less at risk of elimination alterations because bowel activity is affected minimally or not at all.

Surgery that involves direct manipulation of the bowel can temporarily stop peristalsis. This condition, called **paralytic ileus**, usually lasts about 24–48 hours. If the patient remains inactive or is unable to eat after surgery, return of normal bowel function may be further delayed.

Infection

Many bacteria, parasites and viruses can cause GI infection, including *Escherichia coli*, *Giardia lamblia*, *norovirus* and *rotavirus*. *Helicobacter pylori* is a bacterial infection which contributes to the development of gastric ulcers and gastritis, and significantly increases the risk of gastric cancer (Plummer et al 2015). Chronic gastritis can result from *Helicobacter pylori* infection in childhood leading to degeneration of the stomach wall and altered digestion and elimination as well as failure to absorb essential vitamins and minerals (Sipponen & Maaroos 2015). *Clostridium difficile* is another bacteria that causes serious GI infection, particularly in hospitalised patients and frail older people. It is caused by a Gram-positive anerobic spore-producing bacteria and can result in life-threatening severe colitis and shock (Wilcox et al 2015). It is a common hospital-acquired infection transmitted by the faecal–oral route. The spores are not killed by hand hygiene solutions; therefore, handwashing and use of gloves is required when caring for a person suspected of having a *C. difficile* infection (Hand Hygiene Australia 2015).

Medications

Many common medications can affect bowel elimination (Table 32-2). These effects include slowing peristalsis,

TABLE 32-2 Medications and the gastrointestinal system

Medications	Action
Antibiotics	May produce diarrhoea by disrupting the normal bacterial flora in the GI tract, especially if administered orally. If the diarrhoea and associated abdominal cramping become severe, the patient might need to change medications
Anticholinergic drugs, such as atropine	Inhibit gastric acid secretion and depress GI motility (Bryant & Knights 2014). Although useful in treating hyperactive bowel disorders, anticholinergics can cause constipation
Anticholinergic/antispasmodic drugs, such as dicyclomineHCl (Merbentyl)	Suppresses peristalsis and can decrease gastric emptying
Aspirin	A prostaglandin inhibitor, it can interfere with the formation and production of protective mucous and can predispose patients to gastritis
Histamine-2 (H2) antagonists	Suppress the secretion of hydrochloric acid and may interfere with the digestion of some foods
Iron	Can cause discolouration of the stool (black) and lead to constipation
Narcotic analgesics	Slow peristalsis and segmental contractions, often resulting in constipation
Non-steroidal anti-inflammatory drugs	Promote gastrointestinal irritation that can range from dyspepsia to life-threatening haemorrhage (Bryant & Knights 2014)

Bryant B, Knights K 2014 Pharmacology for health professionals, 4th edn. Mosby, Sydney; Tiziani A 2010 Havard's nursing guide to drugs, 8th edn. Mosby, Sydney.

increasing peristalsis and changing the bowel flora. Laxatives, **cathartics** and stool softeners soften the stool and promote peristalsis. Although similar to cathartics, **laxatives** are milder in action. When used correctly, laxatives and cathartics safely promote and maintain normal elimination patterns. However, long-term use of cathartics can cause the large intestine to lose muscle tone and become less responsive to stimulation by laxatives. Laxative overuse can also cause serious diarrhoea which can lead to dehydration and electrolyte depletion.

Diagnostic tests

Diagnostic examinations that involve the viewing of GI structures often require portions of the bowel to be empty of contents. In the case of evaluation through the use of an enema or endoscopy, the person usually has a low-residue diet for 3 days and receives cathartics until the bowel contents that are expelled are clear. Such emptying of the bowel can interfere with elimination until normal eating is resumed. The person is not allowed to eat or drink after midnight of the day preceding examinations such as endoscopy of the lower GI tract (colonoscopy and sigmoidoscopy).

Common bowel elimination problems

Nurses commonly care for people who have, or are at risk of, elimination problems because of physiological changes in the GI tract, surgical alteration of intestinal structures, other prescribed therapy, or disorders impairing defecation.

Constipation

Constipation is characterised by a decrease in frequency of normal bowel movements, normally accompanied by straining and prolonged or difficult evacuation of faeces (Collins & O'Brien 2015). Constipation is a common health issue in the community-dwelling population. According to Schmidt and de Gouveia Santos (2014), the incidence of constipation in adults is between 2.6% and 26.9%. The incidence in hospitalised people is likely to be much higher. Constipation is more common in women and in low socioeconomic populations (Costilla & Foxx-Orenstein 2014).

Constipation is a symptom that should not be ignored, as it may indicate a serious underlying disease or motility disorder of the GI tract (Collins & O'Brien 2015). When intestinal motility slows, the faecal mass becomes exposed for an increased time to the intestinal walls and most of the faecal water content is absorbed. Little water is left to soften and lubricate stools. Passage of a dry, hard stool may cause pain on defecation. An important consideration when assessing a person's bowel elimination pattern is that defecation patterns vary between individuals. Not every adult has a daily bowel movement. A bowel movement only every 3 or more days may be considered normal if it is not associated with pain, passage of hard faeces or bloating.

The causes of constipation are multifactorial. Primary constipation can be classified as functional, outlet dysfunction and slow transit. Secondary constipation may be caused by diet, medications and underlying medical conditions (Costilla & Foxx-Orenstein 2014). Common medications that can cause constipation include antacids, iron supplements, anticholinergics, antidepressants, calcium channel blockers, beta-blockers, non-steroidal anti-inflammatory drugs (NSAIDs), diuretics and narcotic

BOX 32-1 Common causes of constipation

Lifestyle:
- Irregular bowel habits and ignoring the urge to defecate
- Low-fibre diet, high in processed foods
- Low fluid intake
- Lengthy bed rest or lack of regular exercise

Ageing:
- Slowed peristalsis, loss of abdominal muscle elasticity and reduced sense of rectal fullness
- Reduced physical or cognitive functioning (including dementia)

Neurological and neuromuscular disorders:
- Neurological conditions that block nerve impulses to the colon (e.g. spinal cord injury, multiple sclerosis, tumour)
- Stroke, Parkinson's disease

Psychiatric disorders:
- Depression, learning difficulties, anorexia/bulimia
- Pregnancy and puerperium

Colonic disorders:
- Irritable bowel syndrome, cancer, diverticular disease, idiopathic slow-transit constipation

Endocrine disorders:
- Organic illnesses such as hypothyroidism, diabetes mellitus, hypocalcaemia, hypokalaemia

Iatrogenic:
- Tranquillisers, opiates, anticholinergics, iron, diuretics, antacids with calcium or aluminium and antiparkinsonian drugs
- Amiodarone, calcium channel blockers, antacids, non-steroidal anti-inflammatory drugs

analgesics (Collins & O'Brien 2015) (see Table 32-2). Medical causes include anal and colonic disorders such as anal stricture and colon cancer; neurological disorders such as spinal cord injury or Parkinson's disease; metabolic disorders such as hypothyroidism and diabetes; as well as pelvic floor muscle weakness and rectocele. In addition, lifestyle factors, such as insufficient dietary fibre and low fluid intake, lack of exercise and voluntary suppression of defecation, commonly contribute to the development of constipation (Collins & O'Brien 2015). Prolonged constipation can have significant adverse health effects, including the development of haemorrhoids, faecal impaction, urinary incontinence (due to direct pressure of a faecal mass on the bladder), pelvic floor damage, urinary retention and urinary tract infection (due to incomplete bladder emptying) (Costilla & Foxx-Orenstein 2014).

Impaction

Faecal **impaction** results from unrelieved constipation. It is a collection of hardened faeces (with or without overflow faecal incontinence), obstructing the rectum, which cannot be expelled (Hussain et al 2014). In cases of severe impaction, the mass can extend up into the sigmoid colon. Frail older adults, who are debilitated or confused (e.g. people with dementia), or people who are unconscious or have an intellectual disability are most at risk for impaction.

An obvious sign of impaction is the inability to pass a stool for several days, despite a repeated urge to defecate. If a continuous oozing of diarrhoeal stool develops, impaction should be suspected. The liquid portion of faeces located higher in the colon seeps around the impacted mass. Loss of appetite (anorexia), abdominal distension and cramping, and rectal pain may accompany the condition.

WORKING WITH DIVERSITY

Focus on older adults

Constipation is a common health issue in the community. Older adults are prone to developing constipation because of the interaction of a number of factors:

- *Physiological* – lack of dietary fibre intake, poor fluid intake, inappropriate dietary habits, poor dentition
- *Functional* – decrease in mobility due to chronic joint disease, increase in sedentary lifestyle, ignoring the urge to defecate, poor lifelong bowel habits
- *Mechanical* – any condition that slows peristalsis or obstructs the colon and rectum; lack of sufficient abdominal muscle tone
- *Psychological* – depression, confusion, stress, avoidance of defecation (e.g. in a four-bed ward), recent environmental change
- *Systemic* – conditions that alter the physiology of the gastrointestinal tract
- *Pharmacological* – numerous medications that slow peristalsis, alter absorption or change the physiology of the gastrointestinal tract, e.g. antacids, opioid analgesics, antidepressants, sedatives, overuse of laxatives

Diarrhoea

Diarrhoea is an increase in the number of stools and the passage of liquid, unformed faeces. It is a symptom of disorders affecting digestion, absorption and secretion in the GI tract. Intestinal contents pass through the small and large intestines too quickly to allow the usual absorption of fluid and nutrients. Irritation within the colon can result in an increased mucous secretion. As a result, faeces become watery and the person may be unable to control the urge to defecate.

It is often difficult to assess diarrhoea in infants. An infant who is bottle-fed may have one firm stool every second day, whereas a breastfed baby may pass five to eight small soft stools daily. Any sudden increase in the number of stools, any reduction in faecal consistency with an increase in fluid content and a tendency for faeces to be greenish may indicate the need for further assessment.

Excess loss of colonic fluid can result in serious fluid and electrolyte or acid–base imbalances. Infants and older adults are particularly susceptible to associated complications (see Chapter 34). Because repeated passage of diarrhoeal stools also exposes the skin of the perineum and buttocks to irritating intestinal contents, meticulous skin care is needed to prevent skin breakdown (see Chapter 29), and containment of faecal drainage is needed.

Diarrhoea can be acute or chronic and can be caused by many conditions (Table 32-3). The aims of treatment are to remove precipitating conditions and to slow peristalsis. Box 32-2 lists nursing interventions that can be used in the treatment of acute diarrhoea in a hospitalised patient.

Incontinence

Faecal **incontinence** is defined as 'the inability to control passage of faecal material and/or flatus' (Abrams et al 2013:1897). It is a debilitating condition which is estimated to affect up to 10% of adults, with the incidence rising to 50% in the residential care population (Willson et al 2014). Physical conditions that impair anal sphincter function or control can cause incontinence; for example, damage to the anal sphincter during childbirth, pelvic

TABLE 32-3 Conditions and interventions that cause diarrhoea

Condition/Intervention	Physiological effects
Emotional stress (anxiety)	Increased intestinal motility
Colon disease (colitis, Crohn's disease)	Inflammation and ulceration of intestinal walls, reduced absorption of fluids, increased intestinal motility
Food allergies	Reduced digestion of food elements
Food intolerance (greasy foods, coffee, alcohol, spicy foods)	Increased intestinal motility, increased mucous secretion in colon
Intestinal infection (streptococcal or staphylococcal enteritis)	Inflammation of intestinal mucosa, increased mucous secretion in colon
Laxatives (short term)	Increased intestinal motility
Medications	
Iron	Irritation of intestinal mucosa
Antibiotics	Superinfection allowing overgrowth of normal flora, inflammation and irritation of mucosa
Surgical alterations	
Gastrectomy	Loss of reservoir function of stomach, improper absorption because food is moved into duodenum too quickly
Colon resection	Reduced size of colon, reduced amount of absorptive surface
Tube feedings	Hyperosmolarity of some enteral solutions results in diarrhoea, because hyperosmolar fluids draw fluids into the gastrointestinal tract

BOX 32-2 Summary of nursing interventions for the management of acute diarrhoea in a hospitalised patient

- *Reduce risk of spread of infective organism* – use standard and transmission-based infection control precautions.
- *Fluid replacement* – provide measures to maintain, or restore, fluid status and electrolyte balance.
- *Assessment* – observe vital signs for systemic manifestations such as fever, leucocytosis, fluid volume deficits, electrolyte imbalances.
- *Nutrition* – consult dietitians and encourage foods that are nourishing and tempting, little and often.
- *Skin care* – maintain perianal skin integrity by cleansing area and drying well.

Adapted from Australian Commission on Quality and Safety in Healthcare 2010 Australian guidelines for the prevention and control of infection in healthcare. Australian Government Canberra; Hall V 2010 Acute uncomplicated diarrhoea management. Pract Nurs 21(3):118–22.

floor dysfunction and neurological disorders such as multiple sclerosis, Parkinson's disease and spinal cord injury. In postpartum women the incidence of faecal incontinence is estimated to be 17% in the first 12 months (Brown et al 2015). Conditions that create frequent, loose, large-volume, watery stools also predispose a person to incontinence; for example, inflammatory bowel disease. In acute care settings, the incidence of faecal incontinence can be up to 33% (Willson et al 2014).

Flatulence

As gas accumulates in the lumen of the intestines, the bowel wall stretches and distends (**flatulence**). This is a common cause of abdominal fullness, pain and cramping. Normally, intestinal gas escapes through the mouth (burping) or the anus (passing of flatus). However, if there is a reduction in intestinal motility resulting from opiates, general anaesthetics, abdominal surgery or immobilisation, flatulence can become severe enough to cause abdominal distension and severe, sharp abdominal pain.

Haemorrhoids

Haemorrhoids are dilated engorged veins in the lining of the rectum. They are either external or internal. *External haemorrhoids* are clearly visible on the outside of the anus as protrusions of skin. If the underlying vein is hardened, there can be a purplish discolouration (thrombosis). This causes increased pain and the haemorrhoid may need to be surgically removed. *Internal haemorrhoids* have an outer mucous membrane. Increased venous pressure from chronic straining at defecation, pregnancy, obesity, heart failure and chronic liver disease can cause haemorrhoids.

Bowel diversions

Certain diseases, such as colorectal cancer and inflammatory bowel disease (ulcerative colitis and Crohn's disease), may result in the need for a temporary or permanent opening (stoma) in the abdominal wall. A **stoma** is a piece of bowel which is exteriorised and brought through the abdominal wall to re-route the passage of faeces or urine (Burch 2013). Temporary stomas are used to allow for healing at the site of surgery (the colon) or healing of a diseased part of the colon. Depending on the reason for the temporary stoma and the expected rate of healing, the person may have the stoma for only a few weeks or several months. The stoma reversal procedure involves the re-anastomosis of the ends of the colon or ileum, and then the muscle and skin of the abdominal wall are sutured closed. There are two main types of bowel stoma: colostomy and ileostomy (Figure 32-4).

The patient's specific health issue and general state of health determine the location of the colostomy stoma. Typically they are located in the ileum, ascending, transverse, descending or sigmoid colon. The location of the ostomy determines the consistency of stool. An **ileostomy** is formed in the ileum and bypasses the entire large intestine. As a result, the output of gas and stools is frequent, and stools have a thickened liquid consistency. The stoma is active throughout the day and the appliance will need to be emptied between four and six times per day (Burch 2015). A **colostomy** is formed from the large bowel or colon, and therefore the stool is a more solid and formed (depending on the location in the colon). A colostomy located in the sigmoid colon has a more predictable pattern of elimination of stool and gas, occurring from daily to three times per week (Burch 2015).

There are two main types of colostomy construction: *loop* colostomy (in the transverse colon), and the *end* colostomy.

A *loop colostomy* is usually performed when closure of the colostomy is anticipated. These are usually temporary large stomas constructed in the transverse colon (Figure 32-5). The surgeon pulls a loop of bowel onto the abdomen. An external supporting device such as a plastic rod, or bridge, is temporarily placed under the bowel loop to keep it from slipping back. The surgeon then opens the bowel and sutures it to the skin of the abdomen. A communicating wall remains between the proximal and distal bowel. The loop ostomy has two openings through the stoma. The proximal end drains stools, whereas the

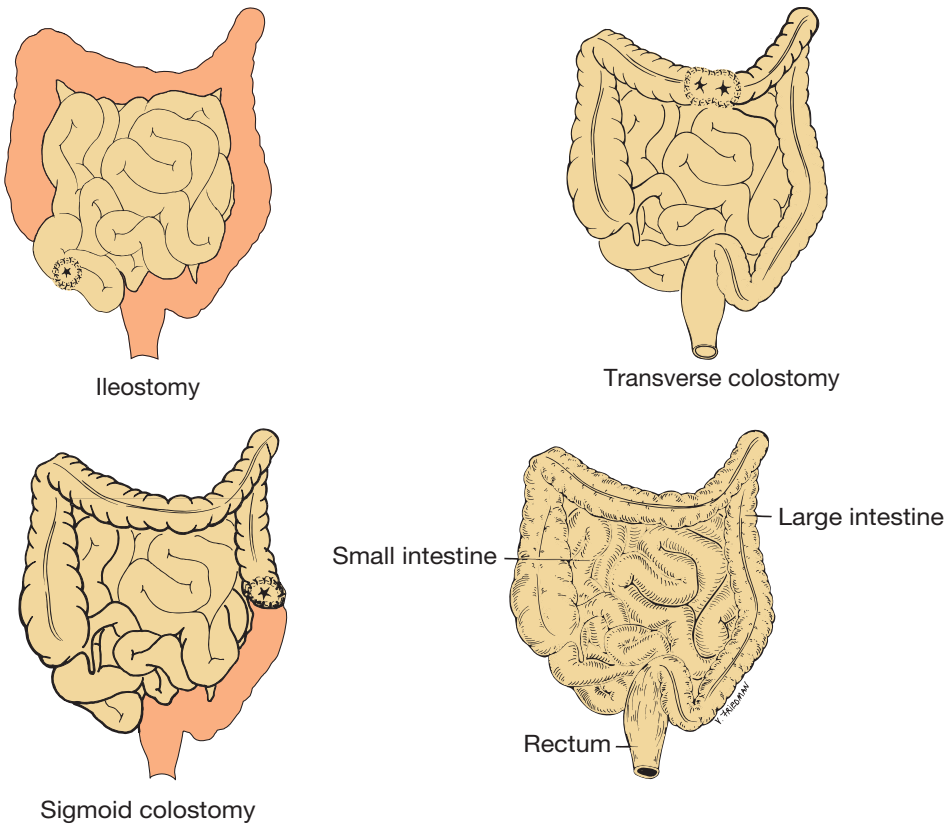

Figure 32-4 **Normal intestines (bottom right) and three types of ostomy. Shaded areas indicate excised tissue.**

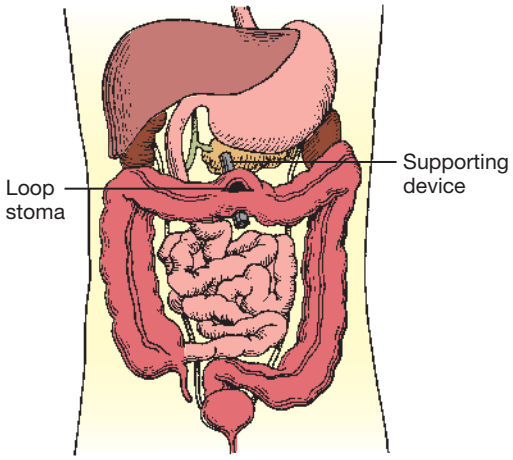

Figure 32-5 Loop colostomy. Loop of colon is exteriorised over plastic rod for temporary faecal diversion.

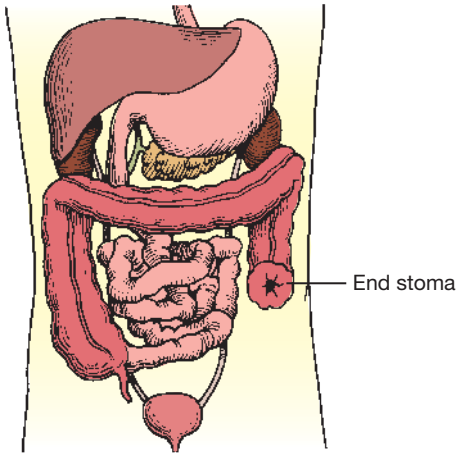

Figure 32-6 End colostomy (permanent). Terminal end of descending or sigmoid colon is brought out through peritoneum and muscle and sutured to skin.

Modified from Phillips N 2007 Berry & Kohn's Operating room technique. Mosby, St Louis.

distal portion drains mucous. Within 7–10 days the external supporting device is removed.

The *end colostomy* consists of one stoma formed from the proximal end of the bowel with the distal portion of the GI tract either removed or sewn closed (called a Hartmann's pouch) and left in the abdominal cavity. For many people, end colostomies are a result of surgical treatment of colorectal cancer. In such cases, the rectum might also be removed. Patients with diverticulitis who are treated surgically often have a temporary end colostomy with a Hartmann's pouch (Figure 32-6).

Psychosocial considerations

Consider for a moment how you would feel if you were not confident you could get to the toilet on time. Incontinence and faecal urgency significantly affect a person's quality of life and can lead to depression, anxiety and a decrease in general wellbeing (Meyer & Richter 2015, Wilson 2015). The embarrassment of soiling clothes can lead to social isolation.

Having a stoma significantly changes the way the body looks and functions and can cause significant psychological distress for the person and their family (Taylor 2015). Changes to the person's ability to complete daily tasks (including their usual work), diet, changes to sexuality and sexual function (including erectile dysfunction in men), social isolation, changes to general wellbeing and perception of quality of life are all possible consequences of living with a bowel stoma (Perez-Merino 2014). An important factor in the person's reaction to living with a stoma is the character of faecal secretions and the ability to control them. Foul odours, the fear of spillage or leakage of liquid stools and inability to regulate bowel movement can severely affect the person's quality of life.

CLINICAL REASONING PROCESS

Successful clinical decision-making requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes and intellectual and professional standards. Assessment of a person for risk factors or actual bowel elimination problems requires specific knowledge and sensitivity in approaching health issues that the person may find difficult to discuss (see Figure 32-7).

GATHERING RELEVANT INFORMATION AND DATA

To assess bowel elimination patterns and determine the aetiology of symptoms requires a focused nursing history, physical assessment, including abdominal examination, specimen inspection and skin assessment. As bowel function is closely linked with a person's nutrition, activity and exercise patterns, mobility and neurological function, you may need to assess these areas in conjunction with a focused bowel elimination assessment. All hospitalised people should be screened for risk factors for constipation, so that interventions can be implemented to promote normal bowel elimination.

Nursing history

The focused nursing history provides a review of the person's usual bowel pattern and habits. Identifying normal and abnormal patterns, habits and the person's perception of normal and abnormal bowel function enables identification of possible problems and gives direction to the physical examination. Much of the nursing history can be organised around the factors that affect elimination:

APPLYING CRITICAL THINKING

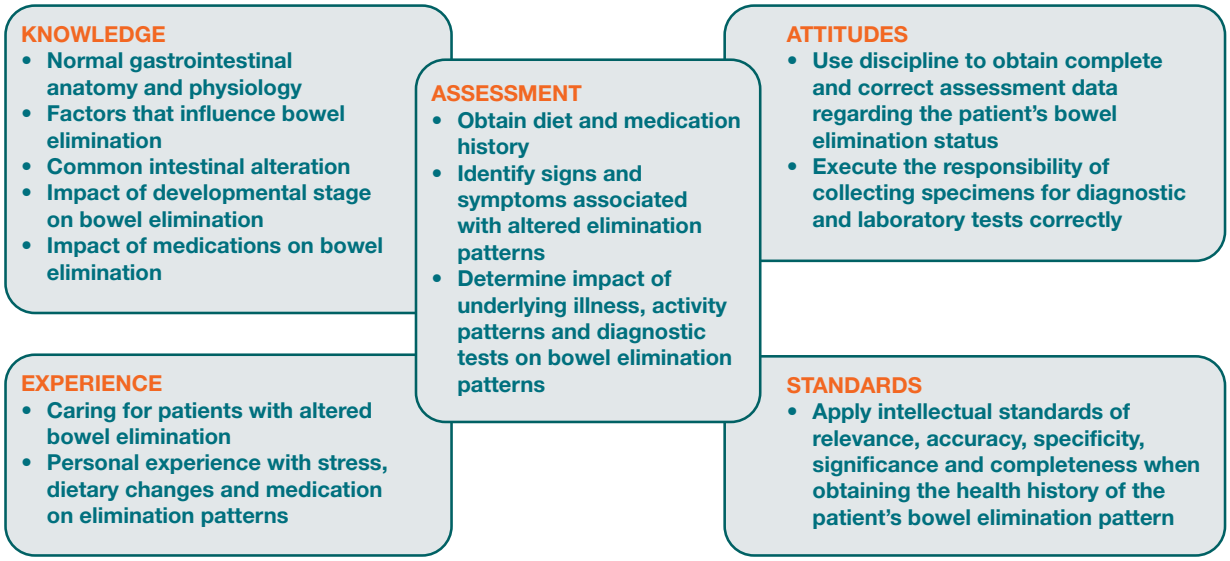

Figure 32-7 **Critical thinking associated with the assessment phase for bowel elimination.**

- *The person presenting's concern*. It is important to acknowledge the person's perception of their bowel elimination problem and how this affects their quality of life. Keep in mind that people who have faecal incontinence are likely to be reluctant to discuss their concerns (Olsson et al 2015). You need to approach this with empathy and tact.
- *Usual bowel elimination pattern*. Frequency and time of day are included. Having the person or caregiver complete a 'bowel diary' can enhance accurate assessment of the current bowel elimination pattern. To improve accuracy, the person completing the diary must understand what information must be recorded. Normally, a bowel diary would be kept for at least three 24-hour periods, preferably 7 days, so that the person's normal bowel elimination patterns can be determined. The information collected includes the date and time, and frequency and consistency of bowel movements, including incontinence episodes. The person is asked to describe their usual stool using the Bristol Stool Chart. This chart is a validated tool for describing stool appearance (Lewis & Heaton 1997). It has a 7-point scale (see Figure 32-8). Stool types 3 and 4 are considered to be the most usual or normal consistency.
- *Description of any recent change in elimination pattern*. This information is perhaps the most significant, because elimination patterns are variable and the person can best detect change. For example, a change in character or frequency of bowel elimination, history of recent overseas travel, eating take-away food, etc. Ask the person to describe any change in detail.
- *Bowel and anal symptoms*. Ask the person to describe any abnormal symptoms they are experiencing. For example, presence of blood or mucous in the stool, presence of pain before, during or after defecation, sense of incomplete emptying, or anal symptoms such as itchiness or pain.
- *Past health history*. Personal or family history of health issues affecting the GI tract; for example, abdominal surgery, neurological disease, family history of bowel

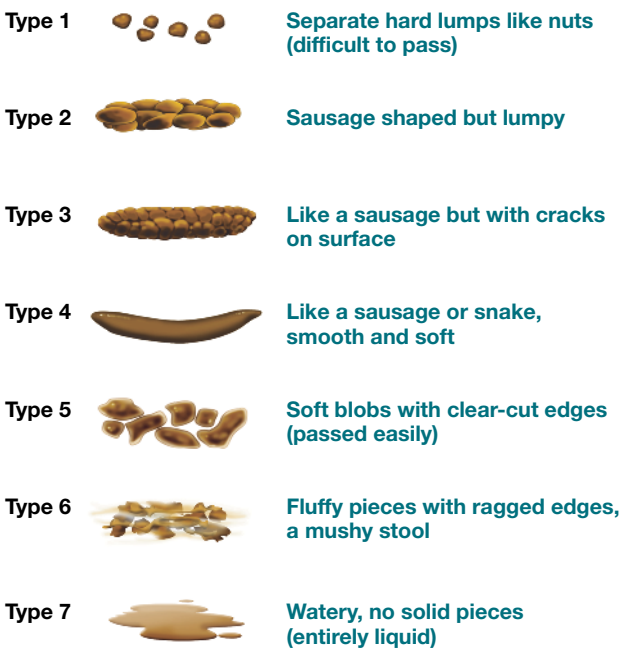

Figure 32-8 **Bristol Stool Chart, developed by KW Heaton and SJ Lewis at the University of Bristol, England.**

cancer. If the patient has an ostomy, ask them about the frequency of faecal drainage, character of faeces, appearance and condition of the stoma (colour, swelling and irritation), type of appliance used and methods used to maintain the ostomy's function. For women – ask about obstetric history, number and type of births, weight of infants, and history of bowel problems after each birth.

- *Usual diet*. The most accurate way of collecting this information is for the person to complete a food diary. If this is not possible, ask the person to recall their food intake over the last 24-hour period. Take note of types of food consumed (fresh or processed), the amount of dietary fibre in the diet and the variety of foods eaten. The information may indicate the need for referral to a dietitian for specific dietary advice.
- *Description of daily fluid intake*. This includes the type and amount of fluid. The person might have to estimate the amount using common household measurements.
- *Medication history*. Ask the person about their usual medications (such as laxatives, antacids, iron supplements and analgesics) that might alter defecation or faecal characteristics.
- *Smoking* – ask about current and former cigarette smoking. Smoking can affect bowel function and is a risk factor for bowel cancer.
- *Activity and exercise*. Describe the type and amount of daily exercise, as lack of exercise is linked to constipation.
- *Mobility and dexterity* – ability to care for self. You need to make a judgement about the need for questioning in this area based on your observation of the person; for example, the person may need assistance to get to the toilet, undressing/redressing, hygiene, and use of toileting aids (commode chairs, raised toilet seats, etc). Where patients live may affect their toileting habits. If the patient is sharing living quarters, how many bathrooms are there? Do patients have their own bathroom, or do they need to share and thus adjust the time they use the bathroom to accommodate others?
- *Routines followed to promote normal elimination*. Examples are drinking hot liquids, using laxatives, eating specific foods or taking time to defecate during a certain part of the day.
- *Other self-care practices*. Health screening related to faecal occult blood testing (FOBT) in people over 50 years of age, rectal examination and colonoscopy (where there is a risk of bowel cancer). Use of continence aids and appliances if the person has a bowel control problem.

CRITICAL REFLECTION POINT

A 17-year-old male with a history of good health and regular exercise is seen by the school nurse. He complains of increasing diarrhoea and abdominal cramping. He states that on rare occasions he has noticed blood on the toilet paper he has used. What additional pieces of assessment data do you need?

Physical assessment

Focused physical examination (see Chapter 23) of body systems and functions related to elimination problems should be carried out. You will need to make a judgement about the specific areas to include in your examination, which may include assessment of the mouth, abdomen, perianal area and rectum.

Mouth

An assessment includes inspection of the patient's teeth, tongue and gums. Poor dentition or poorly fitting dentures influence the ability to chew (see Chapter 29), which is a major reason for older people consuming insufficient dietary fibre.

Abdomen

Inspect all four abdominal quadrants for contour, shape, symmetry and skin colour. Inspection also includes noting masses, scars, stomas and lesions. Abdominal distension appears as an overall outward protuberance of the abdomen. Intestinal gas, large tumours, or fluid in the peritoneal cavity may cause distension. The skin of a distended abdomen appears taut, as if stretched.

Auscultation of the abdomen with the stethoscope is performed to assess bowel sounds in each quadrant (see Chapter 23). Auscultation of the bowel sounds is not done in the usual order of physical assessment, but is done prior to palpation. Normal bowel sounds occur every 5–15 seconds and last from 1 second to several seconds. While auscultating, note the character and frequency of bowel sounds.

- An increase in pitch or a tinkling sound may be heard with abdominal distension.
- Absent or hypoactive sounds (< 5 sounds per minute) occur with paralytic ileus, such as after abdominal surgery.
- High-pitched and hyperactive bowel sounds (35 or more sounds per minute) occur with small-intestine obstruction and inflammatory disorders.

Palpation of the abdomen is performed to determine distension (a drum-like tightness), areas of tenderness or the presence of masses (see Chapter 23). It is important for the person to relax. Tensing abdominal muscles interferes with palpating underlying organs or masses. If the examination reveals significant tenderness in any area of the abdomen, note the location of the tenderness and do not progress with further palpation or percussion. Refer the person to a medical practitioner for further assessment, as the pain/tenderness may indicate serious underlying pathology such as acute appendicitis or inflammation of the bowel. A person with severe constipation or faecal impaction may have faecal matter in the sigmoid or descending colon which you may be able to palpate on the left lower abdominal region.

Percussion detects lesions, fluid or gas within the abdomen. Familiarity with the five percussion notes (see Chapter 23) also permits identification of underlying abdominal structures, for example, a distended bladder. Gas or flatulence creates a tympanic note. Masses, tumours and fluid are dull to percussion.

Perianal area

Inspect the area around the anus for faecal matter, lesions, discolouration, inflammation and haemorrhoids. Abnormalities should be carefully recorded (see Chapter 23).

RESEARCH HIGHLIGHT

Research focus

Faecal incontinence (FI) is a taboo subject, and people living with it can feel stigmatised. This article reports on a 10-year qualitative follow-up to an initial constructivist-grounded theory project, investigating living with FI. The article reviews the initial study and the 5-year follow-up study undertaken.

The research examines the challenges associated with living with FI and different ways of managing the condition, including the importance of social support.

Research abstract

This study builds upon two previous studies conducted over a 10-year period. Ethics approval was granted. The research design was qualitative using multivariational sampling to ensure a varied sample of participants. Nine participants (three men and six women) were included in the study. Data were collected using semi-structured, guided interviews. The majority of the interviews were audio-recorded with the participant's permission. The interviews were transcribed, coded and analysed for themes. Five themes emerged from the data that described the participant's experience of living with faecal incontinence over time. These themes were: impact of faecal incontinence on self (self-esteem, confidence, mood swings, feeling of control, social acceptability, attitudes to faecal incontinence), response to impact of faecal incontinence on lifestyle (the occurrence of faecal incontinence, 'ownership' of faecal incontinence, adaptions made and responsibility for progress in self-management), interaction (with significant others, the generalised 'other' (public) and others who have feacal incontinence – 'insiders'), direction in life (upwards – positive narrative, downwards – negative narrative, or level progress), and the quality of interaction with health professionals.

Wilson describes a process of a dynamic continuum related to these themes where participants move from being overwhelmed to mastery (adaption), moving from a negative narrative to a more positive narrative. At the 10-year follow-up none of the participants expected a cure and had accepted their faecal incontinence. Significant others, particularly partners and children, assisted with adaption. They continued through trial and error to develop and refine their lifestyle, dietary and medicinal strategies. Although incontinence in public was still avoided, most had incorporated the possibility into their lives, enabling more freedom to enjoy a range of foods and activities. The participants felt less inhibited to talk about their faecal incontinence publicly, although speaking about it was still considered to be a social taboo. Participants described a sense of 'teamwork' related to the support they received from their partners and health professionals. Interactions with other people with faecal incontinence facilitated shared experience, a finding that had not been found in these participants in the previous studies. Some participants had improved and others had learnt to cope with faecal incontinence. Ageing and comorbidity posed further challenges to adaption to faecal incontinence.

Evidence-based practice

Faecal incontinence has a serious impact on people's lives over a long period of time. People are likely to avoid discussing their condition, so it is important for health professionals to ask relevant questions during a health assessment and to create a climate in which the person feels able to disclose their faecal incontinence. Concealment of faecal incontinence may prevent people from gaining support from other people who also have faecal incontinence – 'insiders'. It is important to include partners in the care plan as they are likely to be the primary support.

Reference

Wilson M 2015 Living with faecal incontinence: a 10-year follow-up study. British Journal of Nursing 24(5):268–74.

Faecal characteristics

Inspection of faecal characteristics (see Table 32-4) can reveal information about the nature of elimination alterations. The stool should be inspected for colour, consistency, amount, odour and appearance. Several factors can influence each characteristic. Normally the colour of faeces is brown and the consistency is soft. Use the Bristol Stool Form Chart (see Figure 32-8) to determine consistency. Record your observations as descriptively and accurately as possible.

Laboratory tests

Laboratory and diagnostic examinations yield useful information concerning elimination problems. Laboratory analysis of faecal contents can detect pathological conditions such as tumours, GI haemorrhage, infection and parasites.

Faecal specimens

Ensure that specimens are accurately obtained, properly labelled in appropriate containers and transported to the laboratory on time. Institutions provide special containers for faecal specimens. Some tests require specimens to be placed in chemical preservatives.

Because about 25% of the solid portion of a stool is bacteria from the colon, you must wear disposable gloves when handling specimens. Hand hygiene is necessary for anyone who might come in contact with the specimen. Often the patient can obtain the specimen if properly instructed. Explain that faeces cannot be mixed with urine or water. For this reason the patient must defecate into a clean, dry bed pan or special container placed under the toilet seat.

TABLE 32-4 Faecal characteristics

Characteristic	Normal	Abnormal	Abnormal cause
Amount	150 g per day (adult)		
Colour	Infant: yellow; adult: brown	White or clay	Absence of bile
		Black or tarry	Iron ingestion or upper gastrointestinal (GI) tract bleeding
		Red	Lower GI tract bleeding, haemorrhoids
		Pale with fat (steatorrhoea)	Malabsorption of fat
Consistency	Soft, formed	Liquid	Diarrhoea, reduced absorption
		Hard	Constipation
Constituents	Undigested food, dead bacteria, fat, bile pigment, cells lining intestinal mucosa, water	Blood, pus, foreign bodies, mucous, worms	Internal bleeding, infection, swallowed objects, irritation, inflammation
Frequency	Varies:		Hypomotility or hypermotility
	Infant 4–6 times daily (breastfed) or 1–3 times daily (bottle-fed)	Infant more than 6 times daily or less than once every 1–2 days	
	Adult daily or 2–3 times a week	Adult more than 3 times a day or less than once a week	
Odour	Pungent; affected by food type	Noxious change	Blood or fat in faeces or infection
Shape	Resembles diameter of rectum	Narrow, pencil-shaped	Obstruction, rapid peristalsis

Tests performed by the laboratory for occult (microscopic) blood in the stool and stool cultures require only a small sample; collect about 2 cm of formed stool or 15–30 mL of liquid diarrhoeal stool. Tests for measuring the output of faecal fat require a 3- to 5-day collection of stool. All faecal material must be saved throughout the test period.

After obtaining a specimen, label and tightly seal the container and complete the laboratory requisition forms. Then record the specimen collection in the patient's medical record. It is important to avoid delays in sending specimens to the laboratory. Some tests, such as measurement for ova and parasites, require the stool to be warm; this is called a 'hot' specimen. When stool specimens are allowed to stand at room temperature, bacteriological changes that alter test results can occur.

Faecal occult blood test (FOBT)

The FOBT is a common laboratory test which measures microscopic amounts of blood in faeces. There are two main types of tests for FOB: guaiac and immunochemical. Immunochemical techniques (iFOBT) are considered to be more reliable, as their accuracy is not influenced by diet and the use of certain medications. The FOBT is useful as a diagnostic screening test for colon cancer. The Australian federal government funds a National Bowel Screening Program aimed at detecting bowel cancer early so that it can be effectively treated. The New Zealand Ministry of Health has a similar bowel screening program for New Zealanders. See Box 32-3.

Diagnostic examinations

Diagnostic tests related to genitourniary (GU) function can be performed in the outpatient or inpatient setting. Viewing of GI structures may be by endoscopic or radiological examination.

Endoscopic procedures

Instruments that are introduced through the mouth or the rectum enable inspection of the integrity of mucosa, blood vessels and organ parts. A colonoscopy uses a **fibre-optic endoscope** with a lens viewer, a long flexible tube and a light source at the end to view the colon and rectum. It allows viewing of structures at the tip of the tube and insertion of special instruments for biopsy. Proctoscopes and sigmoidoscopes are rigid, tube-shaped instruments with attached light sources; the proctoscope looks like a speculum with a light. These instruments are less flexible than fibre-optic scopes and more capable of causing discomfort.

Lower GI examinations require bowel preparation for several days prior to the procedure. The person has a restricted, low-fibre diet for several days and then clear fluids on the day prior to the procedure. They are also required to take a strong stimulant laxative (e.g. PicoPrep, ColonLYTELY) the day prior to the procedure. This is taken orally, usually 1 litre of fluid per hour for 2 hours. It has a strong osmotic effect in the bowel and may cause abdominal distension and cramping. The person should be advised to stay close to the toilet as it will result in high volumes of watery diarrhoea within 30 minutes to 3 hours following ingestion (Australian Medicines Handbook 2015).

Upper GI **endoscopy** or **gastroscopy** enables viewing of the oesophagus, stomach and duodenum for tumours, vascular changes, mucosal inflammation, ulcers, hernias and obstructions. A gastroscope enables the removal of tissue specimens (**biopsy**), abnormal tissue growth (e.g. **polyps**) and enables coagulation of sources of bleeding.

Conscious sedation is often used during these procedures. Midazolam, a sedative-antianxiety agent, may be used, possibly augmented with a narcotic analgesic for lower GI procedures.

BOX 32-3 Screening for colorectal cancer

Risk factors

- Age: over 50; risk increases with age – median diagnosis is 70 years
- Family history: colon polyps or colorectal cancer
- History of inflammatory bowel disease (ulcerative colitis, Crohn's disease)
- People who have had adenomas (polyps) previously
- Diet: high intake of fats, low fibre intake

Warning signs

- Recent and persistent change in bowel habits
- Rectal bleeding or any sign of blood after a bowel motion
- Unexplained tiredness (a symptom of anaemia)

Screening tests

- Faecal occult blood test (FOBT) – the Australian National Bowel Screening Program screens at ages 50, 55, 60, 65, 70 and 74 years. A free testing kit is sent in the mail. Research has shown screening for bowel cancer, using an FOBT, can reduce deaths from the disease by 15–25%. The New Zealand government is currently carrying out a pilot to test whether bowel screening should be introduced nationally.
- Colonoscopy is undertaken every 1–3 years for people at high risk or who have had a positive FOBT.

Cancer Council Australia 2008 – Clinical practice guidelines for the prevention, early detection and management of colorectal cancer. Cancer Council Australia, Sydney. Online. Available: www.cancer.org.au/File/HealthProfessionals/ClinicalpracticeguidelinesJuly2008.pdf

In upper GI procedures, a local anaesthetic spray is used to help overcome gagging (Bryant & Knights 2014). It is essential to understand the safety precautions involved concerning the use of this form of anaesthesia. Most institutions require nurses to have specialised skills in anaesthetic care nursing to look after such patients. Resuscitation equipment must be present at the bedside, and the patient must be monitored continuously with pulse oximetry.

Nursing implications before diagnostic procedures concerning the GI system include the following:

Prior to the procedure:

- Record baseline observations including oxygen saturation (SpO_2).
- Check that the patient has signed an informed consent form after the steps of the procedure have been explained to them.
- Check that the patient has performed the necessary bowel preparation.
- Check that the patient has not had anything to eat or drink for the required period of time prior to the procedure (as instructed by the medical practitioner).
- If conscious sedation is used, explain to the patient that they will have an intravenous cannula inserted prior to the procedure. The sedation will make them very sleepy, but they may hear voices of the staff involved in the procedure. They will recover quickly following the procedure.

For procedures involving the upper GI tract:

- If conscious sedation is not used, explain that the patient may feel fullness in the throat and a sense of gagging during the test.
- Explain that the patient will be unable to speak as the endoscope enters the oesophagus.

For procedures involving the lower GI tract:

- During the test, air is used to distend the bowel for better viewing; explain that the patient may have 'wind pains' after the procedure.

Following the test:

- For upper GI procedures – instruct the patient to avoid eating or drinking until the gag reflex returns (2–4 hours). To check for the gag reflex, the nurse places a tongue blade at the back of the patient's tongue. Hoarseness and a sore throat are normal for several days; cool fluids and Normal saline gargling relieve soreness. The person should not drive a car or operate machinery for 12 hours after the procedure when conscious sedation is used.
- For lower GI procedures – the nurse observes for bleeding, fever, abdominal pain and blood in the stool. The person should not drive a car or operate machinery for 12 hours after the procedure when conscious sedation is used.

Radiological examination

The plain abdominal X-ray is the most common radiological investigation for gastrointestinal health problems. Other tests include: barium swallow, barium enema, CT and MRI scanning, cholangiography and nuclear imaging scans (especially for liver and hepatobilary function) and various procedures using ultrasound.

Patient expectations

People expect the nurse to be able to answer all their questions regarding diagnostic tests and the preparation for those tests. They will be concerned about discomfort and exposure of their body. For some, fear of loss of control over bowel elimination is distressing. They need information verbally and in writing and reassurance that their needs will be met and that the healthcare staff will be supportive.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

A nursing assessment of the person's bowel function may reveal data that indicates an actual or potential elimination problem or a problem resulting from an elimination health problem (Box 32-4). Associated issues, such as body-image changes or skin breakdown, require intervention as part of the comprehensive care plan.

The ability to identify the correct nursing diagnosis/patient problem depends not only on the thoroughness of the assessment, but also on recognition of the defining characteristics and factors that can impair elimination (Box 32-5). It is important to identify any areas of potential

BOX 32-4 Examples of priority problems associated with people with alterations in bowel elimination

- Faecal incontinence
- Constipation
- Diarrhoea (acute or chronic)
- Skin integrity, impaired
- Abdominal pain

BOX 32-5 Sample priority problems

ACUTE DIARRHOEA

Possible nursing diagnosis	Diarrhoea related to infection, changes in diet or alteration in gastrointestinal functioning
Assessment activities	**Defining characteristics**
Have patients describe pain, cramping, or any associated factors.	Pain is colicky in nature and spasmodic.
Have patient describe onset of symptoms, relationship to diet, recent travel, etc.	Acute onset. May have recent history of ingestion of contaminated food, contact with another person with same symptoms or recent travel.
Auscultate bowel sounds.	Bowel sounds will be hyperactive and may be audible without a stethoscope.
Assess frequency of stools.	Frequency is an early indication of increased risk of fluid and electrolyte imbalance, which is further indicated by muscle cramps.
Assess hydration status.	Loss of skin turgor and dry mucous membranes indicate fluid deficit. Concentrated urine – high specific gravity.
Evaluate perianal area for redness and irritation.	Frequent stools lead to breakdown of perianal tissues.

risk for bowel elimination problems and plan interventions in conjunction with the person to promote normal bowel function.

Planning

Care planning requires the synthesis of information from multiple sources (Figure 32-9). Critical thinking ensures that the plan of care integrates knowledge about the patient and the clinical problem. The guidelines outlined for urinary incontinence (see Chapter 33) should be used in care planning to protect the patient's skin, promote continence and reduce the embarrassment associated with faecal incontinence. In addition, the use of current guidelines for the reduction of pressure injury should be used in the care of people with bowel incontinence (see Chapter 26). When the person requires surgical intervention, a care pathway may be used to coordinate the activities of the multidisciplinary healthcare team.

SETTING PRIORITIES AND ESTABLISHING GOALS

The care plan establishes goals and expected outcomes in collaboration with the person (and in some situations, the family) (see *Sample student nursing care plan*). Health education and the provision of good quality information is critical to a successful plan of care.

The goals of care for patients with elimination problems include:

- understanding normal elimination
- attaining/maintaining soft, formed, easy-to-eliminate stool
- understanding and maintaining healthy fluid and food intake
- achieving regular activity and exercise
- achieving comfort
- maintaining skin integrity
- maintaining self-concept
- improving health-related quality of life.

Outcomes for a goal of attaining/maintaining a soft, formed stool every 1–3 days, would include: identifying measures to prevent constipation, Bristol stool score 3–4 with minimal straining on defecation, increasing fibre in the diet and increasing fluid intake.

Setting priorities depends on the person's condition and perceived need. Some people perceive that they are constipated if they do not open their bowels every day; others do not worry until they become uncomfortable and have hard, dry stools.

Continuity of care

Patients who are discharged from hospital with unresolved bowel problems may require ongoing community care. Appropriate nursing services (e.g. Royal District Nursing Service) will be involved in teaching and monitoring the patient and meeting any ongoing needs. As well, the person with alterations in bowel function may require intervention from many members of the healthcare team – the general practitioner, **stomal therapy nurse**, pharmacist and physiotherapist can provide information, support, expertise and assistance. When the person has a disability or is debilitated by illness, it is necessary to include the family in the plan of care.

Certain tasks, such as assisting patients onto the bed pan or bedside commode, are appropriate to delegate to nursing assistants (e.g. a personal care worker or health assistant) after the nurse makes an assessment of the situation. It is, however, important to remind the assistant to report any abnormal findings or difficulties with elimination.

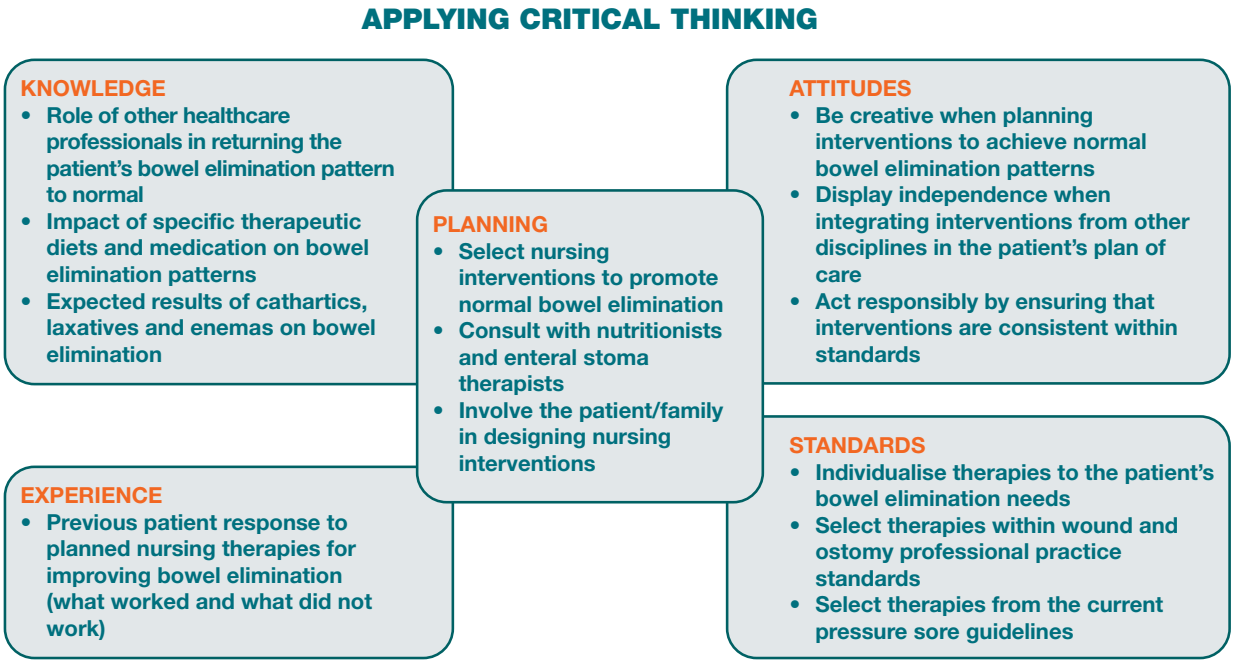

Figure 32-9 **Critical thinking associated with the planning phase for bowel elimination.**

PREPARING FOR AND TAKING ACTION

The success of nursing interventions depends on improving patients' and family members' understanding of bowel elimination.

Health promotion

One of the most important concepts a nurse can teach regarding bowel elimination is to take time for defecation. To establish regular bowel elimination patterns, a person must know when the urge to defecate normally occurs. Advise the person to begin establishing a routine during a time when defecation is most likely to occur, usually an hour after a meal. If the person is restricted to bed or requires assistance in moving, they should be offered a bed pan or assistance to reach the toilet.

Many people have established rituals for defecation. In a hospital or extended-care facilities, make certain that treatment routines do not interfere with these schedules. It is also important to provide privacy. When patients are forced to use a bed pan or share rooms with other people, pull the curtain around the area so that they can relax, knowing that interruptions will not occur. The call button should always be placed within a patient's reach. Bathroom doors should be closed, although you may need to stand close in case the patient needs assistance.

Promotion of normal defecation

To help patients evacuate bowel contents normally and without discomfort, a number of interventions can stimulate the defecation reflex, affect the character of faeces or increase peristalsis.

TOILETING POSITION You might need to give assistance to people who have difficulty getting onto a toilet because of muscular weakness and mobility problems. Regular toilets are often too low for people who are unable to lower themselves to a semi-squatting position because of pain, immobility or muscle weakness. Elevated toilet seats and grab rails can be purchased for use in the home, making sitting and standing easier and safer.

POSITIONING ON BED PAN Patients restricted to bed must use bed pans for defecation. Women use bed pans to pass both urine and faeces, whereas men use bed pans only for defecation. Sitting on a bed pan can be extremely uncomfortable. You may need to assist the person to get positioned comfortably. Two types of bed pans are available (Figure 32-10). The regular bed pan, made of metal or hard plastic, has a curved smooth upper end and a sharp-edged lower end and is about 5 cm deep. A slipper pan, designed for patients who have limited ability to move or who must lie flat, has a shallow upper end about 1.3 cm deep. The upper end of the pan fits under the buttocks towards the sacrum, with the lower end just under the upper thighs. The pan should be high enough so that faeces enter the pan.

When assisting the person onto the bed pan, the aim is to achieve as near-normal body position for toileting as possible. Figure 32-11 shows correct and incorrect positions on a bed pan. The best method is to be sure the patient is positioned high in bed. Raise the patient's head about 30 degrees, to prevent hyperextension of the back and to provide support to the upper torso, as the patient raises the hips by bending the knees and lifting the hips upwards. An overbed handrail to assist the patient to pull themselves off the mattress may also be used.

If the patient is immobile or it is unsafe to allow them to exert such effort, they can roll onto the bed pan by using the following steps:

1. Lower the head of the bed flat and help the patient roll onto one side, back towards you.
2. You may need to apply talcum powder lightly to the back and buttocks to prevent skin from sticking to the pan.

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data*

Chris White (a registered nurse working in a rehabilitation centre) is assessing Mr John Moore on admission to the centre from an acute care hospital following a right total hip replacement **4 days ago**. Mr Moore is 75 years old and has a history of osteoarthritis for approximately 15 years. This has caused pain and reduced movement in both hips and knees. He had his left hip replaced 18 months ago. He has no other health problems and his only regular medication prior to surgery was 'Panadol osteo'. He was taking 2 tablets three times a day. He has progressed well following surgery and is keen to be involved in a rehabilitation program. The wound is healing well and has no signs of redness or swelling. Mr Moore is progressing well with increasing his mobility. His main health concern relates to bowel elimination. On this issue, the assessment revealed the following data:

- Normally has one soft bowel movement per day. Experienced constipation following previous hip replacement surgery.
- Has a poor appetite since the surgery, eating only small amounts. Drinking approximately 1500 mL of water and cups of tea per day.
- Feels bloated, feels like he needs to have his bowels opened but can't. Last bowel movement 4 days ago.
- Had patient-controlled analgesia of morphine for 24 hours postoperatively and then Oxynorm for pain.
- Abdominal examination: slightly convex shape to abdomen, **bowel sounds decreased in all four quadrants**. Tender on palpation, especially in left lower quadrant.
- Digital rectal examination not performed.

** Important data to cluster in setting priorities in bold.*

Priority problem

Constipation related to opiate-containing pain medication, change of diet and mobility.

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Mr Moore will pass a soft, formed stool within the next 24 hours. Mr Moore will voice relief from constipation. Mr Moore will identify measures that will prevent constipation.	Mr Moore will drink at least 1500 mL of fluid over the next 8 hours. Mr Moore will report passage of soft stool without straining. Mr Moore will increase the fibre content of his diet. Mr Moore discusses effect of exercise on elimination.
Preparing for and taking action	**Rationale**
Constipation management • Encourage fluid intake of appropriate fluids, fruit juice, water. • Encourage activity within the limits of patient's mobility regimen. • 2 tsp twice daily psyllium husk powder in 250 mL of water (e.g. Metamucil). • Provide privacy for toileting.	Adequate fluid intake is necessary to prevent hard, dry stool. Even minimal activity (such as leg lifts) increases peristalsis. Psyllium husk powder retains a large amount of fluid and increases the bulk of the stool, increasing intestinal motility. Patients should feel relaxed when moving bowels – this is often difficult in a hospital setting.

Evaluating impacts and outcomes

- Re-evaluate in 24 hours – may need stronger laxative.
- Observe Mr Moore's subsequent stool for characteristics such as consistency and colour (type 3–4 on Bristol Stool Scale).
- Ask Mr Moore to identify foods high in fibre.
- Observe Mr Moore's activity.
- Ask Mr Moore to plan menus to increase fibre.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

3. Place the bed pan firmly against the buttocks, down into the mattress with the open rim towards the patient's feet (Figure 32-12).
4. Keeping one hand against the bed pan, place the other around the patient's upper hip. Ask the patient to roll back onto the pan, flat in bed. Do not push the pan under the patient.
5. With the patient positioned comfortably, raise the head of the bed 30 degrees.
6. Place a rolled towel or small pillow under the lumbar curve of the patient's back for added comfort.
7. Ask the patient to bend the knees to assume a semi-squatting position.

The privacy of a patient using a bed pan needs to be maintained. The call light and a supply of toilet paper should be within easy reach. Ensure the bed rails are raised to provide a secure environment for the patient. When the patient finishes, respond to the call signal immediately and remove the pan. When handling a bed pan, always wear gloves. To remove the pan, ask the patient to roll off to the side or raise the hips. The bed pan should be covered with a paper pan cover before taking it to the utility room to place in the pan flusher. Avoid pulling or shoving the pan from under the patient's hips because this can pull the patient's skin and cause tissue injury such as a pressure ulcer (see Chapter 26). After the pan is removed, assist the patient to clean the anal and perineal areas.

After assessing the stool, immediately empty the bed pan's contents into the pan flusher in the utility room. The bed pan is sterilised before being used by another person. After removing the gloves and performing hand hygiene, chart the characteristics of the faeces. After the patient has used a bed pan offer them a warm face washer or bowl of water and a towel so that they can wash their hands.

People who are unable to get to the toilet should be offered a bed pan or assistance to get to the toilet often. Patients may accidentally soil bedclothes if forced to wait and they may be reluctant to ask for assistance. Many patients try to avoid using a bed pan because it is embarrassing and uncomfortable. They may try to get to the toilet and risk increasing their pain or falling.

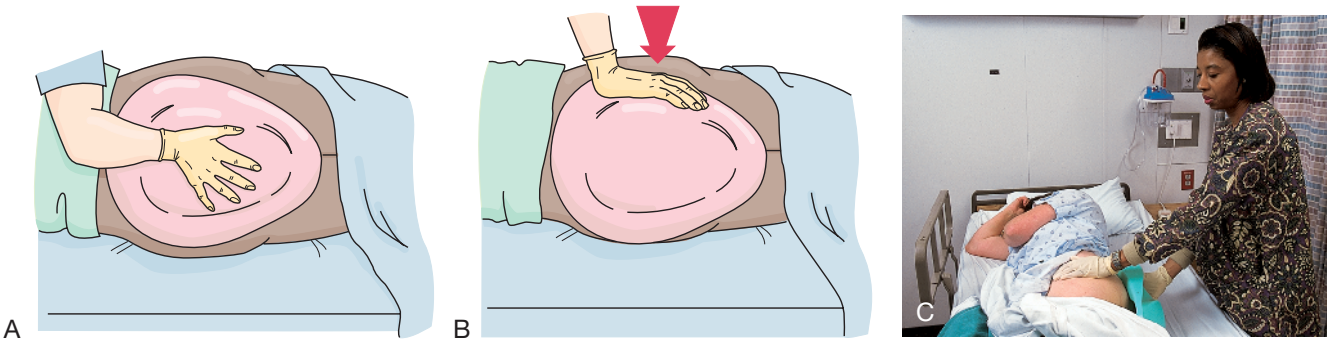

Figure 32-12 Positioning an immobilised patient on a bed pan.

A: Place bed pan firmly against buttocks. B: Push buttocks down into mattress with open rim towards feet. Once bed pan is in this position, place one hand against pan and the other on the patient's upper hip and ask the patient to roll onto the pan.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

FACILITATION OF THE GASTROCOLIC REFLEX As described previously, when food is chewed and swallowed, and moved into the stomach, a **gastrocolic reflex** is triggered causing an increase in peristalsis throughout the rest of the GI tract. The contents of the bowel are moved into the sigmoid colon and rectum, giving the person a sensation of wanting to defecate. The urge to defecate usually occurs approximately 30 minutes after eating, especially after a period of fasting, such as after breakfast. The aim is to harness this natural reflex to promote normal bowel function. It is a useful strategy, even for people who are confused and may not be able to communicate the need to defecate (such as a person with dementia) or who have impaired sensation such as paraplegia.

The reflex can be harnessed by establishing a routine time for breakfast (which is high in fibre and includes fluids), encouraging light exercise where possible and going to the toilet approximately 30 minutes after eating. Some people may need to wait for a while for the sensation to become evident. It is important to inform people not to ignore the urge to defecate, because once the urge is overridden it may not return for 24 hours.

ENCOURAGING FLUID AND FOOD INTAKE In choosing a diet for promoting normal elimination, consider the person's current frequency of defecation, the characteristics of faeces, and types of foods that promote normal bowel elimination. The person with constipation requires an increased intake of high-fibre foods and more fluids. When diet alone does not provide enough fibre, a fibre supplement such as psyllium husk powder can be added. Psyllium husk powder can be sprinkled on cereals or taken with a glass of water.

When acute diarrhoea is a problem, consider recommending foods with low fibre content and discouraging consumption of foods that typically cause gastric upset or abdominal cramping, for example, spicy foods. If the person cannot tolerate foods or liquids orally, intravenous therapy (with potassium supplements) is often necessary. They need to return to a normal diet slowly, often beginning with fluids. Excessively hot or cold fluids may stimulate peristalsis, causing abdominal cramps and further diarrhoea. As the tolerance to liquids improves, solid foods are introduced. For a person with chronic diarrhoea, diet is also important; however, determining the exact cause for the diarrhoea is necessary before dietary modifications are made. People with chronic diarrhoea are often referred to a continence nurse specialist and a dietitian for ongoing assessment and evaluation of their treatment plan.

During the first weeks after bowel surgery requiring formation of an ostomy, many surgeons recommend low-fibre diets, particularly for ileostomy patients, because the small bowel requires time to adapt to the diversion. Low-fibre foods include bread, noodles, rice, cream cheese, eggs (not fried), strained fruit juices, lean meats, fish and poultry. As the bowel and stoma heals and the person's condition improves, they can start to eat a variety of foods. High-fibre foods such as fresh fruits and vegetables help ensure a more solid stool, needed to achieve a more regular elimination pattern for the person with a sigmoid colostomy. People who have an ileostomy should be advised to eat slowly and chew food completely to reduce the risk of intestinal blockage caused by undigested foods. Drinking 10–12 glasses of water daily also prevents blockage. They may benefit from avoiding foods that cause gas and odour, for example, broccoli, cabbage, cauliflower, dried beans and Brussels sprouts. Individuals vary in their tolerance to certain foods, so for some they need to try foods and assess their effects.

Promotion of regular activity and exercise

Exercise and activity help to prevent constipation. For community-dwelling people, walking, running, riding a stationary bicycle or swimming stimulates peristalsis. People who are sedentary at work are most in need of regular exercise. Hospitalised patients who are temporarily immobilised should be encouraged to walk as soon as possible. If the condition permits, assist the postoperative patient to walk to a chair as soon as possible after surgery. The patient should be encouraged to walk further each day.

Promotion of comfort

Many people have discomfort from alterations in bowel function. Pain results when haemorrhoidal tissues are directly irritated. Flatus production can also create discomfort, particularly if distension develops.

The main goal for the person with haemorrhoids is to have soft-formed, painless stools. A high-fibre diet, fluids, and regular activity and exercise improve the likelihood of stools being soft. If the patient becomes constipated, passage of hard stools may cause bleeding and irritation. Local heat may provide temporary relief to swollen haemorrhoids. A sitz bath is the most effective means of heat application (see Chapter 26).

To relieve the discomfort of gaseous distension, use interventions that aim to reduce flatus or promote its escape. Swallowing of air increases flatus. The patient can reduce the amount of air swallowed by not drinking carbonated beverages, not using straws for drinking and not chewing gum or hard lollies. Some people find herbal teas, such as peppermint, help to reduce the discomfort of flatus. When trapped gas in the colon results in abdominal cramping, encourage the person to walk as this promotes passage of flatus. Having the person walk down the hall may be enough to stimulate peristalsis and relieve cramping.

Maintenance of skin integrity

The patient with diarrhoea or faecal incontinence is at risk of skin breakdown when faecal contents remain on the skin. The same problem exists for the patient with an ostomy that drains liquid stool. Liquid stool is usually acidic and contains digestive enzymes. Irritation from repeated wiping with toilet paper aggravates skin breakdown. Bathing the skin after soiling helps, but may result in more breakdown unless the skin is thoroughly dried.

When caring for a frail person who has faecal incontinence or urgency and is unable to ask for assistance, frequently assess for episodes of incontinence. The anal areas can be protected with a protective barrier cream (e.g. a zinc oxide and olive oil cream) that protects and holds moisture in the skin, preventing drying and cracking. Yeast infections (e.g. *Candida albicans* – 'thrush' infection) of the skin can develop easily. Several powdered antifungal agents are effective against this type of infection. Talcum powder should not be used, because it has no therapeutic properties and frequently cakes on the skin, making it difficult to remove.

Reducing the psychosocial impact of alterations in bowel elimination

As discussed previously, bowel elimination problems can have a significant psychological impact. Unpredictable elimination patterns, faecal incontinence, malodorous stools and the presence of a stoma and ostomy appliance are just a few factors that may cause psychosocial distress. For the person with a stoma, while in hospital they are focused on recovery and learning to manage the stoma and change the appliances. When they get home they often begin to question how they will cope, fear that the stoma appliance may leak or smell, and worry that their personal relationships will be affected and whether they can return to their normal activities (Burch 2013). The following interventions are aimed at minimising the psychosocial impact of bowel elimination problems:

- Give the patient an opportunity to discuss concerns or fears about elimination problems.
- Provide the patient and family with information to understand and manage the elimination problem.
- Provide opportunities to reinforce information and address misconceptions.
- Give positive feedback when the patient attempts self-care measures.
- Help the patient manage the condition and allow time for adjustment.
- Provide privacy during care.
- Show acceptance and understanding.
- Inform the person and the family about support networks, sources of good quality information and the roles of other health professionals in the multidisciplinary team.

CRITICAL REFLECTION POINT

The local retirement village has invited you to do a presentation to residents about bowel health and prevention of constipation. What points of information would you want to include in your presentation?

Cathartics and laxatives

If dietary and other interventions as described above have not resulted in a normal bowel action, further interventions may be required to alleviate constipation. Cathartics and laxatives have the short-term action of emptying the bowel. They are also used in bowel evacuation for patients undergoing GI tests and abdominal surgery. Although the terms 'cathartic' and 'laxative' are often used interchangeably, cathartics have a stronger effect on the intestines. Five types of laxatives and cathartics are available (Table 32-5). Cathartics and laxatives are available in oral tablet and suppository dosage forms (see Chapter 27). You should always aim to start with the milder type of laxative first. For example, start with a mild osmotic laxative such as lactulose syrup before moving on to a stronger laxative (e.g. Movicol or Coloxyl with senna). However, this will depend on your assessment of the patient. If the patient has significant symptoms or is taking narcotic analgesia, you may need to start with a stronger laxative and use a combination of laxatives. Dietary and other interventions should be continued.

Rectal suppositories and enemas

Suppositories and enemas are used when the patient has significant symptoms associated with their constipation to provide them with immediate relief. They work more quickly than oral preparations because of their local stimulant effect on the rectal mucosa.

RECTAL SUPPOSITORIES A suppository is a preparation that is solid until it is inserted into the rectum, where it melts and releases the active substance. The most commonly used preparation for the treatment of constipation is glycerine suppositories. They usually have an effect within 15 minutes to 1 hour. Stimulant suppositories such as bisacodyl (e.g. Durolax) can act within 30 minutes. Frail older adults often get a strong sudden urge to defecate with bisacodyl. Ensure the patient can reach the call bell, or has easy and quick access to the toilet area.

ENEMAS An **enema** is the instillation of a solution into the rectum and sigmoid colon. The main reason for an enema is to promote defecation by stimulating peristalsis and softening the faecal mass. The most common use for an enema is temporary relief of acute constipation. Other indications include removing impacted faeces and to empty the bowel before diagnostic tests or surgery.

The most commonly administered enemas are commercial preparations administered with a 5 mL plastic squeeze tube and a long insertion nozzle, for example, a Microlax microenema (see Table 32-5). Non-sterile gloves are worn to prevent the transmission of faecal microorganisms onto the hands. You should explain the procedure, including the position to assume, precautions to take to avoid discomfort, and the length of time necessary to retain the solution before defecation. If the patient is to receive the enema at home, explain the procedure to a family member or carer. Skill 32-1 outlines the steps for an enema administration.

Antidiarrhoeal agents

The most effective antidiarrhoeal agents are opiates such as codeine phosphate and diphenoxylate (e.g. Lomotil). Antidiarrhoeal opiate agents decrease intestinal muscle tone to slow the passage of faeces. Opiates inhibit peristaltic waves that move faeces forward, but they also increase segmental contractions that mix intestinal contents. As a result, the intestinal walls absorb more water. Opiate antidiarrhoeal agents should be used with caution because opiates are potentially habit-forming.

CRITICAL REFLECTION POINT

Mrs Maureen Green, a 72-year-old, has been transferred to the rehabilitation ward for intensive therapy following a right-sided haemorrhagic stroke. Outline the interventions you would plan to promote normal bowel function for this woman.

Care of a person with a bowel stoma

Patients who have temporary or permanent bowel diversions have unique health needs. A person with a stoma must wear pouches or appliances to collect the faecal matter and gas discharged from the stoma. Patients with ostomies must also follow good health practices, such as maintaining proper dietary habits and exercising regularly, to maintain normal elimination patterns. Patients with an ostomy have many education needs (Box 32-6).

TABLE 32-5 Common types of laxatives and cathartics used to prevent or treat constipation*

Agent/brand name	Action/onset of action	Indications	Precautions/side effects
Bulk-forming			
Psyllium (Metamucil)/ Ispaghula (Fybogel) Methylcellulose Sterculia (Normafibe) Bran	High-fibre content absorbs water and increases solid intestinal bulk Acts by stretching the intestinal wall to stimulate peristalsis Usually has an effect within 24 hours	Least irritating, most natural and safest cathartics Drugs of choice for mild or chronic constipation (e.g. pregnancy, low-residue diet) May also be used to relieve mild, watery diarrhoea	Should be administered with at least 250 mL of water or juice and swallowed quickly Caution is used with bulk-forming laxatives that also contain stimulants Not used in patients for whom large fluid intake is contraindicated (heart failure, renal failure)
Mild osmotic laxatives and stool softeners			
Lactulose (Actilax, Duphalac, Lac-Dol)	Reduce pH in the colon; broken down in the colon by bacteria to acetic and lactic acids. These acids stimulate peristalsis and exert a local osmotic effect in the colon A bulk-forming and irritant laxative Usually has an effect within 24 hours	Used in acute or chronic constipation	Slow in onset of action Unlike other osmotic laxatives, lactulose may be used long term Not used in patients with kidney dysfunction (toxic build-up of magnesium)
Docusate sodium (Coloxyl)	Stool softeners are detergents that lower surface tension of faeces, allowing water and fat to penetrate. They may increase secretion of water by the intestine Usually has an effect within 24–48 hours	Used for short-term therapy to relieve straining on defecation (e.g. haemorrhoids, perianal surgery, pregnancy, recovery from myocardial infarction)	Tolerance can develop with prolonged use Excessive use may cause hypomagnesaemia
Stronger osmotic laxatives			
Macrogol (Movicol sachets)	Acts by its osmotic effect in the gut which draws water into the colon and softens the stool Usually has an effect within 24–48 hours	Acute or chronic constipation	May cause severe cramping and abdominal distension Not for long-term use Prolonged use may result in electrolyte disturbance due to excessive loss of water
Stimulant laxatives			
Sennosides (Senakot)	Increase intestinal motility, water and electrolyte secretion Usually has an effect within 6–12 hours	Used in more severe, acute/short-term constipation	May cause cramping Not for long-term use Chronic use may cause fluid and electrolyte imbalances
Docusate sodium and sennosides (Coloxyl with Senna)	Docusate – stool softener Sennosides – increase intestinal motility, water and electrolyte secretion Usually has an effect within 6–12 hours	Used in more severe, acute/short-term constipation	May cause cramping Not for long-term use Chronic use may cause fluid and electrolyte imbalances
Suppositories and enemas			
Glycerine suppositories (adult and child forms)	Inserted high into the rectum against the rectal wall; have an osmotic laxative action Usually has an effect within 15 minutes to 1 hour	Used in more severe, acute/short-term constipation	Rarely – cramping pain, rectal discomfort

continued

TABLE 32-5 ***continued***

Agent/brand name	Action/onset of action	Indications	Precautions/side effects
Microlax/Enamax enema (5 mL)	Stool softener, distends the rectum and stimulates the defecatory reflex Usually has an effect within 15 minutes to 1 hour	Used in more severe, acute/short-term constipation	Rectal bleeding, burning or pain
Bisacodyl suppositories (Durolax)	Inserted high into the rectum against the rectal wall; a stimulant laxative Usually has an effect within 15 minutes to 1 hour	Used in more severe, acute/short-term constipation	Continued use may lead to inflammation of the anus Pain and rectal discomfort
Bisacodyl enema (Bisalax)	A stimulant laxative Usually has an effect within 15–30 minutes	Should only be used after other measures have failed	Continued use may lead to inflammation of the anus Pain and rectal discomfort
Phosphate enema (Fleet)	Distends the rectum and stimulates the defecatory reflex Usually has an effect within 5–10 minutes	Should only be used after other measures have failed	Rectal bleeding, burning or pain Caution in patients with heart or renal failure or frail older people May cause fluid and electrolyte shifts – especially sodium, potassium and phosphate

* Often a combination of products is used. Most are not nurse-initiated – they require a medical prescription.

SKILL 32-1

Administering a prepared enema

Delegation and other considerations

This task requires the problem-solving and knowledge-application skills of registered nurses. For this reason, delegation of this task to nurse assistants or personal care workers is inappropriate.

- Position patient, being particularly aware of those who have mobility restrictions.
- Use non-sterile gloves to prevent the transmission of pathogens.

Equipment

- Non-sterile gloves
- Water-soluble lubricant
- Waterproof, absorbent pad to cover bed sheets
- Blanket or large towel to cover patient
- Toilet paper
- Bed pan, bedside commode or access to toilet
- Washbasin, washcloths, towel and soap (if person cannot get to the bathroom)
- Prepackaged enema
- Prepackaged enema container with rectal tip

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess health status of patient: last bowel movement – Bristol stool chart type, normal bowel patterns, presence of haemorrhoids, immobility, external anal sphincter control, abdominal pain. Auscultate abdomen for presence of bowel sounds.	Determines factors indicating need for enema and influencing the type of enema used. An enema should only be used when less-invasive methods have been used and have not resulted in relief of constipation.
2. Assess for presence of increased intracranial pressure, glaucoma or recent rectal or prostate surgery.	Conditions contraindicate use of enemas.
3. Determine patient's level of understanding of the need for an enema.	Allows nurse to plan for appropriate teaching measures.
4. Liaise with medical staff about need for an enema. Obtain written order.	Order by doctor is required. Determines number and type of enema to be given.
5. Collect appropriate equipment.	
6. Correctly identify patient and explain procedure.	Information promotes patient cooperation and reduces anxiety.
7. Provide privacy by closing curtains around bed or closing door.	Reduces embarrassment for patient.
8. Raise bed to appropriate working height for the nurse. Raise side rail on opposite side and assist patient into left side-lying (Sims') position with right knee flexed. Children may also be placed in dorsal recumbent position.	Promotes good body mechanics and patient safety. Allows enema solution to flow downwards by gravity along natural curve of sigmoid colon and rectum, thus improving retention of solution.
9. Perform hand hygiene. Put on non-sterile gloves.	Reduces transmission of microorganisms.
■ **Critical decision point: If patient is suspected of having poor sphincter control, position on bed pan. Patient will have difficulty retaining enema solution.**	
10. Place waterproof pad under hips and buttocks.	Used in case patient is unable to retain enema solution.
11. Cover patient with blanket/towel, exposing only rectal area, so anus is clearly visible.	
12. Place bed pan or commode in easily accessible position. If patient will be using the toilet, ensure that toilet is free. (If patient will be getting up to go to bathroom, place patient's slippers and dressing gown in easily accessible position.)	
13. Administer enema: (1) Remove plastic cap from rectal tip of prepackaged disposable – you may also need to remove a seal on the container. Tip is already lubricated, but more lubricant can be applied as needed.	Lubrication provides for smooth insertion of rectal tube without causing rectal irritation or trauma.

STEPS	RATIONALE
(2) Gently separate buttocks and locate rectum. Instruct patient to relax by breathing out slowly through mouth.	Breathing out promotes relaxation of external rectal sphincter.
(3) Insert tip of container gently into rectum, pointing tip in direction of patient's umbilicus. Length of insertion varies: Adult: 7–10 cm Child: 5–7 cm Infant: 2–4 cm	Gentle insertion prevents trauma to rectal mucosa. Insertion beyond proper limit can cause bowel perforation.
(4) Squeeze container until all of solution has entered rectum.	Only small volumes, to stimulate defecation.
14. Explain to patient that feeling the need to defecate is normal. Ask patient to retain solution as long as possible while lying quietly in bed (usually takes 15 minutes to 1 hour to take effect). (For infant or young child, gently hold buttocks together for a few minutes.)	Length of retention varies with type of enema and patient's ability to contract rectal sphincter. Longer retention promotes more effective stimulation of peristalsis and defecation.
15. Discard enema container and tubing in contaminated waste bin. Remove gloves and discard into waste bin.	Reduces transmission and growth of microorganisms.
16. Perform hand hygiene.	
17. Help patient to bathroom or help to position patient on bed pan. (Caution patient against flushing toilet before inspection.)	Normal squatting position promotes defecation.
18. Observe amount and character of faeces – amount, colour and type (use Bristol Stool Scale).	Note abnormalities such as presence of blood or mucous.
19. Help patient as needed to cleanse anal area (if nurse administers perineal care, use gloves). If patient cannot get to the bathroom, offer them a basin of warm water, soap and a towel to wash their hands.	Faecal contents can irritate skin. Hygiene promotes patient's comfort.
20. Assess condition of abdomen; cramping, rigidity or distension can indicate a serious problem.	Determines whether distension is relieved.

RECORDING AND REPORTING

- Record time and type of enema given and characteristics of results.
- Report failure of patient to defecate to medical practitioner.

HOME CARE CONSIDERATIONS

Instruct family about safe administration of enemas.

BOX 32-6 Health education for a person with a bowel stoma

Objective

- Patient will confidently, safely and effectively manage stoma care before discharge from hospital.

Teaching strategies

- Ascertain the person's current knowledge about stoma care and their readiness and ability to learn.
- Advise them to avoid using alcohol-based cleansing solutions around the stoma. Alcohol dilates capillaries and can cause bleeding of the stomal margin. Similarly, peroxide is an irritant and should not be used.
- Demonstrate how to wash around the stoma with water and a mild soap. Pat the skin dry, but do not rub.
- Advise them not to use skin creams on the skin surrounding the stoma because it prevents the pouch or skin barrier from adhering to the skin.
- Teach the person to assess the health of the stoma and surrounding skin daily:
  - observe a stoma that is moist, shiny and dark pink to red.
  - observe for and report excessive bleeding, oedema, or abnormal discharge or colour to a nurse or medical practitioner
  - assess when the stoma bag needs cleaning or replacement.
- Advise that if a yeast infection occurs, thoroughly clean the area, pat dry and apply an antifungal agent such as clotrimazole or nystatin.
- Teach the person how to:
  - select and apply correctly sized skin barrier
  - fit and apply the ostomy pouch
  - empty the pouch
  - employ techniques to reduce odour
  - troubleshoot when leakage occurs.
- Inform the person about where to get further ostomy supplies.

Evaluation

- The person will correctly perform ostomy skin care procedures and be able to assess the health of the stoma and periostomal skin.
- Patient will correctly assess the need for and replace the ostomy pouch.
- The person is able to identify sources for further ostomy supplies.

Pouching ostomies

An ostomy requires a pouch to collect faecal material. An effective pouching system protects the skin, contains faecal material, remains odour-free and is comfortable and inconspicuous. A person wearing a pouch should feel secure in participating in any activity.

Many pouching systems are available. To ensure that a pouch fits well and meets the person's needs, you need to consider the location of the ostomy, type and size of the stoma, type and amount of ostomy drainage, size and contour of the abdomen, condition of the skin around the stoma, physical activities of the patient, the patient's personal preference, age and dexterity, and cost of equipment. A stomal therapy nurse is a registered nurse who specialises in the care of patients with a faecal or urinary diversion. The person is usually referred to the stomal therapy nurse prior to surgery for preoperative counselling and siting of the position of the stoma. The stomal therapy nurse will work with the person to decide which pouching system is the most suitable.

A pouching system consists of a pouch and a skin barrier. Some pouching systems are attached to the person's skin along the product's adhesive surface, while other pouching systems are non-adhesive. Pouches come in one- and two-piece systems that are disposable or reusable. Some pouches have the opening pre-cut by the manufacturer; others require the stoma opening to be custom-cut to the patient's specific stoma size.

Skin barriers include wafers, pastes, powders and liquid film which are applied to the skin around the stoma. Some wafer skin barriers are permanently attached to the ostomy pouch. These are called one-piece pouch systems. In a two-piece system, the pouch can be detached from the skin barrier for emptying or changing. This allows the skin barrier to remain around the person's stoma for several days, thus minimising the chance of skin damage from too-frequent removal of the skin barrier from the peristomal skin. When using a two-piece pouching system, it is important to remember that the skin barrier and pouch must correspond in size and be from the same manufacturer. The pouch from one manufacturer will not fit correctly on the skin barrier from another manufacturer. Make sure to use an ostomy pouch made for collecting faecal matter (colostomy or ileostomy) and not one for collecting urine.

It is important to measure the stoma size carefully when selecting and cutting out the opening on the wafer skin barrier. A good skin barrier protects the skin, prevents irritation from repeated removal of the pouch and is comfortable for the patient to wear. Skill 32-2 describes general steps for applying one- and two-piece pouching systems.

• CRITICAL REFLECTION POINT

Ms Dianne Jones, a 52-year-old woman, is to undergo a bowel resection for bowel cancer. She will have a temporary ileostomy formed following the surgery. She and her partner need to be taught to learn what this means for her future elimination needs. What information would you include in an education session?

Inserting and maintaining a nasogastric tube

Decompression of the GI tract may be indicated following some types of abdominal surgery (see Chapter 39), trauma to the GI tract and for conditions in which peristalsis is absent (such as

SKILL 32-2

Pouching an ostomy

Delegation considerations

Pouching an ostomy, especially a newly established ostomy, requires the problem-solving and knowledge-application skills of a registered nurse (RN). Delegation of this skill as a whole is inappropriate. Pouching of an established ostomy can be delegated to enrolled nurses for the following aspects:

- Help caregiver and patient in selecting appropriate pouch and skin barrier.
- Educate caregiver and patient about the signs of stomal and peristomal skin changes that should be reported to an RN.
- Have caregiver or patient monitor and report characteristics and volume of ostomy output.

Equipment (see illustration)

- Pouch, clear drainable colostomy/ileostomy in correct size for two-piece system or custom cut-to-fit one-piece type with attached skin barrier
- Pouch closure device, such as clamp
- Adhesive remover (optional)
- Non-sterile disposable gloves
- Deodorant (if required)
- Gauze pads or washcloth
- Towel or disposable waterproof barrier
- Basin with warm tap water
- Scissors
- Skin barrier paste (pectin)
- Sealant wipes

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
Avoid unnecessary changing of the entire pouching system. A one-piece pouch with attached skin barriers or the skin barrier of a two-piece pouching system should be changed every 3–7 days, not daily.	Pouches should be emptied when one-third to half full, because the weight of contents may dislodge the skin seal, and ostomy drainage is irritating to the skin. Also, pouches collect flatus (gas), which needs to be expelled because it can disrupt the skin seal.
1. Assemble equipment and close room curtains or door.	Optimises use of time; conserves patient's and nurse's energy. Provides privacy.
2. Auscultate for bowel sounds.	Documents presence of peristalsis.
3. Observe skin barrier and pouch for leakage and length of time in place. Depending on type of pouching system used, the nurse may have to remove the pouch to fully observe the stoma (such as with an opaque pouch). Clear pouches permit the viewing of the stoma without their removal.	May indicate need for different type of pouch or sealant.
4. Observe stoma for colour, swelling, trauma, moisture and healing; stoma should be moist and reddish-pink. Assess type of stoma. Stomas can be flush with the skin or be a bud-like protrusion on the abdomen (see illustration for a normal bud stoma).	Stoma characteristics should be one of the factors to consider when selecting an appropriate pouching system.

STEPS	RATIONALE
 Equipment.	 Step 4 Bud stoma.
5. Measure the stoma with each pouching change. Follow pouch manufacturer's directions and measuring guide as to which pouch to use based on patient's stoma size.	Determines correct-size equipment, preventing trauma to stoma.
6. Observe abdominal incision (if present).	Relationship to stoma determines proper placement of pouch.
7. Observe effluent from stoma and keep a record of intake and output. Ask patient about skin tenderness.	
Critical decision point: Do not put holes in ostomy pouch for flatus to escape.	
8. Assess abdomen for best type of pouching system to use. Consider: a. Contour and peristomal plane b. Presence of scars, incisions c. Location and type of stoma	Determines pouching system selection and need for other equipment.
9. Assess the patient's self-care ability to determine the best type of pouching system to use.	Patients who have difficulty using their hands or who have limited vision may find a one-piece system or a pre-cut pouch and skin barrier more desirable to use; others prefer being able to keep the skin barrier in place for several days, changing just the pouch, and therefore prefer the two-piece system.

STEPS	RATIONALE
10. Determine the patient's emotional response and knowledge and understanding of an ostomy and its care.	Assists in determining extent to which patient is able to participate in care and need for teaching and information clarification.
11. Explain procedure to patient; encourage patient's interaction and questions.	Lessens anxiety and promotes patient's participation.
12. Position patient, either standing or supine, and drape. If seated, position either on or in front of the toilet.	When patient is supine, fewer wrinkles allow for ease of application of pouching system; maintains patient's dignity.
13. Perform hand hygiene and put on disposable gloves.	Reduces transmission of microorganisms.
14. Place towel or disposable waterproof barrier under the patient if supine.	Protects bedclothes.
15. Remove used pouch and skin barrier gently by pushing the skin away from the barrier. An adhesive remover may be used to facilitate removal of the skin barrier. After skin barrier and pouch removal, assess skin around stoma, noting scars, folds, skin breakdown and peristomal suture line, if present.	Reduces trauma; jerking irritates the skin and can cause tears, especially in older patients.
16. Clean peristomal skin gently with warm tap water using gauze pads or clean washcloth; do not scrub the skin; dry completely by patting the skin with gauze or towel.	Avoid use of soap because it leaves a residue on the skin that interferes with pouch adhesion to the skin. Skin must be dry; pouch does not adhere to wet skin. If blood appears on the gauze pad, do not be alarmed; the stoma, if rubbed, may ooze some blood from the cleaning process. Bleeding into the pouch is abnormal. The stoma's surface is a highly vascular mucous membrane.
17. Measure the stoma for correct size of pouching system needed, using the manufacturer's measuring guide (see illustration).	Ensures accuracy in determining correct pouch size needed. Stoma shrinks and does not reach final size for 6–8 weeks.
18. Select appropriate pouch for patient based on patient assessment. With a custom cut-to-fit pouch, use an ostomy guide to cut opening on the pouch 1.5–3 mm larger than stoma before removing backing. Prepare pouch by removing backing from barrier and adhesive (see illustration). With ileostomy, apply thin circle of barrier paste around opening in pouch; allow to dry.	The paste facilitates seal and protects skin. Correct size of pouch opening keeps drainage off skin and lessens risk of damage to stoma during peristalsis or activity. Pouch and skin barrier are changed whenever leaking. Can also be changed before or after tub bath or shower. Stool is alkaline and this irritates the skin; faecal bacteria can colonise on the skin and increase risk of infection. Change when patient is comfortable; before a meal is better, because this avoids increased peristalsis and chance of evacuation during the pouch change.
19. Apply the skin barrier and pouch (see steps below). If creases next to stoma occur, use barrier paste to fill in; allow to dry for 1–2 minutes.	

■ **Critical decision point: If patient has surgical incision near stoma, the skin barrier may have to be trimmed for fit.**

STEPS	RATIONALE
 Step 18 Measuring stoma.	 Step 19 Preparing suitable opening in pouch.
A. For one-piece pouching system	
(1) Use skin sealant wipes on skin directly under where adhesive skin barrier of pouch will be applied; allow to dry. (2) Hold pouch by skin barrier, centre over stoma, and press down gently on barrier; bottom of pouch should point towards patient's knees. Press the adhesive backing smoothly against the skin, starting from the bottom and working up and around the sides. (3) Maintain gentle finger pressure around the barrier for 1–2 minutes.	
B. For two-piece pouching system	
(1) Apply flange (barrier with adhesive) as in steps above for one-piece system. Then snap on pouch and maintain finger pressure.	Creates wrinkle-free, secure seal; decreases irritation from the adhesive on skin.
20. Apply non-allergic paper tape around the pectin barrier paste in a 'picture frame' method. Half the tape should be on the skin barrier and half on the patient's skin. Some patients may prefer a belt attached to the pouch for extra security rather than tape.	'Picture framing' the pectin skin barrier adds to the security of keeping the pouch system attached securely.

STEPS	RATIONALE
Critical decision point: Be sure belt is not too tight by placing two fingers between belt and skin.	
21. Although many ostomy pouches are odour proof, some nurses and patients like to put a small amount of ostomy deodorant into the pouch. Do not use 'home remedies', such as aspirin, to control ostomy odour – inform the person of this.	Aspirin or other substances can harm the stoma.
22. Fold bottom of drainable open-ended pouches up once and close using a closure device such as a clamp (or follow manufacturer's instructions for closure).	Maintains secure seal to prevent leaking.
23. Properly dispose of old pouch and soiled equipment. Consider spraying deodorant in room if needed.	Lessens odours in room.
24. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.
25. Ask whether patient feels discomfort around stoma.	Determines presence of skin irritation.
26. Note appearance of skin around stoma and existing incision (if present) while pouch is removed and skin is cleaned. Inspect condition of skin barrier and adhesive.	Determines condition of tissues and progress of healing. Determines presence of leaks.
27. Auscultate bowel sounds and observe characteristics of stool.	Determines return of peristalsis and bowel elimination.
28. Observe patient's non-verbal behaviours as pouch is applied. Ask whether patient has any questions about pouching.	May indicate emotional response to stoma and readiness for teaching. Determines level of understanding of procedure.
29. Change pouch every 3–7 days unless leaking; pouch can remain in place for bath or shower; after bath, pat adhesive dry.	Avoids unnecessary trauma to skin from too-frequent changes. Drying ensures adhesion of pouch.

RECORDING AND REPORTING

- Chart type of pouch and skin barrier applied.
- Record amount and appearance of stool, texture, the condition of peristomal skin and sutures.
- Report any of the following to the nursing unit manager and/or doctor:
  - abnormal appearance of stoma, suture line, peristomal skin, character of output, absence of bowel sounds
  - no flatus in 24–36 hours and no stool by third day.
- Document abdominal distension and excessive tenderness, nature of bowel sounds.
- Record patient's level of participation and need for teaching.

HOME CARE CONSIDERATIONS

- Evaluate the patient's home toileting facilities. This includes presence of adequate toileting facilities, flushable toilet and number and location of toilets.
- Caution the patient that most ostomy pouches and barriers cannot be flushed down the toilet; they clog the system. Dispose of used ostomy pouch according to local sanitation regulations.
- Instruct patient to use a washcloth or any soft material to clean around stoma.

TABLE 32-6 Purposes of nasogastric intubation

Purposes	Description	Type of tube
Compression	Internal application of pressure by means of inflated balloon to prevent internal oesophageal or gastrointestinal (GI) haemorrhage	Sengstaken-Blakemore
Decompression	Removal of secretions and gaseous substances from GI tract; prevention or relief of abdominal distension	Large bore: Salem sump, Levin
Feeding (gavage) (see Chapter 36)	Instillation of liquid nutritional supplements or feedings into stomach for patients unable to swallow fluid	Fine bore: radio-opaque enteral feeding tube
Lavage	Irrigation of stomach in cases of active bleeding, poisoning or gastric dilation	Levin, Salem sump

bowel obstruction). When a nasogastric (NG) tube is used for decompression of the GI tract, the aim is to remove any gastric secretions (or food and fluids) from the stomach to prevent their build-up in the stomach and small intestine.

An NG tube is a pliable tube that is inserted through the person's nasopharynx into the stomach. The tube has a hollow lumen that allows removal of gastric secretions and introduction of solutions into the stomach. Nasogastric insertion has several purposes (Table 32-6); however, the following discussion only refers to use of an NG tube for decompression.

The Levin tube is most commonly used for stomach decompression. It is a single-lumen tube with holes near the tip. It may be connected to a drainage bag or to an intermittent suction device to drain stomach secretions.

Nasogastric tube insertion (Skill 32-3) does not require sterile technique. The person may experience a burning sensation as the tube passes through the sensitive nasal mucosa and when the tube reaches the back of the pharynx, they may begin to gag. You will need to encourage the person to relax to make tube insertion easier. Some institutions allow lignocaine jelly (e.g. topical Xylocaine) to be used when inserting the tube as it increases patient comfort during the procedure.

One of the greatest challenges in caring for a patient with an NG tube is maintaining comfort. The tube is a

SKILL 32-3

Inserting and maintaining a nasogastric tube (for decompression)

Delegation considerations

Inserting and maintaining a nasogastric (NG) tube requires the problem-solving and knowledge-application skills of registered nurses. Enrolled nurses may measure and record the drainage from the NG tube and provide oral and nasal hygiene and comfort measures.

Equipment

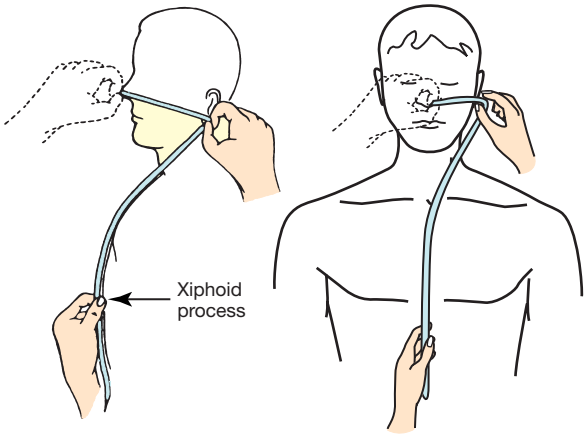
- No. 14 or no. 16 Fr NG tube (smaller lumen catheters are not used for decompression in adults because they must be able to remove thick secretions)
- Water-soluble lubricating jelly
- pH test strips (measure gastric aspirate acidity)
- Tongue blade
- Torch or lamp
- Catheter-tipped syringe
- 2.5 cm wide hypoallergenic tape
- Safety pin and rubber band/tape
- Clamp, drainage bag or suction machine or pressure gauge if wall suction is to be used
- Towel
- Glass of water with straw
- Facial tissues
- Emesis basin
- Non-sterile gloves/safety goggles

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
Inserting	
1. Pull curtain around the bed or close room door.	Provides privacy.
2. Inspect condition of patient's nasal and oral cavity.	Baseline condition of nasal and oral cavity determines need for special nursing measures for oral hygiene after tube placement.
3. Ask whether patient has had history of nasal surgery and note whether deviated nasal septum is present.	Nurse should insert tube into uninvolved nasal passage. Procedure may be contraindicated if surgery is recent.
4. Palpate patient's abdomen for distension, pain and rigidity. Auscultate for bowel sounds.	Baseline determination of level of abdominal distension later serves as comparison once tube is inserted.
5. Assess patient's level of consciousness and ability to follow instructions.	Determines patient's ability to assist in procedure.
■ **Critical decision point: If patient is confused, disoriented or unable to follow commands, get help from another staff member to insert the tube.**	
6. Check medical record for order, type of NG tube to be placed and whether tube is to be attached to suction or drainage bag.	Procedure requires a written medical order. Adequate decompression depends on NG suction.
7. Gather equipment at the bedside.	
8. Identify patient and explain procedure.	Identification prevents error of placing tube in wrong patient. Explanation gains patient's cooperation and lessens possibility that patient will remove tube.
9. Perform hand hygiene and apply disposable gloves and PPE – safety goggles.	Reduces transmission of microorganisms.
10. Position patient in high-Fowler's position (if not contraindicated, e.g. patient with a spinal injury) with pillows behind head and shoulders. Raise bed to a horizontal level comfortable for the nurse.	Promotes patient's ability to swallow during procedure. Good body mechanics prevent injury to nurse or patient.
11. Stand on patient's right side if right-handed, left side if left-handed.	Allows easiest manipulation of tubing.
12. Place towel over patient's chest; give facial tissues to patient. Have emesis basin nearby or place on the patient's lap.	Prevents soiling of patient's gown. Tube insertion through nasal passages may cause eye-watering and coughing with increased salivation.
13. Instruct patient to relax and breathe normally while occluding one nostril. Then repeat this action for the other nostril. Select nostril with greater air flow.	Tube passes more easily through the nostril that is more patent.
14. Using the NG tube, measure distance to insert tube: measure distance from tip of nose to earlobe to xiphoid process (see illustration).	Tube should extend from nares to stomach; distance varies with each patient.

STEPS	RATIONALE



Step 14 Measuring distance to insert tube.

15. Mark length of tube to be inserted with small piece of tape placed so it can be easily removed.	Marks amount of tube to be inserted from nares to stomach.
16. Cut a 10 cm piece of tape. Split one end down the middle lengthwise 5 cm. Place on bed rail or bedside table.	Tape will be used after tube insertion to anchor the tube securely.
17. Curve 10–15 cm of end of tube tightly around index finger, then release.	Curving tube tip aids insertion and decreases stiffness of tube.
18. Lubricate 7–10 cm of end of tube with water-soluble lubricating jelly.	Minimises friction against nasal mucosa and aids insertion of tube.
19. Alert patient that procedure is to begin.	Decreases patient anxiety and increases patient cooperation.
20. Initially instruct patient to extend neck back against pillow; insert tube slowly through the nostril with curved end pointing downwards (see illustration).	Facilitates initial passage of tube through the nostril and maintains clear airway for open nostril.

Step 20 Inserting tube.

STEPS	RATIONALE
21. Continue to pass tube along floor of nasal passage, aiming down towards ear. When resistance is felt, apply gentle downward pressure to advance tube (do not force past resistance).	Minimises discomfort of tube rubbing against upper nasal turbinates. Resistance is caused by posterior nasopharynx. Downward pressure helps tube curl around corner of nasopharynx.
22. If resistance is met, try to rotate the tube and see if it advances. If still resistant, withdraw tube, allow patient to rest, re-lubricate tube and insert into the other nostril.	Forcing against resistance can cause trauma to mucosa. Resting helps relieve patient's anxiety.
Critical decision point: If unable to insert tube in either nostril, stop procedure and notify medical practitioner.	
23. Continue insertion of tube until just past the nasopharynx by gently rotating tube towards opposite nostril.	
a. Stop tube advancement, allow patient to relax and provide tissues.	Relieves patient's anxiety; eye-watering is natural response to mucosal irritation, and excessive salivation may occur because of oral stimulation.
b. Explain to patient that next step requires the patient to swallow. Give patient glass of water unless contraindicated.	Sipping of water aids passage of NG tube into oesophagus.
24. With tube just above oropharynx, instruct patient to flex head forwards, take a small sip of water and swallow. Advance tube 2–5 cm with each swallow of water. If patient is not allowed fluids, instruct to dry-swallow or suck air through straw. Advance tube with each swallow.	Flexed position closes off upper airway to trachea and opens oesophagus. Swallowing closes epiglottis over trachea and helps move the tube into the oesophagus. Swallowing water reduces gagging or choking. Water can be removed later from stomach by suction.
25. If patient begins to cough, gag or choke, withdraw slightly and stop tube advancement. Instruct patient to breathe easily and take sips of water.	Tubing may accidentally enter larynx and initiate cough reflex. Gagging is eased by swallowing water. Risk of aspiration increases if vomiting occurs.
Critical decision point: If vomiting occurs, help patient clear airway; oral suctioning may be needed. Do not proceed until airway is cleared.	
26. If patient continues to cough during insertion, pull tube back slightly.	Tube may enter larynx and obstruct airway.
27. If patient continues to gag, check back of pharynx using torch and tongue blade.	Tube may coil around itself in back of throat and stimulate gag reflex.
28. After patient relaxes, continue to advance tube to the desired distance.	Tip of tube should be within stomach to decompress properly.
29. Once tube is correctly advanced, remove tape used to mark length of tube and place the prepared split tape with non-split side on nose. Anchor with one of split ends while checking tube placement.	Tube should be partially anchored before placement is checked.

STEPS	RATIONALE
30. Checking tube placement: check institutional policy for preferred methods for checking tube placement (for decompression).	
a. Ask patient to talk.	Patient is unable to talk if NG tube has passed through vocal cords.
b. Inspect posterior pharynx for presence of coiled tube.	Tube is pliable and can coil up in back of pharynx instead of advancing into oesophagus.
c. Aspirate gently back on syringe to obtain gastric contents, observing colour (see illustration).	Gastric contents are usually cloudy and green, but may be off white, tan, bloody or brown. Aspiration of contents provides means to measure fluid pH and thus determine tube tip placement in gastrointestinal tract.
d. Measure pH of aspirate with colour-coded pH paper with range of whole numbers 1–11 (see illustration).	Other common aspirate colours include the following: duodenal placement (yellow or bile-stained), oesophagus (may or may not have saliva-appearing aspirate). Gastric aspirates have highly acidic pH values, preferably 4 or less in adults and 5 or less in children, compared with intestinal aspirates, which are usually greater than 4, or respiratory secretions, which are usually greater than 5.5 (Gilbertson et al 2011, Phang et al 2004).
e. If tube is not in stomach, advance another 2–5 cm and repeat Steps 30c and d to check tube position.	Tube must be in stomach to provide decompression.

Step 30c Aspirating back to obtain gastric contents.

Step 30d Measuring pH of aspirate.

STEPS	RATIONALE
31. Anchoring tube:	
a. After tube is properly inserted and positioned, either clamp end or connect it to drainage bag.	Drainage bag is used for gravity drainage. Intermittent suction is most effective for decompression. Patient going to the operating room often has tube clamped.
b. Tape tube to nose; avoid putting pressure on nares.	Prevents tissue necrosis. Tape anchors tube securely.
(1) Before taping tube to nose, apply small amount of tincture of benzoin to lower end of nose and allow to dry (optional). Be sure top end of tape over nose is secure.	Benzoin prevents loosening of tape if patient perspires.
(2) Carefully wrap two split ends of tape around tube (see illustration).	
(3) Alternative: Apply tube fixation device using shaped adhesive patch (see illustration).	

Step 31b(2) Wrapping tape ends around tube, to secure.

Step 31b(3) Patient with tube fixation device.

c. Once tube is taped to nose, the tube can be wound behind patient's ear and taped into position for patient comfort. Fasten end of NG tube to patient's gown by looping rubber band around tube in slip knot. Pin rubber band to gown (provides slack for movement).	Reduces pressure on the nares if tube moves.
d. Unless doctor orders otherwise, head of bed should be elevated 30 degrees.	Helps prevent oesophageal reflux and minimises irritation of tube against posterior pharynx.
e. Explain to patient that sensation of tube should decrease somewhat with time.	Adaptation to continued sensory stimulus.
f. Remove gloves and apply alcoholic hand wash.	Reduces transmission of microorganisms.

STEPS	RATIONALE
32. Safety:	
a. Once placement is confirmed, place a mark, either a red mark or tape, on the tube to indicate where the tube exists in the nose.	The mark or tube length is to be used as a guide to indicate whether displacement may have occurred.
b. Measurement of the tube length from nares to connector is an alternative method.	
c. If tube length is the method used, document the tube length in the patient record.	
33. Don non-sterile gloves and clean equipment and return to proper place. Place soiled linen in utility room or proper receptacle.	Reduces transmission of microorganisms.
34. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.
Maintaining:	
35. Observe amount and character of contents draining from NG tube. Ask whether patient feels nauseated.	Determines whether tube is decompressing stomach of contents.
36. Inspect and palpate the patient's abdomen periodically, noting any distension, pain and rigidity, and auscultate for the presence of bowel sounds.	Determines success of abdominal decompression and the return of peristalsis.
37. Inspect condition of nares and nose.	Evaluates onset of skin and tissue irritation.
38. Observe position of tubing.	Determines whether tension is being applied to nasal structures.
39. Ask whether patient feels sore throat or irritation in pharynx.	Evaluates level of patient's discomfort.
Removing	
40. Discontinuation of NG tube:	
a. Verify order to discontinue NG tube.	Written medical order required for procedure.
b. Explain procedure to patient and reassure that removal is less distressing than insertion.	Minimises anxiety and increases cooperation. Tube passes out smoothly.
c. Perform hand hygiene and put on non-sterile gloves. Put on PPE – safety goggles.	Reduces transmission of microorganisms.
d. Disconnect NG tube from drainage bag. Remove tape from bridge of nose and unpin tube from gown.	Have tube free of connections before removal.
e. Stand on patient's right side if right-handed, left side if left-handed.	Allows easiest manipulation of tube.

STEPS	RATIONALE
f. Hand the patient facial tissue; place clean towel across chest. Instruct patient to take and hold a deep breath.	Patient may wish to blow nose after tube is removed. Towel may keep gown from getting soiled. Airway will be temporarily obstructed during tube removal.
g. Clamp or kink tubing securely and then pull tube out steadily and smoothly into towel held in other hand while patient holds breath.	Clamping prevents tube contents from draining into oropharynx. Reduces trauma to mucosa and minimises patient's discomfort. Towel covers tube, which can be an unpleasant sight. Holding breath helps to prevent aspiration.
h. Measure amount of drainage in the bag and note character of content. Dispose of tube and drainage equipment in contaminated waste bin. Remove gloves.	Provides accurate measure of fluid output. Proper disposal of equipment and soiled gloves prevents spread of microorganisms and ensures proper exchange procedures.
i. Apply clean gloves. Clean nares and provide mouth care.	Promotes comfort.
j. Position patient comfortably and explain procedure for drinking fluids, if not contraindicated.	Depends on medical order. Sometimes patients are allowed nothing by mouth (NBM) for up to 24 hours. When fluids are allowed, the order usually begins with a small amount of ice chips each hour and increases as patient is able to tolerate more.

RECORDING AND REPORTING

- Record in patient progress notes time and type of NG tube inserted, patient's tolerance of procedure, confirmation of placement, character of gastric contents, pH value and whether tube is clamped or connected to drainage device.
- Record in patient progress notes and/or flow sheet amount and character of contents draining from NG tube every shift, unless ordered more frequently by medical practitioner.

constant irritation to nasal mucosa. Frequent assessment of the condition of the nares and mucosa with regard to inflammation and excoriation should be undertaken. The tape used to anchor the tube often becomes soiled, and should be changed every day to lessen irritation. Frequent lubrication of the nares also minimises excoriation. With one nostril occluded, the patient may breathe through the mouth. Frequent mouth care (at least every 2 hours) helps minimise drying of oral mucosa. A glass of cool water for rinsing is useful, but the patient who is allowed nothing by mouth (NBM) should not swallow the water. The person may complain of a sore throat. An ice bag applied externally to the throat sometimes helps. Gargling with topical lignocaine jelly and/or lozenges may be used if ordered by the medical practitioner.

After the tube is inserted, its patency must be maintained. If the tip of the tubing rests against the stomach wall or if the tube becomes blocked with thick secretions, irrigation may be necessary. Flushing the tube with water by way of an irrigation syringe clears blockage within the tube (see Skill 32-3). If an NG tube continues to poorly drain after irrigation, advancing or withdrawing the tube slightly may reposition it. Any change in tube position requires reassessment of the placement of the tube in the patient's GI tract. Repositioning the person regularly helps to promote emptying of stomach contents.

EVALUATING IMPACTS AND OUTCOMES

Patient care

The effectiveness of care depends on success in meeting the goals and expected outcomes of care. At best, the patient will be able to defecate regularly, producing soft-formed, painless stools. The patient is the only one who is able to determine whether the bowel elimination problems have been relieved and which therapies were the most effective (Figure 32-13). The person will also be able to demonstrate information gained regarding establishment of a normal elimination pattern. The patient will be able to demonstrate any skills learnt, such as ostomy protocols and skin protection. The patient will be able to accomplish normal defecation by adjusting their diet, fluid intake and exercise. The patient will have minimal reliance on artificial means of defecation such as enemas and laxative use.

APPLYING CRITICAL THINKING

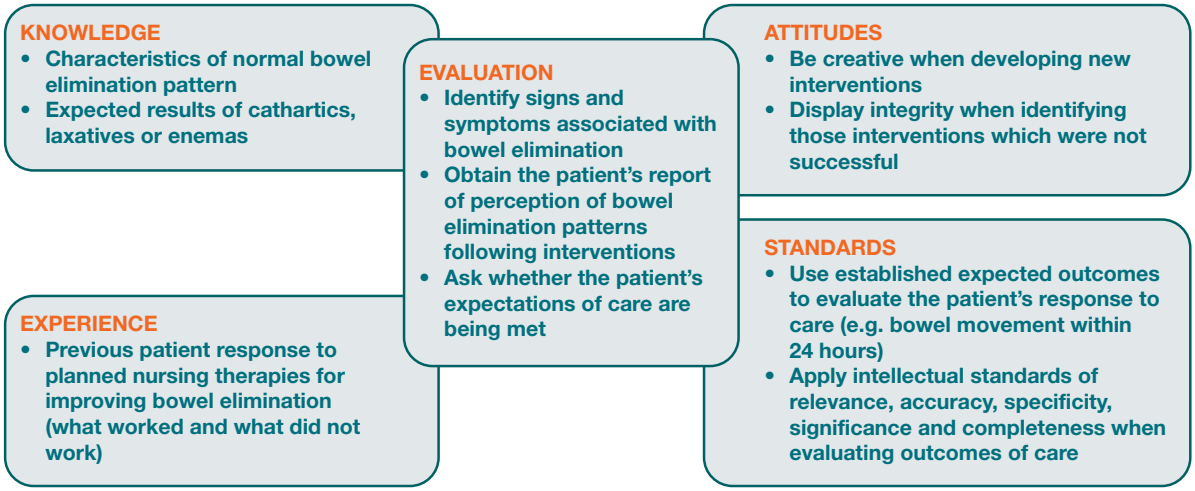


Figure 32-13 **Critical thinking associated with the evaluation phase for bowel elimination.**

Patient expectations

If you have been successful in establishing a therapeutic relationship with the person, they will feel comfortable in discussing the intimate details often associated with bowel elimination. They will not be embarrassed and will have a feeling of comfort and freedom from pain as elimination needs are met within the limits of their health condition and treatment.

Key concepts

- Mechanical breakdown of food elements, gastrointestinal (GI) motility and selective absorption and secretion of substances by the large intestine influence the character of faeces.
- Food high in fibre content and an increased fluid intake keep faeces soft.
- The greatest danger from acute diarrhoea is development of fluid and electrolyte imbalance.
- The location of an ostomy influences consistency of stools.
- Assessment of elimination patterns should focus on bowel habits, factors that normally influence defecation, recent changes in elimination, past history, lifestyle and physical examination.
- Diagnostic procedures related to the lower GI tract usually require cleansing the bowel before the procedure.
- The nurse should consider frequency of defecation, faecal characteristics and effect of foods on GI function when advising on a diet promoting normal elimination.
- Proper positioning on a bed pan enables the patient to assume a position similar to that on a toilet without experiencing muscle strain or discomfort.
- Normal bowel elimination patterns can be promoted by attention to toileting posture, facilitating the gastrocolic reflex, appropriate diet and fluid intake and an increase in activity and exercise.
- Proper selection and use of an ostomy pouching system is necessary to prevent damage to the skin around the stoma.
- Skin breakdown can occur after repeated exposure to liquid stools.
- Changes to bowel elimination can have significant psychosocial impacts on the person and their family.

Learning outcomes

Mastery of content will enable you to:

- describe the physiological process of micturition
- identify factors that commonly influence urinary elimination
- compare and contrast common alterations in urinary elimination
- obtain a nursing history and perform a physical examination for a patient with urinary elimination problems
- describe characteristics of normal and abnormal urine
- describe the nursing implications of common diagnostic tests of the urinary system
- identify nursing diagnoses appropriate for patients with alterations in urinary elimination
- discuss nursing interventions to promote normal voiding
- discuss nursing interventions to promote continence
- discuss nursing interventions to reduce urinary tract infection

- use clinical reasoning and best practice evidence in the provision of care to people who have urinary elimination problems.

Normal elimination of waste products via the urine is a basic function most people take for granted. When the upper urinary tract fails to function properly, virtually all organ systems can potentially be affected. Similarly, a change in function of the lower urinary tract can significantly affect upper urinary tract function, and a person's health and quality of life.

Urinary system

Urinary elimination depends on the function of the kidneys, ureters, bladder and urethra. Kidneys remove wastes from the blood to form urine. Ureters transport urine from the kidneys to the bladder. The bladder holds urine until the urge to urinate develops. Urine leaves the body through the urethra. The kidneys and ureters form the *upper urinary tract*; the bladder and urethra form the *lower urinary tract*. All organs of the urinary system must be intact and functional for successful removal of urinary wastes (Figure 33-1).

Kidneys

The *kidneys* are reddish-brown, bean-shaped organs, one on either side of the vertebral column, posterior to the peritoneum and lying against the deep muscles of the back. The kidneys extend to the twelfth thoracic and third lumbar vertebrae. Normally, the left kidney is 1.5–2 cm higher than the right because of the anatomical position of the liver on the right side of the abdomen. Each kidney typically measures approximately 12 × 7 cm and weighs 120–150 g. Each kidney is covered by a tough capsule and surrounded by a cushion of fat.

The kidneys filter the waste products of metabolism that collect in the blood. Blood reaches each kidney by a *renal artery* which branches from the abdominal aorta. The renal artery enters the kidney at the hilum. Approximately 20–25% of the cardiac output circulates each minute through the kidneys. The **nephron**, the functional unit of the kidney, forms the urine. The nephron is composed of the glomerulus, Bowman's capsule, proximal convoluted tubule, loop of Henle, distal tubule and collecting duct (Figure 33-2).

Blood reaches nephrons through the *afferent arterioles*. A cluster of these blood vessels forms the capillary network of the glomerulus, which is the initial site of filtration of the blood and the beginning of urine formation. The glomerular capillaries are porous and permit filtration of water and substances such as glucose, amino acids, urea, creatinine and major electrolytes into the *Bowman's capsule*. Large proteins and blood cells do not normally filter through the glomerulus. The presence of large proteins in the urine (**proteinuria**) is one sign of glomerular injury. The glomerulus filters approximately 125 mL of filtrate per minute. The amount of filtrate formed in the renal corpuscle (a Bowman's capsule and a glomerulus) of both kidneys each minute is known as the glomerular filtration rate (GFR). Initially the filtrate closely approximates the composition of blood plasma minus the large proteins. Only a small amount of the glomerular filtrate is excreted as urine. About 99% of the filtrate is reabsorbed into the plasma, with the remaining 1% excreted as urine. Thus the kidneys play a key role in fluid and electrolyte balance

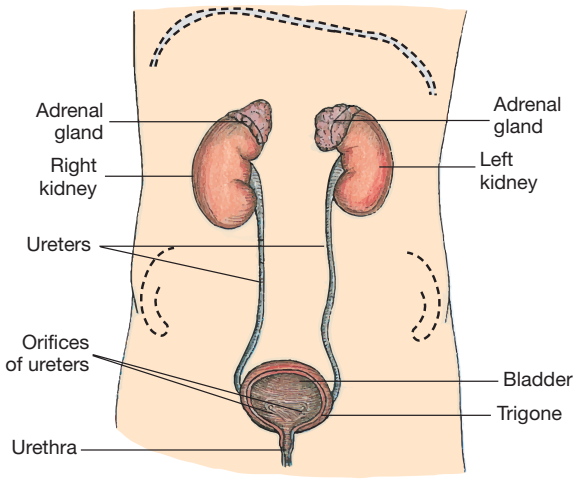

Figure 33-1 Organs of the urinary system.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

(see Chapter 34). Although urine output does depend on intake, the normal adult 24-hour output of urine is about 1500–1600 mL. An output of less than 0.5 mL/kg per hour may indicate alterations in renal function.

The kidneys also produce several *hormones* vital to the production of red blood cells (RBCs), blood pressure regulation and bone mineralisation. The kidneys are responsible for maintaining a normal RBC volume by producing erythropoietin. As a hormone, **erythropoietin** functions within the bone marrow to stimulate RBC production and maturation (McCance & Huether 2013). Erythropoietin also prolongs the life of mature RBCs. People with chronic alterations in kidney function cannot produce sufficient quantities of this hormone and are, therefore, prone to anaemia.

Renin is another hormone produced by the kidneys. Its major role is the regulation of the systemic circulation in times of renal ischaemia (decreased blood supply to the kidneys). Renin is released from juxtaglomerular cells (Figure 33-3).

Renin functions as an enzyme to convert angiotensinogen (a plasma substance synthesised by the liver) into angiotensin I. As angiotensin I circulates through the lungs, it is converted to angiotensin II and angiotensin III. Angiotensin II exerts its effect on vascular smooth muscle to cause vasoconstriction and stimulates aldosterone release from the adrenal cortex. Aldosterone causes retention of water, which increases blood volume. Angiotensin III exerts similar effects, but to a lesser degree. The net effect of both these mechanisms is an increase in arterial blood pressure and renal blood flow (McCance & Huether 2013).

The kidneys also play a role in *calcium and phosphate regulation*. They are responsible for producing a substance which converts vitamin D into its active form. People with chronic alterations in kidney function do not make sufficient amounts of the active vitamin D metabolite. They are therefore prone to developing renal bone disease resulting from the demineralisation of bone secondary to impaired intestinal calcium absorption unless the active form of vitamin D is supplied.

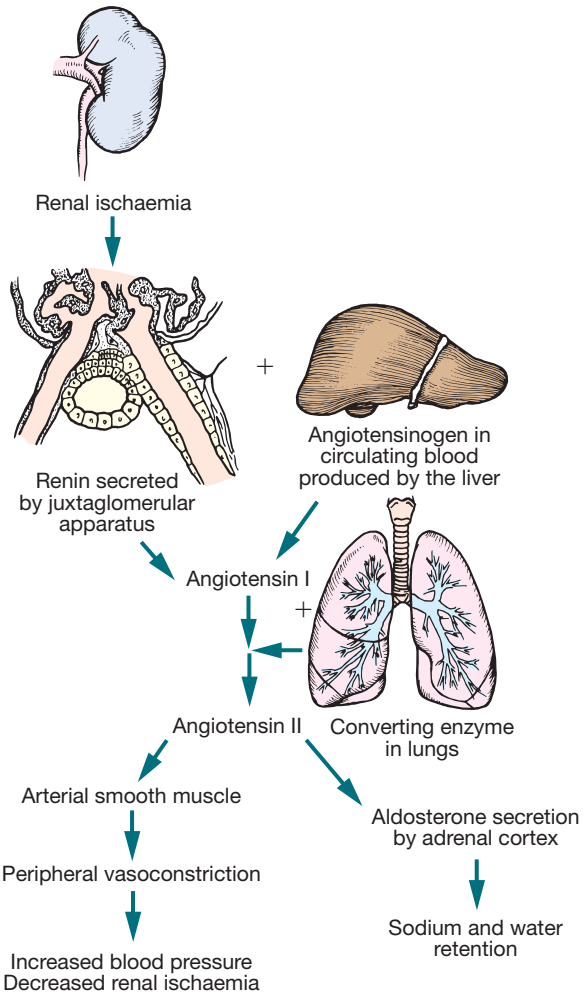

Figure 33-3 Physiological effects of the renin–angiotensin mechanism.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Ureters

Urine enters the renal pelvis from the collecting ducts. A *ureter* joins each renal pelvis to the urinary bladder. Ureters are tubular structures measuring 25–30 cm in length and approximately 3–4 mm in diameter in the adult (Marieb & Hoehn 2014). They extend retroperitoneally to enter the urinary bladder in the pelvic cavity at the ureterovesical junction. Urine draining from the ureters to the bladder is usually sterile.

Three layers of tissue form the wall of the ureter. The inner layer is a mucous membrane continuous with the lining of the renal pelvis and urinary bladder. The middle layer consists of smooth muscle fibres that transport urine through the ureters by peristaltic waves stimulated by distension with urine. An outer layer of fibrous connective tissue supports the ureters.

Peristaltic waves cause the urine to enter the bladder in spurts, rather than steadily. The ureters enter obliquely through the posterior bladder wall. This arrangement normally prevents the reflux of urine from the bladder into the ureters during the act of micturition by the compression of the ureter at the ureterovesical junction (the juncture of the ureters with the bladder). An obstruction within a ureter, such as a kidney stone (**renal calculus**), results in strong peristaltic waves that attempt to move the obstruction into the bladder. These strong peristaltic waves result in pain, often referred to as renal colic.

Bladder

The urinary *bladder* is a hollow, distensible, muscular organ which is both a reservoir for urine and the organ of excretion. The size and shape of the bladder will vary depending on its state of fullness. When empty, the bladder lies in the pelvic cavity behind the symphysis pubis. In men the bladder lies against the anterior wall of the rectum and in women it rests against the anterior wall of the uterus and vagina.

The bladder expands as it becomes filled with urine. Pressure within the bladder is usually low, even when partly full, a factor which protects against reflux of urine back up the ureters into the kidneys. In a healthy adult, bladder capacity is approximately 500 mL and when the bladder is emptied there is no residual urine volume. Both men and women will void at 3- to 5-hour intervals during the day and usually do not need to void at night. Keep in mind, however, that the habits of individuals will vary. When the bladder is full, it expands and extends above the symphysis pubis. A greatly distended bladder may reach the umbilicus. In a pregnant woman the developing fetus pushes against the bladder, causing a feeling of fullness and reducing the bladder's capacity. This effect is more likely to occur in the first and third trimesters.

The *trigone* (a smooth, triangular area on the inner surface of the bladder) is at the base of the bladder. An opening exists at each of the trigone's three angles. Two are for the ureters, and one is for the urethra. This area does not change shape very much during bladder filling and is very sensitive to stretch due to the large number of sensory nerve endings it contains (Marieb & Hohen 2014).

The *wall* of the bladder has four layers: an inner mucous coat, a submucous layer of connective tissue, a muscular layer and an outer serous coat. The muscular layer has bundles of muscle fibres that form the detrusor muscle. Parasympathetic nerve fibres stimulate the *detrusor muscle* during urination. In the male, the bladder neck provides a powerful sphincter mechanism. It also prevents retrograde ejaculation into the bladder during orgasm. The male internal urethral sphincter is made of a ring-like band of muscle which has a rich nerve supply. In the female, the bladder neck is a far weaker structure than in the male (Marieb & Hohen 2014): the smooth muscle fibres extend longitudinally along the urethra; there are no circular muscles.

Urethra

Urine travels from the bladder through the *urethra* and passes outside the body through the *urethral meatus*. Normally, the turbulent flow of urine through the urethra washes it free of bacteria. Mucous membrane lines the urethra, and urethral glands secrete mucous into the urethral canal. The mucous is believed to be bacteriostatic and forms a mucous plug to prevent entrance of bacteria. Thick layers of smooth muscle surround the urethra. In addition, the urethra descends through a layer of skeletal muscle called the *pelvic floor muscles*. When these muscles are contracted, it is possible to prevent urine flow through the urethra (McCance & Huether 2013).

In women, the urethra is approximately 3.5–5.5 cm long. The external urethral sphincter, located about halfway down the urethra, permits voluntary flow of urine. The short length of the urethra predisposes women to ascending infection. Bacteria can easily enter the urethra from the perineal area. In men, the urethra, which is both a urinary canal and a passageway for semen, is 18–23 cm long. The male urethra has three sections: the prostatic urethra, the membranous urethra and the cavernous or penile urethra. The prostate gland encircles the male urethra at the base of the bladder. In a female, the urinary **meatus** (opening) is located between the labia minora, above the vagina and below the clitoris. In a male, the meatus is located at the distal end of the penis.

Pelvic floor muscles

The bony pelvis forms the solid structure for the muscles and ligaments of the anterior, posterior and lateral pelvic walls and pelvic floor, which play an important role in supporting the position of the pelvic organs. The pelvic floor muscles include the coccygeus muscle and the levatorani and are referred to as the *pelvic diaphragm*. The anal canal, urethra and vagina pass through the pelvic diaphragm. The levatorani muscles support the pelvic organs and function as a sphincter for the anal canal and urethra (Jenkins & Tortora 2013).

The *perineum* is located inferior to the pelvic diaphragm. The perineum extends from the symphysis pubis anteriorly to the coccyx posteriorly and the ischial tuberosities laterally. The muscles of the perineum are in two layers: superficial and deep. The deep muscle layer of the perineum includes the external urethral sphincter and external anal sphincter, which assist in maintaining urinary and faecal continence (Jenkins & Tortora 2013).

Micturition

Several brain structures influence bladder function, including the cerebral cortex, thalamus, hypothalamus and brainstem. Together they suppress contraction of the bladder's detrusor muscle until a person decides to urinate (void). Once voiding (**micturition**) occurs, the response is

a contraction of the bladder and coordinated relaxation of the pelvic floor muscles.

The desire to urinate can be sensed when the bladder contains approximately 150–200 mL of urine in an adult and 50–200 mL of urine in a child. As the volume increases, the bladder walls stretch, sending sensory impulses to the *micturition centre* in the sacral spinal cord. Parasympathetic impulses from the micturition centre stimulate the detrusor muscle to contract rhythmically. The internal urethral sphincter also relaxes so that urine may enter the urethra, although voiding does not yet occur. As the bladder contracts, nerve impulses travel up the spinal cord to the pons and cerebral cortex. A person is thus conscious of the need to urinate. Older children and adults can respond to or ignore this urge, thus making urination under voluntary control. If the person chooses not to void, the external urinary sphincter remains contracted, and the micturition reflex is inhibited. When a person is ready to void, the external sphincter relaxes, the micturition reflex stimulates the detrusor muscle to contract, and efficient emptying of the bladder occurs.

Factors affecting urinary elimination

Many factors influence the volume of urine and a person's ability to urinate. Some pathophysiological conditions may be acute and reversible (e.g. acute urinary tract infection), while others may be chronic and irreversible (e.g. slow, progressive development of renal impairment). There are changes that occur to the urinary system from normal growth and development, for example, development of continence in a child. There are also a number of changes that occur with normal ageing that predispose older people to problems related to their kidneys and bladder.

Growth and development

Infants and young children cannot effectively concentrate urine. In relation to their small body size, infants and children excrete large volumes of urine. For example, a 6-month-old infant who weighs 6–8 kg excretes 400–500 mL of urine daily.

A child cannot control micturition voluntarily until 18–24 months old. A child must be able to recognise the feeling of bladder fullness, to hold urine for 1–2 hours and to communicate the sense of needing to void to an adult. The young child needs parents' understanding, patience and consistency. A child may not gain full control of micturition until age 4 or 5 years. Daytime control of micturition is easier to accomplish than night-time control and occurs earlier in the child's development, usually by 2–3 years of age (see *Working with diversity*).

The adult normally voids 1500–1600 mL of urine daily, although this is dependent on the amount of fluid ingested and the amount of insensible loss through, for example, sweating or breathing. The kidney concentrates urine, normally producing light-yellow-coloured urine. A person does not normally wake to void during sleep because of reduction of renal blood flow during rest and the kidneys' ability to concentrate urine.

Changes in kidney and bladder function also occur with ageing. The glomerular filtration rate declines, but the kidneys' ability to concentrate urine also declines.

WORKING WITH DIVERSITY

Focus on children

Bedwetting (nocturnal enuresis) is common in children and can occur until the teen years. According to the Continence Foundation of Australia, 1 in 5 Australian children wet their bed. There are three main causes of bedwetting:

- the inability to waken to the sensation of a full bladder at night
- over-activity of the bladder at night, causing loss of urine
- an abnormal amount of urine production occurring at night (nocturnal polyuria) when the child is asleep and unable to sense the fullness of the bladder.

Most children will gain night-time continence with time. The Continence Foundation of Australia suggests parents should seek assistance from a healthcare professional if a child who has been dry at night suddenly starts wetting at night; the episodes are frequent after 5 years of age; the wetting bothers the child or makes them angry or frustrated; the child is socially affected; or if the child states they want to become dry.

There are several approaches – bladder-training programs to increase the child's functional bladder capacity; night alarms that wake the child when there is leakage, so they learn to wake when their bladder is full; and the use of some medications.

At home, parents can praise success and ignore failure; encourage the child to drink plenty of water; encourage the child to take responsibility for the problem (assist when changing sheets, etc); provide a high-fibre diet, as constipation can aggravate the problem; and avoid 'toileting' the child during the night – this does not improve bladder control.

Parents can be advised to seek help from:

- Continence Foundation of Australia, www.continence.org.au/ or helpline 1800 33 00 66
- Continence New Zealand, www.continence.nz/ or helpline 0800 650 659.

Thus the older adult often experiences **nocturia** (urination at night). The bladder loses its muscle tone and capacity to hold urine, resulting in increased **urinary frequency**. Because the bladder cannot contract as effectively, an older person often retains urine in the bladder after voiding (**residual urine**). Older men may also suffer from *benign prostatic hypertrophy*, which makes them prone to urinary retention and incontinence. These changes increase the risk for bacterial growth and development of urinary tract infections (UTIs). Another factor related to urinary elimination difficulties is constipation. Constipation and resulting bowel fullness may put external pressure on the bladder, reducing the effective capacity and causing frequency or even incontinence (see Chapter 32).

In the female, childbearing and/or the hormonal changes of menopause may cause changes that lead to urinary difficulties. During a pregnancy, urinary frequency is common and susceptibility to UTIs is increased. Temporary or permanent changes that result from repeated vaginal deliveries or hormonal changes may result in decreased pelvic floor muscle tone, leading to urgency and stress incontinence (see Chapter 18). The changes in the urethral mucosa associated with loss of oestrogen during and after menopause also contribute to increased susceptibility to infection (McCance & Huether 2013).

Fluid balance

The kidneys maintain a sensitive balance between retention and excretion of fluids (see Chapter 34). If fluids and the concentration of electrolytes and solutes are in equilibrium, an increase in fluid intake causes an increase in urine production. Ingested fluids increase the body's circulating plasma and thus increase the volume of glomerular filtrate and urine excreted.

This amount varies with food and fluid intake. The volume of urine formed at night is about half that formed during the day, because both intake and metabolism decline. This results in a reduction in the volume of renal blood flow. In a healthy person, the intake of water in food and fluids balances the output of water in urine, faeces and insensible losses in perspiration and respiration. An excessive output of urine is known as **polyuria**.

Ingestion of certain fluids directly affects urine production and excretion. Coffee, tea, cocoa and cola drinks that contain caffeine promote increased urine formation (**diuresis**). Alcohol inhibits the release of antidiuretic hormone (ADH), resulting in increased water loss in urine. Foods that contain a high fluid content, such as fruits and vegetables, may also increase urine production.

Febrile conditions affect urine production. The patient who becomes diaphoretic loses a large amount of fluids through insensible water loss, which decreases urine production. However, the increased body metabolism associated with fever increases accumulation of body wastes. Although urine volume may be reduced, it is highly concentrated.

Changes to renal function

Disease processes that primarily affect renal function (changes in urine volume or quality) are generally categorised as prerenal, renal or postrenal in origin (Box 33-1). Prerenal alterations in urinary elimination decrease circulating blood flow to and through the kidneys, with subsequent decreased perfusion to renal tissue. In other words, the alterations are outside the urinary system. The decrease in renal perfusion leads to **oliguria** (diminished capacity to form urine) or, less commonly, **anuria** (inability to produce urine). *Renal alterations* result from factors that cause injury directly to the glomerulus or renal tubule, interfering with their normal filtering, reabsorptive and secretory functions. *Postrenal alterations* result from obstruction to the urinary collecting system anywhere from the calyces (drainage structures within the kidney) to the urethral meatus (i.e. outside the kidney but within the urinary

BOX 33-1 Conditions causing alterations in renal function

Prerenal conditions

- Decreased intravascular volume: dehydration, haemorrhage, significant burns, shock
- Altered peripheral vascular resistance: sepsis, anaphylactic (allergic) reactions
- Cardiac pump failure: heart failure, myocardial infarction, hypertension, valvular disease, pericardial tamponade

Renal conditions

- Systemic diseases (e.g. diabetes mellitus)
- Hereditary diseases (e.g. polycystic kidney disease)
- Nephrotoxic agents (e.g. gentamycin)
- Diseases of the glomeruli (e.g. glomerulonephritis)
- Renal neoplasms
- Infections
- Transfusion reactions

Postrenal conditions

- Ureteral, bladder or urethral obstruction: calculi, blood clots, tumours, stricture
- Prostatic hypertrophy or tumour
- Neurogenic bladder
- Pelvic tumours

system). Urine is formed by the urinary system but cannot be eliminated by normal means.

Changes to bladder function

Several diseases can affect the ability to void normally. Any lesion of peripheral nerves leading to the bladder causes loss of bladder tone, reduced sensation of bladder fullness and difficulty in controlling urination. For example, diabetes mellitus and multiple sclerosis cause neuropathic conditions that alter bladder function.

Illness and frailty

Reduced mobility or disability sometimes makes it difficult for a person to reach a toilet in time or to manage clothing or hygiene requirements. Rheumatoid arthritis, degenerative joint disease and Parkinson's disease are examples of conditions that make it difficult to reach and use toilet facilities. A person with rheumatoid arthritis often cannot sit on or rise from a toilet without an elevated seat or handrails.

Any alteration in cognitive function can impair a person's perception of the need to void or impair their ability to get themselves to the toilet and complete toileting activities. This is particularly relevant when a person who has dementia is admitted to an acute care hospital or moves from home to residential care. The change in environment can increase the person's confusion and make episodes of urinary incontinence more likely. A major goal when caring for a person in this situation is to reduce the impact of the change in environment by close observation of the person's responses, so that the nurse can anticipate the cues that the person needs to go to the toilet, reinforce the location of the toilet and provide frequent reassurance.

Psychological and environmental factors

Anxiety and emotional stress may cause a sense of urgency and increased frequency of urination. An anxious person may have the urge to void even after voiding only a few minutes earlier. Anxiety may also prevent a person from being able to urinate completely. Emotional tension makes it difficult to relax abdominal and pelvic floor muscles. If the external urethral sphincter is not completely relaxed, voiding may be incomplete and urine is retained in the bladder.

When people are hospitalised they are often reluctant to void in a shared ward environment or to use a bed pan or urinal. Where possible, the person should be assisted to the toilet to void. Men may need assistance to stand to void. Staying close by and leaving the person with a call bell may encourage a more normal environment in which they feel comfortable for voiding to occur.

Surgical procedures

The stress of surgery initially triggers the general adaptation syndrome (see Chapter 37). The posterior pituitary gland releases an increased amount of ADH, which increases water reabsorption and reduces urine output. The surgical patient is often in an altered state of fluid balance before surgery due to the disease process or preoperative fasting, which aggravates the reduction in urine output. The stress response also elevates the level of aldosterone, resulting in reduction of urine output in an effort to maintain circulatory fluid volume.

Anaesthetic and narcotic analgesics may slow the glomerular filtration rate, reducing urine output. These pharmacological agents also impair sensory and motor impulses between the bladder, spinal cord and brain. Patients recovering from anaesthesia and deep analgesia are often unable to sense bladder fullness and are unable to initiate or inhibit micturition. Spinal anaesthetics, in particular, create the risk of urinary retention because of an inability to sense the need to void and a possible inability of the bladder muscles and sphincters to respond.

Surgery of lower abdominal and pelvic structures can impair voiding because of local trauma to surrounding tissues. Pain can interfere with relaxation of pelvic floor and sphincter muscles and make voiding difficult or painful. After returning from surgery involving the ureters, bladder and urethra, patients routinely have an indwelling urinary catheter.

Medications

Diuretics prevent reabsorption of water and certain electrolytes to increase urine output. Urinary retention may be caused by use of some anticholinergic, antihistamine, antihypertensive or beta-adrenergic blocker medications. Some medications change the colour of urine; for example, amitriptyline causes a green or blue discolouration, while levodopa may discolour the urine to brown or black (Bryant & Knights 2015). People who have impairment in kidney function require dosage adjustments of medications excreted by the kidneys.

Common urinary elimination problems

People with urinary problems most commonly have disturbances in voiding that involve a failure to store

urine or a failure to empty urine. These disturbances result from impaired bladder function, obstruction to urine outflow or inability to voluntarily control micturition. Chronic kidney disease is a significant health problem in the Australian and New Zealand community, causing a serious and ongoing health burden on the person, their family and the healthcare system.

Lower urinary tract infections

Urinary tract infections are very common throughout the life span but are more prevalent in older people. It is estimated that the overall incidence rate is 18 per 1000 people per year (Puca 2014). When the infection is confined to the bladder and urethra it is termed a lower urinary tract infection. Bacteria in the urine (**bacteriuria**) may lead to the spread of organisms into the kidneys (upper urinary tract infection).

The most common organism that causes UTIs in otherwise healthy people is *Escherichia coli* (Puca 2014). Microorganisms most commonly enter the urinary tract through the urethral route. Bacteria inhabit the distal urethra, external genitalia and vagina in women. Organisms enter the urethral meatus easily and travel up the inner mucosal lining to the bladder. Risk factors for developing a UTI include being a postmenopausal woman, sexual activity in women, pregnancy, and underlying anatomical abnormality (vesico-ureteric reflux, history of recurrent UTI, urinary obstruction, presence of renal calculi). Older adults and people with progressive underlying disease or decreased immunity are also at increased risk.

Most children and adults with lower UTIs have pain or burning during urination (**dysuria**) as urine flows past inflamed tissues. An irritated bladder causes a frequent and urgent sensation of the need to void. Irritation to bladder and urethral mucosa can result in blood-tinged urine (**haematuria**). The urine can appear concentrated and cloudy because of the presence of white blood cells (WBCs) or bacteria. The signs and symptoms of UTI in older adults can be less obvious. Often the first symptoms may be confusion and dehydration. An infection in the upper urinary tract (kidneys – **pyelonephritis**) can cause more-severe symptoms such as (commonly) flank pain, tenderness, nausea, vomiting, fever and chills.

Urinary incontinence

Urinary incontinence is defined as the complaint of any involuntary loss of urine (Abrams et al 2013). It may be transient or ongoing. Urinary incontinence can be further defined according to the person's symptoms: stress incontinence, urge incontinence, mixed incontinence (a mix of stress and urge symptoms), nocturnal enuresis, post-micturition dribble, overactive bladder and functional incontinence (Abrams et al 2013) (see Table 33-1 for definitions, risk factors and defining characteristics).

Urinary incontinence affects up to 37% of Australian women and 13% of Australian men (Australian Institute of Health and Welfare (AIHW) 2013b). Severe urinary incontinence (UI) affects up to 1.5% of Australian men and women. It is more common in females, and people over 65 years of age are 12 times more likely to experience severe UI than those under 65 years (AIHW 2014a). In New Zealand, 25–34% of adult women and 5–22% of adult men have experienced urinary incontinence (Continence New Zealand 2015).

Urinary incontinence significantly affects a person's quality of life, including the person's daily activities, sexuality, body image and self-esteem (Abrams et al 2015). Efforts to cope with the problem may lead to the person reducing their fluid intake, increasing the frequency of voiding and avoiding social contact (Gordon & Drake 2014, Yip et al 2013). There is also evidence in the literature that continence problems have significant impact on family caregivers, including depression (Lobchuk & Rosenberg 2014).

Prostatic hypertrophy and prostate cancer

Benign enlargement of the prostate gland that occurs with ageing can obstruct the urethra and make voiding difficult. *Benign prostatic hypertrophy* (BPH) is a common condition affecting more than 50% of men by 60 years of age (Bechis et al 2014). The typical symptoms are decreased urinary stream, hesitancy, intermittent stream, nocturia, frequency and urgency (see Table 33-2 for a description of common types of lower urinary symptoms). Some men may develop acute or chronic urinary retention (see below). Treatment for men who have symptomatic BPH include medications which aim to relax the smooth muscles at the bladder neck (alpha-blockers) or to reduce the size of the prostate gland (5-alpha-reductase inhibitors), or surgery – for example, trans-urethral resection of the prostate (Eifler 2014).

Prostate cancer is the most common cancer that occurs in men. The risk of developing prostate cancer to age 75 years is 1 in 7 for Australian men (AIHW 2014b). In New Zealand males, the incidence of prostate cancer is estimated to be 1 in 13 to age 75 (Prostate Cancer Foundation of New Zealand 2015). Prostate cancer is essentially a disease of older men, with 85% diagnosed after 65 years of age (Cancer Council Australia 2015). Prostate cancer is rare before the age of 40 years and its incidence rises rapidly after age 60 years.

TABLE 33-1 Types of urinary incontinence

Description	Risk factors	Symptoms
Urgency urinary incontinence		
Involuntary leakage of urine after a strong sense of urgency to void	Decreased bladder capacity; irritation of bladder wall; alcohol or caffeine ingestion; increased fluid intake; infection	Significant urinary urgency – inability to defer voiding once the urge has occurred, often with frequency (more often than every 2 hours)
Stress urinary incontinence		
Involuntary leakage of urine on effort or exertion or on sneezing or coughing	Coughing, laughing, sneezing or lifting with a full bladder; obesity; full uterus in third trimester; incompetent bladder outlet; vaginal or uterine prolapse; weak pelvic floor muscles	Loss of urine with increased intra-abdominal pressure. Usually small amounts of urine lost
Mixed urinary incontinence		
Involuntary leakage of urine associated with urgency and also with effort or exertion or on sneezing or coughing	Coughing, laughing, sneezing or lifting with a full bladder; obesity; full uterus in third trimester; incompetent bladder outlet; vaginal or uterine prolapse; weak pelvic floor muscles	Loss of urine with increased intra-abdominal pressure, urinary urgency and frequency. Can be a small or large amount of urine lost
Functional urinary incontinence		
Involuntary urine loss that occurs because of impaired functional status – impaired cognitive status, impaired mobility and dexterity and/or environmental barriers that block toilet access	Change in environment: sensory, cognitive or mobility deficits	Urge to void that causes loss of urine before reaching appropriate receptacle. The patient with cognitive changes may have forgotten what to do or not recognise the place to void
Nocturnal enuresis		
Involuntary loss of urine occurring during sleep	Abnormal night-time secretion of antidiuretic hormone, developmental delay in development of control of the micturition reflex, family history of enuresis. Exacerbated by urinary tract infection	Urinary loss while asleep
Overactive bladder		
Symptoms of urgency with or without urge incontinence, usually with frequency and nocturia	Neurological disorders such as stroke, dementia, Parkinson's disease; stress urinary incontinence, inflammation, idiopathic	Diagnosed with urodynamic testing. Bothersome urgency usually associated with frequency and nocturia
Post-micturition dribble		
Feeling of involuntary urine loss immediately after finishing voiding	Urinary retention, urethral abnormalities such as a diverticulum in women and post prostatectomy in men	Men will complain of urine loss immediately after voiding; women will complain of urine loss on rising from the toilet
Neurogenic detrusor overactivity		
Urinary incontinence, urinary retention. Urine leakage occurs without warning	Disruption of the central nervous system regulation of the micturition reflex as seen in neurological disorders such as spinal cord injury, multiple sclerosis, etc	Urine leakage occurs without warning

Adapted from: Abrams P, Cardozo P, Khoury S, Wein A (eds), Incontinence – 5th international consultation on incontinence – Paris, 5th edn, ICUD-EAU.

The cause of prostate cancer is unknown. Apart from advancing age and being male, the strongest established risk factor is a family history of the disease (Zhu et al 2012). Part of the concern for men and for healthcare workers is the non-specific nature of the typical presenting signs and symptoms associated with prostate cancer. In the early stages they are likely to be asymptomatic. Differential diagnosis involves a health assessment and will include a prostatic-specific antigen (PSA) test, digital rectal examination (DRE) and biopsy. Treatment options for prostate cancer include surgery (radical prostatectomy), androgen deprivation therapy and radiation therapy.

TABLE 33-2 Common lower urinary tract symptoms

Symptoms	Description	Causes or associated factors
Storage/filling symptoms		
Frequency	Voiding more frequently than normal during the day – usually more than 8 times per day (but this varies)	Increased fluid intake, bladder inflammation (usually from infection), increased pressure on bladder (pregnancy, psychological stress), overactive bladder
Nocturia	Waking from sleep to void more than once per night	Excessive fluid intake before bed (especially coffee or alcohol), renal disease, ageing process, prostate enlargement, heart failure, incomplete bladder emptying, use of sedatives and hypnotics
Urgency	Strong and immediate need to void immediately that is not easily deferred	Bladder irritation or inflammation from infection, incompetent urethral sphincter, psychological stress
Emptying/voiding symptoms		
Dysuria	Painful or difficult urination – often described as a 'burning' sensation	Bladder inflammation (usually from infection), trauma or inflammation of the urethra (urethritis)
Hesitancy	Difficulty initiating urination and delay in onset of voiding	Prostate enlargement, anxiety, urethral oedema
Incomplete bladder emptying	The sensation that urine remains in the bladder after micturition	Abnormal bladder sensations, bladder outlet obstruction, neurological diseases, pelvic organ prolapse

Adapted from Staskin D, Kelleher C, Bosch R et al 2013 Initial assessment of urinary incontinence in adult male and female patients. In P Abrams, P Cardozo, S Khoury, A Wein (eds), Incontinence – 5th international consultation on incontinence – Paris, 5th edn, ICUD-EAU.

Urinary retention

Urinary retention is the inability to fully empty the bladder after voiding or a complete inability to urinate despite effort (Staskin et al 2013). Urinary retention can be acute or chronic. In *acute retention*, key signs are bladder distension and absence of urine output over several hours. The bladder may hold as much as 2000–3000 mL of urine. The person may experience significant discomfort, tenderness over the symphysis pubis, restlessness and diaphoresis (sweating). Acute retention is most common in men due to obstruction of the urethra as a result of benign enlargement of the prostate gland. It can also occur in people in the postoperative period, particularly following a lengthy surgical procedure, in people who have had an epidural anaesthetic or infusion, following removal of an indwelling catheter, in people who have poorly controlled pain and after vaginal birth (Johansson et al 2013). It is a medical emergency that requires immediate intervention.

Chronic retention results from incomplete bladder emptying over a period of time. It results from either a partial obstruction of the urethra (e.g. urethral stricture, enlarged prostate, chronic constipation) and/or from reduced ability of the detrusor (bladder) muscle to contract during voiding (e.g. spinal cord injury, nerve damage from diabetes mellitus). As retention progresses, retention with overflow may develop. Pressure in the bladder builds to a point where the external urethral sphincter is unable to hold back urine. The person may have an urge to void but is only able to void small amounts. Some people may experience intermittent episodes of incontinence, while others experience constant dribbling of urine. Depending on the cause of the chronic retention, the person may or may not be aware of the incomplete bladder emptying. Chronic retention caused by partial obstruction can result in increased pressures within the urinary tract causing damage to the kidneys (postrenal obstruction). Incomplete bladder emptying can predispose the person to UTIs.

Chronic kidney disease

Diseases that cause irreversible damage to the glomerulus or tubules result in permanent alterations in renal function. Chronic kidney disease (CKD) or end-stage kidney disease (ESKD) are the terms used to describe the resulting decline in kidney function from these processes. CKD is damage to the kidneys or reduced renal function lasting more than 3 months (AIHW 2015). It is estimated that 13% of Australians are living with CKD (AIHW 2015). Aboriginal and Torres Strait Islander people, especially those living in remote communities, are at high risk of developing CKD and the incidence is increasing (AIHW 2013a). There is a similar incidence of CKD in New Zealand, with 16% of New Zealanders having some form of kidney damage, and a higher incidence in Māori and Pacific Islanders (Joshy et al 2010). A major risk factor for developing CKD is diabetes. Other risk factors include

hypertension, cigarette smoking, obesity, family history of CKD and being over 50 years of age (Kidney Health Australia 2015).

The person with ESKD manifests numerous metabolic disturbances that require treatment for survival. The associated symptoms experienced by the patient occur as a result of the **uraemic syndrome**. This syndrome is characterised by an increase in nitrogenous wastes in the blood, altered regulatory functions (causing marked fluid and electrolyte abnormalities), nausea, vomiting, headache, coma and convulsions. The problem may be managed conservatively with medications and a regimen of dietary and fluid restrictions. However, as worsening of the uraemic symptoms becomes evident, more-aggressive treatment is required. These treatments are known as **renal replacement therapies**. Dialysis and organ transplant are the two methods of renal replacement; the two methods of dialysis are haemodialysis and peritoneal dialysis. Both dialysis methods can be applied for a short or a long time, and they require specialised equipment and nurses who are renal clinical specialists.

Haemodialysis involves using a machine equipped with a semipermeable filtering membrane (artificial kidney) that removes accumulated waste products from the blood. In the dialysis machine, dialysate fluid is pumped through one side of the filter membrane (artificial kidney) while the patient's blood passes through the other side. The processes of diffusion, osmosis and ultrafiltration clean the patient's blood, and it is returned through a specially placed vascular access device (Dring & Hipkiss 2015).

Peritoneal dialysis uses the peritoneal membrane in the abdomen and its blood supply for diffusion and osmosis of waste products and excess fluid volume. Dialysis fluid is infused into the abdomen via a catheter into the peritoneum. The dialysis fluid is left in the abdomen for a period of time and then drained (Dring & Hipkiss 2015).

Transplantation is the surgical replacement of the person's diseased kidney with a healthy one from a living or cadaveric donor of compatible blood and tissue type. Immunosuppressive medications are administered for life to prevent the body rejecting the transplanted organ. Unlike the other treatments, a successful organ transplant offers the patient the potential for restoration of normal kidney function for varying periods of time.

Renal calculi (nephrolithiasis)

Urinary calculi are stones that occur in the urinary tract including the kidney, ureters, bladder and urethra, and can be classified according to their point of origin, location and composition. The calculi can vary in size from microscopic to several centimetres in diameter. They can cause significant morbidity for people who develop them. Urinary calculi are common worldwide affecting 10% of the population with an increasing prevalence (Turner & Semins 2014). The lifetime risk of developing kidney stones is 1 in 10 for Australian men and 1 in 35 for Australian women (Renal Resource Centre 2015). Stones form by a process of crystallisation where growth occurs around a central nucleus. Classification of urinary stones is commonly based on their composition and one or more substances may form them. The most common urinary stones (80%) are composed of calcium; 5–10% are uric acid, 10–15% are struvite and may form a stag horn calculus in the renal pelvis, and 1% are composed of cystine (Khan 2012). The most common presentation with urinary calculi is severe pain, usually of sudden onset and the person may have microscopic or macroscopic haematuria (Khan 2013). The person may find it difficult to void because of pain or obstruction. Treatment options for urinary calculi can be classified as either non-invasive (watchful waiting) or invasive (actual removal of the stone/s). Initial management for an acute presentation includes intravenous fluids, treatment of nausea and vomiting and pain relief. However, in many cases the person requires hospital admission and urgent intervention, for example, if there is evidence of infection, a reduction in renal function on the affected side, uncontrolled pain, solitary kidney or bilateral renal obstruction (Gayed & Semins 2014).

• CRITICAL REFLECTION POINT

Successful clinical reasoning requires a synthesis of knowledge, experience, information gathered from patients, critical-thinking attitudes, and intellectual and professional standards. Assessment of a person for risk factors or actual urinary elimination problems requires specific knowledge and sensitivity in approaching health issues which the person may find difficult to discuss (see Figure 33-4).

CLINICAL REASONING PROCESS

GATHERING RELEVANT INFORMATION AND DATA

Assessing urinary elimination patterns and determining the aetiology of symptoms requires a focused nursing history, physical assessment, including abdominal examination, and specimen testing, assessment of skin, mobility and, where necessary, cognition. In most cases, you would also need to assess bowel function (see Chapter 32).

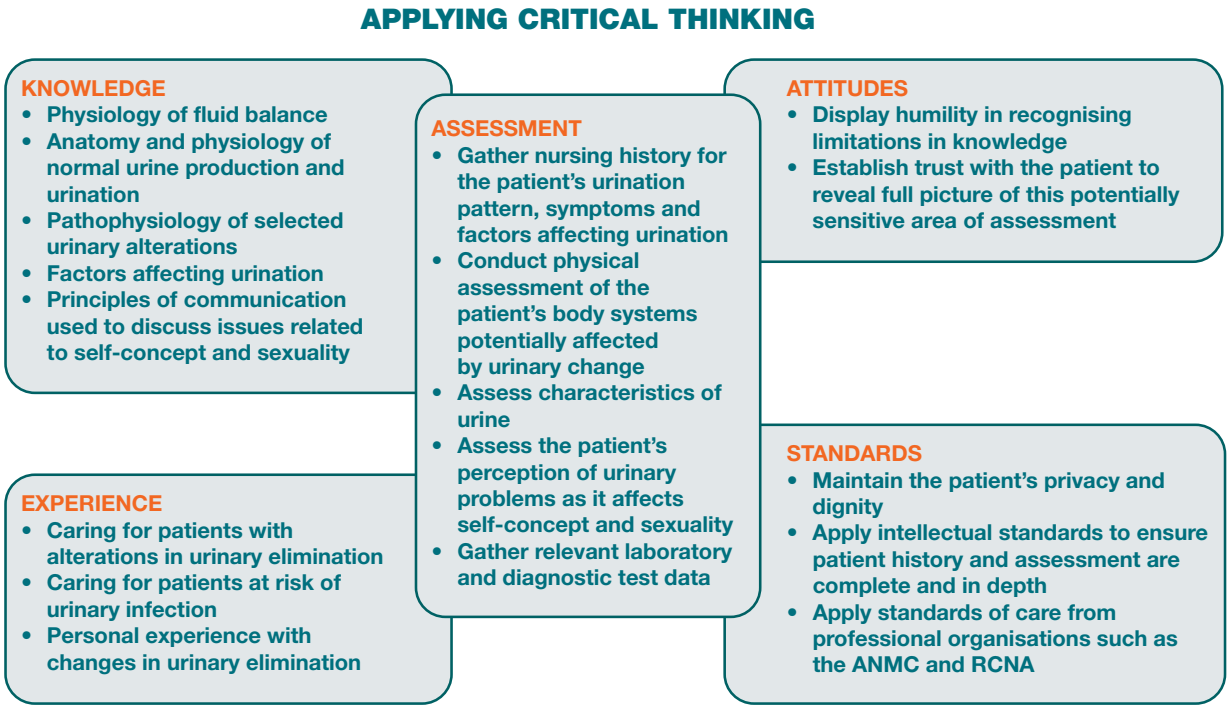

Figure 33-4 **Critical thinking associated with the assessment phase for urinary elimination.**

Nursing history

The focused nursing history provides a review of the person's usual urinary elimination pattern and toileting habits. This information enables identification of possible health problems and gives direction to the physical examination. The nursing history includes a review of the patient's elimination pattern, LUTS and an assessment of other factors that may be affecting the ability to urinate normally.

- *Determine the concern being presented by the person.* It is important to acknowledge the person's perception of their urinary elimination problem and how this affects their quality of life. How does this problem affect their work, school, activities, relationships, and so on?
- *Determine the usual voiding pattern.* Ask the person about the frequency and pattern of urination, including frequency and times of day, normal volume at each voiding and any recent changes. Frequency varies among individuals and with intake and other types of fluid losses. The common times for urination are on waking, after meals and before bedtime. Most people void an average of five or more times a day and no more than once overnight. Information about the pattern of urination establishes a baseline for comparison. Having the person or caregiver complete a 'voiding or bladder diary' can enhance accurate assessment of the person's urinary pattern. The information collected in a typical voiding diary includes: time of voiding and the measured amount voided, fluid intake and type, presence of symptoms (e.g. urge, incontinence). To improve accuracy, the person completing the diary must understand what information must be recorded. Normally a voiding diary would be kept for three 24-hour periods so that the person's normal urinary elimination patterns can be determined. Keep in mind that normal changes with ageing predispose older adults to certain elimination problems (see *Research highlight*).
- *Characteristics of the urine.* Ask the person about the colour, odour, clarity, etc of their urine.
- *Fluid intake/fluid balance.* In a hospitalised patient, assessment of fluid balance is often undertaken. The data is recorded on a fluid balance chart, and intake and output are compared over a 24-hour period (see below). The information in the voiding diary will help you determine the amount and types of fluid that the person usually consumes. If the person has not completed a voiding diary, ask them about their usual fluid intake (type and amount) and pattern of intake.
- *History of change or disturbance in urinary function.* Detail any changes in function that the person has noticed and for how long this has been a problem, what has the person done about it.
- *Pain.* There are several sites for pain associated with urinary tract dysfunction. These include flank pain (costovertebral angle), usually unilateral, which is associated with a problem in the kidney or renal pelvis; and suprapubic pain which is associated with UTI. Ask about the frequency and character of the pain. Is the pain associated with voiding? How long has the pain been present? How does the pain rate from 1 to 10? What has the person done to relieve the pain? Are there any associated symptoms (e.g. nausea, frequent urination, fatigue)?
- *Lower urinary tract symptoms.* LUTS may occur in more than one type of disorder. During assessment ask the patient about the LUTS listed in Table 33-2. Also investigate the factors that precipitate or aggravate symptoms.

RESEARCH HIGHLIGHT

Research focus

There are risks associated with the use of indwelling urinary catheters; in particular, they are the cause of approximately 80% of urinary tract infections in acute care. The majority of research aimed at minimising IUC use has focused on limiting the duration of catheterisation and there is evidence that interventions in this area can achieve positive outcomes. Interventions to reduce the duration of use of indwelling urethral catheters (e.g. reminder systems) have been found to be effective. This paper evaluates attempts to minimise the initial placement of IUCs.

Research abstract

This research aimed to systematically evaluate the evidence of the effectiveness of interventions to minimise the initial placement of indwelling urinary catheters in adults in acute care environments. A systematic review of the published literature was undertaken in order to accurately identify, evaluate and summarise the findings of all relevant studies. Studies incorporating an intervention to reduce the initial placement of indwelling urinary catheters in an acute care environment in patients aged 18 and over that reported on the incidence of indwelling urethral catheter placement were included in the review. The MEDLINE, CINAHL, EMBASE, National Health Service Centre for Review and Dissemination and Cochrane Library databases were used to identify relevant publications. Results of the search identified 2689 studies which were scanned for eligibility. Only eight studies were found that reported any change (increase or decrease) in the level of initial placement of indwelling catheter as a result of an intervention in acute care. Of the eight, six had an uncontrolled before–after design. Seven demonstrated a reduction in the initial use of indwelling catheter post-intervention. There was insufficient evidence to support or rule out the effectiveness of interventions due to the small number of studies, limitations in study design and variation in clinical environments.

The authors outlined several key observations from the study. Clinical education was the most common intervention component, although they found that multiple interventions are likely to be required to implement a change in clinical practice. These could include education sessions, introduction of checklists which clinicians could use to confirm the need for catheterisation, improved access to bladder scanners, improved collaboration and communication between medical and nursing colleagues, the need for healthcare organisations to address ritualised practice and improved reporting of indwelling catheter use. The authors also noted the wide variation in the content and reported acceptability of the 'indications for catheter placement' reported in the reviewed studies. The authors concluded that more work is needed to establish when the initial placement of an indwelling catheter is appropriate in order to better understand when indwelling catheters are overused and inform the development of methodologically robust research on the potential of interventions to minimise the initial placement of indwelling urinary catheters.

Evidence-based practice

Urinary catheterisation is a significant cause of morbidity in hospitalised patients. The financial burden to the healthcare system of catheter use is high. There is a need for greater understanding of when the placement of a urinary catheter is necessary, what constitutes urinary catheter overuse and the eventual development of a set of consistent, evidence-based, setting-appropriate, clinician-friendly indicators for the initial placement of a urinary catheter. Clinicians need to carefully examine the indications for catheter use and every effort should be made to reduce the incidence of urinary catheterisation in acute care patients.

Reference

Murphy C, Fader M, Prieto J 2014 Interventions to minimise the initial use of indwelling urinary catheters in acute care: a systematic review. International Journal of Nursing Studies 51(1):4–13.doi:10.1016/j.ijnurstu.2012.12.007.

It is important to specifically ask people about the presence of urinary incontinence. People are embarrassed about this problem and are often reluctant to talk about it (Strickland 2014).

- *Other symptoms.* Generalised symptoms can also result from urinary elimination problems, especially CKD and upper UTI. Ask the person about the presence of fever, nausea and vomiting, weight gain or loss, peripheral oedema, fatigue and lethargy, headache, itching skin, etc.
- *Past health history.* Personal or family history of health issues affecting the urinary tract; for example, infection; urinary calculi; family history of renal or bladder cancer; neurological disorders; surgery, including gynaecological, spinal or bowel surgery; diabetes, urinary catheterisation or any issues with constipation. For men, ask about history of prostate cancer. For women, ask about obstetric history (e.g. number of births, birthweights, type of birth) and, if relevant, menopausal symptoms.
- *History of smoking.* Smoking is a known risk factor for bladder and renal cancer and can contribute to voiding problems.
- *Self-care practices.* Ask about activity and exercise patterns, toileting and hygiene, use of continence aids and appliances. The patient's mobility and dexterity

need to be evaluated to determine whether the patient needs assistive devices or personnel. You need to make a judgement about the need for questioning in this area based on your observation of the person. For example, questions regarding assistance needed to get to the toilet, undressing/redressing, hygiene, and use of toileting aids (commode chairs, raised toilet seats, etc). Where patients live may affect their toileting habits. If the patient is sharing living quarters, how many bathrooms are there? Do they have their own bathroom, or do they need to share and thus adjust the time they use the bathroom to accommodate others? Work environment – location and access to toilets. For men over 50 years – ask about prostate checks.

- *Medications (prescribed and over-the-counter) currently being used.* Many medications can affect bladder function.

CRITICAL REFLECTION POINT

Ms Sally O'Connor is an 18-year-old student who is attending the university health clinic for the first time. She is complaining of urgency and frequency on voiding. Outline areas for further subjective data collection that you would ask Ms O'Connor.

Physical examination

The physical examination is focused on body systems and functions related to urinary elimination problems (see Chapter 23). You will need to make a judgement about the specific areas to include in your examination, which may include assessment of fluid balance (including skin and mucous membranes), abdomen and perineal area/skin. You will also need to complete a urinalysis and may be involved in specimen collection for microscopic examination and microbiological and biochemical analysis. Start with vital signs (see Chapter 24).

Skin and mucous membranes

Problems with urinary elimination are often associated with fluid and electrolyte disturbances. By assessing skin turgor and the oral mucosa, you are assessing the person's hydration status. A more general skin assessment may be required if the person has urinary incontinence. Specifically assess the health of skin on the upper thighs, groin and perineal area.

Abdominal assessment

As mentioned previously, often an assessment of urinary elimination is done at the same time as an assessment of bowel elimination. Specific aspects of an abdominal assessment relevant to urinary elimination involve inspection, palpation and percussion.

Inspect all four abdominal quadrants for contour, shape, symmetry and skin colour. Inspection also includes noting masses, scars, stomas and lesions. In adults the bladder rests below the symphysis pubis and cannot be examined abdominally. When distended, the bladder rises above the symphysis pubis at the midline of the abdomen and may extend to just below the umbilicus. A significantly distended bladder may appear as a protuberance on the central lower abdomen.

Palpation of the abdomen is performed to determine distension (a drum-like tightness), areas of tenderness or the presence of masses (see Chapter 23). It is important for the person to relax. Tensing abdominal muscles interferes with palpating underlying organs or masses. If the examination reveals significant tenderness in any area of the abdomen, note the location of the tenderness and do not progress with further palpation or percussion. Refer the person to a medical practitioner for further assessment, as the pain/tenderness may indicate serious underlying pathology such as acute appendicitis or inflammation of the bowel.

The partially filled bladder normally feels smooth and rounded. As you apply light pressure to the bladder, the patient may feel tenderness or even pain. Even when the bladder is not visible, palpation may cause the urge to urinate. A person with urinary retention may have a significantly distended bladder which you may be able to palpate centrally on the lower abdomen. The suprapubic area may also be tender if the person has a UTI.

Percussion detects lesions, fluid or gas within the abdomen. On percussion, a distended bladder will elicit a dull percussion tone. If the kidneys become infected or inflamed, flank pain typically develops. If you find that the person has kidney pain, they should be referred to a medical practitioner for further assessment.

In most acute care hospitals you will have access to a bladder scanner. This is an ultrasound device which detects and measures the volume of urine in the bladder. It is commonly used to determine the volume (if any) of residual urine left in the bladder after voiding. A conductive gel is applied to the lower abdomen and the transducer is placed on the skin and moved about until a reading is obtained. Once the bladder volume is determined, the person is asked to void normally. The scan is repeated to determine the presence of a residual urine volume. The accuracy of the scan is determined by correct use of the equipment and patient selection. You will need to follow the manufacturer's instructions on correct use of the bladder scanner.

Urethral meatus

Assess the urinary meatus to note the presence of discharge, inflammation and lesions. This assessment screens for infections and other abnormalities. To examine the female, a dorsal recumbent position provides full exposure of the genitalia. While wearing gloves, retract the labial folds to see the urethral meatus. Normally the meatus is pink and appears as a small slit-like opening below the clitoris and above the vaginal orifice. There is normally no discharge from the meatus. If present, specimens of urethral discharge should be obtained before the patient voids.

The male urethral meatus is normally a small opening at the tip of the penis. Inspect the meatus for discharge, inflammation and lesions. It may be necessary to retract the foreskin in uncircumcised men to see the meatus.

Assessment of fluid intake and output

As mentioned previously, assessment of fluid balance is often undertaken for a hospitalised patient. The data are recorded on a fluid balance chart, and intake and output are compared over a 24-hour period. All sources are included, including oral intake, intravenous fluid infusions, tube feedings and fluid instilled into nasogastric or gastric tubes.

The volume of urinary output is measured with each voiding using a bed pan or urinal and measuring jug. If the person has a urinary catheter, precise measurement of the volume of urine

is done by using a measuring device which is part of the urinary drainage bag. The urine drains passively into the urimeter, which holds 100–200 mL of urine. After measuring the urine in the urimeter, typically at hourly or 2-hourly intervals, the urine can be drained directly into the large drainage bag without opening the closed drainage system. If there is no need to measure hourly or 2-hourly urine output, urine volume can be measured by draining the urine from the drainage bag into a plastic graduated measuring receptacle (Figure 33-5). Standard infection control precaution measures should be used when measuring urine.

Record and report any extreme increase or decrease in urine volume. An hourly output of less than 0.5 mL/kg for more than 2 hours is abnormal and should be reported to a medical practitioner. Similarly, consistently high volumes of urine (polyuria), more than 2000–2500 mL daily, should be reported.

Assessment of urine

The characteristics of the urine should also be recorded. Inspect the urine for colour, clarity and odour. Normal urine ranges from a pale straw colour to amber, depending on its concentration. Urine is usually more concentrated in the morning or with a fluid volume deficit. As the person drinks more fluids, urine becomes less concentrated. Bleeding from the kidneys or ureters causes urine to become dark red or tea-coloured; bleeding from the bladder or urethra causes bright-red urine. Various medications also change urine colour. Eating beetroot, rhubarb or blackberries may cause red urine. Special dyes used in intravenous diagnostic studies eventually discolour urine. Dark-amber urine may be the result of high concentrations of bilirubin caused by liver dysfunction. Document and report any abnormal colour or sediment, especially if the cause is unknown.

Figure 33-5 Urine drainage bag.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

Normal urine is transparent at voiding; urine that stands several minutes in a container can become slightly cloudy. Freshly voided urine in patients with renal disease may be cloudy or foamy because of high protein concentrations. Urine can be thick and cloudy as a result of bacteria.

Urine has a characteristic odour. The more concentrated the urine, the stronger the odour. Stagnant urine has an ammonia odour. A sweet or fruity odour occurs from acetone or acetoacetic acid (by-products of incomplete fat metabolism) seen with diabetes or starvation. Keep in mind that some foods, for example asparagus, can change the odour of urine. If you detect an unusual odour, especially when there are no other abnormalities in the urine, ask the person what they have been eating in the last 12–24 hours.

Urine testing

Urine specimens are often collected for laboratory testing. The type of test determines the method of collection. Specimens that need to be sent to the laboratory for analysis should be labelled with the person's name and date and time of collection. They should be transported to the laboratory in a timely fashion to ensure accuracy of test results. Standard infection control precaution measures should be used when collecting urine specimens (see Chapter 25). In all cases you need a fresh urine sample.

Collecting a clean voided urine specimen

A clean, freshly voided specimen is collected so that urinalysis and inspection of the urine can be performed. The person is asked to void into a clean urine cup, urinal or bed pan. Most people are able to do this independently; however, if the person has poor mobility or cognitive impairment they may require assistance. The person should void before defecating so that faeces does not contaminate the specimen. Female patients are also instructed not to place toilet tissue in the bed pan. Only 50–100 mL of urine is needed for accurate testing. After the specimen is collected, the urine is inspected and then tested using the appropriate testing strips (dipsticks).

Collecting a midstream urine specimen

To obtain a specimen relatively free of the microorganisms growing in the lower urethra, the patient will need to be instructed about the method for obtaining a midstream urine specimen (Skill 33-1). This type of specimen is needed to culture urine to determine the presence of bacteriuria and to check for antibiotic sensitivity (micro-culture and sensitivity or MC&S test). After appropriate cleaning (using warm water and a mild soap) of the external genitalia, the person begins voiding, allowing a small amount of urine to escape; then during the middle portion of voiding, the person collects the specimen in a sterile container. The initial stream of urine cleans or flushes the urethral orifice and meatus of resident bacteria. It is easiest for a patient to obtain midstream urine specimens while using toilet facilities. If possible collect the first voided specimen of the day as it is likely to contain higher levels of bacteria and other constituents.

Collecting a urine specimen from a patient with an indwelling urinary catheter

You may need to perform a urinalysis using dipsticks or collect a specimen for laboratory analysis from a person who has an indwelling urinary catheter. A urine specimen is not collected

SKILL 33-1

Collecting a midstream (clean-voided) urine specimen

Delegation considerations

If appropriate, an alert patient who is physically able may be instructed to collect the specimen.

Equipment

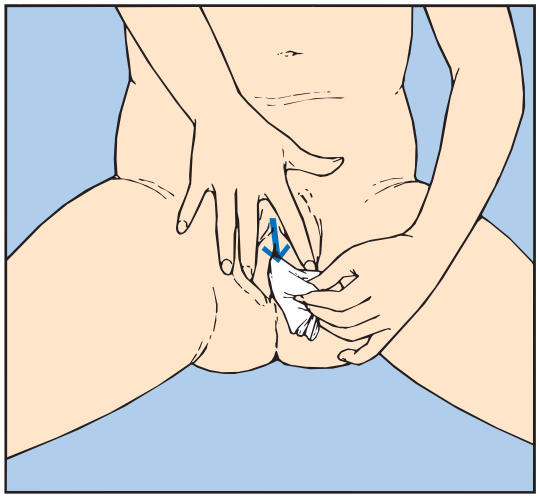
- A mild soap or cleaning solution, washcloth and towel or disposable cleansing towel
- Sterile specimen collection jar with lid
- Non-sterile gloves
- If the person cannot collect the specimen themselves, they can be assisted while seated on a bed pan in bed or using a bedside commode
- Completed pathology requisition for the procedure (signed by a medical practitioner or nurse practitioner – may be an electronic document)

Therapeutic relationship and patient considerations

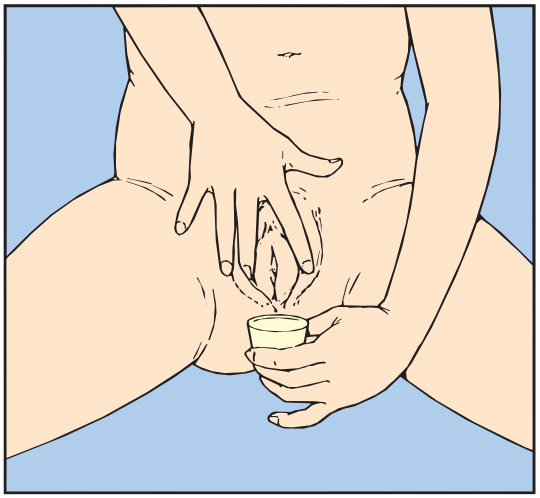
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess the general health status of patient:	
a. When patient last voided	May indicate bladder fullness.
b. Level of education, health literacy and developmental stage	Reveals patient's ability to cooperate during procedure.
c. Mobility, balance and physical limitations	Determines level of assistance.
2. Assess patient's understanding of purpose of test and method of collection.	Information allows you to clarify misunderstandings and promotes patient cooperation.
3. Explain procedure to patient:	Helps patient understand the procedure.
a. Reason midstream specimen is needed	
b. Ways patient and family can assist	
c. Ways to obtain specimen free of faeces	Faeces change characteristics of urine and may cause abnormal values.
4. Provide fluids to drink 30 minutes before collection unless contraindicated (i.e. fluid restriction) if patient does not feel urge to void.	Improves likelihood of patient being able to void.
5. Ask the person to go to the toilet/bathroom or provide privacy for patient by closing door or bed curtain.	Privacy allows patient to relax and produce specimen more quickly.

STEPS	RATIONALE
6. Perform hand hygiene and put on non-sterile gloves. Assist non-ambulatory patients with perineal care. Help female patient onto bed pan. Remove gloves and perform hand hygiene.	Prevents transmission of microorganisms to nurse; provides easy access to perineal area to collect specimen.
7. Open the sterile specimen container, placing cap with sterile inside surface up; do not touch inside of container or cap (see Chapter 25).	Aseptic technique is essential to maintain sterility of equipment and specimen. Contaminated specimen is most frequent reason for inaccurate reporting of urine cultures and sensitivities.
8. Assist (wearing non-sterile gloves) or ask the patient to independently clean perineum and collect specimen:	
A. Female	
(1) Spread labia with thumb and forefinger of non-dominant hand.	Provides access to urethral meatus.
(2) Clean area with soap and water or moistened disposable towel moving from front (above urethral orifice) to back (towards anus) (see illustration).	Clean from area of least contamination to area of greatest contamination (near anus), to reduce chance of bacterial contamination with faecal bacteria.
(3) While continuing to hold labia apart, patient should initiate stream and after stream is achieved, pass container into stream and collect 30–60 mL (see illustration).	Initial stream flushes out microorganisms that accumulate at urethral meatus and prevents transfer into specimen.



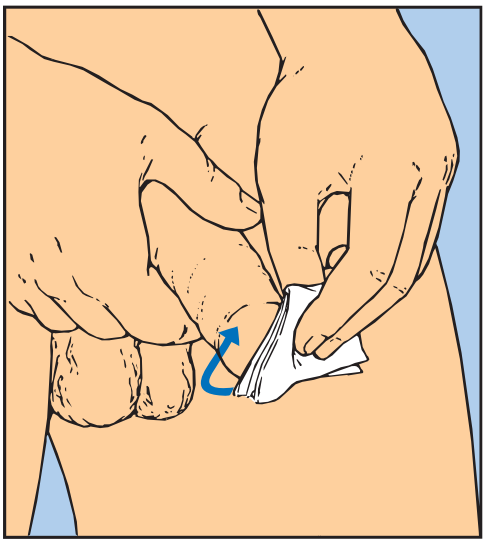
Step 8A(2) Cleaning technique (female).



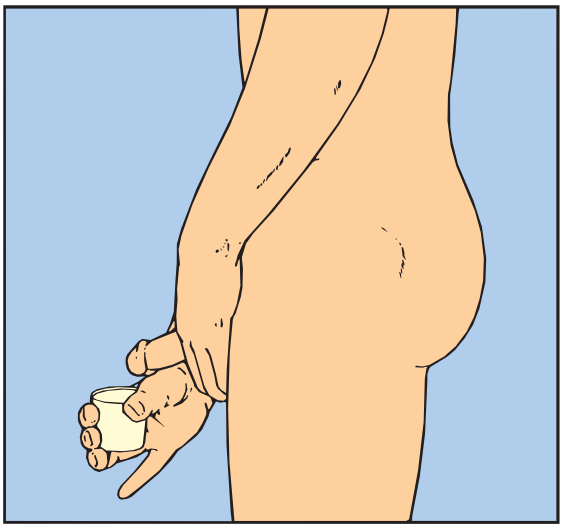
Step 8A(3) Specimen collection (female).

B. Male	
(1) Hold penis with one hand and, using circular motion, clean end of penis, moving from centre to outside (see illustration). In uncircumcised men, the foreskin should be retracted prior to cleaning.	Clean from area of least contamination to area of greatest contamination, to decrease bacterial levels.

STEPS	RATIONALE
(2) After patient has initiated urine stream, pass specimen collection container into stream, and collect 30–60 mL (see illustration).	Initial stream flushes out microorganisms that accumulate at urethral meatus and prevents transfer into specimen.



Step 8B(1) Cleaning technique (male).



Step 8B(2) Specimen collection (male).

9. Remove specimen container before flow of urine stops and before releasing labia or penis. Patient finishes voiding in bed pan or toilet. If foreskin was retracted for specimen collection, it must be replaced over the glans.	Prevents contamination of specimen with skin flora. If foreskin not replaced, swelling and constriction may occur, causing pain and possible obstruction to urine flow.
10. Replace cap securely on specimen container (touch outside only).	Retains sterility of inside of container and prevents spillage of urine.
11. Clean any urine from exterior surface of container, and place in a plastic specimen bag.	Prevents transfer of microorganisms to others.
12. Remove bed pan (if applicable), and make sure that the patient is clean and comfortable.	Promotes relaxing environment.
13. Remove gloves, dispose of in waste bin and perform hand hygiene.	Reduces transmission of infection.

■ **Critical decision point: If patient is menstruating, indicate information on laboratory requisition.**

14. Label specimen, including the date and time of collection, place in plastic biohazard transport self-seal bag and attach pathology requisition (if required by the laboratory).	Prevents inaccurate identification that could lead to errors in diagnosis or treatment.
15. Arrange for transport of the specimen to laboratory within 15 minutes or refrigerate immediately.	Bacteria grow quickly in urine, and specimen should be analysed immediately to obtain correct results.

RECORDING AND REPORTING

- Record date and time urine specimen was obtained, and place information in clinical progress notes.

HOME CARE CONSIDERATIONS

- If patient is to collect specimen as outpatient, proper instruction for collection needs to be given.
- Appropriate equipment will need to be given to patient and family.
- Information on storing specimen until time for delivery to local pathology service or hospital laboratory needs to be given.

for culture from a urine drainage bag. Bacteria grow rapidly in the drainage bags and could cause an inaccurate result. The aim is to obtain a fresh urine sample while maintaining the closed system between the catheter and the urine drainage bag. The sample needs to be drawn from the needleless sampling port in the drainage bag tubing. You should not disconnect the catheter from the drainage bag tubing, nor insert a needle into the catheter or the drainage bag tubing. The following steps should be undertaken:

- Inform the patient of the purpose of collecting the urine.
- Place the urine drainage bag tubing so that a loop near the drainage port is lying flat on the patient's bed or chair (so that urine will collect in the tubing). In some cases you may need to clamp off the tubing; however, make sure that you return to take the sample within 15 minutes so that urine does not build up in the bladder.
- After performing hand hygiene, put on non-sterile gloves.
- Assemble a sterile 10 mL syringe.
- If the specimen is for laboratory analysis, have a sterile pathology specimen container close by – do not touch the inside of the container or the lid. Make sure that the container is labelled with the patient's details and date and time of the specimen collection. Also make a note on the label that the urine was obtained from a patient with an indwelling catheter.
- Wipe the needleless port with an antimicrobial swab. When this has dried, carefully insert the hub of the syringe through the needleless port into the catheter lumen. Aspirate 5–10 mL of urine and remove the syringe from the sampling port. Transfer the urine into the sterile container using an aseptic technique (see Chapter 25).
- Return the drainage bag tubing to the usual position so that urine will flow freely into the drainage bag.
- Remove the gloves and properly dispose of equipment. Perform hand hygiene.

The specimen is transferred to the laboratory in a sealed plastic bag with the request slip for testing. It generally takes 24 hours to culture the bacteria and 48 hours to identify sensitivity to antimicrobial agents.

Collecting urine over a specific time period

Some tests of renal function and urine composition, such as measuring levels of adrenocortical steroids or hormones, creatinine clearance or protein quantitation tests, require collection of urine over 2-, 12- or 24-hour intervals. The urine is collected each time the person voids and placed in a specially labelled container over the prescribed period of time. The timed collection period begins after the person urinates. This sample is discarded and the collection begins at this time. You will need to inform the patient that all urine must now be collected, and note the starting time on the collection container and on the laboratory requisition. The person then collects all urine voided in the timed period. Each voiding is collected in a clean container and immediately emptied into the larger container. Any missed specimens will make test results inaccurate. The person should be reminded to void before defecating so that faeces or toilet paper do not contaminate urine. The person should void the last specimen at the end of the timed period. For example, for a 24-hour collection the person first voids at 0800. This sample is discarded and the 24-hour time period begins. All urine from this time onwards is saved until 0800 the next day. The person voids as close to 0800 as possible. This urine is added to the collection container and the time period is completed.

Collecting urine from children

Specimen collection from infants and children is often difficult. Adolescents and school-age children are usually able to cooperate, although they may be embarrassed. Preschool children and toddlers have difficulty voiding on request. Offering a young child fluid 30 minutes before requesting a specimen may help. Gain cooperation from the parents in obtaining the specimen.

A young child may be reluctant to void in unfamiliar receptacles. A potty-chair or large specimen container placed under the toilet seat is usually effective. For infants or toddlers who are not toilet-trained, clear plastic, single-use bags with self-adhering material (paediatric urine collector) can be attached over the child's urethral meatus. Specimens should not be obtained by squeezing urine from the nappy material. When the specimen is obtained, it is placed in a sterile container and labelled with the child's details and date and time of the specimen collection. Also, make a note on the label that the urine was obtained using a paediatric urine-collecting device.

Common urine tests

Urine tests include urinalysis, specific gravity and urine culture.

Urinalysis is a test commonly performed by nurses in all healthcare settings. The urine specimen should be fresh. The purpose of the urinalysis is to determine the constituents of the urine and determine the presence of abnormalities. Using standard infection control guidelines, dip the reagent strips

Figure 33-6 Checking urine test results of a chemical reagent strip (dipstick).

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

(often called dipsticks) into the urine, making sure that all of the reagent pads are submerged in the urine. Taking care to drain the urine off the dipstick, observe for a colour change in the time interval designated on the packaging (Figure 33-6). Various brands of urine dipsticks test for varying abnormalities. Typically the strips test for glucose, bilirubin, ketones, specific gravity, microscopic blood, pH, protein, urobilinogen, nitrites and leucocytes. The exact detail of the results of the urinalysis is recorded in the patient's clinical progress notes. Urine may also be sent to the laboratory where urinalysis is performed using specialised equipment. Table 33-3 lists normal values for a urinalysis.

Diagnostic examinations

There are many imaging and other diagnostic studies used to examine urinary tract structures.

Imaging procedures

ABDOMINAL X-RAY Also referred to as plain abdominal film or KUB (kidney, ureter, bladder), X-ray of the abdomen is commonly used to assess the gross structures of the urinary tract for abnormalities. It can determine size, symmetry, shape and location of the kidneys, ureters and bladder structures. It is also useful in showing calculi (if calcified) or tumours in these organs. In addition, the ribs or other surrounding support structures can be assessed for fractures or abnormalities. Lack of positive findings on the X-ray does not rule out the possibility of abnormalities in the urinary tract; additional diagnostic studies may be needed. No special preparation is needed prior to this procedure.

INTRAVENOUS UROGRAM (IVu) This technique enables visualisation of the collecting ducts and renal pelvis and outlines the ureters, bladder and urethra. Although this procedure is non-invasive, it requires the patient to receive an intravenous injection of a radio-opaque dye. Because the kidneys and ureters lie behind the intestines, it is necessary that the patient has bowel preparation to empty the intestines before the procedure. In many hospitals, non-contrast CT (see below) has replaced the IVU, especially for emergency evaluation of acute abdominal and flank pain.

RADIONUCLIDE TESTS Radionuclide tests such as renal scans allow indirect viewing of urinary tract structures after an intravenous injection of radioactive isotopes. The emissions from the radionuclides can be photographed by special cameras. The isotope can be detected without the need for bowel preparation. A very low dose of radioisotope is used. No precautions against radioactive exposure are needed except for the use of disposable gloves if the patient uses a bed pan or urinal to void. Rinse the bed pan or urinal and double-flush urine down the toilet to dilute any possible remaining radiation hazard.

After a radionuclide is injected, it circulates through the kidneys and is excreted. The renal scan measures radioactive concentrations. Except for the venepuncture, it is painless. The scanning procedure is completed in about 1 hour. Information pertaining to renal blood flow, anatomical structures and their excretory function can be obtained from this procedure.

COMPUTED TOMOGRAPHY (CT) AND MAGNETIC RESONANCE IMAGING (MRI) A CT is a computerised X-ray procedure used to obtain detailed images of structures within a selected plane of the body. The tomographic scanner is a large machine that contains specialised computers and X-ray detector systems that function simultaneously to photograph internal structures in thin, transverse cross-sections (Figure 33-7). The computer, through a series of complex manipulations, is able to 'reconstruct' the cross-sectional image as a recognisable photograph on the television monitor. With this procedure it is possible to see abnormal pathological conditions such as tumours, obstructions, retroperitoneal masses and lymph node enlargement. Although this procedure is non-invasive, in some examinations oral or intravenous contrast material is used to enhance the areas under study. If intravenous contrast is used, it may be necessary to administer a bowel-cleaning solution orally, especially if additional organs in the abdominal cavity will be examined.

MRI uses radio waves to alter magnetic fields produced by the body. So while it is an imaging procedure, it does not use radiation like the other procedures that have been discussed. It can produce images from any perspective and can generate dynamic images. The detail of the MRI scan can be enhanced with the use of an intravenous injection of a contrast media (Skennerton 2012).

ULTRASONOGRAPHY A valuable non-invasive diagnostic tool in the assessment of urinary disorders, ultrasonography or ultrasound makes use of high-frequency inaudible sound waves that reflect off tissue structures. Some of the sound waves are reflected back to the transducer as echoes; the velocity of the sound waves varies with tissue density. The patient is usually prone during the procedure, but can be positioned in a sitting position. Ultrasound is often used to identify gross renal structures and structural abnormalities of the kidneys or lower urinary tract, and to assist with percutaneous biopsy. Abnormalities such as tumours or cysts in the kidney are easily identified. If a Doppler is used with the transducer, examination of blood flow through the kidney can also be performed. This procedure is painless.

Endoscopic procedures

Endoscopy is the visual inspection of a hollow body organ with the aid of a fibre-optic instrument. A cystoscopy enables visualisation of the interior of the bladder and urethra. The

TABLE 33-3 Routine urinalysis – adults

Measurement and normal value	Interpretation
Dipstick examination	
Bilirubin (trace)	Positive in obstructive jaundice and hepatitis.
Blood (none)	Damage to glomeruli or tubules may allow red blood cells (RBCs) to enter the urine. Trauma, disease or surgery of the lower urinary tract also may cause blood to be present. In women, blood in a routine urine specimen may be contaminated with menstrual fluid
Glucose (none)	Diabetic patients have glucose in urine as a result of inability of tubules to reabsorb high glucose concentrations. Ingestion of high concentrations of glucose may cause some glucose to appear in urine of healthy people
Ketones (none)	Patients whose diabetes mellitus is poorly controlled experience breakdown of fatty acids. End-products of fat metabolism are ketones. Patients with dehydration, starvation or excessive aspirin usage also may have ketonuria
Leucocyte esterase (none)	Detects significant numbers of white blood cells (WBCs) which are suggestive of urinary tract infection (UTI). When combined with the nitrite test, it has a predictive value of 74% if both tests are positive
Nitrite (none)	Nitrites are produced by bacteria. It will be positive in UTI; however, a negative test does not rule out infection because some organisms do not produce nitrites (e.g. *Streptococcus faecalis*). Urine must be retained in the bladder for several hours for the reaction to take place
pH (4.5–8.0; average 5.0–6.0)	pH helps indicate acid–base balance. Urine that stands for several hours becomes alkaline. An acid pH helps protect against bacterial growth
Protein (none)	Normally protein is not present in urine. It is seen in renal disease because damage to glomeruli or tubules allows protein to enter urine
Specific gravity (1.016–1.022)	Specific gravity measures concentration of particles in urine. High specific gravity reflects concentrated urine, and low specific gravity reflects diluted urine Dehydration, reduced renal blood flow and increased antidiuretic hormone (ADH) secretion elevate specific gravity Overhydration, early renal disease and inadequate ADH secretion reduce specific gravity Dipstick evaluations may be falsely high when the urine pH is < 6 and falsely low when the pH is > 7
Urobilinogen (trace)	Positive in cirrhosis, chronic hepatic failure, hepatitis, hyperthyroidism
Microscopic examination	
Bacteria (normally none)	In symptomatic patients > 10^6/L colony count of bacteria indicates urinary tract infection
Casts (none)	Casts are cylindrical bodies whose shapes take on likeness of objects within the renal tubule. Types include hyaline, WBCs, RBCs, granular cells and epithelial cells. Their presence is always an abnormal finding and indicates renal alterations
WBCs	> 10 × 10^6 white blood cells is suggestive of UTI

Shutterstock.

cystoscope is inserted through the patient's urethra into the bladder. The instrument has an outer plastic or rubber sheath, an obturator that keeps the scope rigid during insertion, a telescope for viewing the bladder and urethra, and a channel for inserting catheters or special surgical instruments.

A flexible cystoscopy is performed using local anaesthesia (xylocaine gel) which is inserted into the urethra prior to inserting the endoscope. During the test, urine and tissue specimens may be collected. This procedure can be performed in an operating room or in a procedure room in a clinic. In some hospitals, registered nurses who have undertaken specific education perform this procedure, especially in situations where patients are having frequent procedures to monitor bladder tumours. This test is commonly performed as an outpatient.

The person may eat and drink as normal prior to the test and will be able to leave the hospital shortly after the procedure. They should be encouraged to observe their urine for signs of bleeding or infection and be advised to increase fluid intake.

Urodynamic testing

Urodynamics is the general name given to a series of diagnostic tests that measure lower urinary tract pressure, flow and electrical response (McCooty & Latthe 2013). A cystometrogram (CMG) is one such test that determines the level of function of the detrusor muscle. This test is used to determine the type and degree of urinary incontinence. A catheter is inserted, residual volume is measured and discarded and the bladder is filled with sterile saline in predetermined increments. Pressure readings are taken at those increments. During the filling time, the patient's perceptions related to bladder fullness, urge to void and the ability to inhibit voiding are documented.

Patient expectations

People depend on their caregivers to recognise and meet their needs. The person with needs related to urinary function expects that the nurse will be respectful of privacy needs and sensitive to the impact of urinary impairments on their quality of life and self-concept. The person should be included in the plan of care and in the development of goals that are mutually acceptable. Cultural practices and personal preferences should also be considered.

• CRITICAL REFLECTION POINT

Mrs Baker is a 37-year-old woman who has been admitted to the day surgery centre for a cystoscopy. She has noticed blood in her urine for several weeks.

1. **What is the purpose of the cystoscopy?**
2. **What advice would you give her following the procedure?**

BOX 33-2 Examples of priority problems associated with urinary elimination

- Incontinence (specify type)
- Pain
- Self-care deficit, toileting
- Skin integrity, impaired or risk for impairment of skin integrity
- Risk for urinary tract infection
- Urinary retention (acute or chronic)

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

A thorough assessment of the patient's urinary elimination function reveals patterns of data that allow the nurse to make relevant and accurate nursing diagnoses. The diagnosis may be an actual problem or a problem that the patient is at risk of developing (Box 33-2).

The diagnosis may focus on a specific urinary elimination alteration or on associated problems such as impaired skin integrity related to urinary incontinence. Identification of defining characteristics leads the nurse to select an appropriate diagnosis (Box 33-2). Specifying related factors for each diagnosis allows selection of individualised nursing interventions.

Planning

Critical thinking ensures that the patient's plan of care integrates knowledge about the individual as well as key critical thinking elements (Figure 33-8). Professional standards are especially important to consider when developing a plan of care. These standards often establish scientifically proven guidelines for selecting effective nursing interventions.

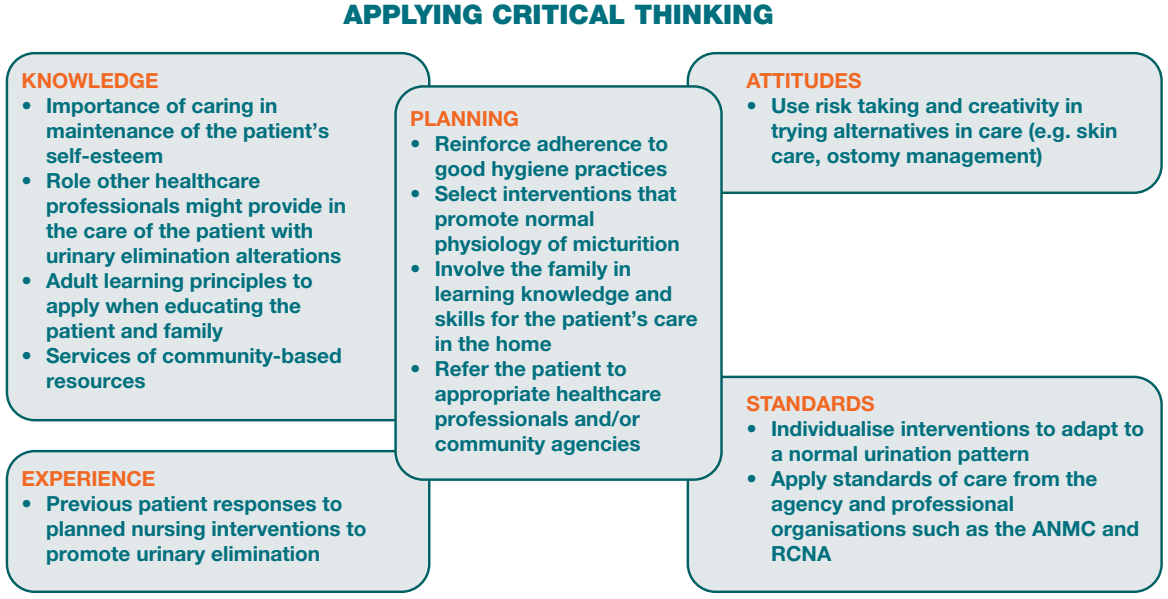

Figure 33-8 Critical thinking associated with the planning phase for urinary elimination.

The plan incorporates health promotion activities and therapeutic interventions for people with urinary elimination problems. Preventive interventions may be required for patients at risk of urinary problems. It is important in the nursing process to consider the patient's home environment and normal elimination routines when planning therapies. In planning care for some patients, consultation with other healthcare professionals may be needed. For example, the physiotherapist can design an exercise plan to increase strength and endurance so the patient will be able to walk to the bathroom.

SETTING PRIORITIES AND ESTABLISHING GOALS

Planning care also involves an understanding of the person's need to control body function. Alterations in urinary elimination can be embarrassing, uncomfortable and often frustrating. General goals for the person may include:

- understanding normal urinary elimination
- promoting normal voiding
- achieving complete bladder emptying
- preventing infection
- maintaining skin integrity
- gaining a sense of comfort.

Setting priorities

Problems involved with alterations in urinary elimination are often interrelated and complex. You also need to anticipate problems that may develop as a result of therapy. For example, the diagnosis of risk of infection is appropriate when a patient has an indwelling catheter. Determining the most imperative diagnosis will depend on each individual patient's condition.

Continuity of care

For hospitalised people, planning should include preparations for discharge; for example, assessment of the need for any aids that will be required and the person and their family educational needs. Health education is important in enabling people to care for themselves. For example, a patient being discharged with an indwelling catheter will need to perform catheter care, understand ways to empty the drainage bag safely, measure urine accurately and know signs and symptoms

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data*

Jenny Smith (a registered nurse) is assisting Mrs Christine Bryant to have a shower. Mrs Bryant, 81 years of age, was admitted to the orthopaedic ward 5 days previously via the emergency department after sustaining a fractured pubic ramus from a fall in the backyard of her house. She has a medical history of osteoporosis and has been taking weekly strontium (Protos) for the past 2 years. She is otherwise well and does not take any regular medication. She is active in the local bowls club and is involved in local community groups. She lives with her husband (84 years old), who has chronic obstructive pulmonary disease and macular degeneration, which limits his activities to staying around the house. Since admission she has been on bed rest and has been getting up to go to the toilet and shower with assistance and a gutter frame walker. She is taking oxycodone (OxyNorm) for pain which has good effect when she is resting; however, she finds walking very painful. While in the shower she tells Jenny that she has been **losing urine on the way to the toilet**, especially if there is a delay in the nurse coming to assist her after she rings the call bell. Jenny tells her she will assist her to get dried and dressed and they can talk about this further.

The assessment reveals the following data:

- **Normally has no urinary incontinence**, never needs to use a pad.
- **No other LUTS – no frequency, urgency or dysuria**. She **feels she can hold on a long time but because she needs assistance** it sometimes takes a long time for a nurse to give her assistance to get to the toilet. She says that she is reluctant to call for help because 'the nurses are so busy'.
- **Only small amounts of urine lost – only on walking to the toilet when she has a very full bladder.** Gets up once at night to go to the toilet.
- **Normally no loss of urine on sneezing or coughing except when she has a very full bladder.**
- History of **three vaginal births** (all over 3.5 kg birthweight); 1st delivery with forceps.
- No history of constipation. Bowels open yesterday – Bristol type 3.
- **Eating and drinking normally** – drinking 5 cups of tea per day and water (approx. 1L).
- Beginning to mobilise well with assistance. Likelihood of a two-week hospital stay.
- Abdominal examination – soft abdomen, bowel sounds in all four quadrants.
- Skin on upper thighs and perineum intact and healthy.
- Urine analysis – urine clear, pH 6.5, no abnormalities detected.

** Important data to cluster in setting priorities in bold.*

Priority problems

Functional incontinence. Mild stress incontinence (when bladder very full) related to weakened pelvic floor muscles (age and childbirth).

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Mrs Bryant will have reduced episodes of incontinence within 2 days.	Mrs Bryant will report less-frequent episodes of incontinence.
Preparing for and taking action	**Rationale**
• Ensure that the call bell is readily available at all times. Alert all nursing staff at handover of the need to attend to Mrs Bryant's call bell promptly.	Reduces the likelihood that she will have a very full bladder. Gives her more time to get to the toilet within current mobility constraints.
• Health education regarding: – the need to call for assistance when she first feels the need to void – that she is not causing a problem for the nursing staff – the importance of strong pelvic floor muscles – the importance of not becoming constipated. – the need to keep drinking fluids, especially water.	Encourages Mrs Bryant to feel empowered to take control and not feel a burden on nursing staff Motivates her to participate in PFM training. Makes it easy for her to be independent without risk of falling. Pelvic floor exercises strengthen the muscles that control continence; 4–6 weeks of exercises will result in decreased leakage.
• Trial of having a commode chair beside her bed at night. Instruct Mrs Bryant on safely standing out of bed and transferring to the commode chair. Have her demonstrate this.	
• Instruct Mrs Bryant in how to do pelvic floor exercises.	

Evaluating impacts and outcomes

- Evaluate the change in frequency of incontinence episodes (use voiding diary).
- Ask Mrs Bryant about satisfaction with bladder control.

of urinary infection. The need for home health services should be explored, and appropriate referrals should be made. Good discharge planning will result in the person's smooth transition from healthcare agency to home.

PREPARING FOR AND TAKING ACTION

Promotion of normal voiding patterns

There are many nursing interventions to promote normal voiding in people at risk of urinary elimination difficulties and in people with established urinary elimination health problems. The nurse can initiate many of these interventions independently.

Provide privacy and time to void

Encourage people not to rush voiding so that their bladder empties fully. Privacy is essential. If they cannot reach the bathroom, make sure that a curtain encloses the bedside area. In the home, the debilitated person may prefer using a bedside commode enclosed behind a partition or room divider. Some patients are embarrassed by the sound of voiding. Running water or flushing the toilet masks the sound. Young children are often unable to void in the presence of persons other than their parents.

It is very important to respond to patients' need to urinate in a timely manner. Delay in helping patients to the bathroom may interfere with normal voiding and contribute to incontinence. Attempts by frail older people or those with a disability or a mobility problem to get to the toilet alone can contribute to falls (Gosch et al 2014).

Stimulating micturition reflex

It is often difficult for hospitalised patients to void due to the effects of surgery, an anaesthetic, pain or medications. The patient's ability to void depends on feeling the urge to urinate, being able to control the urethral sphincter and being able to relax during voiding. You can help a patient learn to relax and stimulate the reflex to void by assuming the normal position for voiding. A woman is better able to void in a sitting position, leaning forward with feet flat on the floor. This position promotes contraction of the pelvic and intra-abdominal muscles which assist in sphincter control and bladder contraction. If the patient is unable to use toilet facilities, assist the person to position themselves in a semi-squatting position on a bed pan or bedside commode. A man voids more easily in the standing position. If the man cannot reach the toilet, he may stand at the bedside and void into a urinal (a metal or plastic receptacle for urine) (Figure 33-9). At times it may be necessary for one or more nurses to assist a man to stand.

Other measures that promote relaxation and the ability to void include sensory stimuli. The sound of running water may help the patient void through the power of suggestion. If the patient

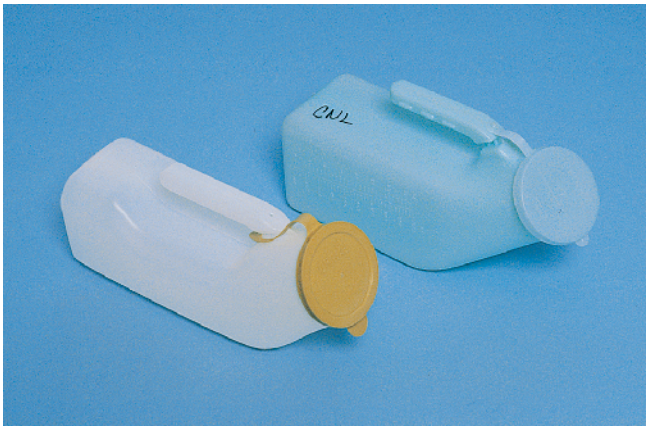

Figure 33-9 Types of male urinals.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

is confined to bed the nurse can also pour warm water over their perineum and create the sensation to urinate. If urine output is to be measured, the nurse must first measure the volume of water to be poured over the perineal area. Offering fluids the patient will drink may also promote voiding.

Maintaining adequate fluid intake

A simple method of promoting normal micturition is by maintaining good fluid intake. A person with normal renal function who is not on fluid restriction should drink 1500–2000 mL of fluid daily. However, an average daily intake of 1200–1500 mL of fluids is usually adequate (in hot weather, increase fluid intake to compensate for increased loss through perspiration).

When fluid intake is increased, the excreted urine flushes out solutes or particles that may collect in the urinary system. Because a person may be unwilling to drink 2000 mL of water daily, encourage fluids that the patient prefers. Many vegetables and fruits also have a high fluid content. At home it may help to set a schedule for drinking fluids (e.g. with meals or medications).

Maintaining normal bowel function

Constipation can cause obstruction of the urethra and contribute to a sense of urinary urgency. Promotion of normal bowel function needs to be part of the care plan for any patient who has a urinary elimination problem. See Chapter 32 for details on promoting normal bowel function.

Patient education

The success of therapies aimed at eliminating or minimising urinary elimination problems depends in part on the person understanding their urinary elimination problem. For example, people who experience recurrent UTIs may benefit from learning about normal sterility of the urinary tract and ways to prevent infection. Health teaching can be incorporated when giving nursing care, for example, discussing the benefits of increasing fluid intake while giving fluids with medications or meals.

Catheterisation

Catheterisation of the bladder involves introducing a tube, usually made of silicone- or hydrogel-coated latex, through the urethra and into the bladder. The catheter provides a continuous flow of urine in people unable to control voiding or those with a urethral obstruction. It also provides a means of assessing hourly urine output in haemodynamically unstable patients. Because bladder catheterisation carries the risk of UTI and trauma to the urethra, it is preferable to rely on other measures for either specimen collection or management of incontinence.

WORKING WITH DIVERSITY

Focus on cultural care

The Victorian Continence Resource Centre conducted a project titled 'Awareness of incontinence in ethnic communities'. The aim of the project was to explore the awareness of people from different ethnic communities in relation to the prevention, treatment and management of incontinence.

Twenty focus groups were undertaken in selected ethnic communities in Victoria. Participants (n = 218) included older men and women, and middle-aged women (167 female and 52 male). The communities represented included Arabic-speaking, Chinese, Greek, Italian, Polish, Vietnamese, Macedonian, Russian, Spanish-speaking and Turkish. Interpreters were used when needed.

Key findings included:

- Knowledge of incontinence was low across all ethnic groups.
- Not all languages have a term to describe 'incontinence', or the translated term often has a negative or detrimental meaning.
- Limitation to social participation was a common impact of incontinence.
- Incontinence could lead to religious restriction for Muslim men and women.
- Cultural and religious influences were expressed in relation to preferences for information in a specific language and for healthcare professionals who spoke their language or were a specific gender.
- Communication and language barriers were perceived to limit access to information and support services.

Methods of achieving drainage of the urinary tract

There are several methods for achieving drainage of the urinary tract:

- *Indwelling urethral catheterisation* A self-retaining indwelling urethral catheter (Foley catheter) has a small inflatable balloon that encircles the catheter just below the tip. When inflated, the balloon rests against the bladder outlet to anchor the catheter in place. The indwelling retention catheter also has two or three lumens within the body of the catheter (Figure 33-10B). One lumen drains urine through the catheter to a collecting tube. A second lumen carries sterile water to and from the balloon when it is inflated or deflated. A third (optional) lumen may be used to instil fluids or medications into the bladder. It is easy to determine the number of lumens by the number of drainage and injection ports at the catheter's end. An indwelling catheter is used when constant drainage is required, for example, when there has been surgery to the abdomen or pelvic area, or when accurate measurement of urine is required. Indwelling catheters can be left in for long periods of time. It is necessary to change indwelling catheters periodically – usually every 6–8 weeks, depending on the individual's requirements.
- *Intermittent catheterisation*. With the intermittent technique, a straight single-use catheter (Figure 33-10A) is introduced long enough to drain the bladder (5–10 minutes). When the bladder is empty, the catheter is withdrawn. The straight single-use catheter has a single lumen with a small opening about 1.3 cm from the tip. Urine drains from the tip, through the lumen, to a receptacle. Intermittent catheterisation can be repeated as necessary, usually several times per day. Some people require intermittent catheterisation for many months or years and are taught to catheterise themselves; this is termed intermittent self-catheterisation (ISC).
- *Suprapubic catheterisation*. A suprapubic catheter is surgically inserted into the bladder via a puncture wound on the lower abdomen. These are used in patients who have chronic retention of urine, neurological disease (such as spinal cord injury or multiple sclerosis), prior pelvic or gynaecological surgery, urethral trauma or those who require long-term drainage of urine (Tompkins et al 2014). They can be more comfortable for people who require long-term urinary drainage. Suprapubic catheters are self-retaining – they have a balloon at the catheter tip. Suprapubic catheters need to be changed the same way that indwelling urethral catheters are changed. Registered nurses who have had appropriate training are able to change these catheters.
- *Other methods* to achieve drainage from the urinary tract. There are several other devices that can be used to drain urine from the upper urinary tract. Nephrostomy tubes are surgically inserted in the flank region straight into the pelvis of the kidney. These are used when there is obstruction in the upper ureter from urinary calculi or tumours or resulting from oedema when there has been surgery to the upper tract. A sterile drainage bag is applied to the person's skin and urine can drain freely. Stents can also be endoscopically inserted into the ureter so that drainage is maintained.

Catheters come in many diameters to fit the size of a patient's urethra. Suggestions on catheter selection are provided in Box 33-3.

INDICATIONS FOR CATHETERISATION Catheterisation may be indicated for many reasons. When catheterisation time will be short and minimising infection is a priority, the intermittent method is best. Intermittent catheterisation is also preferred for people who have chronic retention of urine (without urethral obstruction), such as a person with diabetes who has developed an atonic bladder. By intermittently draining the bladder on a routine basis, these patients have fewer infections (Bermingham et al 2013). Indwelling catheterisation is used when long-term bladder emptying is necessary. Box 33-4 outlines specific indications for catheterisation.

CATHETER INSERTION Urethral catheterisation may require a medical prescription. Aseptic technique is used to minimise the risk of introducing microorganisms into the bladder (see

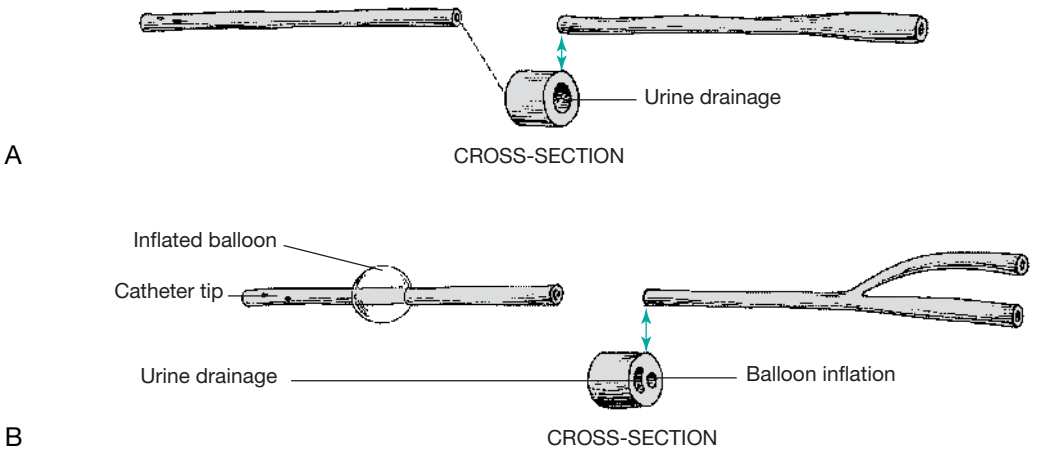

Figure 33-10 Types of urinary catheters.

A, Non-retaining or straight catheter. B, Self-retaining indwelling (Foley) catheter.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

BOX 33-3 Guidelines for appropriate catheter selection

- The catheter size should be determined by the size of the person's urethral canal. When the French system (Charrière or French Gauge) is used, the larger the gauge number, the larger the catheter size. One Charrière is ⅓ of a millimetre. Generally, children require an 8–10 FG, women require a 12–14 FG and men require a 16–18 FG. To prevent trauma, the smallest effective catheter size is preferred
- The expected time required for the catheterisation will determine the catheter material selection
  - PVC catheters are suitable only for intermittent use due to their inflexibility
  - Silicone-coated latex catheters are recommended for use up to 1 month – although these are usually only used for short periods (1 week)
  - Hydrogel-coated catheters are recommended for use up to 3 months; these are comfortable for the person as they cause little friction in the urethra
  - Pure silicon catheters are best suited for long-term use (2–3 months), as they cause less encrustation at the urethral meatus. They have a large lumen as they are not coated
- Balloon size is also important in selecting an indwelling catheter. Use the smallest balloon size possible, as a large balloon can cause irritation at the bladder neck
  - Balloon sizes range from 3 mL for babies and children to 5–30 mL for adults. In adults, the 10 mL is the most common. A 30 mL size is used after prostate surgery to provide haemostasis of the prostatic bed
- Only sterile water should be used to inflate the balloon as saline may crystallise, resulting in incomplete deflation of the balloon at the time of removal

Adapted from Australian and New Zealand Urological Nurses Society 2013 Catheterisation clinical guidelines. Online. Available: www.anzuns.org/wp-content/uploads/2011/12/ANZUNS-Catheterisation-final-Document-October-20131.pdf; accessed 19 Feb 2016.

BOX 33-4 Indications for catheterisation

- Relief of acute or chronic urinary retention
- Measurement of urinary output in acutely ill patients:
  - to bypass an obstruction (e.g. enlarged prostate, tumour or clot)
  - to assist with drainage of urine in patients with neurogenic bladder dysfunction who cannot manage intermittent self-catheterisation
  - to empty the bladder prior to procedures or surgery
- Following surgery on the bladder, urethra and surrounding structures:
  - to permit continuous or intermittent bladder irrigation or instil medication
  - to protect skin from urine (e.g. serious decubitus ulcers of the buttocks, burns to thighs)
  - to alleviate discomfort in terminally ill patients
  - to determine residual urine volume in the absence of ultrasound equipment (bladder scanner)
  - to manage intractable incontinence (only a last resort).

Adapted from Australian and New Zealand Urological Nurses Society 2013 Catheterisation clinical guidelines. Online. Available: www.anzuns.org/wp-content/uploads/2011/12/ANZUNS-Catheterisation-final-Document-October-20131.pdf; accessed Feb 2016.

Chapter 25). The steps for inserting indwelling and single-use straight catheters are basically the same. The difference lies in the procedure taken to inflate the indwelling catheter balloon and secure the catheter. Skill 33-2 lists steps for performing female and male urethral catheterisation.

CLOSED DRAINAGE SYSTEMS After inserting an indwelling catheter, a closed urinary drainage system is maintained to minimise the risk of infection. Urinary drainage bags are plastic and can hold about 1000–1500 mL of urine. The bag should hang on the bed frame or wheelchair without touching the floor. When the patient moves about, the nurse or patient carries the bag below the patient's waist. The drainage bag should never be raised above the level of the patient's bladder, so that urine does not flow back from the tubing into the bladder.

Most drainage bags contain an anti-reflux valve to prevent urine in the bag from re-entering the drainage tubing and contaminating the patient's bladder. A valve at the base of the bag provides a means for emptying the bag. The valve should always be closed, except during emptying, and tucked into the protective pouch on the side of the bag. To keep the drainage system patent, frequently check for kinks or bends in the tubing, avoid positioning the patient on the drainage tubing and observe for clots or sediment that may occlude the collecting tubing.

For the person who will go home from hospital with an indwelling urinary catheter, a smaller leg bag is connected to the catheter. Leg bags are designed to be strapped to the person's leg so that they can carry on their usual daily activities without having to carry a large urine bag. Because the leg bag only holds approximately 500 mL of urine, it will need to be emptied frequently throughout the day. This can easily be done into a toilet or plastic jug. A larger overnight bag is connected (at the base of the leg bag) before the person goes to sleep so that their sleep is not interrupted by the need to empty the smaller leg bag.

ROUTINE CATHETER CARE Patients with indwelling catheters have a number of special care needs. Nursing interventions are directed at preventing infection and maintaining an unobstructed flow of urine through the catheter drainage system.

Perineal hygiene Build-up of secretions or encrustation at the catheter insertion site is a source of irritation and potential infection. The person can shower normally with a catheter, and they should be encouraged to use mild soap and water to wash their genital area at least daily. If the person is unable to shower on their own they will need assistance with their personal hygiene either in the shower or during a bed bath.

Fluid intake All patients with catheters should be encouraged to have a daily intake of 2000–2500 mL of fluid if not contraindicated. This can be achieved through oral intake or intravenous infusion. A high fluid intake produces a large volume of urine that flushes the bladder and keeps the catheter tubing free of sediment.

Bowel care As mentioned previously, constipation can affect urinary elimination. Promotion of normal bowel elimination is also important in catheterised patients. Assessment of bowel function should be conducted daily.

Ongoing assessment A patient who has a urinary catheter needs focused assessment at least three times per day (once per shift). The assessment should include:

- daily inspection of the urethral meatus for signs of inflammation and leakage of urine
- checking of the closed drainage system for patency
- inspection of the urine for colour and clarity
- abdominal palpation for bladder distension
- checking that the catheter is secured to the upper thigh or lower abdomen with an appropriate device such as a catheter strap.

PREVENTING INFECTION The most common cause of infection in hospitalised patients is the introduction of instruments into the urinary tract. For example, the introduction of a catheter through the urethra provides a direct route for microorganisms. Catheter associated urinary tract infection (CAUTI) is said to be one of the most common healthcare-associated infections worldwide (Krein & Saint 2014). A CAUTI is a symptomatic UTI in a person with a urinary catheter. According to Lo et al (2014), the risk of bacteriuria varies from 3% to 7% per day when an indwelling urethral catheter remains in situ. Hence, a goal of care is to remove the urinary catheter as soon as possible.

Bacteria ascend along the outside of the catheter on the urethral wall or travel up the catheter's lumen. The catheter interferes with the normal voiding mechanism that acts as a defence against organisms entering the urethra. Local irritation to the urethra or bladder further predisposes tissues to bacterial invasion.

Pooling of urine in the drainage bag tubing should also be avoided. Urine in the drainage bag is an excellent medium for microorganism growth. Bacteria can travel up drainage tubing to grow in pools of urine in the tubing. If this urine flows back into the patient's bladder an infection is likely to develop. Bacteria can also enter the bladder at the connection between the catheter and the drainage bag. Maintaining a closed urinary drainage system is important in infection control, as a break in the system can lead to introduction of microorganisms. Suggestions for ways to prevent infections in catheterised patients are provided in Box 33-5.

REMOVAL OF INDWELLING URETHRAL CATHETER The aim when removing an indwelling catheter is to prevent trauma to the urethra.

The equipment required to remove a catheter is a disposable towel or plastic bed protection pad; a rubbish receptacle; and a sterile syringe the same size as the volume of the catheter balloon. The distal end of each catheter contains a label that denotes the volume of solution (5–30 mL) within the balloon. Standard infection control precautions are also required (hand hygiene and non-sterile gloves).

- Explain the procedure to the person. The removal of the catheter is likely to cause minor discomfort but is unlikely to be painful.
- Position the person comfortably lying down with legs slightly apart.

BOX 33-5 Tips for preventing infection in catheterised patients

- Follow hand hygiene guidelines (see Chapter 29)
- Maintain a closed system – catheter, drainage tubing and drainage bag
- Do not open the drainage system at connecting points to collect specimens
- If the drainage tube becomes disconnected, do not touch the ends of the catheter or tubing. Wipe the end of the tubing and catheter with an antimicrobial solution before reconnecting
- Prevent pooling of urine in the tubing and reflux of urine into the bladder:
  - avoid raising the drainage bag above the level of the bladder
  - avoid allowing large loops of tubing to lie on the bed
  - provide for drainage of urine from the tubing to the bag by positioning the tubing
  - before exercise or walking, drain urine from the tubing into the drainage bag
- Do not allow the drainage port on the drainage bag to touch the floor
- Empty the drainage bag at least every 8 hours. If large outputs are noted, empty more frequently
- Remove the catheter as soon as clinically warranted
- Secure the catheter appropriately for the patient (see Skill 33-2)

- After removing catheter-securing devices such as a catheter strap, place the towel/bed protection pad between a female patient's thighs or over a male patient's thighs.
- Insert the syringe into the balloon port. Slowly withdraw all of the solution to totally deflate the balloon. If a portion of the solution remains, the partially inflated balloon will traumatise the urethra and cause pain as the catheter is removed.
- When all of the solution from the balloon has been aspirated, pull the catheter out smoothly and slowly. If the balloon does not deflate or you have trouble removing the catheter, do not cut the tubing. Refer the problem to a specialist clinical nurse (e.g. a urology or continence nurse) or a medical practitioner.

It is normal for the patient to experience some dysuria post catheter removal, especially if the catheter has been in place for several days or weeks. The catheter causes inflammation of the urethra. Until the bladder regains full tone and capacity, the person may also experience frequency of urination or urinary retention.

Assess the person's urinary function by noting the time of first voiding after catheter removal, and document the time and amount of voiding for the next 24 hours. Encourage the person to drink plenty of water. If the voided amounts are small (less than 100 mL), frequent assessment for retention of urine is

SKILL 33-2

Inserting a straight or indwelling catheter

Delegation considerations

Catheterisation requires the problem-solving and knowledge-application skills of registered nurses; therefore, delegation of this task to nurse assistants or personal care workers is inappropriate.

Insertion of a urinary catheter normally requires a medical request.

Equipment

- Catheterisation kit containing the following sterile items:
  - Gloves (extra pair optional)
  - Drapes, one fenestrated
  - Lubricant (usually water-based for women and xylocaine gel (2%) in a pre-filled syringe for men/or women)
  - Antiseptic cleaning solution (aqueous chlorhexidine), Normal saline or sterile water
  - Gauze swabs
  - Forceps
  - Syringe with sterile water to inflate the balloon of indwelling catheter
  - Receptacle or basin (usually bottom of disposable catheterisation tray)
- Blanket/large towel to cover patient
- Catheter of correct size and type for procedure (i.e. intermittent or indwelling)
- Sterile urine drainage bag
- Catheter strap or other catheter-securing device
- PPE – safety goggles
- Lamp/torch

Therapeutic relationship and patient considerations

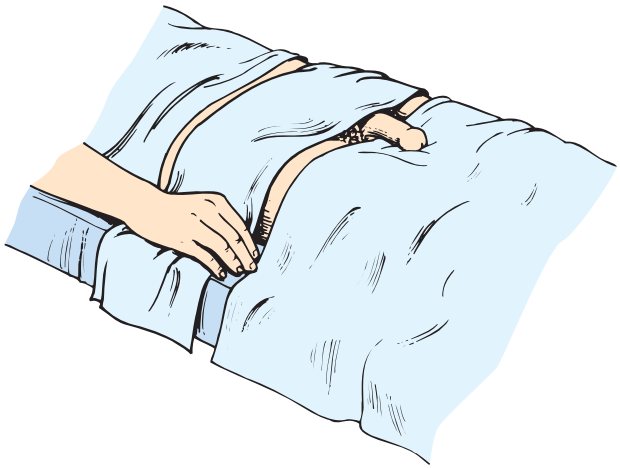
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess the general health status of patient:	
a. Time of last urination; ask patient, check fluid balance chart	
b. Level of education, health literacy and developmental stage	Reveals the patient's ability to cooperate and level of explanation needed.
c. Mobility and physical limitations of patient	Affects way the nurse positions patient.
d. Patient's gender and age	Determines catheter size: see Box 38-4.
e. Distended bladder – use a portable ultrasound bladder scanner or palpate bladder	Causes pain. Can indicate need to insert catheter if patient is unable to void independently. Bladder fullness may be detected with deep palpation above the symphysis pubis or with a portable ultrasound bladder scanner.
f. Perineum erythema, drainage and odour	Determines condition of the perineum.

STEPS	RATIONALE
g. Any pathological condition that may impair passage of catheter (e.g. enlarged prostate in men)	Obstruction prevents passage of catheter through urethra into the bladder.
h. Allergies	Determines allergy to antiseptic (if aqueous chlorhexadine is used), tape, latex and lubricant (xylocaine gel).
2. Review patient's medical record, including medical request and nurses' clinical progress notes.	Determines purpose of inserting catheter. Assess for previous catheterisation, including catheter size, response of patient and time of last catheterisation; history of previous difficult catheterisation procedure.
3. Assess patient's knowledge of the purpose of catheterisation.	Reveals need for patient instruction.
4. Explain procedure to patient and gain the patient's consent for the procedure.	Promotes cooperation.
5. Arrange for extra nursing personnel to help as necessary.	Patient may be unable to assume positioning for procedure.
6. Perform hand hygiene.	Reduces transmission of microorganisms.
7. Close curtain or door.	Offers privacy, reduces embarrassment and aids in relaxation during procedure.
8. Raise bed to appropriate working height.	Promotes use of proper body mechanics.
9. Facing patient, stand on left side of bed if right-handed (on right side of bed if left-handed). Clear the bedside table and arrange equipment.	Successful catheter insertion requires nurse to assume comfortable position with all equipment easily accessible. The materials in the kit are arranged in sequence of use.
10. Raise side rail on opposite side of bed, and put side rail down on working side.	Promotes patient safety.
11. Place waterproof pad under patient.	Prevents soiling of bedclothes.
12. **Position patient.**	Provides good view of perineal structures.
A. Female patient	
(1) Help into dorsal recumbent position (supine with knees flexed). Ask patient to relax thighs so the hips can be externally rotated.	Legs may be supported with pillows to reduce muscle tension and promote comfort.
(2) Position female patient in side-lying (Sims') position with upper leg flexed at hip if unable to be supine. Support patient with pillows if necessary to maintain position.	This position is used if patient cannot abduct leg at hip joint (e.g. if patient has arthritic joints). Also, this position may be more comfortable for patient.

STEPS	RATIONALE
B. Male patient	
(1) Help into supine position with thighs slightly abducted.	Comfortable position for patient that gives good view.
13. **Drape patient:** **A. Female patient** (see illustration) Drape with blanket/towel. Place blanket diamond-fashion over patient, with one corner at patient's neck, side corners over each arm and side, and last corner over perineum. **B. Male patient** (see illustration) Drape upper trunk with blanket/towel, and cover lower extremities with bed sheets, exposing only genitalia.	Avoids unnecessary exposure of body parts and maintains patient's comfort.

Step 13A Draping technique (female).



Step 13B Draping technique (male).

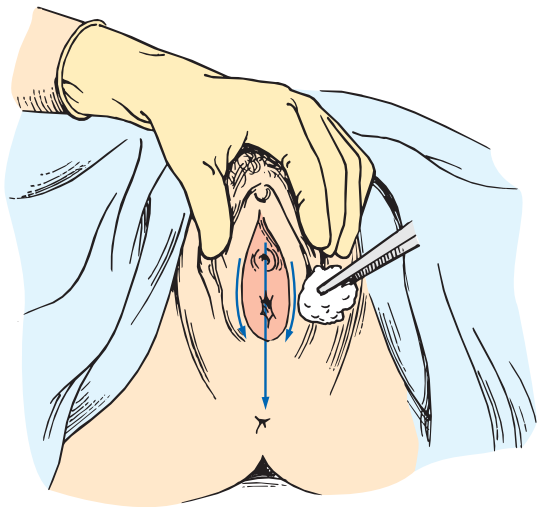
14. Position lamp (if necessary) to illuminate perineal area. (When using torch, have an assistant hold it.)	Permits accurate identification and good view of urethral meatus.
15. Wearing non-sterile gloves, wash perineal area with mild soap and water as needed; dry.	Reduces microorganisms near urethral meatus and allows further opportunity to see perineum and landmarks.
16. For men: take pre-filled syringe of xylocaine gel (2%). Insert tip of syringe into the urethral meatus, holding the penis firmly and straight. Gently instil the gel into the urethra. Ask the man to hold the end of his penis to stop the gel coming out.	Wait several minutes before inserting the catheter so that the anaesthetic agent has time to take effect.

STEPS	RATIONALE
17. Remove and discard gloves; perform hand hygiene.	Prevents transmission of microorganisms from table or work area to sterile supplies.
18. Open package containing drainage system; place drainage bag over edge of bottom bed frame, and bring drainage tube up between side rails and mattress (indwelling catheter only).	
19. Perform hand hygiene. Open catheterisation kit according to directions, keeping bottom of container sterile. Don PPE – safety goggles.	
20. Put on sterile gloves (see Chapter 29).	Allows nurse to handle sterile supplies without contamination.
21. Organise supplies on sterile field. Open inner sterile package containing catheter. Pour sterile cleansing solution into correct compartment containing sterile gauze squares. Open sterile packet containing lubricant. Open catheter onto sterile field.	Maintains principles of surgical asepsis and organises work area.
22. Lubricate 2–5 cm of catheter for women and 12–18 cm for men.	
23. **Apply sterile drape:**	
A. Female patient	
(1) Allow top edge of drape to form a cuff over both hands. Place drape down on bed between patient's thighs. Slip cuffed edge just under buttocks, taking care not to touch contaminated surface with gloves.	Outer surface of drape covering hands remains sterile. Sterile drape against sterile gloves is sterile.
(2) Pick up fenestrated sterile drape, and allow it to unfold without touching an unsterile object. Apply drape over perineum, exposing labia, and being sure not to touch contaminated surface.	Maintains sterility of work surface.
B. Male patient	
(1) Two methods are used for draping depending on preference. First method: apply drape over thighs and under penis without completely opening fenestrated drape. Second method: apply drape over thighs just below penis. Pick up fenestrated sterile drape, allow it to unfold and drape it over penis with fenestrated slit resting over penis.	Maintains sterility of work surface.
24. Place sterile tray and contents on sterile drape.	Provides easy access to supplies during catheter insertion. Maintains aseptic technique during procedure.

STEPS	RATIONALE
25. Clean urethral meatus:	
A. Female patient	
(1) With non-dominant hand, carefully retract labia to fully expose urethral meatus. Maintain position of non-dominant hand throughout procedure.	Full view of urethral meatus is provided. Full retraction prevents contamination of urethral meatus during cleaning.
(2) Using forceps in sterile dominant hand, pick up gauze square saturated with cleansing solution/sterile water and clean perineal area, wiping from front to back from clitoris towards anus. Using a new gauze square for each area, wipe along the far labial fold, near labial fold and directly over centre of urethral meatus (see illustration).	Cleaning reduces number of microorganisms at urethral meatus. Use of a single gauze square for each wipe prevents transfer of microorganisms. Cleaning proceeds from area of least contamination to that of most contamination. Dominant hand remains sterile.

■ **Critical decision point: Closure of labia during cleaning requires that the cleaning procedure be repeated because the area has become contaminated.**

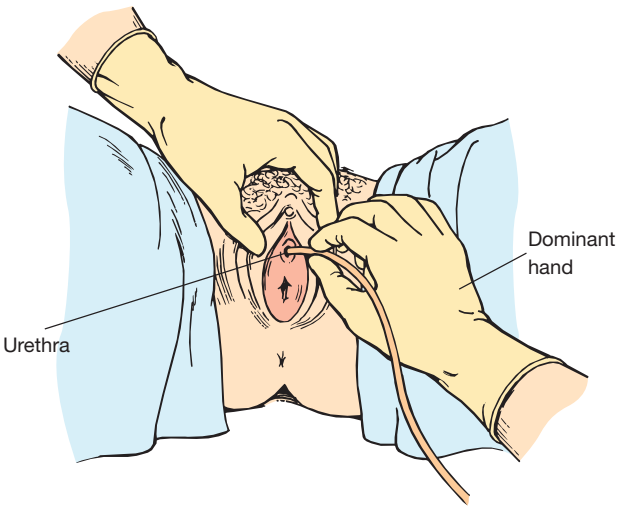
B. Male patient	
(1) If patient is not circumcised, retract foreskin with non-dominant hand. Grasp penis at shaft just below glans. Retract urethral meatus between thumb and forefinger. Maintain non-dominant hand in this position throughout procedure.	Accidental release of foreskin or dropping of penis during cleaning requires process to be repeated because area has become contaminated.
(2) With dominant hand, pick up gauze square with forceps and clean penis. Move in a circular motion from urethral meatus down to base of glans. Repeat cleaning three more times, using a clean gauze square each time (see illustration).	Reduces number of microorganisms at urethral meatus and moves from area of least to most contamination. Dominant hand remains sterile.



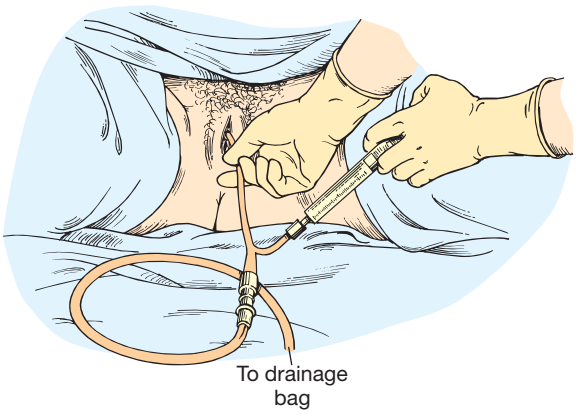
Step 25A(2) Cleaning female perineum.

Step 25B(2) Cleaning male urinary meatus.

STEPS	RATIONALE
26. Pick up catheter with gloved dominant hand 8–10 cm from catheter tip. Hold end of catheter loosely coiled in palm of dominant hand (optional: may grasp catheter with forceps).	
27. **Insert catheter:**	
A. Female patient	
(1) Slowly insert catheter through urethral meatus (see illustration).	
(2) Advance catheter a total of 5–8 cm in adult or until urine flows out of catheter's end. When urine appears, advance catheter another 2–5 cm. Do not force against resistance.	Female urethra is short. Appearance of urine indicates that catheter tip is in bladder or lower urethra. Advancement of catheter ensures bladder placement.
■ **Critical decision point: If no urine appears, check that catheter has not been inserted in the vagina instead of the urethra. If misplaced, leave catheter in vagina as landmark indicating where not to insert, and insert another (you will need to start the procedure again unless you have another nurse attending who can open another sterile catheter onto the sterile field).**	
(3) Release labia, and hold catheter securely with non-dominant hand. Inflate balloon if retention catheter is used (see illustration). Only put in the amount of sterile water that is indicated on the catheter.	Bladder or sphincter contraction may cause accidental expulsion of catheter. Over-inflation of the balloon may cause it to burst or block off the drainage holes of the catheter. Under-inflation can result in the catheter falling out.



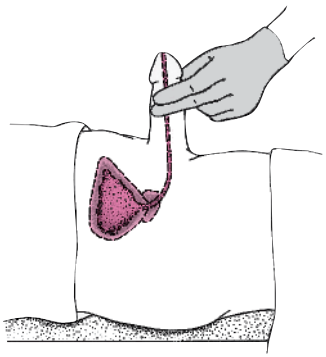
Step 27A(1) Inserting catheter.



Step 27A(3) Inflating balloon of retention catheter.

B. Male patient	
(1) Lift penis to position perpendicular to patient's body and apply light traction (see illustration).	Straightens urethral canal to ease catheter insertion.
(2) Slowly insert catheter through urethral meatus.	

STEPS	RATIONALE
(3) Advance catheter 18–23 cm in adult or until urine flows out catheter's end. If resistance is felt, withdraw catheter; do not force it through urethra. When urine appears, advance catheter another 2–5 cm.	The adult male urethra is long. It is normal to meet resistance at the prostatic sphincter. When resistance is met, nurse should hold catheter firmly against sphincter without forcing catheter. After a few seconds, the sphincter relaxes, and the catheter is advanced. Appearance of urine indicates catheter tip is in bladder or urethra. Further advancement of catheter ensures proper placement.
(4) Lower penis and hold catheter securely in non-dominant hand. Place end of catheter in urine tray. Inflate balloon if retention catheter is used. Only put in the amount of sterile water that is indicated on the catheter.	Catheter may be accidentally expelled by bladder or urethral contraction. Collection of urine prevents soiling and provides output measurement. Over-inflation of the balloon may cause it to burst or block off the drainage holes of the catheter. Under-inflation can result in the catheter falling out.
(5) Reduce (or reposition) the foreskin.	Paraphimosis (retraction and constriction of the foreskin behind the glans penis) secondary to catheterisation may occur if foreskin is not reduced.
28. Remove straight, single-use catheters when drainage ceases. Withdraw catheter slowly but smoothly until removed.	



Step 27B(1) Positioning penis prior to catheter insertion.

Step 28 Drainage bag attached to lower bed frame.

For indwelling catheterisation – attach end of catheter to tube of drainage bag system (see illustration). Make sure drainage port at the base of the drainage bag is closed. Drainage bag must be below level of bladder; attach bag to bed frame, do not place bag on side rails of bed. Ensure patient is informed of correct position for drainage bag.	Establishes a closed system for urine drainage.
29. Pack up equipment and leave it on the trolley so that it can be easily disposed of shortly.	

STEPS	RATIONALE
30. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.
31. **Anchor catheter:**	
A. Female patient	
(1) Secure catheter tubing to inner thigh with a catheter strap or other catheter-securing device. Allow for slack so movement of thigh does not create tension on catheter.	Anchoring catheter to inner thigh reduces pressure on urethra, thus reducing possibility of tissue injury and reduces risk of urinary tract infection.
B. Male patient	
(1) Secure catheter tubing to top of thigh or lower abdomen (with penis directed towards chest). Allow slack in catheter so movement does not create tension on catheter.	Anchoring catheter to lower abdomen reduces pressure on urethra at junction of penis and scrotum, thus reducing possibility of tissue injury.
32. Ensure that the patient is clean and comfortable.	Maintains comfort and security.
33. Dispose of equipment, drapes and urine in proper receptacles. Perform hand hygiene.	Reduces transmission of microorganisms.
34. Palpate bladder.	Determines whether distension is relieved.
35. Ask about patient's comfort.	Determines whether patient's sensation of discomfort or fullness has been relieved.
36. Observe character and amount of urine in drainage system.	Determines whether urine is flowing adequately.
37. Determine that there is no urine leaking from catheter or tubing connections.	Prevents injury to patient's skin.
38. Perform hand hygiene when leaving the patient's bed area.	

RECORDING AND REPORTING

- Report and record type and size of catheter inserted, amount of water used to inflate the balloon, characteristics of urine, amount of urine, reasons for catheterisation, specimen collection if appropriate and patient's response to procedure and teaching concepts.
- Initiate fluid balance chart.
- If catheter is definitely in bladder and no urine is produced within an hour, absence of urine should be immediately reported to a medical practitioner.

HOME CARE CONSIDERATIONS

- Patients who are at home may use a leg bag during the day and attach a large-volume bag at night so sleep can be uninterrupted.
- Patients may catheterise themselves at home using a clean technique.

necessary. Most hospitals use ultrasonic bladder scanners to assess post-void residual urine volumes. Guidelines vary on the amount of residual urine that is considered acceptable. The post-void residual volume is compared with the actual amount voided. If over 8 hours elapse without voiding in a patient who is drinking good amounts, it may become necessary to reinsert a catheter.

Interventions to promote continence

All of the interventions mentioned previously that promote normal voiding patterns are also used to promote continence. There are a number of interventions that are used to treat urinary incontinence. The treatment plan can only be developed after careful assessment of the problem. Implementing toileting programs without a detailed assessment and identification of the specific continence issue is not likely to result in an improvement in the person's continence.

Strengthening pelvic floor muscles

Continence, especially in women, relies on strong pelvic floor muscles. **Pelvic floor exercises** (PFEs), also known as Kegel exercises, are designed to improve the strength of pelvic floor muscles. They consist of repetitive contractions of specific muscle groups. PFEs can be used to promote continence as well as for rehabilitation when a continence problem exists. As PFEs involve the identification and conscious recruitment of the pelvic floor muscles, the person must be able to follow instructions and repeat a series of exercises without supervision over a long period of time. Therefore, people who have short-term memory problems, inattention or impaired conscious state may not be suitable candidates for a PFE program. The elements of a PFE program are described in Box 33-6. Both the Continence Foundation of Australia and the New Zealand Continence Association have excellent brochures, posters and teaching materials related to PFEs.

WORKING WITH DIVERSITY

Focus on older adults

- When frail older adults can no longer maintain their independence in personal care, nurses must assume responsibility for their urinary care.
- Dilute urine discourages bacterial growth, so older adults should be encouraged to drink at least 6–8 glasses of fluids a day, unless medically contraindicated.
- Since acidic urine prevents or inhibits bacterial growth in urine, fluids that acidify the urine (e.g. cranberry juice) should be offered daily.
- Urinary catheterisation increases the incidence of nosocomial infection. Indwelling catheters should not be used in a routine manner.
- Incontinence is not a normal part of ageing, and efforts should be made to assess incontinence and provide interventions to promote return to continence.
- Hospitalised older adults who have no pre-existing urinary incontinence should not be given continence pads 'just in case' they are incontinent or instead of being assisted to go to the toilet.

BOX 33-6 Health education: pelvic floor muscle exercises

Objective

Prevent incontinence through increased pelvic floor muscle tone.

Important points

Explanation about:

- anatomy and function of pelvic floor muscles (PFMs)
- causes of weakness in PFMs.

Recognition of PFMs

- Have the person attempt to tighten PFMs during voiding by attempting to stop the flow of urine or get them to visualise squeezing the muscles between vagina and anus (or scrotum and anus in men). Pull muscles up into the body. Get the sense of the squeezing and lifting sensation. (Don't tighten the buttocks, abdominal muscles or thighs.)

PFM training

- Have the person squeeze and lift these muscles and hold for 5–10 seconds (the best they can do) before relaxing. Breathe in and out during the contraction. Repeat the squeeze and lift 8–12 times.
- When they have perfected the technique, advise them to repeat these exercises three times a day (8–12 squeeze-and-lifts with a rest in between) each day while lying down, sitting or standing. It may take months for the person to work up to a 10-second squeeze repeated 8–12 times. Reassure them that it will improve with time.

Other points

- Provide written instructions with diagrams of anatomy (you can get brochures from the Continence Foundation of Australia or the New Zealand Continence Association).
- Talk with the person about good bladder and bowel habits (drink well, eat a healthy diet, healthy weight, stop smoking, good toilet habits, avoiding constipation).
- If the person has difficulty in identifying their PFMs refer to a continence nurse or continence physiotherapist.
- Refer to a continence nurse or the person's general practitioner if they have any other lower urinary tract symptoms.

Evaluation

- Patient reports ease of completing the exercises.
- Reduced episodes of urinary incontinence on coughing, sneezing, etc.

Resources

- Brochures and teaching materials available from the Continence Foundation of Australia (http://www.continence.org.au and http://www.continence.org.au/resources.php) or Continence New Zealand (www.continence.org.nz).
- For further assistance to locate a continence nurse or continence physiotherapist or for advice call the relevant continence helpline: Australia – 1800 33 00 66, New Zealand – 0800 650 659.

Continence aids and appliances

Aids and appliances form the key to achieving social continence. Social continence refers to the use of continence aids and appliances to keep urinary leakage and odour contained, enabling the person to engage in normal daily activities. Continence aids and appliances are an important part of active treatment plans for many people because they give the person the confidence they need to engage in normal daily activities and social interactions. For some people, social continence may be the goal of treatment. There are various continence aids and appliances available. These include continence pads and pants, absorbent bed sheets and chair covers, and other products that assist with voiding, such as bed pans, urinals, commode chairs, raised toilet seats and chairs; most hospitals and healthcare agencies will have a selection in stock. Some of these products can be misused. A study by Zisberg (2011) found that continent adult women, especially those with impaired mobility, were being given continence pads in the acute care setting. Zisberg makes the point that using continence pads for these people is likely to result in reduced self-esteem and quality of life, increased risk of skin problems and urinary tract infections and may increase the risk of urinary incontinence in frail older people. It is not acceptable practice to give a person a continence pad when they do not have any urinary incontinence.

A person with an ongoing continence problem should be referred to a continence nurse specialist for assessment and management of their continence problem. Continence nurse specialists are registered nurses with postgraduate qualifications and experience in promoting continence and managing incontinence. A continence nurse specialist can provide expert advice on appropriate continence aids and appliances and can assist the person to access government funding schemes. Individual needs must be taken into account when selecting continence products. These include the amount of urine that the pad needs to contain, rate of loss of urine, gender, size of the person, cognitive function, manual dexterity and strength, the person's lifestyle, access to laundry and/or disposal facilities, and the personal preference of the person (Cottenden et al 2013).

URINARY SHEATH The urinary sheath (or the 'condom' in condom drainage) is a non-invasive soft, pliable, silicone or latex sheath that slips over the penis (Skill 33-3). It is suitable for men who have urinary incontinence but still have complete and spontaneous bladder emptying. It may be worn continuously or at night only, depending on the person's needs. The success of the urinary sheath relies on correct choice of size of the device

SKILL 33-3

Applying a sheath/condom drainage device

Delegation considerations

Applying a sheath/condom can be delegated to enrolled nurses, the person if he is able, or a family carer in the home context.

- Ensure that person/caregiver knows standard precautions guidelines relating to body fluids.
- Clarify that skin of penile shaft is intact and free of swelling, redness or open lesions before sheath/condom drainage device is applied.
- Clarify the person's/caregiver's understanding of how to apply the adhesive strip that secures the sheath/condom drainage device.
- Clarify the person's understanding of signs of infection, skin breakdown or poor circulation in penis and knowledge of where and when to seek assistance from a health professional.

Equipment

- Sheath/condom drainage device kit
  - Latex/silicone condom sheath (proper size) (check for possible rubber or latex allergy)
  - Skin preparation solution or swab (may be required)
- Urinary collection bag with tubing or leg bag with straps
- Basin with warm water and mild soap
- Towels and washcloths
- Non-sterile disposable gloves
- Blanket/towel
- Scissors and/or personal trimmer (patient's own)

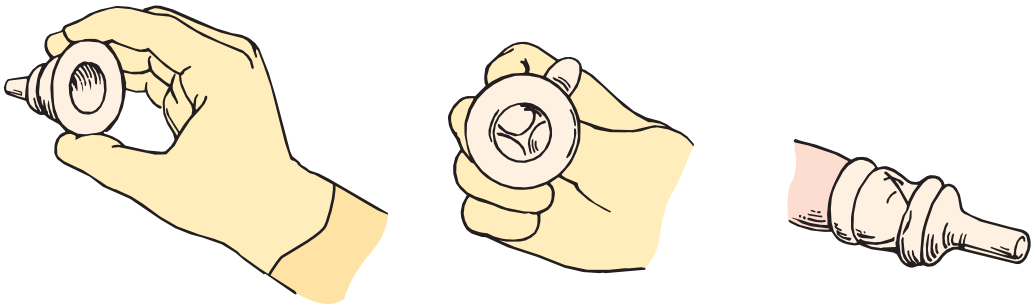
Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess urinary elimination patterns, patient's ability to voluntarily urinate and continence.	Patients who are incontinent are at high risk of skin breakdown.
2. Provide privacy by closing door or bed curtains.	Maintains patient's self-esteem.
3. Assess the person's level of education and health literacy so appropriate teaching related to sheath device can be implemented.	Some male patients may be incontinent only at night. Teaching can be implemented to instruct patient on self-application.
4. Assess condition of penis and assess for appropriate sheath size using a sizing chart.	Provides a baseline to compare changes in condition of skin after condom application.
5. Assess patient's knowledge of the purpose of a sheath device.	Reveals need for patient instruction.
6. Explain procedure to patient.	Reduces anxiety and promotes cooperation.
7. Perform hand hygiene.	Reduces transmission of microorganisms.
8. Raise bed to appropriate working height for the nurse. Raise side rail on opposite side of bed, and lower rail on working side.	Promotes patient safety and proper use of body mechanics by nurse.
9. Help patient into semi-Fowler's position. Place blanket/towel over upper torso. Fold bed sheets so that lower extremities are covered; only genitalia should be exposed.	Promotes patient comfort and prevents unnecessary exposure of body parts.
10. Prepare urinary drainage collection for connection to sheath/condom. Clamp off all drainage exit ports. Secure collection bag to bed frame; bring drainage tubing up through side rails onto bed. Prepare leg bag for connection to sheath/condom if necessary.	Provides easy access to drainage equipment after sheath/condom is applied.
11. Put on non-sterile gloves. Assess the required size of the sheath/condom using the manufacturer's guide.	Sheath/condoms come in a variety of sizes (circumference and length). It is very important to use the correct size for comfort and so that the sheath/condom remains in place for the required period of time.
12. Wash area with mild soap and water or ask the patient to do this for himself if he is able (see Skill 38-2), and dry thoroughly.	Removes irritating secretions. Rubber/latex sheath rolls onto dry skin more easily. The adhesive will adhere to dry skin. Be aware of possible latex allergy.
13. Clip hair at base of penis. In some cases, shaving the hair at the base of the penis may be necessary.	Hair adheres to sheath/condom and is pulled during sheath/condom removal or may get caught as sheath/condom is applied.
14. Roll sheath/condom onto penis – try to keep the glans centrally within the sheath. You may need to put gentle tension on the penis to keep it straight within the sheath. As the adhesive is on the inside of the sheath/condom, you need to gently press the sheath onto the shaft of the penis as you unroll it (see illustrations).	Make sure that the foreskin remains over the glans to protect the glans from the adhesive on the inside of the sheath/condom. Gentle pressure and the heat from your hand will help make sure that the adhesive is well applied to the penile shaft.

STEPS	RATIONALE

■ **Critical decision point: Allow 2–5 cm of space between tip of glans penis and end of sheath/condom (see illustration, Step 14).**



Step 14 Technique for rolling sheath/condom onto penis.

15. Connect drainage tubing to end of sheath/condom. Be sure sheath/condom is not twisted. The sheath/condom can be attached to large-volume bag or leg bag (see illustrations).	Allows urine to be collected and measured. Keeps patient dry. Twisted sheath/condom obstructs urine flow.

Step 15 Attaching sheath/condom to large-volume or leg bag.

16. If using a large-volume urine bag, secure tubing to the top of the patient's thigh, allowing some slack so as to not create tension and risk dislodging condom/sheath. Place excess coiling of tubing on bed, and secure to bottom sheet.	Promotes free drainage of urine.
17. Place patient in a safe, comfortable position. Lower bed, and place side rails accordingly.	Promotes safety and comfort.
18. Dispose of contaminated supplies. Remove gloves, and wash hands.	Reduces spread of microorganisms.
19. Observe urinary drainage.	Determines whether normal voiding is occurring.

STEPS	RATIONALE
20. Inspect penis with sheath/condom in place within 30 minutes after application. Look for swelling and discolouration, and ask patient if there is any discomfort. Ensure there is no leakage of urine from the device.	Determines whether sheath/condom has been applied correctly.
21. Remove and change sheath/condom and inspect skin on penile shaft for signs of breakdown or irritation at least daily when hygiene is performed and when the sheath/condom is reapplied.	Indicates whether sheath/condom or urine is causing irritation. Frequent assessment of good blood circulation to glans penis is important to determine whether sheath/condom has been applied too tightly.

RECORDING AND REPORTING

- Record and report pertinent information: sheath/condom application, condition of skin, voiding pattern.
- Monitor fluid balance chart as indicated.

HOME CARE CONSIDERATIONS

- If leg bag is used, assess leg for circulatory impairment. Switch to a large-volume drainage bag at night.
- Teach patient that a collection bag that fills completely may put unnecessary tension on the catheter and contribute to problems keeping the sheath/condom intact.
- Some men have difficulty in getting the adhesive to stick to their skin. These men may benefit from the use of skin preparation wipes to the shaft of penis (these can be purchased from the sheath/condom manufacturer). These remove skin oils and adhesive from previous applications and may assist the adhesion of the sheath.

and its correct application to the penis. Urinary sheaths come in varying lengths and diameters. Each brand of sheath will come with a sizing guide; care must be taken to ensure that whatever type or size is used, blood supply to the penis is not impaired. Each sheath has adhesive on the inside so that it is comfortably fitted and stays in place without leaking. The penis needs to be clean and dry for the adhesive to stick properly. Some men may need to reduce the amount of pubic hair (using a personal trimmer) so the adhesive sticks properly.

The distal end of the sheath fits into plastic drainage tubing. A drainage bag can be attached to the side of the bed, or a leg bag can be strapped to the patient's leg. The sheath itself poses little risk of infection. Infections with urinary sheaths usually result from a build-up of secretions around the urethra, trauma to the urethral meatus or a build-up of pressure in the outflow tubing.

The man (or their carer) should be advised to gently remove and discard the sheath daily. This provides a good opportunity to check the skin of the penis for irritation and inflammation. Normal personal hygiene can be attended to, such as showering, and a new sheath fitted.

For a man with a retracted penis, maintaining a conventional urinary sheath may prove difficult. Special devices are available to help alleviate this problem (Figure 33-11). Manufacturers' guidelines for product application should be consulted.

Figure 33-11 Retracted penis pouch external urinary device.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

• CRITICAL REFLECTION POINT

Mr Miller is a 75-year-old widower who has had prostate surgery for benign prostatic hypertrophy. He thought his problems would be over, but now he is experiencing continual dribbling of urine. He has been trying to deal with the problem by using an absorbent pad in his underwear, but he feels as though everyone is aware of it. The embarrassment of having an odour often keeps him at home. He has given up going to the golf club which he usually attends three times per week.

1. **Outline the areas for further assessment of his problem.**
2. **Describe a plan of care for Mr Miller.**

Maintenance of skin integrity

The normal acidity of urine is irritating to skin. Urine allowed to be in contact with the skin becomes alkaline, causing encrustations or precipitates to collect on the skin, fostering breakdown. Continuous exposure of the perineal area leads to gradual maceration and excoriation (see Chapter 26). Washing with mild soap and warm water is the best way to remove urine from skin. A non-perfumed body lotion keeps skin moisturised, and skin barriers (e.g. zinc and castor oil cream) provide a barrier to the urine.

If the skin becomes inflamed, a medical practitioner may prescribe a cream containing a corticosteroid such as hydrocortisone. If a fungal infection develops, a topical antifungal containing an agent such as nystatin or clotrimazole is effective.

Voiding programs

Voiding programs should not be commenced until a detailed assessment has been undertaken and the specific continence problem(s) identified. Bladder training programs aim to increase bladder capacity by gradually increasing the interval between voids, for example, in a person with urge incontinence who may be voiding frequently. These programs consist of an educational program about how the bladder works and how continence is maintained; a voiding program based on the person's current voiding pattern (determined by a voiding diary); and an ongoing support program as it is likely to take several months to achieve the desired increase in voiding frequency (Moore et al 2013).

Habit training, timed voiding and prompted voiding are methods of bladder re-education aimed at re-establishing a normal voiding pattern. These programs are used for people with stress, urge and mixed incontinence and are often used with frail or cognitively impaired people to reduce incontinence episodes (Moore et al 2013). Habit training involves identification of the person's usual voiding pattern and pre-empting incontinence episodes by decreasing voiding intervals, while keeping these intervals as long as possible. Timed voiding is a program of voiding according to a schedule which is determined from a voiding diary (Ostaszkiewicz et al 2013). *Prompted voiding* is a program in which the nurse (or carer) checks the person at regular intervals to see if they are wet or dry, provides feedback to the person about their own perception of being wet or dry and offers assistance with toileting. Positive responses are praised and incontinent episodes are managed without comment. This type of voiding program is most suited to people with mild to moderate cognitive impairment or with functional incontinence due to immobility. While these programs are extensively used in practice, there is very little published evidence on their efficacy and patient outcomes (Ostaszkiewicz et al 2013).

EVALUATING IMPACTS AND OUTCOMES

The patient is the best source of evaluation of outcomes and responses to nursing care (see Figure 33-12). Although most people will be able to assess for themselves whether their goals have been met, the nurse will also evaluate the effectiveness of

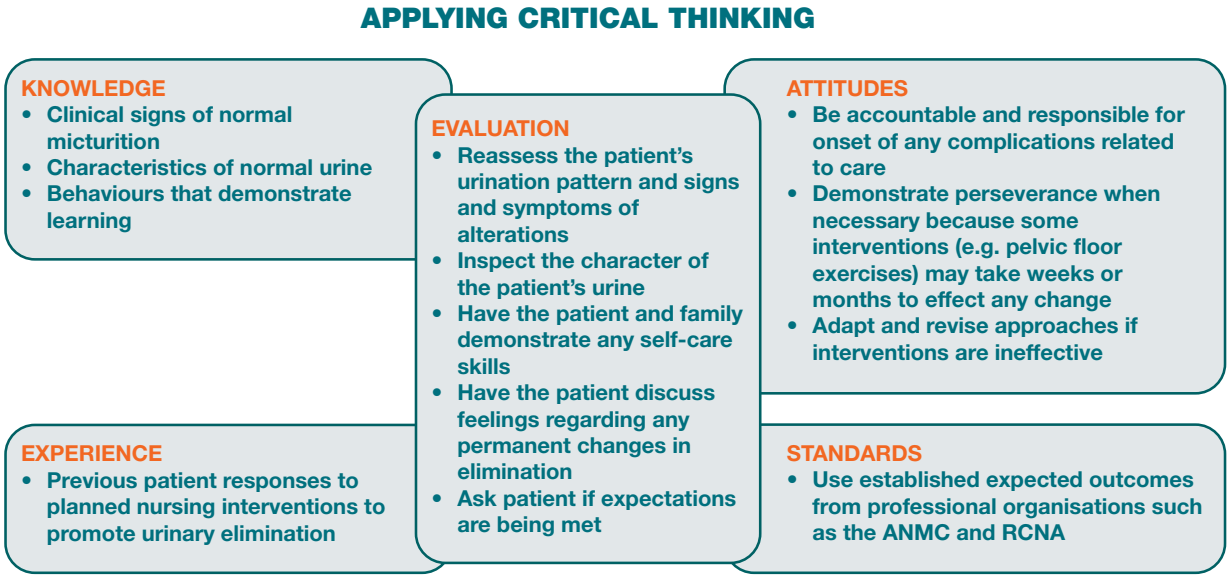


Figure 33-12 **Critical thinking associated with the evaluation phase for urinary elimination.**

nursing interventions through comparisons with baseline data. The nurse evaluates for change in the patient's voiding pattern, presence of urinary tract alteration, and physical condition. Outcomes are compared with expectations to determine the person's health status. Continuous evaluation allows the nurse to determine whether new or revised therapies are required or if any new nursing diagnoses have developed.

Patient expectations

If the nurse has developed a relationship of trust with the person, indications of the person's degree of satisfaction with the care will be evident. Keep in mind that it may take several months before any measurable improvement in urinary incontinence can be determined. These people need ongoing support so that their treatment goals can be realised. The nurse can also assist the person in redefining unrealistic goals when impairment in function is not likely to be altered as completely as the person might like.

CRITICAL REFLECTION POINT

Mrs Joseph is an 82-year-old woman with mild cognitive changes associated with Alzheimer's disease. Her daughter, with whom she lives, has brought her to the general practitioner's clinic for assessment and advice. You are the practice nurse in the clinic. As you assess Mrs Joseph, you ask her daughter how she is coping with caring for her mother. The daughter replies that her mother does not seem to remember how to go to the toilet. Mrs Joseph will go into the bathroom but forget to pull down her underwear before going to the toilet. After such an incident she becomes upset and blames her daughter for her wetness. The daughter asks you for suggestions on how to manage, as she has noticed that her mother's perineal skin is reddened and sore.

What assessments would you need to complete before planning interventions for Mrs Joseph's care?

Key concepts

- The act of micturition or voiding is influenced by voluntary control from higher brain centres and involuntary control from the spinal cord.
- Symptoms common to urinary disturbances include urgency, frequency, dysuria, incontinence, nocturia, polyuria, oliguria and difficulty in starting the urinary stream.
- Methods of promoting the micturition reflex help patients sense the urge to urinate and control urethral sphincter relaxation.
- An increased fluid intake results in increased urine formation that flushes particles and solutes from the urinary system.
- An indwelling urinary catheter remains in the bladder for an extended period, making the risk of infection greater than with intermittent catheterisation.
- One of the main functions of the elimination process is fluid and electrolyte balance.
- A catheter drainage system should remain a closed system and the drainage bag should be positioned to allow free drainage of urine by gravity.
- Incontinence is a significant health issue. An accurate assessment must be undertaken to determine the type of continence problem before a treatment program can be developed.
- Alterations in the urinary system can cause alterations in other organ systems.

CHAPTER

34

Balancing fluid, electrolyte and acid–base status

Karen Wotton

Learning outcomes

Mastery of content will enable you to:

- use knowledge of the distribution, composition, movement and regulation of body fluids and electrolytes to discuss physiological mechanisms that maintain fluid balance in all body compartments
- develop a beginning understanding of the meaning of changes in laboratory results associated with common fluid, electrolyte and acid–base imbalances
- demonstrate an ability to apply theoretical concepts to clinical practice in the determination of appropriate screening, prescription and monitoring of intravenous (IV) fluids and electrolyte administration in patients in ambulatory and acute care settings
- discuss reasons for nursing interventions for patients with fluid, electrolyte and acid–base imbalances
- construct a plan of care (assessment, plan, implementation and evaluation) for maintaining fluid, electrolyte and acid–base balance:
  - for a patient ordered oral fluids and diet
  - for a patient ordered nasogastric (enteral) replacement
  - for a patient ordered nil by mouth and either or both IV crystalloids or colloids
  - for a patient requiring a blood transfusion.

Fluid and electrolyte balance is where *all* compartments of the body contain the appropriate water volume and concentration of electrolytes. Nurses must assume that all patients have a fluid and electrolyte imbalance. Nurses must therefore comprehensively assess fluid and electrolyte status and be able to articulate, at any time throughout the shift, the clinical indicators which prove the patient's degree of fluid and electrolyte balance or imbalance. An understanding of the distribution of body fluids, constituents of body fluids and processes used by the body to maintain fluid and electrolyte balance (Figure 34-1) will assist in early identification and management of factors that contribute to fluid and electrolyte imbalances and monitoring the effectiveness of interventions.

Water is the largest single component of the body and adaptive physiological mechanisms ensure that healthy, mobile, well-oriented adults maintain normal fluid, electrolyte and acid–base balance.

Students should aim to develop the ability to use concepts covered in this chapter in developing knowledge of what is normal, identification of risk factors for fluid, electrolyte and acid–base imbalances, skills in comprehensive assessment, and knowledge of appropriate fluid and electrolyte replacement therapy for different imbalances.

Distribution of body fluids

Total body water (TBW) is generally about 60% of body weight, with the following variations: 80% in newborns; 60% in adult males; 50% in adult females; around 50% in obese people and 70% in lean people. The lower percentage of TBW in females and obese individuals is due to higher body fat content. Nurses need to understand differences in usual TBW based on age, usual weight and gender, to understand the significance of a fluid loss or gain based on calculated TBW. TBW calculations for an adult male are 0.6 × usual bodyweight = TBW (litres) and for an adult female 0.55 × usual bodyweight = TBW (litres) (Table 34-1).

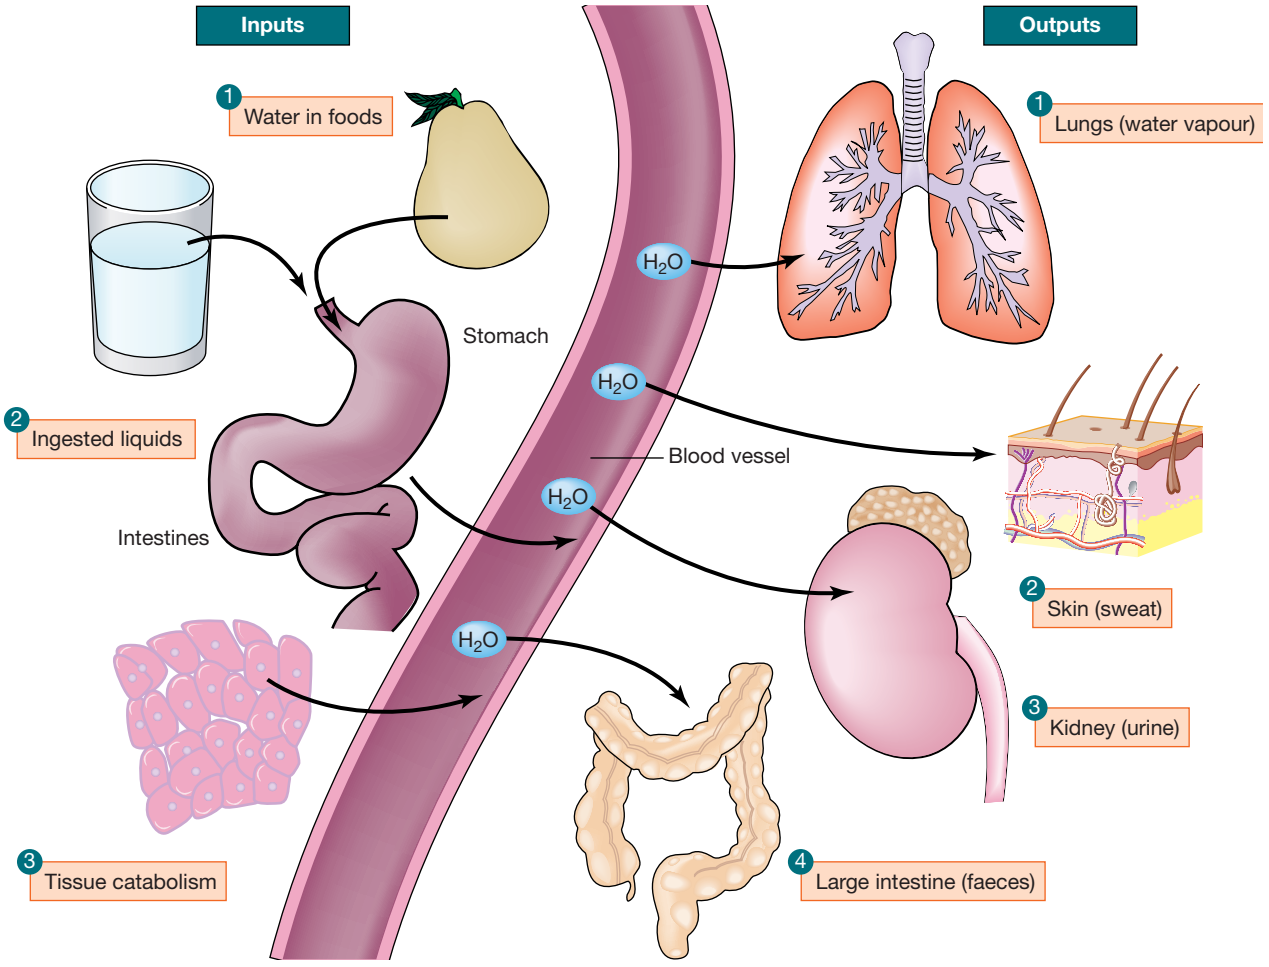

Figure 34-1 **Sources of fluid input and output.**

TABLE 34-1 Expected TBW based on gender and weight

Usual weight (kg)	Gender	Total body water (L)
50	Male	30
	Female	27.5
60	Male	36
	Female	33
70	Male	42
	Female	38.5
80	Male	48
	Female	44

Adapted from Wotton K, Crannitch K, Munt R 2008 Prevalence, risk factors and strategies to prevent dehydration in older adults. Contemp Nurse 31(1):44–56.

• CRITICAL REFLECTION POINT

This critical thinking exercise is designed to increase understanding of the importance of usual weight in interpreting the significance of possible alterations in TBW.

Activity

Using TBW data in Table 34-1, identify which of the following patients has the greatest health risk from a fluid loss of 1000 mL.

Patients: Mrs Gardener weight 50 kg, Mr Hermes weight 60 kg, Mrs McMaster weight 70 kg, Mr Kenyard weight 80 kg.

Process	Example: Ms Hunter weighs 60 kg and vomited 500 mL. What percentage of TBW is this loss?
Calculate the TBW for each patient by referring to information in Table 34-1	TBW 33 L
Change L into mL by x 1000 = mL	mL = 33 x 1000 = 33,000 mL
Calculate the percentage TBW lost for each patient	% TBW loss
Volume lost x 100	500 x 100
TBW (mL)	33,000 = 1.5%

Body fluids are distributed in two distinct compartments, one containing intracellular fluids and the other, extracellular fluids (Figure 34-2). Almost two-thirds of TBW is in the intracellular compartment (*intracellular fluid*); the other third is extracellular (*extracellular fluid*). Various semipermeable cell membranes separate TBW into these and further compartments, allowing compartments to function relatively independently (Patton & Thibodeau 2016). The microspores in the capillary membrane facilitate the exchange of fluids between compartments.

Intracellular fluid (ICF) comprises all fluid within body cells constituting approximately 40% of bodyweight in adult males and 35% in females (Patton & Thibodeau 2016). The ICF compartment is a 'virtual compartment' consisting of an extremely large number of small collections of fluids high in potassium and low in sodium and chloride ions.

Extracellular fluid (ECF) is all fluid outside the cells, divided into two main smaller compartments containing

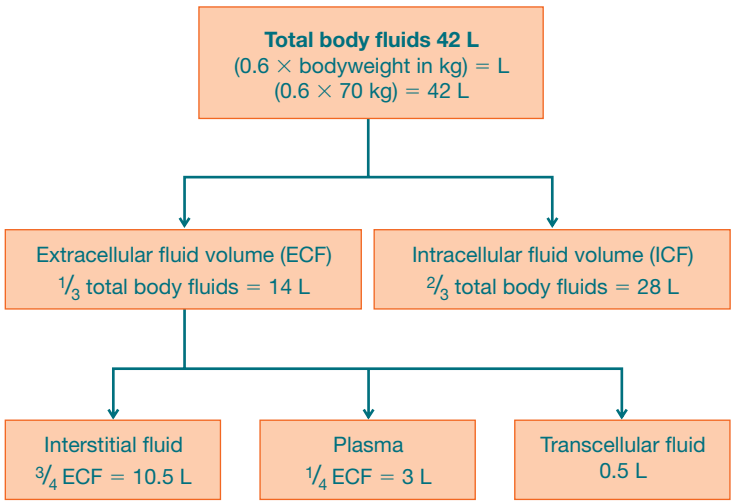

Figure 34-2 Volumes of fluid compartments for a male weighing 70 kg.

interstitial fluid and intravascular fluid. **Interstitial fluid** (ISF) exists between the cells and outside the blood vessels. ISF bathes all body cells and carries oxygen, nutrients, wastes and chemical messengers. **Intravascular fluid** consists of blood plasma and lymph. Plasma exists as a real fluid collection in one location. It differs from ISF in higher protein content and contains suspended red and white cells (Hall 2015). The lymphatic system returns protein and excess ISF to the circulation. About 25% of the ECF is in the intravascular compartment and 75% is interstitial fluid. Other ECFs are *transcellular fluid*, *cerebrospinal fluid* (found in the ventricles of brain and surrounding the brain and spinal cord); *synovial fluid* (found inside synovial joint capsules); *gastrointestinal tract fluids* (saliva and gastric, pancreatic and intestinal juices); *eye and ear fluids* (vitreous and aqueous humour); *pleural*, *pericardial* and *peritoneal fluids* and *glomerular filtrate* (Patton & Thibodeau 2016). ECF ion concentration is opposite to ICF being low in potassium and high in sodium and chloride ions (Patton & Thibodeau 2016).

Table 34-2 shows the difference in expected fluid volumes in the various fluid compartments based on gender and weight.

• CRITICAL REFLECTION POINT

Daily weight informs health professionals about a patient's fluid balance. This critical thinking exercise is designed to further consolidate an understanding of the importance of knowing an individual's usual weight and expected volumes in different body compartments. This knowledge is essential in interpreting the significance of possible alterations in fluid balance.

Activity

Refer to plasma volume data in Table 34-2 to identify which of the following patients has the greatest health risk from a blood loss of 1000 mL. Patients: Mrs Gardener weight 50 kg, Mr Hermes weight 60 kg, Mrs McMaster weight 70 kg, Mr Kenyard weight 80 kg.

Process	Example: Ms Hunter weighs 60 kg and vomited 500 mL. What percentage of plasma volume is lost?
1. Calculate the plasma volume for each patient by referring to information In Table 34-2	1. Plasma volume 2.75 L
2. Change L into mL by x 1000	2. mL = 2.75 x 1000 = 2750 mL
3. Calculate the percentage plasma volume loss for each patient Volume lost x 100 Plasma volume (mL)	3. 500 x 100 2750 = 18.2% plasma volume loss

Composition of body fluids

Body fluids contain dissolved solutes essential to fluid and electrolyte balance and metabolism – technically known as electrolytes. An electrolyte is an element or compound which, when dissolved in water, separates into ions and is able to carry an electrical current. An **ion** is an

TABLE 34-2 Expected body fluid volumes (L) based on gender and weight

Usual weight (kg)	Gender	Total body water (L)	ICF (= ⅔ TBW) (L)	ECF (= ⅓ TBW) (L)	ECF	
					Interstitial (= 75% ECF) (L)	Plasma (= 25% ECF) (L)
50	Male	30	20	10	7.5	2.5
	Female	27.5	18.33	9.17	6.89	2.28
60	Male	36	24	12	9	3
	Female	33	22	11	8.25	2.75
70	Male	42	28	14	10.5	3.5
	Female	38.5	25.66	12.83	9.63	3.2
80	Male	48	32	16	12	4
	Female	44	29.3	14.66	10.96	3.67

ECF = extracellular fluid; ICF = intracellular fluid; TBW = total body water.

Calculation of TBW:
Male 0.6 × usual bodyweight = x litres
Female 0.55 × usual bodyweight = x litres

Adapted from Wotton K, Crannitch K, Munt R 2008 Prevalence, risk factors and strategies to prevent dehydration in older adults. Contemp Nurse 31(1):44–56.

atom or molecule that possesses a positive or a negative charge. Positively charged ions are **cations** (sodium Na^+, potassium K^+, calcium Ca^{2+}, magnesium Mg^{2+}, iron Fe^{2+} and hydrogen H^+). Negatively charged electrolytes are **anions** (chloride Cl^-, bicarbonate HCO_3^-, sulfate SO_4^{2-}, phosphate HPO_4^{3-} and protein anions) (Table 34-3).

Electrolytes are measured in millimoles per litre (mmol/L). A mole is a particle standard (6.02×10^{23} atoms). One mole (mol) is defined as the molecular (or atomic) weight of a substance, in grams. One millimole (mmol) is thus equal to one-thousandth of a mole, in milligrams. In clinical practice, measurement of an amount of a substance is reported as the concentration of that substance in a particular volume; thus mass per unit of volume (Hall 2015). The unit of measurement frequently used in the clinical setting is millimoles per litre (mmol/L). Millimoles per litre are a measure of the weight of a particular ion (the solute) dissolved in 1 L of a liquid (the solvent). The liquid formed by dissolving the solute in the solvent is called a solution.

Knowledge of the function of electrolyte anions and cations and their role in maintaining electrolyte balance in the human body will assist in understanding the patient's maintenance and restorative dietary and fluid needs. Electrolyte concentrations differ between ICF and ECF (Table 34-3). The body fluids and electrolytes in the ICF and ECF compartments are also in a constant state of mobility where electrolyte distribution is a primary determinant of water concentration in a particular compartment. Knowledge of the electrolytes in different body fluids (Table 34-4) can assist nurses in identifying potential fluid and electrolyte imbalances when fluids are lost from particular sources, and therefore in understanding the appropriateness of replacement fluids and other interventions.

TABLE 34-3 Electrolyte levels in intracellular and extracellular fluids

	Extracellular fluid (mmol/L)		
Electrolyte	Plasma	Interstitial	Intracellular fluid (mmol/L)
Cations			
Calcium, Ca^{2+}	2.2–2.6	2.2–2.6	0.5–1
Magnesium, Mg^{2+}	0.7–0.95	1	14–15
Potassium, K^+	3.1–4.2	4.1	150–155
Sodium, Na^+	137–145	145	15–20
Anions			
Bicarbonate, HCO_3^-	22–32	27	10–12
Chloride, Cl^-	98–106	114	1–4
Phosphate, HPO_4^{3-}	0.7–1.25	0.7–1.25	33–35

CRITICAL REFLECTION POINT

Nurses are involved in the assessment and the thoughtful and knowledgeable implementation of the orders of medical staff and evaluation of the effectiveness of therapies to manage fluid and electrolyte imbalances. The following activity is designed to assist students in developing an understanding of the cause of an imbalance and rationale for prescribed fluids and electrolytes.

Activity

Refer to data in Table 34-4 in calculating which electrolyte/s would be required in replacement diet and fluids for each of the following patients:

1. **Mr Luke, 34 years, who has a temperature of 39.6°C and is diaphoretic.**
2. **Mrs Tesler, 69 years, who has been vomiting for 24 hours.**

TABLE 34-4 Electrolyte levels in common body fluids

	Na^+ (mmol/L)	K^+ (mmol/L)	Cl^- (mmol/L)	HCO_3^- (mmol/L)
Bile	150	5–10	40–80	20–40
Cerebrospinal fluid	147	3	113	25
Colonic fluid	140	5	85	60
Gastric juice	20–100	5–10	120–160	0
Ileal fluid	140	5	105	40
Pancreatic juice	120	5–10	10–60	80–120
Perspiration	65	8	39	16
Saliva	20–80	10–20	20–40	20–60

3. **Mr Smyth, 66 years, who is fifth-day post ileostomy with ileostomy bag needing to be changed seven times over the last shift.**
4. **Amy, a 4-year-old child, who has had acute diarrhoea with some vomiting for the past 24 hours. Use your knowledge of electrolytes contained in diarrhoea and vomitus and mechanisms for diarrhoea to explore whether Amy should be given any of the lemonade (flat), Gatorade or Gastrolyte her mother has purchased.**

Minerals (e.g. iron, zinc and magnesium; see Table 34-5) are constituents of all body tissues and fluids and are important in maintaining physiological processes. Minerals serve as co-factors in the thousands of enzyme-controlled body reactions; they act as catalysts in nerve response, muscle contraction and metabolism of nutrients in foods; regulate electrolyte balance and hormone production; and strengthen skeletal structures (Patton & Thibodeau 2016). It is essential for nurses to be aware that all trace minerals can be toxic in moderate to high doses.

Minerals do not work alone, but in balance with one another and with the metabolism of proteins, carbohydrates, fats and vitamins. An imbalance in one mineral can cause a chain reaction of deficiencies.

• CRITICAL REFLECTION POINT

Nurses are responsible for completing and documenting patient history within 24 hours of admission. This history should include information concerning the patient's usual diet and over-the-counter medications. The risk for mineral consumption above daily requirement is increased because of the availability of over-the-counter mineral supplements (tablets, capsules, powders) and the addition of trace elements to: dietary supplements, cold preparations, nasal preparations and hygiene products.

Mrs Henshaw has a history of chronic renal injury and admitted with fatigue, hypotension, bruising and bleeding gums. She has been self-medicating with Milk of Magnesia for constipation, Mylanta for indigestion and, because of her ill-fitting dentures, is using additional denture adhesive. She loves pineapple, raspberries and strawberries.

Activity

Refer to Tables 34-5 and 34-6 in deciding what, if any, trace element could be partly responsible for Mrs Henshaw's admission signs and symptoms.

TABLE 34-5 Major minerals and their function

Mineral	Daily INTAKE	Function	Source
Iron	8 mg/day (male) 18 mg/day (female)	Haemoglobin formation, electron transport, oxygen transport, enzyme activator	There are two types of iron in food: 1. *haem iron* found in meat and offal (lean red meat, poultry or game, liver, kidney) 2. *non-haem iron* derived from some vegetables, fruit, fish, grains and nuts – apricots, blackcurrants, figs, prunes, beans, lentils, broccoli, peas, cabbage, spinach, eggs, liquorice, mackerel, oysters, sardines, tuna, wholegrain cereals and breads
Zinc	4–14 mg	Antioxidant; maintenance of immune system, protein synthesis, carbon dioxide transport, sexual function, insulin storage, carbohydrate metabolism, wound healing	Water, meat and cereal products – brown rice, wholegrain breads, cheese, crab, lobster, mussels, oysters, sardines, duck, kidney, red meat, turkey, venison. Homeopathic medications, cold lozenges, nasal gels/sprays and denture adhesive cream
Magnesium	300–400 mg	Assists in absorption and breakdown of vitamins and minerals, e.g. calcium and vitamin C; present in bones, liver, muscles, transfer of intercellular water, alkaline balance, neuromuscular activity	Apricots, bananas, figs, prunes, raisins, brown rice, granary bread, wholemeal bread and pasta, nuts, pulses, courgettes/zucchini, green leafy vegetables, okra, parsnips, peas, sweetcorn, lean meat, milk, yoghurt. Laxative Milk of Magnesia (Bailey et al 2011) and included in Mylanta (Zajac et al 2013)
Copper	2–5 mg	Synthesis and function of proteins, enzymes, connective tissues (collagen and elastin), myelin and other phospholipids; tyrosinasein melanin synthesis (pigmentation of skin); thermal regulation, glucose metabolism, blood clotting	Mushrooms, spinach, greens, seeds, raw cashews, raw walnuts, tempeh, barley
Manganese	3–4 mg	Formation of connective tissue, bones, blood clotting factors and sex hormones; fat and carbohydrate metabolism, calcium absorption, regulation blood glucose; necessary for brain and nerve function	Spelt grain, brown rice, beans, spinach, pineapple, tempeh, rye, soybeans, thyme, raspberries, strawberries, garlic, squash, eggplant, cloves, cinnamon, turmeric

TABLE 34-6 Example of causes and signs and symptoms of mineral deficits

	Causes	Signs and symptoms
Hypomagnesemia > 0.75 mmol/L	Renal wasting, chronic alcohol use, diabetes mellitus, malnutrition, refeeding syndrome, parathyroidectomy, diarrhoea, hyperthyroidism, primary aldosteronism, pancreatitis	Weakness, muscle fasciculation, tremors, tetany, increased reflexes; personality changes, disorientation; convulsions, psychosis, stupor, coma; arrhythmias, ECG abnormalities
Hypermagnesemia > 1.3 mmol/L	Over-replacement of magnesium, antacid/ laxative overuse, renal dysfunction; rapid IV infusions of magnesium	< 5 mEq/L: serious symptoms rare; bradycardia, flushing, sweating, sensation of warmth, nausea, vomiting > 5 mEq/L: lethargy, mental confusion, hypotension; decreased clotting mechanisms > 7.5 mEq/L: coma, paralysis, decreased clotting, respiratory distress, cardiac arrest
Hypocupremia	Chronic diarrhoea, malabsorption syndrome, long-term parenteral nutrition; enteropathies, bowel resection, vegetarian diet	Abnormal glucose tolerance, arrhythmias, hypercholesterolemia, atherosclerosis, depressed immune function, demineralisation of bones, pathological fractures
Hypercupremia	Ingestion > 15 mg of elemental copper, long-term parenteral nutrition	Nausea, vomiting, intestinal cramps, diarrhoea, shock, hepatic necrosis, haemolysis, renal impairment, coma and death
Hypozincemia	Decrease intake, malabsorption, increased loss, rapidly growing adolescents; menstruating, lactating, or pregnant women; low meat intake; institutionalised chronically ill residents, chronic diarrhoea, zinc-deficient parenteral nutrition solutions, diabetes mellitus, and diuretic therapy	Dysgeusia (decreased taste), hyposmia (diminished smell), Pica, growth retardation, anaemia, hepatosplenomegaly, impaired wound healing, diarrhoea, vomiting, alopecia and oral, anal or genital skin lesions
Hyperzincemia	People rarely consume too much dietary zinc. Zinc toxicity may be associated with: consuming foods/ beverages packaged in a zinc-coated (galvanised) container, zinc supplements, zinc oxide fumes (welding, dyes, galvanising, electroplating), zinc in cough lozenges, zinc in false teeth adhesives (Maret & Sandstead 2006)	Zinc poisoning is a potentially life-threatening emergency. Symptoms include: convulsions, seizures, fever, non-specific aches and pains, shock, metallic taste, difficulty with micturition, rash, hypotension and vomiting.

RESEARCH HIGHLIGHT

Research focus

To explore mortality and frequency of arrhythmias in patients admitted with acute myocardial infarction (AMI) treated with IV magnesium therapy.

Research abstract

This prospective randomised controlled trial randomly divided patients admitted with AMI (n = 100) into two groups of 50 patients each. Group one administered IV magnesium (age 59.52 years ± 15.03), Group 2 a placebo (age 59.14 years ± 13.41) and a control group of 20 healthy volunteers. Patients with AMI were admitted to hospital within 12 hours of the onset of chest pain; serum magnesium was measured on admission, days 2 and day 5.

Research findings

Incidence of cardiac arrhythmias, heart failure and hospital mortality were significantly lower in the magnesium-treated group. Mortality as well as morbidity was very less in the magnesium-treated group of patients compared to the placebo-treated patients.

Conclusion

Intravenous magnesium is a safe and effective method of reducing the frequency of arrhythmias and mortality following the acute myocardial infarction. Magnesium therapy reduces the incidence of arrhythmias and mortality, even in the absence of demonstrable magnesium deficiency.

Movement of body fluids

Fluids and electrolytes constantly shift from compartment to compartment to facilitate body processes such as tissue oxygenation, acid–base balance and urine formation. Cell membranes separating the body fluid compartments are selectively permeable, allowing water to pass through them easily. Most ions and molecules pass through them more slowly. Fluids and solutes move across these membranes by four processes: osmosis, diffusion, filtration and active transport.

Osmosis

Osmosis is the net movement of water molecules through a selectively permeable membrane down a water potential gradient; the water molecules move from an area of high water potential (low solute concentration, called **hypotonic**) to an area of low water potential (high solute concentration, called **hypertonic**) (Figure 34-3) (Haynie 2008). The membrane is permeable to the solvent (water), but is impermeable to the solute. The rate of osmosis depends on the concentration of the solutes in the solution, the temperature of the solution, the electrical charges of the solutes and the differences between the *osmotic pressures* exerted by the solutions. The concentration of a solution is measured in **osmols**, which reflect the amount of a substance in solution in the form of molecules, ions or both.

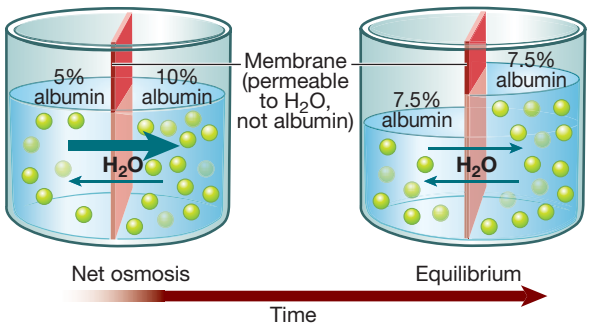

Figure 34-3 Osmosis through a semipermeable membrane.

Patton KT, Thibodeau GA 2010 Anatomy and physiology, 7th edn. Mosby, St Louis.

Osmotic pressure is the drawing power for water in osmosis, and depends on the number of molecules in solution. Osmotic pressure is the minimum hydrostatic pressure applied to a solution to oppose the movement of water across a semipermeable membrane in response to differing solute concentration between the two sides of the semipermeable membrane (Hall 2015). If the concentration of the solute is greater on one side of the selectively permeable membrane, the rate of osmosis is quicker, with a more rapid transfer of solvent across the membrane. This continues until equilibrium is reached. The osmotic pressure of a solution is called its **osmolality**, which is expressed in osmols per kilogram (Osm/kg) or milliosmols per kilogram (mOsm/kg) of the solution. The normal serum osmolality is 280–295 mOsm/kg.

Osmolarity is the number of osmoles of solute in a litre of solution (Osm/L). Although the terms *osmolality* and *osmolarity* are often used interchangeably, the osmolality of a substance in serum is about 6% higher than its osmolarity because of proteins and lipids present in plasma. Osmolarity is the measure used to evaluate serum and urine in clinical practice. Table 34-7 shows the use of the formula (2 × Na) + (2 × K) + Glucose + Urea (solutes) (Fazekas et al 2013) in the bedside calculation of serum osmolarity for three patients. As the osmolarity of ECF is approximately equal to that of ICF, serum osmolarity is a guide to intracellular osmolarity. Changes in extracellular osmolarity may result in changes in both ECF and ICF volume.

Solutions are classified as *hypertonic*, *isotonic* or *hypotonic*. An **isotonic** solution (a solution of the same osmolarity as blood plasma) expands the body's fluid volume without causing a fluid shift from one compartment to another; a *hypertonic* solution (a solution of higher osmotic pressure) pulls fluid from cells; and a *hypotonic* solution (a solution of lower osmotic pressure) moves fluid into the cells, causing them to enlarge (Figure 34-4, Table 34-8). Each of these actions occurs through osmosis.

TABLE 34-7 Bedside calculation of serum osmolarity

Patient	Na	K	Glucose	Urea	Application of formula (2 × Na) + (2 × K) + Glucose + Urea	Estimated serum osmolarity (ECF)
1	132	3.5	5.5	8	(2 × 132) + (2 × 3.5) + 5.5 + 8	284 (normal – isotonic)
2	140	5	9	10	(2 × 140) + (2 × 5) + 9 + 10	309 (high – hypertonic)
3	125	3	5	6	(2 × 125) + (2 × 3) + 5 + 6	267 (low – hypotonic)

ECF = extracellular fluid; Glucose = glucose level; K = potassium ion (K+) level; Na = sodium ion (Na+) level; Urea = urea level; all levels measured in mmol/L.

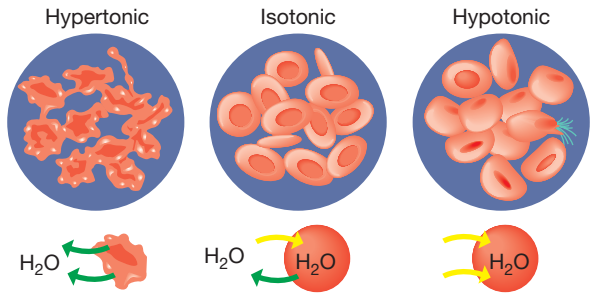

Figure 34-4 Hypertonic, isotonic and hypotonic solutions.

LadyofHats, Wikimedia Commons http://commons.wikimedia.org/wiki/File: Osmotic_pressure_on_blood_cells_diagram.svg.

Nurses need to be fully cognisant of each patient's fluid, nutritional and electrolyte needs in understanding the type of IV fluid prescribed, expected outcomes and associated risks. The administration of an incorrect solution can result in unwanted changes in cell volume and function, which includes a redistribution of water between the intracellular and extracellular fluid (ICF and ECF) compartments, resulting in a rapid change in cell volume and cellular dysfunction or injury.

The osmotic pressure of the blood is affected by plasma proteins, especially albumin. Albumin exerts colloid osmotic (oncotic) pressure, which tends to keep fluid in the intravascular compartment (Hall 2015). Knowledge of the actions of **colloid osmotic pressure** is essential if nurses are to understand situations that cause decreases in osmotic pressure and reasons for the use of intravenous (IV) **colloids** and **crystalloids**. IV colloids may, for example, be used to increase tissue osmotic pressure when an increase in capillary permeability leads to an escape of proteins into the interstitial space resulting in insufficient osmotic pressure to maintain fluid in the intravascular compartment.

The *net filtration pressure* (NFP) is the difference between the hydrostatic pressure (pressure exerted by the fluid) and the **oncotic pressure**. Fluid leaves the capillary and enters the interstitial space when hydrostatic pressure is greater than *oncotic pressure* (Hall 2015). Fluid enters the capillary from the interstitial space when hydrostatic pressure is less than oncotic pressure.

Fluid moves out of the *arterial end* of the capillary into the interstitial space because of a positive NFP of +5 mmHg, the difference between the hydrostatic pressure (30 mmHg) and the oncotic pressure (25 mmHg). Thus, with this dominant hydrostatic pressure, fluid and diffusible solutes move out of the capillary into the interstitial space, and thus flow out of the circulation (Figure 34-5).

Fluid moves out of the interstitial space into the *venous end* of the capillary because of a negative NFP of –5 mmHg, the difference between the hydrostatic pressure (20 mmHg) and the oncotic pressure (25 mmHg). Oncotic pressure therefore dominates at the venous end of the capillary, and fluid and diffusible solutes move *into* the capillary from the interstitial space (Figure 34-5). The excess fluid and solutes remaining in the interstitial space are returned to the intravascular compartment by the lymph channels (Patton & Thibodeau 2016).

Diffusion

Diffusion is the movement of a solute (which can be a dissolved gas) in a solution across a semipermeable membrane from an area of higher solute concentration to an area of lower solute concentration (Figure 34-6) to ensure the maintenance of equilibrium and the even distribution of the solute in the solution or gas. For example, if a small amount of red food colouring is added

TABLE 34-8 Osmotic response to hypotonic, isotonic and hypertonic solutions

Type of solution	Definition	Osmotic response
Hypotonic solution	Dilute solution, with a higher water concentration than the cell Example: 0.45% saline, 0.5% sodium chloride, 0.33% sodium chloride	Cell will gain water through osmosis. Osmotic pressure of the ECF is less than ICF, causing increased cell volume and potentially lysing the cell (breaking down the cell wall – cytolysis).
Isotonic solution	Solution with exactly the same water concentration as the cell Example: O.9 % sodium chloride, lactated Ringer's solution, 5% dextrose in water (D5W) and blood components	No net movement of water across the cell membrane as the osmotic concentration of both ICF and ECF are the same.
Hypertonic solution	Concentrated solution, with a lower water concentration than the cell Example: 5% dextrose in Normal saline, 10% dextrose in water, 3% sodium chloride, 25% albumin, TPN	Cell will lose water by osmosis. Osmotic pressure of ECF exceeds that of ICF and water flows out of cell causing the cells to shrink (crenate).

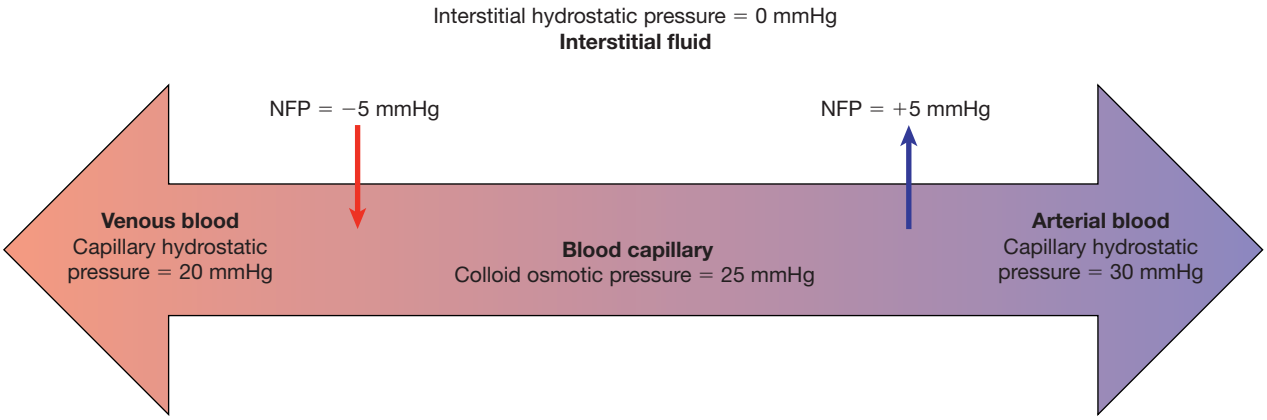

Figure 34-5 **Capillary hydrostatic and osmotic pressure. NFP = net filtration pressure.**

RESEARCH HIGHLIGHT

Research focus

Lymphoedema is a build-up of lymph fluid causing swelling in an area of the body. Lymph fluid comes from capillaries into the body tissues and normally drains into lymph vessels which return the lymph fluid back into the bloodstream. Causes of lymphoedema include blockage, damage, removal or compression of lymph nodes or lymph drainage. Although lymphoedema of the arm is a well-known complication of breast and axillary surgery, breast lymphoedema has received scant attention.

Research abstract

Characterise breast lymphoedema's incidence, associated symptoms, clinical course, and impact on quality of life.

Method

Subjects were enrolled prospectively from a consecutive sample of patients undergoing non-mastectomy breast procedures (excisional biopsy or wide local excision ± lymph node removal) and followed for signs and symptoms of lymphoedema in the operated breast. Symptoms and distress were serially assessed with 11-point linear analog scales. Breast lymphoedema was diagnosed independent of symptoms, based on the distribution and degree of oedema and erythema. One hundred and twenty-four women were followed for a median of 11 months, and breast lymphoedema was diagnosed in 38 (31%) women.

Research findings

Breast lymphoedema was more frequent after breast surgery with axillary node removal (49%) compared to breast surgery alone (0%), $p < 0.0001$. Breast lymphoedema involved multiple quadrants in most women and was characterised by oedema in 100% and erythema in 79%. Patients with breast lymphoedema were significantly more likely than those without breast lymphoedema to report symptoms of breast heaviness (65% vs 22%, $p < 0.0001$), redness (62% vs 29%, $p = 0.0006$), and swelling (59% vs 22%, $p < 0.0001$), but symptom-associated distress was low overall. Three of 32 breast lymphoedema patients with clinical follow-up developed chronic oedema.

Conclusion

Breast lymphoedema occurs in approximately one-half of women who undergo breast surgery with axillary node removal. The condition is characterised by diffuse skin oedema and erythema, as well as self-reported symptoms with a low level of distress.

to a glass of water without stirring, over time the red food colouring molecules will evenly diffuse through the whole glass, giving an overall pink rather than a red appearance. A physiological example is the movement of oxygen and carbon dioxide between the alveoli and blood vessels in the lungs. The difference between the two concentrations is known as a **concentration gradient** (Hall 2015). The diffusion process is relatively slow and can be expedited by several factors, including smaller molecular size of the particles, higher temperature, greater concentration difference between the two compartments, and higher permeability of the substance.

Filtration

Filtration is the process by which water and diffusible substances move together in response to fluid (hydrostatic) pressure. This process is active in capillary beds, where **hydrostatic pressure** differences determine the movement of water (Figure 34-7). When there is increased hydrostatic pressure on the venous side of the capillary bed, as occurs in heart failure (HF), the normal movement of water from the interstitial space into the intravascular space by filtration is reversed, resulting in an accumulation of excess fluid in the interstitial space, known as **oedema**.

Active transport

Unlike diffusion, osmosis and filtration, **active transport** requires metabolic activity and expenditure of energy to move materials across cell membranes. This allows cells to admit larger molecules than they would otherwise be able to admit, or to move molecules 'uphill' from areas of lesser concentration to areas of greater concentration. An example of active transport is the sodium and potassium pump (Figure 34-8). Sodium is pumped out of the cell and potassium is pumped in, against the concentration gradient. This process makes it possible to keep a higher concentration of potassium in the ICF and a higher concentration of sodium in the ECF (Hall 2015).

Active transport is enhanced by carrier molecules in a cell, which bind themselves to incoming molecules. For example, glucose is able to enter cells after it binds with the transport vehicle insulin. Active transport is the mechanism by which cells absorb glucose and other substances to carry out metabolic activities.

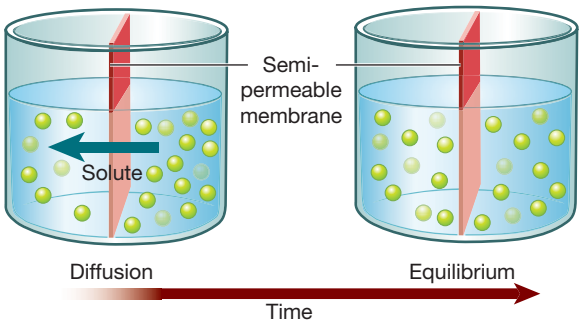

Figure 34-6 Diffusion across a semipermeable membrane.

Regulation of body fluids

Body fluids are regulated by fluid intake, hormonal controls and fluid output. This physiological balance is termed **homeostasis** (Lewis et al 2014). In health, a number of feedback mechanisms work together to maintain homeostasis (Figure 34-9).

Fluid intake

Fluid intake is regulated mainly through the thirst mechanism. *Thirst* is the conscious desire for water and is one of the major factors that determine fluid intake (Patton & Thibodeau 2016). The thirst-control centre, located

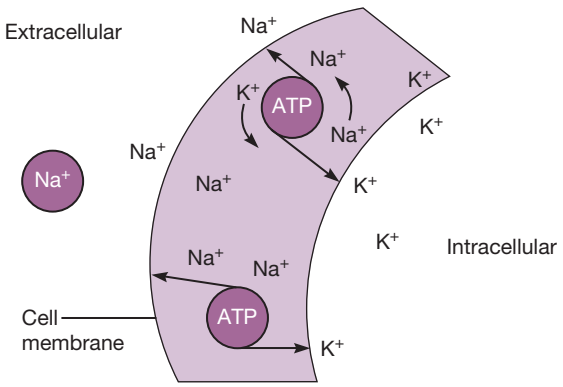

Figure 34-8 Sodium–potassium pump.

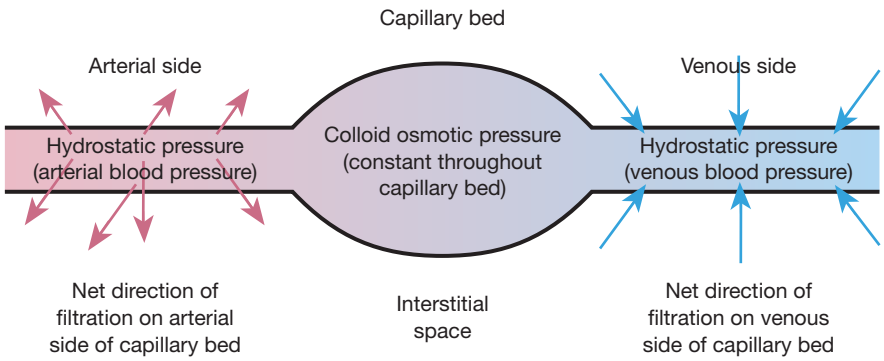

Figure 34-7 An example of filtration and hydrostatic pressure.

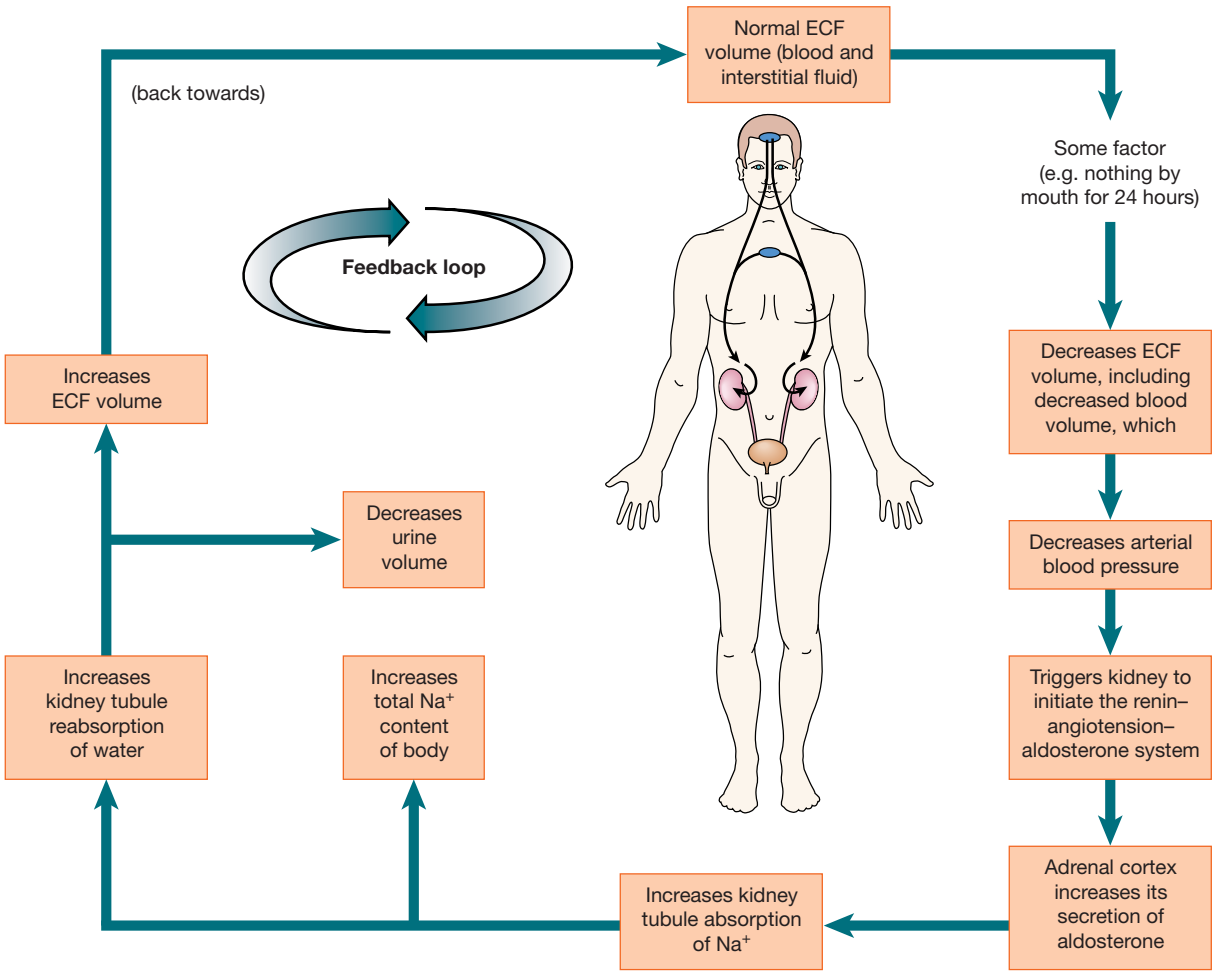

Figure 34-9 **Feedback mechanisms for maintaining fluid balance.**
ECF = extracellular fluid.

within the hypothalamus in the brain, is stimulated by three processes:

- decrease in saliva results in dry mucosa in the mouth and pharynx
- increase in blood osmotic pressure stimulates osmo receptors in the hypothalamus
- decrease in blood volume leads to the renin–angiotensin–aldosterone system (RAAS) stimulating the thirst centre in the hypothalamus (Figure 34-10).

The **osmoreceptors** continually monitor the solute concentration of the plasma. Osmoreceptors indirectly monitor 'water balance' and control the distribution of water between intracellular and extracellular fluid. Osmoreceptors respond to changes in osmotic pressure and tonicity caused by an excess or a deficit of water. Tonicity measures the osmotic pressure gradient between two solutions but only takes into account solutes which cannot cross the semipermeable membrane (Hall 2015).

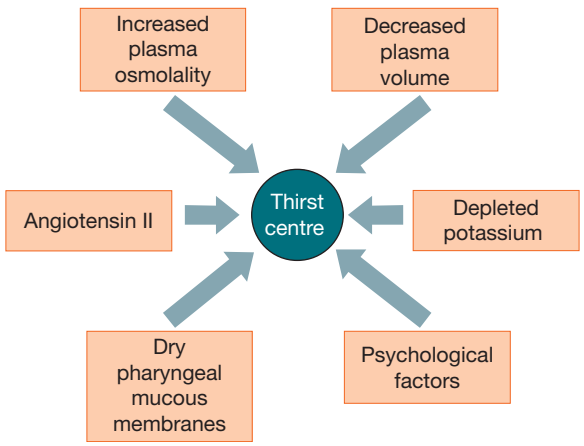

Figure 34-10 **Stimuli affecting the thirst mechanism.**

Osmolarity, on the other hand, measures all solutes – that is, those that can and cannot cross the semipermeable membrane.

When osmolality increases, the hypothalamus is stimulated. Increased plasma osmolality can occur with any condition that interferes with the oral ingestion of fluids, or it can occur with the intake of hypertonic fluids. The hypothalamus will also be stimulated when excess fluid is lost and **hypovolaemia** occurs, as in excessive vomiting and haemorrhage. If the thirst centre is activated, fluid deficit has already occurred to some extent. The response of the thirst reflex to fluid deficit is, however, diminished by older age, hypothalamic dysfunction, diminished cognitive function and infancy. Infants are at a higher risk than adults for dehydration, burns, illnesses or trauma because of a physiological inability of their renal tubules to concentrate urine, a higher metabolic rate, a larger body surface area and a poorly developed thirst mechanism.

Hormonal regulation

Hormones regulate fluid intake through various mechanisms.

Antidiuretic hormone (ADH) is stored in the posterior pituitary gland. The osmoreceptors in the hypothalamus are stimulated to release ADH if there is an increase in blood osmolality. ADH works directly on the renal tubules and collecting ducts to increase their permeability to water. This in turn causes water to return to the intravascular space circulation, which dilutes the blood and decreases its osmolality. As the body attempts to compensate, the patient will experience a temporary decrease in urinary output. When the blood has been sufficiently diluted, the osmoreceptors stop the release of ADH and urinary output is restored.

Aldosterone is released by the adrenal cortex in response to increased plasma potassium levels or as a part of the RAAS to counteract hypovolaemia. It acts on the distal portion of the renal tubule to increase the reabsorption (saving) of sodium and the secretion and excretion of potassium and hydrogen. Because sodium retention leads to water retention, the release of aldosterone acts as a volume regulator (Patton & Thibodeau 2016).

Renin, a proteolytic enzyme secreted by the kidneys, responds to decreased renal perfusion secondary to a decrease in extracellular volume. Renin acts to produce angiotensin I, which causes some vasoconstriction, but angiotensin I almost immediately becomes reduced by an enzyme's action to angiotensin II. Angiotensin II causes massive selective vasoconstriction of many blood vessels and relocates and increases the blood flow to the kidney, improving renal perfusion. Angiotensin II also stimulates the release of aldosterone when the sodium concentration is low (Patton & Thibodeau 2016).

Fluid output

Fluid output occurs through four organs: the kidneys, the skin, the lungs and the gastrointestinal (GI) tract. The kidneys are the major regulatory organs of fluid balance. They receive approximately 180 L of plasma to filter each day and produce 1200–1500 mL of urine daily.

Water loss from the skin is regulated by the sympathetic nervous system, which activates sweat glands. Water loss from the skin can be a sensible or an insensible loss. An average of 400–500 mL of sensible and insensible fluid is lost via the skin each day (Patton & Thibodeau 2016). With fever, another 50 to 75 mL/day may be lost for each 1°C of temperature elevation above normal. **Insensible water loss** from the skin is continuous, and the usual rate of 0.4–0.5 mL/kg/h is not usually perceived by the individual. **Sensible water loss** from the skin occurs through excess perspiration and can be perceived by the patient or by the nurse through inspection. The amount of sensible perspiration is directly related to the stimulation of the sweat glands.

The lungs expire about 400 mL of water daily. This insensible water loss may increase in response to changes in respiratory rate and depth. In addition, devices for administering oxygen can increase insensible water loss from the lungs.

The GI tract plays a vital role in fluid regulation. Approximately 3–6 L each day of isotonic fluid is moved into the GI tract and then returns to the extracellular fluid. Under normal conditions, the average adult loses only 100–200 mL of the 3–6 L gastrointestinal tract (GIT) fluids each day through faeces. However, in the presence of a disease process, for example, diarrhoea, the GI tract may become the site of a large amount of fluid loss. This loss may have a significant impact on maintaining normal fluid regulation.

Regulation of electrolytes

Cations

Major cations within the body fluids include sodium (Na^+), potassium (K^+), calcium (Ca^{2+}) and magnesium (Mg^{2+}). Cations interchange when one cation leaves the cell and is replaced by another. This occurs because cells tend to maintain electrical neutrality. Regulation of individual cations is included in Table 34-9.

Anions

The three major anions of body fluids are chloride (Cl^-), bicarbonate (HCO_3^-) and phosphate (PO_4^{3-}) ions. Their regulation is included in Table 34-10.

TABLE 34-9 Major cations: function, regulation, distribution and imbalances

Cation	Dietary source	Function and regulation	Distribution	Causes of imbalances	Signs and symptoms
Sodium (Na^+) Normal level: 137–145 mmol/L	Table salt, sea vegetables, milk, spinach, beets, celery, drinking water; Worcestershire and soy sauce, onion salt, garlic salt, bouillon cubes; processed meats (bacon, sausages, ham), canned soups and vegetables	Na^+ is a major contributor to maintaining water balance through its effect on serum osmolality; Na^+ accounts for half the osmolarity of ECF Essential for electrical activity of neurons and muscle cells Mechanisms regulating Na^+ are dietary intake, aldosterone, ANP and ADH	Represents about 90% of extracellular cations	*Hyponatraemia* caused by vomiting/diarrhoea, NG suction, decreased Na+ intake, pyrexia, diaphoresis, increased water intake, burns and wounds, renal disease, DKA, malnutrition	*Physical examination:* apprehension, personality change, postural hypotension, dizziness, abdominal cramping, nausea and vomiting, diarrhoea, tachycardia, convulsions and coma *Laboratory findings:* serum $Na^+ < 137$ mmol/L, serum osmolality < 285 mOsm/kg, urine specific gravity < 1.010 (if not caused by SIADH)
				Hypernatraemia caused by increased Na^+ intake, decreased water intake, renal disease, pyrexia, increased insensible water loss, type 2 diabetes, hyperglycaemia	*Physical examination:* thirst, dry and flushed skin, dry and sticky tongue and mucous membranes, fever, agitation, convulsions, restlessness, irritability *Laboratory findings:* serum $Na^+ > 145$ mmol/L, serum osmolality > 295 mOsm/kg, urine specific gravity > 1.030 (if not caused by type 2 diabetes)
Potassium (K^+) Normal level: 3.5–4.2 mmol/L	Legumes, potato skin, tomatoes, bananas, papayas, lentils, dry beans, whole grains, avocados, yams, soybeans, spinach, chard, sweet potato, turmeric, dark leafy greens, potatoes, squash, yoghurt, fish, mushrooms	K^+ major electrolyte and principal cation in the intracellular compartment It regulates many metabolic activities and is necessary for glycogen deposits in the liver and skeletal muscle Establishes resting membrane potential and is essential in the repolarisation phase of action potentials in nervous and muscle tissue K^+ aids maintenance of fluid volume in cells, regulation of pH. Serum level controlled by aldosterone. K+ is regulated by dietary intake and renal excretion. The body conserves potassium poorly, so any condition that increases urine output decreases the serum potassium concentration	Most abundant intracellular cation; Creates most of the osmotic pressure in ICF	*Hypokalaemia* caused by decreased K^+ intake, starvation, malabsorption syndromes, GI losses, diuresis, nephritis, alkalosis	*Physical examination:* weakness and fatigue, decreased muscle tone, intestinal distension, decreased bowel sounds, ventricular dysrhythmias, paraesthesias, weak, irregular pulse *Laboratory findings:* serum $K^+ < 3.1$ mmol/L and ECG abnormalities (e.g. ventricular dysrhythmias)
				Hyperkalaemia caused by increased K^+ intake, renal disease/failure, adrenal insufficiency, metabolic acidosis, severe dehydration, burns, crushing injuries, haemolysis	*Physical examination:* anxiety, dysrhythmias, paraesthesia, weakness, abdominal cramps, diarrhoea *Laboratory findings:* serum $K^+ > 4.2$ mmol/L and ECG abnormalities (bradycardia, heart block, dysrhythmias); eventually widening of QRS pattern and cardiac arrest

Cation	Dietary source	Function and regulation	Distribution	Causes of imbalances	Signs and symptoms
Calcium (Ca^{2+}) Normal level: 2.2–2.6 mmol/L	Dairy products, eggs, canned fish with bones (salmon, sardines), green leafy vegetables, nuts, seeds, tofu, thyme, oregano, dill, cinnamon	Role in bone and teeth formation, blood clotting, hormone secretion, cell membrane integrity, cardiac conduction, transmission of nerve impulses and muscle contraction The primary regulator of plasma levels of Ca^{2+} stems from the parathyroid hormone	Extracellular cation; abundant in the body due to bone content, stored in bone, plasma and body cells	*Hypocalcaemia* caused by decreased dietary calcium, vitamin D deficiency, renal insufficiency, diuretics, hypoparathyroidism, alkalosis, increased serum protein	*Physical examination:* numbness and tingling of fingers and circumoral region, hyperactive reflexes, positive Trousseau's sign (carpopedal spasm with hypoxia), positive Chvostek's sign (facial tick when facial nerve tapped), tetany, muscle cramps, pathological fractures *Laboratory findings:* serum Ca^{2+} < 2.2 mmol/L and ECG abnormalities
				Hypercalcaemia caused by acidosis, prolonged immobilisation, kidney disease, hyperparathyroidism, excessive administration	*Physical examination:* anorexia, nausea and vomiting, weakness, lethargy, low back pain (from renal calculi), decreased level of consciousness, personality changes, cardiac arrest *Laboratory findings:* serum Ca^{2+} > 2.6 mmol/L; ECG abnormalities
Magnesium (Mg^{2+}) Normal levels: 0.7–0.95 mmol/L	Raw nuts, soybeans, cocoa mass, spinach, chard, sea vegetables, tomatoes, halibut, beans, ginger, cumin, cloves	Essential for ATP production, enzyme activities, neurochemical activities and cardiac and skeletal muscle excitability; serum magnesium is regulated by dietary intake, renal mechanisms and actions of PTH	Abundant cation in ICF; 50–60% of Mg^{2+} magnesium contained within the muscles and bone, only 1% within the ECF compartment; the rest located inside the cell	*Hypomagnesia* caused by decreased intake, malabsorption syndromes, increased renal excretion, patients postoperatively, diabetes, alcoholism, burns, hypokalaemia	*Physical examination:* muscular tremors, hyperactive deep tendon reflexes, confusion and disorientation, dysrhythmias, positive Chvostek's sign and Trousseau's sign *Laboratory findings:* serum Mg^{2+} < 0.7 mmol/L
				Hypermagnesia caused by: chronic renal disease, decreased GFR and decreased magnesium excretion, ECF deficit, administration of Mg-containing drugs	*Physical examination:* hypoactive deep tendon reflexes, decreased depth and rate of respirations, hypotension, flushing *Laboratory findings:* serum Mg^{2+} > 0.95 mmol/L

ANP = atrial natriuetic peptide; ATP = adenosine triphosphate; DKA = diabetic ketoacidosis; ECF = extracellular fluid; ECG = electrocardiogram; FVD = fluid volume deficit; ICF = intracellular fluid; GFR = glomerular filtration rate; GI =gastrointestinal; NG = nasogastric; PTH = parathyroid hormone; SIADH = syndrome of inappropriate antidiuretic hormone.

TABLE 34-10 Major anions: function, regulation, distribution and imbalances

Anion	Source	Function and regulation	Distribution	Causes of imbalances	Signs and symptoms
Chloride (Cl^-) Normal level: 98–106 mmol/L	Table salt (sodium chloride) is the main source of dietary intake	Helps balance anions in different fluid compartments; regulates osmotic pressure Regulated by dietary intake and the kidneys; and indirectly by aldosterone, due to relationship with sodium	Most prevalent anion in ECF Diffuses easily between interstitial space and ICF Chloride is a part of HCl in gastric juices and passively follows sodium	*Hypochloraemia* from decreased Cl^- intake or absorption, low dietary Na^+, K^+ deficiency and metabolic alkalosis. IV dextrose without electrolytes, prolonged diarrhoea or diaphoresis, loss of HCl in GIT secretions, increased water intake or use of mercurial diuretics	*Physical examination:* muscle hypertonicity, tetany, shallow depressed breathing, hyponatraemia, muscle weakness and twitching *Laboratory findings:* serum Cl± < 98 mmol/L, serum pH > 7.45
				Hyperchloraemia from increased Cl^- intake, high dietary Na^+, decreased water intake, increased fluid loss e.g. by vomiting or diarrhoea	*Physical examination:* deep rapid breathing, generalised weakness, decreased cognition, coma *Laboratory findings:* serum Cl^- > 106 mmol/L; serum pH < 7.35
Bicarbonate (HCO_3^-) Normal level: 22–32 mmol/L		Major buffer of H+ in plasma Helps maintain correct balance of anions and cations in ECF and ICF Important anion of the bicarbonate buffer system Used to transport CO_2 in blood; excretion and reabsorption and thus serum level controlled by the kidneys	Second most prevalent anion in ECF; small amount found in ICF	*Decreased bicarbonate* caused by increased GIT or IV intake, increased acid production or intake, decreased acid excretion or loss by the renal system	*Physical examination:* fatigue, headache, abdominal pain, nausea, vomiting, respiratory depression, Kussmaul's breathing, metabolic acidosis *Laboratory findings:* metabolic acidosis – low HCO_3^-, acidic urine
				Increased bicarbonate caused by administration or production of alkaline sodium bicarbonate or other antacid, acid-losing alkalosis (loss of H^+ from GIT in chronic vomiting), decreased K^+	*Physical examination:* non-specific signs and symptoms with concurrent hypokalaemia weakness, myalgia and polyuria; hypoventilation from inhibition of the medullary respiratory centre with decreased ionised Ca^{2+} tetany, Chvostek's sign, Trousseau's sign; decreased cognition and seizures *Laboratory findings:* metabolic alkalosis – increased HCO_3^-, increased $PaCO_2$; if secondary to volume depletion, urine Cl^- < 20 mEq/L

continued

TABLE 34-10 ***continued***

Anion	Source	Function and regulation	Distribution	Causes of imbalances	Signs and symptoms
Phosphate (PO_4^{3-}) Normal level: 0.7–1.25 mmol/L	Red meat, dairy foods, fish, poultry, bread, rice, oats	Phosphate is part of DNA, RNA, ATP and phospholipids, as well as the phosphate buffer system; assists in acid–base regulation; helps develop and maintain bones and teeth; promotes normal neuromuscular action; participates in carbohydrate mechanism Regulated by dietary intake, renal excretion, intestinal absorption and PTH	Buffer anion mainly in ICF 85% of the body's phosphate is found in bones and teeth Vitamin D is required to absorb phosphate, through the GIT	*Hypophosphatemia* caused by poor PO_4^{3-} absorption, GIT surgery, vitamin D deficiency, aluminium hydroxide (e.g. Amphogel), low serum Mg^{2+}, high serum Ca^{2+}, urinary loss of bicarbonate in kidney dysfunction, diuretics, hyperactive parathyroid or thyroid gland, type 1 diabetes, alcoholism	*Physical examination:* muscle weakness, tremor and paraesthesia; peripheral hypoxia; neurological irritability *Laboratory findings:* serum PO_4^{3-} 0.64–0.81 mmol/L (moderate), < 0.31 mmol/L (severe); urine PO_4^{3-} increased
				Hyperphosphataemia is usually asymptomatic unless leading to hypocalcaemia, with tetany and seizures	*Physical examination:* signs and symptoms result from accompanying hypocalcaemia and hyperthyroidism; if left untreated, renal dysfunction occurs *Laboratory findings:* serum PO_4^{3-} > 1.45 mmol/L; urine PO_4^{3-} decreased

ATP = adenosine triphosphate; CO_2 = carbon dioxide; DNA = deoxyribonucleic acid; ECF = extracellular fluid; ICF = intracellular fluid; GIT = gastrointestinal tract; HCl = hydrochloric acid; IV = intravenous; $PaCO_2$ = arterial partial pressure of carbon dioxide; PTH = parathyroid hormone; RNA = ribonucleic acid.

Regulation of acid–base balance

Metabolic processes maintain a steady balance between acids and bases to maintain optimal functioning of the cells. Arterial pH is an indirect measurement of hydrogen ion (H^+) concentration: the higher the pH, the more acidic the solution (contains more H^+ ions); a lower pH, a more alkaline solution (fewer H^+ ions) (Hall 2015). pH is a scale for measuring the acidity or alkalinity of a fluid. A pH value of 7 is neutral, below 7 is acid, and above 7 is alkaline. Normal pH values in arterial blood range from 7.35 to 7.45.

The pH is regulated by two broad control systems, the *chemical buffer systems* (bicarbonate, phosphate and protein buffer systems) and the *physiological buffer systems* (the respiratory and renal response systems) (Patton & Thibodeau 2016). A hydrogen ion buffer is a substance or a group of substances that can absorb or release H^+ to correct an acid–base imbalance. Acid–base balance exists when the net rate at which the body produces acids or bases equals the rate at which acids or bases are excreted. Normal hydrogen ion levels are necessary to maintain cell membrane integrity and the speed of cellular enzymatic actions. Although **buffers** can raise the pH of body fluids, they do not remove the H+ from the body; this is left to the physiological buffers (Patton & Thibodeau 2016).

Chemical buffer systems

Several buffering agents bind hydrogen ions to prevent or reduce changes in pH. Extracellular buffers include bicarbonate and ammonium ions; intracellular buffers include proteins and phosphate ions.

The most important chemical buffer in ECF is the *carbonic acid and bicarbonate buffer system*, which reacts to imbalances within seconds (Figure 34-11). The equation below demonstrates how hydrogen ions (H^+) and carbon dioxide (CO_2) concentrations are directly related to each other, in that an increase in one causes an increase in the other. An increase in carbon dioxide concentration produces an increase in hydrogen ions; an increase in hydrogen ions results in increased carbon dioxide production (McCance & Huether 2014).

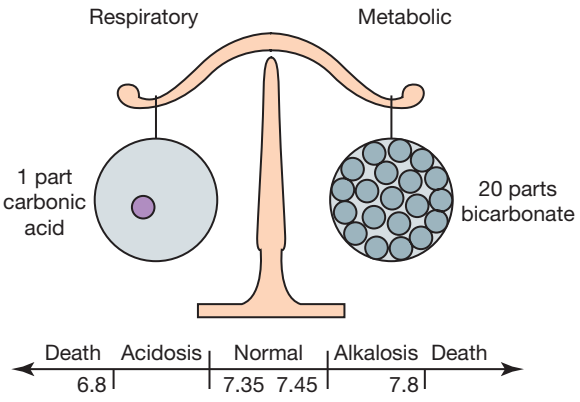

Figure 34-11 Carbonic acid–bicarbonate ratio and pH.

$$CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows HCO_3^- + H^+$$

A second type of chemical buffering occurs with the *absorption or release of hydrogen ions* by cells. This buffering occurs after the carbonic acid and bicarbonate buffering, and takes 2–4 hours. The positively charged hydrogen ion is exchanged with another positively charged ion, frequently potassium (K^+). In conditions with excess acid, a hydrogen ion enters the cell and a potassium ion leaves the cell and enters the ECF, thus causing elevated serum potassium.

Another buffer is the *haemoglobin–oxyhaemoglobin system*. Carbon dioxide diffuses into the red blood cells (RBCs) and forms carbonic acid. The carbonic acid dissociates into hydrogen ions and bicarbonate ions. The hydrogen ions attach to haemoglobin, and the bicarbonate ion becomes available for buffering by exchanging with extracellular chloride (McCance & Huether 2014).

The last buffer is the *chloride shift* within RBCs. When blood is oxygenated in the lungs, bicarbonate diffuses into the cells and chloride travels from the haemoglobin to the plasma to maintain electrical neutrality. The reverse occurs when CO_2 moves into RBCs in tissue capillary beds.

Physiological buffer systems

The two physiological buffers in the body occur in the lungs and the kidneys. The excretion of CO_2 as a consequence of metabolism is controlled mainly by the lungs, and the excretion of hydrogen and bicarbonate ions is controlled by the kidneys.

The lungs respond rapidly to acid–base imbalances to return the pH towards normal before the biological buffers act. Increased levels of hydrogen ions and CO_2 provide the stimulus for respiration. The lungs expel CO_2, which raises pH, because hydrogen ions have to be consumed with bicarbonate ions in order to produce CO_2. To prevent too many hydrogens ions from being lost, the kidneys remove excess bicarbonate ions. As a result, the equilibrium is shifted to the right (so that more bicarbonate ions are produced to replace the lost ones), and as a result, more hydrogen ions are produced, which lowers the pH. When the body uses energy, CO_2 is produced. This CO_2 is partially dissolved in plasma and red blood cells, but the majority is combined with water to form carbonic acid (H_2CO_3), which further dissociates into H+ ions and HCO_3^- ions. The bicarbonate (HCO_3^-) ions then are transported through the circulation system until they reach the lungs, when they combine with hydrogen ions to form CO_2 and water. This CO_2 is then expelled out by the lungs.

When the concentration of hydrogen ions is altered, the lungs react to correct the imbalance by altering the rate and depth of respiration. For example, when metabolic acidosis is present, respirations are increased, resulting in a greater amount of CO_2 being exhaled; this results in a decrease in the acidic level. Conversely, when metabolic alkalosis is present, the lungs retain CO_2 by decreasing the respirations, thereby increasing the acidic level (Madias & Adrogue 2003).

The kidneys, a powerful acid–base regulatory system, take from a few hours to several days to regulate acid–base imbalance (Hall 2015). In *acidosis* (excess acid):

- cells in the renal tubules reabsorb more bicarbonate ions from the tubule fluid
- cells in the renal collecting duct secrete more hydrogen ions and generate more bicarbonate ions
- there is increased formation of ammonia through the ammonia mechanism (see below).

In addition, the kidneys use a phosphate ion (PO_4^{3-}) to excrete hydrogen ions by forming phosphoric acid (H_3PO_4); sulfuric acid (H_2SO_4) may also be excreted. The ammonia mechanism regulates acid–base balance by certain amino acids being chemically changed within the renal tubules into ammonia; this, in the presence of hydrogen ions, forms ammonium and is excreted in the urine, hence releasing hydrogen ions from the body (Roth & Chan 2001).

In *alkalosis* (acid deficit), the kidneys excrete more bicarbonate ions by decreasing hydrogen ion secretion from the epithelial cells of the renal tubules, and lowering rates of glutamine metabolism and ammonium ion excretion.

Disturbances in electrolyte, fluid and acid–base balances

Disturbances in **electrolyte**, fluid or acid–base balances seldom occur alone, and disrupt many other normal body

processes. Loss of body fluids due to dehydration, burns, illnesses or trauma or an increase of body fluids because of hypervolaemia, acute kidney injury (AKI) or HF, also put the patient at risk of electrolyte imbalances. In addition, some untreated electrolyte imbalances (e.g. potassium loss) result in acid–base disturbances.

Electrolyte imbalances

Sodium imbalances

Hyponatraemia is a lower-than-normal concentration of sodium in the blood (serum), which can occur with a net sodium loss or net water excess (Table 34-9). It occurs frequently in seriously ill patients, but can also occur in water intoxication, when someone drinks too much water too quickly, leading to haemodilution. Almond and others (2005) studied 488 runners in the 2002 Boston marathon; 13% of runners were found to have hyponatraemia (a serum sodium concentration of ≤ 135 mmol/L) and 0.6% critical hyponatraemia (≤ 120 mmol/L). In this situation hyponatraemia was associated with substantial weight gain, consumption of more than 3 litres of water during the race, female gender and low body mass index (BMI).

Nurses' awareness of the effect of medications on serum sodium levels should increase early identification of hyponatraemia through regular appraisal of serum electrolyte results. Antidepressant medication, specifically selective serotonin re-uptake inhibitors (SSRIs), and diuretics were associated with an increased risk of hyponatraemia (Mannesse et al 2010, Movig et al 2002).

Clinical indicators and treatment depend on the cause of the hyponatraemia and association with normal, decreased or increased ECF volume (McCance & Huether 2014). The usual situation is a loss of sodium without a loss of fluid, resulting in decreased ECF osmolality. The body initially adapts by reducing water excretion and thus sodium excretion to maintain serum osmolality at near-normal levels. As the sodium loss continues, the body continues to preserve the blood and interstitial (tissue) volume. As a result, the sodium in ECF becomes diluted.

Hypernatraemia is an increased concentration of ECF sodium, caused by excess water loss or an overall sodium excess (see Table 34-9). When the cause of hypernatraemia is increased aldosterone secretion, sodium is retained and potassium is excreted. When hypernatraemia occurs, the body attempts to conserve as much water as possible through renal reabsorption.

Potassium imbalances

Because the normal levels of serum potassium are low, there is little tolerance for fluctuations.

Hypokalaemia is an inadequate amount of potassium in ECF (see Table 34-9). When severe, hypokalaemia can affect cardiac conduction and function. The most common cause of hypokalaemia is the use of potassium-wasting diuretics such as thiazide and loop diuretics.

Hyperkalaemia is an increased amount of serum potassium. Severe hyperkalaemia produces marked cardiac conduction abnormalities (see Table 34-9). The main cause of hyperkalaemia is renal failure and thus decreased excretion of potassium.

• CRITICAL REFLECTION POINT

Among nurses' responsibilities are monitoring whether prescribed diet and fluids meet each patient's nutritional needs. This cannot be achieved without knowledge of patient diagnoses and interpretation of the pattern and trend of serum electrolytes and consultation/referral to a medical officer and dietitian.

Activity

Mr Stanley Knowles is ordered a diet that is low in potassium as part of the intervention for acute kidney injury (AKI) and hyperkalaemia.

1. **Use the information in Table 34-11 to determine if a lunch menu of 1 piece of fish (Atlantic salmon), baked potato (with skin), spinach ½ cup, ½ sweet potato; dessert – fresh strawberries, 1 cup with plain non-fat yoghurt (237 mL) meets the criteria for a low potassium diet.**
2. **Construct a menu which would be lower in potassium, based on the information in Table 34-11.**

Calcium imbalances

Hypocalcaemia represents a drop in serum and/or ionised calcium levels. It can result from illnesses that directly affect the thyroid and parathyroid glands (see Table 34-9) and from renal insufficiency (in which the kidneys' inability to excrete phosphorus causes the phosphorus level to rise and the calcium level to decline). Signs and symptoms can be related to a diminished function of the neuromuscular, cardiac and renal systems.

Hypercalcaemia is an increase in the total serum concentration of calcium and/or ionised calcium. Hypercalcaemia is frequently a symptom of an underlying disease resulting in excess bone reabsorption with a release of calcium.

Magnesium imbalances

Disturbances in magnesium levels result in changes in neuromuscular excitability (see Table 34-9). *Hypomagnesaemia*, a decrease in serum magnesium, occurs with malnutrition and with malabsorption disorders. Signs and symptoms are directly related to the neuromuscular system.

TABLE 34-11 Foods and potassium content (mg)

Food	Potassium	Food	Potassium	Food	Potassium
Apple 1 large	148 mg	Corned beef 85 g*	61 mg	Peaches 1 medium	186 mg
Apple sauce ½ cup	90 mg	Dried apricots	1162 mg	Pork 85 g	105 mg
Apricots fresh 3	378 mg	Eggs 1	55 mg	Potatoes baked with skin	569 mg
Avocado	485 mg	Fish (Atlantic Salmon)	628 mg	Salmon canned 85 g*	484 mg
Bacon 3 slices*	45 mg	Grapefruit juice ½ cup	180 mg	Spinach 1 cup	840 mg
Banana mashed 1 cup	540 mg	Grapes 10 medium	72 mg	Strawberries 1 cup	255 mg
Banana 1 medium	422 mg	Ham 85 g*	182 mg	Sweet potato1 medium	695 mg
Beef 85 gm	290 mg	Lamb 85 g	259 mg	Squash	437 mg
Blueberries ½ cup	50 mg	Milk fat-free 237 mL	380 mg	Tomato 1 cup	430 mg
Bologna 1 slice	48 mg	Mushrooms	396 mg	Tuna canned 85 g*	484 mg
Broccoli 1 cup	460 mg	Nectarines 1 medium	273 mg	White beans	561mg
Cantaloupe (rockmelon) 1 cup	368 mg	Orange 1 medium	237 mg	Yoghurt plain non-fat 237 mL	579 mg
Chicken 85 gm	383 mg	Orange juice ¾ cup	355 mg		

*Note these foods are high in sodium

Adapted from: Bellows L, Moore R 2013 Potassium and the Diet Fact Sheet No 9.355 © 2015 Colorado State University Extension, www.ext.colostate.edu/pubs/foodnut/09355.html; accessed May 30 2015.

Hypermagnesaemia, an increase in serum magnesium levels, depresses skeletal muscles and nerve function. Hypermagnesaemia occurs during renal failure, aldosterone deficiency and hypothyroidism and by excess intake of antacids containing Mg^{2+}. Hypermagnesaemia causes hypotension, muscle weakness, nausea, vomiting and altered mental functioning (Lewis et al 2014).

Chloride imbalances

Hypochloraemia occurs when serum chloride levels fall below normal (see Table 34-10). Vomiting or prolonged and excessive nasogastric or fistula drainage can result in hypochloraemia because of the loss of hydrochloric acid. The use of loop and thiazide diuretics also results in increased chloride loss, as sodium is excreted. When serum chloride levels fall, metabolic alkalosis results as the body adapts by increasing reabsorption of the bicarbonate ion to maintain electrical neutrality. *Hyperchloraemia* is where the serum chloride levels rise above normal (see Table 34-10), which usually occurs when serum bicarbonate levels fall or sodium levels rise.

Hypochloraemia and hyperchloraemia rarely occur as single disease processes, but are commonly associated with acid–base imbalance. There is no single set of symptoms associated with these two alterations.

Fluid disturbances

The basic types of fluid imbalance are isotonic and osmolar. *Isotonic deficit* and excess exist when water and electrolytes are gained or lost in equal proportions. In contrast, *osmolar imbalances* are losses or excesses of only water, so that the concentration (osmolality) of the serum is affected. Table 34-12 lists the causes and symptoms of common fluid disturbances.

• CRITICAL REFLECTION POINT

Your friend meets with you for coffee after playing cricket (bowling and fielding) on a day when the air temperature is 39.2°C. He appears agitated and is experiencing muscle cramps, lethargy, nausea, problems concentrating and has a severe headache. On asking what he has consumed during the day, he states he has had around 4 litres of plain water.

Activity

Refer to Table 34-12 in determining the type of fluid imbalance and reasons for this imbalance, including appropriateness of his intake throughout the day, knowledge of the fluid and electrolytes he would have lost and possible replacement therapy.

Acid–base balance disturbances

Arterial blood gas (ABG) analysis is the best way to evaluate acid–base balance. Measurement of ABGs

TABLE 34-12 Fluid disturbances

Causes	Signs and symptoms
Isotonic imbalances	
Fluid volume deficit (FVD) – water and electrolytes lost in equal or isotonic proportions	
Losses from the GI system, e.g. diarrhoea, vomiting or drainage from fistulas or tubes Loss of plasma or whole blood, e.g. burns or haemorrhage Loss of fluid: excessive perspiration, fever, diuretics Decreased oral intake of fluids	**Physical examination:** postural hypotension, decreased pulse pressure, decreased MAP, tachycardia, dry mucous membranes, poor skin turgor, thirst, confusion, rapid weight loss*, slow vein filling, lethargy, oliguria, weak pulse **Laboratory findings:** urine specific gravity: 1.025; increased haematocrit level, 50%; and increased BUN level, > 8 mmol/L (haemoconcentration) * Weight is either stationary or increases in third space fluid shift
Fluid volume excess (FVE) – water and sodium retained in isotonic proportions	
Chronic heart failure Renal failure Cirrhosis of the liver Increased serum aldosterone and steroid levels Excessive sodium intake or administration	**Physical examination:** rapid weight gain, peripheral oedema, hypertension, increased pulse pressure, increased MAP, polyuria (if renal mechanisms are normal), increased jugular venous pressure, increased venous pressure, bi-basal lung crepitation **Laboratory findings:** decreased haematocrit level, 35%; and decreased BUN level > 3 mmol/L (haemodilution)
Osmolar imbalances	
Hyperosmolar imbalance – dehydration	
Type 2 diabetes Interruption of neurologically-driven thirst drive Diabetic ketoacidosis Osmotic diuresis Administration of hypertonic parenteral or enteral fluids	**Physical examination:** dry and sticky mucous membranes, flushed and dry skin, thirst, elevated body temperature, irritability, convulsions, coma **Laboratory findings:** increased serum sodium level > 145 mmol/L; and increased osmolality > 295 mOsm/kg
Hypo-osmolar imbalance – water excess	
SIADH Excess water intake	**Physical examination:** nausea, muscle cramps, decreased ability to concentrate, agitation, decreased level of consciousness, convulsions, coma **Laboratory findings:** decreased serum sodium level < 137 mmol/L; and decreased serum osmolality < 285 mOs/kg

BUN = blood urea nitrogen; MAP = mean arterial pressure (of blood); SIADH = syndrome of inappropriate antidiuretic hormone.

involves analysis of six components: pH, $PaCO_2$, PaO_2, oxygen saturation, base excess and HCO_3^-. Deviation from a normal value will indicate that the patient is experiencing an acid–base imbalance.

pH

pH measures hydrogen ion (H^+) concentration. Even a slight change can be potentially life-threatening. An increase in H^+ concentration makes a solution more acidic; a decrease makes the solution more alkaline. Normal pH values are 7.35–7.45 (acidic is < 7.35, and alkaline is > 7.45).

$PaCO_2$

$PaCO_2$ is the partial pressure of carbon dioxide in arterial blood, and reflects the depth of pulmonary ventilation. The normal range is 35–45 mmHg. A $PaCO_2$ of < 35 mmHg is an indication of *hyperventilation*. As rate and depth of respiration increase, more carbon dioxide is exhaled and the carbon dioxide concentration decreases. *Hypoventilation* causes increased $PaCO_2$, above 45 mmHg. As rate and depth of respiration decrease, less carbon dioxide is exhaled and more is retained, increasing the concentration of carbon dioxide.

PaO_2

PaO_2 is the partial pressure of oxygen in arterial blood. It has no primary role in acid–base regulation if it is within normal limits. The normal range is 80–100 mmHg. A PaO_2 of less than 60 mmHg (hypoxaemia) can lead to anaerobic metabolism, resulting in lactic acid production and

metabolic acidosis. There is a normal decline in PaO_2 in older adults. Hypoxaemia also may cause hyperventilation, resulting in respiratory alkalosis (McCance & Huether 2014).

Oxygen saturation

Oxygen saturation (SaO_2) is the percentage of available haemoglobin bound to oxygen. Oxygen saturation can be affected by changes in temperature, pH and $PaCO_2$. The normal range is 95–99%.

Base excess

Base excess is the amount of blood buffer (haemoglobin and bicarbonate) that exists. The normal range is –2 to +2. A high value indicates *alkalosis* and can result from the ingestion of large amounts of sodium bicarbonate solutions (some antacids), citrate excess with rapid blood transfusions or intravenous infusion of sodium bicarbonate to correct ketoacidosis. A low value indicates *acidosis* and is usually the result of the elimination of too many bicarbonate ions. An example is diarrhoea and prolonged loss (vomiting or nasogastric suction) of deep GI contents that force the loss rather than the absorption of bicarbonate-containing fluid (Berry & Pinard 2002).

Bicarbonate

Serum bicarbonate (HCO_3^-) is the major renal component of acid–base balance, and is excreted and produced by the kidneys to maintain a normal acid–base environment. It is the principal buffer of the ECF of the body, and once bicarbonate is in the ECF it is maintained at a concentration of 20 times that of the fluid concentration of carbonic acid (Berry & Pinard 2002). The normal range is 22–26 mmol/L, < 22 mmol/L usually indicates *metabolic acidosis*; > 26 mmol/L indicates *metabolic alkalosis*.

Types of acid–base imbalances

The four main types of acid–base imbalance are respiratory acidosis, respiratory alkalosis, metabolic acidosis and metabolic alkalosis (Table 34-13).

Respiratory acidosis

Respiratory acidosis is marked by an increased arterial carbon dioxide concentration ($PaCO_2$), excess carbonic acid (H_2CO_3) and an increased hydrogen ion concentration (decreased pH). With respiratory acidosis, the cerebrospinal fluid and brain cells become acidic, causing neurological changes. Hypoxaemia occurs because of respiratory depression, resulting in further neurological impairment. Electrolyte changes such as hyperkalaemia and hypercalcaemia may accompany the acidosis.

Respiratory alkalosis

Respiratory alkalosis is marked by decreased $PaCO_2$ levels and increased pH. Like respiratory acidosis, respiratory alkalosis can begin outside the respiratory system (e.g. anxiety with hyperventilation) or within the respiratory system (e.g. initial phase of an asthma attack).

TABLE 34-13 Acid–base imbalances

Causes	Signs and symptoms
Respiratory acidosis	
Hypoventilation resulting from primary respiratory problems	
Atelectasis (obstruction of small airways) Pneumonia Cystic fibrosis Respiratory failure Airway obstruction Chest wall injury	**Physical examination:** confusion, dizziness, lethargy, headache, ventricular dysrhythmias, warm and flushed skin, muscular twitching, convulsions, coma **Laboratory findings:** arterial blood gas alterations – pH 7.35, $PaCO_2$ 45 mmHg, PaO2 80 mmHg; and bicarbonate level normal (if uncompensated) or 32 mmol/L (if compensated)
Hypoventilation resulting from factors outside the respiratory system	
Drug overdose with a respiratory depressant Paralysis of respiratory muscles caused by various neurological alterations Head injury Obesity	**Physical examination:** confusion, dizziness, lethargy, headache, ventricular dysrhythmias, warm and flushed skin, muscular twitching, convulsions, coma **Laboratory findings:** arterial blood gas alterations – pH 7.35, $PaCO_2$ 45 mmHg, PaO_2 80 mmHg; and bicarbonate level normal (if uncompensated) or 32 mmol/L (if compensated)

continued

TABLE 34-13 ***continued***

Causes	Signs and symptoms
Respiratory alkalosis	
Hyperventilation resulting from primary respiratory problems	
Asthma Pneumonia Inappropriate mechanical ventilator settings	**Physical examination:** dizziness, confusion, dysrhythmias, tachypnoea, numbness and tingling of extremities, convulsions, coma **Laboratory findings:** arterial blood gas alterations – pH 7.45, $PaCO_2$ 35 mmHg, PaO_2 normal; and bicarbonate level normal (if short-lived or uncompensated) or 22 mmol/L (if compensated)
Hyperventilation resulting from factors outside the respiratory system	
Anxiety Hypermetabolic states Disorders of the central nervous system (head injuries, infections) Salicylate overdose	**Physical examination:** dizziness, confusion, dysrhythmias, tachypnoea, numbness and tingling of extremities, convulsions, coma **Laboratory findings:** arterial blood gas alterations – pH 7.45, $PaCO_2$ 35 mmHg, PaO_2 normal; and bicarbonate level normal (if short-lived or uncompensated) or 22 mmol/L (if compensated)
Metabolic acidosis	
High anion gap	
Starvation Diabetic ketoacidosis Renal failure Lactic acidosis from heavy exercise Use of drugs (methanol, ethanol, formic acid, paraldehyde, aspirin)	**Physical examination:** headache, lethargy, confusion, dysrhythmias, tachypnoea with deep respirations, abdominal cramps, flushed skin **Laboratory findings:** arterial blood gas alterations – pH 7.35, $PaCO_2$ normal (if uncompensated) or 35 mmHg (if compensated), PaO_2 normal or increased (with rapid, deep respirations); bicarbonate level 22 mmol/L and oxygen saturation normal
Normal anion gap	
Renal tubular acidosis Diarrhoea	In patients with a normal anion gap, the drop in HCO_3^- is almost completely compensated for by an increase in Cl^- and hence is also known as hyperchloraemic acidosis; symptoms are similar to those of the other types of metabolic acidosis
Metabolic alkalosis	
Excessive vomiting Prolonged gastric suctioning Hypokalaemia or hypercalcaemia Excess aldosterone Use of drugs (steroids, sodium bicarbonate, diuretics)	**Physical examination:** dizziness; dysrhythmias; numbness and tingling of fingers, toes and circumoral region; muscle cramps; tetany **Laboratory findings:** arterial blood gas alterations – pH 7.45, $PaCO_2$ normal (if uncompensated) or 45 mmHg (if compensated), PaO_2 normal; and bicarbonate level 32 mmol/L

$PaCO_2$ = partial pressure of carbon dioxide in arterial blood; PaO_2 = partial pressure of oxygen in arterial blood.

Metabolic acidosis

Metabolic acidosis results from abnormal loss of bicarbonate or accumulation of excess metabolic acids causing high acid content of the blood (Hall 2015). Identification of the cause of metabolic acidosis requires an analysis of serum electrolytes to detect an anion gap.

An **anion gap** reflects unmeasurable anions present in plasma, and is calculated by subtracting the sum of chloride and bicarbonate levels from the plasma sodium level (Table 34-14). The anion gap is thus an artefact of measurement, and not a physiological reality. Anion gap is an 'artificial' and calculated measure which is representative of the serum ions not routinely measured when testing serum electrolytes. Unmeasured cations include calcium, magnesium and most other minerals; unmeasured anions include albumin, phosphates, sulfates and organic acids (Kraut & Nagami 2013). Unmeasured cations (~7 mmol/L) include calcium, magnesium, and most other minerals. Unmeasured anions (~24 mmol/L) include proteins such as albumin and compounds such as phosphates, sulfates, and organic acids.

Calculating the anion gap is useful in distinguishing between anion-gap and non-anion-gap metabolic

TABLE 34-14 Differentiation of causes of metabolic acidosis from examination of normal vs elevated anion gap

Anion gap	Values	Causes
Low anion gap	< 12 mmol/L	Low anion gap may suggest: • Hyponatraemia • Multiple myeloma • Hypoalbuminemia • Plasma cell dyscrasia • Monoclonal protein • Bromide intoxication • Normal variant
Normal anion gap	12 (±2) mmol/L	• Loss of bicarbonate (i.e. diarrhoea) • Recovery from diabetic ketoacidosis • Ileostomy fluid loss • Carbonic anhydrase inhibitors (acetazolamide, dorzolamide, topiramate) • Renal tubular acidosis • Arginine and lysine in parenteral nutrition • Ingestion of ammonium chloride • Mineralocorticoid deficiency (Addison disease) • Normal variant
Increased anion gap	> 14 mmol/L	A high anion gap indicates a loss of HCO_3^- without a concurrent increase in Cl^-. Causes include: • Milk-alkali syndrome • Uremia • Diabetic ketoacidosis • Ethylene glycol, methanol, propyl alcohol • Isoniazid intoxication • Lactic acidosis • Ethanol ethylene glycol • Rhabdomyolysis/renal failure • Salicylate and methanol toxicity • Increased fat metabolism (diabetes, alcohol, starvation)

Tortora GJ, Grabowski SR 2010 Principles of anatomy and physiology, 8th edn. New York, HarperCollins; Kraut JA, Nagami GT 2013 The serum anion gap in the evaluation of acid-base disorders: what are its limitations and can its effectiveness be improved? Clin J Am Soc Nephrol 8:2018–24.

CLINICAL EXAMPLE

Mrs Sinclair was admitted with blood pressure 90/70 mmHg, pulse 126 beats per minute, respirations 32 breaths per minutes and a 2-day history of nausea and vomiting, excessive thirst and polyuria. She was recently diagnosed with type 2 diabetes. Her arterial blood gas results reveal metabolic acidosis. Below is the calculation of the anion gap using laboratory information of Na^+ 135, Cl^- 92 and HCO_3^- 16.

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-)$$
$$= 135 - (92 + 16)$$
$$= 135 - 108 = 27 \text{ mmol/L}$$

Interpretation

27 mmol of anions per/L, other than the chloride and bicarbonate anions and thus further assessment and investigations required to confirm a diagnosis.

acidosis, differentiating between causes of metabolic acidosis, assessing the biochemical severity of acidosis, and monitoring response to treatment. If the laboratory report does not include an anion gap it can be calculated from the formula:

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-).$$

Metabolic alkalosis

Metabolic alkalosis is marked by the heavy loss of acid from the body or by increased levels of bicarbonate. The most common causes of acid loss are vomiting and gastric suction. Other causes include the overcorrection of metabolic acidosis, loss of chloride, use of diuretics causing resorption of bicarbonate, hyperaldosteronism and excessive ingestion of alkali (Berry & Pinard 2002).

Application of knowledge of fluid and electrolyte balance to practice

Nurses who are aware of their own and others' fluid and electrolyte requirements and factors contributing to an imbalance in a range of different contexts will be better prepared to assess, interpret and manage early indicators of fluid and electrolyte imbalance. Knowledge of average daily intake and output in healthy adults (Table 34-15) will assist in interpreting reasons for an imbalance.

Nurses' knowledge underpinning fluid and electrolyte balance needs to be more specific than described above. Many formulas exist for calculating the amount of fluid required per day. A general guide for the amount of fluid required in a healthy adult is 30 mL/kg/day (Eaton et al 1999). If, for example, a student weighed 50 kg they would require 30 mL × 50 kg = 1500 mL fluid per day. This is only a rough example and calculations need to be much more specific in calculating the amount of fluid required per day. For example, fluid required per day for a healthy adult can be calculated as: (100 mL/kg for the first 10 kg) + (50 mL/kg for next 10 kg) + (25 mL/kg for the remaining kg) (Austin 1996). Table 34-16 demonstrates the difference between fluid requirements using the general formula and this more specific formula for individuals weighing 50 kg and 60 kg. To obtain hourly required fluid intake, the results of the above calculations would need to be divided by 24. Hourly maintenance fluid volumes can also be calculated using the 4:2:1 method: (4 mL/kg for first 10 kg) + (2 mL/kg for next 10 kg) + (1 mL/kg for remaining kg). If a patient weighed 60 kg, their 24-hour intake would be (1000 + 500 +1000) = 2500 mL/day – hourly fluid intake; therefore, 2500/24 = 104 mL/hr. Using the 4:2:1 method, the hourly fluid intake would be (40 + 20 + 40) = 100 mL/hr.

TABLE 34-15 Daily fluid intake and output

Intake	mL	Output	mL
Oral fluids	1500	Urine	1800
Fluid in food	1000	Faeces	100
Metabolic production	300	Insensible loss – skin (500) and lungs (400)	900
TOTAL	2800		2800

• CRITICAL REFLECTION POINT

This critical thinking exercise is designed to increase understanding of the importance of nurses' calculation and monitoring daily maintenance fluid volume and contribution of diet in achieving minimal fluids requirements.

Activity

Use the information in Tables 34-9 and 34-10 to demonstrate the risks to fluid and electrolyte balance for four patients who decrease dietary intake and only consume 1.5 L total fluid per day over 3 days.

Patients: Mrs Gardener living at home weight 50 kg, Mr Hermes 4 days post hemicolectomy weight 60 kg, Mrs McMaster a nursing home resident weight 70 kg or Mr Kenyard admitted with emphysema weight 80 kg. Complete all calculations for one patient before moving to the next.

1. **Calculate daily maintenance fluid volume using the formula: 100 mL/kg first 10 kg + 50 mL/kg next 10 kg + 25 mL/kg remaining kg.**
2. **Use maintenance volume to calculate fluid required over 3 days.**
3. **Calculate actual fluid intake over 3 days.**
4. **Calculate fluid deficit. Required maintenance volume minus volume consumed over 3 days.**

Process	Example: Ms Hunter weighs 60 kg
1. Calculate maintenance fluid volume using the formula: 100 mL/kg first 10 kg + 50 mL/kg next 10 kg + 25 mL/kg remaining kg	1. Maintenance fluid volume (100 mL/kg for first 10 kg = 1000) + (50 mL/kg next 10 kg = 500) + (25 mL/kg x 40 = 1000) = maintenance volume = 2500 mL/day

TABLE 34-16 Calculating daily fluid requirements

kg	Formula A and B	Calculation	Daily total	Hrly
50	A. 30 mL/kg/day	30 mL × 50 kg	1500 mL	1500/24 = 63 mL
	B. 100 mL/kg first 10 kg + 50 mL/kg next 10 kg + 25 mL/kg remaining kg	(100 mL × 10 kg) + (50 mL × 10 kg) + (25 mL × 30 kg) = (1000 + 500 + 750) mL	2250 mL	2250/24 = 94 mL
60	A. 30 mL/kg/day	30 mL × 60 kg	1800 mL	1800/24 = 75 mL
	B. 100 mL/kg first 10 kg + 50 mL/kg next 10 kg + 25 mL/kg remaining kg	(100 mL × 10 kg) + (50 mL × 10 kg) + (25 mL × 40 kg) = (1000 + 500 + 1000) mL	2500 mL	2500/24 = 104 mL

2. Use maintenance volume to calculate fluid required over 3 days	2. Maintenance fluid volume over 3 days 2500 x 3 = 7500 mL
3. Calculate actual fluid intake over 3 days	3. Calculate actual fluid intake over 3 days 1500 x 3 = 4500 mL
4. Calculate fluid deficit. Required maintenance volume minus volume consumed over 3 days	4. Calculate fluid deficit. Required maintenance volume minus volume consumed over 3 days 7500 – 4500 = 3000 mL fluid volume deficit

Determining the appropriateness of urine output is also important in the assessment of each of the situations described above. Nurses should therefore be aware of the expected urine output based on gender and weight. The minimum urine output is the minimum amount of urine production required to ensure adequate renal function and to eliminate the body of waste products. A general rule is that urine output indicative of adequate renal function should be equal to, or more than, 30 mL/h. This is only a general guide and may lead to over- or underestimation of the adequacy of urine output. A more specific formula for adequate urine output is 0.5 mL/kg for an adult male and 0.4 mL/kg for an adult female; infants and children weighing < 30 kg require 1 ml/kg/h. Thus, the expected urine output for a male weighing 65 kg is 34–5 mL/h and for a female weighing 65 kg is 26 mL/h.

Nurses should assume that every patient is at risk for fluid and electrolyte imbalances. Infants, severely ill adults, disoriented or immobile patients and older adults are often at greater risk because of an inability to independently respond to early signs and symptoms of haemodynamic instability. Over time, the body's adaptive compensatory mechanisms can no longer adequately maintain fluid and electrolyte or acid–base balance, and the patient's health becomes compromised. For example, kidney function, urine concentration, thirst sensation, aldosterone secretion and renin activity are all significantly lowered with age (Lancaster et al 2003, Xiao et al 2004). Prolonged or severe compromises may lead to irreversible chronic health problems that decrease the quality of life of the patient, caregiver(s), guardians, parents, families and/or friends (Box 34-1).

CLINICAL REASONING PROCESS

Nurses have a professional obligation to observe, recognise, discriminate and interpret clinical evidence in order to reach a judgement about a patient's fluid, electrolyte and acid–base balance (Wotton 2011). Any delay in the identification of changes in haemodynamic status has direct consequences for the patient, their family and the healthcare institution.

BOX 34-1 Risk factors for fluid, electrolyte and acid–base imbalances

Risk factor	Specific risk factor
Age	• Very young • Very old
Health status	• Three or more medical conditions • Alterations in mental health status • High or low body mass index • Infection • New admission to a residential care facility/hospital • Swallowing disorders and alteration in oral health status • Hyperglycaemia • Decreased cognition • Dementia
Alterations in sensations	• Decreased olfactory sensation • Decreased taste sensation • Decreased visual acuity • Decreased ability to feel/touch
Environmental extremes	• High temperatures • Exertion in high heat and humidity
Chronic diseases	• Cancer • Cardiovascular disease such as congestive heart failure • Endocrine disease such as Cushing's disease and type 1 diabetes • Malnutrition • Chronic obstructive pulmonary disease • Renal disease such as progressive renal failure
Changes in level of consciousness	
Trauma	• Crush injuries • Head injuries
Burns	• Internal and external losses
Therapies	• Diuretics • Steroids • Intravenous therapy • Total parenteral nutrition • Polypharmacy
Gastrointestinal losses	• Gastroenteritis • Nasogastric suctioning • Fistulas

Clinical reasoning involves the rational analysis and review of all patient data and is not just one episode of thinking, but a cyclical process of data collection and analysis (data interpretation or re-interpretation and problem formulation or re-formulation) in the development of a progressively broader and deeper understanding of patients' fluid and electrolyte status (Wotton 2011). During assessment (Figure 34-12), the nurse must consider all critical-thinking elements, as well as data about the specific patient, to make appropriate nursing diagnoses.

GATHERING RELEVANT INFORMATION AND DATA

Nurses must possess a well-developed understanding of the physiology of fluid, electrolyte and acid–base balances in order to appropriately assess patients. To be able to effectively reason in the nursing domain, nurses require knowledge of their patient. This 'knowledge' is not only theoretical (e.g. relationship of cues to health status), but also refers to 'knowing' the patient. Knowing the patient means understanding the patient's situation and responses to fluid, electrolyte or acid–base balance from a physiological, pharmacological, psychological and social perspective (Wotton et al 2008). A comprehensive assessment which incorporates a review of all information in patient case and bed notes, patient history and physical examination will assist nurses to identify patients at risk of fluid and electrolyte problems and identify all appropriate nursing diagnoses.

Nursing history

The nursing assessment begins with a patient history, which is designed to reveal any risk factors or pre-existing conditions that may cause or contribute to a disturbance of fluid, electrolyte and acid–base balances. The nurse explores with the patient any factors contributing to a disturbance and integrates the information with knowledge of fluid volume regulation, electrolyte concentration and acid–base regulation.

Age

The nurse first considers the patient's age. An *infant's* percentage of total body water is greater than that of children or adults. As infants ingest and excrete a greater daily water volume relative to their weight than adults (McCance & Huether 2014), they are at a greater risk of **fluid volume deficits (FVDs)** and hyperosmolar imbalance because body water loss is proportionately greater per kilogram of weight.

Children aged 2–12 years have higher body water content, higher metabolic rate and a higher turnover of fluids and electrolytes. As regulatory responses to fluid and electrolyte imbalance are less stable, children are more susceptible to volume depletion. Indeed, significant fluid losses may occur rapidly, leading to significant depletion of the intravascular volume. Children frequently respond to illnesses with pyrexia or hyperpyrexia, which increases the rate of insensible water loss.

Adolescents have increased metabolic processes and increased water production because of the major and rapid changes that occur in the anatomical and physiological process of adolescence. Changes in fluid balance are greater in adolescent girls because of hormonal changes associated with the menstrual cycle.

Older adults experience a number of age-related changes that can affect fluid, electrolyte and acid–base balances. The kidneys have a decrease in renal blood flow and functioning glomeruli, causing a decreased glomerular filtration rate (Touhy & Jett 2011). In the presence of fluid and electrolyte imbalances the older adult may be unable to maintain homeostasis and the imbalance is instead worsened. The changes in lung function

APPLYING CRITICAL THINKING

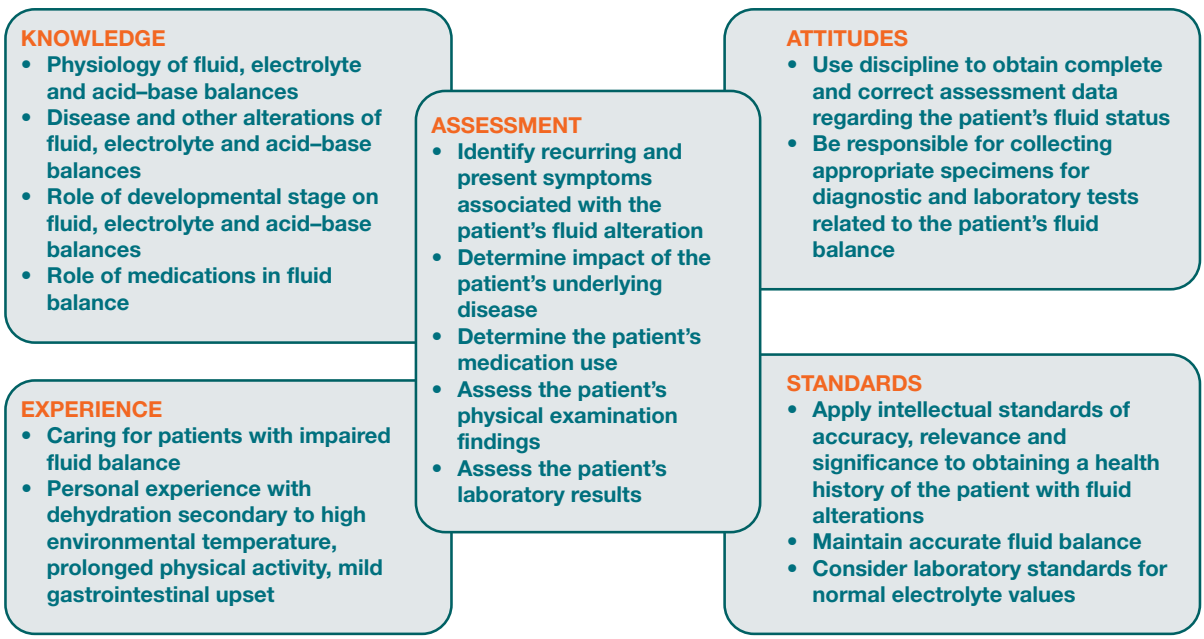

Figure 34-12 Critical thinking associated with the assessment phase for fluid, electrolyte and acid-base balance.

that accompany ageing can lead to respiratory acidosis and the inability to compensate for metabolic acidosis. The older adult who has any condition involving renal function, fluid and electrolyte balance or acid–base balance is more likely than younger adults to experience more serious consequences. Thirst responses in the older adult can be impaired, which increases their vulnerability to dehydration (see *Research highlight*).

Acute illness

Recent surgery, head and chest trauma, shock and burns are conditions that place patients at high risk of fluid, electrolyte and acid–base alterations. The stress response experienced in acute illness may cause fluid-balance changes when aldosterone, glucocorticoids and ADH are increasingly secreted, causing sodium and chloride retention, potassium excretion and decreased urinary output.

Extensive surgical intervention and longer operative time increases both external and internal (third space fluid shift) fluid losses. Patients can also exhibit acid–base changes after surgery. The patient who is reluctant to breathe deeply and cough may develop respiratory acidosis due to retained $PaCO_2$. The patient with nasogastric suction may develop metabolic alkalosis due to the loss of gastric acid, fluids and electrolytes. As well, surgical patients may be dehydrated preoperatively because of the combination of nil by mouth (NBM) for protracted periods of time and delays in surgery.

Leakage of fluid (third space fluid shift)

Resection, inflammation or acute or chronic obstruction of lymphatics contributes to increased capillary permeability and leakage of fluid and plasma proteins directly into extravascular spaces. Where the rate of capillary leakage into the interstitial space exceeds the rate of lymphatic absorption there is decreased return of both fluids and plasma proteins to the venous circulation and therefore decreased circulatory volume (Paula 2011, Wilson et al 2010).

Burns

The greater the body surface burned, the greater the fluid loss (Ibrahim et al 2013). The burns patient loses body fluids by one of five routes (McCance & Huether 2014).

1. Plasma leaves the intravascular space and becomes trapped in the interstitial space. This is also called the *plasma-to-interstitial fluid shift*. This internal 'loss' is accompanied by a loss of serum proteins from the bloodstream into the interstitial space because of increased capillary permeability.
2. Plasma and interstitial fluids are lost externally as burn exudate.
3. Water vapour and heat are lost in proportion to the amount of skin that is burned.
4. Blood leaks from damaged capillaries, adding to the intravascular fluid volume loss.
5. Sodium and water shift into the cells, further compromising extracellular fluid volume.

Respiratory disorders

Many alterations in respiratory function predispose the patient to respiratory acidosis. For example, inadequate gas exchange in pneumonia, sedative and narcotic overdose and exacerbated chronic airflow cause hypoventilation, which interferes with the elimination of carbon dioxide. As the carbon dioxide continues to build up in the bloodstream, the body's compensatory mechanisms can no longer adapt and the pH decreases. Likewise, hyperventilation associated with fever or anxiety causes respiratory alkalosis by the exhalation of too much carbon dioxide with the increased respiratory rate.

Head injury

Head injury can result in cerebral oedema. Occasionally this oedema creates pressure on the pituitary gland and, as a result, ADH secretion is changed. Two alterations can occur;

RESEARCH HIGHLIGHT

Research focus

More than one-third of older adults have a reduced thirst sensation resulting in inadequate water consumption and increased risk of **dehydration**. Awareness of thirst is an important mechanism to increase water consumption.

Method

Data were from three American surveys on national health and nutrition from 1994 to 2000 with a sample of over 8000 adults aged 60 years or older. Participants self-reported their daily dietary intake. Bodyweight was either self-reported or measured by an examiner.

Research findings

Thirty per cent of participants did not meet the recommendation of 30 mL/kg for total water consumption. Additionally, those not meeting the recommendation drank approximately 2–3 times less plain water and consumed about 1.5 times less moisture from foods and beverages than did those meeting the recommendations.

Conclusion

Careful monitoring of fluid intake and types of fluids consumed, dietary intake and living arrangements on a regular basis throughout the day is essential. Nurses should encourage adequate intake of water, increasing intake of foods with high moisture content such as fruit and vegetables and compensating for the diuretic effect of caffeinated fluids such as coffee. Monitoring is also required of the effect of medication on hydration, ensuring rooms are not overheated and avoiding excesses of physical activity.

Reference

Juan W, Basiotis P 2002 More than one in three older Americans may not drink enough water. Nutrition insights. A publication of the USDA Center for Nutrition Policy and Promotion, September.

type 2 diabetes occurs when too little ADH is secreted and the patient excretes large volumes of diluted urine with a low specific gravity; the second alteration is *syndrome of inappropriate antidiuretic hormone* (SIADH) with continued inappropriate secretion of ADH. This results in water intoxication characterised by fluid-volume expansion and hyponatraemia, and hypotonicity of fluids as a result of high urine osmolality and low serum osmolality (McCance & Huether 2014).

Chronic illness

As chronic disease (e.g. cancer, HF, renal disease) can create fluid, electrolyte and acid–base imbalances, the nurse must review the normal course of such conditions to understand how fluid, electrolyte and acid–base status may be affected.

Cancer

Fluid and electrolyte imbalances observed in a patient with cancer depend on the type and progression of the cancer. All electrolyte imbalances can occur in the patient with cancer; they are caused by anatomical distortion and functional impairment from tumour growth, and tumour-caused metabolic and endocrine abnormality. In addition, patients with cancer are at risk of fluid and electrolyte imbalances related to the side effects (e.g. diarrhoea and anorexia) of chemotherapeutic and radiological treatments (Mooney 2013).

Cardiovascular disease

In the patient with chronic cardiovascular disease, a diminished cardiac output reduces kidney perfusion, causing decreased urinary output. Sodium and water are retained, resulting in circulatory overload and the risk of pulmonary oedema. Fluid and electrolyte imbalances associated with heart failure can be controlled for a time with medications, and fluid and sodium restrictions. The goal of restricting fluid intake is to decrease left ventricular workload by reducing the excess circulating fluid volume.

Renal disorders

Kidney disease alters fluid and electrolyte balance by the abnormal retention of sodium, chloride, potassium and water in the extracellular compartment. The usual renal compensatory mechanisms such as bicarbonate reabsorption are not available, so the body's ability to restore normal acid–base balance is limited. The severity of fluid and electrolyte imbalance is proportional to the degree of renal failure. The plasma levels of metabolic waste products, such as blood urea nitrogen and creatinine, are elevated because the kidneys are unable to filter and excrete the waste products of cellular metabolism. This elevation is toxic to cellular processes. Metabolic acidosis results when hydrogen ions are retained due to decreased renal function. Occasionally, shock induced by acute kidney injury (AKI) or a decrease in extracellular fluid will be reversible. Although chronic renal failure is progressive, the patient may be treated successfully with dietary control of protein and salt intake, diuretic medications and fluid restrictions and, ultimately, haemodialysis (Ibrahim et al 2013).

Gastrointestinal disturbances

Gastroenteritis and nasogastric suctioning result in a loss of fluid and potassium and chloride ions. Hydrogen ions are also lost, causing a disturbance in acid–base balance. Timely education of infant and child caregivers is necessary to prevent dehydration when the infant or child is experiencing diarrhoea. Gastrointestinal fistulas can also result in a loss of potassium, resulting in an increased risk of hypokalaemia. The loss of potassium also increases the risk of acid–base disturbances.

Regardless of the presence of any disease process, the nurse must determine how long the patient has suffered from that disease and the type of treatment currently prescribed. In addition to chronic health problems, the nurse determines if the patient has a history of new-onset acute illnesses such as diarrhoea, vomiting, ileostomy, nasogastric suctioning or intestinal drainage. Any condition that results in the loss of GI fluids predisposes the patient to dehydration and a variety of electrolyte disturbances.

Environmental factors

The nurse should include certain environmental factors in the nursing history. Patients who have participated in vigorous exercise or who have been exposed to temperature extremes may have clinical signs of fluid and electrolyte alterations. Exposure to environmental temperatures exceeding 28–30°C results in excessive diaphoresis with weight loss. Loss of fluid from diaphoresis varies, and can reach a maximal rate of 4 L/hour (McCance & Huether 2014). A bodyweight loss above 7% decreases the ability of the cooling mechanism to conserve water. Inadequate fluid replacement can lead to fluid-volume disturbances. High environmental temperatures plus humidity work together to disrupt fluid balance, especially in the elderly and young children.

TABLE 34-17 Fluid requirements based on weight and variations in activity level and climate

Adapted from Daily Water Intake Calculator, MedIndia, www.medindia.net/patients/calculators/daily-water-requirement.asp#ixzz3UKwQJytj.

• CRITICAL REFLECTION POINT

The daily fluid and electrolyte requirements depend on the person's wellness, activity level and environmental conditions (Table 34-17).

Activity

Consider the fluid and electrolyte loss and the appropriate type and amount of fluid and electrolyte replacement for: a person sitting in their lounge on a winter's day, a person playing tennis in a temperature of 36°C, a bricklayer building an outside wall in summer in an environmental temperature of 39°C or a child with diarrhoea and vomiting with a temperature of 38.6°C.

Diet

A patient's current dietary history is an important component of nursing assessment. Dietary intake of fluids, salt, potassium, calcium, magnesium and the necessary carbohydrates, fats and protein helps maintain normal fluid, electrolyte and acid–base status. Recent changes in appetite or the ability to chew and swallow can affect nutritional status and hydration. When nutritional intake is inadequate, the body tries to preserve its protein stores by breaking down glycogen and fat stores. When excess free fatty acids are released, metabolic acidosis can occur because the liver converts free fatty acids to ketones, a strong acid. However, after normal glycogen and fat stores are depleted, the body begins to destroy protein stores. When serum protein levels decrease below normal, hypoalbuminaemia occurs. Hypoalbuminaemia results in decreased serum colloid osmotic pressure with resultant fluid shifts from the circulating blood volume to interstitial fluid spaces (for example, in the peritoneal cavity) and, ultimately, fluid volume deficit (FVD).

Lifestyle

Lifestyle factors should also be included in the nurse's history. Pre-existing medical risks, such as smoking or caffeine or alcohol consumption, can further impair the patient's ability to adapt to fluid, electrolyte and acid–base alterations. Long-term use of alcohol and tobacco can ultimately cause respiratory depression, which can result in respiratory acidosis and alteration in maintaining adequate fluid and electrolyte balance. Although caffeine acts as a diuretic and could cause tachycardia and arrhythmia in patients with a cardiac disease, it was shown not to make any significant difference in the hydration level of healthy adults (Killer et al 2014).

Alcohol consumption has the potential to increase urine output so that it is greater than fluid intake and therefore cause moderate-to-severe dehydration. Alcohol intake increases urine output because it blocks the release of ADH required for water reabsorption in the kidneys (Wiese et al 2000) resulting in segments of the kidney's tubule system becoming impermeable to water, thus preventing water being reabsorbed back into the circulation (Swift & Davidson 1998). The diuretic effect of alcohol can be quite significant with four shots each containing 50 g of alcohol with a total fluid volume of around 250 mL resulting in urinary elimination of 600 to 1000 mL (Swift & Davidson 1998). As excessive alcohol consumption not only causes dehydration but also prerenal failure, nurses should assess any patient admitted following alcohol consumption for the level of hydration and ensure that dehydration is managed (Wiese et al 2000). Nurses should also be aware of the risk factors of excessive alcohol consumption and be able to use these in community education.

• CRITICAL REFLECTION POINT

This critical thinking exercise is designed to increase understanding of the importance of nursing assessment of hypovolaemia and advocacy for fluids and electrolyte management for patients admitted to hospital with alcohol intoxication.

You are working in the emergency department (ED) for the night shift. At 0230 hrs Travis, a 19-year-old male, is admitted after suffering a knife wound to his left lower arm; admission observations T 36.8, P99, Resps 18, BP 100/80. Travis's wound has been assessed as requiring suturing, but his case is labelled as non-urgent and the RN informs you to let Travis 'sleep it off' as the medical officer is unable to attend for at least another 2 hours. His friend (the nominated driver) transported Travis and his intoxicated girlfriend to the ED. The girlfriend, who vomited in the car, is incoherent and is sleeping on a chair in the waiting room. The friend informs you that Travis, who played soccer that day (environmental temperature 38°C), had about five beers at the club room and around eight alcoholic drinks at the nightclub.

Activity

1. **Use information from Table 34-17 and information above on the effects of alcohol on urine output and renal function to prove if and why both Travis and his girlfriend could have a fluid and electrolyte imbalance.**
2. **Provide a rationale for the need for further monitoring of Travis to the RN who stated to let Travis 'sleep it off'.**

Medication

A final category to include in the nurse's assessment is a history of medication use (Box 34-2).

If the assessment reveals either a prescribed or an over-the-counter medication with the potential to cause a fluid, electrolyte or acid–base disorder, the nurse must closely examine laboratory values and consult with the medical officer. In addition, the nurse should assess the patient's knowledge of side effects and adherence to medication schedules (Touhy & Jett 2011).

Physical assessment

A thorough examination is necessary, because fluid and electrolyte imbalances or acid–base disturbances can affect all body systems. While examining each system, the nurse carefully considers the signs and symptoms expected as a result of any imbalance (see Table 34-18). For example, an examination of the oral cavity is likely to reveal signs of dehydration if the nurse suspects the patient is experiencing a fluid loss.

Measuring fluid intake and output

Immediately measuring and recording all liquid intake and output during each shift, for a 24-hour period and throughout admission (cumulative fluid balance), is a vital part of the patient's assessment for fluid and electrolyte balance. It is important not to wait until the end of the shift, but to also *regularly* review fluid balance charts and note and respond to patterns and trends in the intake and output (e.g. a gradually decreasing urine output can indicate the body's compensation for a fluid volume deficit or hyperosmolar fluid imbalance). A progressive cumulative fluid balance should be recorded

BOX 34-2 Medications that cause fluid, electrolyte and acid–base disturbances

Medication	Disturbance in electrolyte and acid–base balance
Antihistamines	Increased urine output
Diuretics	Metabolic alkalosis, hyperkalaemia and hypokalaemia
Laxatives	Increases water into bowel and therefore increases faecal water content
Steroids	Metabolic alkalosis
Potassium supplements	GI disturbances, including intestinal and gastric ulcers and diarrhoea
Respiratory centre depressants such as narcotic analgesics	Decreased rate and depth of respirations, resulting in respiratory acidosis
Antibiotics	Nephrotoxicity (e.g. vancomycin, methicillin, aminoglycosides); hyperkalaemia and/or hypernatraemia (e.g. azlocillin, carbenicillin, piperacillin, ticarcillin, Unasyn)*
Calcium carbonate (Caltrate, Rennies, Titralac)	Mild metabolic alkalosis with nausea and vomiting*
Magnesium hydroxide (Milk of Magnesia)	Hypokalaemia
Vasodilators	Dilate blood vessels leading to additional venous fluid retention and decreased circulating volume
ACE inhibitors (dilate blood vessels; decrease production of aldosterone)	Decrease aldosterone secretion – increased urine output

** Data from McKenry LM, Salerno E 2003 Mosby's pharmacology in nursing, 21st edn. Mosby, St Louis.*

TABLE 34-18 Physical and behavioural nursing assessment for fluid, electrolyte and acid–base imbalances

Assessment	Imbalance
Weight changes	
2–5% loss	Mild fluid volume deficit (FVD) – reduced urine output, thirst, dry mucous membranes, mild tachycardia
5–10% loss	Moderate FVD – dry mucous membranes, tachycardia, abnormal respiratory pattern, lethargy, reduced skin turgor, sunken eyes
10–15% loss	Severe FVD – all signs for moderate FVD plus poor perfusion (mottled, cool limbs, decreased capillary refill); altered consciousness, shock – thready peripheral pulses with marked tachycardia
15–20% loss	Death
2% gain	Mild fluid volume excess (FVE)
5% gain	Moderate FVE
8% gain	Severe FVE
Head	
History:	
Headache	FVD, metabolic or respiratory acidosis, metabolic alkalosis
Dizziness	FVD, respiratory acidosis or alkalosis, hyponatraemia
Observation:	
Irritability	Metabolic or respiratory alkalosis, hyperosmolar imbalance, hypernatraemia, hypokalaemia
Lethargy	FVD, metabolic acidosis or alkalosis, respiratory acidosis, hypercalcaemia
Confusion, disorientation	FVD, hypomagnesaemia, metabolic acidosis, hypokalaemia

continued

TABLE 34-18 ***continued***

Assessment	Imbalance
Eyes	
Inspection:	
Sunken, dry conjunctivae, decreased or absent tearing	FVD
	FVE
Periorbital oedema, papilloedema	
History:	
Blurred vision	FVE
Throat and mouth	
Inspection:	
Sticky, dry mucous membranes, dry cracked lips, decreased salivation	FVD, hypernatraemia
Longitudinal tongue furrows	
Cardiovascular system	
Inspection:	
Flat neck veins	FVD
Slow venous filling	FVD
Distended neck veins	FVE
Palpation:	
Oedema (dependent body parts: back, sacrum, legs)	FVE
Dysrhythmias (also noted as ECG changes)	Metabolic acidosis, respiratory alkalosis and acidosis, potassium imbalance, hypomagnesaemia
Increased pulse rate	Metabolic alkalosis, respiratory acidosis, hyponatraemia, FVD, hypomagnesaemia
Decreased pulse rate	Metabolic alkalosis, hypokalaemia
Weak pulse	FVD, hypokalaemia
Decreased capillary filling	FVD
Bounding pulse	FVE
Auscultation:	
Blood pressure low – Orthostatic hypotension	FVD, hyponatraemia, hyperkalaemia, hypermagnesaemia
Third heart sound	FVE
Hypertension	FVE
Respiratory system	
Inspection:	
Increased rate	FVE, respiratory alkalosis, metabolic acidosis
Dyspnoea	FVE
Auscultation:	
Crackles	FVE
Gastrointestinal system	
History:	
Anorexia	Metabolic acidosis
Abdominal cramps	Metabolic acidosis

continued

TABLE 34-18 ***continued***

Assessment	Imbalance
Inspection:	
Sunken abdomen	FVD
Distended abdomen	Third-space syndrome
Vomiting	FVD, hypercalcaemia, hyponatraemia, hypochloraemia, metabolic alkalosis
Diarrhoea	Hyponatraemia, metabolic acidosis
Auscultation:	
Hyperperistalsis with diarrhoea, or hypoperistalsis	FVD, hypokalaemia
Renal system	
Inspection:	
Oliguria or anuria	FVD, FVE
Diuresis (if kidneys are normal)	FVE
Increased urine specific gravity	FVD
Neuromuscular system	
Inspection:	
Numbness, tingling	Metabolic alkalosis, hypocalcaemia, potassium imbalances
Muscle cramps, tetany	Hypocalcaemia, metabolic or respiratory alkalosis
Coma	Hyperosmolar or hypo-osmolar imbalances, hyponatraemia
Tremors	Respiratory acidosis, hypomagnesaemia
Palpation:	
Hypotonicity	Hypokalaemia, hypercalcaemia
Hypertonicity	Hypocalcaemia, hypomagnesaemia, metabolicalkalosis
Percussion:	
Decreased or absent deep tendon reflexes	Hypercalcaemia, hypermagnesaemia
Increased or hyperactive deep tendon reflexes	Hypocalcaemia, hypomagnesaemia
Skin	
Body temperature:	
Increased	Hypernatraemia, hyperosmolar imbalance, metabolic acidosis
Decreased	FVD
Inspection:	
Dry, flushed	FVD, hypernatraemia, metabolic acidosis
Palpation:	
Inelastic skin turgor, cold, clammy skin	FVD

FVD = fluid volume deficit (FVD); FVE = Mild fluid volume excess.

Adapted from Tortora GJ, Grabowski SR 2010 Principles of anatomy and physiology, 8th edn. HarperCollins, New York; Wotton K, Crannitch K, Munt R 2008 Prevalence, risk factors and strategies to prevent dehydration in older adults. Contemp Nurse 31(1):44–56.

at least every 24 hours to demonstrate patterns and trends in fluid intake and output throughout the patient's admission (Table 34-19). Nurses must recognise that fluid balance charts do not take into account insensible loss, and must also know whether a positive or negative balance is the expected clinical outcome for the patient for the particular shift. For example, in Table 34-15, the positive 24-hour and cumulative balance for Patient A would be expected to demonstrate appropriateness of replacement fluid; and a negative cumulative balance of 5 L (remember the patient was 6 kg = 6 L overloaded on admission) would be expected for patient B who was admitted with HF treated with IV diuretics.

TABLE 34-19 Examples of cumulative fluid balance

Day	Total intake (mL)	Total output (mL)	24-hour balance (mL) including insensible loss	Cumulative balance (mL)
Patient A admitted with dehydration				
1	3500	1700	1800 +ve (– insensible loss of 400) = 1400 +ve	1400 +ve (Day 1)
2	3200	2000	1200 +ve (– insensible loss of 400) = 800 +ve	2200 +ve (Day 1 + Day 2)
3	3000	2100	900 +ve (– insensible loss of 400) = 500 +ve	2700 +ve (Day 1 + 2 + 3)
Patient B admitted with HF and weight increase of 6 kg and treated with IV diuretics				
1	1500	3500	2000 –ve (+ insensible loss of 400) = 2400 –ve	2400 –ve (Day 1)
2	1500	2500	1000 –ve (+ insensible loss of 400) = 1400 –ve	3800 –ve (Day 1 + Day 2)
3	1500	2300	800 –ve (+ insensible loss of 400) = 1200 –ve	5000 –ve (Day 1 + 2 + 3)

–ve = negative; +ve = positive; HF = heart failure; IV = intravenous.

• CRITICAL REFLECTION POINT

Activity

Please note that calculations for the two patients in Table 34-19 use the lowest average daily insensible loss. Now recalculate the above cumulative balance if:

- **Patient A, admitted with dehydration, also had a temperature of 39°C (calculate the daily insensible loss at 500 mL plus an additional 50–75 mL/day for each 1°C increase above normal body temperature).**
- **Patient B, admitted with HF, also has a respiratory rate above 30 each day so use a daily insensible loss of 800 mL in your recalculation.**

Commencing a fluid balance chart is a nurse-initiated action. In the hospital, forms for recording fluid balance are included in the bedside chart (see Figure 34-13). To ensure that nurses monitor patients' fluid balance throughout the shift, a subtotal of intake and output is usually calculated and documented every 6 hours. The 24-hour total is calculated at midnight or 6.00 a.m., depending on agency policy. Generally, fluid balance is routinely measured for patients after surgery, in cases of chronic cardiopulmonary or renal disease and for patients whose conditions are unstable or deteriorating, patients who have pyrexia and patients prescribed fluid restriction, diuretics, and intravenous (IV) or nasogastric therapy.

• CRITICAL REFLECTION POINT

Activity

Examine the pattern and trend in the 24-hour record of fluid intake and urine output for Mr Henri Gradeven (Figure 34-13).

1. **If Henri's usual weight was 65 kg, what urine volume per hour would indicate adequate kidney function (Male: 0.5 mL × weight = mL/hr)?**
2. **Are you concerned at any stage throughout the 24 hours of the adequacy of urine output? Hint – In the examination of the appropriateness of urine output it is essential to recalculate urine output into mL/hr. For example, Mr Henri Gradeven's urine output from 0200–0600 hours is 200 mL. This is over 4 hours – thus hourly urine output is 200 ÷ 4 = 50 mL/hr.**
3. **Calculate hourly urine output from 1800–2400 hours. What could be the reason for the decreased urine output from 1800–2400 hours?**
4. **Mr Henri Gradeven has an indwelling urinary catheter in situ. Would you change measurement and recording of urine output to hourly? Provide a rationale for your response.**
5. **Calculate whether Mr Gradeven's hourly intake is equal to or above hourly maintenance fluid requirements (see Table 34-16).**

Oral intake includes all liquids taken by mouth, such as custard, ice cream, soup, juice, vegetables, fruit and water. Liquid intake also includes fluids given through nasogastric or jejunostomy feeding tubes (see Chapter 36), liquids given as IV fluids (including both continuous infusions and intermittent IV piggybacks) and blood or its components. Output includes urine, diarrhoea, vomitus, gastric suction and wound drainage (see Chapter 44). Although insensible loss is not recorded, nurses should also approximate such losses.

Ambulatory patients' urinary output is recorded after each trip to the bathroom. The nurse explains the reasons why measurements are required and instructs the patient and family not to dispose of any urine, but to call the nurse. A patient using a toilet should be instructed to use a calibrated insert (if available), which attaches to the rim of the toilet bowl (see Figure 34-14), or ask for a pan/urinal.

When a patient has an indwelling urinary catheter, drainage tube or suction, the output is recorded hourly, 4-hourly, or at the end of each shift, depending on the severity of the patient's condition. The nurse should *measure*, not estimate, intake and output.

Recording accurate and timely fluid balance is essential for accurate assessment of fluid and electrolyte balance or imbalance. Over a 24-hour period, medications administered in liquid form, medications administered nasogastrically and fluids used to flush nasogastric tubes after medication administration

can amount to significant intake and should always be immediately recorded on the fluid balance chart.

Laboratory studies

Laboratory tests include serum and urinary electrolyte levels, haematocrit, serum creatinine, blood urea nitrogen (BUN), urine specific gravity and arterial blood gas (ABG) readings.

Serum electrolytes

Serum electrolytes are routinely measured on patient admission to hospital to screen for alterations and to serve as a baseline for future comparisons. Laboratory results should be reviewed and interpreted in light of the patient's diagnoses, other assessment findings and current treatment modalities to make decisions about fluid, electrolyte and acid–base balance (Box 34-3). The frequency with which these electrolyte levels are measured depends on the severity of the patient's illness.

Full blood count

The full blood count is a determination of the number and type of red and white blood cells per litre of blood. When the patient does not have anaemia, the pattern and trend of haemoglobin (Hb) and haematocrit can be an indication of the hydration status. Haematocrit (Hct) or packed cell volume (PCV) is the volume percentage of red blood cells in the plasma and is normally 45% in males and 40% in females. Relationships between haematocrit and viscosity are important for interpreting fluid imbalance. The Hb and Hct will increase (become more concentrated) in situations where fluid (not blood) is lost, whereas Hb and Hct will decrease where fluid is excessively retained in the vascular space.

Serum creatinine

Serum creatinine is useful in determining kidney function. Creatinine is a normal by-product of muscle metabolism and is excreted by the kidneys at fairly constant levels, regardless of factors such as fluid intake, diet or exercise (Hall 2015). An increased creatinine level indicates renal disease, since no other pathological condition would result in an elevation. Generally, 50% of renal function is lost before there is an increase in the serum creatinine level. A decreased level may reflect a loss of muscle mass. The normal serum creatinine level is 0.05–0.12 mmol/L.

Blood urea nitrogen

Blood urea nitrogen is the amount of nitrogenous substance present in the blood as urea. An elevation in the BUN level may or may not indicate renal dysfunction: rapid cell destruction from an infection or steroidal therapy may produce an elevation. The BUN level is therefore not the most reliable indicator of renal disease. A decreased BUN level may indicate malnutrition or hepatic damage. The normal serum BUN level is 3.0–8.0 mmol/L.

The BUN:creatinine ratio may be a better indicator of renal function. The normal ratio is 10:1. When there is an intravascular fluid volume deficit, the BUN level rises more rapidly than the creatinine level, causing an increase in the ratio. An increase in

RESEARCH HIGHLIGHT

Research focus

To identify and describe current clinical nursing practice in fluid balance monitoring and measurement accuracy in ICUs.

Research abstract

A descriptive, exploratory study design. An audit of 103 ICU records was conducted to establish the current practices and accuracy in recording of fluid balance monitoring.

Research findings

The total of 71 (68.9%) fluid balance charts (n = 103) were incorrect by approximately 500 mL of that calculated by the researcher. Fourteen recorded calculations (13.5%) were incorrect by between 500 mL and 1000 mL, while seven recorded calculations (6.8%) were incorrect by 1000 mL to 2000 mL. Six recorded calculations (5.8%) were incorrect by > 2000 mL. Furthermore, a significant relationship was shown between inaccurate calculation of FBC totals and the inappropriate administration of diuretics.

Conclusion

The majority of fluid balance records were incorrectly calculated. The incorporation of bodyweight and other clinical parameters is essential in interpreting FBC data and in making clinical judgements.

BOX 34-3 Laboratory data for fluid, electrolyte and acid–base imbalances

Imbalance	Laboratory values
Fluid and electrolyte imbalance	• Altered serum sodium Na^+, potassium K^+, magnesium Mg^+, calcium Ca^+, chloride Cl^- and bicarbonate HCO_3^- (venous carbon dioxide CO_2 contentions) • Increased haematocrit (Hct), blood urea nitrogen (BUN), Na^+ and serum osmolality (related to loss of extracellular fluid or gain of solutes) • Decreased Hct, BUN, Na^+ and serum osmolality (related to gain of extracellular fluid or loss of solutes) • Concentrated urine: urine specific gravity > 1.030 • Dilute urine demonstrated by a specific gravity < 1.012
Metabolic alkalosis	• pH > 7.45 • $PaCO_2$ normal or > 45 mmHg if lungs are compensating • PaO_2 normal • Oxygen saturation (SaO_2) normal • HCO_3^- > 32 mmol/L • K^+ < 3.1 mmol/L
Metabolic acidosis	• pH < 7.35 • $PaCO_2$ normal or < 35 mmHg if lungs are compensating • PaO_2 normal • SaO_2 normal • HCO_3^- < 22 mmol/L • K^+ > 4.2 mmol/L • K^+ < 3.1 mmol/L
Respiratory alkalosis	• pH > 7.45 • $PaCO_2$ < 35 mmHg • PaO_2 normal • SaO_2 normal • HCO_3^- normal • K^+ < 3.1 mmol/L
Respiratory acidosis	• pH < 7.35 • $PaCO_2$ > 45 mmHg • PaO_2 normal or < 80 mmHg, depending on cause of acidosis • SaO_2 normal or < 95%, depending on cause of acidosis • HCO_3^- normal if early respiratory acidosis or > 32 mmol/L if kidneys are compensating • K^+ > 4.2 mmol/L

both the BUN and the creatinine levels is usually an indicator of renal dysfunction.

Serum osmolality

Serum osmolality measures the concentration of the plasma. The osmolality decreases in hypo-osmolar fluid imbalance (water excess) or hyponatraemia. Decreased serum osmolality results in the movement of fluid into body cells (cellular oedema) by osmosis. The osmolality increases in hyperosmolar fluid imbalance (water deficit) or hypernatraemia or other gains of solutes such as glucose (Hall 2015). This results in the movement of fluid out of body cells into the interstitial space (cellular shrinkage). Both cellular oedema and shrinkage will disrupt normal cell processes.

Urine specific gravity

The urine specific gravity (SG) measures the urine's degree of concentration and evaluates the kidney's ability to conserve or excrete water. The specific gravity, measured on the ward with dipsticks, normally ranges between 1.010 and 1.025 and compares the density of urine to the density of water (SG = 1.000). Dark-coloured urine is more concentrated in solutes and increases SG. Clearly, any increase or decrease in urinary SG (Table 34-20) must be reported so that further investigations can be carried out to identify the cause.

Arterial blood gas

Arterial blood gas (ABG) analysis provides information on the status of acid–base balance and the effectiveness of ventilatory

TABLE 34-20 Interpreting changes in urine SG

urine SG	Meaning	Indication
> 1.025	High (hypersthenuria) increased concentration of urinary solutes	Dehydration, diarrhoea, emesis, excessive diaphoresis, urinary tract/bladder infection, hyperglycaemia, renal artery stenosis, hepatorenal syndrome, excess antidiuretic hormone caused by SIADH (McPherson & Pincus 2011).
< 1.101	Low (hyposthenuria) decreased concentration of urinary solutes	Renal failure, pyelonephritis, diabetes insipidus, acute tubular necrosis, interstitial nephritis, and excessive fluid intake, increased intracranial pressure (McPherson & Pincus 2011).

SIADH = syndrome of inappropriate antidiuretic hormone.

function in oxygen–carbon-dioxide exchange. The ABG result should be evaluated using the following systematic approach.

1. *Interpretation of pH*. First decide whether the ABG indicates acidosis or alkalosis. Low pH (below 7.35) indicates an acid state and high pH (above 7.45) indicates an alkaline state. However, acidotic and an alkalotic process can occur at the same time. The pH will indicate which is the stronger of the two processes. For the purpose of interpreting the ABG readings, consider a pH of less than 7.4 being acidotic and above 7.4 being alkalotic.

pH	< 7.35	7.35 to 7.45	> 7.45
	Acidosis	Normal or compensated	Alkalosis

2. *Interpretation of $PaCO_2$*. The second decision is made by examining $PaCO_2$, often called the respiratory parameter. High $PaCO_2$ indicates respiratory acidosis, whereas low $PaCO_2$ indicates respiratory alkalosis.

$PaCO_2$	< 35	35 to 45	> 45
	Respiratory	Normal or compensated	Respiratory

3. *Interpretation of HCO_3^-*. The third component to be considered is whether the reading indicates metabolic involvement. HCO_3^- describes the non-respiratory or metabolic parameter. Two conditions associated with abnormalities in HCO_3^- are metabolic alkalosis and metabolic acidosis. Increased HCO_3^- indicates metabolic alkalosis and decreased HCO_{33}^- indicates metabolic acidosis.

HCO_3^-	< 22	22 to 26	> 26
	Metabolic	Normal or compensated	Metabolic

A method for interpretation of ABGs

Interpretation of ABGs is easy using the arrow method. This involves identification of an increase or decrease from normal for pH, $PaCO_2$ and HCO_3. An upward arrow is placed alongside the data if it is higher than the normal value and a downward arrow if the data is below the normal value. Note that the arrow for the pH should always be placed first.

If the reading is 'Respiratory', the arrow for $PaCO_2$ will be opposite to that for pH.

If the reading is 'Metabolic', the arrow for HCO_3^- will be the same way as for pH (see Table 34-21).

• CRITICAL REFLECTION POINT

You are caring for a 52-year-old man who has been seen in the emergency department (ED) after being involved in a motor vehicle accident. He complains of difficulty breathing, has a suspected pneumothorax and has a respiratory rate of 40 breaths per minute.

Activity

1. **Using information in the discussion of ABGs above, including Table 34-21, interpret the patient's last ABG results: pH 7.30; PaO_2 70; $PaCO_2$ 50; HCO_3^- 24.**
2. **Discuss the possible reasons for your interpretation based on information about reasons for the patient's admission.**

TABLE 34-21 Interpretation of arterial blood gas (ABG) results

Patient	pH Normally [7.35 (7.4) 7.45]	$PaCO_2$ (mmHg) Normally 35–45	HCO_3^- (mmHg) Normally 22–26	Interpretation
A	7.2 ↓ Acid	48 ↑ Respiratory	24 – Normal	Respiratory acidosis
B	7.49 ↑ Alkaline	30 ↓ Respiratory	25 – Normal	Respiratory alkalosis
C	7.25 ↓ Acid	36 – Normal	30 ↑ Metabolic	Metabolic acidosis
D	7.48 ↑ Alkaline	36 – Normal	20 ↓ Metabolic	Metabolic alkalosis

Patient expectations

Often a fluid, electrolyte or acid–base disturbance is so acute that the patient's condition prevents a review of their expectations. If a patient is alert enough to discuss care with the nurse, a review of expectations may reveal short-term needs (e.g. provision of comfort from nausea) or long-term needs (e.g. understanding how to prevent alterations from occurring in the future). The role of the nurse is to ensure that the patient understands the implications of fluid, electrolyte or acid–base changes and is able to express expectations of care.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

When caring for patients with suspected fluid, electrolyte and acid–base imbalances, it is particularly important that the nurse makes clinical judgements (Box 34-4). Assessment data establishing the risk or actual presence of a nursing diagnosis in these areas may be subtle, and patterns and trends emerge only when the nurse consciously assesses for them. The nurse must keep in mind that many body systems may be involved. Clustering of defining characteristics will lead the nurse to selection of the appropriate diagnoses. For example, the assessment and defining characteristics for the nursing diagnosis of fluid volume deficit is developed in Skill 34-1.

An important part of formulating nursing diagnoses is identifying the relevant causative or related factor. The nursing interventions chosen must treat or modify the related factor for the diagnosis to be resolved. Fluid volume deficit related to loss of GI fluids via vomiting will require therapies that are slightly different from therapies needed for fluid volume deficit related to elevated body temperature.

BOX 34-4 Examples of priority problems associated with fluid, electrolyte and acid–base alterations

- Body temperature, altered
- Breathing pattern, ineffective
- Cardiac output, decreased
- Fluid volume deficit
- Fluid volume excess
- Gas exchange, impaired
- Mobility, impaired
- Oral mucous membrane, altered
- Skin integrity, impaired
- Skin integrity, impaired, risk of
- Tissue integrity, impaired
- Tissue perfusion, altered, peripheral

SETTING PRIORITIES AND ESTABLISHING GOALS

During the planning process, nurses need to synthesise information from multiple sources (Figure 34-15). Critical thinking ensures that the patient's plan of care integrates both scientific and nursing knowledge with comprehensive knowledge about the individual patient. Professional standards are especially important to consider when the nurse develops a plan of care. These standards often establish scientifically

SKILL 34-1

Assessment of fluid status

Delegation considerations

Assessment of fluid status may be undertaken by enrolled and student nurses under the guidance of the RN. Assessment data must be reported to the RN, who is primarily responsible for interpretation of assessment data.

- Ensure review of the distribution, composition, movement and regulation of body fluids and the physiological mechanisms that maintain fluid balance in all body compartments.
- Ensure that hand hygiene is performed and personal protective equipment is worn when appropriate.

Equipment

- Non-sterile gloves
- Bed pan, urinal, catheter bag
- Measuring jug
- Fluid balance chart
- Scales
- Stethoscope and sphygmomanometer
- Tympanic thermometer

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE	
1. Determine need to assess fluid status of patient.	All patients should be assumed to have a fluid imbalance until proven otherwise.	
2. Focused health history – elicit further information about risk factors for fluid imbalance (see Boxes 34-1 and 34-2).		
3. Knowing the patient Critical analysis of existing patient information.	Analysis of pattern and trend in data: from handover, relevant charts, progress notes and diagnostic test results.	
4. History of fluid and dietary intake See Table 34-16 for calculation of minimal daily and hourly fluid intake.	Only applicable for those patients able to control their fluid intake and/or possess the cognitive ability to provide history of fluid and dietary intake.	
	FLUID VOLUME DEFICIT	**FLUID VOLUME OVERLOAD**
	Daily intake less than maintenance fluid requirement.	Daily intake > maintenance fluid requirements or > prescribed fluid restriction.
5. Observe for abnormal losses/ gains of fluids.	V1g, diarrhoea, abdomen distended – internal loss confirmed by intake equal to, or above, maintenance volume, weight normal or increased with signs and symptoms of hypovolaemia.	Intake > maintenance fluid requirements or above prescribed fluid restriction.
6. Physical examination	Needs to be comprehensive as fluid imbalances or disturbances can affect and be affected by all body systems.	
Temperature	Pyrexia	May be subnormal due to the increased circulating volume.
Pulse Rate Depth Orthostatic tachycardia	Tachycardia – weak, difficult to feel pulse because of less blood distending the artery. Absence of tachycardia does not refute FVD. Orthostatic tachycardia increases by 10 beats when position changes from lying to sitting or standing are usually indicative of compensatory phase hypovolaemia.	Tachycardia: very strong, forceful, bounding pulse because of the additional blood volume distending the artery.
Respirations Rate Depth Shortness of breath Auscultation	Respirations increased due to increased sympathetic activity in an attempt to increase oxygen delivery to the tissues.	Tachypnoea, dyspnoea Crackles Shortness of breath in HF usually made worse when lying flat

STEPS	RATIONALE	
	FLUID VOLUME DEFICIT	FLUID VOLUME OVERLOAD
Blood pressure Assess blood pressure (BP) – lying and sitting or standing.	Hypotension late sign of FVD as peripheral vasoconstriction and increased cardiac contractility initially maintains BP. Orthostatic hypotension, SBP decrease by 10 mmHg when position changes from lying to sitting or standing, is an earlier sign of compensatory FVD.	Hypertension associated with initial phase of hypervolaemia. If the LV fails and cardiac output decreases hypotension may be present.
Pulse pressure (PP) Systolic BP – diastolic BP Normal PP between 30 to 50 mmHg	Narrow PP sign of decreasing cardiac output (decreasing SBP) and increasing peripheral vascular resistance (increasing DBP).	PP often increases due to increasing SBP and lowering DBP.
Weight changes 1 kg = 1 litre increase/decrease in body fluid Weight is unattainable in acutely ill and immobile patients.	Weight loss – patient experiences sudden weight loss Calculate % FVD: mild 5%, moderate 5–10%, severe 10%	Sudden weight increase Calculate % FVE: mild 5%, moderate 5–10%, severe 10%
Head Examine anterior fontanelle – usually closes within 7–19 months. Headache	A noticeably sunken fontanelle Headache (due to decrease blood supply to brain), dizziness	Fontanelles bulging Irritability or lethargy, confusion, disorientation
Face	Pinched, drawn facial expression	Puffy eyelids and cheeks
Neck Measuring the level of blood backflow in the internal jugular vein provides a measure of the pressure in the right atrium.	Flat jugular veins where no distention occurs with bed elevated at 30–45°	Inspect neck veins with bed elevated at 30–45°. Suspect FVE if JV visible > 3 cm above sternal angle and if visible when patient lying flat.
Eyes	Dull eyes, slightly sunken, dry conjunctiva, tears absent in moderate FVD	Periorbital oedema, pappiloedema
Mouth Inspect mucous membranes for degree of moisture. Tongue turgor – more accurate than tissue turgor for not age-dependent.	Sticky, dry mucous membrane, dry cracked lips, decreased salivation, longitudinal tongue furrows, tongue smaller	Mouth moist, increased saliva. If pulmonary oedema present, clear frothy with/without, blood-specked sputum

STEPS	RATIONALE	
	FLUID VOLUME DEFICIT	FLUID VOLUME OVERLOAD
Skin Skin temperature Skin turgor (elasticity): pinch a fold of skin on sternum or inner thigh and time how long it takes to return to normal position when released. Loss of elasticity in the elderly makes tissue turgor unreliable.	Dry, flushed, hot skin mild–moderate FVD; severe – skin may be cold and clammy In a well-hydrated person the skin will immediately fall back to its normal position	Cool; moist skin; swollen and puffy skin as excess body fluid leaks into tissues beneath the skin
Axillary moisture	Dry axilla moderate sensitivity and excellent specificity to detect FVD	Moist
Skin turgor Pinch a fold of skin on sternum or inner thigh and time how long it takes to return to normal position when released (brisk within 1–2 seconds).	Skin turgor decreased; document stays tented for 2+, 3+ or 4+ seconds, e.g. clavicular skin recoil 4 seconds Loss of elasticity in the elderly makes tissue turgor unreliable	Tissue turgor – often decreased and described as moist/doughy/boggy
Hand veins Elevate hand – note time for hand vein emptying. Lower hand – note hand vein filling.	When hands lowered takes longer than 3–5 seconds to fill	On elevation of hands takes longer than 3–5 seconds for hand veins to empty
Thirst	Dehydration	Thirst could also be a sign of FVE. Decreased cardiac output stimulates thirst mechanism
Insensible loss Estimate	Lungs 400 mL/day increases with increased rate and depth of respiration. Skin (0.4–0.5 mL/kg/hr) or 400–500 mL/day + additional 50–75 mL/day for each 1°C temperature elevation. GIT 100–200 mL/day in faeces.	
Capillary refill Hold patient's hand at heart level, press for 5 seconds on the pad of the middle finger, releasing pressure and measuring time (seconds) until normal colour returns. Normal < 2–3 seconds; elderly 2–4 seconds.	Slow capillary refill time > 3 seconds	Quick capillary refill < 3 seconds

STEPS	RATIONALE	
	FLUID VOLUME DEFICIT	FLUID VOLUME OVERLOAD
Oedema	Assessing oedema is important for this fluid is not available for general circulation and in some cases, e.g. third space fluid shift, can cause FVD.	Oedema in the legs, ankles and feet, arms, abdomen, face, and around the eyes can be the result of FVE, particularly with concurrent HF or AKI. Pitting oedema assessed by pressing fingertips into the skin and measuring the depth of indentations that slowly disappear. Oedema may not be evident until 6% FVE.
Urine Urine colour Urine specific gravity (SG) – norm 1.016–1.022	Darker amber urine and raised urine specific gravity > 1.022 indicates increased solute to water concentration. Decreased urine output late sign of hypovolaemia; oliguria or anuria.	Light lemon to clear urine and low SG < 1.016 indicative of dilution of solutes in larger amounts of water. Initially larger volume of urine.

■ **Critical decision point: Urinary output is an indicator of fluid status in most patients and normally should not be < 1 mL/kg/hr (children); < 1–2 mL l/kg/hr (infants); < 2 mL/kg/hr (neonates); < 0.5 mL/kg/hr (adult male); < 0.4 mL/kg/hr (adult female).**

RECORDING AND REPORTING

1. Measuring and recording fluid intake and output for 24-hour period – fluid balance charting (FBC).
   a. Identify fluid balance chart/form for the patient.
   b. Record all oral/IV/nasogastric/PEG intake on the FBC throughout a 24-hour period.
   c. Record all urinary/faecal fluid/nasogastric drainage/other drainage e.g. wound on the FBC throughout a 24-hour period.
   d. Cumulative fluid balance. The 24-hour total is collected at midnight or 0600 depending on healthcare facility policy for the 24-hour period. In patient with suspected fluid imbalance FBC is subtotalled every 4 hours.

Where assessment reveals a fluid imbalance documentation should include:

1. Assessment parameters which prove this imbalance.
2. Nursing interventions.
3. Patient's response to intervention – documenting assessment parameters supporting this response.
4. Referral to medical officer.
5. Medical interventions prescribed.
6. Patient's response to intervention – documenting assessment parameters supporting this response.
7. Patient education provided.
8. Plan for continuing monitoring and care.

HOME CARE CONSIDERATIONS

Education for the identification of risk factors affecting fluid status and the interruption of the activities of daily living cycle.

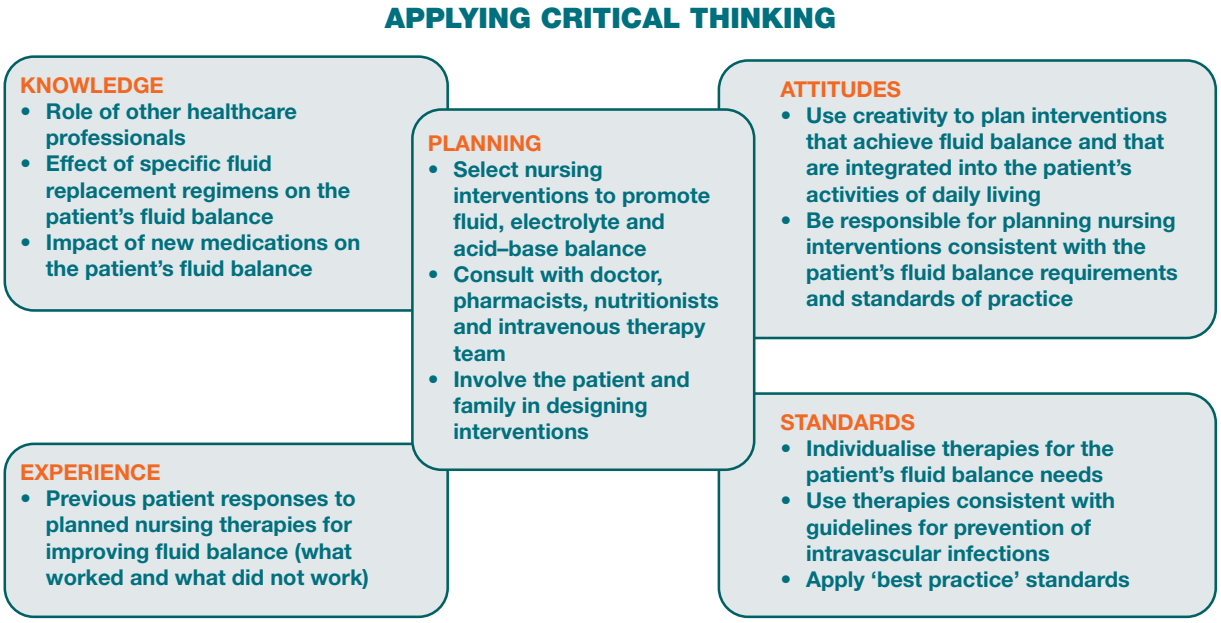

Figure 34-15 **Critical thinking associated with the planning phase for fluid, electrolyte and acid–base balance.**

proven guidelines for selecting effective nursing interventions. For example, the Infusion Nurses Society (2011) *Standards of practice* should be applied when intravenous therapy becomes a part of the plan. The nurse develops an individual plan of care for each of the nursing diagnoses (see *Sample student nursing care plan*).

Goals and outcomes

The nurse and the patient set realistic expectations for care. Goals are to be individualised and realistic, with measurable outcomes. During planning, the nurse collaborates as much as possible with the patient and family and other members of the interdisciplinary healthcare team. The family can be particularly helpful in identifying subtle changes in a patient's behaviour associated with any imbalances (e.g. anxiety, confusion, irritability). The nurse also incorporates patient preferences and resources into the plan of care. One goal for a patient with a fluid volume deficit related to immobility would be to offer frequent fluids so that intake is equal to daily maintenance volume (if not contraindicated). Outcomes for this would be: 'Fluid balance chart indicates intake is at least equal to maintenance fluid requirements (see Table 34-16), urine is clear, straw-coloured, specific gravity of 1.015 and balanced with intake, patient's mucous membranes are moist, patient states she is no longer thirsty (note that thirst may be dampened in the elderly).' If this patient's usual weight is 55 kg, daily fluid intake according to formula B (Table 34-6) should be (100 mL × 10 + 50 mL × 10 + 25 × 35) = 2375 mL/24 hours.

Setting priorities

The patient's clinical condition will determine the priority of diagnoses. Many nursing diagnoses in the area of fluid, electrolyte and acid–base balances are of highest priority because the consequences for the patient can be serious or even life-threatening. Consultation with the patient's doctor may assist in setting realistic timeframes for the goals of care, particularly when the patient's physiological status is unstable.

Continuity of care

Discharge planning must begin as early as possible. The nurse anticipates the needs of the patient and collaborates with other members of the healthcare team such as the doctor, dietitian and pharmacist to ensure that care can continue in the home or long-term care setting with few disruptions. For example, for the patient who is discharged on IV therapy, the nurse must determine the knowledge and skills of the family member or friend who is to assume caregiving responsibilities, provide education to maintain or improve the health of the client and prevent other issues, for example, infection at cannula site, and make a referral to home nursing services as soon as possible. The dietitian can be a valuable resource in recommending food sources to either increase or reduce intake of certain electrolytes. Chapter 44 describes various therapeutic diets (e.g. low sodium). The pharmacist can offer advice on possible side effects affecting fluid, electrolyte or acid–base disturbances of prescribed medications.

PREPARING FOR AND TAKING ACTION

Health promotion

Health promotion activities in the area of fluid, electrolyte and acid–base imbalances focus mainly on patient teaching. Patients and caregivers need to recognise risk factors for these imbalances and implement appropriate preventive measures. For example, parents of infants need to understand that GI losses can quickly lead to serious imbalances; therefore, when vomiting or diarrhoea occur in the infant parents need to promptly seek health care to restore normal balance. Healthy adults are at risk of developing imbalances when subjected to elevated environmental temperatures. In high environmental temperatures nurses need to advise individuals to supplement the fluid loss from perspiration by increasing oral fluids which replace the fluid and electrolytes lost, maintain adequate environmental ventilation and refrain from excessive activity during this period of time.

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data*

Mrs Hilda Bottomley, 72 years, visited her doctor this morning with complaints of **productive cough, chills, malaise, anorexia, a temperature of 38.3°C and body aches**. She reports a history of respiratory congestion for the last 2 weeks and has noted that her **secretions are now thick and yellow-greenish**. She admits that she **has not felt like eating and drinking** much lately. After an outpatient chest X-ray, Mrs Bottomley was admitted for respiratory physiotherapy, IV antibiotic and fluid therapy. On admission her **vital signs are within normal limits except for a temperature of 38.2°C, an increased respiratory rate of 28 breaths per minute, shortness of breath with activity and rhonchi breath sounds. Arterial blood gas results indicate a mild respiratory acidosis, and the chest X-ray reveals left lower lobe pneumonia**. The doctor orders oxygen at 4 L/min with humidification, respiratory treatments, fluids by mouth and IV, pulse oximetry and activity with assistance.

Priority problem(s)

Ineffective airway clearance because of increased mucous in response to airway infection and manifested by mild respiratory acidosis. Risk of fluid volume deficit related to reduced fluid and dietary intake.

** Important data to cluster in setting priorities in bold.*

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Mrs Bottomley's airway will be free from secretions with normal arterial blood gas (ABG) levels within 48 hours.	ABG levels will be within normal limits in 48 hours. Respiratory rate will be within normal limits with activity in 48 hours. Temperature will be within normal limits in 48 hours. Breath sounds will be clear on auscultation. Mucous will become thin and clear in 72 hours. Vital signs will remain within normal limits.
Mrs Bottomley's fluid volume will return to within normal limits.	Fluid intake will be consistent with calculations for hourly maintenance volume based on weight with additional fluid to account for fluid loss prior to admission and increased insensible loss during admission. Output (including insensible loss) will demonstrate sufficient blood flow to kidneys > 0.4 mL/kg/hr. Mucous membranes will remain moist.

Preparing for and taking action†	Rationale
Airway maintenance • Schedule coughing and deep-breathing exercises every 2 hours while awake. • Administer chest physiotherapy every 4 hours while Mrs Bottomley is awake to affected regions of the lung. • Encourage Mrs Bottomley to move position every 2 hours and to sit out of bed on chair often. • Provide Mrs Bottomley with an additional 500 mL of non-caffeinated oral fluids every 8 hours.	Cough control exercises and deep breathing promote pulmonary secretion clearance (Strickland et al 2013). Chest physiotherapy, breathing exercises, cough techniques and moving the patient are effective in promoting airway clearance (Strickland et al 2013). Increased fluid intake helps to liquefy pulmonary secretions and facilitate productive coughing (Strickland et al 2013). Additional intake is required to replace insensible loss from increased temperature and increased respirations

† Intervention classification labels from McCloskey JC, Bulechek GM 2000 Nursing interventions classification (NIC), 3rd edn. Mosby, St Louis.

Evaluating impacts and outcomes

- Monitor ABG results, vital signs, fluid balance, daily weight and oxygen saturation levels.
- Auscultate breath sounds every 4 hours.
- Evaluate effectiveness of coughing and deep-breathing exercises.
- Identify methods to provide for adequate rest.

It can sometimes be difficult to separate the effects of age-related changes from changes associated with disease processes (Touhy & Jett 2011). For example, an older adult living with a chronic condition involving renal or respiratory function is more likely to suffer serious consequences when an acute disease process occurs.

All patients with a chronic health alteration are at risk of developing changes in their fluid, electrolyte and acid–base balances. They need to understand and monitor for risk factors and implement measures to avoid imbalances. For example, patients with renal failure must weigh themselves daily and avoid excess intake of fluid, sodium, potassium and phosphorus. Through diet education, these patients learn the types of foods to avoid and the suitable volume of permitted daily fluid (see Chapter 44). A patient with heart failure should be instructed to obtain an accurate bodyweight each day at approximately the same time and to inform the doctor of significant changes of weight from one day to another. Significant increases in weight, shortness of breath, orthopnoea and dependent oedema are associated with fluid retention.

Acute care

Fluid, electrolyte and/or acid–base imbalance can occur in all settings, and in acute care settings the nurse must manage the patient's complex medical care in a shorter span of time.

Daily weights and intake and output measurement

Daily weight and fluid balance measurements are just two of the assessments required when assessing fluid volumes where 1 kg is equal to 1 litre. *Daily weights* are the single most important indicator of fluid status. Weight should be measured at the same time each day, after the patient voids, with the patient wearing the same clothes and using the same scale. The scale should be routinely calibrated.

Fluid balance charts provide additional information about fluid balance (see Assessment section). Intake and output measurements, when examined for trends, can indicate whether excess fluid volume is excreted in the form of urine or whether excretion of fluids through the kidneys has diminished. The fluid balance chart is not as accurate as daily weights in assessing daily fluid balance unless measurement has been strict and precise.

Enteral replacement of fluids

The appropriateness of oral replacement of fluids and electrolytes and the need for rapid fluid replacement depends on the patient's degree of instability. Oral rehydration solutions (ORS) should be encouraged for mild to moderate dehydration. Vomiting and diarrhoea are not initially contraindications for oral rehydration therapy (ORT) (King et al 2003). ORS should be given slowly, in small volumes but frequently, to minimise vomiting. However, oral fluid replacement is contraindicated in protracted vomiting, worsening diarrhoea, where oral replacement fluids are insufficient to replace losses, mechanical obstruction of the GI tract, risks for aspiration, decreased consciousness and impaired swallowing (King et al 2003).

When replacing fluids by mouth in a patient with a fluid deficit, it is wise to choose appropriate fluid volume and fluids with adequate calories and electrolyte content (e.g. fluid replacements like Pedialyte and Gastrolyte) (see Table 34-22; see also Chapter 36). Homemade oral rehydration solutions or fluids with high glucose or lactose content may draw fluid into the gut, causing more diarrhoea. Liquids containing caffeine or a low-sodium content may not be appropriate when the patient has diarrhoea.

TABLE 34-22 Typical fluid content of a range of foods

Food	Volume of fluid (mL)	Food	Volume of fluid (mL)
100 g cooked meat (lamb, beef, pork)	60	1 cup cooked porridge	160
2 tbsp gravy/sauce	40	100 g cantaloupe (rockmelon)	70
100 g ham	80	100 g watermelon	80
100 g cottage cheese	100	1 apple	80
100 g canned asparagus	115	½ cup melon	100
100 g cabbage	70	100 g pineapple	100
100 g potato (baked)	115	1 banana	85
100 g baked beans	80	100 g apricots, canned	70
100 g broccoli	70	100 g fruit salad	100
100 g cucumber	50	2 scoops of ice cream	40
1 large hard-boiled egg	40	½ cup jelly or custard	100
1 cup cooked rice	100	1 small tub yoghurt	160

tbsp = tablespoon.

Adapted from Wotton K, Crannitch K, Munt R 2008 Prevalence, risk factors and strategies to prevent dehydration in older adults. Contemp Nurse 31(1):44–56.

A feeding tube may be appropriate when the patient's GI tract is healthy but the patient cannot ingest fluids (e.g. after oral surgery or with impaired swallowing). Fluids can also be replaced through a gastrostomy or jejunostomy feeding tube, or they can be administered via a small-bore nasogastric feeding tube (see Chapter 36).

Restriction of fluids

Patients who retain fluids and have **fluid volume excess (FVE)** require restricted fluid intake. Fluid restriction is often difficult for patients, particularly if they take medications that dry the oral mucous membranes or they breathe through the mouth and experience the sensation of thirst. The nurse should explain why fluids are restricted and the amount of fluid permitted orally, and should understand that ice chips, gelatine, ice cream and other foods (see Table 34-22) contain fluid. The patient should help to decide the amount of fluid with each meal, between meals, before bed and with medications. Often patients on fluid restriction can swallow a number of tablets with as little as 30 mL of liquid.

A good rule of thumb for fluid restrictions is to allow half of the allotted total oral fluids between 7.00 a.m. and 3.00 p.m., the period when patients are usually more active, receive two meals and take most of their oral medications. Patients on fluid restriction require frequent mouth care to moisten mucous membranes, decrease the chance of mucosal drying and cracking and maintain comfort (see Chapter 34).

Subcutaneous replacement of fluids and electrolytes

Hypodermoclysis (Skill 34-2), the administration of fluids into the subcutaneous layer of the skin, allows fluid to be absorbed into the circulation through the extensive subcutaneous

SKILL 34-2

Subcutaneous infusion (hypodermoclysis)*

Delegation considerations

Initiating SC infusion requires the problem-solving and knowledge-application skills of professional nurses. In Australia, a registered nurse is able to insert SC cannulas. Refer to relevant agency policy.

Equipment

- 24 gauge, 0.75 inch catheter
- Transparent dressing (e.g. Opsite, Tegaderm)
- IV catheter extension set
- 3 mL syringe
- Interlink syringe cannula
- 5 mL 0.9% Normal saline for injection
- Alcohol swabs
- Gloves
- Non-allergenic tape
- Needle disposal container (sharps container)
- Infusion order
- Fluid balance chart

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
PREPARING THE SC SOLUTION	
1. Check solution using the seven rights of drug administration (see Chapter 27). Check type of fluid, amount, rate and route of administration with written doctor's orders.	Solutions are medications and should be carefully checked by two nurses to reduce risk of error. Type of fluid: the most appropriate solutions are sodium chloride 0.9% or 0.45%, and 2.5% glucose in 0.45% sodium chloride. Rate: the usual rate is only 1 mL/minute per site, with maximum of 1.5 L in 24 hours using a single site or 3 L in 24 hours if using two sites.

STEPS	RATIONALE
2. Check solution for colour, clarity and expiration date. Check bag for leaks, which is best done before reaching the bedside.	Solutions that are discoloured, contain particles or are expired are not to be used. Leaky bags present an opportunity for infection and must not be used.
3. Assess patient's history of allergies.	May reveal information that affects insertion of devices, such as allergy to iodine, adhesive or latex.
4. Open infusion set, maintaining sterility of both ends of tubing. Many sets allow for priming of tubing without removal of end cap.	Prevents bacteria from entering infusion equipment.
5. Place roller clamp about 2–5 cm below drip chamber and move roller clamp to 'off' position (see illustration at Step 18).	Close proximity of roller clamp to drip chamber allows more accurate regulation of flow rate. Moving clamp to 'off' prevents accidental spillage of fluid and decreases amount of air bubbles when priming line.
6. Remove protective sheath over IV-giving set tubing.	Provides access for insertion of infusion tubing into solution.
7. Insert infusion set into fluid bag. Remove protector cap from tubing insertion spike (keeping spike sterile), and insert spike into opening of IV bag (see illustration at Step 18).	Prevents contamination of solution from contaminated insertion spike.
8. Prime infusion tubing by filling with IV solution. Compress drip chamber and release, allowing it to fill one-third to half full.	Creates suction effects; fluid enters drip chamber to prevent air from entering tubing.
9. Slowly release roller clamp to allow fluid to travel from drip chamber through tubing to needle or catheter adapter. Line can be primed without removing tubing protector cap. Return roller clamp to 'off' position after tubing is primed (filled with solution).	Slow fill of tubing decreases turbulence and chance of bubble formation. Removes air from tubing and permits tubing to fill with solution. Closing the clamp prevents accidental loss of fluid.
10. Be certain tubing is clear of air and air bubbles.	Prevents bubble formation in the cannula.
11. Remove tubing protector cap and replace with 'threader link cannula' or 'lever lock cannula' leaving the protector on end of these until ready to attach to the 'Interlink injection site', which is an Interlink connector attached to the subcutaneous cannula.	Prepares the IV-giving set for connection to the SC cannula. Maintains system sterility.
INSERTION OF SC CATHETER	
12. Perform hand hygiene and use aseptic technique; observe standard precautions.	Reduces transmission of microorganisms.
13. Explain procedure and expected outcomes to patient. Assess patient's perception of possible discomfort and site preference.	Determines level of emotional support and patient education required.

STEPS	RATIONALE
14. Select appropriate insertion site. a. Suitable sites are abdomen, upper chest, above the breast, over an intercostal space and over the scapula; thighs; and the outer aspect of the upper arm.	The SC infusion should be sited in a position with good lymphatic drainage to maximise absorption.
b. Unsuitable sites include those with pre-existing oedema, lymphoedemata, previous radiotherapy site, skin damage, swelling or scarring, mastectomy site or close to a stoma. Sites over bony prominences or near a joint are also unsuitable.	Any site where tissue viability or perfusion is compromised and absorption is affected should be avoided.
15. Consider the application of EMLA (topical anaesthetic) cream for patients with needle phobia.	EMLA cream makes subcutaneous cannulation relatively painless; must be applied at least 1 to 1.5 hours before the proposed procedure.
16. Prime the SC catheter: Draw 1.5 mL of Normal saline into syringe. Inject 1 mL Normal saline via the sterile Interlink injection cap into the SC cannula and tubing. Clamp tubing to maintain Normal saline in cannula and tubing. Detach syringe. Be careful not to contaminate distal end of tubing.	Priming the IV line ensures that Normal saline will fill dead space and air will not be administered.
17. Put on gloves.	Reduces transmission of microorganisms.
18. Clean insertion site (see illustration): Using a firm, circular motion (middle to outwards), clean with alcohol, and allow to dry. Clean again, using same method, with povidone–iodine solution and allow to dry; refrain from touching the cleaned site. If the patient is allergic to iodine, use 70% alcohol and allow to dry for 60 seconds.	Reduces the risk of transfer of transient microorganisms and resident microorganisms from skin to subcutaneous tissues. Povidone–iodine reduces skin surface bacteria; touching the cleaned area introduces organisms from nurse's glove. Povidone–iodine must dry to be effective in reducing microbial counts. Use of alcohol reduces the possible adverse effects of povidone–iodine.

Step 18 Cleaning insertion site.

STEPS	RATIONALE
19. Using thumb and index finger, pinch the skin and tissue around the insertion site, creating a roll of about 1.25–2.5 cm in diameter.	Pinching the skin elevates the SC tissue and ensures cannulation into SC tissue above the underlying fascia.
20. Insert the entire length of the catheter at a 45-degree angle with the bevel of the needle up.	Shallower positioning, i.e. less than 45°, may shorten the life of the infusion site.
21. Remove the stylet (needle) and discard carefully into the sharps disposal container.	Reduces the risk of needle-stick injury and cross-infection.
22. Check SC placement:	
a. Cleanse Interlink injection cap and attach syringe containing remaining Normal saline.	
b. Draw back to ensure the over-the-needle cannula is not placed in a blood vessel. If blood appears in tubing, remove the over-the-cannula needle, discard used equipment and re-site.	Ensures that cannula has not entered a capillary or vein.
c. If blood does not appear in tubing, flush tubing with remaining 0.5 mL of Normal saline.	Flushing ensures effective hypodermoclysis.
COMMENCING THE SC INFUSION	
23. Attach the IV-giving set to the SC cannula.	To connect the fluid to the cannula.
24. If SC fluids are ordered, remove the protective tubing from the 'threaded link cannula' or 'lever lock cannula' on the patient end of the IV-giving set and connect it to the 'Interlink injection site' (bung/cap) which should now be on the end of the SC cannula. Adjust the flow rate as desired.	Prompt connection of infusion set maintains sterility.
25. Subcutaneous fluids should be administered via gravity using a standard administration set (20 drops/mL).	The administration of SC fluids relies on the permeability of the subcutaneous tissues to gravity-fed fluids. SC fluids should never be given via an infusion pump.
26. Curl a loop of tubing alongside the SC cannula and apply transparent dressing, ensuring that needle and tubing are well anchored.	Creating a loop in the tubing around the needle site avoids inadvertent dislodgement of the needle. Dressing the insertion site with a clear occlusive dressing allows for regular observation of the site. Tape on top of tape makes it easier to access hub/tubing junction. Securing loop of tubing reduces risk of dislodging catheter.
27. Write insertion date on dressing; attach label on IV line with SC fluid in progress.	Noting date of insertion clearly communicates change times for IV tubing. Attaching a label with the SC fluid in progress decreases risk for errors in infusing incorrect fluids; labelling of fluids and lines has been recognised to increase the safe administration of fluids.

STEPS	RATIONALE
28. Check order for SC fluids; calculate drops per minute and commence infusion. Document on infusion record and fluid balance chart.	The administration line should be labelled with the date and time of commencement, and this should also be documented in the patient's health records; this assists in the identification of time and date for change of line.
MANAGING THE SC INFUSION	
29. Check the site within 30 minutes of commencement of infusion and at regular times thereafter. a. Check site within 30 minutes of commencement of hypodermoclysis to assess skin integrity. b. Check site at least 2-hourly for signs of redness, induration, tenderness, bleeding, oedema or leaking. c. A minimum of 4-hourly, check vital signs and analysis of FBC to determine level of hydration.	Regular observation of site will ensure identification of early signs of inflammation (erythema), oedema or poor absorption (hard SC swelling) and need for re-siting of the SC cannula. Redness, swelling or inflammation at infusion site may be due to local reaction to cannula and may require the use of a Teflon cannula to reduce inflammatory response. Tenderness at infusion site may require the position of the cannula to be adjusted/re-sited as the cannula may have been inserted intradermally (at too shallow an angle). Analysis of 4-hourly vital signs aids in the early identification and response to pulmonary oedema, hypovolaemia and the monitoring of clinical progress.
30. Infusion site and giving sets are usually changed every 48–72 hours. The site must be changed according to unit policy regardless of its duration, and when any complications are observed.	Changing SC sites according to unit policy will decrease risk of infection. Sites should be rotated to minimise tissue damage.
DISCONTINUING A CONTINUOUS INFUSION	
31. Check written order for discontinuation.	Discontinuation of a continuous infusion will be undertaken based on doctor's orders.
32. Gather equipment: • Alcohol swabs • Gloves • Interlink cannula (if leaving SC site in situ) • 3 mL syringe (for saline flush) (if leaving SC site in situ) • 5 mL 0.9% Normal saline for injection (if leaving SC site in situ)	
33. Explain procedure and expected outcomes to the patient and/or family.	Patient's awareness of the procedure will reduce anxiety and increase cooperation.
34. Perform hand hygiene. Put on gloves.	Reduces transmission of microorganisms.
35. Stop continuous infusion: disconnect IV tubing. Remove Interlink threaded lock cannula from 'Interlink injection site'.	

STEPS	RATIONALE
36. Remove SC cannula: a. Remove transparent dressing. b. Pull out over-the-needle cannula. c. Discard into medical waste container. d. Apply pressure if bleeding or fluid leakage, followed by application of bandaid or small dressing.	Gentle removal of transparent dressing first will limit any damage to the skin. Immediate discarding of cannula into correct receptacle reduces risk of cross-infection.

RECORDING AND REPORTING

Documentation:

- Sign the infusion therapy chart; complete the time and date started.
- Complete and attach a change of line label to the IV tubing.
- Enter the SC fluid type and volume onto the fluid balance chart.
- Document the insertion site and date in the patient record/care plan/infusion chart.
- Attach a SC time label to the IV bag.
- Record patient's response to SC fluid, amount infused in shift report; integrity and patency of system according to agency policy.
- Report to oncoming nursing staff: type of fluid, flow rate, status of SC site, amount of fluid remaining in present solution, expected time to hang next bag, and any side effects.

HOME CARE CONSIDERATIONS

See Box 34-6.

- Patient and relatives are involved in the assessment of burdens and benefits of SC infusion therapy.
- Teach caregiver to apply pressure with sterile gauze if SC catheter is accidentally removed.
- Teach patient and caregiver to perform bed bath without getting SC tubing wet. Refer to relevant agency policy for management practices.
- Teach patient and family to monitor and report any possible complications.
- Teach patient and family to monitor fluid balance using household measuring devices.

* Procedure adapted from Woodward M 2013 Guidelines to effective hydration in aged care facilities. Aged and Residential Care Services, Heidelberg Repatriation Hospital, Victoria, Australia.

lymphatic and blood vessel network. It can be used for short-term hydration in mild to moderate hypovolaemia in adult patients who are unable to take adequate oral fluids and in whom it is difficult or impractical to insert an IV line. The recommendation for no more than 1 mL per minute (60 mL/h, 1.5 L/day) is not a limitation, as the use of two concurrent subcutaneous infusions sites can deliver around 3 L per day (Moriarty & Hudson 2013). Sites include the upper chest (avoiding breast tissue), abdomen (at least 5 cm from navel), thighs and upper arms. Preferred solutions include Normal saline, half-Normal saline and glucose with saline although lactated Ringer's and solutions containing potassium can also be administered (Remington & Hultman 2007).

As subcutaneous infusions can be initiated by registered nurses (RNs), they are appropriate in residential (Woodward 2103) and palliative care settings (Good et al 2014). These agencies require a protocol that identifies criteria for initiation of hypodermoclysis and rules for determination of type of fluid and hourly volume.

Parenteral replacement of fluids and electrolytes

Fluid and electrolytes may be replaced through infusion directly into the bloodstream rather than via the digestive system. Parenteral replacement includes total parenteral nutrition (TPN), IV fluid and electrolyte therapy (crystalloids) and volume expanders, blood and blood component (colloids) administration.

With the increased risk to health workers of transmission of the human immunodeficiency virus (HIV), the cause of acquired immunodeficiency syndrome (AIDS), hepatitis B virus (HBV) and other infectious diseases, blood and body substance precautions must be practised when administering parenteral fluids (see Chapter 34).

Vascular access devices are catheters, cannulas or infusion ports placed into larger vessels (central veins), which are designed for long-term, repeated access to the vascular system. These devices are more effective than peripherally placed catheters for administering medications and solutions that are irritating to veins, and for the delivery of long-term IV therapy.

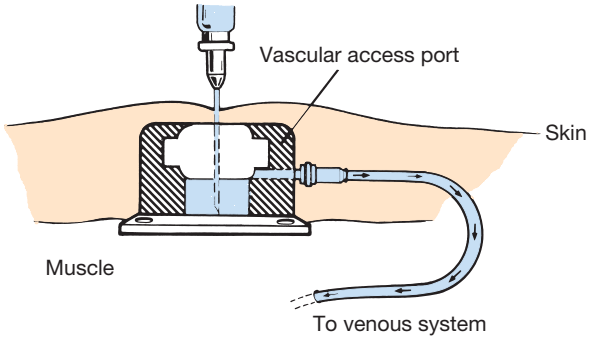

Figure 34-16 Implantable infusion port.

Increased use of central venous catheters and implanted infusion ports (Figure 34-16) requires nurses to be educated in the care of these devices.

Total parenteral nutrition

Total parenteral nutrition is a nutritionally balanced hypertonic solution consisting of glucose and other nutrients and electrolytes given through a peripherally inserted central catheter (PICC) or central venous catheter (CVC) (see Chapter 36).

Intravenous therapy (crystalloids)

The goal of IV fluid administration is to correct or prevent fluid and electrolyte disturbances. It allows for direct access to the vascular system, permitting the infusion of continuous fluids over a period of time. Intravenous fluid therapy must be closely regulated because of continual changes in the patient's fluid and electrolyte balance. Crystalloid solutions contain small molecules (solutes) capable of crystallisation that flow easily across semipermeable membranes, therefore transferring from the bloodstream into the cells and body tissues.

When IV fluid administration is required, the nurse must know reasons for the prescription of the particular solution and amount, the correct prescribed solution, the equipment needed, the procedures required to initiate an infusion, how to regulate the infusion rate and maintain the system, how to identify and correct problems and how and when to discontinue the infusion if necessary.

Administration of intravenous therapy

Types of solutions

Many prepared IV solutions are available (Table 34-23) and include isotonic, hypotonic or hypertonic solutions (Lewis et al 2014). *Isotonic* solutions have the same effective osmolality as body fluids, *hypotonic* solutions have an effective osmolality less than body fluids and *hypertonic* solutions have an effective osmolality greater than body fluids.

In general, isotonic fluids are used most commonly for extracellular volume replacement (e.g. fluid volume deficit after prolonged vomiting). The decision to use a hypotonic or a hypertonic solution is based on the specific fluid and electrolyte imbalance. For example, a patient with a hypertonic fluid imbalance will generally receive a hypotonic IV solution to dilute the extracellular fluids and rehydrate the cells.

All IV fluids should be given carefully, especially hypertonic solutions because these pull fluid into the vascular space by osmosis, resulting in an increased vascular volume that can lead to pulmonary oedema, particularly in patients with heart or renal failure. Certain additives, most commonly vitamins and potassium chloride (KCl), are frequently added to IV solutions.

Patients with normal renal function who are NBM may require potassium added to IV solutions. The body cannot conserve potassium; even when the serum level falls, the kidneys continue to excrete potassium. If there is no oral or parenteral potassium intake, hypokalaemia can develop quickly. Conversely, the nurse should verify current serum potassium level and that the patient has adequate urine output before administering an IV solution containing potassium, because hyperkalaemia can also develop quickly. However, under no circumstances can potassium chloride (KCl) be given as an IV bolus and must therefore be administered with an infusion pump. A direct IV infusion of KCl is fatal. A doctor's prescription for IV fluid must include the required additives, for example: 'Bag 1: 1000 mL 4% dextrose in 0.18% saline with 20 mmol KCl at 125 mL/hour.' Nurses must check the serum electrolyte results before commencing and throughout IV therapy and should check all orders with infusions immediately they are allocated the care of a patient with IV therapy (see *Research highlight*).

Equipment

Correct selection and preparation of IV equipment assists in safe and timely commencement of an IV infusion. Because fluids are instilled into the bloodstream, sterile technique is necessary. The equipment the nurse must have at the bedside includes

TABLE 34-23 Intravenous solutions

Solution	Concentration
Glucose (= dextrose) in water solutions	
Glucose 5% in water*	Isotonic
Glucose 10% in water	Hypertonic
Saline solutions	
0.45% sodium chloride (half-Normal saline)	Hypotonic
0.9% sodium chloride (Normal saline)	Isotonic
3–5% sodium chloride	Hypertonic
Glucose (= dextrose) in saline solutions	
Glucose 5% in 0.9% sodium chloride	Hypertonic
Glucose 5% in 0.45% sodium chloride	Hypertonic
Multiple electrolyte solutions	
Compound sodium lactate Hartmann's solution	Isotonic
Compound sodium lactate and glucose 5% Hartmann's solution and glucose	Hypertonic

* Glucose is quickly metabolised, leaving free water to be distributed evenly in all fluid compartments

Horne MM et al 1997 Mosby's pocket guide series: fluid, electrolyte, and acid–base balance, 3rd edn. Mosby, St Louis.

RESEARCH HIGHLIGHT

Research focus
To assess on a multinational level the frequency, characteristics, contributing factors, and preventive measures of administration errors in parenteral medication in intensive care units.

Research abstract
Observational, prospective 24-hour cross-sectional study.

Research findings
A total of 861 medication errors affected 441 patients. These medication errors equated to 74.5 events per 100 patient days. Three-quarters of the errors were classified as errors of omission. Twelve patients experienced permanent harm or died because of medication errors at the administration stage. Odds ratios for the occurrence of at least one parenteral medication error were raised for number of organ failures; use of any intravenous medication; number of parenteral administrations; larger intensive care unit; number of patients per nurse; and occupancy rate. Parenteral medication errors were decreased where there was increased basic monitoring; an existing critical incident reporting system; an established routine of checks at nurses' shift change; and an increased ratio of patient turnover to the size of the unit.

Conclusions
Parenteral medication errors at the administration stage are common and a serious safety problem in intensive care units. With the increasing complexity of care in critically ill patients, organisational factors such as error reporting systems and routine checks can reduce the risk for such errors.

cannulas, tourniquet, gloves, a transparent dressing (e.g. Opsite, Tegaderm), IV solution, various types of tubing, IV pumps or volume-control devices and different types of IV administration sets (see Skill 34-3).

Initiating the intravenous line

This procedure is only initiated by RNs and medical staff accredited in IV cannulation. Preparation for the procedure and assisting the person initiating the IV therapy is a nursing responsibility. The person cannulating assesses the patient for a **venepuncture** site (Skill 34-3) and considers conditions and contraindications that exclude certain sites. Common IV puncture sites include the hand and the arm (Figure 34-17); the foot is used in children, but is avoided in the adult because of the danger of **phlebitis** (Joanna Briggs Institute 2003). The patient should be consulted about the appropriate site

SKILL 34-3

Initiating a peripheral intravenous (IV) infusion

Delegation considerations
Initiating IV therapy requires the problem-solving and knowledge-application skills of professional nurses. For this procedure, delegation is inappropriate. In Australia, a registered nurse (RN) is required to be accredited before being able to routinely cannulate. However, all nurses should be aware of all the components of initiating a peripheral IV infusion, as they are usually required to collect the equipment and assist the medical officer or accredited RNs throughout the procedure. Refer to relevant agency policy. Note that many acute care agencies have an IV trolley which contains all necessary equipment and supplies.

Equipment
- Special patient gown with press-studs at shoulder seams (makes removal with IV tubing easier)
- IV infusion chart
- Prescribed IV fluid (with time tape attached)
- Over-the-needle catheter (ONC) for venepuncture (gauge will vary with patient's body size and reason for IV fluid administration)

For IV fluid infusion:

- Administration set (choice depends on type of solution and rate of administration; infants and children require microdrip tubing, which provides 60 drops/mL)
- Extension tubing (used when a longer IV line is necessary)
- Alcohol and povidone–iodine cleaning swabs or sticks (Rosenthal 2003).
- EMLA cream
- Towel (to place under patient's hand or arm)
- IV pole, rolling or ceiling-mounted
- Disposable gloves

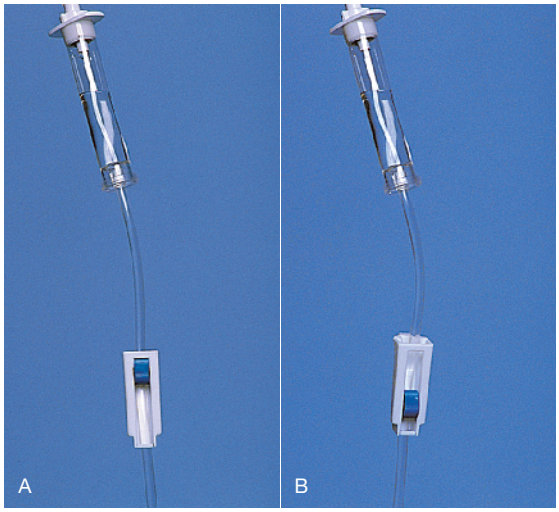
- Tourniquet (can be a source of contamination; use a single-use product)
- Arm board, if needed (used to maintain wrist or elbow joint position)
- Non-allergenic tape
- Needle disposal container (sharps container)
- Transparent dressing (e.g. Opsite, Tegaderm)
- 'Interlink injection site' (also called IV bung/plug/cap); connects to IV cannula; allows needleless connection to the IV cannula
- 'Lever lock cannula' or 'threaded lock cannula'; attaches to the IV-giving set and connects the giving set to the cannula. Note that the giving set is never directly attached to the IV cannula without either of these Interlink connections
- 1–3 mL of Normal saline
- 5 mL syringes with Interlink needle

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
ASSESSMENT	
1. Review doctor's order for type and amount of IV fluid, rate of fluid administration and purpose of infusion. In addition, follow the seven rights for administration of medications (see Chapter 27).	A prescription for peripheral IV fluids must be made by a doctor before the implementation of this procedure. Assists in selection of appropriate access device.
2. Review clinical data for indications of type of fluid and electrolyte imbalance and reason for prescribed infusion; e.g. admission diagnosis, signs and symptoms (e.g. bodyweight, blood pressure, pulse, skin turgor, urine output, fluid balance chart, serum electrolytes, full blood count – haemoglobin [Hb] and haematocrit [Hct]).	Nurse is fully aware of reason for the prescribed solution and rate of infusion and ongoing monitoring required. Provides baseline data for later evaluation of change in fluid and electrolyte status.
3. Assess patient's history of allergies.	May reveal information that affects insertion of devices, such as allergy to iodine, adhesive or latex.
4. Assess patient's previous or perceived experience with IV therapy and arm placement preference.	Determines level of emotional support and patient education required.
5. Consider the application of EMLA cream for children and patients with needle phobia.	Although the application of EMLA cream makes IV cannulation relatively painless, it must be applied at least 1 to 1.5 hours before the proposed procedure. It is effective for up to 4 hours post-application. Not recommended for infants under 3 months of age.
6. Determine whether patient is to undergo any planned surgery or is to receive blood infusion later.	Allows placement of appropriate-size catheter (i.e. 18 or 16 gauge for surgery) which will not interfere with medical procedures.
7. Assess for the following risk factors: child or older adult, presence of heart failure or renal failure or low platelet count.	Persons at extremes in age develop fluid imbalances more rapidly because of a proportionately larger ECF volume; persons with heart failure and acute kidney disease may require fluid restriction and cannot adapt to sudden increases in vascular volume. A low platelet count predisposes patients to bleeding at IV site.

STEPS	RATIONALE
PREPARATION OF PATIENT	
8. Prepare patient and family by explaining the procedure, its purpose and what is expected of patient.	Decreases anxiety and promotes cooperation.
9. Help patient into comfortable sitting or supine position.	
10. Change patient's gown to the more easily removed gown with press-studs at the shoulder.	Use of a special IV gown facilitates safe removal of the gown.
11. Perform hand hygiene.	Reduces transmission of microorganisms.
12. Organise equipment on clean, clutter-free bedside stand or overbed table.	Reduces risk of contamination and accidents. Maintains sterility of equipment and reduces spread of microorganisms.
PREPARING THE IV SOLUTION	
13. Check IV solution and any prescribed additives, using the seven rights of drug administration (see Chapter 27).	IV solutions are medications and should be carefully checked by two nurses to reduce risk of error.
14. Check solution for colour, clarity and expiration date. Check bag for leaks, which is best done before reaching the bedside.	Solutions that are discoloured, contain particles or are expired are not to be used. Leaky bags present an opportunity for infection and must not be used.
15. Open infusion set, maintaining sterility of both ends of tubing. Many sets allow for priming of tubing without removal of end cap.	Prevents bacteria from entering infusion equipment and bloodstream.
16. Place roller clamp about 2–5 cm below drip chamber and move roller clamp to 'off' position (see illustration).	Close proximity of roller clamp to drip chamber allows more-accurate regulation of flow rate. Moving clamp to 'off' prevents accidental spillage of fluid and decreases amount of air bubbles when priming line.



Step 16 A, Position of roller clamp below drip chamber. B, Roller clamp in 'off' position.

STEPS	RATIONALE
17. Remove protective sheath over IV-giving set tubing port on plastic IV solution bag (see illustration). For bottled IV solution, remove metal cap and metal and rubber disks beneath cap.	Provides access for insertion of infusion tubing into solution.
18. Insert infusion set into fluid bag or bottle. Remove protector cap from tubing insertion spike (keeping spike sterile), and insert spike into opening of IV bag (see illustration).	Prevents contamination of solution from contaminated insertion spike.
19. Prime infusion tubing by filling with IV solution. Compress drip chamber and release, allowing it to fill one-third to half full.	Creates suction effects; fluid enters drip chamber to prevent air from entering tubing.
20. Slowly release roller clamp to allow fluid to travel from drip chamber through tubing to needle or catheter adapter. Line can be primed without removing tubing protector cap. Return roller clamp to 'off' position after tubing is primed (filled with IV fluid).	Slow fill of tubing decreases turbulence and chance of bubble formation. Removes air from tubing and permits tubing to fill with solution. Closing the clamp prevents accidental loss of fluid.
21. Be certain tubing is clear of air and air bubbles. To remove small air bubbles, firmly tap IV tubing where air bubbles are located. Check entire length of tubing to ensure that all air bubbles are removed (see illustration).	Large air bubbles can act as emboli.
22. Remove tubing protector cap and replace with 'threader link cannula' or 'lever lock cannula', leaving the protector on end of these until ready to attach to the 'Interlink injection site', which is an Interlink connector attached to the IV cannula.	Prepares the IV-giving set for connection to the IV cannula. Maintains system sterility.

Step 17 Removal of protective sheath.

Step 18 Inserting spike into opening of IV bag.

Step 21 Tapping to dislodge small air bubbles in tubing.

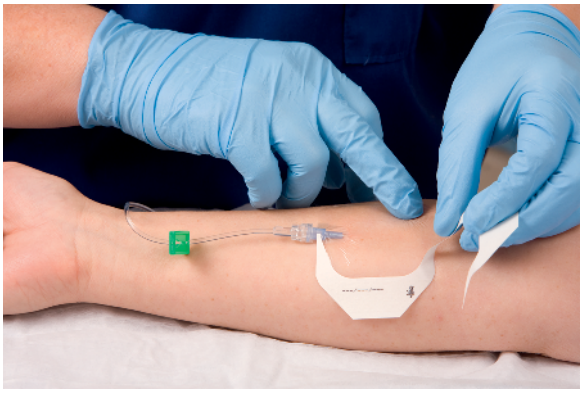
STEPS	RATIONALE
INSERTION OF IV CATHETER/CANNULA	
23. Put on disposable gloves.	Reduces transmission of microorganisms.
24. Identify accessible vein for IV placement. Apply tourniquet 10–15 cm above the proposed insertion site (see illustration). Check for presence of radial pulse. Option: Apply blood pressure cuff instead of tourniquet. Inflate to a level just below patient's normal diastolic pressure.	Tourniquet should be tight enough to impede venous return but not occlude arterial flow.

Step 24 Identifying accessible vein after tourniquet applied.

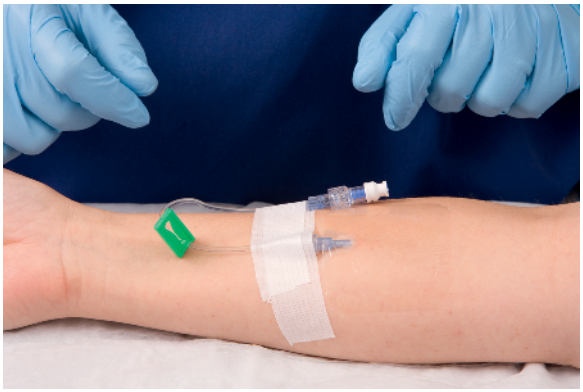
25. Select the vein. a. Use the most distal site in the non-dominant arm, if possible. b. Avoid: • areas that are painful to palpation • areas that interfere with patient's activities of daily living (ADLs) or planned procedures • sites distal to previous venepuncture site • sclerosed or hardened cord-like veins • infiltrated site or phlebotic vessels, bruised areas and areas of venous valves or bifurcation • fragile dorsal veins in older adults and vessels in an extremity with compromised circulation (e.g. in cases of mastectomy, dialysis graft or paralysis). c. Select a vein large enough for catheter placement. d. Palpate the vein by pressing downwards and noting the resilient, soft bouncy feeling as the pressure is released. Always use the same finger to palpate. e. Promote venous distension by instructing the patient to open and close the fist several times, lowering the patient's arm in a dependent position, rubbing or stroking the patient's arm from distal to proximal below proposed site.	Venepuncture should be performed distal to proximal, which increases the availability of other sites for future IV therapy.
26. Release tourniquet temporarily and carefully. Clip arm hair with scissors (if necessary). Do not shave area.	Prevents interruption of venous flow while preparing IV site. Hair impedes venepuncture or adherence of dressing. Shaving can cause microabrasions and predispose patient to infection.

STEPS	RATIONALE
27. Clean insertion site (see illustration).  Step 27 Cleaning the insertion site. a. Using a firm, circular motion (middle to outwards) clean with alcohol and allow to dry. b. Clean again, using same method, with povidone–iodine solution and allow to dry; refrain from touching the cleaned site. If the patient is allergic to iodine, use 70% alcohol and allow to dry for 60 seconds.	Povidone–iodine reduces skin surface bacteria; touching the cleaned area introduces organisms from nurse's hand. Povidone–iodine must be dry to be effective in reducing microbial counts. Use of alcohol improves visualisation of the IV site and reduces the possible adverse effects of povidone–iodine.
28. Reapply tourniquet.	Tourniquet time should be as short as possible. Avoid the use of a tourniquet in areas of compromised circulation. The tourniquet should not interfere with arterial blood flow to the extremity.
29. Perform venepuncture. Anchor vein by placing thumb over vein and by stretching the skin against the direction of insertion 5–7.5 cm distal to the site.	Places needle parallel to vein. When vein is punctured, risk of puncturing posterior vein wall is reduced.
30. To puncture the vein, the catheter is held in the dominant hand. With the bevel up, the skin is entered in the direction of the vein at a 30- to 45-degree angle (see illustration).	 Step 30 Angle for entering vein.
31. After just entering into the vein the angle of the catheter is reduced until it is nearly parallel to the skin. If the vein appears to roll (move), the venepuncture is commenced applying counter-tension against the skin just below the entry site using the non-dominant hand.	
32. The catheter is advanced into the vein until blood is seen in the flashback chamber of the catheter (see illustration).	 Step 32 Diagram of ONC catheter showing flash back chamber.
33. After the vein is entered, the needle is left stationary and the plastic catheter (over the needle) is advanced into the vein. The plastic catheter should slide forward easily and should not be forced into the vein.	
34. The tourniquet should now be released.	

STEPS	RATIONALE
35. Gentle pressure is applied over the vein proximal to the entry site while the needle is removed from the catheter and disposed of into the sharps container. The needle should never be reinserted into the catheter as there is a risk of shearing off a part of the plastic catheter causing an embolus.	Prevents risk of exposure to blood.
36. Attach the 'Interlink injection site' (bung/cap) to the IV cannula and flush the IV line.	Flushing will reaffirm patency and decrease risk of intra-cannula clotting.
37. If IV fluids are ordered, remove the protective tubing from the 'threaded link cannula' or 'lever lock cannula' on the patient end of the IV-giving set and connect it to the 'Interlink injection site' (bung/cap) which should now be on the end of the IV cannula. Adjust the flow rate as desired.	Prompt connection of infusion set maintains patency of vein. Maintains sterility.
38. If no IV fluids are ordered, flush IV cannula with 1–3 mL of sterile Normal saline (saline lock), using an Interlink needle through the 'Interlink injection site' (bung/cap).	
39. Tape the catheter in place using a transparent (clear) dressing. a. Carefully remove adherent backing. b. Apply one edge of dressing and then gently smooth remaining dressing over site, leaving end of 'Interlink injection site' (bung/cap) uncovered (see illustration).	Transparent dressing allows early observation for phlebitis. Securing the catheter and tubing prevents movement and tension on the device, reducing mechanical irritation and possible phlebitis or infection. It is advisable not to use the 'chevron' taping technique.
40. Curl a loop of tubing alongside the arm and place a second piece of tape to secure tubing in two places (see illustration).	Tape on top of tape makes it easier to access hub/tubing junction. Securing loop of tubing reduces risk of dislodging catheter from accidental pull.
41. Label the IV site with the date, time and initials.	



Step 39 Applying transparent dressing to secure catheter.



Step 40 Securing tubing.

■ **Critical decision point: No more than three attempts at inserting an IV should be made by a single nurse (check agency policy).**

STEPS	RATIONALE
42. Release roller clamp slowly to begin infusion at a rate to maintain patency of IV line (not necessary with a heparin/saline lock).	Permits venous flow and prevents clotting of vein and obstruction of flow of IV solution.

■ **Critical decision point: Be sure to calculate rate so as not to infuse IV solution too rapidly or slowly.**

43. Note date and time, gauge size and size of catheter and placement of IV line and dressing.	Documents when IV was inserted and when subsequent changes in IV cannula are required (check agency policy).
44. Dispose of used needles in appropriate sharps container. Discard supplies in contaminated waste bin. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms and protects staff from injury.
45. Observe patient every hour to determine if fluid is infusing correctly. a. Check if correct amount of solution is infused as prescribed by looking at time tape. b. Count flow rate. c. Check patency of IV catheter or needle: briefly compress cannulated vein proximal to site. Observe for slowing or cessation of IV rate. d. Also observe patient during compression of the vein for signs of discomfort. e. Inspect insertion site for absence of infiltration, phlebitis or inflammation (Table 34-19).	Compression results in mechanical obstruction of vein. When IV catheter is patent, compression results in slowing or cessation of flow rate. No change in flow rate may indicate infiltration. Provides continuous evaluation of type and amount of fluid delivered to patient. Hourly inspection prevents accidental fluid overload or inadequate infusion rate and identifies early incidence of vein inflammation or tissue damage.
46. Observe patient every hour to determine response to therapy (i.e. measure vital signs, conduct post-procedure assessments).	IV fluids and additives are given to maintain or restore fluid and electrolyte balance. They can also cause unexpected effects, which can be serious.

RECORDING AND REPORTING

- Documentation:
  - sign the infusion therapy chart; complete the time and date started (see illustration)
  - complete and attach a change of line label to the IV tubing
  - enter the IV fluid type and volume onto the fluid balance chart
  - document the insertion site and date in the patient record/care plan/infusion chart
  - attach an IV time label to the IV bag.
- Record patient's response to IV fluid, amount infused in shift; report integrity and patency of system every hour or according to agency policy.
- Report to oncoming nursing staff: type of fluid, flow rate, status of venepuncture site, amount of fluid remaining in present solution, expected time to hang next IV bag or bottle and any side effects.

HOME CARE CONSIDERATIONS

See Box 34-6.

- Teach caregiver to apply pressure with sterile gauze if catheter falls out and, if patient is on anticoagulant therapy, to tape several pieces of sterile gauze in place for at least 20 minutes or until bleeding stops.
- Teach patient and caregiver to perform bed bath without getting IV tubing wet. For showering, the patient must insert hand and forearm into a plastic bag. Tape bag in place to ensure that IV site is completely covered. IV pumps are not designed to be located in moist bathroom environments during the bathing or showering process. Refer to relevant agency policy for management practices.
- Teach patient and family to monitor fluid balance using household measuring devices.

for the IV catheter. Because the very young, and older adults, have fragile veins, the dorsal surface of the hand should be avoided (see *Working with diversity* boxes). Venepuncture is contraindicated in a site that has signs of infection (red, tender, swollen, warm to the touch, exudate), infiltration or thrombosis and an extremity with a vascular (dialysis) graft/fistula or on the side of a mastectomy. An infected site is not used because of the danger of introducing bacteria from the skin surface into the bloodstream. Where possible, IV cannulas should be placed at the most distal point which allows for future use of proximal sites if the patient needs a venepuncture site change.

Venepuncture

Venepuncture is a technique in which a vein is punctured through the skin by a sharp, rigid stylet, a partially covered plastic catheter (over-the-needle catheter, ONC) or a needle

WORKING WITH DIVERSITY

Focus on older adults

- In older adults, use the smallest gauge intravenous (IV) catheter or needle possible (e.g. 24 to 26 gauge), depending on prescribed IV fluid and rate. This gauge is less traumatic to the vein. This gauge can be used for hourly flow rates of crystalloids of 75–100 mL/h.
- Avoid the back of the older adult's hand or the dominant arm for venepuncture because these sites greatly interfere with the older adult's independence.
- If the older adult has fragile skin and veins, use minimal tourniquet pressure.
- When the older adult has lost subcutaneous tissue, the veins lose stability and will roll away from the needle. To stabilise the vein, apply traction to the skin below the projected insertion site.
- Using an angle of 5–15 degrees on insertion is helpful because the older adult's veins are more superficial.
- In the older person with fragile skin, prevent skin tears by minimising the amount of tape used.

attached to a syringe. The general purposes of venepuncture are to collect a blood specimen, instill a medication, start an IV infusion or inject a radio-opaque or radioactive tracer for special examinations. Although central venous catheters are inserted by doctors, nurses are responsible for their maintenance.

Regulating the infusion flow rate

After the IV cannula is secured and the line is patent, the nurse must regulate the rate of infusion according to the doctor's prescription (Skill 34-4). The nurse calculates the infusion rate to prevent too-slow or too-rapid administration of the IV fluids. The minimal rate used to keep a vein patent is about 10–15 mL/h using a microdrip infusion. An **infusion pump** (e.g. an IVAC) is designed to deliver a measured amount of fluid over a period of time (e.g. millilitres per hour). The pump has a drop sensor and an alarm that will sound if drops are not detected at the appropriate rate. There are also alarms to alert the nurse to increased system pressure that can occur with an **infiltration** (IV fluid seeping into the tissue instead of the vascular space).

A second type of infusion device is an IV-giving set that delivers fluids with the aid of gravity; IV-giving sets deliver fluids based on a determination of millilitres per hour. The rate is controlled by a roller clamp that is adjusted to a specified number of drops per minute. The rate of infusion depends on the height of the IV fluid container, diameter of IV tubing and fluid viscosity. IV-giving sets are less precise than the IV pump in delivering IV fluids.

Close monitoring is required to verify infusion of the correct IV solution and to detect the occurrence of any complications. *Patency* of the IV catheter confirms lack of clots within or at the tip of the cannula, the cannula tip is

WORKING WITH DIVERSITY

Focus on infants and children

- Consider application of 0.5–1g EMLA to site 60–90 minutes prior to insertion (Department of Health and Human Services 2015, The Royal Children's Hospital 2015).
- Ensure another person to hold, comfort and reassure infant or child.
- Vein selection should include: vein runs straight, stands up a little and fills and empties easily (The Royal Children's Hospital 2015).
- The saphenous vein (knee and ankle), cubital fossa and superficial temporal vein should be avoided for peripheral cannulas and reserved for insertion of percutaneous central venous catheters (DHHS 2015, The Royal Children's Hospital 2015).
- Accurate replacement in infants and children needs to be very closely monitored. Such monitoring includes weighing the infant or child prior to the commencement of therapy, 6 hourly if ongoing losses and otherwise daily (Wells et al 2005).
- Nurses need to regularly check serum electrolytes results.
- Timely fluid balance chart documentation and analysis of all input, losses and urine output (dry weight of infant nappies should be written on the nappy; urine output is difference between dry and wet nappy weight: weight on removal of nappy – dry weight of nappy).
- Because children are susceptible to fluid excess and deficit and are generally active (even when ill), care of an intravenous (IV) line becomes imperative. Hockenberry et al (2003) suggest:
  - use a needleless system to administer the solution
  - use an infusion pump to deliver the ordered fluid at the prescribed rate
  - secure the IV catheter firmly and cover it with a transparent dressing
  - secure the IV line so the child cannot accidentally dislodge it
  - consider a commercial protective device to prevent the child from interfering with the insertion site.

Hockenberry MJ et al 2003 Wong's nursing care of infants and children, 7th edn. Mosby, St Louis.

not against the vein wall and the dressing does not impede fluid flow. The nurse can assess patency by checking fluid flow from the drip chamber when the roller clamp is open (to IV rate ordered) by applying pressure distal to the insertion site; if patent, the IV flow should stop on finger pressure and commence when finger pressure is relieved (Wotton et al 2008). The tubing and area around the insertion site should be inspected for: a knot or kink in the tubing, patient not lying or sitting on tubing and position of wrist or elbow does not impede flow rate. The occasional use of an arm

SKILL 34-4

Regulating intravenous flow rate

Delegation considerations

Regulating IV therapy requires the problem-solving and knowledge-application skills of professional nurses. For this procedure, delegation is inappropriate.

Equipment

- IV infusion chart with IV order
- Watch with second-hand
- Paper and pencil
- IV infusion pump (optional)
- Volume-control device (optional)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Observe for patency of IV line and needle or catheter:	For fluid to infuse at proper rate, IV line and cannula must be free of kinks, knots and clots.
a. Compress cannulated vein slightly proximal to the end of the catheter and observe the drip chamber.	Cessation of drops from drip chamber indicates cannula is in vein. If fluid continues to drip, infiltration may be present.
2. Check patient's medical record for correct solution, any additives and time of infusion. Record also shows time over which each litre is to infuse.	Seven rights of drug administration ensure correct fluids are given to correct patient.
3. Check patient's knowledge of how positioning of the IV site affects flow rate.	Fosters patient participation in maintaining most effective position of arm with IV equipment.
4. Verify with patient how venepuncture site feels (e.g. determine whether there is pain or burning).	Pain or burning may be early indication of phlebitis. Includes patient in decision-making.
5. Have paper and pencil to calculate flow rate.	The beginning student is unfamiliar with IV fluid rates and should use mathematical calculations to obtain correct rate.
6. Know calibration (drop factor) in drops per millilitre of infusion set: a. Microdrip: 60 drops/mL b. Macrodrip: 20 drops/mL	Microdrip tubing, also called paediatric tubing, universally delivers 60 drops/mL and is used when small or very precise volumes are to be infused. Macrodrip tubing should be used when large quantities or fast rates are necessary.

■ **Critical decision point: Know the drip rate of the infusion sets your agency uses; calculations must be checked by two nurses.**

STEPS	RATIONALE
7. Determine hourly rate by dividing volume by hours; for example: 1000 mL over 8 hours = 125 mL/h 3 L over 24 hours = 3000/24 = 125 mL/h	Provides even infusion of fluid over prescribed hourly rate.
8. Select following formula to calculate flow rate (drops per minute, DPM) after determining mL/h: $\text{Flow rate (DPM)} = \frac{\text{Vol/h} \times \text{Drop factor}}{\text{Time in minutes*}}$ *Note: a. If time is per hour, the hour will be multiplied by 60 to convert the time into minutes. b. If the time is already in minutes, no further conversion is required.	Once hourly rate has been determined, the formulas for drops per minute (DPM) gives correct flow rate.
Example: Using 20-drop factor infusion set a. 125 mL/h using drop factor of 20 = $\frac{125 \times 20}{1\text{ h} \times 60} = 42$ DPM b. 100 mL over 20 minutes using drop factor of 20 = $\frac{100 \times 20}{20} = 100$ DPM	
Example: Using 60-drop factor infusion set a. 125 mL/h using drop factor of 60 = $\frac{125 \times 60}{1\text{ h} \times 60} = 125$ DPM b. 100 mL over 20 minutes using drop factor of 60 = $\frac{100 \times 60}{20} = 300$ DPM	
9. Place adhesive or fluid indicator tape on IV bag next to volume markings (see illustration).	Time-taping IV bag gives nurse visual cue as to whether fluids are being administered over correct period of time. Time tapes should be used for all IV infusions, including those on therapies infused via electronic infusion devices.

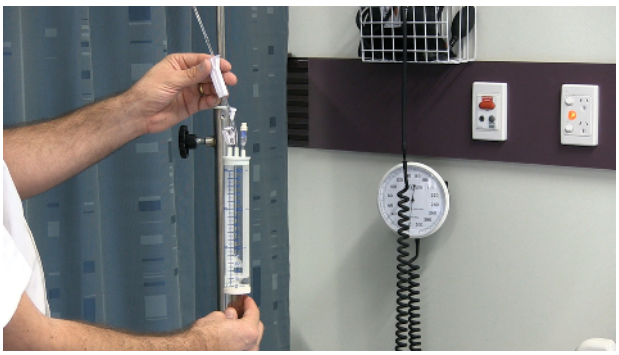
Step 9 Time-taping the IV bag.

■ **Critical decision point: Do not use felt-tip pens or permanent markers on IV bags, because ink could contaminate the solution.**

STEPS	RATIONALE
10. Time flow rate by counting drops in drip chamber for 1 minute by watch, then adjust roller clamp to increase or decrease rate of infusion (see illustration).	Determines whether fluids are being administered too slowly or too fast.

Step 10 Timing of flow rate.

11. Follow the manufacturer's directions for set-up of the infusion (see illustration) using infusion controller or pumps in your organisation: a. Drip regulator must be open while infusion controller or pump is in use.	Infusion pumps move fluid by compressing and milking IV tubing, thus propelling fluid through tubing. Infusion controllers or pumps are not infallible and do not replace frequent, accurate nursing assessments.
b. Monitor infusion rates and IV site for infiltration according to agency policy.	Infusion pumps may continue to infuse IV fluids after an infiltration has begun.
c. Assess patency and integrity of system when alarm sounds.	Alarm indicates that electronic eye has noted imprecise number of drops from drip chamber, an empty solution bag or bottle, kink in tubing, closed drip regulator, infiltrated, clotted catheter and/or air in the tubing.



Step 11 Setting up infusion.

Critical decision point: Special infusion tubing is required for some pumps (check agency policy).

12. Follow this procedure for volume-control device (burette): a. Place burette between IV bag and insertion spike of infusion set (see illustration). b. Place 2 hours' allotment of fluid into burette.	Prevents IV line from running dry if nurse does not return in exactly 60 minutes. In addition, if there is accidental increase in flow rate, patient receives at most only a 2-hour allotment of fluid.

STEPS	RATIONALE
c. Assess system at least hourly; add fluid to burette. Regulate flow rate.	Reduces risk of sudden increase in fluid volume.

Step 12a Examples of positioning of burette.

13. Observe patient for signs of overhydration or dehydration to determine response to therapy and restoration of fluid and electrolyte balance.	Signs and symptoms of dehydration or overhydration warrant changing rate of fluid infused.
14. Evaluate for signs of infiltration: inflammation at site, clot in catheter, kink or knot in infusion tubing.	Prevents decrease or cessation of flow rate.

RECORDING AND REPORTING

- Record name of solution, rate of infusion, DPM and mL/h in nurses' notes every shift or according to agency policy.
- Record IV fluid administered every hour on the fluid balance chart.
- Immediately record in nurses' notes any new IV fluid rates.
- Document use of any infusion-controlling device and number on that device.
- At change of shift or when leaving on break, report rate of infusion and amount remaining in bag to be infused to nurse in charge or next nurse assigned to care for patient.

HOME CARE CONSIDERATIONS

- Ensure that patient is able and willing to operate the infusion device (if applicable) and administer IV therapy, or that there is a reliable caregiver or nursing support personnel at home to provide this IV therapy care.
- Teach patient and primary caregiver to time DPM using watch with second hand.

board may help to keep the joint extended (Figure 34-18) and provides some protection to the IV site and tubing. The incorrect height of the IV bag can also affect flow rates; therefore raising the bag usually increases the rate because of increased gravitational pressure.

A cool, clammy, swollen and in some cases painful insertion site could signal an infiltration, where the cannula has dislodged from the vein and is in the subcutaneous space. When an infiltration occurs, the IV cannula must be discontinued and a new cannula inserted. When caring for a patient with an infusion, the nurse should assess the site and the infusion rate at least every hour.

A sudden increase in IV infusion rate can cause a rapid increase in vascular volume, which can make the patient critically ill or even cause death. Volume-control devices, such as a burette, can prevent sudden excessive increases in the volume of IV solution infused.

Maintaining the system

After insertion of the IV cannula and regulation of the flow rate, the nurse must maintain the system. Agency policy provides guidelines for when peripheral and central IV cannulas must be removed and reinserted, the time for IV line changes and the response to an IV site scoring system, for example, phlebitis

Figure 34-18 IV arm board.

Potter PA, Perry AG 2004 Fundamentals of nursing, 6th edn. Mosby, St Louis.

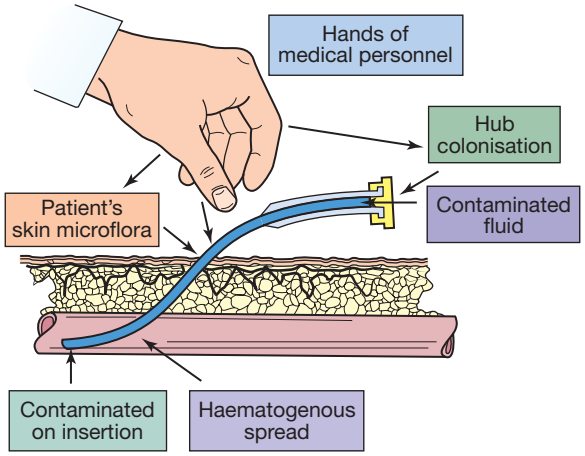


Figure 34-19 Potential sites for contamination of an intravascular device.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

score. Line maintenance is achieved by (1) keeping the system sterile, (2) changing solutions, tubing and for CVC lines site dressings and (3) assisting the patient with self-care activities so as to not disrupt the system.

Figure 34-19 demonstrates the potential sites for contamination of an IV device. Procedures during IV insertion should control the patient's microflora and thus potential contamination during insertion. Other factors are controlled through conscientious use of infection-control principles. This begins with the use of thorough handwashing before and after the nurse handles any component of the IV system.

The maintenance of a closed circuit will ensure the integrity of the IV system. The nurse never disconnects tubing because it becomes tangled or when positioning or moving a patient. If a patient needs more room to manoeuvre, extension tubing can be added to an IV line. A sterile bung must be attached to all available IV ports. The connection of a luer-lock bung to the IV catheter decreases the risk of accidental disconnection and decreases risk of infection by ensuring the maintenance of a closed circuit.

An injection port must be cleaned thoroughly with 70% alcohol or povidone–iodine solution before accessing the system. Needleless intravascular devices and ports are now the equipment of choice for IV medication regimens, to reduce the number of needle-stick injuries. IV administration sets can remain sterile for 72 hours (O'Connell et al 2008). The exception is tubing containing blood, blood products and lipid emulsions, which are more likely to promote bacterial growth and require more-frequent tubing changes. It is easier to change tubing when a new IV bag or bottle is being hung. To prevent entry of bacteria into the bloodstream, sterility must be maintained during tubing and solution changes (Skill 34-5).

SKILL 34-5

Changing intravenous solution and infusion tubing

Delegation considerations

Changing IV solutions and tubing requires the problem-solving and knowledge-application skills of professional nurses. For this procedure, delegation is inappropriate.

Equipment

- Bag of IV solution as ordered by doctor
- Time tape
- Infusion tubing
- J-loop, or short extension tubing (if necessary)
- 'Lever lock cannula' or 'threaded lock cannula'; attaches to the IV-giving set and connects the giving set to the cannula

Normal saline flush:

- Syringes
- Transparent IV dressing
- Tape
- Disposable non-sterile gloves

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems

- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

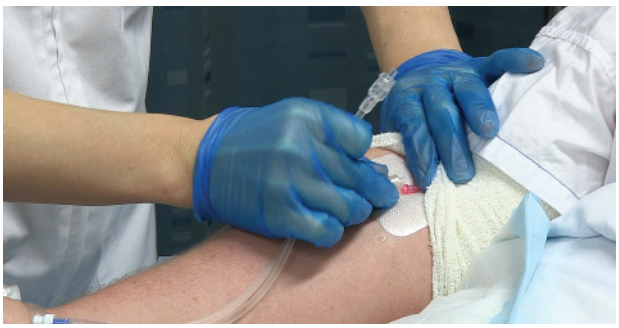
STEPS	RATIONALE
CHANGING IV SOLUTION	
1. Check doctor's orders.	Ensures that correct solution will be used.
2. Determine the compatibility of all IV fluids and additives by consulting appropriate literature or the pharmacy.	Incompatibilities can cause physical, chemical and therapeutic patient changes.
3. Determine patient's understanding of need for continued IV therapy.	Reveals need for patient instruction.
4. Assess patency of current IV access site.	If patency is not verified, a new IV access site may be needed. Notify doctor.
5. Have next solution prepared at least 30 minutes before needed. If prepared in pharmacy, ensure it has been delivered to the patient's hospital unit. Check that solution is correct and properly labelled. Check solution expiry date.	Adequate planning reduces risk of clot formation in vein caused by empty IV bag. Checking prevents medication error.
6. Prepare to change solution when less than 50 mL of fluid remains in bottle or bag.	Prevents air from entering tubing and vein from clotting from lack of flow.
7. Prepare patient and family by explaining the procedure, its purpose and what is expected of patient.	Decreases anxiety and promotes cooperation.
8. Be sure drip chamber is at least half full.	Provides fluid to vein while bag is changed.
9. Perform hand hygiene.	Reduces transmission of microorganisms.
10. Prepare new solution for changing. If using plastic bag, remove protective cover from IV tubing port. If using glass bottle, remove metal cap and metal and rubber disks. Determine sterility of bag. Check seven rights of drug administration. Make sure prescribed additives and an additive label have been added. Check solution for colour, clarity, expiry date.	Permits quick, smooth and organised change from old to new solution. IV solutions are medications and as such should be carefully checked to reduce risk of error.
11. Move roller clamp to stop flow rate.	Prevents solution remaining in drip chamber from emptying while changing solutions.
12. Remove old IV fluid container from IV pole.	Brings work to nurse's eye level.
13. Quickly remove spike from old solution bag or bottle and, without touching tip, insert spike into new bag or bottle.	Reduces risk of solution in drip chamber running dry and maintains sterility.

STEPS	RATIONALE
Critical decision point: If spike is contaminated, a new IV tubing set is required.	
14. Hang new bag or bottle of solution.	Gravity assists with delivery of fluid into drip chamber.
15. Check for air in tubing. a. If bubbles form, they can be removed by closing the roller clamp, stretching the tubing downwards, and tapping the tubing with the finger (the bubbles rise in the fluid to the drip chamber). b. For a larger amount of air, use a pair of forceps below the injection port of the IV tubing, insert a needle and syringe into a port below the air and aspirate the air into the syringe; remove forceps. Swab port with alcohol and allow to dry before inserting needle into port. Reduce air in tubing by priming slowly instead of allowing a wide-open flow.	Reduces risk of air embolus. Use of an air-eliminating filter also reduces this risk.
16. Make sure drip chamber is one-third to half full. If the drip chamber is too full, pinch off tubing below the drip chamber, invert the container, squeeze the drip chamber, hang up the flask/bottle and insert giving set into the flask.	Reduces risk of air entering tubing.
17. Release roller clamp and regulate flow to prescribed rate.	Maintains measures to restore fluid balance and deliver IV fluid as ordered.
18. Observe patient for signs of overhydration or dehydration to determine response to IV fluid therapy.	Provides ongoing evaluation of patient's fluid and electrolyte status.
19. Observe IV system for patency and development of complications (e.g. infiltration or phlebitis).	Provides ongoing evaluation of IV system.
CHANGING IV TUBING	
20. Determine when new infusion set is needed:	
a. Agency policy will indicate frequency of routine change for IV administration sets and heparin flushes.	Tubing change no more often than 72-hour intervals unless blood/blood products or TPN has been infused (Marschall et al 2014).
b. Puncture of infusion tubing.	Punctured tubing results in fluid leakage and bacterial contamination.
c. Contamination of tubing.	Contamination of tubing allows entry of bacteria into patient's bloodstream.
21. Observe for occlusions in existing tubing. Such occlusions can occur after infusion of packed red cells, whole blood, albumin or other blood components.	Whole blood or blood component products can occlude or partially occlude tubing, because viscous solutions adhere to walls of tubing and decrease the size of the lumen.

STEPS	RATIONALE
22. Prepare patient and family by explaining the procedure, its purpose and what is expected of patient.	Decreases anxiety, promotes cooperation and prevents sudden movement of extremity, which could dislodge IV needle or catheter.
23. Perform hand hygiene.	Reduces transmission of microorganisms.
24. Open new infusion set, keeping protective coverings over infusion spike, remove protection from connector at patient end of giving set and attach to 'lever lock cannula' or 'threaded lock cannula'.	Provides nurse with ready access to new infusion set and maintains sterility of infusion set.
25. Put on non-sterile, disposable gloves.	Reduces risk of exposure to HIV, hepatitis and other blood-borne bacteria.
26. If needle or catheter hub is not visible, remove IV dressing. Do not remove tape securing needle or catheter to skin.	Catheter or needle hub must be accessible to provide smooth transition when removing old and inserting new tubing.
27. **For IV infusion:**	
a. Move roller clamp on new IV tubing to 'off' position.	Prevents spillage of solution after bag or bottle is spiked.
b. Slow rate of infusion by regulating drip rate on old tubing. Be sure rate is at keep vein open (KVO) rate, usually around 20 mL/h.	Prevents complete infusion of solution that remains in tubing, which can increase risk of occlusion of IV catheter or needle.
c. With old tubing in place, compress drip chamber and fill chamber.	Provides surplus of fluid in drip chamber so there is enough fluid to maintain IV patency while changing tubing.
d. Remove old tubing from solution and hang or tape drip chamber on IV pole 90 cm above IV site.	Allows fluid to continue to flow through IV catheter while nurse is preparing new tubing.
e. Place insertion spike of new tubing into old solution bag opening, and hang solution bag on IV pole.	Permits flow of fluid from solution into new infusion tubing.
f. Compress and release drip chamber on new tubing; slowly fill drip chamber one-third to half full.	Allows drip chamber to fill and promotes rapid, smooth flow of solution through new tubing.
g. Slowly open roller clamp, flush tubing with solution. Usually no need to remove protective cap from 'lever lock cannula' or 'threaded lock cannula'.	Removes air from tubing and replaces it with fluid.
h. Turn roller clamp on old tubing to 'off' position.	Prevents spillage of fluid as tubing is removed from needle or catheter hub.

STEPS	RATIONALE
28. For heparin lock:	
a. Swab 'lever lock cannula' or 'threaded lock cannula' (bung/injection cap) with alcohol.	Removes air to prevent introduction into the vein.
b. Insert syringe with 1–3 mL saline and inject through the bung into the loop or short extension tubing.	Prevents accidental displacement of catheter or needle.
29. Stabilise hub of catheter or needle and apply pressure over vein just above insertion site. Gently pull out old tubing (see illustration). Maintain stability of hub and quickly insert 'lever lock cannula' or 'threaded lock cannula' on the IV-giving set into the 'Interlink injection site' (bung) on the cannula (see illustrations). Re-tape IV tubing along arm.	Prevents clot formation in catheter or needle and backflow of blood.
30. Open roller clamp on new tubing. Allow solution to run rapidly for 30–60 seconds.	Permits IV solution to enter catheter to prevent catheter occlusion.
31. Regulate IV drip according to doctor's orders and monitor rate hourly (see illustration).	Maintains infusion flow at prescribed rate.
32. If necessary, apply new dressing.	Reduces risk of bacterial infection from skin.
33. Discard old tubing in contaminated waste bin.	
34. Remove and dispose of gloves. Wash hands.	Reduces accidental transmission of microorganisms.
35. Evaluate flow rate and observe connection site for leakage.	Maintains prescribed rate of flow of IV fluid and determines if fit is secure.

A.



B.

Step 29A–C Removal of old tubing and insertion of new cannula.

STEPS	RATIONALE

Step 31 Monitoring IV drip rate.

RECORDING AND REPORTING

- Record changing of tubing and solution on patient's record. A special parenteral therapy flow sheet may be used.
- Place a piece of tape or preprinted label with the date and time of tubing change and attach to tubing below the level of drip chamber.

HOME CARE CONSIDERATIONS

- Emphasise to patient and family the importance of changing solutions when IV tubing still contains fluid.

The dressings over IV sites are applied to reduce the entrance of bacteria into the insertion site. Dressings are usually transparent, but for CVC cannula (particularly where the jugular vein is used) these may be gauze. Transparent dressings reliably secure the IV device, allow continuous visual inspection of the IV site, are less easily soiled or moistened and require less-frequent changes than standard gauze (O'Connell et al 2008). Agency policy may require IV dressings to be routinely changed within a certain timeframe (e.g. 48–72 hours) (Skill 34-6).

To prevent the accidental disruption of an IV system, the nurse may need to help the patient with hygiene, comfort measures, meals and moving. Because a patient with an infusion in the arm finds it difficult to meet hygiene needs, the nurse should help with bathing and changing gowns. It helps to use a gown specifically made with press-studs along the top sleeve seam to facilitate changing the gown without disturbing the venepuncture site. Normal gowns are changed by following these seven steps, for maximum arm mobility and speed:

1. Remove the sleeve of the gown from the arm without the infusion onto the tubing connected to the arm with the infusion.
2. Remove the IV bag from its stand and pass it and the tubing through the sleeve ensuring the IV bag is above the patient's arm. If this involves removing the tubing from an IV pump, use the roller clamp to temporary slow/stop the infusion to prevent the accidental infusion of a large volume of solution or medication.
3. Place the clean gown sleeve over the arm with the infusion over the container as if it were an extension of the client's arm, from the inside of the gown to the sleeve cuff.
4. Place the IV bag and tubing through the sleeve (of the arm with IV cannula in situ) of the clean gown and hang it on its stand. (If the IV is connected to a pump, reassemble, recheck orders, reprogram, open the roller clamp and turn the pump on.)
5. Place the IV arm through the gown sleeve.
6. Place the non-IV arm through the gown sleeve.
7. Ensure that rate of flow of the infusion is correct before leaving the bedside.

Where a patient with an IV in situ is allowed to mobilise, the IV solution/pump will need to be transferred to an IV pole with

SKILL 34-6

Changing a peripheral intravenous dressing

Delegation considerations

Changing a peripheral IV dressing requires the problem-solving and knowledge-application skills of professional nurses. For this procedure, delegation is inappropriate.

Equipment

- Povidone–iodine swab/stick according to agency policy
- Alcohol swab/stick
- Adhesive remover (if needed)
- Strips of non-allergenic tape
- Disposable gloves

For gauze dressing:

- Sterile 5 cm × 5 cm gauze pad

OR

For transparent dressing (preferred):

- Sterile transparent dressing

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine when dressing was last changed. Many institutions require nurse to write date and time on dressing and date the device was first placed.	Provides information regarding length of time present dressing has been in place. Transparent occlusive dressing usually only changed when integrity has been breached; central venous catheter (CVC) changed weekly (Rosenthal 2003).
2. Observe present dressing for moisture and intactness.	Moisture is a medium for bacterial growth and renders dressing contaminated.
3. Observe IV system for proper functioning or complications: kinks in infusion tubing or IV catheter. Palpate the catheter site through the intact dressing for inflammation or after subjective complaints of pain or burning.	Unexplained decrease in flow rate requires the nurse to investigate placement and patency of the IV catheter. Pain can be associated with both phlebitis and infiltration.
4. Inspect exposed catheter site for swelling or infiltration.	Indicates fluid infusing into surrounding tissues. Will require removal of IV catheter.
5. Assess patient's understanding of need for continued IV infusion.	Determines need for patient instruction.
6. Explain procedure and purpose to patient and family. Explain that affected extremity must be held still and how long procedure will take.	Decreases anxiety, promotes cooperation and gives patient timeframe around which personal activities can be planned.
7. Perform hand hygiene. Put on disposable gloves.	Reduces transmission of microorganisms.

STEPS	RATIONALE
8. Remove tape, gauze and/or transparent dressing from old dressing one layer at a time, leaving tape that secures IV needle or catheter in place. Be cautious if catheter tubing becomes tangled between two layers of dressing. When removing transparent dressing, hold catheter hub and tubing with non-dominant hand.	Prevents accidental displacement of catheter or needle.
9. Observe insertion site for signs and/or symptoms of infection, namely redness, swelling and exudate.	
10. If infiltration, phlebitis or clot occurs, or if ordered by doctor, discontinue infusion.	
11. If IV is infusing properly, gently remove any tape securing needle or catheter. Stabilise needle or catheter with one hand. Use adhesive remover to clean skin and remove adhesive residue, if needed.	Exposes venepuncture site. Stabilisation prevents accidental displacement of catheter or needle. Adhesive residue decreases ability of new tape to adhere tightly to skin.
12. Keep one finger over catheter at all times until tape or dressing is replaced.	Prevents decannulation from vein.
13. Using circular motion, clean peripheral IV insertion site with alcohol, then povidone–iodine solution (check that patient is not allergic to iodine) starting at insertion site and working outwards, creating concentric circles (see illustration). Allow each solution to dry for 2 minutes.	Circular motion prevents cross-contamination from skin bacteria near venepuncture site.

■ **Critical decision point: Do not tape over connection of access tubing or port to IV catheter.**

Step 13 Cleaning insertion site.

14. Apply new transparent or gauze dressing. (Tape the catheter in place using a transparent (clear) dressing.)	Ensures protection of IV site and reduces chance of infection.
15. Remove and discard gloves and used materials into contaminated waste bin.	Reduces transmission of microorganisms.
16. Anchor IV tubing with additional pieces of tape. When using polyurethane dressing, minimise the tape placed over dressing.	Prevents accidental displacement of IV needle or catheter or separation of IV tubing from needle adapter.

STEPS	RATIONALE
17. Place date and time of dressing change and size and gauge of catheter directly on dressing.	Documents dressing change.
18. Discard equipment and wash hands.	Reduces transmission of microorganisms.
19. Observe functioning and patency of IV system in response to changing dressing.	Validates that IV is patent and functioning correctly.
20. Monitor patient's body temperature.	Elevated temperature indicates an infection that may be associated with bacterial contamination of the venepuncture site.

RECORDING AND REPORTING

- Record appearance of IV site, type of dressing and status of IV fluid infusion.
- A special parenteral fluid flow sheet may be used for recording.

wheels. The nurse helps the patient out of bed and places the pole next to the involved arm. The patient is instructed to hold on to the pole with the involved hand and to push it while walking. The nurse should assess the equipment to ensure the appropriateness of the height of the IV bag, no tension on the tubing and that correct flow rate continues. The patient should be instructed to report blood in the tubing, a stoppage in the flow or increased discomfort.

Complications of intravenous therapy

Infiltration

An infiltration (*tissuing* or *extravasation*) occurs when IV fluids enter the subcutaneous space around the venepuncture site. This manifests as swelling (from increased tissue fluid) and pallor (caused by decreased circulation) around the venepuncture site. In an infiltration, IV flow may continue or may stop; pain may also be present (from pressure of oedema) and increases proportionately as the infiltration continues.

When infiltration occurs, the infusion must be discontinued and the extremity raised to promote venous drainage. Where the IV fluid or its additives are potentially necrotic, procedures for managing extravasations of necrotoxic solutions (e.g. IV antibiotics, chemotherapeutic agents) need to be followed. If IV therapy is still necessary, another cannula needs to be inserted into another extremity.

Phlebitis is an inflammation of the vein. Selected risk factors for phlebitis include the type of catheter material, chemical irritation from IV additives and drugs (e.g. IV antibiotics) and the anatomical position of the catheter. Signs and symptoms include pain, increased skin temperature over the vein and, in some instances, redness travelling along the path of the vein (see Table 34-24). When phlebitis develops, the IV therapy must be discontinued and a new cannula inserted in another vein. Warm, moist heat on the site of phlebitis can offer some relief to the patient (see Chapter 30). Phlebitis can be dangerous because blood clots (thrombophlebitis) can occur and in some cases may result in emboli. Phlebitis is prevented by the routine removal and rotation of IV sites. Most agencies recommend replacing peripheral venous catheters and rotating sites every 48–72 hours (Joanna Briggs Institute 2003).

TABLE 34-24 Phlebitis scale

Score	Clinical signs	Interpretation and response
0	No clinical symptoms	No action required
1	Erythema at access site with or without pain Oedema may or may not be present No streak formation No palpable venous cord	Possible signs of phlebitis Continue to assess
2	Erythema with or without pain Oedema may or may not be present Streak formation No palpable venous cord	Early signs of phlebitis Re-site cannula
3	Erythema with or without pain Oedema may or may not be present Streak formation Palpable venouscord	Signs of phlebitis Re-site cannula Consider treatment

Alexander M, Corrigan A et al 2008 Infusion nursing: an evidence based approach, 3rd edn. Saunders Elsevier, Philadelphia; Smith SF et al 2008 Clinical nursing skills: basic to advanced skills, 7th edn. Prentice Hall, Upper Saddle River, NJ.

Fluid volume excess (FVE)

Fluid volume excess (FVE) occurs when a patient has received a too-rapid administration of IV solutions. The assessment findings include shortness of breath, lung crepitations and tachycardia. The nurse should slow the rate of infusion, notify the doctor,

raise the head of the bed and lower the foot of the bed (if not contraindicated by the patient's underlying condition) and monitor vital signs.

Bleeding

Bleeding can occur around the venepuncture site during the infusion or through the infusion cannula or tubing if these become inadvertently disconnected. Bleeding is common in patients who have received anticoagulant therapy or who have a bleeding disorder (e.g. leukaemia or thrombocytopenia). If bleeding occurs around the venepuncture site and the catheter is in the vein, a pressure dressing may be put over the site to control the bleeding. Bleeding from a vein is usually a slow, continuous seepage and is not serious.

Discontinuing intravenous infusions

Discontinuing an infusion is necessary after the prescribed amount of fluid has been infused, when an infiltration occurs, if phlebitis is present or if the infusion cannula develops a clot at its tip. The nurse discontinuing an infusion first puts on disposable gloves, moves the roller clamp to the off/closed position and then removes the tape and dressing. The nurse places a sterile 5 cm × 5 cm gauze pad over the venepuncture site and, using the other hand, withdraws the cannula by pulling straight back away from the puncture site (Figure 34-20). If necessary, an alcohol swab can be used to remove dried blood or other drainage from around the site. The nurse elevates the extremity and applies pressure to the site for 1–2 minutes to control bleeding and prevent haematoma formation. Patients who have received heparin require longer pressure because of the action of heparin on blood-clotting mechanisms. The nurse records the amount of fluid infused and the time of the discontinuation.

Figure 34-20 **IV catheter is removed slowly, keeping catheter parallel to vein.**

• CRITICAL REFLECTION POINT

You are caring for Betty, a 59-year-old woman, following a total knee replacement. She weighed 74 kg on admission. The doctor ordered Keflin (cephalothin) 1 g in 50 mL Normal saline to run over 30 minutes IV piggyback three times daily. Betty has a continuous infusion of Hartmann's at 75 mL/h in the left forearm.

Activity

1. **Calculate:**
   a) **drops per minute of the Keflin infusion using microtubing (60 drops/mL)**
   b) **drops per minute for the Hartmann's infusing using macrotubing (20 drops/mL).**
2. **Discuss whether the Hartmann's is an appropriate IV solution and 75 mL/h is an appropriate amount for this postoperative patient who is also ordered nil by mouth. Hint: refer to formulas for daily maintenance volumes in Table 34-16.**

Transfusion (colloids)

Transfusion is the IV administration of whole blood or a component such as plasma, packed red blood cells (RBCs) or platelets (see Skill 34-7). The objectives for blood transfusions are to:

1. increase circulating blood volume after surgery, trauma or haemorrhage
2. increase the number of RBCs and to maintain haemoglobin levels in patients with severe anaemia
3. provide selected cellular components as replacement therapy (e.g. clotting factors, platelets, albumin).

Blood groups and types

The most important grouping for transfusion purposes is the ABO system, which includes A, B, O and AB blood types. The determination of blood groups is based on the presence or absence of A and B red-cell antigens. Individuals with A antigens, B antigens, or no antigens belong to groups A, B and O, respectively. The person with A and B antigens has AB blood. People with type A blood naturally produce anti-B antibodies in their plasma. Similarly, type B people naturally produce anti-A antibodies. A type O person has neither type A nor type B antigens, and thus is considered a universal blood donor. A type AB person produces neither antibody, which is why such a person can be a universal recipient and receive any type of blood.

If blood that is mismatched with the patient's blood is transfused, a *transfusion reaction* occurs. The transfusion reaction is an antigen–antibody reaction, and can range from a mild response to severe anaphylactic shock which can be life-threatening.

Another consideration when matching for blood transfusions is the Rhesus (Rh) factor, which is an antigenic substance in the erythrocytes of most people. A person with the factor is Rh positive, and a person without it is Rh negative.

Autologous transfusion

Autologous transfusion is the collection and administration of a patient's own blood. The blood for an autologous

SKILL 34-7

Care of the patient requiring a blood transfusion

Delegation and other considerations

Management of a blood transfusion requires the problem-solving and knowledge-application skills of RNs. For this procedure, delegation is inappropriate.

Equipment

- Special patient gown with press-studs at shoulder seams (makes removal with IV tubing easier)
- Blood transfusion chart (written order for blood, together with patient identification required to retrieve required blood product from facility blood bank)
- 0.9% sodium chloride (Normal saline) for priming line
- Cross-checked blood product

Equipment for the initiation of IV fluid infusion if not in situ

For IV fluid infusion:

- Blood transfusion giving set with a 170–200 micron filter
- Alcohol and povidone–iodine cleaning swabs or sticks (Rosenthal 2003)
- EMLA cream
- Towel (to place under patient's hand or arm)
- IV pole, rolling or ceiling-mounted
- Disposable gloves
- Tourniquet (can be a source of contamination; use a single-use product)
- Arm board, if needed (used to maintain wrist or elbow joint position)
- Non-allergenic tape
- Needle disposal container (sharps container)
- Transparent dressing (e.g. Opsite, Tegaderm)
- 1–3 mL of Normal saline
- 5 mL syringes with Interlink needle

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Check medical notes for reason for transfusion for this patient and patient's past and present medical history.	Knowledge of reasons for the transfusion assists in understanding reason for choice of transfused blood product, monitoring required throughout and post-transfusion and reason for the administration of any medications post-transfusion – e.g. administration of IV Frusemide.
ASSESSMENT	
2. Check patient's vital signs before commencing the transfusion.	Establishes a baseline prior to initiating the blood transfusion so changes in the patient's condition during the transfusion are monitored. A temperature > 37.8°C should be reported to the doctor before proceeding with the transfusion.
3. Check informed consent has been documented on a generic or transfusion-specific consent form or in the medical records.	Documentation of informed consent should provide evidence that patient informed of reason for the transfusion, risks and benefits of the transfusion as well as consequences of not receiving the transfusion.
4. Check doctor's written orders for blood transfusion on transfusion-specific form. Should include patient identification – family and given name, DOB, patient ID; date, timing and urgency of transfusion, blood product, number of units, duration of transfusion; if blood warmer, medications required prior to or during	Ensures that correct blood product and type will be used.

STEPS	RATIONALE
transfusion; known patient allergies and history of adverse drug or previous transfusion reactions and legibly written doctor's full name, contact number.	The doctor ordering the transfusion must be clearly identifiable to minimise delays if the orders require clarification.
5. Blood product must be handed to the RN responsible for commencing the transfusion. Two RNs must then confirm correct blood product, blood type and expiry date, rate of fluid administration and purpose of infusion with patient ID. In addition, RNs must follow the seven rights for administration of medications.	The blood product should never be left anywhere unattended.

■ **Critical decision point: Do not prime, add or infuse medications or solutions through the same tubing with blood components, except 0.9% sodium chloride injection. Dextrose solutions cause red blood cells to clump, swell and haemolyse. Solutions containing calcium (e.g. Haemaccel and lactated Ringer's) counteract citrated anticoagulants in the blood product (Australian Red Cross Blood Service 2015).**

6. Determine patient's understanding of need for blood transfusion.	Reveals need for patient instruction.
7. Assess patient's history of allergies.	May reveal information that affects blood transfusions.
8. Assess patency of current IV access site. Ensure IV giving set and cannula is primed with Normal saline or blood component.	If patency is not verified, notify medical officer for new IV access site.
PREPARATION OF THE PATIENT	
9. Prepare patient and family by explaining the procedure, its purpose and what is expected of patient. Provide patient information brochure on blood transfusion.	Decreases anxiety and promotes cooperation. Patients should be able to articulate what symptoms they need to immediately report to staff during and after the transfusion.
10. Perform hand hygiene.	Reduces transmission of microorganisms.
11. Identify the patient and blood product according to policy. The blood transfusion must be initiated within 30 minutes of arrival; if not, it must be returned to the facility blood bank for storage.	Minimises the risk of bacterial contamination.
12. Inspect and ensure the blood product bag is not compromised (e.g. leaking, spiked, vented, discolouration, turbidity or clots) prior to use.	Do not proceed if indication of break in integrity of the bag or damage to the blood product.
13. Two RNs check the patient identification, blood order sheet and information on the blood product to ensure they are all the same. Checks are: patient's name and ID number, original prescription for blood, group and type of blood, expiry date of the blood unit/ product, and blood product ID number. If there are any discrepancies the blood is not used.	Minimum that should be checked to minimise transfusion errors. If there is no appropriately completed identification wrist band in situ there is no transfusion.

■ **Critical point: You have 30 minutes from retrieval of blood product from blood and initiation of transfusion. If the 30 minutes is exceeded, return the unit to the blood bank fridge. Never use the ward/medication refrigerator for blood storage.**

STEPS	RATIONALE
INITIATING THE BLOOD TRANSFUSION	
14. Gently invert the bag several times.	To ensure cells and plasma are mixed.
15. Wearing gloves, attach the unit of blood to the giving set. Remove protector cap from tubing insertion spike (keeping spike sterile), and insert spike into opening of blood unit.	Prevents contamination of solution from contaminated insertion spike.
16. Prime infusion tubing by filling with blood. Compress drip chamber/filter and release, allowing it to fill one-third to half full.	Creates suction effects; blood enters drip chamber to prevent air from entering tubing.
17. Slowly release roller clamp to allow blood to travel from drip chamber through tubing to cannula. If large volumes of blood are to be transfused rapidly, a blood-warming device is ordered by doctor to prevent hypothermia.	Slow fill of tubing decreases turbulence and chance of bubble formation. Removes air from tubing and permits tubing to fill with blood. Closing the clamp prevents accidental loss of fluid.
18. Begin the transfusion slowly (5 mL/min) for first 15 minutes. The nurse remains with the patient for the first 15 minutes to observe for potential reactions. If no signs of a transfusion reaction, increase to ordered rate for transfusion. Normally blood is transfused over 90 minutes to 4 hours.	Beginning the transfusion slowly reduces the amount of blood the system will react to, and will reduce the severity of the reaction if one occurs.
19. Monitor the patient; take vital signs at 15-minute intervals for the first hour of the transfusion and then every half-hour for the remainder of the transfusion, or according to policy. Observe for signs of febrile reactions: fever, chills, headache and malaise.	Where continuous visual observation is not possible, nurses need to attend the patient for the first 30 minutes of the transfusion as two-thirds of all possible reactions occur within the first 30 minutes after transfusion commencement.
20. Complete the transfusion when the blood unit is empty (or if 4 hours has elapsed since unit of blood removed from the blood fridge). a. Flush the line with Normal saline. b. Wearing gloves, disconnect the blood transfusion giving set from the IV cannula. c. Consult doctor's orders for continuation of IV therapy. d. Dispose of blood unit according to policy. e. Continue to monitor patient's vital signs hourly for 4 hours and then 4th-hourly for 24 hours or according to the patient's clinical status or heath unit policy.	Continue to observe and monitor patient post transfusion, for delayed reaction could still occur. Post transfusion re-check Hb and Hct, bleeding time, serial platelet count according to patient's diagnoses and condition or institution's policy. Discard blood bag and BT set and sharps according to institution's guidelines.

DOCUMENTION AND REPORTING

- Documentation: Many healthcare facilities have specific blood transfusion forms. A synopsis of commencement and completion of transfused components and patient's response needs to be documented in nurse's shift report.

HOME CARE CONSIDERATIONS

- Blood transfusions are not usually a home nursing procedure.

DOCUMENTION AND REPORTING *continued*

The following signs indicate need for immediate nursing intervention:

- Allergic reaction: flushing, urticaria, wheezing, pruritus.
- Haemolytic reaction: restlessness, anxiety, flushing, chest/lumbar pain, tachypnoea, tachycardia, chills and fever.
- Circulatory overload: dyspnoea, hypertension, chest pain, rales and rhonchi, anxiety, diaphoresis, haemoptysis.

The transfusion is stopped if any of these reactions become apparent; signs and symptoms are reported to medical officer immediately; IV access maintained.

Complete the institution's transfusion reaction form for adverse reaction. Documentation of a transfusion reaction in nursing shift report should include: Time and date of transfusion reaction; type and amount of blood infused; clinical signs and symptoms of reaction in order of occurrence; specimens sent to lab; ward urine test results; date and time doctor notified and orders; interventions implemented and patient response.

transfusion can be obtained by preoperative donation up to 5 weeks before the planned surgery (e.g. heart, orthopaedic, plastic, gynaecological). The blood will be tested for HIV and HBV. Another way to collect blood for an autologous transfusion is by perioperative blood salvage (e.g. during vascular and orthopaedic surgery, organ transplant surgery and traumatic injuries) and from mediastinal and chest-tube drainage. The salvaged blood is then reinfused during surgery. Autologous transfusions are safer for the patient because they decrease the risk of complications such as mismatched blood and exposure to blood-borne infectious agents.

Management of blood transfusions (see Skill 34-7)

The medical team is responsible for the decision to transfuse. Such decisions must be based on a comprehensive clinical assessment and be clearly documented in the patient's clinical notes (Australian Red Cross Blood Service 2015). The RN is responsible for assessment before, during and after the transfusion and for regulation of the transfusion. Assessment is critical because of the risk of allergic reactions.

The nurse should assess the venepuncture site for signs of infection, patency and infiltration. An 18-gauge cannula is recommended because blood is more viscous than IV crystalloids. IV administration for blood administration has an inline filter. The tubing should be primed with 0.9% Normal saline prior to commencing the transfusion.

Pre-transfusion assessment also includes information on the patient's knowledge of the reason for the blood transfusion and any history of previous transfusion or transfusion reactions. A prior transfusion reaction does not increase the risk of a reaction with a subsequent transfusion. Before commencing the transfusion, the nurse explains the procedure and instructs the patient to report any side effects (e.g. chills, dizziness, fever) once the transfusion begins. The nurse also checks that the patient has signed an informed consent.

Because of the danger of transfusion reactions, it is important to use specific precautions in administering blood or blood products. The nurse must obtain the patient's baseline vital signs before the transfusion begins. These data allow the nurse to determine when changes in vital signs occur, which can indicate that a transfusion reaction is developing. To ensure that the right patient receives the correct type of blood or blood product, a thorough procedure is used to check the identity of the blood products and the patient and the compatibility of the blood and the patient. The nurse, although not involved in the blood labelling process, is responsible for determining that the blood delivered to the patient corresponds to the patient's blood type

listed in the medical record. Two RNs or one RN and an enrolled nurse (depending on agency policy) must together check the label on the blood product for the type of blood product, expiry date on the bag, the patient's identification number, blood group and complete name. This is then checked against the patient's ID band and chart. If even a minor discrepancy exists, the blood should not be given and the blood bank should be notified immediately.

Initiation of a transfusion begins slowly, to allow for the early detection of a transfusion reaction (Australian Red Cross Blood Service 2015). The RN maintains the infusion rate, monitors for side effects, assesses vital signs and promptly records all findings. The nurse usually stays with the patient during the first 15 minutes, the time when a reaction is most likely to occur (timing of reactions depends on rate of the transfusion flow; the nurse may need to stay with the patient longer if the transfusion rate is slow). The nurse will continue to monitor the patient and obtain vital signs periodically during the transfusion as directed by agency policy. If a transfusion reaction is anticipated or suspected, the nurse will obtain vital signs more frequently (Table 34-25).

The rate of transfusion is usually specified in the doctor's prescription. Ideally, a unit of whole blood or packed RBCs is transfused in 2 hours. This time can be lengthened to 4 hours if the patient is at risk of FVE. Beyond 4 hours there is a risk of the blood becoming contaminated.

When patients have a severe blood loss such as with haemorrhage, they may receive rapid transfusions through a central venous catheter. In this case, a blood-warming device is often necessary, because the tip of the central venous catheter

TABLE 34-25 Adverse transfusion reactions/complications

Reaction	Usual cause	Clinical features	Management	Prevention
Allergic reaction	Hypersensitivity to allergens or plasma proteins in the transfused unit; rarely due to donor medication Occurs in 1–3% of plasma infusions	*Mild allergic reaction:* localised urticaria, pruritus and rash *Severe allergic reaction:* flushing, wheezing, hypotension or angio-oedema	Stop transfusion immediately; follow other steps for managing suspected transfusion reactions (see below) *Mild reaction:* administer antihistamine. Transfusion may be restarted slowly and completed within 4 hours when reaction abates *Severe reaction:* medical emergency – administer adrenaline and/or corticosteroids. Consult haematologist before administering additional blood	Consider premedication and/or washed cells if the patient has recurrent allergic reactions to transfusion
Anaphylactoid reactions or anaphylaxis	Mainly reported in IgA-deficient patients who have anti-IgA antibodies of the IgE class Also due to IgE-mediated allergy to other plasma proteins Rarely due to donor medication Occurs in 1:20,000 to 1:50,000 of transfusions	May be a fatal reaction Sudden onset of cough, bronchospasm, laryngospasm, respiratory distress, vascular instability, nausea, abdominal cramps, vomiting, diarrhoea, shock and loss of consciousness	Stop transfusion immediately; remove the IV line from the cannula; follow other steps for managing suspected transfusion reactions (see below) Maintain airway and intravenous line Administer adrenaline and corticosteroids Treat hypotension, if present Notify blood service	Where appropriate, use autologous, washed components from IgA-deficient donors if future transfusion required Check the recipient's pretransfusion sample for IgA deficiency and presence of anti-IgA antibodies
Circulatory overload	Transfusion-related circulatory overload (TACO) due to rapid or massive transfusion of blood in patients with diminished cardiac reserve or chronic anaemia Occurs in up to 1% of patients receiving transfusions	Dyspnoea, orthopnoea, cyanosis, tachycardia, hypertension, and pulmonary oedema Chest X-ray: septal lines, cephalisation and enlarged vascular pedicle (> 65 mm) Distended neck veins, S3 murmur on cardiac examination and peripheral oedema	Stop transfusion immediately Place the patient in an upright position and treat symptoms with oxygen and diuretics therapy	In susceptible patients, transfusion should be administered slowly and in the most concentrated form possible

continued

TABLE 34-25 ***continued***

Reaction	Usual cause	Clinical features	Management	Prevention
Iron overload	Long-term complication of repeated red cell transfusions with iron deposition in organs Each transfusion contributes about 250 mg of iron	Symptoms and signs of organ damage or failure, especially liver, cardiac and arthropathy Incidence increases with multiple transfusions, especially more than 20 units	Prescribe iron chelating agents for treatment and for prevention, where anticipated	*Investigations:* request serum ferritin and transferrin saturation; organ imaging and liver biopsy
Metabolic complications including hypothermia	Rapid infusion of large volumes of cold blood can depress the body temperature and result in metabolic complications, such as acidosis, hyperkalaemia, hypocalcaemia	Depends on clinical situation, but transfused patients have a great risk of cardiac arrhythmia or cardiac arrest	Slow rate of infusion Use blood warmers where appropriate Use fresh blood components	*Investigations:* perform electrolyte analysis and cardiac monitoring
Non-haemolytic transfusion reaction	Often due to alloimmunisation to donor HLA or other antigens Cytokine accumulation during storage may also precipitate this reaction Occurs in 0.1–1% of transfusions with universal leucocyte depletion; patients previously alloimmunised by transfusion or pregnancy	Unexpected temperature rise of ≥ 1°C from baseline during or shortly after transfusion, in the absence of other pyrexic stimulus Chills, rigors and headache may accompany this reaction	Stop transfusion immediately; follow other steps for managing suspected transfusion reactions (see below)	Clinically assess transfused patients for fever, chills, rigors and headache Exclude other causes, as fever alone may be the first manifestation of a life-threatening reaction Rule out haemolysis, septic reaction and TRALI (see below)
Post-transfusion purpura	Alloimmunisation to platelet-specific antigens, most often HPA-1a While the immune specificity may be to a platelet-specific antigen, both autologous and allogeneic platelets are destroyed	Rare reaction Patients develop dramatic, sudden and self-limiting thrombocytopenia, typically 7–10 days after a blood transfusion	IVIg at 1 g/kg as a total dose, repeat as necessary Request to blood service or jurisdictional approver to access IVIg	*Investigation:* demonstrate antiplatelet antibody
Transfusion-acquired graft-versus-host disease	Viable T lymphocytes in the transfused component engraft in the recipient and react against tissue antigens in the recipient Increased risk in severely immunocompromised recipients	Rare but fatal reaction Transfused patients present with fever, rash, liver function abnormalities and pancytopenia	Provide supportive care Prevention is by gamma irradiation	*Investigations:* request skin biopsy; demonstrate donor leucocyte engraftment
Transfusion-related acute lung injury (TRALI)	Specific pathogenesis not completely understood: due to either HLA or HNA antibodies found in the donor's blood directed against the recipient's leucocyte antigen Variable incidence: occurs in 1:5000 to 1:190,000	Reaction activates neutrophils in the pulmonary microcirculation, releasing oxidases and proteases that cause increased capillary permeability Onset of fever, chills, dyspnoea, tachypnoea, tachycardia, hypotension, hypoxia and non-cardiogenic pulmonary oedema during or within 6 hours of transfusion	Stop transfusion immediately; follow other steps for managing suspected transfusion reactions (see below) Provide cardiovascular and airway support Administer supplemental oxygen and employ ventilation as necessary Notify blood service so they can quarantine and test related components from the same donor	*Investigations:* test the donor or recipient serum for HLA or granulocyte antibody; chest X-ray will show bilateral interstitial infiltrates Record the episode and actions/outcomes in the patient's notes for future reference

continued

TABLE 34-25 ***continued***

Reaction	Usual cause	Clinical features	Management	Prevention
Haemolysis				
Acute intravascular haemolysis	Immunological destruction of transfused red cells, due to incompatibility of antigen on transfused cells with antibody in the recipient circulation Most common cause is transfusion of ABO-incompatible blood (incidence: 1:12,000 to 1:77,000 of transfusions) Rare causes: damage to transfused red cells; may be *physical* (thermal injury due to freezing or overheating) or *chemical* (effects of drugs co-administered with transfusion; or bacterial toxins)	Commences with an increase in temperature and pulse rate Symptoms may include chills, rigors, dyspnoea, chest and/or flank pain, discomfort at infusion site, abnormal bleeding or shock (hypotension) Transfused patients develop oliguria, haemoglobinuria and haemoglobinaemia DIC may be the first signs in an anaesthetised patient	Stop transfusion immediately; remove IV line from cannula; follow other steps for managing suspected transfusion reactions (see below) Seek urgent medical assistance Do not administer additional blood packs until cleared by haematologist or blood service	*Investigations:* Clinically assess patients for common features of haemolysis occurring within 4 hours of transfusion Check clerical records, such as ABO typing of patient and unit Perform DAT and IAT, renal function, and tests for haemolysis (urinary haemosiderin, serum haptoglobulin) Meticulously verify and document patient identification from sample collection to component infusion Ensure correct storage to avoid thermal injury to red cells
Delayed (usually extravascular) haemolysis	Previously red-cell-alloimmunised patients in whom antigens on transfused red cells provoke anamnestic production of red cell antibody Occurs in 1:2500 to 1:11,000 of transfusions	Reaction usually develops in 2–14 days after transfusion Patients may present with unexplained fever, positive DAT, jaundice and unexplained decrease in haemoglobin	Most delayed haemolytic reactions have a benign course and require no treatment If an antibody is identified, antigen-negative blood will be requested for further transfusions	*Investigations:* DAT, IAT, liver function tests and markers of haemolysis
Infectious reactions				
Several infectious agents are transmissible by blood transfusion. Organisms responsible for transfusion-transmitted diseases include bacteria, malaria, variant Creutzfeldt-Jakob disease and viruses.				
Bacterial infection	Gram-positive and Gram-negative bacteria may enter the blood during collection or preparation of components Common in platelets (as these are stored at room temperature) and red-cell components stored for several weeks Occasionally due to contamination of ports during thawing of frozen products in a water bath Incidence: 1:75,000 for platelets and 1:500,000 for red cells	Reaction can be acute, severe and fatal High fever, severe chills, hypotension or circulatory collapse during or soon after transfusion	Stop transfusion immediately; follow other steps for managing suspected transfusion reactions (see below) Seek urgent medical assistance Commence broad-spectrum antibiotics following septic screen Notify blood service	*Investigations:* request septic screen and perform culture and Gram-stain of the blood component Keep the blood bag and giving set (sealed) for further investigation Collect, process, store, thaw and transfuse blood products according to blood service standards and infuse within 4 hours of starting time

continued

TABLE 34-25 ***continued***

Reaction	Usual cause	Clinical features	Management	Prevention
Malaria infection	Malaria is a protozoan disease involving four species of the genus *Plasmodium*; *P. falciparum*, *P. vivax*, *P. ovale* and *P. malariae* invade red cells and pose a risk for transmission by blood Estimated residual risk per blood unit for malaria is 1:4.9 million to 1:10.2 million	Rare transfusion-transmitted infection Fever, headache, nausea, vomiting and orthostatic hypotension Classic malarial paroxysms depend on the specific infecting *Plasmodium* species	Treat the specific parasite with antimalarial drugs Notify blood service	*Investigations:* Clinically assess patients for malaria; request thick and thin blood films to demonstrate the asexual forms of the parasite
Variant Creutzfeldt-Jakob disease (vCJD)	vCJD is a result of an exposure to tainted beef from cattle with bovine spongiform encephalopathy (BSE). Risk of vCJD is possible but not yet reported in Australia. The United Kingdom has reported a small number of cases of putative transfusion transmission since 2004	vCJD is a prion disease that affects the central nervous system Patients can present with fatigue, weight loss, headache, malaise and deficits in higher cortical function	Clinically assess patients for neurodegenerative signs and symptoms Seek expert advice and notify the blood service	No routine tests are available to predict or prevent vCJD from transmission by transfusion
Viral infection	Transfusion-transmitted viral infections may occur due to window-period transmissions	Clinical features of different viral infections, such as hepatitis and human immunodeficiency virus (HIV), are variable Severity can range from asymptomatic to fatal	Treat the specific diagnosis, if available Notify the blood service	*Investigation:* the risk of CMV transmission can be reduced by requesting CMV-seronegative or leucocyte-depleted blood components

ABC = airway, breathing, circulation; ABO = ABO blood classification system; CMV = cytomegalovirus; DAT = direct antiglobulin test; DIC = disseminated intravascular coagulation; HLA = human leucocyte antigen; human neutrophil antigen (HNA); HPA-1a = human platelet antigen 1a; IAT = indirect antiglobulin test; IgA = immunoglobulin A; IgE = immunoglobulin E; IVIg = intravenous immunoglobulin.

Adapted from Australian Red Cross Blood Service 2015 Blood component information: circular of information – an extension of blood component labels. Australian Red Cross Blood Service, Melbourne; and information available on the Australian Red Cross Blood Service website, http://resources.transfusion.com.au/cdm/ref/collection/p16691coll1/id/18; accessed 13 Jan 2016.

lies in the superior vena cava, above the right atrium. Rapid administration of cold blood can result in cardiac dysrhythmias (Lewis et al 2014).

• CRITICAL REFLECTION POINT

Mrs Coleman is admitted with diagnosis of anaemia related to ongoing haemorrhage. She has a haemoglobin level (Hb) of 80 g/L, temperature 36.8°C, pulse 112 beats per minute, blood pressure 88/56 mmHg, respirations 26 breaths per minute.

Activity

1. **What blood product would she receive and why?**
2. **A transfusion was commenced. After 15 minutes the patient states she feels a little hot; her temperature is now 37.4°C. Make a decision on whether you would continue or stop the transfusion and provide a rationale for your decision.**
3. **Can the monitoring of a patient with a blood transfusion be delegated to a student or enrolled nurse?**

Transfusion reactions

A transfusion reaction is a systemic response by the body to incompatible blood. Causes include RBC incompatibility and allergic sensitivity to the components of the transfused blood or to the potassium or citrate preservative in the blood. Several types of acute reactions can result from blood transfusions, as well as other complications (see Box 34-5).

A second category of reactions includes diseases transmitted by infected blood donors who are asymptomatic. Diseases transmitted through transfusions are malaria, hepatitis and HIV. Because all units of blood collected must undergo serological testing and screening for HIV and HBV, the risk of acquiring blood-borne infections from blood transfusions is reduced.

Circulatory overload is a risk when a patient receives massive whole blood or packed RBC transfusions for haemorrhagic shock or when a patient with normal blood volume receives blood. Patients particularly at risk of circulatory overload are children, older adults and those with cardiopulmonary diseases.

Blood transfusion reactions are life-threatening, but prompt nursing intervention can maintain the patient's physiological stability.

BOX 34-5 Steps for managing suspected transfusion reactions

1. Stop the transfusion immediately.
2. Remove the IV line from the cannula (IV line still contains blood which should not be administered to the patient).
3. Maintain intravenous (IV) access (do not flush existing line or cannula) – another cannula is usually inserted in a different site. Transfusing even the small amount of mismatched blood remaining in the tubing can cause a major reaction. A 0.9% Normal saline infusion is commenced using a new line and often a new IV site.
4. Seek urgent medical assistance as this may become an emergency.
5. Remain with the patient, observing signs and symptoms and monitoring vital signs as often as every 5 minutes.
6. Prepare to administer emergency drugs such as antihistamines, vasopressors, fluids and steroids as per doctor's order.
7. Check the right pack has been given to the right patient.
8. Prepare to perform cardiopulmonary resuscitation.
9. Obtain a urine specimen and send it to the laboratory.
10. Keep the blood bag and giving set (sealed) for further investigation.
11. Record the episode and actions/outcomes in the patient's notes for future reference.
12. Notify the medical officer and blood service.
13. Send blood pack to the blood service for urgent culture and Gram stain.

Adapted from Australian Red Cross Blood Service, Blood component information: circular of information – an extension of blood component labels, March 2015.

Interventions for acid–base imbalances

Nursing interventions to promote acid–base balance support prescribed medical therapies and are aimed at reversing an existing acid–base imbalance. Such imbalances can be life-threatening and require rapid correction. The nurse must maintain a functional IV line and frequently check the doctor's orders for new medications or fluids. Prescribed drugs and fluid and electrolyte replacement should be given promptly. Chapter 31 reviews appropriate therapies for patients with respiratory acidosis.

The nurse also monitors patients closely for changes in acid–base balance. Patients with acid–base disturbances usually require repeated ABG analysis. This procedure provides arterial blood samples for analysis of hydrogen ion concentration.

Arterial blood gases

Determination of ABG levels requires the removal of a sample of blood from an artery to assess the patient's acid–base status and the adequacy of ventilation and oxygenation. Arterial blood is drawn from a peripheral artery (usually the radial) or from an existing arterial line inserted by a doctor. After the specimen is obtained, care is taken to prevent air from entering the syringe because this will affect the blood gas analysis. To reduce metabolism of cells, the syringe is submerged in crushed ice and transported immediately to the laboratory. The nurse applies pressure to the puncture site for at least 5 minutes to reduce the risk of bleeding or haematoma formation. The nurse might also reassess the radial pulse after pressure has been removed.

Restorative care

After experiencing acute alterations in fluid, electrolyte or acid–base balance, patients often require ongoing maintenance to prevent a recurrence of health alterations.

Older adults and the chronically ill require special considerations to prevent complications from developing. The following *Research highlight* demonstrates the often unrecognised degree of chronic dehydration in older adults and the need for an interprofessional approach to discharge planning. A discharge plan for all patients who have experienced or are at risk for fluid and electrolyte disturbances (particularly older adults, infants and children) should include a written list of clinical signs and

RESEARCH HIGHLIGHT

Research focus

To compare in-hospital risks and mortality of hypernatraemia for patients admitted to hospital from either a nursing home or their home.

Research abstract

A retrospective observational study of 21,160 patients aged over 65 years.

Research findings

Patients admitted from care homes had 10-fold higher prevalence of hypernatraemia than those from their own homes. Nine in 10 cases of hypernatraemia were nursing home residents. After correcting for age, gender, mode of admission and dementia, care home residents were significantly more likely to be admitted with hypernatraemia than were own-home residents. Compared with own-home residents, care home residents were also at about a two-fold higher risk of in-hospital mortality compared with non-care home residents.

Conclusion

Patients admitted to hospital from care homes are commonly dehydrated on admission and, as a result, appear to experience significantly greater risks of in-hospital mortality.

BOX 34-6 Client teaching for home intravenous (IV) therapy

- Explain to the patient and caregiver the importance of IV therapy in maintaining hydration and access for the delivery of medications.
- Emphasise the risks involved when the IV system is not kept sterile.
- Be sure the patient and/or caregiver is able to manipulate the required equipment.
- Instruct the patient or caregiver in how to change IV solutions, tubing and dressing when they become soiled or dislodged. (Note: the home health nurse may be able to visit often enough to perform scheduled tubing and dressing changes or to assess patient's/family's ability.)
- Instruct the patient and caregiver about signs and symptoms of overhydration, infiltration, phlebitis and infection and to notify the home health nurse immediately.
- Instruct the patient and caregiver to notify the home health nurse if the infusion slows or stops or if blood is seen in the tubing.
- Teach the patient, with the caregiver's assistance, how to walk or move, perform hygiene and participate in other activities of daily living without dislodging or disconnecting catheter and tubing.

symptoms of fluid and electrolyte disturbance, frequency, type and amount of maintenance fluids required and when to seek advice.

Home intravenous therapy

IV therapy is used for patients requiring long-term hydration, parenteral nutrition (see Chapter 36) or long-term medication administration. The patient must have a family member available to assist them to manage the IV therapy. A home care nurse will work closely with the patient to ensure that a sterile IV system is maintained and that complications are avoided or recognised promptly. Box 34-6 summarises patient education guidelines for home IV therapy.

Nutritional support

Most patients who have had electrolyte disorders or metabolic acid–base disturbances require ongoing nutritional support. Depending on the type of disorder, fluid or food intake may be encouraged or restricted (see Chapter 36). The patient needs a nutritionally well-balanced diet. If patients are still responsible for preparing their own meals, they should learn to look at the lists of nutrient content of foods and to read the labels of commercially prepared foods. Nurses should possess knowledge of the fluid content of various foods if they are to be innovative in assisting patients who are reluctant to drink to maintain an appropriate level of fluid intake (see Table 34-22). Nursing staff should identify individual plans for each patient and ensure that such plans include strategies appropriate to the patient and their degree of haemodynamic stability (Table 34-26).

TABLE 34-26 Strategies to maintain oral intake

Aspect	Strategy
Document	Usual fluid intake and eating habits
	Usual weight, usual vital signs
	Fluid preference and preferred temperature of beverage
	Calculate expected maintenance volume based on patient's usual weight
Educate patients and relatives	Importance of hydration and encouragement of drinking, even when not thirsty
	Importance of fluid and foods to hydration
	Early recognition of any decrease in usual patterns
Educate nursing staff	Appropriate and timely assessment of the appropriate initiation of oral rehydration solutions, nasogastric feeding, subcutaneous or intravenous rehydration
	Evaluation of medications for possible dehydrating effects
	Interpretation of patient data, including laboratory results
Strategies to increase fluid consumption	Identify anorexia
	Replenish and refresh fluid supplies regularly
	Balance caffeinated and alcoholic drinks with other fluids
	Offer fluids regularly and encourage their consumption – if necessary 1- to 2-hourly. Use beverage carts to encourage fluid consumption throughout the day, not just at meal-times
	Fluid intake should equate to approximately 75% of the required daily fluid requirement
	Calculation of the required hourly volume depends on dietary intake. If no dietary intake, the hourly required oral intake (taking into account only waking hours) would be approximately 100 mL
	Offer icypoles and fluid-rich foods
	Ensure access to drinks, positioning of residents, use of drinking straws, feeder cups
	Use of visual reminders to drink, e.g. posters
	Check environment for obstacles

Adapted from Wotton K, Crannitch K, Munt R 2008 Prevalence, risk factors and strategies to prevent dehydration in older adults. Contemp Nurse 31(1):44–56.

CRITICAL REFLECTION POINT

Edwin Schell is an elderly resident of a long-term care facility. He is quite immobilised by severe arthritis, and needs help to get into and out of his chair.

Activity

1. **How would you assess his fluid balance?**
2. **What measures could you implement to decrease risk for dehydration?**
3. **What measures could be implemented in the long care facility to manage a diagnosis of dehydration?**

Medication safety

Numerous medications contain components or create potential side effects that can alter fluid and electrolyte balance. Patients with chronic disease who receive multiple medications and those with renal or liver disorders are at significant risk for experiencing medication complications. Once patients return to a restorative-care setting, whether in the home, long-term care or a nursing home, drug safety becomes very important. Patient and family education is essential to provide information on knowing what is contained in a drug and how to monitor for and when to report side effects. The nurse should review all medications with patients and encourage them to consult with the local pharmacist, especially before taking over-the-counter medications.

EVALUATING IMPACTS AND OUTCOMES

Patient care

The evaluation of a patient's clinical status is especially important if an acute fluid and electrolyte or acid–base disturbance exists. The patient's condition can change very quickly, and the nurse must be able to recognise the signs and symptoms of impending problems. To do this well, the nurse uses knowledge about the health alterations of the patient, the effects of medications and fluids, and the patient's presenting clinical status and past medical history (Figure 34-21).

The nurse performs evaluative measures and determines whether changes have occurred from the last patient assessment. For example, if the nurse assesses an increase in serum potassium for a patient diagnosed with hypokalaemia, the implementation of management strategies should see a concurrent decrease in the physical signs and symptoms of hypokalaemia. The patient's heart rhythm becomes more regular and normal bowel function returns.

For patients with less-acute alterations, evaluation is likely to occur over a longer period of time. In this situation the nurse's evaluation may also focus on behavioural changes (e.g. the patient's ability to follow dietary restrictions and medication schedules). The family's ability to anticipate alterations and prevent problems from recurring is also an important element of evaluation.

The patient's level of progress determines whether the nurse needs to continue or revise the plan of care. If there is a failure to meet expected outcomes, the nurse may need to consult with a doctor and discuss additional methods, such as increasing the frequency of an intervention (e.g. provide more fluids to a dehydrated patient), introducing a new therapy (e.g. initiate insertion of an IV) or discontinuing a particular therapy. Once outcomes have been met, the nurse can resolve the nursing diagnosis and focus on other priorities.

Patient expectations

The nurse routinely reviews with the patient any success in meeting their expectations of care, taking into account the patient's likes and dislikes regarding nutritional intake. 'Tell me how you feel' is a question that the nurse might raise if the patient's expectations revolve around comfort and symptom management. If the patient's concerns involve having a better understanding of a chronic problem, the nurse's evaluation might focus on the patient's satisfaction with educational offerings. Often the patient's level of satisfaction with care also depends on the nurse's success in involving family and friends. If the patient has concerns about returning home or to a different care setting, it will be important to evaluate whether the patient feels prepared for the transition from acute care.

• CRITICAL REFLECTION POINT

Mr Green, 56 years of age, weighs 80 kg and has been consuming 1200 mL of fluid (estimated from food and fluid intake) each day for the last week. He attends the emergency department because he was feeling dizzy and passing small amounts of dark, concentrated urine. The hourly urine output for the last 2 hours following the insertion of an indwelling urine catheter was 20 mL and 22 mL.

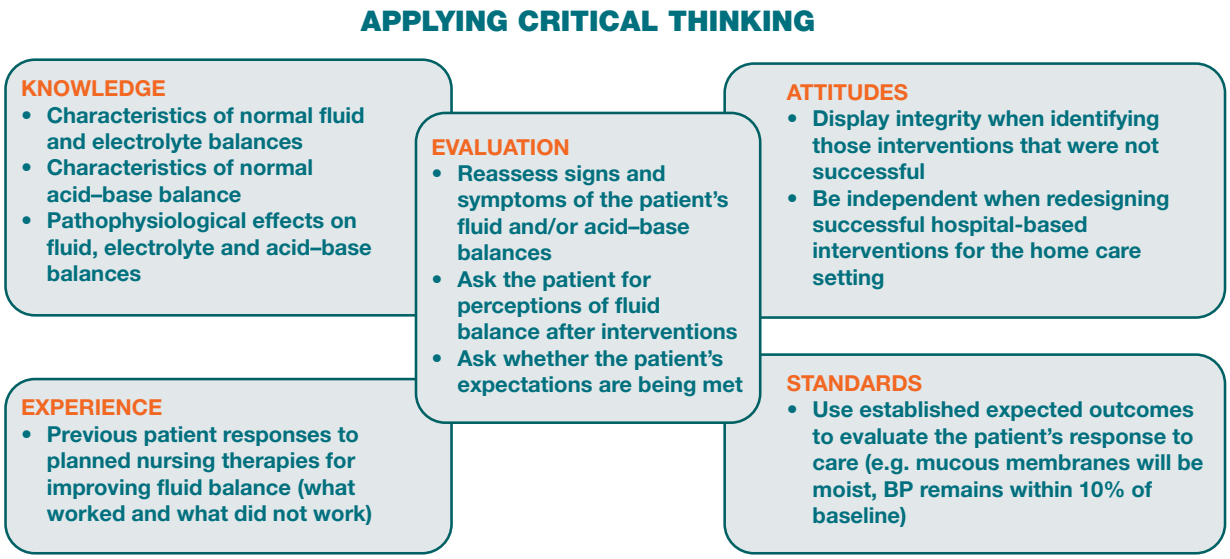

Figure 34-21 **Critical thinking associated with the evaluation phase for fluid, electrolyte and acid–base balance.**

Activity

1. **Use one of the formulas in Table 34-16 to calculate Mr Green's minimal fluid requirement to make a decision on the appropriateness of his current intake.**
2. **Use information in this chapter to determine the adequacy of hourly urine output.**

Key concepts

- Body fluids are distributed in extracellular fluid and intracellular fluid compartments and are composed of electrolytes, minerals, cells and water.
- Body fluids are regulated through fluid intake, output and hormonal regulation.
- Volume disturbances include isotonic and osmolar deficits and excesses.
- Electrolytes are regulated by dietary intake and hormonal controls.
- Acid–base imbalances are buffered by chemical and physiological buffering, especially the lungs and kidneys.
- Patients who are very young or very old, or who are chronically or seriously ill, are at greater risk of fluid, electrolyte and acid–base imbalances.
- Assessment for fluid, electrolyte and acid–base alterations includes nursing history, physical and behavioural assessment, measurements of fluid balance, daily weights and specific laboratory data.
- Osmolar imbalances and fluid volume deficit can be corrected by enteral or parenteral administration of fluid.
- Common complications of intravenous therapy include infiltration, phlebitis, infection, fluid volume excess and bleeding at the infusion site.
- Blood transfusions are given to replace fluid volume loss from haemorrhage, to treat anaemia or to replace coagulation factors.
- Blood transfusions can be donor or autologous, or obtained through perioperative salvage.
- Administration of blood or blood products requires the nurse to follow a specific procedure to identify transfusion reactions quickly.
- The risks of transfusion include transfusion reactions, hyperkalaemia, hypocalcaemia, fluid volume excess and infection.
- Treatment for electrolyte disturbances includes dietary and pharmacological interventions.
- The goals of therapy for acid–base imbalances are to treat the underlying illness and to restore the arterial pH to normal.

Preserving oxygenation

Natashia Scully

Learning outcomes

Mastery of content will enable you to:

- describe the structure (anatomy) and function (physiology) of the cardiovascular and pulmonary systems
- identify physiological processes of cardiac output, myocardial blood flow and coronary artery circulation
- describe the relationship between cardiac output, stroke volume (preload, afterload, contractility) and heart rate
- identify physiological processes involved in ventilation, perfusion and exchange of oxygen and carbon dioxide
- describe neural and chemical regulation of ventilation
- describe the impact of a patient's level of health, age, lifestyle and environment on tissue oxygenation
- identify and describe clinical outcomes as a result of disturbances in conduction, altered cardiac output, impaired valvular function, myocardial ischaemia and impaired tissue perfusion
- identify and describe clinical outcomes of ventilation/perfusion mismatch, diffusion impairment, alveolar hypoventilation and alveolar hyperventilation
- identify nursing care interventions in the primary care, acute care and restorative and extended-care settings that promote oxygenation
- develop foundation skills in undertaking and interpreting electrocardiograms (ECGs).

Introduction

Oxygen is required for the human body's cells to sustain life. The function of the cardiac and respiratory systems is to supply the body's oxygen demands. Cardiopulmonary physiology involves delivery of deoxygenated blood to the right side of the heart and then to the pulmonary circulation where oxygen uptake occurs from the air breathed into the lungs. Oxygenated blood then moves from the lungs to the left side of the heart and is subsequently delivered to the tissues. Blood is oxygenated and carbon dioxide (which is produced by body cells through their metabolic process) is eliminated through the mechanisms of ventilation: the mechanical movement of gas into and out of the lungs; and respiration: the exchange of oxygen and carbon dioxide at tissue level. Neural and chemical regulators control respiratory rate and depth in response to changing tissue oxygen demands.

Cardiovascular physiology

The function of the cardiovascular system is to deliver oxygen, nutrients and other substances to the tissues and to remove the waste products of cellular metabolism through the cardiac pump, the circulatory vascular system and the integration of other systems, including respiratory, gastrointestinal and renal systems.

Structure and function

It is extremely important for nurses to be aware of normal cardiac anatomy and physiology in order to accurately assess patients and interpret assessment findings. The right ventricle pumps blood through the pulmonary circulation while the left ventricle pumps blood to the systemic circulation, supplying oxygen and nutrients to the tissues and removing carbon dioxide and wastes (Figures 35-1 and 35-2). The circulatory system exchanges oxygen, carbon dioxide, nutrients and waste products between the blood and the tissues.

Cardiac blood flow

In normal cardiac anatomy and physiology, blood flow through the heart is unidirectional. There are four heart valves that ensure this forward blood flow (Figure 35-2). Blood flows from the veins into the vena cava (the inferior and superior brances), to the right atrium, through the tricuspid valve to the right ventricle, through the pulmonary semilunar valve, to the pulmonary artery, to the pulmonary capillaries (where diffusion of oxygen from the alveoli to the blood and carbon dioxide from the blood to the alveoli occurs), to the pulmonary vein, to the left atrium, through the bicuspid valve, to the left

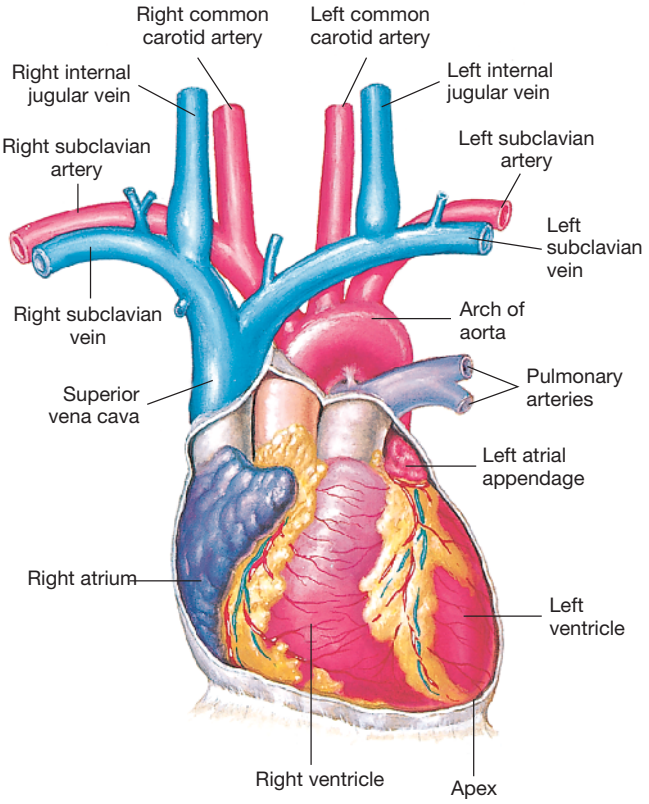

Figure 35-1 Serially connected pulmonary and systemic circulation.

Right heart chambers propel unoxygenated blood through the pulmonary circulation; left heart chambers propel oxygenated blood through the systemic circulation.

Lewis SM et al 2004 Medical–surgical nursing: assessment and management of clinical problems, 6th edn. Mosby, St Louis.

ventricle, through the aortic semilunar valve to the aorta (Figure 35-2).

Cardiac cycle and the myocardial pump

A principle of the movement of blood through the circulatory system is that under normal function, blood flows from an area of higher pressure to lower pressure and it flows unidirectionally (that is, is should not flow backwards). The principal role of the heart is to contract to create a pressure the enables blood to be pumped from the right side of the heart to the lung and the left side of the heart to the systemic circulation. The heart also needs to relax to enable two venous systems (systemic and pulmonary) to deliver blood to the heart. The cardiac cycle refers to the physiology of one full heartbeat – it involves one pump of the heart, when functioning normally, and produces two distinct heart sounds which can be heard with a stethoscope.

When the heart is relaxed (in diastole), the atria fill with blood. During this phase, the atrioventricular (AV) valves (the tricuspid valve between the right atria and ventricle; and the bicuspid valve between the left atria and ventricle) are open and blood moves passively between the atria and the ventricles. When the atria contract they actively push blood from the atria into the ventricles. This adds approximately 30% more blood volume to the ventricles. When the ventricles start to contract the pressure builds up. When the pressure in the ventricles becomes higher than the atria, the AV valves snap shut to prevent the blood from flowing back into the atria. This causes the first heart sound (S1). As the ventricles continue to contract, the pressure continues to rise. When the pressure in the ventricles is higher than in the pulmonary artery and aorta, the semilunar (SL) valves open (the pulmonary SL valve between the right ventricle and pulmonary artery; and the aortic SL valve between the left ventricle and the aorta), allowing blood to flow into those arteries. When the ventricles begin to relax, the pressure in them drops. When the pressure drops below the pressure in the pulmonary artery and aorta, the SL valves snap shut to prevent the blood from flowing back into the ventricles. This produces the second heart sound (S2) (see Figure 35-3).

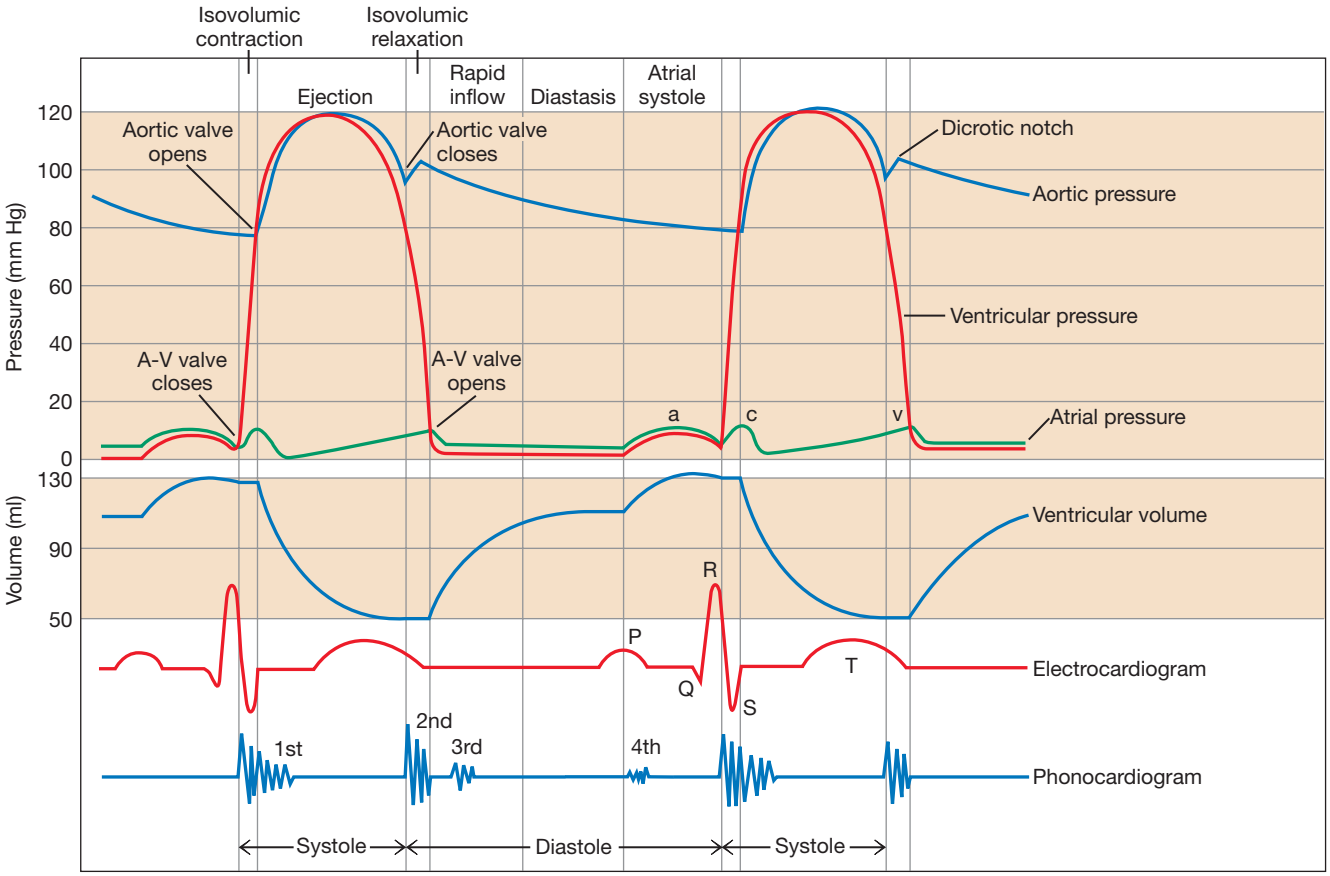

Figure 35-3 Cardiac cycle.

Copstead L, Banasik J 2010 Pathophysiology. Elsevier, Sydney.

The effectiveness of the cardiac cycle can be assessed by monitoring the patient's blood pressure, heart rate and listening to their heart sounds.

The pumping action of the heart is essential for the maintenance of oxygen delivery. Decreased pump effectiveness, as occurs in heart failure, results in a diminished *stroke volume* – the volume of blood ejected from the ventricles during each contraction. Shock, haemorrhage and dehydration decrease pump effectiveness by reducing the volume of circulating blood, thereby decreasing stroke volume.

The chambers of the heart, the right and left atria and ventricles, fill during diastole and partially empty during systole. The effectiveness of the diastolic and systolic events of the cardiac cycle can be assessed by monitoring the patient's blood pressure (see Chapter 24). The myocardial fibres have contractile properties that enable them to stretch during filling. In a healthy heart this stretch is proportionally related to the strength of contraction. As the myocardium stretches, the strength of the subsequent contraction increases; this is known as Starling's law of the heart (or Frank–Starling relationship). In the diseased heart, Starling's law does not apply because the stretch of the myocardium is beyond the heart's physiological limits. The subsequent contractile response results in insufficient ventricular ejection (volume), and blood begins to 'back up' in the pulmonary (left heart failure) or systemic (right heart failure) circulation.

Coronary artery circulation

To maintain adequate blood flow to the pulmonary and systemic circulation, myocardial blood flow must supply sufficient oxygen and nutrients to the myocardium itself. Blood in the atria and ventricles does not supply oxygen and nutrients to the myocardium. The *coronary circulation* is the branch of the systemic circulation that supplies the myocardium with oxygen and nutrients and removes waste. The right and left coronary arteries arise from the aorta just above and behind the aortic valve through openings called the *coronary ostia* (coronary openings). The coronary arteries fill during ventricular diastole. The left coronary artery generally feeds the left atrium and ventricle, while the right coronary artery feeds the right atrium and ventricle. However, there is variation in branching of coronary arteries among individuals (Figure 35-4, Box 35-1).

Systemic circulation

The arteries of the systemic circulation deliver nutrients and oxygen to the tissues and the veins of the systemic circulation remove waste, such as carbon dioxide, from them. Oxygenated blood flows from the left ventricle by way of the aorta and into large systemic arteries. These arteries branch into smaller arteries, then into arterioles and finally into the smallest vessels, the capillaries. At capillary level, oxygen and nutrients diffuse from the blood to the tissues, resulting in tissue oxygenation and cellular metabolism. Carbon dioxide and other waste products of cellular metabolism are diffused from the tissues into the capillaries. The waste products exit the capillary network by way of the venules that join to form veins. These veins form larger veins, which carry deoxygenated blood to

the right side of the heart, where it is returned to the pulmonary circulation.

Cardiac output and blood flow regulation

The amount of blood ejected from the left ventricle each minute is the cardiac output. The normal cardiac output is 4–6 L/min in a healthy 70 kg adult at rest. The circulating volume of blood changes according to the oxygen and metabolic needs of the body. For example, during exercise, pregnancy and fever the cardiac output increases, but during sleep it decreases. Cardiac output is represented by the following formula:

Cardiac output (CO) = Stroke volume (SV) × Heart rate (HR)

Stroke volume is the amount of blood ejected from the left ventricle with each contraction. It can be affected by three entities:

1. the amount of blood in the left ventricle at the end of diastole (*preload*)
2. the resistance to left ventricular ejection (*afterload*)
3. the ability of the heart muscle to contract (*myocardial contractility*).

Preload is essentially the end-diastolic volume. As the ventricles fill, they stretch. The greater the stretch on the ventricle, the greater the contraction and the greater the stroke volume (Starling's law). In clinical situations, the preload and subsequent stroke volume can be manipulated by changing the amount of circulating blood volume. That is, by administering intravenous fluid we can increase the circulating volume, therefore increasing the amount of fluid that is available to fill the heart. For example, in the patient with haemorrhagic shock, fluid therapy and replacement of blood increases volume, thus increasing the preload and cardiac output. If volume is not replaced, preload decreases, the cardiac output decreases and ultimately the venous return to the right atrium decreases, further decreasing preload and cardiac output.

Afterload is the resistance to *left ventricular ejection* – the work the heart must overcome to fully eject blood from the left ventricle. Remember that for normal heart function to occur, blood flows from areas of higher pressure to lower pressure. This means the ventricles need to contract to produce a pressure that is higher than the arteries they intend to inject blood into (the pulmonary artery and the aorta). The pressure in these arteries that the heart must overcome in order to pump out blood is referred to as the 'afterload'. The diastolic aortic pressure is a good clinical measure of afterload. In a patient with an acute hypertensive crisis, the afterload is increased, increasing the cardiac workload (as the heart has to pump harder to produce a higher pressure in order to make the blood flow out into the artery). Afterload in this situation can be manipulated by decreasing systemic blood pressure.

Myocardial contractility also affects stroke volume and cardiac output. Poor contraction of the myocardium decreases the amount of blood ejected by the ventricles during each contraction. Myocardial contractility can be increased by drugs that increase the force of contraction, such as digitalis preparations (e.g. digoxin) and sympathomimetic drugs (drugs that mimic the effects of the sympathetic nervous system), for example, adrenaline. Injury to the myocardial muscle, such as an acute myocardial infarction, can cause a decrease in myocardial contractility. The myocardium of the older adult is more rigid and slower in recovering its contractility (Steven 2011).

Heart rate affects blood flow because of the interaction between rate and diastolic filling time. Diastole is an important part of the cardiac cycle as this is when the heart is relaxed and filling with blood. If there is insufficient time to fill with blood, preload is affected. With a sustained heart rate greater than 160 beats per minute, diastolic filling time decreases, decreasing stroke volume and cardiac output. For a consistent and viable cardiac output,

a regular heart rate is required. Irregular heart rates affect stroke volume and, subsequently, cardiac output and tissue perfusion. The heart rate of the older adult is slow to increase under stress. With the normal ageing process there are significant changes to cardiac structure and function, and the stroke volume may increase to increase the cardiac output and blood pressure (Jet 2008). Heart rate and rhythm can be manipulated and controlled with various anti-arrhythmic medication.

The continuous monitoring of cardiovascular haemodynamics is usually performed in critical-care units. Some step-down or special-care units may also have the capability to continuously monitor haemodynamics.

Conduction system

The rhythmic relaxation and contraction of the atria and ventricles depend on continuous, organised transmission of electrical impulses. These impulses are generated and transmitted by way of the cardiac conduction system (Figure 35-5).

The heart's conduction system generates the necessary action potentials that conduct the impulses required to initiate the electrical chain of events resulting in the heartbeat. The principle of 'excitation–contraction coupling' means that there must be an excitation of the muscle fibres for a contraction to take place, hence why it is necessary for a nurse to have an understanding of the electrical activity that occurs in the heart to assess correct functioning.

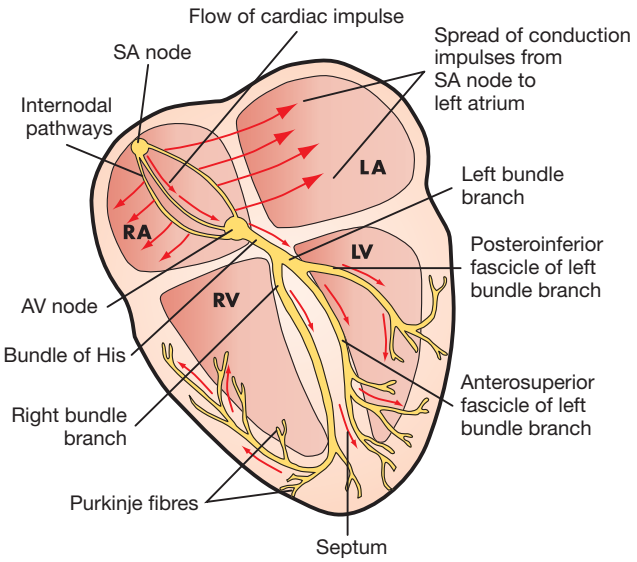

Figure 35-5 Conduction system of the heart.

LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SA, sinoatrial; AV, atrioventricular.

Lewis SM et al 2007 Medical–surgical nursing: assessment and management of clinical problems, 7th edn. Mosby, St Louis.

The autonomic nervous system, consisting of sympathetic and parasympathetic branches, influences the rate of impulse generation as well as the speed of transmission through the conductive pathway and the strength of atrial and ventricular contractions. Sympathetic nerve fibres, which increase the rate of impulse generation and the speed of impulse transmission, innervate all parts of the atria and ventricles. Parasympathetic fibres from the vagus nerve, which decrease this rate, also innervate these parts, as well as the sinoatrial and atrioventricular nodes.

The conduction pathway, illustrated in Figure 35–5, originates with the sinoatrial (SA) node, the 'pacemaker' of the heart. The SA node is in the right atrium next to the entrance of the superior vena cava. Impulses are initiated at the SA node at an intrinsic rate of 60–100 beats per minute, reflecting the resting adult rate, which ranges from 60 to 100 beats per minute. Resting heart rate for infants and children varies with age: 80–150 beats per minute for age 3 months to 2 years, 70–110 beats per minute for 2–10 years and 55–90 beats per minute for over 10 years (Hockenberry et al 2009).

The electrical impulses are then transmitted through the atria along intra-atrial pathways to the atrioventricular (AV) node. The AV node mediates impulses between the atria and the ventricles. The intrinsic rate of the normal AV node is 40–60 beats per minute. The AV node assists atrial emptying by delaying the impulse before transmitting it through the *bundle of His*, which is divided into left and right bundle branches which run down the septum of the ventricles, and the ventricular *Purkinje network*, which are located around the outer margins of the ventricles. The intrinsic rate of the bundle of His and the ventricular Purkinje network is 20–40 beats per minute.

Electrocardiogram

An **electrocardiogram (ECG)** reflects the electrical activity of the conduction system. It monitors the regularity and path of the electrical impulse through the conduction system; however, it does not reflect muscular work of the heart. This electrical impulse is required to stimulate the myocardium to then generate the mechanical event of ventricular contraction. The normal sequence of impulse movement through the conduction system on the ECG is called **normal sinus rhythm (NSR)** (Figure 35-6).

NSR implies that the impulse originates at the SA node and follows the normal sequence through the conduction system. The muscle fibres must depolarise so they can then contract before repolarising to ensure a new impulse can be generated. Hence a normal sequence of electrical impulses travelling through the heart needs to have a

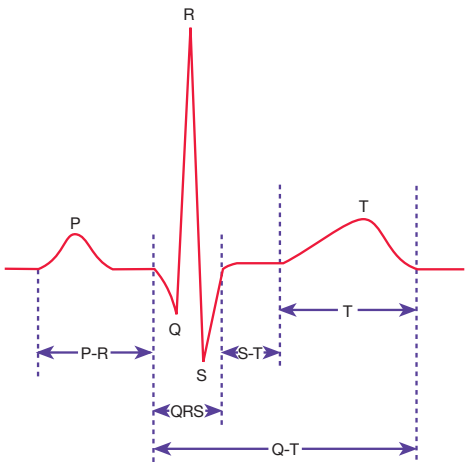

Figure 35-6 Normal ECG waveform.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

depolarisation phase and then a repolarisation phase. Note that the ECG displays only the electrical activity in the heart, not the mechanical activity (i.e. contraction). There needs to be an electrical excitation for a contraction to occur. That is why it is important for a nurse to assess this.

An ECG is recorded on standardised paper. It contains small squares 1 mm^2, which represent 0.04 seconds. Five small squares make one large square, which represents 0.20 seconds. The standardised speed of the paper should be 25 mm/second to ensure accurate interpretation.

ECG interpretation for disease-related abnormalities is an advanced nursing skill; however, all registered nurses (RNs) must know how to identify normal ECG characteristics so they can recognise a deviation from the norm and therefore know when to seek assistance from qualified staff. Below is an explanation of normal ECG characteristics. When conducting an ECG, it is important to interpret the recording immediately, so it may be necessary to find an experienced staff member to assist in completing this task. Figure 35-6 depicts a normal ECG waveform and indicates relevant intervals and segments.

Waves in the ECG

NB: Please refer to Figure 35-6 when reading through this section for a visual representation. Also, please note that this section describes what is seen in a normal, disease-free ECG.

The *P wave* represents atrial depolarisation: the electrical conduction through both atria and is normally small and rounded. Normal P wave duration is approximately 0.12 second. Atrial contraction follows the P wave.

The *QRS complex* indicates ventricular depolarisation: that the electrical impulse has travelled through the ventricles. Normal QRS duration is 1.5–3 small squares on the ECG paper (0.06–0.12 second). An increase in QRS duration indicates a delay in conduction time through the ventricles. Ventricular contraction follows the QRS complex. A QRS complex wider than 3 small squares (0.12 second) should be reported. Every P wave is followed by a QRS complex in a normal ECG, indicating normal cardiac conduction.

The *T wave* represents ventricular repolarisation. The T wave is normally rounded, rising more slowly from the baseline than it returns. Each QRS complex is followed by a T wave in normal cardiac conduction.

It is important to note that the atria also repolarise; however, this is happening at the same time as the ventricles are depolarising so the impulse generated is masked by the QRS complex as this is a much larger electrical event.

Segments and intervals

NB: Please refer to Figure 35-6 when reading through this section for a visual representation.

The *P–R interval* represents the impulse travel time from the SA node through the AV node and the bundle of His to the Purkinje fibres. The normal length of the P–R interval is 3–5 small squares on the ECG paper (0.12–0.20 second). An increase in the P–R of > 5 small squares (0.20 second) indicates that there is a block in the impulse transmission through the AV node, whereas a P–R interval of < 2 small squares (0.08 second) indicates the initiation of the electrical impulse from a source other than the SA node. A P–R interval of > 5 small squares (0.20 second) should be reported. If abnormalities are detected, ensure a suitably qualified health professional is notified as soon as possible.

The *S–T segment* extends from the end of the QRS complex (J point) to the start of the T wave and should be at the baseline (the same level as the line before the P wave, also known as the isoelectric line). Significant displacement from the baseline may be indicative of disease processes such as acute coronary syndrome (Jacobson 2010a).

An ECG can be recorded in different ways, the two main versions of an ECG being continuous cardiac monitoring (also referred to as telemetry) and the 12-lead ECG. Performing an ECG in these forms is covered in Skills 35-1 and 35-2. A 'lead' refers to the aspect in which the heart is being viewed. The electrodes that are attached to the patient are used to create these leads. Think about each lead as being like a camera looking at the heart from a different angle. The formation of the P wave, QRS complex and T wave will appear differently in each lead as the heart is being viewed from different angles.

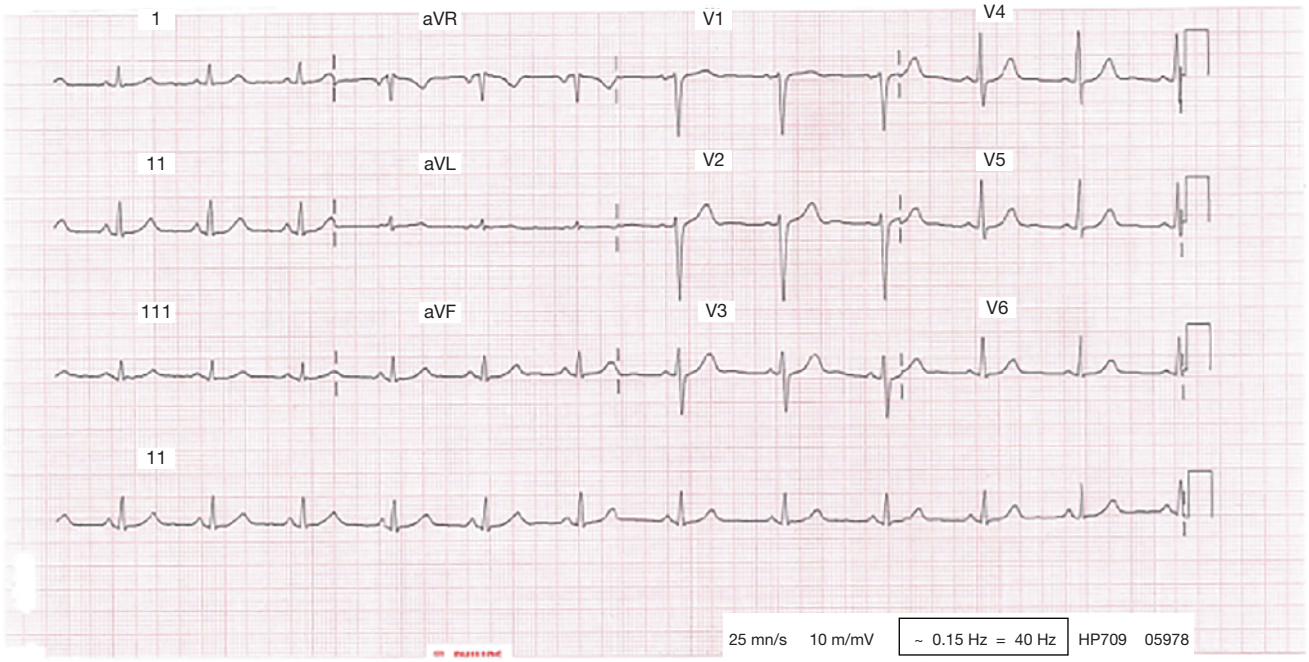

Figure 35-7 Normal 12-lead ECG.

Courtesy N. Scully.

A 12-lead ECG shows 12 different aspects (or views) of the heart and uses 10 electrodes to create these. A 12-lead ECG is like a snapshot of the heart at a particular point in time. The 12 leads are shown in Figure 35-7. Continuous cardiac monitoring generally uses 3 or 5 electrodes. The heart is monitored in one lead at a time (sometimes more if the patient is in a critical care area) and this is usually in lead II as this lead gives the best view of the entire conduction pathway.

Respiratory physiology

Most cells in the body obtain their energy from chemical reactions involving oxygen and the elimination of carbon dioxide. The purpose of the lungs is to facilitate the diffusion of oxygen from the air breathed into them into the blood and the diffusion of carbon dioxide from the blood to the alveoli to be breathed out of the lungs.

Structure and function

Normal adult respiratory rate ranges between 12 and 20 breaths per minute. Respiratory rate in infants and children varies: 25–30 breaths per minute for age 3 months to 2 years, 19–25 breaths per minute for 2–10 years, and 16–19 breaths per minute for over 10 years (Hockenberry et al 2009). Respiration can be altered by conditions or diseases that change the structure and function of the lung. The respiratory muscles, pleural space, lungs and alveoli (Figure 35-8) are essential for ventilation, perfusion and exchange of oxygen and carbon dioxide (Box 35-2). The *pleura* is a membrane which adheres to the lungs and then folds back to connect to the chest wall. The visceral pleura adheres to the lungs, while the parietal pleura adheres to the chest wall. The area between these two is the *pleural space*, normally a potential space containing a small amount of fluid and negative in pressure relative to atmosphere. Problems arise if the negative pressure of this space is not maintained, as, for example, when air (pneumothorax), blood (haemothorax) or fluid (pleural effusion) enters the space.

The exchange of oxygen and carbon dioxide occurs between environmental air and the blood (Figure 35-8). There are three steps in the process of oxygenation: *ventilation/work of breathing*, *perfusion of the lungs* (*pulmonary circulation*) and *diffusion* (*exchange of oxygen and carbon dioxide*). Many of the respiratory disorders arise from a problem with one or more of these mechanisms.

Ventilation and work of breathing

For the exchange of oxygen and carbon dioxide to occur, the organs, nerves and muscles of respiration must be intact and the central nervous system able to regulate the respiratory cycle (Figure 35-9). The respiratory centre lies in the brainstem, which contains a group of neurons (dorsal respiratory group) that regulate the automatic

BOX 35-2 Major anatomical structures of the thorax and their functions

Inspiratory muscles

Diaphragm

Contraction causes the diaphragm to descend, creating a negative pleural pressure and increasing the vertical dimension of the lungs, which contributes to inflation of the lungs. The increase in vertical dimension and the decrease in intrapulmonary pressure (negative with respect to atmospheric pressure) cause air to enter the lungs.

External intercostal muscles

Contraction elevates the anterior ends of the ribs, causing them to move upwards and outwards. This increases the anteroposterior dimension of the thorax.

Accessory muscles

Accessory muscles include the scalene, sternocleidomastoid and trapezius muscles. Contraction elevates the first two ribs and the sternum.

Expiratory muscles

Internal intercostal muscles

Contraction pulls the ribs down and in, thereby decreasing the anteroposterior diameter of the thorax.

Abdominal respiratory muscles

Abdominal respiratory muscles include the rectus, transversus abdominis, internal oblique and external oblique muscles. Contraction depresses the lower ribs, forces the diaphragm up and decreases the vertical dimension of the thoracic cavity.

Pleural space

The pleural space is a potential space that is only a thin film of liquid lying between the outer layer of the lung (visceral pleura) and the inner layer of the chest cavity (parietal pleura). It permits a smooth, gliding movement of the lungs along the chest wall. Normally, air is not present in the pleural space.

Lungs

Left (two lobes) and right (three lobes)

The lungs transfer oxygen from the atmosphere into the alveoli and carbon dioxide from the alveoli to the lungs to be excreted as a waste product. They also filter toxic material from circulation and metabolise compounds such as angiotensin I, bradykinin and prostaglandins.

Alveoli

Alveoli transfer oxygen and carbon dioxide to and from the blood through the alveolar membrane. These tiny air sacs expand during inspiration, greatly increasing the surface area over which exchange of oxygen and carbon dioxide occurs.

rhythm of respiration. The pneumotaxic and apneustic centres of the respiratory centre adjust inspiratory rate and depth. Central chemoreceptors detect slight changes in pH in spinal fluid, reflecting arterial carbon dioxide (see Chapter 34). Changes in carbon dioxide and therefore pH are detected and inspiratory rate and depth adjusted accordingly. Peripheral chemoreceptors detect arterial carbon dioxide and oxygen, but predominantly

oxygen, and are therefore principally responsible for adjusting respiration in response to hypoxaemia. Central chemoreceptors are more sensitive than peripheral chemoreceptors.

Ventilation is the process of moving gases into and out of the lungs. Normal ventilation occurs at a rate of approximately 4 L/min. Ventilation requires coordination of the muscular and elastic properties of the lung and thorax, as well as intact innervation. The major inspiratory muscle of respiration is the diaphragm. It is innervated by the phrenic nerve derived from spinal nerves C3, C4 and C5. A mnemonic to aid memory of the innervation of the diaphragm is 'C3, 4, 5 keeps the diaphragm alive'.

Breathing is the effort required to expand and contract the lungs. The work of breathing is determined by the degree of compliance of the lungs, airway resistance, presence of active expiration, and use of accessory muscles of ventilation.

During normal respiration, we are what is referred to as negative pressure breathers. This means that to draw air into our lungs we create a negative pressure within the lungs. As we know from our study of the heart and blood flow, things travel from an area of high pressure to lower pressure. The process of breathing in air from the atmosphere into our lungs is called bulk flow.

Inspiration is an active process, stimulated by chemical receptors in the aorta. During inspiration the diaphragm contracts and flattens and the external intercostal muscles contract which pulls the ribs up and out. This increases the size of the lungs and decreases the pressure within them to less than atmospheric pressure. Air moves into the lungs from the area of higher pressure (the atmosphere) to lower pressure (the lungs), hence we breathe in.

Expiration is a passive process that depends on the elastic recoil properties of the lungs, requiring little or no muscle work. The diaphragm and external intercostal muscles relax, which decreases the size of the lungs and therefore increases the pressure to higher than atmospheric, hence we breathe out. Other muscles can be utilised to make breathing out a more active process, such as internal intercostal and abdominal muscles.

Elastic recoil is produced by elastic fibres in lung tissue and by surface tension in the fluid film lining the alveoli. *Surfactant* is the chemical produced in the lungs by alveolar type 2 cells that reduces the surface tension of the alveoli and keeps them from 'sticking shut' when collapsed. Patients with advanced chronic obstructive pulmonary disease (COPD) lose the elastic recoil of the lungs and thorax. As a result, the patient's work of breathing is increased.

Accessory muscles of respiration can increase lung volume during inspiration, although not as effectively as the diaphragm. Accessory muscles include the sternocleidomastoid and scalene muscles on the side of the neck and the intercostal muscles. Patients with COPD, especially emphysema, frequently use these muscles to increase lung volume. During assessment nurses may see obvious movement of these neck muscles and retraction of the muscles between the ribs. Prolonged use of the accessory muscles of respiration does not promote effective ventilation and causes fatigue.

Compliance is the ability of the lungs to distend or expand in response to increased intra-alveolar pressure. Compliance is decreased in diseases such as pulmonary oedema, interstitial and pleural fibrosis, and congenital or traumatic structural abnormalities such as kyphosis (curving of the spine causing a roundness of the back) or fractured ribs.

Airway resistance is the pressure difference between the mouth and the alveoli in relation to the rate of flow of inspired gas. Airway resistance can be increased by an airway obstruction, small-airway disease (such as asthma) and tracheal oedema. When resistance is increased, the amount of air travelling through the anatomical airways is decreased.

Decreased lung compliance, increased airway resistance, active expiration or the use of accessory muscles, increases the work of breathing, resulting in increased energy expenditure. To meet this expenditure, the body increases its metabolic rate, and the need for oxygen, as well as for the elimination of carbon dioxide, increases. This sequence is a vicious cycle for a patient with impaired ventilation, causing further deterioration of respiratory status and the ability to oxygenate adequately.

Lung volumes and capacities

Spirometry is used to measure the volume of air entering or leaving the lungs. Variations in lung volumes may be associated with health states such as pregnancy, exercise, obesity or obstructive and restrictive conditions of the lungs. The amount of surfactant, degree of compliance and strength of respiratory muscles can affect pressures and volumes within the lungs.

The volume of air in the lungs is measured in various ways and combined to describe lung capacities (see pulmonary function tests later in the chapter).

Gases are moved into and out of the lungs through pressure changes (Figure 35-10). Intrapleural pressure is negative relative to atmospheric pressure, which is 760 mmHg at sea level. For air to flow into the lungs, intrapleural pressure must become more negative, setting

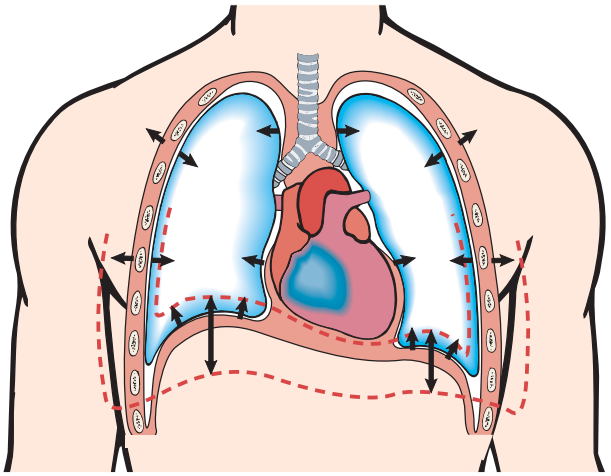

Figure 35-10 Frontal section of chest showing movement of the lung and chest wall during inspiration and expiration.

During inspiration the inspiratory muscles contract and the chest expands. Alveolar pressure becomes subatmospheric with respect to pressure at the airway opening, and air flows into the lungs. During expiration the inspiratory muscles relax. Recoil of the lung causes alveolar pressure to exceed pressure at the airway opening and air to flow out of the lungs. Single arrows show excursion of the lungs and chest wall. Double arrows show movement of the lung bases.

Lewis SM et al 2004 Medical–surgical nursing: assessment and management of clinical problems, 6th edn. Mosby, St Louis.

up a pressure gradient between the atmosphere and the alveoli.

Perfusion/pulmonary circulation

The main function of the pulmonary circulation is to move blood to and from the alveolocapillary membrane for gas exchange to occur. The pulmonary circulation is a reservoir for blood so that the lung can increase its blood volume without large increases in pulmonary artery or venous pressures. The pulmonary circulation also acts as a filter, removing small thrombi before they can reach vital organs.

The pulmonary circulation begins at the pulmonary artery, which receives poorly oxygenated mixed venous blood from the right ventricle. Blood flow through this system depends on the pumping ability of the right ventricle, which has an output of approximately 5 L/min. The flow continues from the pulmonary artery through the pulmonary arterioles to the pulmonary capillaries, where blood comes in contact with the alveolar–capillary membrane and the exchange of oxygen and carbon dioxide occurs. The now oxygen-rich blood then circulates through the pulmonary venules and pulmonary veins, returning to the left atrium.

Pressure and resistance within the pulmonary circulatory system is lower than that within the systemic circulatory system. The walls of the pulmonary vessels are thinner and contain less smooth muscle. The lung accepts the total cardiac output from the right ventricle and, except in some specific pathophysiological circumstances, does not direct blood flow from one region to another.

Diffusion/exchange of oxygen and carbon dioxide

Oxygen and carbon dioxide are exchanged in the alveoli and the capillaries of the body tissues. Oxygen is transferred from the alveoli of the lungs to the pulmonary circulation, and carbon dioxide is transferred from the pulmonary circulation to the alveoli to be exhaled as a waste product. At the tissue level, oxygen is transferred from the arterial blood to tissues, and carbon dioxide is transferred from tissues to the venous blood to return to the pulmonary circulation and alveoli and be exhaled. This transfer depends on the process of *diffusion*.

Diffusion is the movement of molecules from an area of higher concentration to an area of lower concentration (see Chapter 34). Diffusion of oxygen and carbon dioxide occurs at the alveolar–capillary membrane. Oxygen diffuses into the pulmonary circulation from the alveoli and carbon dioxide diffuses from the pulmonary circulation into the alveoli to be expired.

Oxygen transport

The oxygen transport system consists of the respiratory and cardiovascular systems. Delivery depends on the amount of oxygen entering the lungs (ventilation), blood flow to the lungs and tissues (perfusion), rate of diffusion, and oxygen-carrying capacity. The capacity of the blood to carry oxygen is influenced by the amount of dissolved oxygen in the plasma, amount of haemoglobin and tendency of haemoglobin to bind with oxygen. Only a relatively small amount of required oxygen, less than 1%, is dissolved in the plasma (Brashers 2010a). Most oxygen is transported by haemoglobin, which serves as a carrier for oxygen and carbon dioxide. The haemoglobin molecule combines with oxygen to form oxyhaemoglobin. The formation of oxyhaemoglobin is easily reversible, allowing haemoglobin and oxygen to dissociate, which frees oxygen to enter tissues.

Carbon dioxide transport

Carbon dioxide diffuses into red blood cells and is rapidly hydrated into carbonic acid (H_2CO_3) because of the presence of carbonic anhydrase. The carbonic acid

then dissociates into hydrogen (H^+) ions and bicarbonate (HCO_3^-) ions. The reversible process is expressed below:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+$$

The hydrogen ion is buffered by haemoglobin, and the HCO_3^- diffuses into the plasma (see Chapter 34). In addition, some of the carbon dioxide in red blood cells reacts with amino acid groups, forming carbamino compounds. This reaction can occur rapidly without the presence of an enzyme. Reduced haemoglobin (*deoxyhaemoglobin*) can combine with carbon dioxide more easily than oxyhaemoglobin, and therefore venous blood transports the majority of carbon dioxide.

Regulation of respiration

Regulation of respiration is necessary to ensure sufficient oxygen intake and carbon dioxide elimination to meet the body's demands (e.g. during exercise, infection or pregnancy). Neural and chemical regulators control the process of respiration. Neural regulation includes the central nervous system control of respiratory rate, depth and rhythm. Chemical regulation involves the influence of chemicals such as carbon dioxide and hydrogen ions on the rate and depth of respiration (Box 35-3).

BOX 35-3 Neural and chemical regulation of respiration

Neural regulation

Maintains rhythm and depth of respiration and balance between inspiration and expiration.

Cerebral cortex

Voluntary control of respiration delivers impulses to the respiratory motor neurons by way of the spinal cord; accommodates speaking, eating and swimming.

Medulla oblongata

Automatic control of respiration occurs continuously.

Chemical regulation

Maintains appropriate rate and depth of respirations based on changes in the blood's carbon dioxide, oxygen and hydrogen ion (H^+) concentration. Chemical regulation can occur during physical exercise and in some illnesses. It is a short-term adaptive mechanism.

Chemoreceptors

Located in the medulla, aortic body and carotid body. Changes in chemical content of oxygen, carbon dioxide and hydrogen ions stimulate chemoreceptors, which in turn stimulate neural regulators to adjust the rate and depth of ventilation to maintain normal arterial blood gas levels.

Factors affecting oxygenation

Adequacy of ventilation, perfusion and transport of oxygen to the tissues is influenced by four types of factors: (1) physiological, (2) developmental, (3) behavioural and (4) environmental. Physiological factors are outlined below; developmental, behavioural (lifestyle) and environmental factors are discussed in the following section.

Physiological factors

Any condition that affects cardiopulmonary functioning directly affects the body's ability to meet oxygen demands. The general classifications of cardiac disorders include disturbances in conduction, impaired valvular function, myocardial hypoxia, cardiomyopathic conditions and peripheral tissue hypoxia. Respiratory disorders are caused by one or more of the following factors: **ventilation/perfusion (V/Q) mismatch**, diffusion impairment, alveolar hypoventilation and alveolar hyperventilation.

Other physiological processes affecting oxygenation are presented in Table 35-1.

V/Q mismatch: decreased ventilation due to lung infection

Lung infections such as pneumonia decrease the available alveolar space for air to enter, thus deceasing the surface area available for gas exchange. This results in a decrease in oxygen and carbon dioxide diffusion (see Figure 35-11).

Decreased oxygen-carrying capacity

Haemoglobin carries 99% of the diffused oxygen to tissues (Brashers 2010a). Anaemia and inhalation of toxic substances decrease the oxygen-carrying capacity

TABLE 35-1 Physiological processes affecting oxygenation

Process	Effect on oxygenation
Airway obstruction	Limits delivery of inspired oxygen to alveoli
Anaemia	Decreases oxygen-carrying capacity of blood
Decreased chest wall motion (e.g. from musculoskeletal impairments)	Prevents lowering of diaphragm and reduces anteroposterior diameter of thorax on inspiration, reducing volume of air inspired
Fever, pregnancy, infection	Increases metabolic rate and tissue oxygen demand
High altitude	Atmospheric oxygen concentration is lower and inspiratory oxygen concentration decreases
Toxic inhalant	Decreases oxygen-carrying capacity of blood

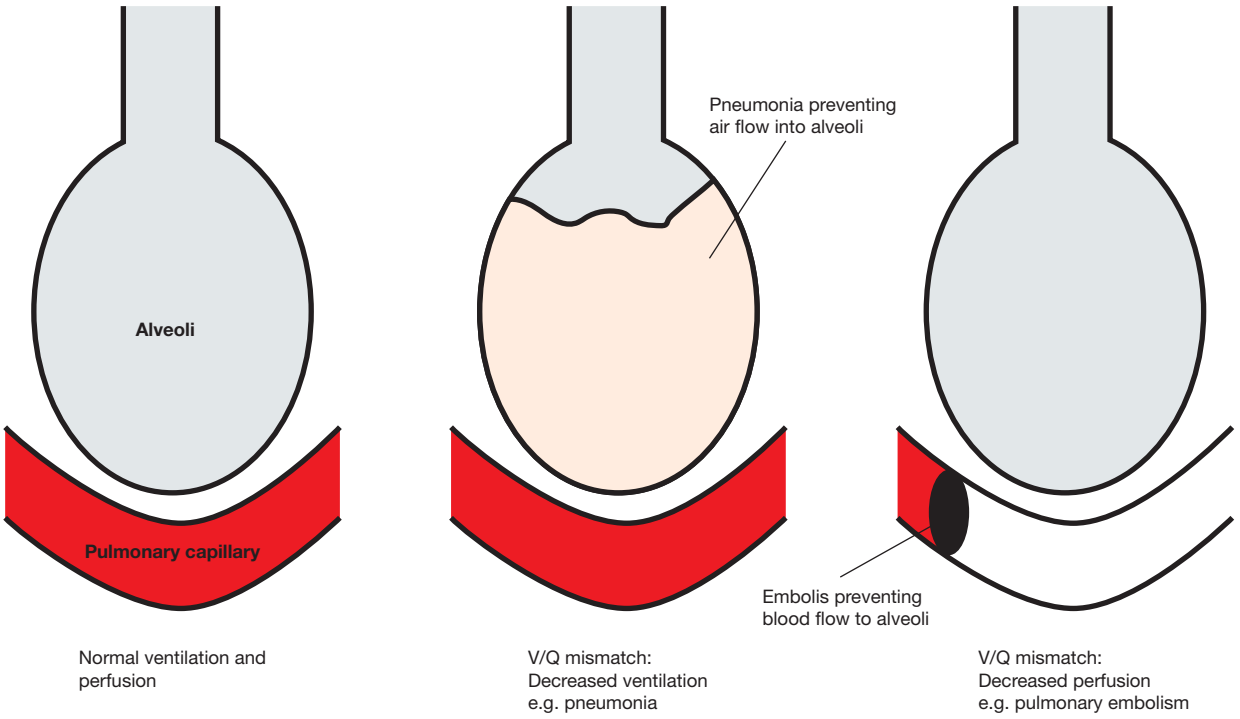

Figure 35-11 **How V/Q mismatch occurs.**

of blood by reducing the amount of available haemoglobin to transport oxygen. *Anaemia*, a lower than normal haemoglobin level, is a result of decreased haemoglobin production, increased red blood cell destruction and/or blood loss. Patients complain of fatigue, decreased activity tolerance and increased breathlessness, as well as pallor (especially seen in the conjunctiva of the eye) and an increased heart rate.

Carbon monoxide is the most common toxic inhalant that decreases the oxygen-carrying capacity of blood. The affinity for haemoglobin to bind with carbon monoxide is greater than 200 times its affinity to bind with oxygen, creating a functional anaemia. Because of the bond's strength, carbon monoxide is not easily dissociated from haemoglobin, making the haemoglobin unavailable for oxygen transport.

Decreased inspired oxygen concentration

When the concentration of inspired oxygen declines, the oxygen carried by the blood is decreased. Decreases in the fraction of inspired oxygen concentration (FiO_2) can be caused by an upper-airway obstruction (e.g. croup in the child) or lower-airway obstruction (e.g. COPD in the adult) limiting delivery of inspired oxygen to alveoli; decreased environmental oxygen, such as at high altitudes; or decreased inspiration as a result of an incorrect oxygen concentration setting on respiratory therapy equipment.

V/Q mismatch: decreased perfusion due to hypovolaemia

Conditions such as shock and severe dehydration resulting from extracellular fluid loss and reduced circulating blood volume cause **hypovolaemia**. With a significant fluid loss, the body tries to adapt by increasing the heart rate and peripheral vasoconstriction through sympathetic nervous system stimulation to increase the volume of blood returned to the heart and, in turn, increase the cardiac output. Consider the child with vomiting and diarrhoea from gastroenteritis. The nursing assessment will likely reveal a child who speaks minimally and is tachypnoeic (Airway and Breathing); pale, tachycardic with capillary refill greater than 3 seconds (Circulation); and is listless (Disability). The loss in circulating volume caused by the extreme fluid loss from the vomiting and diarrhoea means that preload and therefore stroke volume (SV) fall, dropping cardiac output (CO). Remember that CO = SV × HR. The sympathetic nervous system responds by increasing HR (*tachycardic*) and causing vasoconstriction which increases afterload (*pale and capillary refill greater than 3 seconds*), all to try to improve CO. At the same time, the respiratory centre is stimulated to increase respiratory rate (*tachypnoeic*) in an effort to deliver more oxygen. As CO has fallen, perfusion to the brain is diminished and so the child is *listless*.

Increased metabolic rate

Increases in metabolic activity result in an increased oxygen demand. When body systems are unable to meet this increased demand, the level of oxygenation declines. An increased metabolic rate is a normal physiological response to pregnancy, wound healing and exercise because the body is building tissue. Most people can meet the increased oxygen demand and do not display signs of oxygen deprivation. Fever increases the tissues' need for oxygen, and as a result carbon dioxide production also increases. If the febrile state persists, the metabolic rate remains high and the body begins to break down protein stores, resulting in muscle wasting and decreased muscle mass. Respiratory muscles such as the diaphragm and intercostal muscles are also wasted. The body attempts to adapt to the increased carbon dioxide levels by increasing the rate and depth of respiration. The patient's work of breathing increases and the patient eventually displays signs and symptoms of hypoxaemia. Those patients with pulmonary diseases are at greater risk of hypoxaemia and hypercapnoea due to V/Q mismatch and alveolar hypoventilation (see later in the chapter). Assessment findings include an increased rate and depth of respiration, use of the accessory muscles of respiration, pursed-lip breathing and decreased activity tolerance.

V/Q mismatch: decreased ventilation due to conditions affecting chest wall movement

Any condition that reduces chest wall movement can result in decreased ventilation. If the diaphragm cannot fully descend with breathing, the volume of inspired air decreases and less oxygen is delivered to the alveoli and subsequently to tissues. For example, thoracic or abdominal injury or surgery will cause considerable pain, which inhibits diaphragmatic and chest wall movement, reducing inspiration and therefore delivery of oxygen.

Pregnancy

As the fetus grows during pregnancy, the greater size of the uterus pushes abdominal contents upwards against the diaphragm. In the last trimester of pregnancy, the inspiratory capacity declines, resulting in dyspnoea on exertion and increased fatigue.

Obesity

Obese patients have reduced lung volumes from the heavy lower thorax and abdomen, particularly when in the recumbent and supine positions. Obese patients have a reduction in compliance as a result of encroachment of the abdomen into the chest, increased work of breathing and decreased lung volumes, and they may have fatigue and carbon dioxide retention. In some patients an obesity–hypoventilation syndrome develops in which oxygenation is decreased and carbon dioxide is retained, resulting in daytime sleepiness. The obese patient is also susceptible to pneumonia after an upper respiratory tract infection because the lungs cannot fully expand and pulmonary secretions are not mobilised in the lower lobes.

Musculoskeletal abnormalities

Musculoskeletal impairments in the thoracic region reduce oxygenation. Such impairments may result from abnormal structural configurations, trauma, muscular diseases and diseases of the central nervous system. Abnormal structural configurations impairing oxygenation include those that affect the rib cage, such as pectus excavatum (abnormal development of ribs causing caved in appearance), and those that affect the vertebral column, such as kyphosis.

Trauma

Two or more ribs fractured in two or more places results in a flail chest, a condition in which fractures cause instability in part of the chest wall. The unstable chest wall allows the lung underlying the injured area to contract on inspiration and bulge on expiration, resulting in hypoxia. Chest wall or upper abdominal incisions may also decrease chest wall movement as the patient uses shallow respirations to minimise chest wall movement to avoid pain. Narcotic analgesia, for example, morphine, is often prescribed to relieve the pain, thereby facilitating improved chest wall expansion. Should excessive or high doses of narcotic analgesics be administered, this may depress the respiratory centre in the brain, further decreasing respiratory rate and chest wall expansion and therefore decreasing oxygenation.

Neuromuscular diseases

Diseases such as muscular dystrophy affect oxygenation of tissues by decreasing the patient's ability to expand and contract the chest wall. Ventilation is impaired, and atelectasis, hypercapnoea and hypoxaemia can occur. Myasthenia gravis and Guillain-Barré syndrome affect respiratory functioning and result in alveolar hypoventilation (see later in the chapter). Myasthenia gravis interferes with the normal transmission of impulses from nerves to muscles, involving the whole body, including muscles of respiration. Guillain-Barré syndrome causes inflammation and paralysis of muscle groups, which usually results in an ascending pattern of paralysis. Respiratory muscles become paralysed as paralysis ascends to the thoracic region.

Central nervous system alterations

Diseases or trauma involving the medulla oblongata and spinal cord may result in impaired respiration. When the medulla oblongata (contains the respiratory centre) is affected, neural regulation of respiration is damaged and abnormal breathing patterns may develop. If the phrenic nerve is damaged, the diaphragm may not descend, thus reducing inspiratory lung volumes and causing hypoxaemia. Cervical trauma at vertebrae C3 to C5 can result in paralysis of the phrenic nerve. Spinal cord trauma below the fifth cervical vertebra usually leaves the phrenic nerve intact but damages nerves that innervate the intercostal muscles, preventing anteroposterior chest expansion.

Influences of chronic disease

Oxygenation can be decreased as a direct consequence of chronic disease. It can also be decreased as a secondary effect, as with anaemia. The physiological response to chronic hypoxaemia is the development of a secondary polycythaemia. This adaptive response is the body's attempt to increase the amount of circulating haemoglobin to increase the available oxygen-binding sites.

Alterations in cardiac functioning

Illnesses and conditions that affect cardiac rhythm, strength of contraction, blood flow through the atria and ventricles, myocardial blood flow and peripheral circulation cause alterations in cardiac functioning. Remember the following equation when learning about various cardiac conditions and how they affect normal functioning:

Cardiac output = Heart rate (HR) × Stroke volume (SV)

Factors affecting heart rate and rhythm will impact on overall cardiac function, such as disturbances in conduction and influence of hormones. Likewise factors affecting stroke volume, and therefore the three elements determining stroke volume: preload, afterload and contractility, will also affect cardiac function.

Please revise these elements before continuing here as this background knowledge is vital to understanding the pathophysiology of the cardiovascular system.

Disturbances in conduction

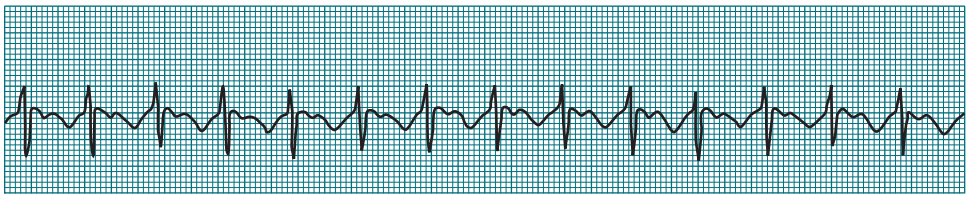
Some disturbances in conduction are a result of electrical impulses that do not originate from the SA node. These rhythm disturbances are called **arrhythmias**, meaning a deviation from the normal sinus rhythm. Some of the common arrhythmias are included in Table 35-2. As mentioned before, ECG interpretation of disease processes is an advanced nursing skill which is continually developed throughout your career and this chapter is designed as an introduction to this. However, all RNs need to be able to recognise normal sinus rhythm and knowledge of these common arrhythmias is a general requirement during your initial experience. Please pay particular attention to the imminently life-threatening arrhythmias. Arrhythmias may occur as a primary conduction disturbance as a response to ischaemia, valvular abnormality, anxiety or drug toxicity; caffeine, alcohol or tobacco use; or as a complication of acid–base or electrolyte imbalance (see Chapter 34).

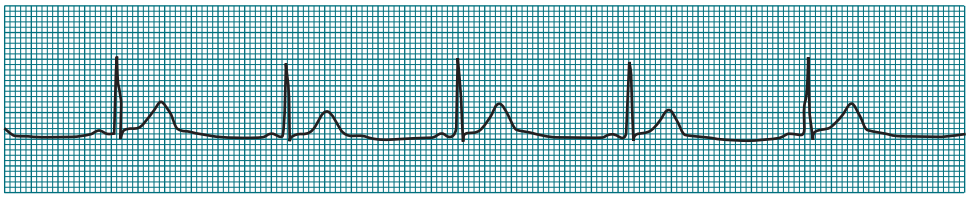
Arrhythmias are classified by site of impulse origin and mechanism of the cardiac response. Cardiac response can be one of *tachycardia* (> 100 beats per minute), *bradycardia* (< 60 beats per minute), a *premature (early) beat* or a *blocked (delayed or absent) beat*. Tachyarrhythmia can lower cardiac output and blood pressure. Tachyarrhythmia reduces cardiac output by decreasing diastolic filling time. Bradyarrhythmia lowers cardiac output because of the decreased heart rate.

Abnormal impulses originating above the ventricles are referred to as *supraventricular arrhythmias*. The abnormality of the waveform is the configuration and placement of the P wave. Ventricular conduction usually remains normal and a normal QRS complex is observed. Junctional arrhythmias represent an abnormal site of impulse conduction above or below the AV node. The P wave can occur before, during or after the QRS complexes and is often inverted if visible. Because the beat originates above the ventricle, ventricular conduction and the QRS complex are usually normal. One of the most common supraventricular arrhythmias is *atrial fibrillation* and occurs most frequently with ageing and in heart failure. There is disorganised chaotic depolarisation of the atria at a very rapid rate (400–600 beats/min) resulting in fibrillatory waves. Conduction of many of these beats is blocked at the AV node and conduction through the ventricle is usually normal. The ventricular rate varies but is usually quite rapid. Due to the lack of synchrony between atria and ventricles, thrombi can form in the atria, potentially causing a stroke when sinus rhythm is restored (Jacobson 2010b). Patients often require anticoagulation, usually with warfarin. A new anticoagulant, dabigatran, appears superior with fewer side effects (Talati & White 2011). Management focuses on either rate control or rhythm control, with neither approach holding an outcome advantage over the other (Van Gelder et al 2002, Wyse et al 2002).

Ventricular arrhythmias represent an ectopic site of impulse formation within the ventricles. The configuration

TABLE 35-2 Common cardiac arrhythmias

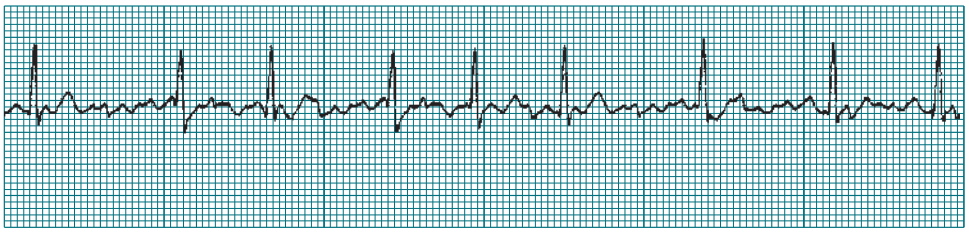
Rhythm characteristics	Aetiology	Clinical significance	Management
Sinus tachycardia			
Regular rhythm, rate 100–180 beats/min (higher in infants), normal P wave, normal QRS complex	Rate increase may be normal response to exercise, emotion or stressors such as pain, fever, heart failure, hyperthyroidism and certain drugs (e.g. caffeine, nitrates, atropine, adrenaline, isoprenaline, nicotine)	May have haemodynamic consequence in patient with damaged heart that is unable to sustain increased workloads (increased myocardial oxygen consumption) brought on by persistent increases in heart rate	Correct underlying factors, remove offending drugs
			


Sinus bradycardia			
Regular rhythm, rate less than 60 beats/min, normal P wave, normal P–R interval, normal QRS complex	Rate decrease may be normal response to sleep or in well-conditioned athlete; abnormal drops in rate may be caused by diminished blood flow to sinoatrial node, vagal stimulation (coughing, gagging, vomiting), hypothyroidism, increased intracranial pressure or pharmacological agents (e.g. digoxin, beta-blockers, calcium channel blockers)	No clinical significance unless associated with signs and symptoms of reduced cardiac output such as dizziness or syncope or presence of chest pain	Symptomatic bradycardia (hypotension with decreased cardiac output) is treated with atropine
			


Sinus arrhythmia			
Irregular rhythm; possibly phasic with respiration, slowing during inspiration and increasing with expiration; rate of 60–100 beats/min; normal P wave; normal P–R interval; normal QRS complex	Sinus rhythm with cyclic variation caused by vagal impulses that influence rhythm during respiration; occurs commonly in children, young adults and older adults; usually disappears as heart rate increases	No clinical significance unless heart rate decreases and symptoms of dizziness occur with decreased rate	None indicated unless heart rate decreases and symptoms occur
			

continued

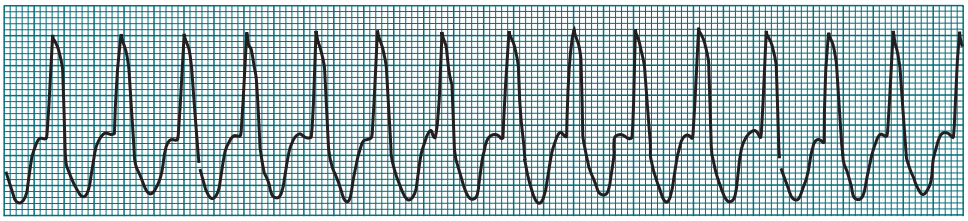
TABLE 35-2 ***continued***

Rhythm characteristics	Aetiology	Clinical significance	Management
Atrial fibrillation (AF)			
Irregularly irregular arrhythmia resulting from uncoordinated atrial activity. P waves are absent replaced by fibrillatory (F) waves which vary from wave to wave. Atrial rate 400–600 beats/min, ventricular rate varies 60–160 beats/min as atrioventricular blocks many of the impulses. P–R interval absent as no P waves, QRS usually normal	Prevalent in the elderly (9% in those over 80 years) Common cardiac causes include heart failure, hypertension, valvular disease Non-cardiac causes include alcohol (binge drinking), hyperthyroidism and chronic obstructive pulmonary disease	May have haemodynamic consequences of decreased cardiac output due to loss of synchrony between atria and ventricles. This loss of synchrony between atria and ventricles results in pooling of blood in the atria and the potential for thrombus formation leading to stroke. Thromboembolism and stroke from AF have significant morbidity and mortality	Management choices are rate control or rhythm control with no evidence that one approach is superior to another Rate-control drug choices include beta-blockers and digoxin. The patient should also be anticoagulated Rhythm control can be achieved electrically through elective cardioversion. The patient must first be anticoagulated to prevent thromboembolism. Rhythm-control drug choices include amiodarone and flecainide
			


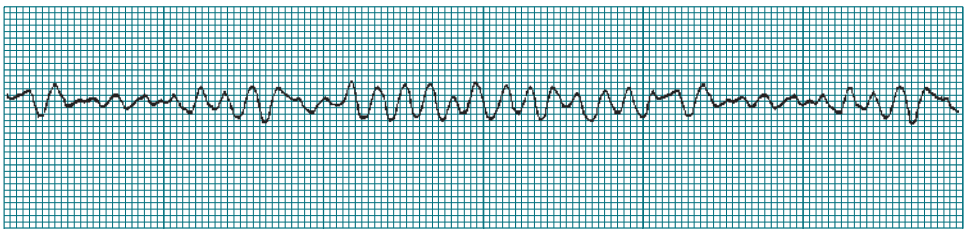
Premature ventricular contractions (PVCs)			
Irregular rhythm with ectopic beats followed by full compensatory pause; rate normal or increased, depending on number of ectopic beats; P wave absent in ectopic beat; P–R interval absent; QRS complex widened and distorted; T wave in opposition to R wave	Caused by irritable focus within ventricle, commonly associated with myocardial infarction; other causes include hypoxia, hypocalcaemia, acidosis	PVCs occurring frequently (more than 6/min) or in pairs, indicating increased ventricular irritability	Suppress PVCs; if PVCs are frequent, administer intravenous bolus of lignocaine 1–1.5 mg/kg IV push followed by continuous IV infusion; administer additional antiarrhythmic agents as needed; treat underlying cause
			
Ventricular tachycardia (VT)			
Rhythm slightly irregular, rate 100–200 beats/min, P wave absent, P–R interval absent, QRS complex wide and bizarre, > 0.12 second	Caused by irritable ventricular foci firing repetitively, commonly caused by ischaemic heart disease, trauma and underlying electrolyte abnormalities	Often a forerunner of ventricular fibrillation; if condition is persistent and rapid, causes decreased cardiac output because of decreased ventricular filling time VT can present with or without a clinically detectable cardiac output. VT without a clinically detectable cardiac output is referred to as pulseless VT	VT with a cardiac output: most episodes terminate abruptly without treatment; administer lignocaine bolus 1–1.5 mg/kg IV followed by continuous IV drip; cardioversion may be indicated Pulseless VT: proceed straight to defibrillation

continued

TABLE 35-2 ***continued***

Rhythm characteristics	Aetiology	Clinical significance	Management
			


Ventricular fibrillation (VF)			
Chaotic ventricular rhythm. P wave absent, P–R interval absent, QRS absent. Deflections from baseline undulate with different shape and amplitude	Commonly caused by ischaemic heart disease, electrolyte abnormalities, increased sympathetic nervous system activity, heart failure, hypertrophy	As there is no coordinated depolarisation of the ventricles, the myocardium does not contract and there is no cardiac output and therefore no pulse	VF is always a cardiac arrest situation – proceed straight to defibrillation
			



Aehlert B 2011 ECGs made easy, 4th edn. Mosby, St Louis; Australian Resuscitation Council (ARC) 2016 Guideline 8, cardiopulmonary resuscitation. ARC, Melbourne. Online. of the QRS complex is usually widened and bizarre. P waves may or may not be present; often they are buried in the QRS complex. Ventricular tachycardia and ventricular fibrillation are life-threatening arrhythmias that require immediate intervention. Ventricular tachycardia is considered a life-threatening arrhythmia because of the decreased cardiac output and the potential to deteriorate into ventricular fibrillation (Jacobson 2010b).

Altered cardiac output

Failure of the myocardium to eject sufficient volume to the systemic and pulmonary circulations can result in heart failure. Failure of the myocardial pump results from primary coronary artery disease, cardiomyopathic conditions, valvular disorders and pulmonary disease. Some of the common cardiac disorders are discussed here. It may be beneficial to review the cardiac anatomy and physiology before studying the following section to remind yourself of normal function and terminology.

Left-sided heart failure

Left-sided heart failure is an abnormal condition characterised by impaired functioning of the left ventricle due to elevated afterload. If left ventricular failure is significant, the amount of blood ejected from the left ventricle (stroke volume) drops greatly, resulting in decreased cardiac output. Consider the patient experiencing an acute episode of heart failure. The nursing assessment will likely reveal a person who speaks in phrases, is tachypnoeic, is using accessory muscles of respiration, has crackles on auscultation of lung fields, has low oxygen saturations (Airway and Breathing) and is hypotensive and tachycardic with capillary refill greater than 3 seconds (Circulation). As the left ventricle is unable to pump effectively and stroke volume and therefore CO is reduced (*hypotensive*), sympathetic nervous system stimulation increases HR (tachycardic) and causes vasoconstriction (*capillary refill greater than 3 seconds*) to compensate. The increased volume and therefore pressure in the left ventricle due to its ineffective pumping action causes the pressure to be reflected backwards into the pulmonary circulation. The increased pressure forces fluid out of the pulmonary circulation into the interstitium and alveoli (*crackles on auscultation*), impairing oxygenation (*low oxygen saturations*). The respiratory centre is stimulated, resulting in an increased respiratory rate (*tachypnoeic*) to compensate and try to deliver more oxygen. Other assessment findings may include decreased activity

tolerance, dizziness and confusion as a result of tissue hypoxia from the diminished cardiac output. Also, cough and paroxysmal nocturnal dyspnoea may be evident due to the pulmonary congestion.

Right-sided heart failure

Right-sided heart failure results from impaired functioning of the right ventricle characterised by venous congestion in the systemic circulation. Right-sided heart failure more commonly results from pulmonary disease or as a result of long-term left-sided failure (both of which cause an increased afterload on the right ventricle). The primary pathological factor in right-sided failure is elevated pulmonary vascular resistance (PVR), which increases afterload on the right ventricle. As the PVR continues to rise, the right ventricle must generate more work, and the oxygen demand of the heart increases. As the failure continues, the amount of blood ejected from the right ventricle declines, and blood begins to 'back up' in the systemic circulation. Clinically, the patient has weight gain due to fluid retention, distended neck veins, hepatomegaly and splenomegaly and dependent peripheral oedema.

Impaired valvular function

Valvular heart disease is an acquired or congenital disorder of a cardiac valve characterised by stenosis and obstructed blood flow or valvular degeneration and regurgitation of blood. When stenosis occurs in the semilunar valves (aortic and pulmonic valves), the adjacent ventricles must work harder to move the ventricular volume beyond the stenotic valve. Over time, the stenosis can cause the ventricle to hypertrophy (enlarge), and if the condition is untreated, left- or right-sided heart failure can occur. If stenosis occurs in the atrioventricular valves (mitral and tricuspid valves), the atrial pressure rises, causing the atria to hypertrophy. When regurgitation occurs, there is a backflow of blood into an adjacent chamber. For example, in mitral regurgitation the mitral leaflets do not close completely. When the ventricle contracts, blood escapes back into the atria, causing a murmur or 'whooshing' sound (see Chapter 24).

Myocardial ischaemia/ acute coronary syndrome

Myocardial ischaemia results when the supply of blood to the myocardium from the coronary arteries is insufficient to meet the oxygen demands of the organ. This is most often due to the development of atherosclerosis. Atherosclerotic plaque develops, narrowing the lumen of the coronary artery and leading to thrombus formation and eventually occlusion. Two common manifestations of this ischaemia are angina pectoris and myocardial infarction. These collectively are termed *acute coronary syndrome*. When a patient first presents with ischaemic type chest pain, the diagnosis of acute coronary syndrome is made until it is determined whether the presentation is angina pectoris or a myocardial infarction. This prevents delay in management.

Angina

Angina pectoris is usually a transient imbalance between myocardial oxygen supply and demand due to reversible myocardial ischaemia. The condition results in chest pain that is aching, sharp, tingling or burning, or that feels like pressure. The chest pain may be left-sided or substernal and may radiate to the left or both arms, and to the jaw, neck and back. In some patients, anginal pain may not radiate and may present atypically, such as with back pain or a more generalised pain; this is particularly common for women. Patients report that pain is often precipitated by activities that increase myocardial oxygen demand (e.g. exercise, anxiety or stress). The pain is usually relieved with rest and coronary vasodilators, the most common being a glyceryl trinitrate preparation.

Myocardial infarction

Myocardial infarction results from sudden decreases in coronary artery blood flow or an increase in myocardial oxygen demand without adequate coronary artery perfusion. Infarction occurs when ischaemia (which is reversible) remains untreated or inadequately treated or there is a complete blockage to one or more coronary arteries and results in necrosis (which is not reversible) of myocardial tissue.

Chest pain associated with myocardial infarction is usually described as crushing, squeezing or stabbing. The pain may be retrosternal and left praecordial, and it may radiate down the left arm to the neck, jaws, teeth, epigastric area and back. The pain occurs at rest or exertion, lasts more than 30 minutes and is unrelieved by rest, position change or sublingual glyceryl trinitrate administration.

Research indicates that there is a significant difference between men and women in relation to coronary artery disease. It is known that women do not always present the same type of symptoms as men (Miracle 2010). Symptoms are likely to be more subtle in women, with atypical presentation such as a sensation of indigestion, heaviness or general discomfort. Dyspnoea, fainting, nausea, fatigue and palpitations are also common symptoms in women. A first presentation of coronary artery disease in women is likely to be angina, while in men a first presentation is more likely to be a myocardial infarction (Miracle 2010). Oestrogen replacement in healthy postmenopausal

women may reduce and prevent coronary artery disease. Additional risk factors for coronary artery disease in women include menopause and hormonal contraceptives, such as birth-control pills.

Wanda Johnson is a 56-year-old postmenopausal woman with a history of hypertension. What would you include in the teaching portion of her plan of care?

Alterations in respiratory functioning

Illnesses and conditions that affect ventilation or oxygen transport cause alterations in respiratory functioning. The main alterations are ventilation/perfusion (V/Q) mismatch, diffusion impairment, alveolar hypoventilation, alveolar hyperventilation and hypoxia.

Alveolar hyperventilation

The goal of ventilation is to produce a normal arterial carbon dioxide tension ($PaCO_2$) between 35 and 45 mmHg and maintain a normal arterial oxygen tension (PaO_2) between 95 and 100 mmHg. Arterial oxygen levels can be monitored using a non-invasive oxygen saturation monitor. The normal range is 95–100%.

Alveolar hyperventilation is a state of ventilation in excess of that required to eliminate the normal venous carbon dioxide produced by cellular metabolism. Anxiety, infections, drugs or an acid–base imbalance can induce alveolar hyperventilation, as well as hypoxia associated with pulmonary embolus or shock. Acute anxiety can lead to alveolar hyperventilation and may cause loss of consciousness from excess carbon dioxide exhalation. Fever can cause alveolar hyperventilation. For each increase of 1°C there is a 12% increase in metabolic rate, thereby increasing carbon dioxide production. The clinical response is an increased rate and depth of respiration.

Alveolar hyperventilation may also be chemically induced. Salicylate (aspirin) poisoning causes excessive stimulation of the respiratory centre as the body attempts to compensate for excess carbon dioxide. Amphetamines also increase ventilation by raising carbon dioxide production. Alveolar hyperventilation can also occur as the body tries to compensate for metabolic acidosis by producing a respiratory alkalosis. For example, the patient with diabetes mellitus who has gone into diabetic ketoacidosis is producing large amounts of metabolic acids. The respiratory system tries to correct the acid–base imbalance by increasing the respiratory rate. Ventilation increases to reduce the amount of carbon dioxide available to form carbonic acid (see Chapter 34).

TABLE 35-3 Differentiating alveolar hyperventilation from hypoventilation

Hyperventilation	Hypoventilation
Features	
Mental status	Disorientation
Disorientation	Lethargy
Light-headedness	Dizziness
Dizziness	Headache

Tachycardia	Arrhythmias
Chest pain	Cardiac arrest
Shortness of breath	
Neurological signs and symptoms	
Blurred vision	
Paraesthesias	
Extremity and circumoral numbness	
Carpopedal spasm (tetany)	
Tinnitus	
Other	
Acid–base and electrolyte imbalances	Acid–base and electrolyte imbalances

Alveolar hyperventilation produces many signs and symptoms that can be assessed (Table 35-3). Haemoglobin does not release oxygen to tissues as readily, and tissue hypoxia results. As symptoms worsen, the patient may become more agitated, which further increases the respiratory rate and can result in respiratory alkalosis.

Alveolar hypoventilation

Alveolar hypoventilation occurs when alveolar ventilation is inadequate to meet the body's oxygen demand or to eliminate sufficient carbon dioxide. As alveolar ventilation decreases, $PaCO_2$ is elevated (hypercapnoea). Severe atelectasis can produce alveolar hypoventilation. **Atelectasis** is a collapse of the alveoli that prevents normal diffusion of oxygen and carbon dioxide. As alveoli collapse, less of the lung can be ventilated and alveolar hypoventilation occurs.

Patients with chronic obstructive pulmonary disease (COPD) have a progressive deterioration of the airways, leading to a loss of lung function resulting in alveolar hypoventilation. COPD is an umbrella term which

includes the two conditions: chronic bronchitis and emphysema. Some people with COPD have a chronically elevated $PaCO_2$ and low PaO_2. In this instance, the central chemoreceptors primarily responsible for detecting changes in pH (and $PaCO_2$) are less sensitive, and peripheral chemoreceptors are now the primary stimulus to ventilation. Remember that peripheral chemoreceptors are more sensitive to oxygen than carbon dioxide (Brashers 2010a). A small percentage of these patients in response to supplemental oxygen will experience a significant elevation in $PaCO_2$, which causes drowsiness and lethargy. This is known as *hypercapnoeic encephalopathy* or *CO_2 narcosis* (Simmons & Simmons 2004). To avoid this complication, supplemental oxygen therapy should be titrated to achieve oxygen saturations of 88–92% (Beasley et al 2011).

Signs and symptoms of alveolar hypoventilation are presented in Table 35-3. If untreated, the patient's status can rapidly decline. Convulsions, unconsciousness and death can result. Treatment for alveolar hyperventilation and alveolar hypoventilation requires improving tissue oxygenation, restoring ventilatory function, treating the underlying cause and achieving acid–base balance.

Ventilation/perfusion mismatch

For oxygenation to occur, both adequate ventilation (airflow into the alveoli) and adequate perfusion (blood flow to the alveoli) are needed. This is termed the ventilation/perfusion (V/Q) ratio and is normally approximately 4 : 5 (ventilation 4 L/min : perfusion 5 L/min). If there is impairment with either mechanism, a V/Q mismatch occurs. The patient with pneumonia will have V/Q mismatch due to impaired ventilation, as the alveoli are blocked with secretions and pus; a patient with a pulmonary embolism will have a V/Q mismatch due to impaired perfusion as the embolism is blocking blood flow to a region of the lungs. The overall result is a lowering of oxygen (Pierce 2007). See Figure 35-11 for a visual illustration of the V/Q mismatch.

Diffusion impairment

The rate of diffusion of oxygen can be affected by the thickness of the alveolar–capillary membrane and the available surface area for diffusion. Increased thickness of the membrane impedes diffusion because oxygen takes longer to diffuse across the membrane. Patients with pulmonary oedema or pneumonia have an increased thickness of the alveolar–capillary membrane, resulting in slowed diffusion, slowed exchange of oxygen and impaired delivery of oxygen to tissues. The surface area of the membrane can be altered as a result of a chronic disease (e.g. emphysema), an acute disease (e.g. pneumothorax) or a surgical process (e.g. lobectomy). The alveolar–capillary membrane can be destroyed or may thicken, changing the rate of diffusion. When fewer alveoli are functioning, the surface area is decreased. This alteration in membrane thickness and/or surface area which results in impaired gas exchange is termed **diffusion impairment** (Pierce 2007).

Tissue hypoxia

Hypoxia is inadequate tissue oxygenation at the cellular level. This can result from a deficiency in oxygen delivery or oxygen utilisation at the cellular level. Hypoxia can be caused by:

1. a decreased haemoglobin level and lowered oxygen-carrying capacity of the blood
2. a diminished concentration of inspired oxygen, which may occur at high altitudes
3. the inability of the tissues to extract oxygen from the blood, as with cyanide poisoning
4. diffusion impairment as in pneumonia
5. poor tissue perfusion with oxygenated blood, as with shock
6. V/Q mismatch as with multiple rib fractures or chest trauma.

The clinical signs and symptoms of hypoxia include apprehension, restlessness, inability to concentrate, a declining level of consciousness, dizziness and behavioural changes (Box 35-4). The patient with a narcotic overdose, such as a heroin overdose, which depresses the respiratory centre leading to a decreased ventilatory drive, may display signs of alveolar hypoventilation. During early stages of hypoxia, the blood pressure is elevated unless the condition is caused by shock. As the hypoxia worsens, the respiratory rate may decline as a result of respiratory muscle fatigue.

Cyanosis, blue discolouration of the skin and mucous membranes caused by the presence of desaturated haemoglobin in capillaries, is a late sign of hypoxia. The presence or absence of cyanosis is not a reliable measure of oxygenation status. Central cyanosis, observed in the tongue, soft palate and conjunctiva of the eye, where blood flow is high, indicates hypoxaemia. Peripheral cyanosis, seen in the extremities, nail beds and earlobes, is often a result of vasoconstriction and stagnant blood flow.

Hypoxia is a life-threatening condition. Untreated, it can lead to metabolic acidosis due to anaerobic metabolism which can produce fatal cardiac arrhythmias. Hypoxia is managed by administration of oxygen and treatment of the underlying cause, such as airway obstruction.

BOX 35-4 Tissue hypoxia – signs and symptoms

Restlessness
Apprehension, anxiety
Disorientation
Decreased ability to concentrate
Decreased level of consciousness
Increased fatigue
Dizziness
Behavioural changes
Increased pulse rate
Increased rate and depth of respiration
Elevated blood pressure
Cardiac arrhythmias
Pallor
Cyanosis
Clubbing
Dyspnoea
Hypoventilation

Paediatric cardinal signs

Restlessness
Irritability
Increased rate of respiration
Increased pulse rate
Profuse sweating
Nasal flaring
Intercostal, subcostal recession
Tracheal tug
Grunt on expiration
Head bobbing

Developmental factors

The developmental stage of the patient and the normal ageing process can affect tissue oxygenation.

Premature infants

Premature infants are at risk of respiratory distress syndrome (previously known as hyaline membrane disease), which is caused by a surfactant deficiency. The surfactant-synthesising ability of the lungs develops late in pregnancy, around the seventh month, and may therefore be lacking in preterm infants (Wheeler 2009).

Infants and toddlers

Maternal antibodies provide protection from infection in the infant under 3 months of age. Infants and toddlers are at risk of upper respiratory tract infections as a result of frequent exposure to other children and exposure to secondhand smoke. In addition, during the teething process some infants develop nasal congestion, which encourages bacterial growth and increases the potential for respiratory tract infection. Upper respiratory tract infections are usually not dangerous, and infants or toddlers recover with little difficulty. Common airway infections are nasopharyngitis (e.g. rhinoviruses, respiratory syncytial virus and adenovirus), pharyngitis (e.g. viral and beta-haemolytic streptococci), *Haemophilus influenzae* infection and tonsillitis. Airway obstruction can also occur with aspirated foreign objects, such as food, buttons and lollies. Airways are smaller in younger children and can narrow considerably from oedema of mucous membranes accompanying an infection. The chest wall is thin and therefore very compliant, and accessory muscles of respiration are poorly developed. Both of these characteristics limit the child's ability to increase depth of breathing or tidal volume, the volume of air in a breath. Consequently, tachypnoea is a characteristic response to illness (Kendrick & Morrison 2007, Wilson 2009).

School-age children and adolescents

School-age children and adolescents are exposed to respiratory infections and respiratory risk factors such as second-hand smoke and cigarette smoking. A healthy child usually does not have adverse pulmonary effects from respiratory infections. A person who starts smoking in adolescence and continues to smoke into middle age, however, has an increased risk of cardiopulmonary disease and lung cancer.

Young and middle-aged adults

Young and middle-aged adults are exposed to multiple cardiopulmonary risk factors: an unhealthy diet, lack of exercise, stress, occupational hazards, drugs and smoking. Reducing these modifiable factors may decrease the patient's risk of cardiac or pulmonary diseases. This is also the time when lifelong habits and lifestyles are established. It is important to help these patients make good choices and informed decisions about the rest of their lives and their healthcare practices.

Older adults

The cardiac and respiratory systems undergo changes throughout the ageing process. In the arterial system, atherosclerotic plaques develop and the systemic blood pressure may rise. Chest wall compliance is decreased in the older adult as a result of osteoporosis and calcification of the costal cartilages. The respiratory muscles weaken, and the pulmonary vascular circulation becomes less

distensible (see *Working with diversity*). The trachea and large bronchi become enlarged from calcification of the airways, and alveoli enlarge, decreasing the surface area available for gas exchange. In addition, the number of functional cilia is reduced. Decreased ciliary action and effectiveness of cough mechanisms put the older adult at increased risk of respiratory infections (Ebersole et al 2008). Ventilation and diffusion of oxygen and carbon dioxide decline with age. Osteoporotic changes of the thoracic cage and kyphosis of the vertebrae occur normally with ageing (Jet 2008). With these changes the lungs are unable to expand fully, leading to lower oxygenation levels (Table 35-4).

WORKING WITH DIVERSITY

Focus on older adults

- Older adults generally have a respiratory rate between 16 and 25 breaths per minute. Positioning can greatly affect the older adult as they depend on changes in intra-abdominal pressure. Position the patient to maximise ventilation. Positions such as semi-Fowler's and high-Fowler's provide the best ventilation. The older patient should be encouraged to sit up in the chair to promote good lung expansion.
- Frequent, smaller meals and fewer bloating and gas-producing foods will help prevent an over-distended abdomen and reduce pressure on the diaphragm.
- Obese patients may need to sleep in semi-Fowler's position.

TABLE 35-4 Changes in the ageing lung

Function	Pathophysiological change	Key clinical findings
Breathing mechanics	Decreased chest wall compliance Decreased pulmonary compliance Loss of elastic recoil Decreased respiratory muscle mass and strength Uneven alveolar ventilation	Decreased thoracic wall excursion Decreased vital capacity Increased residual volume Decreased forced expiratory volume Decreased airway clearance (coughing)
Oxygenation	Increased physiological dead space Ventilation/perfusion mismatch Decreased alveolar surface area Decreased carbon dioxide diffusion capacity	Decreased arterial partial pressure of oxygen (PaO_2) Increased alveolar–arterial oxygen gradient
Ventilation control and breathing pattern	Decreased responsiveness of central and peripheral chemoreceptors to hypoxaemia and hypercapnia	Decreased tidal volume Increased respiratory rate Increased minute ventilation Decreased airway clearance
Lung defence mechanisms	Decreased number of cilia and effectiveness of the mucociliary clearance Decrease in mucous production Diminished cough reflex Decreased T-cell function Decreased immunoglobulin A (IgA) production	Increased risk of infection Thickened secretions Increased risk of aspiration
Sleep and breathing	Decreased ventilatory drive Decreased tone of upper airway muscles Decreased arousal	Increased risk of apnoea, hypopnoea and arterial oxygen desaturation during sleep Increased risk of aspiration Snoring Obstructive sleep apnoea
Exercise capacity	Muscle deconditioning and efficiency Decreased muscle mass Decreased reserves	Decreased maximum oxygen consumption Breathlessness at low exercise levels

Modified from Pierson DJ 1992 Effects of aging on the respiratory system. In Pierson DJ, Kacmarek RM (eds) Foundations of respiratory care. Churchill Livingstone, New York; Criddle LM 2009 Caring for the critically ill elderly patient. In Carlson KK (ed) 2009 Advanced critical care nursing. Saunders, St Louis.

Lifestyle factors

Lifestyle factors that influence cardiopulmonary functioning include nutrition, exercise, cigarette smoking, substance abuse and stress (Box 35-5).

Nutrition

Nutrition affects cardiopulmonary function in several ways. Severe obesity decreases lung expansion, and the increased bodyweight increases oxygen demands to meet metabolic needs. The malnourished patient may experience respiratory muscle wasting, resulting in decreased muscle strength and respiratory excursion. Cough efficiency is reduced secondary to respiratory muscle weakness, putting the patient at risk of retention of pulmonary secretions. Diets high in fat increase cholesterol and atherogenesis in the coronary arteries.

Patients who are obese and/or malnourished are at risk of anaemia. Diets high in carbohydrates may play a role in increasing the carbon dioxide load for patients with carbon dioxide retention. As carbohydrates are metabolised, an increased load of carbon dioxide is created and excreted via the lungs.

Restricting dietary sodium levels to below 75 mmol/day can reduce blood pressure by 4–5 mmHg in hypertensive patients. The effect is more marked in systolic blood pressure and on standing, and is greater in the elderly and in severely hypertensive patients (National Heart Foundation of Australia 2006a).

Potassium supplements can also lower blood pressure in people with moderate to severe hypertension. Potassium supplements should not normally be used with potassium-sparing diuretics or angiotensin-converting enzyme (ACE) inhibitors or in patients with renal insufficiency (National Heart Foundation of Australia 2006a).

BOX 35-5 Cardiopulmonary health promotion*

- Maintain ideal bodyweight.
- Eat a low-fat, low-salt, kilojoule-appropriate diet.
- Monitor cholesterol and triglyceride levels.
- Engage in regular aerobic exercise.
- Use stress-reduction techniques.
- Be smoke-free.
- Avoid secondhand smoke and other pollutants.
- Use a filter mask when exposed to occupational hazards.
- Monitor blood pressure.
- Get an annual influenza vaccine if at risk of developing influenza.
- Get a pneumococcal vaccine if appropriate.
- Reduce exposure to secondary infections.

* Target population: young to older adults.

Exercise

Exercise increases the body's metabolic activity and oxygen demand. The rate and depth of respiration increase, enabling the person to inhale more oxygen and exhale excess carbon dioxide. A physical exercise program has many benefits (see Chapter 28). People who exercise 3–4 times per week for 20–40 minutes have a lower pulse rate and blood pressure, decreased cholesterol level, increased blood flow and greater oxygen extraction by working muscles. In addition to the effects on blood pressure, exercise training has the potential to make people feel better, will facilitate weight reduction in the obese and has metabolic benefits (National Heart Foundation of Australia 2006b).

Cigarette smoking

Cigarette smoking is associated with a number of diseases, including heart disease, COPD and lung cancer. Cigarette smoking can worsen peripheral vascular and coronary artery diseases (National Heart Foundation of Australia 2009). Inhaled nicotine causes vasoconstriction of peripheral and coronary blood vessels, increasing blood pressure and decreasing blood flow to peripheral vessels. The risk of lung cancer is 10 times greater for a person who smokes than for a non-smoker. Exposure to secondhand smoke increases the risk of lung cancer in the non-smoker. While lung cancer rates among men are falling, the rates among women continue to rise. Women who take oral contraceptive pills and smoke cigarettes are at increased risk of cardiovascular problems such as thrombophlebitis and pulmonary emboli (Cancer Council New South Wales 2005).

Substance abuse

Excessive use of alcohol and other drugs can impair tissue oxygenation in two ways. First, the person who chronically abuses substances often has a poor nutritional intake. With the resultant decrease in intake of iron-rich foods, haemoglobin production declines. Second, excessive use of alcohol and certain other drugs can depress the respiratory centre, reducing the rate and depth of respiration and the amount of inhaled oxygen. Substance abuse, by either smoking or inhaling substances such as crack cocaine or inhaling fumes from paint or glue cans, causes direct injury to lung tissue that can lead to permanent lung damage and impaired oxygenation.

Stress/anxiety

A continuous state of stress or severe anxiety increases the body's metabolic rate and the oxygen demand. The body responds to anxiety and other stresses with an increased rate and depth of respiration. Most people can adapt, but some, particularly those with chronic illnesses or acute life-threatening illnesses such as a myocardial infarction, cannot tolerate the oxygen demands associated with anxiety.

Environmental factors

The environment can also influence oxygenation. The incidence of pulmonary disease is higher in smoggy, urban areas than in rural areas. In addition, a person's workplace may increase the risk of pulmonary disease. Occupational pollutants include asbestos, talcum powder, dust and airborne fibres. For example, agricultural workers are exposed to airborne grain dust, pesticides and microorganisms. Asbestosis is an occupational lung disease that develops after exposure to asbestos. The lung in asbestosis is characterised by diffuse interstitial fibrosis, creating a restrictive lung disease. It can also cause pleural mesotheliomas and pleural plaques. People at risk of developing asbestosis include those working with textiles, fireproofing or milling, or in the production of paints, plastics or some prefabricated construction. People exposed to asbestos who also smoke are at increased risk of developing lung cancer.

CLINICAL REASONING PROCESS

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical-thinking attitudes, and intellectual and professional standards. Nursing practice occurs often in unpredictable and dynamic environments. Clinical judgements and decisions need to reflect this; they are dynamic and require nurses to anticipate the information necessary, analyse the data and make decisions regarding the patient. During assessment nurses must consider all elements that build towards identifying appropriate nursing problems (Figure 35-12).

When considering a patient with a primary cardiovascular problem, to understand the oxygen demands of a patient and the ability of the patient's body to meet those demands, the

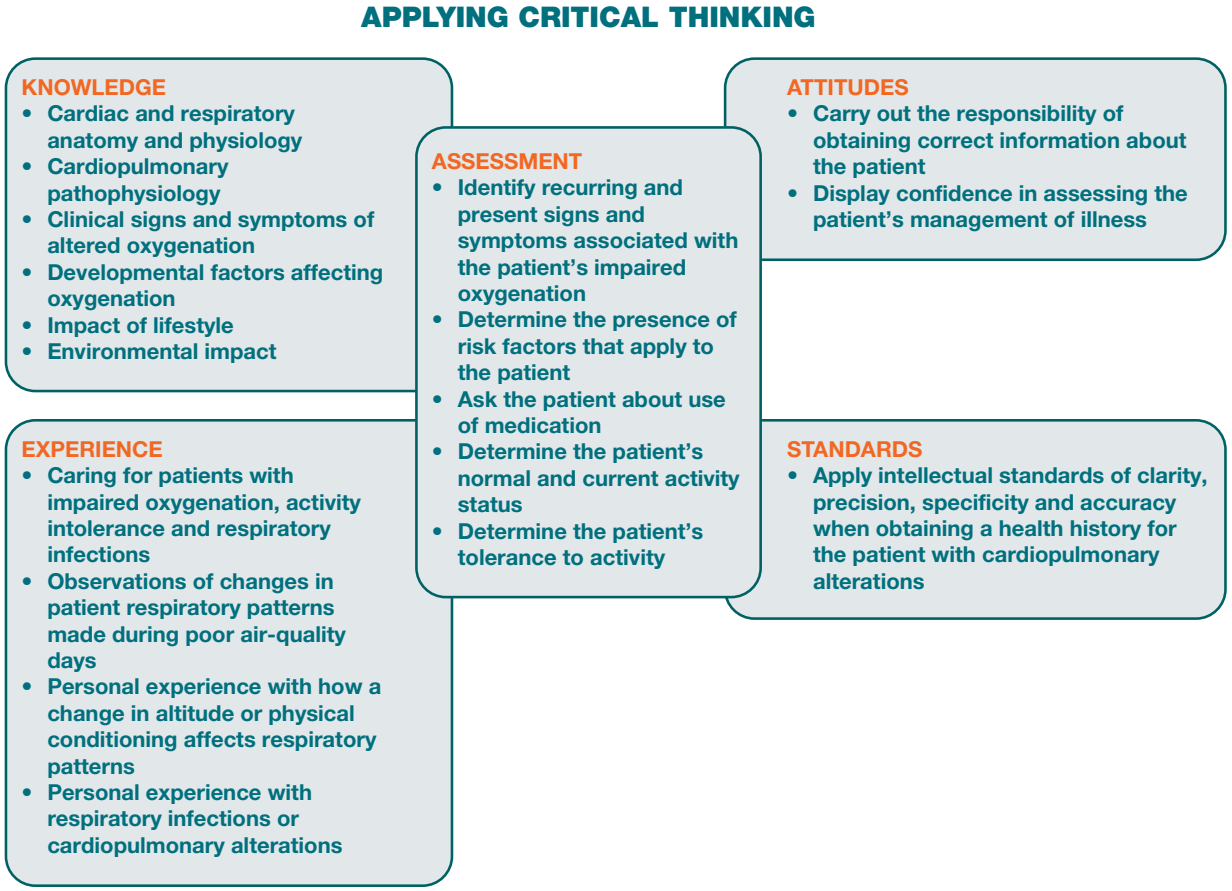

Figure 35-12 **Critical thinking associated with the assessment phase for oxygenation.**

nurse integrates knowledge from nursing and other disciplines, previous experiences, and information gathered from patients. Nurses must consider current and future oxygenation demands, plan for change in patient status and develop a plan that can change with the changing demands of the patient. The use of resources such as those supplied by the Cancer Council, the National Heart Foundation of Australia, the Australian Safety and Compensation Council and Asthma Australia, along with the guidelines set by professional bodies, are valuable in the care, education and management of patients with altered oxygenation.

The possession of sound clinical reasoning skills to provide safe, effective and excellent evidence-based care is a cornerstone of the profession.

GATHERING RELEVANT INFORMATION AND DATA

The nursing assessment of a patient's cardiopulmonary functioning should include data collected from the following areas:

- nursing history of the patient's normal and present cardiopulmonary function, past impairments in circulatory or respiratory functioning, and measures that the patient may use to optimise oxygenation
- physical examination of the patient's cardiopulmonary status, including inspection, palpation, percussion and auscultation
- review of laboratory and diagnostic test results, including a full blood count, ECG, pulmonary function test, sputum, and oxygenation such as arterial blood gas tests or pulse oximetry.

Nursing history

The nursing history should focus on the patient's ability to meet oxygen needs. The nursing history for cardiac function includes pain and characteristics of pain, dyspnoea, fatigue, peripheral circulation, cardiac risk factors and the presence of past or concurrent cardiac conditions. The nursing history for *respiratory function* includes the presence of a cough, sputum production, shortness of breath, changes in exercise tolerance, wheezing, pain, environmental exposure, frequency of respiratory tract infections, pulmonary risk factors, past respiratory problems, current medication use and smoking history or secondhand smoke exposure.

Fatigue

Fatigue is a subjective sensation in which the patient reports a loss of endurance. Fatigue in the patient with cardiopulmonary alterations is often an early sign of a worsening of the chronic underlying process. There are numerous fatigue scoring tools available, most of which require further research for validation. A visual analogue fatigue scale is a simple and quick tool to use. This rates fatigue on a scale of 0–10, with 10 being the worst level of fatigue and 0 representing no fatigue. Other short tools which have good psychometric properties are the Fatigue Severity Scale, the Fatigue Impact Scale and the Brief Fatigue Inventory (Whitehead 2009).

Dyspnoea

Dyspnoea is a clinical sign of hypoxia and manifests as breathlessness. It is the subjective sensation of difficult or uncomfortable breathing. *Physiological dyspnoea* is shortness of breath associated with exercise or excitement. *Pathological dyspnoea* is the inability to catch a breath without relation to activity or exercise.

Dyspnoea can be associated with clinical signs such as exaggerated respiratory effort, use of the accessory muscles of respiration, nasal flaring and marked increases in the rate and depth of respirations. There are a number of dyspnoea scoring tools available; two validated tools include the Modified Medical Research Council (MMRC) Dyspnoea Scale and the Modified Borg Scale (Australian Lung Foundation 2009). The Modified Borg Scale is an easy-to-use 10-point scale with descriptors to quantify the severity of breathlessness, and can be used to determine the effect of treatment (Australian Lung Foundation 2009) (Box 35-6). The Modified Borg Scale is an effective tool to assess the dyspnoea associated with heart failure and COPD.

The nursing history of dyspnoea includes the circumstances under which it occurred, such as with exertion, stress or respiratory tract infection. The extent to which dyspnoea affects the patient's activities of daily living should also be assessed. Nurses also determine whether the patient's perception of dyspnoea affects the ability to lie flat. **Orthopnoea** is an abnormal condition in which the person must use multiple pillows when preparing for sleep and rest or must sit with the arms elevated and leaning forward to breathe. The number of pillows required for sleeping, such as two or three, usually quantifies the presence of orthopnoea.

Cough

A cough is a sudden, audible expulsion of air from the lungs. The person breathes in, the glottis is partially closed and the accessory muscles of expiration contract to expel the air forcibly. Coughing is a protective reflex to clear the trachea, bronchi and lungs of irritants and secretions. The carina, the point of bifurcation of the right and left mainstem bronchi, is the most sensitive area for cough production. A cough is difficult to evaluate, and almost everyone has periods of coughing. Patients with a chronic cough tend to deny, underestimate or minimise their coughing, often because they are so accustomed to it that they are unaware of how often it occurs.

BOX 35-6 Borg Scale – breathlessness

7	Very severe
8	
9	Very, very severe
10	Maximal

Borg CR10 Scale®. © Gunnar Borg. To obtain the scale with correct instructions see http://www.borgperception.se/

Coughing is classified according to the time when the patient most frequently coughs. Patients with chronic sinusitis may cough only in the early morning or immediately after rising from sleep. This clears the airway of mucous resulting from sinus drainage occurring overnight in sleep. Patients with chronic bronchitis generally produce sputum all day, although greater amounts are produced after rising from a semi-recumbent or supine position. This is as a result of the dependent accumulation of sputum in the airways and is associated with reduced mobility (see Chapter 28).

Once the nurse determines that the patient has a cough, it must be identified as productive or non-productive and its frequency must be assessed. A productive cough results in the patient producing sputum, material coughed up from the lungs that may be swallowed or expectorated. Sputum contains mucous, cellular debris and microorganisms, and it may contain pus or blood. Nurses must collect data about the type and quantity of sputum (Box 35-7). The patient is instructed to try to produce some sputum, being careful not to simply clear the throat to produce a sample of saliva. Sputum should not be collected after meals, as the specimen may be contaminated by food. Nurses then inspect it for colour, consistency, odour and amount. The patient is asked about the amount of sputum produced in a day, using household measures to estimate amounts (teaspoon, tablespoon, cupful).

If **haemoptysis** (bloodstained sputum) is reported, the nurse determines if it is associated with coughing and bleeding from the upper respiratory tract, from sinus drainage or from the gastrointestinal tract (**haematemesis**). In addition, the haemoptysis should be described according to amount, colour and duration and whether it is mixed with sputum. When a patient reports bloody or blood-tinged sputum, diagnostic tests, such as examination of sputum specimens, chest X-ray examinations, bronchoscopy and other X-ray studies, should be performed.

Decreased

Consistency
Frothy
Watery
Tenacious, thick

Presence of blood
Occasional
Early morning
Bright or dark red
Blood-tinged

Wheezing

Wheezing is characterised by a high-pitched musical sound caused by high-velocity movement of air through a narrowed airway. Wheezing may be associated with asthma, acute bronchitis or pneumonia. Wheezing can occur on inspiration, expiration or both. Nurses should determine any precipitating factors, such as respiratory infection, allergens, exercise or stress.

Pain

The presence of chest pain needs to be thoroughly evaluated with regard to location, duration, radiation and frequency. Cardiac pain does not occur with respiratory variations and is most often on the left side of the chest and radiates to the left arm in men. Chest pain in women is much less definitive and may be a sensation of choking, breathlessness or pain that radiates through to the back. Pericardial pain resulting from an inflammation of the pericardial sac is usually non-radiating and may occur with inspiration.

Pleuritic chest pain is peripheral and may radiate to the scapular regions. It is worsened by inspiratory manoeuvres, such as coughing, yawning and sighing. Pleuritic pain is often caused by an inflammation or infection in the pleural space and is described as knife-like, lasting from a minute to hours and always in association with inspiration.

Musculoskeletal pain may be present following exercise, rib trauma and prolonged coughing episodes. This pain is also aggravated by inspiratory movements and may easily be confused with pleuritic chest pain.

Environmental or geographical exposures

Environmental exposure to many inhaled substances is closely linked to respiratory disease. Nurses should investigate exposure in the patient's home and workplace. The most common environmental exposures in the home are cigarette smoke and carbon monoxide. Nurses should determine whether a patient who is a non-smoker is passively exposed to smoke. Carbon monoxide poisoning can result from a blocked flue or chimney or from a poorly maintained heater. The patient may have vague complaints of general malaise, flu-like symptoms and excessive sleepiness. People are particularly at risk in the late autumn when central heating or other heating devices are used or they begin to use a fireplace again.

An employment history is obtained to assess exposure to substances such as asbestos, coal, cotton fibres, fumes or chemical inhalants. This is particularly important with middle-aged and older adults, who may have worked in places without regulations to protect workers from carcinogens, such as asbestos.

Exposure to substances may occur during travel. Severe acute respiratory syndrome (SARS) is an infection of the respiratory system that causes about 10% fatality. From its inception in China, it subsequently spread to many South-East Asian countries and threatened Australia and New Zealand.

Respiratory infections

A nursing history should contain information about the patient's frequency and duration of respiratory tract infections. Although everyone occasionally experiences a cold, for some people it can result in bronchitis or pneumonia. On average, people will have four colds per year. Nurses should determine if the patient has had a pneumococcal or flu vaccine in the past and should also

RESEARCH HIGHLIGHT

Research focus

For many years, clinicians (both nursing and medical) believed that patients with chronic obstructive pulmonary disease (COPD) would stop breathing if given oxygen or too much oxygen. This was related to the hypoxic drive theory, which has been disproven. Despite the theory being disproven, some clinicians continued to follow this belief (Simmons & Simmons 2004). On the other hand, other clinicians administered high concentrations of oxygen, desiring to avoid the significant risks associated with hypoxia (Beasley et al 2011). However, research has shown that high concentrations of oxygen in some patients with COPD can significantly increase carbon dioxide levels, resulting in drowsiness and lethargy, termed hypercapnoeic encephalopathy or CO_2 narcosis. The British Thoracic Society therefore developed guidelines for administration of oxygen to patients with COPD, recommending titration of oxygen to achieve oxygen saturation levels of 88–92% (O'Driscoll et al 2008). These guidelines have not been widely adopted. Researchers hypothesised that the poor uptake of the guidelines may be related to the lack of clear evidence of benefit for titrated oxygen (Austin et al 2010).

Research abstract

A randomised controlled trial was conducted to compare high-flow oxygen therapy with titrated oxygen therapy for patients with an acute exacerbation of COPD (Austin et al 2010). The setting was Hobart, Tasmania. A total of 405 patients with a presumed diagnosis of COPD participated in the trial: 226 patients received high-flow oxygen, while 179 received oxygen titrated to an oxygen saturation level of 88–92%. Titrated oxygen is any inspired oxygen concentration that achieves a patient oxygen saturation level of 88–92%. Mortality was 9% for those patients receiving high-flow oxygen and 4% for those patients receiving titrated oxygen. Of those patients who were proven to have COPD confirmed by lung-function testing, mortality was 9% in the high-flow oxygen group and 2% in the titrated oxygen group.

Also, the COPD patients who received titrated oxygen were less likely to have a respiratory acidosis or hypercapnoea. Overall, the use of titrated oxygen significantly reduced mortality for COPD patients. Mortality was also significantly reduced for those patients with breathlessness but who did not have COPD (Austin et al 2010).

Evidence-based practice

- Titrated oxygen therapy to achieve an oxygen saturation level of 88–92% should be administered to all patients with COPD.
- Nurses should closely monitor oxygen saturations, increasing or decreasing inspired oxygen to achieve the target oxygen saturation.
- Education plans should be developed to effect this change in practice. This should include identification of facilitators and barriers to implementation. Education strategies should optimise facilitators and overcome barriers.

ask about any known exposure to tuberculosis and the results of the tuberculin skin test.

The patient's risk of human immunodeficiency virus (HIV) infection is also determined. Patients with a history of intravenous (IV) drug use and multiple unprotected sexual partners are at risk of developing HIV infection. Patients may not display any symptoms of HIV infection until they present with *Pneumocystis carinii* (PCP) or *Mycoplasma pneumoniae*. Presentation with PCP or *Mycoplasma pneumoniae* indicates a significant depression of the patient's immune system and progression to acquired immune deficiency syndrome (AIDS).

Risk factors

Nurses must also investigate familial and environmental risk factors, such as a family history of lung cancer or cardiovascular disease. Documentation should include which blood relatives have had the disease and their present level of health or age at time of death. Other family risk factors include the presence of infectious diseases, particularly tuberculosis. Nurses should determine who in the patient's household has been infected and the status of treatment.

Medications

The last component of the nursing history should describe medications the patient is using. These include prescribed and over-the-counter medicines, traditional medicine, herbal medicines, alternative therapies and illicit drugs and substances. Such medications may have adverse effects by themselves or because of interactions with other drugs. A person using a prescribed bronchodilator drug, for example, may decide that using an over-the-counter inhalant as well will be beneficial. Many of these contain ephedrine or ma huag, a natural ephedrine, which acts like adrenaline. This product may react

with the prescribed medication by increasing or decreasing the effect of the prescribed medication.

As with all medication, nurses assess the patient's knowledge and ability to use the 'five rights' (or 'seven rights') of medication administration (see Chapter 27) (Levett-Jones et al 2010). Of particular importance is the nurses' assessment of the patient's understanding of potential side effects of the medications. Patients should be able to recognise adverse reactions and be aware of the dangers in combining prescribed medications with over-the-counter drugs (Levett-Jones et al 2010).

When patients are prescribed drugs for which toxic levels can be monitored by blood analysis, nurses need to review these laboratory values. Common drugs that can be monitored include theophylline preparations, digoxin preparations and anticoagulants such as warfarin. Toxic effects of these medications can impair cardiopulmonary functioning. Illicit drugs, particularly parenterally administered narcotics, which are often diluted with talcum powder, can cause pulmonary disorders resulting from the irritant effect of the powder on lung tissues.

Physical examination

The physical examination performed to assess the patient's level of tissue oxygenation includes evaluation of the entire cardiopulmonary system. Inspection, palpation, auscultation and percussion techniques are used (see Chapter 24).

Examination techniques

INSPECTION Using inspection techniques, nurses perform a head-to-toe observation of the patient for skin and mucous membrane colour, general appearance, level of consciousness, adequacy of systemic circulation, breathing patterns and chest wall movements (Tables 35-5 to 35-7). Any abnormalities should be investigated during palpation, percussion and auscultation.

Inspection includes observations of the nails for clubbing. Clubbed nails, obliteration of the normal angle between the base of the nail and the skin, are seen in patients with prolonged oxygen deficiency, endocarditis and congenital heart defects.

PALPATION Palpation of the chest provides assessment data in several areas. It documents the type and amount of thoracic excursion, elicits any areas of tenderness and can identify tactile fremitus, thrills, heaves and the apical impulse. Palpation also allows the nurse to feel for abnormal masses or lumps in the axilla and breast tissue.

Palpation of the extremities provides data about the peripheral circulation, the presence and quality of peripheral pulses, skin temperature, colour and capillary refill (see Chapter 24). Palpation should assess for the presence or absence of peripheral oedema in the feet and legs. Patients with alterations in their cardiac function, such as those with chronic heart failure or hypertension, often have pedal or lower extremity oedema. Oedema is graded from 1+ to 4+, depending on the depth of visible indentation after firm application of a finger.

Palpation of the pulses in the neck and extremities is performed to assess arterial blood flow. A scale of 0 (absent pulse) to 3+ (full, bounding pulse) is used to describe what is palpated. The normal pulse is graded as 2+, and a weak, thready pulse is graded as 1+.

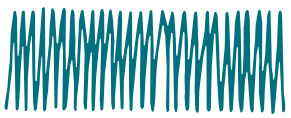
PERCUSSION Percussion allows the nurse to detect the presence of abnormal fluid or air in the lungs. It is also used to determine diaphragmatic excursion (see Chapter 24).

TABLE 35-5 Inspection of cardiopulmonary status

Location	Abnormality	Cause
Eyes	Xanthelasma (yellow lipid lesions on eyelids)	Hyperlipidaemia
	Corneal arcus (whitish opaque ring around junction of cornea and sclera)	Hyperlipidaemia in young to middle-aged adults, normal finding in older adults with arcus senilis
	Pale conjunctivae	Anaemia
	Cyanotic conjunctivae	Hypoxaemia
	Petechiae on conjunctivae	Fat embolus or bacterial endocarditis
Mouth and lips	Cyanotic mucous membranes	Decreased oxygenation (hypoxia)
	Pursed-lip breathing	Associated with chronic lung disease
Neck veins	Distension	Associated with right-sided heart failure
Nose	Flaring nares	Air hunger, dyspnoea
Chest	Retractions	Increased work of breathing, dyspnoea
	Asymmetry	Chest wall injury
Skin	Peripheral cyanosis	Vasoconstriction and diminished blood flow
	Central cyanosis	Hypoxaemia
	Decreased skin turgor	Dehydration (normal finding in older adults as a result of decreased skin elasticity)
	Dependent oedema	Associated with right- and left-sided heart failure
	Periorbital oedema	Associated with kidney disease
Fingertips and nail beds	Cyanosis	Decreased cardiac output or hypoxia
	Splinter haemorrhages	Bacterial endocarditis
	Clubbing	Chronic hypoxaemia

AUSCULTATION Auscultation enables the nurse to identify normal and abnormal heart and lung sounds (see Chapter 24). Auscultation of the cardiovascular system should include assessment for normal S1 and S2 sounds, the presence of abnormal S3 and S4 sounds (gallops) and murmurs or rubs. Auscultation of murmurs and rubs is an advanced skill. Auscultation is also used to identify a bruit (pronounced '*brew-ee*') over the carotid arteries, abdominal aorta and femoral arteries.

TABLE 35-6 Respiratory pattern

Type and pattern	Rate (breaths per minute)	Clinical significance
Eupnoea	16–20	Normal
		
Tachypnoea	> 35	Respiratory failure Response to fever Anxiety Shortness of breath Respiratory infection
		
Bradypnoea	< 10	Sleep Respiratory depression Drug overdose Central nervous system (CNS) lesion
		
Apnoea	Periods of no respiration lasting > 15 seconds	May be intermittent, such as in sleep apnoea Respiratory arrest
		
Hyperpnoea	16–20	Can result from anxiety or response to pain Can cause marked respiratory alkalosis, paraesthesia, tetany, confusion
		
Kussmaul's	Usually > 35, may be slow or normal	Tachypnoea pattern associated with diabetic ketoacidosis, metabolic acidosis or renal failure
		


Cheyne-Stokes	Variable	Increasing and decreasing pattern caused by alterations in acid–base status; underlying metabolic problem or neurocerebral insult
		
Biot's	Variable	Periods of apnoea and shallow breathing caused by CNS disorder; found in some healthy people
		
Apneustic	Increased	Increased inspiratory time with short grunting expiratory time; seen in CNS lesions of the respiratory centre
		

Weilitz PB 1991 Pocket guide to respiratory care. Mosby, St Louis.

TABLE 35-7 Assessment of abnormal chest wall movement

Abnormality	Cause
Increased anteroposterior diameter	Emphysema, chronic obstructive pulmonary disease, advancing age
Paradoxical breathing – asynchronous breathing; chest contraction during inspiration and expansion during expiration	Flail chest resulting from rib fractures due to chest trauma or cardiopulmonary resuscitation
Retraction or recession – sinking in of soft tissues of chest between and around cartilaginous and bony ribs, such as intercostal space, intraclavicular space and trachea, and substernally* worsening with need for increased inspiratory effort	Any condition that causes increased inspiratory effort (e.g. airway obstruction, asthma, tracheobronchitis)

*Infants can experience sternal and substernal retractions with only slight inspiratory effort because the thin chest wall is highly compliant.

Auscultation of lung sounds involves listening for movement of air throughout all lung fields: anterior, posterior and lateral. Adventitious breath sounds such as crackles and wheeze occur with collapse of a lung segment, fluid in a lung segment or narrowing or obstruction of an airway. Auscultation also evaluates the patient's response to interventions for improving the respiratory status.

Examination of infants and children

Due to the physiological characteristics whereby the ability to increase tidal volume is limited, infants and young children with respiratory distress will exhibit tachypnoea without an increase in depth of breathing. Also evident may be tracheal tug (recession of trachea), nasal flaring, tachycardia and listlessness. Poor feeding may be apparent due to fatigue and the energy required for feeding and breathing (Kendrick & Morrison 2007, Wilson 2009). The older child in respiratory distress will show increased depth of breathing as well as tachypnoea. Substernal, suprasternal and intercostal retractions may also be seen, along with restlessness and anorexia (Wilson 2009). A previously present stridor or wheeze which suddenly disappears may indicate deterioration, as the child is unable to produce enough tidal volume to cause the added sounds. This is a sign of imminent collapse. Also, a decreasing respiratory rate needs to be closely monitored as this may also indicate imminent collapse due to fatigue rather than improvement. Signs of early cardiovascular compromise are often subtle, and include unexplained tachycardia, pale, cool peripheries, tachypnoea and irritability. Hypotension is a late sign of cardiovascular compromise (Kendrick & Morrison 2007, Wilson 2009).

Diagnostic tests

Cardiac conduction tests

Tests used to determine the cardiac conduction of the heart include ECG, Holter monitor, the **exercise stress test** and electrophysiological studies.

ELECTROCARDIOGRAM The 12-lead ECG produces a graphic recording of the heart's electrical activity from 12 separate views, detecting transmission of impulses and the electrical position of the heart (the axis). This is covered in Skill 35-2.

HOLTER MONITOR The **Holter monitor** (also referred to as continuous cardiac monitoring or telemetry) is a portable device that records the heart's electrical activity and produces a continuous ECG tracing over a specified period, generally for 24 hours. The Holter monitor allows patients to continue with their normal activities while recording the heart's electrical activity. Patients keep a diary of activity, noting when they experience rapid heartbeats or periods of dizziness. Correlation between activities and abnormal electrical activity can then be determined. Continuous cardiac monitoring is covered in Skill 35-1.

EXERCISE STRESS TESTS are used to evaluate the cardiac response to physical stress. These provide information on myocardial response to increased oxygen requirements and determine the adequacy of coronary blood flow. Heart rate, electrical activity and cardiac recovery time are reflected in the ECG tracing. In addition, data about the patient's blood pressure, presence of chest pain, changes in respiration, colour and rate of muscular fatigue are monitored. There are more false-positive findings in women; it is therefore a less valuable tool for evaluation of cardiac response in women.

THALLIUM STRESS TEST Thallium imaging involves IV injection of thallium-201, a potassium analogue that accumulates in the heart in proportion to blood flow. Stress testing determines whether coronary blood flow changes with increased activity (treadmill exercises).

ELECTROPHYSIOLOGICAL STUDIES An **electrophysiological study (EPS)** is an invasive measure of electrical activity. An electrode catheter is inserted into the right atrium, usually via the femoral vein. Electrical stimulation is then delivered through the catheter while the ECG monitors and computers record the heart's electrical response to the stimulus. Specific arrhythmias can also be induced to determine the pathways through the heart, provide more specific information about difficult-to-treat arrhythmias and assess the adequacy of antiarrhythmic medication.

Myocardial contraction and blood flow studies

Echocardiography, scintigraphy, cardiac catheterisation and **angiography** are used to determine myocardial contraction and blood flow.

SKILL 35-1

Continuous cardiac monitoring ECG

Delegation considerations

Establishing ECG continuous cardiac monitoring (CCM) requires the skill of the registered nurse or an enrolled nurse. A registered nurse with the ability to rapidly interpret the ECG tracings needs to be monitoring the patient constantly – this interpretation part of the skill cannot be delegated.

Equipment

- ECG continuous monitor and telemetry device with the ability to record in all limb leads and V lead.
- 3 to 5 adhesive electrodes
- 3 to 5 electrode cords (one for each electrode) attached to telemetry device (see illustration) labelled as follows:
  - RA (white), LA (black), LL (red), RL (green) and V (brown)
- Razor (to shave body hair to ensure appropriate electrode attachment
- Tape (to secure electrodes if necessary, e.g. diaphoresis)
- Disposable bag for waste
- Gauze/alcohol wipes

Therapeutic relationship and patient considerations

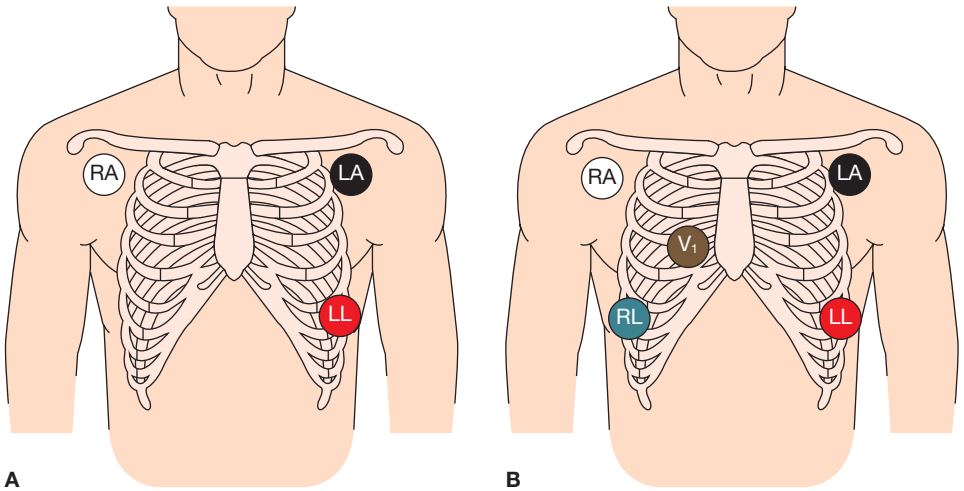
- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Ensure correct indication for ECG continuous cardiac monitoring (CCM).	CCM is used to continuously monitor a person's heart rate and rhythm. It is indicated in patients who have been diagnosed with a cardiac abnormality or a condition which could lead to a cardiac abnormality necessitating monitoring. These include conditions such as chest pain, acute coronary syndrome, syncope, arrhythmia, etc. Knowing the indication for CCM is paramount to their continued nursing care.

■ **Critical decision point: It is important to determine if 3 or 5 electrode monitoring is required; this is based on the indication for CCM: 3 electrodes enables leads I, II and III to be monitored; 5 electrodes also enables leads aVR, aVL and aVF as well as either V1 or V2 to be monitored, and is used for more complex patient conditions. The number of electrodes used can be a nursing or medical decision.**

2. Gather and prepare equipment and position patient.	Attach the lead wires and clips to the electrodes. Supine or semi-Fowler's/semi-recumbent positions are generally used for establishing CCM.
3. Explain procedure to the patient, assess patient's understanding of procedure and obtain verbal consent.	Reveals need for patient instruction and encourages cooperation. The patient will be wearing the device continually; it is necessary for them to understand how to care for it and what to do if something goes wrong.
4. Ensure telemetry device and monitor are operational.	CCM can occur with the patient connected directly to a monitor at the bedside (such as in an emergency department or intensive care unit) or via telemetry, where the patient is connected to a device which sends signals to a remote monitor, generally located at the staff base in the ward.
5. Perform hand hygiene, don non-sterile gloves and other PPE if indicated.	Consider risk for contact with blood products or respiratory secretions.
6. Prepare the region where the electrodes will be placed (based on the system to be used): a. Remove clothing from upper body to expose the person's chest. b. Clean the skin with gauze or alcohol wipes. c. Shave excess hair.	Shaving or clipping excess hair ensures good contact of electrodes with skin to prevent artefact.
7. Place adhesive electrodes on cardiac landmarks (see illustration). a. Remove the backing from the pre-gelled electrode first. Ensure the gel is moist, otherwise discard. b. Apply the electrode to the site and press firmly to ensure a tight seal. c. Attach correct clips/leads to each of them. Repeat with the remaining electrodes. **A. For 3 electrode monitoring:** RA: Right arm (Red) LA: Left arm (Black) LL: Left leg (White)	While the limp electrodes can be placed on any part of the patient's limbs, as many patients are mobile during CCM, it is often wise to place the 'arm' electrodes on the shoulders and the 'leg' electrodes on the hips or lower torso to facilitate accurate reading as well as to maximise patient comfort.

STEPS	RATIONALE
B. For 5 electrode monitoring: RA: Right arm (Red) LA: Left arm (Black) LL: Left leg (White) RL: Right leg (Green) V: V1 or V2 location (4th intercostal space, right or left sternal border) (Brown)	



Step 7 Electrode placement for continuous cardiac monitoring. A, 3-electrode system. B, 5-electrode system.

■ **Critical decision point: The placement of the coloured leads is often confusing. Here is a way to recall lead placement: 'white' rhymes with 'right', the 'black' above 'red' because 'smoke goes over a fire' and 'brown' is in the middle because it is chocolate, which, if loved, is 'close to the heart'.**

8. Enter the patient's details into the monitor or telemetry device.	This ensures that the continuous ECG tracing appearing on the monitor is clearly identified with the correct patient details.
9. Turn on the monitor or telemetry device. a. Once the monitoring device has been switched on, check the waveform for clarity, position and size for accuracy. b. Select an appropriate lead for monitoring.	Ensuring the ECG tracing is clear and free from artefact at the commencement of monitoring prevents issues with interpretation of rhythm. The lead selected for monitoring depends on the indication for CCM. Lead II is the most common as it provides a clear picture of the entire cardiac conduction system.
10. Set the upper and lower limits of heart rate alarms based on patient condition and unit policy	Refer to the hospital protocol for emergency medical response criteria (e.g. Code blue/ MET call) and to the patient's notes for acceptable range of heart rate.
11. Obtain a rhythm strip by pressing the record key at either the bedside or staff base depending on monitoring type, to interpret the rhythm strip for baseline reference. a. Determine if it is normal sinus rhythm: is there a P wave, QRS complex and T wave in each beat? b. Determine the heart rate. c. Determine the regularity.	Do not delay the interpretation of the ECG – refer to an experienced and qualified RN or medical officer.

STEPS	RATIONALE
Author's note: The interpretation of ECG is a complex skill which is considered an advanced nursing skill. The RN is expected to have basic ECG interpretation skills, and to be able to identify quickly if there are abnormalities that require further interpretation by a more experienced person.	
12. Measure patient's vital signs after commencing CCM.	This provides a baseline reference. Palpating the pulse to measure heart rate and comparing to the ECG tracing provides a cross-reference.
■ **Critical decision point: It is important to read the ECG recording of the patient's heart rate and palpate the pulse simultaneously. Rate and rhythm can be observed from the ECG recording, but by palpating the pulse the strength and presence of cardiac systole can only be determined, as pulseless electrical activity (PEA)/electromechanical dysfunction (EMD) is possible. Blood pressure is also an excellent indicator of cardiac output, hence giving vital information as to the effectiveness of the heart's contractions.**	
13. Clean used equipment and dispose of any waste.	
14. Document in the patient's notes.	Document in the patient progress notes that the CCM has been established, the initial interpretation and how often the monitor should be assessed by an RN. If a rhythm strip was printed, this should be added to the patient's medical record.
15. Monitor the patient for signs of cardiac dysfunction.	Regardless of the indication, if a patient requires CCM it is because they require monitoring for cardiac dysfunction. The frequency by which the monitor should be checked depends on the one indication for CCM and general stability of the patient's condition. Patients and monitors should be checked routinely and not only when the monitor alarms.

SKILL 35-2

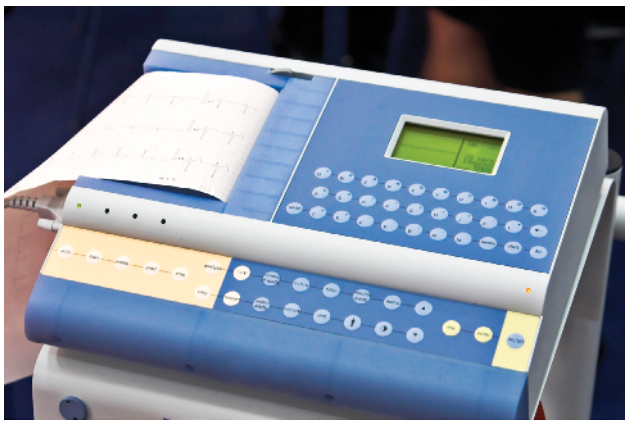
Conducting a 12-lead ECG

Delegation considerations

Performing an ECG requires the skill of the registered nurse or an enrolled nurse. Ideally this skill would be performed by a registered nurse with the ability to interpret the results immediately. Delegation to healthcare workers who are not registered or enrolled nurses is inappropriate.

Equipment

- ECG machine/monitor (see illustration) with the ability to record 12-lead ECGs
- 10 adhesive electrodes
- 10 electrode cords attached to the ECG machine labelled as follows:
  - V1, V2, V3, V4, V5, V6
  - LL, RL, LA, RA
- ECG paper
- Razor (to shave body hair to ensure appropriate electrode attachment)
- Tape (to secure electrodes if necessary, e.g. diaphoresis)
- Disposable bag for waste
- Gauze/alcohol wipes

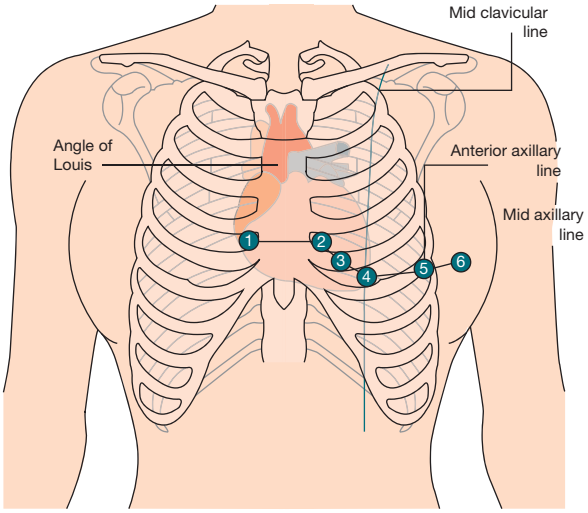


Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine the indication for 12-lead ECG.	ECG is an important diagnostic tool for heart disease such as acute coronary syndromes (angina and acute myocardial infarction) as well as arrhythmias and other disruptions to normal cardiac function. Also used to assess patient's responses to medication and other interventions. Used to provide a baseline measure of cardiac function. Knowing why an ECG is indicated assists in both conducting it and interpreting the results.
2. Gather equipment. a. Position patient in a supine or semi-Fowler's/ semi-recumbent position. b. Maintain privacy and dignity of the patient. c. Measures to minimise/eliminate artefact.	The patient should be comfortable and in a position to ensure minimal muscle movement while exposing the chest for the purpose of performing the ECG. Artefact is the distortion of the ECG tracing that occurs due to interference with electrical activity or muscle movement. Remove any electronic devices (including mobile phones) which may interfere with ECG recording.
3. Explain procedure to the patient. a. Assess patient's understanding of procedure and obtain verbal consent.	Reveals need for patient instruction and encourages cooperation.
4. Ensure the ECG machine is loaded with standardised paper set to a speed of 25 mm/second and calibrated with an amplitude recording of 2 large squares.	This is the set standard for recording of ECGs in Australia and New Zealand. If the machine is calibrated differently, interpretation of the ECG will be inaccurate.
5. Perform hand hygiene, don non-sterile gloves and other PPE if indicated.	Consider risk for contact with blood products or respiratory secretions.
6. Prepare the region where the electrodes will be placed (based on the system to be used): a. Remove clothing from upper body to expose the person's chest. b. Clean the skin with gauze or alcohol wipes. c. Shave excess hair.	This will ensure good contact of electrodes with skin and prevent artefact.

STEPS	RATIONALE
7. Place adhesive electrodes on the patient's cardiac landmarks. a. Remove the backing from the pre-gelled electrode. Ensure the gel is moist, otherwise discard. b. Apply the electrode to the site and press firmly to ensure a tight seal and attach correct clips/cords to each of them. c. Repeat with the remaining electrodes. **A. Limb electrodes:** RA: Right arm LA: Left arm RL: Right leg LL: Left leg **B. Chest electrodes:** V1: 4th intercostal space, right sternal margin V2: 4th intercostal space, left sternal margin V3: midway between V2 and V4 V4: 5th intercostal space, mid clavicular line V5: midway between V4 and V6 V6: 5th intercostal space, mid axillary line	Limb electrodes can be placed on any part of the patient's limb. Place them close to the shoulder/thigh to prevent excess muscle movement interference. All adhesive electrodes should be placed in equivalent positions (i.e. both LA and RA on the forearm/shoulder etc.) and pointing in the same direction. Place chest leads V2 and V4 before placing V3; likewise place V4 and V6 before placing V5. Avoid placing electrodes over burnt or damaged skin where possible. Ensure accurate placement of electrodes on women with large breasts. Chest leads should be placed according to anatomical cardiac landmarks. This ensures correct lead placement over the heart for accurate interpretation of the ECG recording.

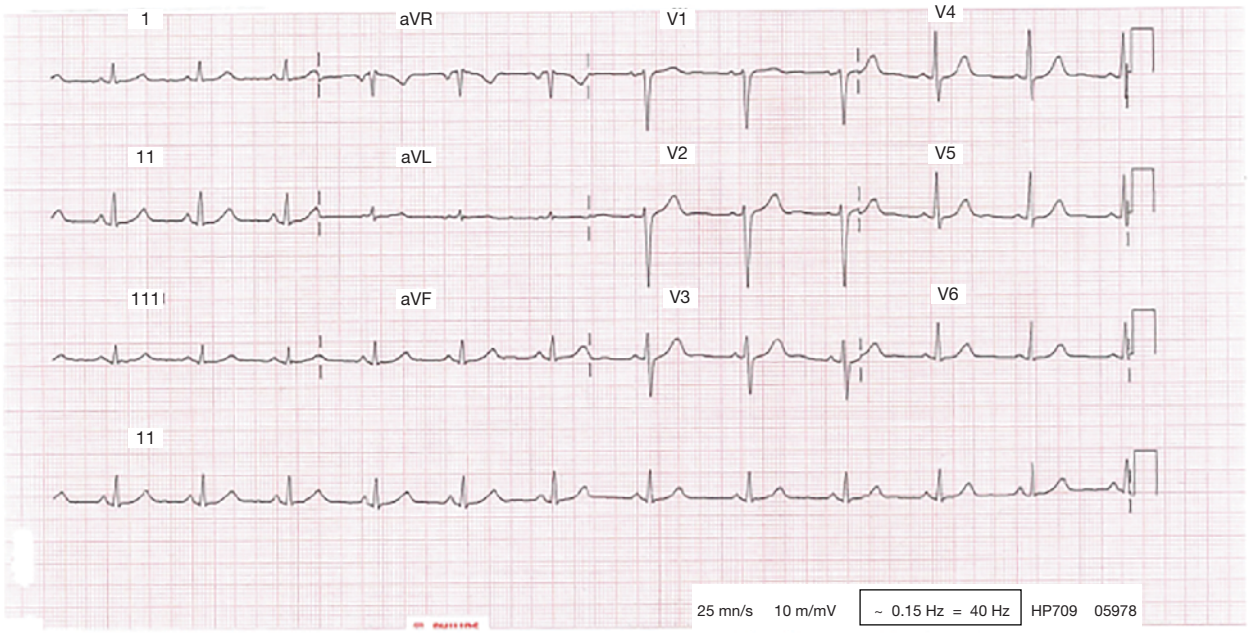


Step 7B Placement of 6 chest electrodes.

Critical decision point: The terms 'electrode' and 'lead' are not interchangeable. 'Electrode' refers to the often pre-gelled device that is placed on the patient's chest. A 'lead' provides the aspect from which the heart is viewed and constitutes the actual recording printed on the ECG paper. Ten electrodes are placed in specific positions to create 12 leads in the ECG.

8. Enter the patient's details into the ECG machine.	To ensure the printed ECG belongs to the correct patient. If the machine does not have this function use the patient's Unit Record label to place on the ECG printout; write the patient's details on the printout immediately the recording is complete.

STEPS	RATIONALE
9. Start the machine. a. Instruct the patient to lie still while the ECG is recorded. b. Observe the trace quality. The machine will record all 12 leads automatically, recording 3 consecutive leads simultaneously. c. Record the ECG and print a copy ensuring the presence of the rhythm strip in addition to the 12-lead ECG.	Ensure a clear recording with no artefact present. See illustration for an example of a normal 12-lead ECG.



A normal 12-lead ECG.

10. Annotate the presence of relevant symptoms on the ECG printout.	Recording the indication for the ECG is beneficial in being able to accurately interpret it. For example, chest pain, dizziness, palpitations, medications, blood tests (such as troponin) taken at the same time are all relevant. Recording the blood pressure also provides a comprehensive picture of the patient's health at the time the ECG is recorded. If the patient is having serial ECGs recorded, also record the current ECG number in the series.

■ **Critical decision point: Interpreting ECGs is a complex skill. An ECG alone is rarely used as a diagnostic tool; it is usually used in conjunction with other assessment tools and procedures. A short annotation of the patient's symptoms and vital signs is valuable to the interpretation process, and provides important assessment data leading to diagnosis.**

11. Refer the ECG immediately to a qualified RN or doctor for analysis and interpretation: **A. Interpretation of the rhythm strip:** a. Determine if it is normal sinus rhythm: is there a P wave, QRS complex and T wave in each beat?	An ECG should never be filed in the patient's notes for interpretation at a later time. Even if the indication is for a baseline recording, the ECG should be interpreted immediately by a qualified RN or the medical officer.

STEPS	RATIONALE
b. Determine the heart rate. c. Determine the regularity. **B. Using the 12 leads:** a. Group the leads according to heart region. b. Interpret the leads in each group together to determine common abnormalities.	

■ **Critical decision point: The automatic interpretation on the printout (including the heart rate) should not be used in the actual interpretation process.**

Author's note: The interpretation of 12-lead ECG is a complex skill which is considered an advanced nursing skill. The RN is expected to have basic ECG interpretation skills, and to be able to identify quickly if there are abnormalities that require further interpretation by a more experienced person.

12. Clean a used equipment and dispose of any waste.	
13. Document in the patient's notes.	Document in the patient's progress notes that the ECG has been performed and if there were any abnormalities or interventions as a result. Once analysed, the ECG printout must also be filed in the patient's medical record.
14. Monitor the patient for signs of cardiac dysfunction.	Depending on the indication for the 12-lead ECG, the patient may require further monitoring for cardiac dysfunction.

- **Echocardiography** is a non-invasive measure to evaluate the internal structures of the heart and heart wall motion. Sonar (radar) technology is used to measure ultrasonic waves and translate them into formed images. The echocardiogram graphically demonstrates overall cardiac performance. This can be performed using a transthoracic or transoesophageal approach.
- **Scintigraphy**, or radionuclide angiography, is a non-invasive imaging technique. Radioisotopes are used to evaluate cardiac structures, myocardial perfusion and contractility.
- **Cardiac catheterisation** and angiography are invasive procedures used for viewing cardiac chambers, valves, the great vessels and coronary arteries and to measure pressure and volumes within the four chambers. The procedures require insertion of a catheter into the heart via a percutaneous venous puncture. Contrast material is injected through the catheter, and fluoroscopic pictures are obtained. Often a device called a stent is inserted to open the occluded coronary artery. Both right- and left-sided catheterisation can be performed.

Diagnostic cardiac catheterisation is usually done as a day-surgery procedure. If there are no complications from the procedure, the patient may go home in 4–8 hours. Some patients may need to stay overnight for observation. Other patients may be taken directly to the operating room if the catheterisation reveals significant, life-threatening coronary artery disease and/or blockage. Complications associated with the cardiac catheterisation procedure include arrhythmias, bleeding at the puncture site, haematoma and stroke.

Ventilation and oxygenation studies

Pulmonary function tests, peak expiratory flow rates, arterial blood gas tests, oximetry and full blood counts (see section on blood studies) are used to assess the adequacy of ventilation and oxygenation.

Pulmonary function tests determine the ability of the lungs to efficiently exchange oxygen and carbon dioxide. Basic ventilation studies are performed with a spirometer and recording device as the patient breathes through a mouthpiece into a connecting tube. For example, measurements can include tidal volume (Vt), inspiratory reserve volume (IRV) residual volume (RV) and functional residual capacity (FRC) (Table 35-8). Pulmonary functions are variable by ethnic group (see *Working with diversity*).

Pulmonary function tests are usually performed in a pulmonary function laboratory. A nose clip prevents air from being inhaled or exhaled through the nose. The patient breathes through a mouthpiece attached to a spirometer for measuring lung volume, and is asked at certain times in the test to inhale or

TABLE 35-8 Pulmonary function measurements

Measurement	Description	Average value	Clinical significance
Functional residual capacity (FRC)	Volume of air (mL) left in lungs after a normal exhalation	2400 mL	Increased in patients with obstructive lung disease and older patients as a result of changes in chest wall compliance, elastic recoil of the lungs and decreased respiratory muscle mass and strength
Residual volume (RV)	Volume of air (mL) left in lungs after a maximal exhalation	1200 mL	Increased in patients with chronic obstructive pulmonary disease and older patients as a result of changes in elastic recoil of the lungs, chest-wall compliance and decreased respiratory muscle mass and strength
Total lung capacity (TLC)	Total volume of air (mL) in lungs following a maximal inhalation	6000 mL	Decreased in restrictive lung disease; increased in obstructive lung disease
Tidal volume (VT)	Volume of air (mL) inhaled or exhaled per breath	5–10 mL/kg	Decreased in restrictive lung disease and older adult
Vital capacity (VC)	Volume of air (mL) exhaled after a maximal inhalation	4800 mL	Decreased in association with decreased flow rates found in pulmonary oedema, atelectasis and changes associated with ageing, such as decreased respiratory muscle strength and chest wall compliance

WORKING WITH DIVERSITY

Focus on cultural care

Pulmonary functions vary between cultures as a result of the variation in chest size. Caucasians have the largest chest volumes, followed by Africans then Asians. The variations in the chest size affect the forced expiratory volume (FEV1), forced vital capacity (FVC) and the FEV1/FVC ratio.

	FEV1 (L)	FVC (L)	FEV1/FVC (%)
Caucasian	3.22	4.3	74.4
African	2.85	3.7	76.7
Asian	2.53	3.27	77.0

Reference

Modified from Lueckenotte AG 2000 Gerontologic nursing, 2nd edn. Mosby, St Louis.

exhale as much air as possible. The patient's cooperation is critical to ensure accurate results.

PEAK EXPIRATORY FLOW RATE The **peak expiratory flow rate (PEFR)** is the point of highest flow during maximal expiration. The PEFR reflects changes in large-airway sizes and correlates well with the FEV1 (forced expiratory volume in 1 second). The peak expiratory flow meter is a handheld instrument that allows patients with asthma to monitor their disease. All patients with asthma should monitor their PEFR, just as patients with diabetes monitor their blood glucose level.

ARTERIAL BLOOD GAS TESTS Arterial blood gas (ABG) measurement is performed in conjunction with pulmonary function tests to determine the hydrogen ion concentration, partial pressure of carbon dioxide and oxygen concentration and oxyhaemoglobin saturation. ABG tests provide information about diffusion of oxygen and carbon dioxide across the alveolar–capillary membrane and adequacy of tissue oxygenation (see Chapter 34). ABGs can provide information on conditions such as metabolic and respiratory acidosis and alkalosis. Taking an ABG sample and analysis of the results are advanced nursing skills.

OXIMETRY Continuous measurements of capillary oxygen saturation are available with cutaneous **oximetry** (see Skill 23-2). Oxygen saturation is the percentage of haemoglobin saturated with oxygen. Transcutaneous oximeter measurements have the advantages of being easy to use, non-invasive and readily available. Patients with ventilation/perfusion (V/Q) abnormalities such as pneumonia, emphysema, chronic bronchitis, asthma, pulmonary embolism or chronic heart failure are ideal candidates for pulse oximetry.

The most common oximetry is done with the pulse oximeter, which displays the amplitude of the pulse with the oxygen saturation reading. The nurse usually attaches a non-invasive sensor to the patient's finger, toe, earlobe or bridge of the nose to monitor capillary blood oxygen saturation. If using the finger or toe, dark-coloured or frosted nail polish should be removed as this may interfere with sensing and result in falsely low readings. Similarly, false fingernails may also interfere with readings. The nasal probe is recommended in low perfusion states because the blood flow in the nasal septum anterior ethmoid artery remains greater than peripheral flow in compromised flow states. Continuous monitoring of oxygen saturation is useful in assessing sleep disorders, exercise tolerance, weaning from mechanical ventilation, and transient decreases in oxygen saturation. Use during cardiac resuscitation is not reliable (Pierce 2007).

The accuracy of the pulse oximetry value is directly related to the perfusion of the probe area. Patients with poor tissue perfusion caused by shock, hypothermia or peripheral vascular diseases may not have reliable oximetry measures. The accuracy of the pulse oximetry is decreased when the systolic blood pressure is less than 90 mmHg. Spot-check oximetry readings have little clinical value; trends over time provide the best information about the patient's oxygenation.

Blood studies

FULL BLOOD EXAMINATION A full blood examination (FBE) determines the number and type of red and white blood cells per cubic millimetre of blood. The nurse obtains a venous blood sample by performing a venepuncture. Normal values for a FBE vary with age and gender.

The FBE measures the haemoglobin level in the red blood cells (erythrocytes). A deficiency in red blood cells decreases the blood's oxygen-carrying capacity because there are fewer haemoglobin molecules available to carry oxygen to tissues. When the number of red blood cells is increased, such as with polycythaemia in chronic lung conditions and cyanotic heart conditions, the oxygen-carrying capacity of the blood is increased. However, increased red blood cells increase blood viscosity and the patient's risk of thrombus formation.

Cardiac enzymes are used to diagnose acute myocardial infarction. The primary markers of myocardial damage are the plasma cardiac troponins I (TnI) and T (TnT) (Chew et al 2011). Blood is taken for troponin levels when the patient first presents with symptoms, and serial serum levels are repeated over several days. Elevated tropionin levels are indicative of a myocardial infarction (Chew et al 2011).

Other, less specific markers include creatine phosphokinase (CK) and CKMB (isoenzyme portion of CK specific for myocardial damage).

SERUM ELECTROLYTES It is important to monitor the serum electrolytes of patients with cardiac disease, and especially if receiving diuretic therapy for hypertension and suffering from chronic heart failure. The potassium (K^+) level should be between 3.5 and 5 mmol/L. Patients receiving diuretic therapy are at risk of hypokalaemia. Patients taking diuretics are usually monitored within 4 weeks of initiation of therapy, then every 6–12 months.

Nurses should also be alert for hyperkalaemia (elevated potassium) in patients receiving ACE inhibitors. ACE inhibitors are used for patients with chronic heart failure or left ventricular dysfunction following acute myocardial infarction, and to treat systemic hypertension. Hypokalaemia and hyperkalaemia can result in cardiac arrhythmias.

Cholesterol patients with risk factors for coronary artery disease need to have their cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol and triglyceride levels measured and monitored. A fasting total triglyceride level should be less than 1.5 mmol/L, and total cholesterol should be less than 5.0 mmol/L. LDL should be less than 2.0 mmol/L and HDL should be greater than 1.0 mmol/L (National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand 2005).

Factors such as cigarette smoking, obesity, lack of regular exercise, beta-adrenergic blocking agents, genetic disorders of HDL metabolism, hypertriglyceridaemia and type 2 diabetes contribute to low levels of HDL cholesterol. High levels of LDL cholesterol (hypercholesterolaemia) are caused by excessive intake of saturated fatty acids, dietary cholesterol intake and obesity. Familial hypercholesterolaemia and hyperlipidaemia are also contributing factors, as well as hypothyroidism, nephrotic syndrome and type 1 diabetes. Obesity, excessive alcohol intake, type 1 diabetes, beta-adrenergic blocking agents and familial hypertriglyceridaemia cause hypertriglyceridaemia.

• CRITICAL REFLECTION POINT

Chen Lee, age 72 years, has been having chest pain, shortness of breath and pain down his left arm for about 2 hours. He comes to the emergency department for care. What problems can you identify for this patient?

Viewing structures of the respiratory system

Chest X-ray examination, bronchoscopy and lung scans are used to show structures of the respiratory system.

CHEST X-RAY EXAMINATION A chest X-ray consists of a radiograph of the thorax that allows the doctor and nurse to observe the lung fields for fluid (e.g. occurs with pneumonia), masses (e.g. lung cancer), fractures (e.g. rib and clavicular fractures) and other abnormal processes (e.g. tuberculosis). Usually anterior/posterior (AP) and lateral films are taken to adequately show all the lung fields.

BRONCHOSCOPY is a visual examination of the tracheobronchial tree through a narrow, flexible fibre-optic bronchoscope. **Bronchoscopy** is performed to obtain a biopsy and fluid or sputum samples and to remove mucous plugs or foreign bodies that have become lodged in the airways.

The patient is usually kept NBM (nil by mouth) for 4 hours or more before bronchoscopy. Nurses may prepare the patient for the procedure by administering medications such as a sedative or atropine to reduce oral secretions. Nurses continue to observe and monitor the patient after the procedure for signs and symptoms of respiratory distress, haemoptysis or hypoxia. Before beginning oral fluids, nurses assess that the patient's gag and swallow reflex is intact, as often a topical local anaesthetic agent is sprayed on the posterior pharyngeal wall.

LUNG SCAN The most common lung scan is the *computed tomography* (CT) scan. CT scanning combines radiographical and computer technology. X-ray beams pass through a section or plane of the thorax from different angles, and the computer calculates tissue absorption and displays a printout and scan picture of the tissues, showing densities of various intrathoracic structures. A CT scan can identify abnormal masses by size and location but cannot identify tissue types; this requires a biopsy.

Determining abnormal cells or infection in the respiratory tract

Tests to determine whether there are abnormal cells or infection in the respiratory tract include throat cultures, sputum specimens, skin testing and thoracentesis. Any specimens collected for culture and sensitivity (C&S) to detect the presence of pathogenic microorganisms should be collected prior to the commencement of antibiotics.

THROAT CULTURES A throat culture sample is obtained by swabbing the oropharynx and tonsillar regions with a sterile swab. The throat culture determines the presence of pathogenic microorganisms. If a C&S is ordered, the antibiotics to which the microorganisms are resistant and those to which they are sensitive can also be determined.

When obtaining a throat culture, the nurse inserts the swab into the pharyngeal region and passes it along reddened areas and areas with exudate. Some patients have an active gag reflex, making it difficult to obtain the specimen. The reflex may be less active if the patient is sitting straight and leaning forward

slightly. The patient may be able to control gagging if told that the procedure will take only a few seconds.

Sputum specimens are obtained to identify the type of organism growing in the sputum. Early-morning specimens yield the most reliable results. A C&S identifies a specific microorganism and its drug resistance and sensitivities. A sputum specimen may also be obtained to screen for the presence of acid-fast bacilli (AFB). The AFB specimen is obtained on three consecutive days in the early morning before eating. Sputum for cytology is a sputum specimen obtained to identify abnormal lung cancer by cell type. It also involves a serial collection of three early-morning specimens before eating.

Nurses must teach the patient to cough effectively so that the sputum specimen consists of mucous from deep in the bronchus, and not saliva. The colour, consistency, amount and odour of the sputum are recorded, and the date and time the specimen was sent to a specific laboratory for analysis is documented.

Skin testing enables the clinician to determine the presence of bacterial, fungal or viral pulmonary diseases. The antigen is injected intradermally (see Chapter 27); the injection site may be circled, and the patient is instructed not to wash it off. This procedure enables the clinician to evaluate the response. Tuberculin skin tests are read at 48 hours. Positive results are based on the size of the induration, which is a palpable, elevated, hardened area around the patient's injection site. It is caused by oedema and inflammation from the antigen–antibody reaction. The induration is measured in millimetres. Reddened flat areas are not positive reactions and should not be measured. Tuberculin testing in older adults is less reliable (see *Working with diversity*).

Thoracentesis is perforation of the chest wall and pleural space with a needle to aspirate fluid for diagnostic or therapeutic purposes or to remove a specimen for biopsy. The procedure is performed with aseptic technique using a local anaesthetic. The patient usually sits upright with the anterior thorax supported by pillows or an overbed table (Figure 35-13).

Figure 35-13 Position for thoracentesis.

Wilson SF, Thompson JM 1990 Respiratory disorders. Mosby, St Louis.

Whether this procedure is painful depends on the patient's tolerance for pain (see Chapter 41). Nurses can reduce the patient's anxiety by explaining the procedure and telling the patient what to expect. The patient must understand the importance of holding the breath as requested and of not coughing during the procedure. Sudden movements may result in lung puncture by the thoracentesis needle. The patient is instructed to notify the doctor before coughing or sneezing, so that the needle can be withdrawn.

After the procedure the nurse monitors the patient for signs of pneumothorax (air in the pleural space): sudden shortness of breath (see Box 35-6), tracheal deviation, oxygen desaturation and anxiety. The development of a pneumothorax following thoracentesis is an emergency. This type of pneumothorax is known as a tension pneumothorax and can result in cardiopulmonary arrest if it is not treated promptly.

Patient expectations

Nurses should ask patients what they expect with regard to their care, including what they expect from the encounter and what their priority is for management of their health. It also includes involving patients in the decision-making process about what will happen to them. For example, planning a quit-smoking or weight-reduction program for a patient who is not ready for the change will be frustrating for both the patient and nurses. Short-term realistic goals should be established that build to a larger goal. For example, reducing the fat in the patient's diet may start out with replacing food such as whole milk with 2% milk and gradually introducing skimmed milk. A plan for adding exercise to the patient's lifestyle may start with a commitment to exercise once a week for 20 minutes, or the patient may commit to a weight-reduction plan of 2 kg per month.

It is important to remember that the goals and expectations of nurses may not always coincide with those of the patient. By considering the patient's concerns and expectations, nurses will establish a relationship that can encompass other healthcare goals and expected outcomes.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Patients with an altered level of oxygenation can have problems that are primarily of a cardiovascular or pulmonary

WORKING WITH DIVERSITY

Focus on older adults

- The tuberculin skin test is an unreliable indicator of tuberculosis in older adults. They frequently display false-positive or false-negative skin test reactions. Older adults are at an increased risk of reactivation of dormant organisms that have been present for decades as a result of age-related changes in the immune system.
- The standard 5-TU Mantoux test is given and repeated or repeated with the 250-TU strength test to create a booster effect. If the older adult has a positive reaction, a complete history is necessary to determine any risk factors.
- Weight loss, night sweats, haemoptysis and fatigue are signs and symptoms that should alert the nurse to possible tuberculosis. Early morning sputum for acid-fast bacilli (AFB) and a chest X-ray are usually indicated.

BOX 35-8 Examples of priority problems associated with cardiopulmonary dysfunction

Activity intolerance
Difficulty in clearing airway
Anxiety
Ineffective breathing pattern
Decreased cardiac output
Fear
Impaired gas exchange
Infection, associated with
Knowledge deficit (specify)
Altered tissue perfusion (cardiopulmonary)
Inability to sustain spontaneous ventilation

BOX 35-9 Examples of clinical reasoning processes associated with cardiopulmonary dysfunction

Assessment activities	Defining characteristics	Problem identified
Observe patient while breathing.	Dyspnoea Tachypnoea Use of accessory muscles Nasal flaring Diaphoresis	Ineffective airway clearance related to thickened pulmonary secretions
Inspect patient's skin and mucous membranes.	Cyanotic nail beds Circumoral cyanosis Pale mucous membranes	
Auscultate lung fields.	Lower lobe crackles Inspiratory wheezes throughout fields	
Observe cough and inspect sputum.	Poor cough Patient tires trying to produce sputum Thick, yellow sputum	

origin (Box 35-8). Each diagnosis is based on specific defining characteristics and the related aetiology. Nurses use the information gathered in the nursing assessment to identify and cluster the defining characteristics. The clustered defining characteristics support the diagnostic process (Box 35-9).

• CRITICAL REFLECTION POINT

Mr Majid has recently migrated to Australia to join his family. He is at the medical centre to see a doctor because he has become increasingly tired, has had a persistent cough and has been losing weight. What questions would be important to ask when completing the health history interview?

SETTING PRIORITIES AND ESTABLISHING GOALS

Goals and outcomes

During planning, nurses will synthesise information from multiple resources (Figure 35-14). Critical thinking ensures that the patient's plan of care integrates all that nurses know about the individual, as well as key critical-thinking elements.

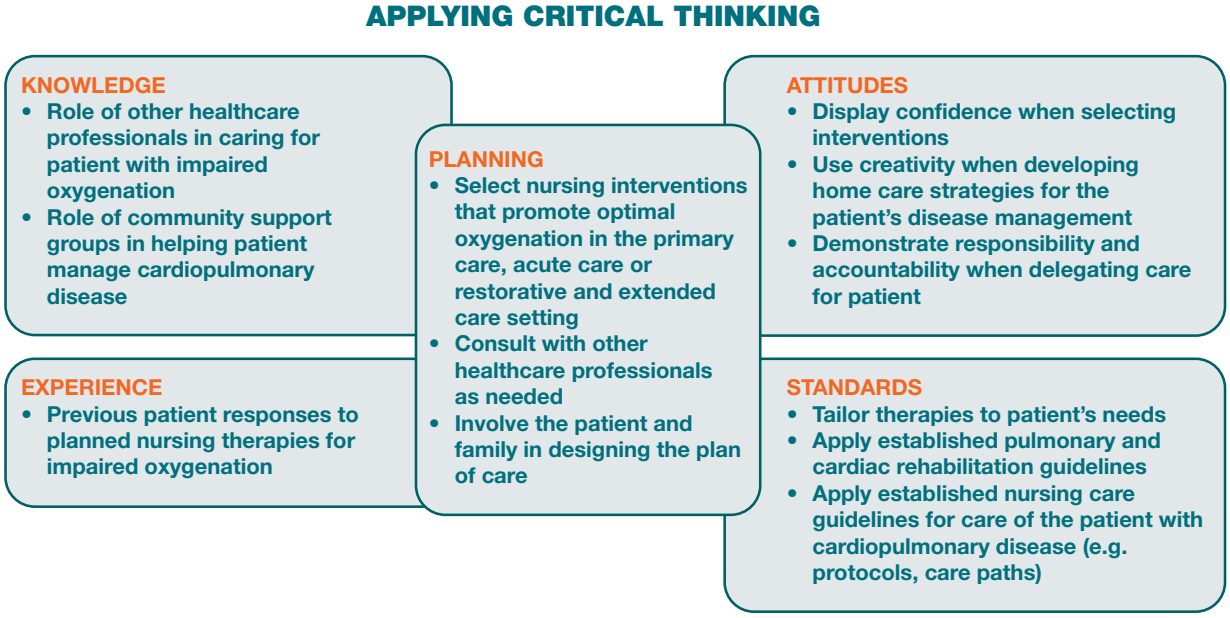


Figure 35-14 **Critical thinking associated with the planning phase for oxygenation.**

Professional standards are especially important, and often establish scientifically proven guidelines for selecting effective nursing interventions.

Depending on the patient's clinical condition, the care may be directed by an appropriate clinical pathway. A clinical pathway is a standardised management plan based on current evidence. Where the patient's clinical condition is complex, nurses develop an individualised plan of care to manage identified problems. Nurses and the patient set realistic expectations of care. Goals are to be individualised and realistic with measurable outcomes.

Patients with impaired oxygenation require a nursing care plan directed towards meeting the actual or potential oxygenation needs of the patient (see *Sample student nursing care plan*). Individual outcomes are derived from patient-centred needs. Nurses identify specific outcomes of nursing care and identify the appropriate interventions necessary to achieve the desired outcome. The plan includes one or more of the following patient-centred outcomes (Ackley & Ladwig 2011):

- The patient maintains a patent airway.
- The patient achieves and maintains adequate gas exchange and ventilation demonstrated by respiratory rate and pattern and pulse oximetry.
- The patient achieves and maintains adequate cardiac output demonstrated by blood pressure, heart rate and rhythm.
- The patient achieves and maintains adequate electrolyte and acid–base balance.
- The patient achieves maintenance and promotion of lung expansion.
- The patient demonstrates effective coughing and clear breath sounds.
- Tissue oxygenation is maintained or improved.
- The patient will be able to increase endurance for activities of daily living.

Setting priorities

Alterations in oxygenation are always among the most important problems and require immediate and continual work until the problem is overcome. The patient's level of health, age, lifestyle and environmental risks affect the level of tissue oxygenation. Patients with severe impairments in oxygenation often require nursing interventions in multiple areas.

A clinical pathway or clinical practice guideline can provide a multidisciplinary template for care.

Continuity of care

When the patient is discharged, care is assumed by the patient, a family member or a community healthcare professional. Patients who have chronic oxygenation problems can live comfortably in their own homes for many years with appropriate equipment and the support of their healthcare professionals.

PREPARING FOR AND TAKING ACTION

Nursing interventions for promoting and maintaining adequate oxygenation are included in the domains of provision and coordination of care and collaborative and therapeutic practice (Nursing and Midwifery Board of Australia 2016). These include independent nursing actions, such as health-promotion and prevention behaviours, positioning and coughing techniques and interdependent or dependent interventions such as oxygen therapy, lung inflation techniques, hydration, medications and chest physiotherapy.

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data*

Mr Edwards, an older adult with a history of COPD, comes to the medical centre with complaints of coughing. He states that he has been **coughing for about a week**, and his ribs are getting sore. He denies sputum production and states that there is nothing to cough up. He notes that his mouth is dry, however, and he has had **increased fatigue** over the past week. He continues to **smoke 2–3 cigarettes a day**, an improvement from his previous 10–15 per day. His skin and mucous membranes are dry. Lung sounds reveal crackles in the upper lobes. The lower lobes are clear. He is **unable to produce a sputum sample** for evaluation.

** Important data to cluster in setting priorities in bold.*

Priority problem(s)

Difficulty clearing airway because of retained secretions.

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Mr Edwards will be able to effectively clear secretions.	Lung sounds will be normal in 48 hours.
Mr Edwards' oxygenation will be optimised.	Sputum will be thin, white and watery.
	Respiratory rate will be within 20–24 breaths per minute in 48 hours. Respiratory pattern will be normalised with no use of accessory muscles. SpO_2 will be > 92%.
	Mr Edwards will be able to clear airway by coughing.

Preparing for and taking action	Rationale
Airway management	
• Adjust fluid intake to ensure sputum remains liquid (Kauffman 2008).	Fluids help to liquefy secretions and promote ease of removal.
• Have Mr Edwards deep-breathe and cough every 2 hours 4–5 times (Kauffman 2008).	Retained secretions predispose patient to atelectasis and pneumonia.
• Consider chest physiotherapy (CPT) if there is evidence of infiltrates on chest X-ray and sputum production (Tang et al 2010).	Standards for CPT include sputum production greater than 25 mL/day or infiltrates on chest X-ray (American Association of Respiratory Care 2003).
• Humidification: humidified oxygen if oxygen delivery > 6 L/min.	Decreases insensible fluid loss and helps liquefy secretions.

† Intervention classification labels from Kaufman JS 2008 Nursing management: obstructive pulmonary disease. In Brown D, Edwards H (eds) Lewis's medical–surgical nursing, 2nd edn. Mosby, Sydney.

Evaluating impacts and outcomes

- Observe Mr Edwards' ability to deep-breathe and cough effectively.
- Auscultate for adventitious lung sounds.
- Assess Mr Edwards' respiratory rate, pattern and use of accessory muscles.
- SpO_2 > 92%.
- Assess patient's level of hydration.
- Observe appearance of sputum.

Health promotion

Maintaining the patient's optimal level of health is important in reducing the number and/or severity of respiratory symptoms. Prevention of respiratory infections is foremost in maintaining optimal health. Nurses provide cardiopulmonary-related health information to patients and their families (Boxes 35-10 and 35-11; see also *Working with diversity*).

BOX 35-10 Patient teaching for cardiovascular disease

Objectives

- Patient will be able to demonstrate knowledge of relevant modifiable cardiovascular risk factors and their management.
- Patient will have an awareness of behaviour modification required to minimise the impact of relevant risk factors.

Intervention

- Undertake patient assessment to identify relevant modifiable risk factors for the individual patient.
- Provide education about the above-identified risk factors and their management. This may include information regarding low-fat, low-salt and kilojoule-appropriate diets, including sample menus; strategies for stress reduction; benefits of exercising for 20–30 minutes 3–4 times per week to help reduce weight and help lower blood pressure.
- Provide education about the importance of regular blood pressure monitoring.
- Provide education about the importance of blood lipid monitoring.
- Provide education about the importance of taking medications as prescribed.
- Set realistic goals with the patient for achievement of behaviour modification to address relevant risk factors.
- Determine age-related, cultural, religious or economic issues that may interfere with patient's ability to complete the plan of care and identify strategies to address these issues.

Teaching strategies

- Include relevant family members/significant others wherever possible.
- Suitable interviewing and teaching techniques, e.g. professional behaviour, appropriate eye contact, open-ended questions, jargon-free language, clarifying statements, appropriately timed sessions.

continued

- Augment session with teaching materials, e.g. video, pamphlets, electronic resources.
- Consider group teaching for peer learning and support.

Evaluation

- Request patient paraphrase their understanding of the teaching session.
- Clarify any unclear issues.
- Patient returns for follow-up as scheduled.

Muma RD 2012 An approach to patient education. In Muma RD, Lyons, BA (eds), Patient education: a practical approach, 2nd edn. Jones & Bartlett Learning, Sudbury, MA; National Heart Foundation of Australia 2009 Guidelines for the assessment of absolute cardiovascular disease risk. Online. Available: http://heartfoundation.org.au/for-professionals/clinical-information/absolute-risk; accessed 1 April 2016.

BOX 35-11 Patient teaching for respiratory disease

Objectives

- Patient will be able to demonstrate knowledge of relevant modifiable respiratory risk factors and their management.
- Patient will have an awareness of behaviour modification required to minimise the impact of relevant risk factors.

Intervention

- Undertake patient assessment to identify relevant risk factors for the individual patient.
- Provide education about the above-identified risk factors and their management. This may include information regarding smoking and exposure to secondhand smoke, repeated respiratory infections, vaccination (pneumococcal and influenza), exposure to allergens, pollution level and 'bad air' days and secondary infections.
- Provide education about the importance of taking medications as prescribed.
- Provide education and have patient demonstrate proper technique and sequencing of metered-dose inhalers, including the use of spacers if relevant.
- Provide education for the patient with asthma about importance of monitoring the peak expiratory flow rate (PEFR).
- Provide education and have patient demonstrate proper use of the peak expiratory flow meter.
- Set realistic goals with the patient for achievement of behaviour modification to address relevant risk factors.
- Determine age-related, cultural, religious or economic issues that may interfere with patient's ability to complete the plan of care.

Teaching strategies

- Include relevant family members/significant others wherever possible.
- Suitable interviewing and teaching techniques, e.g. professional behaviour, appropriate eye contact, open-ended questions, jargon-free language, clarifying statements, appropriately timed sessions.
- Augment session with teaching materials, e.g. video, pamphlets, electronic resources.
- Consider group teaching for peer learning and support.

Evaluation

- Request patient paraphrase their understanding of the teaching session.
- Clarify any unclear issues.
- Request patient demonstrate proper coughing and sneezing techniques.
- Patient is able to demonstrate proper use of metered-dose inhalers and spacer use.
- Patient is able to demonstrate proper use of the peak expiratory flow meter.
- Patient returns for follow-up as scheduled.

WORKING WITH DIVERSITY

Focus on infants and children

Many Australian children spend part or most of their day in childcare. Acute respiratory illness is a problem in this context and causes discomfort to the child as well as extra costs to the parents as they stay home from work to look after the child. McCutcheon and Fitzgerald (2001) suggest that public health nurses become involved with this subpopulation to facilitate health promotion in childcare facilities. Education about respiratory hygiene practices, infectious diseases and how they can be prevented, assessment of mild, moderate and severe acute respiratory illness, support for childcare workers and information on nutrition, comfort and care of the ill child were suggested to improve care.

Influenza and pneumococcal vaccine

Most healthy adults will recover from influenza within a few days without any complications; however, some people, especially those aged 65 years or more and people with certain medical conditions, can suffer complications. This can include pneumonia requiring hospitalisation, and can even result in death. Older people are by far the worst affected by influenza. In Australia, the free vaccination program for those aged over 65 years was implemented in 2000 and has resulted in a reduction in deaths in the older population. In 2009, deaths attributed to pneumonia and influenza as the single cause were reduced to 1796, although these respiratory infections are implicated frequently as a co-cause of death in those suffering concomitant diseases. Deaths attributed to Influenza A-H1N1 (swine flu) numbered 77 (Australian Bureau of Statistics 2011). A similar program has been implemented for Aboriginal and Torres Strait Islander people and in New Zealand; the free vaccinations are also available in both countries for pregnant women and those with chronic medical conditions who are most at risk of dangerous respiratory infections.

The Department of Health and Ageing (2009) recommends routine annual influenza vaccination for all people aged over 65 years, or over 50 for Aboriginal and Torres Strait Islander peoples. It also advises vaccination for those in the following groups: adults with chronic debilitating diseases, especially those with chronic cardiac, pulmonary, renal and metabolic disorders; children with cyanotic congenital heart disease; adults and children receiving immunosuppressive therapy; and residents of nursing homes and other extended-care facilities. Annual vaccination should also be considered for staff who care for immunocompromised patients and staff of nursing homes and other chronic-care facilities. It is recommended that vaccination take place in the autumn in anticipation of winter outbreaks.

People with a known sensitivity to eggs or with a current febrile illness should not be vaccinated. The vaccines are formulated annually based on worldwide surveillance data. The influenza virus mutates all the time, and the vaccine is changed to match the current circulating virus. The vaccine will provide about 70% protection against infection for about 1 year. Annual vaccination is necessary to provide continuing protection against the most recent influenza virus. Current influenza vaccines include coverage for swine flu (Department of Health and Ageing 2009).

Pneumococcal vaccine is recommended for patients at increased risk of developing pneumonia, especially for Indigenous minorities, residents of institutions, the elderly and the immunosuppressed (such as those receiving treatment for HIV/AIDS). Revaccination is recommended every 5 years. In all age groups, Indigenous rates of invasive pneumococcal infection are up to 75 times higher than in other groups (Department of Health and Ageing 2009).

The influenza vaccine can be used in pregnant women. Pneumococcal vaccine is contraindicated in pregnancy, unless there is an increased risk of invasive pneumococcal disease, for example, impaired immunity (Department of Health and Ageing 2009). However, in all cases it is important to consult the patient's obstetrician before administering either vaccine.

• CRITICAL REFLECTION POINT

Mrs Amanda Miller, age 45 years, has been admitted to hospital with community-acquired pneumonia. She has a productive cough, fever, chills, crackles and wheezes on auscultation of her chest, and a heart rate of 104 beats per minute. What problems can you identify for this patient?

Environmental pollutants

Avoiding exposure to secondhand smoke is essential to maintaining optimal cardiopulmonary function. All government buildings, businesses and restaurants in Australia and New Zealand now ban smoking. If people are exposed to secondhand smoke in their home environments, counselling and support may be necessary to help the smoker stop smoking or alter behaviour patterns, such as smoking outside.

Exposure to chemicals and pollutants in the work environment must also be considered. People such as farmers, painters and carpenters benefit from the use of particulate filter masks to reduce inhalation of particles.

Healthy lifestyle behaviour

Identification and elimination of risk factors for cardiopulmonary disease are important parts of primary care. Patients are encouraged to eat a healthy low-fat, high-fibre diet; monitor their cholesterol level, triglyceride level and HDL/LDL ratio; reduce stress; exercise; and maintain a bodyweight in proportion to their height. Elimination of cigarettes and other tobacco products, reduction of pollutants, monitoring of air quality and adequate hydration are additional healthy behaviours. Patients should be encouraged to examine their habits and make changes to achieve their goals.

Exercise is a key factor in promoting and maintaining a healthy heart and lungs. Patients should be encouraged to exercise 3–4 times a week for 20–30 minutes. Aerobic exercise is necessary to improve lung function, strengthen muscles and achieve the desired outcome. Walking is one of the most efficient ways to achieve a good aerobic workout.

Patients with cardiopulmonary alterations need to minimise their risk of infection, especially during the winter months. Following infection-control practices, patients should be counselled to avoid large, crowded places and keep their mouth and nose covered when sneezing or coughing to minimise the risk of transmission. This is especially important during the peak of the influenza season.

Patients with known cardiac disease and those with multiple risk factors should be cautioned to avoid exertion in cold weather. Diving into a cold swimming pool has been known to precipitate a cardiac event in many patients. Patients are advised to avoid alcohol, since it blunts the respiratory drive when used to excess and may contribute to exposure to the cold by making the patient feel warm when they are really not protected. Patients should also be taught to plan for the hot summer months. Activities should be limited to early in the day or late in the evening, when temperatures are lower. Care should be taken to maintain adequate hydration and sodium intake, especially in those patients who are taking diuretics. Caffeinated and alcoholic beverages should be limited or avoided completely, since they act as diuretics and can contribute to dehydration.

Acute care

Patients with acute pulmonary illnesses require nursing interventions directed towards halting the pathological process, as with a respiratory tract infection; shortening the duration and severity of the illness, such as hospitalisation with pneumonia; and preventing complications from the illness or treatments, such as healthcare-associated (nosocomial) infection resulting from invasive procedures.

Dyspnoea management

Dyspnoea is difficult to quantify and to treat. Treatment needs to be individualised for each patient, and usually more than one therapy is implemented. The underlying process that causes or worsens dyspnoea must be treated and stabilised initially, then four additional therapies – pharmacological measures, oxygen therapy, physical techniques and psychosocial techniques – are implemented. Pharmacological agents may include bronchodilators, steroids, mucolytics and low-dose anxiolytic medications. Oxygen therapy can reduce dyspnoea associated with exercise. Physical techniques, such as cardiopulmonary reconditioning, breathing techniques and cough control, can help to reduce dyspnoea. Relaxation techniques, biofeedback and meditation are physiological measures that can lessen the sensation of dyspnoea.

Airway maintenance

The airway is patent when the trachea, bronchi and large airways are free from obstructions. Airway maintenance requires adequate hydration to prevent thick, tenacious secretions; proper coughing techniques to remove secretions and keep the airway open; and a variety of interventions to help the patient with alterations in airway clearance, such as suctioning, chest physiotherapy and nebuliser therapy.

The ability of a patient to mobilise pulmonary secretions may make the difference between a short-term illness and a long recovery involving complications. Nursing interventions that promote mobilisation of pulmonary secretions help the patient achieve and maintain a clear airway and help promote lung expansion and gas exchange.

HYDRATION Maintenance of adequate systemic hydration keeps mucociliary clearance normal. In patients with adequate hydration, pulmonary secretions are thin, clear to white, watery and easily expectorated with minimal coughing. Excessive coughing to clear thick, tenacious secretions is tiring and energy-depleting. The best way to maintain thin secretions is to provide a fluid intake of 1500–2000 mL/day (or up to 3 L/day in tropical areas), unless contraindicated by cardiac status. The colour, consistency and ease of secretion expectoration can determine adequacy of hydration.

HUMIDIFICATION is the process of adding water to gas. Temperature is the most important factor affecting the amount of water vapour a gas can hold. The percentage of water in the gas in relation to its capacity for water at a specific temperature is the relative humidity. Air or oxygen with a high *relative humidity* keeps the airways moist and helps loosen and mobilise pulmonary secretions. **Humidification** is necessary for patients receiving oxygen therapy at greater than 4 L/min, to moisten the mucociliary system. When the thin layer of fluid that supports the mucous layer over the cilia is allowed to dry, the cilia are damaged and cannot adequately clear the airway. Bubbling oxygen through warm (37ºC) water can add humidity to the oxygen delivered to the upper airways, as with a nasal catheter, nasal cannula or face mask. The oxygen (humidity) tent is used for infants and children with illnesses such as croup and tracheitis to liquefy secretions and help reduce fever (Overend et al 2001). The nebuliser at the top of the humidity tent must remain filled with water to prevent non-humidified air or oxygen from entering the tent. Air in the humidity tent can become cool and fall below 20°C, causing the child to become hypothermic. Nurses monitor the child's body temperature as well as respiratory status. Children in humidity tents require frequent changes of clothing and bedclothes to remain warm and dry.

NEBULISATION is a process of adding moisture or medications to inspired air by mixing particles of varying sizes with the air. A nebuliser uses the aerosol principle to suspend a maximum number of water droplets or particles of the desired size in inspired air. The moisture added to the respiratory system through nebulisation improves clearance of pulmonary secretions. Nebulisation is often used for administration of bronchodilators and mucolytic agents. Humidification through nebulisation enhances mucociliary clearance, the body's natural mechanism for removing mucous and cellular debris from the respiratory tract.

The major types of nebulisers are the jet-aerosol nebuliser and the ultrasonic nebuliser. A jet-aerosol nebuliser uses gas under pressure, and the ultrasonic nebuliser uses high-frequency vibrations to break up the water or medication into fine drops or particles. When inspired with air or administered oxygen, the drops or particles are then deposited throughout the tracheobronchial tree.

COUGHING TECHNIQUES Coughing is effective for maintaining a patent airway. Coughing permits the patient to remove secretions from both the upper and the lower airways. The normal series of events in the cough mechanism are deep inhalation, closure of the glottis, active contraction of the expiratory muscles, and glottis opening. Deep inhalation increases the lung volume and airway diameter, allowing the air to bypass partially obstructing mucous plugs or other foreign matter. Contraction of the expiratory muscles against the closed glottis causes a high intrathoracic pressure to develop. When the glottis opens, a large flow of air is expelled at high speed, providing momentum for mucous to move to the upper airways where it can be expectorated or swallowed.

The effectiveness of coughing is evaluated by clearing of adventitious sounds by auscultation, sputum expectoration or the patient's report of swallowed sputum. Patients with chronic pulmonary diseases, upper respiratory tract infections and lower respiratory tract infections should be encouraged to deep-breathe and cough at least every 2 hours while awake. Patients with a large amount of sputum should be encouraged to cough every hour while awake and every 2–3 hours during sleep time until the acute phase of mucous production has ended. Coughing techniques include deep-breathing and coughing (for the postoperative patient), cascade, huff and quad coughing.

- *Deep-breathing and coughing* is taught preoperatively for use postoperatively. The patient simply inhales as deeply as possible, holds the breath for 2 or 3 seconds and coughs forcefully on exhalation to clear airways. To be effective, postoperative pain must be controlled.
- With the *cascade cough*, the patient takes a slow, deep breath and holds it for 2 seconds while contracting

expiratory muscles. Then the patient opens the mouth and performs a series of coughs throughout exhalation, thereby coughing at progressively lowered lung volumes. This technique promotes airway clearance and a patent airway in patients with large volumes of sputum.

- The *huff cough* stimulates a natural cough reflex and is generally effective only for clearing central airways. While exhaling, the patient opens the glottis by saying the word huff. With practice the patient inhales more air and may be able to progress to the cascade cough.
- The *quad cough* technique is used for patients without abdominal muscle control, such as those with spinal cord injuries. While the patient breathes out with a maximal expiratory effort, the patient or nurse pushes inwards and upwards on the abdominal muscles towards the diaphragm, causing the cough.

POSITIVE EXPIRATORY PRESSURE (PEP), although not a cough technique, also works to mobilise secretions. The patient inhales a larger than normal volume of air and exhales through a resistor. The resistance causes the patient's exhalation to be 3–4 times as long as the inhalation, and is thought to increase the volume of air distal to the secretions. After several breaths using this technique, the patient follows with huff coughing. There is some evidence that PEP increases sputum expectoration in patients with COPD (Tang et al 2010).

CHEST PHYSIOTHERAPY (CPT) is a group of therapies used in combination to mobilise pulmonary secretions (Box 35-12). These therapies include postural drainage, chest percussion and vibration. **Chest physiotherapy** should be followed by productive coughing and suctioning of the patient who has a decreased ability to cough. Chest physiotherapy is recommended for patients who produce greater than 25 cm^3 of sputum per day or have evidence of atelectasis by chest X-ray examination. There is insufficient evidence to demonstrate that the CPT techniques detailed below improve expectoration of secretions in patients with COPD or pneumonia (Tang et al 2010, Yang et al 2010). This procedure can be safely used with infants and young children; however, conditions and diseases unique to children may at times contraindicate this procedure.

Chest percussion involves striking the chest wall over the area being drained. The hand is positioned so that the fingers and thumb touch and the hand is cupped (Figure 35-15). Percussion on the surface of the chest wall sends waves of varying amplitude and frequency through the chest, changing the consistency and location of the sputum. Chest percussion is performed by alternating hand motion against the chest wall (Figure 35-16). Percussion is performed over a single layer of clothing, not over buttons, press-studs or zips. The single layer of clothing prevents slapping the patient's skin. Thicker or multiple layers of material dampen the vibrations.

Percussion is contraindicated in patients with bleeding disorders, osteoporosis or fractured ribs. Caution should be taken to percuss the lung fields and not the scapular regions, otherwise trauma may occur to the skin and underlying musculoskeletal structures.

Vibration is a fine, shaking pressure applied to the chest wall only during exhalation. This technique is thought to increase the velocity and turbulence of exhaled air, facilitating secretion removal. Vibration increases the exhalation of trapped air and may shake mucous loose and induce a cough.

BOX 35-12 Procedural guidelines for chest physiotherapy

Nursing care and selection of chest physiotherapy (CPT) skills are based on specific assessment findings. The following guidelines help nurses in physical assessment and subsequent decision-making.

- Know the patient's normal range of vital signs. Conditions such as atelectasis and pneumonia requiring CPT can affect vital signs. The degree of change is related to the level of hypoxia, overall cardiopulmonary status and tolerance to activity.
- Know the patient's medications. Certain medications, particularly diuretics and antihypertensives, cause fluid and haemodynamic changes. These may decrease the patient's tolerance to the positional changes of postural drainage. Steroid medications increase the patient's risk of pathological rib fractures and often contraindicate rib shaking.
- Know the patient's medical history. Certain conditions such as increased intracranial pressure, spinal cord injuries and abdominal aneurysm resection contraindicate the positional changes of postural drainage. Thoracic trauma or surgery may also contraindicate percussion, vibration and rib shaking.
- Know the patient's level of cognitive function. Participation in controlled coughing techniques requires the patient to follow instructions. Congenital or acquired cognitive limitations may alter the patient's ability to learn and participate in these techniques.
- Be aware of the patient's exercise tolerance. CPT manoeuvres are tiring. When the patient is not used to physical activity, initial tolerance to the manoeuvres may be decreased. However, with gradual increases in activity and planned CPT, patient tolerance for the procedure improves.

Postural drainage involves the use of positioning techniques that promote the movement of secretions from specific segments of the lungs and bronchi into the trachea. It improves mobilisation of secretions in patients with cystic fibrosis (McIlwaine et al 2010) and for those who have problems expectorating large volumes of sputum. However, it has limited benefit for the majority of patients (Fink 2002, Tang et al 2010, Yang et al 2010). Coughing or suctioning normally removes secretions from the trachea. The procedure for postural drainage can include most lung segments. Because patients may not require postural drainage of all lung segments, the procedure is based on clinical assessment findings. For example, patients with left lower lobe atelectasis may require postural drainage of only the affected region, whereas a child with cystic fibrosis may require postural drainage of all lung segments.

SUCTIONING TECHNIQUES When a patient is unable to clear respiratory tract secretions with coughing, nurses must use

Figure 35-15 Hand position for chest wall percussion during physiotherapy.

Potter PA, Perry AG 2004 Fundamentals of nursing, 6th edn. Mosby, St Louis.

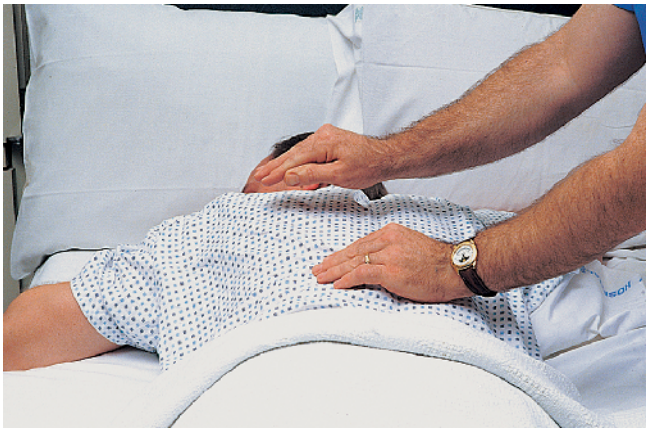

Figure 35-16 Chest wall percussion, alternating hand clapping against the patient's chest wall.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

suctioning to clear the airways. The suctioning techniques include oropharyngeal and nasopharyngeal suctioning, orotracheal and nasotracheal suctioning and suctioning an artificial airway.

These techniques are based on common principles. Because the oropharynx and trachea are considered sterile, sterile technique is used for suctioning. The mouth is considered clean, and therefore the suctioning of oral secretions should be performed after suctioning of the oropharynx and trachea. Each type of suctioning requires the use of a round-tipped catheter with a number of side holes at the distal end of the catheter. Frequency of suctioning is determined by patient assessment and need. If secretions are identified by inspection or auscultation techniques, suctioning is required. Sputum is not produced continuously or every 1–2 hours but occurs as a response to a pathological condition; therefore, there is no rationale for routine suctioning of all patients every 1–2 hours. In addition, suctioning reduces the amount of oxygen available in the dead space in the oropharynx and trachea, often resulting in significant desaturation of the patient. Nurses must be careful to monitor the patient to ensure adequate oxygenation. Too-frequent suctioning or increased length of time suctioning can put the patient at risk of developing hypoxaemia, hypotension or arrhythmias and possible trauma to the mucosa of the trachea.

OROPHARYNGEAL AND NASOPHARYNGEAL SUCTIONING

The oropharynx extends behind the mouth from the soft palate above the level of the hyoid bone and contains the tonsils. The nasopharynx is located behind the nose and extends to the level of the soft palate. Oropharyngeal or nasopharyngeal suctioning is used when the patient is able to cough effectively but is unable to clear secretions by expectorating or swallowing. The suction procedure is used after the patient has coughed (Skill 35-3). As the amount of pulmonary secretions is reduced and the patient is less fatigued, the patient may be able to expectorate or swallow the mucous and suctioning is no longer required.

OROTRACHEAL AND NASOTRACHEAL SUCTIONING

Orotracheal or nasotracheal suctioning is necessary when the patient with pulmonary secretions is unable to manage secretions by coughing and does not have an artificial airway present (see Skill 35-3). A catheter is passed through the mouth or nose into the trachea. The nose is the preferred route because stimulation of the gag reflex is minimal. The procedure is similar to nasopharyngeal suctioning, but the catheter tip is moved further into the patient's trachea. The risk of traumatic bleeding during nasopharyngeal suctioning is increased due to the sensitive nasal mucosa, which has an abundant blood supply. The entire procedure from catheter passage to its removal should be done quickly, lasting no longer than 15 seconds. Unless in respiratory distress, the patient should be allowed to rest between passes of the catheter. If the patient is using supplemental oxygen, the oxygen cannula or mask should be replaced during rest periods.

Tracheal suctioning is accomplished through an artificial airway such as an endotracheal tube or tracheostomy tube. The suction catheter should be no greater than half the size of the internal diameter of the artificial airway, so as not to cause an obstruction. Secretion removal should be as atraumatic as possible. To avoid trauma to the mucosa of the lung, suction pressure should never be applied while inserting the catheter, and suction pressure should be maintained between 100 and 150 mmHg. The suction catheter is inserted until a cough is initiated or until resistance is met. The catheter should be withdrawn by approximately 1 cm before applying suction, to prevent adherence to the trachea mucosa. Suction is applied intermittently as the catheter is withdrawn, to minimise the risk of adherence to the tracheal wall. Rotating the catheter will enhance removal of secretions that have adhered to the sides of the endotracheal or tracheostomy tube (Pierce 2007). Nurses should wear a mask and goggles and may need to wear a barrier gown to prevent splashes with body fluids.

ARTIFICIAL AIRWAYS An artificial airway is indicated for patients with decreased level of consciousness or with airway obstruction, and to aid in removal of tracheobronchial secretions.

Guedel airway A Guedel airway, the simplest type of artificial airway, prevents obstruction of the trachea caused by

SKILL 35-3

Suctioning

Delegation considerations

Suctioning requires the problem-solving and knowledge-application skills of professional nurses. Delegation is inappropriate.

Equipment

- Appropriate-size suction catheter (smallest diameter that will remove secretions effectively) or Yankauer catheter (oral suction)
- Small Y adapter (if catheter does not have a suction-control port)
- Two sterile gloves or one sterile and one non-sterile glove
- Sterile basin
- Sterile Normal saline solution or water (about 50 mL)
- Clean towel
- Portable or wall suction
- Connecting tube (1.5 metres)
- Nasal or oral airway (if indicated)
- Mask or face shield

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

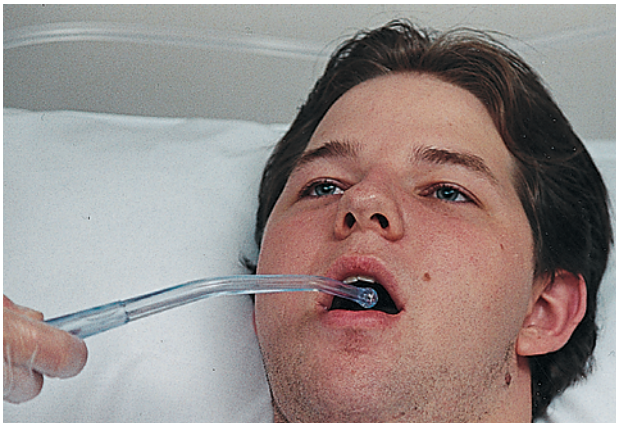
STEPS	RATIONALE
1. Assess signs and symptoms of upper and lower airway obstruction requiring nasotracheal or orotracheal suctioning, including respiratory rate or adventitious sounds, nasal secretions, drooling, gastric secretions or vomitus in mouth. • Assess signs and symptoms associated with hypoxia and hypercapnia: increased respiratory rate and/or increased pulse rate, decreased depth of breathing, low oxygen saturations, elevated blood pressure, pallor, cyanosis and dyspnoea, apprehension, anxiety, decreased ability to concentrate, lethargy, decreased level of consciousness (especially acute), increased fatigue, dizziness, behavioural changes (especially irritability).	Physical signs and symptoms result from decreased oxygen to tissues as well as pooling of secretions in upper and lower airways.
2. Determine factors that normally influence upper or lower airway functioning.	
a. Fluid status	Fluid overload may increase amount of secretions. Dehydration promotes thicker secretions.
b. Lack of humidity	The environment influences secretion formation and gas exchange, necessitating airway suctioning when patient cannot clear secretions effectively.

STEPS	RATIONALE
c. Infection	Patients with respiratory infections are prone to increased secretions that are thicker and sometimes more difficult to expectorate.
d. Anatomy	Abnormal anatomy can impair normal drainage of secretions. For example, nasal swelling, a deviated septum or facial fractures may impair nasal drainage. Tumours in or around the lower airway may impair secretion removal by occluding or externally compressing the lumen of the airway.
3. Assess patient's understanding of procedure.	Reveals need for patient instruction and encourages cooperation.
4. Obtain medical prescription if indicated by agency policy.	Some institutions require a medical prescription for tracheal suctioning.
5. Explain to patient how procedure will help clear airway and relieve breathing problems and that temporary coughing, sneezing, gagging or shortness of breath is normal. Encourage patient to cough out secretions. Practise coughing, if able. Splint surgical incisions, if necessary.	Encourages cooperation and minimises risks, anxiety and pain.
6. Help patient to assume position comfortable for nurse and patient (usually semi-Fowler's or sitting upright with head hyperextended, unless contraindicated).	Reduces stimulation of gag reflex, decreases patient discomfort, assists secretion drainage and prevents aspiration and nurse strain. Hyperextension facilitates insertion of catheter into trachea.
7. Place towel across patient's chest.	Reduces transmission of microorganisms by protecting gown from secretions.
8. Perform hand hygiene, and put on goggles and mask or face shield if available.	Reduces transmission of microorganisms.
9. Connect one end of connecting tubing to suction machine and place other end in convenient location near patient. Turn suction device on and set vacuum regulator to appropriate negative pressure (100–150 mmHg) (Pierce 2007).	Excessive negative pressure damages nasopharyngeal and tracheal mucosa and can induce greater hypoxia.
10. If indicated, increase supplemental oxygen therapy to 100% or as prescribed. Encourage patient's deep breathing.	These measures reduce suction-induced hypoxaemia.
11. Prepare suction catheter:	
a. Open suction kit or catheter with use of aseptic technique. If sterile drape is available, place it across patient's chest or on the overbed table. Do not allow the suction catheter to touch any non-sterile surfaces.	Maintains asepsis and reduces transmission of microorganisms.

STEPS	RATIONALE
b. Unwrap or open sterile basin and place on bedside table. Be careful not to touch inside of basin. Fill with about 50 mL of sterile Normal saline solution or water.	Saline or water is used to clean tubing after each suction pass.
12. Put sterile glove on each hand, or non-sterile glove on non-dominant hand and sterile glove on dominant hand.	Reduces transmission of microorganisms and allows nurse to maintain sterility of suction catheter.
13. Pick up Yankauer or suction catheter with dominant hand without touching non-sterile surfaces. Pick up connecting tubing with non-dominant hand. Secure catheter to tubing (see illustration).	Maintains catheter sterility. Connects catheter to suction.
14. Suction small amount of Normal saline solution from basin.	Ensures equipment function. Lubricates internal catheter and tubing.
15. Suction airway. **A. Oropharyngeal**	
(1) Insert catheter or Yankauer into mouth along gum line to pharynx. Move around mouth until secretions are cleared (see illustration). Encourage patient to cough. Replace oxygen mask.	Catheter provides continuous suction. Take care not to allow suction tip to invaginate oral mucosal surfaces. Coughing moves secretions from lower airway into mouth and upper airway.

■ **Critical decision point: Be careful not to dislodge any oral tubing or tubing in posterior pharynx, such as nasogastric tubes.**

Step 13 Attaching catheter to suction.



Step 15A(1) Suctioning secretions from mouth.

(2) Rinse catheter with water in cup or basin until connecting tubing is cleared of secretions. Turn off suction. May need to wash face if secretions are present on client's skin.	Rinsing catheter reduces probability of transmission of microorganisms. Cleaning suction tubing enhances delivery of set suction pressure. Prevents skin breakdown.

STEPS	RATIONALE
B. Nasopharyngeal and nasotracheal	
(1) Remove oxygen delivery device, if applicable, with non-dominant hand. Without applying suction and using dominant thumb and forefinger, gently but quickly insert catheter into the nostril during inhalation with slight downward slant. Do not force through the nostril (see illustration).	 Step 15B(1) Distance of insertion of nasotracheal catheter.

■ **Critical decision point: Be sure to insert catheter during patient inspiration, especially if inserting catheter into trachea, because epiglottis is open. Do not insert during swallowing, or catheter will most likely enter oesophagus. NEVER APPLY SUCTION DURING INSERTION.**

(2) Prior to nasopharyngeal or nasotracheal suctioning, ask patient to take several slow deep breaths.	Increases oxygen saturation and inflates lungs with oxygen-rich air to partially compensate for volume lost during suction procedure.
(a) Nasopharyngeal suctioning: In adults, insert catheter about 16 cm; in older children, 8–12 cm; in infants and young children, 4–8 cm. Rule of thumb is to insert catheter distance from tip of nose (or mouth) to base of earlobe.	
(b) Nasotracheal suctioning: In adults, insert catheter about 20 cm; in older children, 14–20 cm; in young children and infants, 8–14 cm.	
(c) Positioning: In some instances turning patient's head to right helps nurse suction left mainstem bronchus; turning head to left helps nurse suction right mainstem bronchus.	Application of suction pressure while introducing catheter into trachea increases risk of damage to mucosa and increases risk of hypoxia because of removal of entrained oxygen present in airways. Epiglottis is open on inspiration and facilitates insertion into trachea. Patient should cough. If patient gags or becomes nauseated, catheter is most likely in oesophagus and must be removed.
(d) If resistance is felt after insertion of catheter for maximum recommended distance, catheter has probably hit carina. Pull catheter back 1 cm before applying suction.	

■ **Critical decision point: Use nasal approach and perform tracheal suctioning before pharyngeal suctioning whenever possible. The mouth and pharynx contain more bacteria than the trachea does. If copious oral secretions are present before beginning the procedure, suction mouth with Yankauer suction device.**

STEPS	RATIONALE
(3) Apply intermittent suction for up to 10–15 seconds by placing and releasing non-dominant thumb over vent of catheter and slowly withdrawing catheter while rotating it back and forth between dominant thumb and forefinger. Encourage patient to cough. Replace oxygen device, if applicable.	Intermittent suction and rotation of catheter prevent injury to mucosa. If catheter 'grabs' mucosa, remove thumb to release suction. Suctioning longer than 10 seconds can cause cardiopulmonary compromise, usually from hypoxaemia or vagal overload.
(4) Rinse catheter and connecting tubing with Normal saline or water until cleared.	Removes secretions from catheter. Secretions that remain in suction catheter or connecting tubing decrease suctioning efficiency.
(5) Assess for need to repeat suctioning procedure. Allow adequate time between suction passes for ventilation and oxygenation. Ask patient to deep-breathe and cough. Replace the oxygen delivery device.	Observe for alterations in cardiopulmonary status. Suctioning can induce hypoxaemia, arrhythmias, laryngospasm and bronchospasm. Deep-breathing reventilates and reoxygenates alveoli. Repeated passes clear the airway of excessive secretions but can also remove oxygen and may induce laryngospasm.
(6) When pharynx and trachea are sufficiently cleared of secretions, perform oropharyngeal suctioning to clear mouth of secretions. Do not suction nose again after suctioning mouth.	Removes upper airway secretions. More microorganisms are generally present in mouth.
C. Tracheostomy tube – permanent and longstanding	
(1) Hyperoxygenate patient before suctioning (approx. 30 seconds) (Pierce 2007) if patient is being administered supplemental oxygen.	Preoxygenation converts large proportion of resident lung gas to 100% oxygen to offset amount used in metabolic consumption while oxygenation is interrupted during suctioning.
(2) Open swivel adapter or if necessary remove oxygen or humidity delivery device with non-dominant hand. If a closed system suction device is in place, no disconnection is necessary. The catheter is inserted through the plastic sheath which protects the catheter.	Exposes artificial airway.
(3) Without applying suction, gently but quickly insert catheter using dominant thumb and forefinger into artificial airway (best to time catheter insertion with inspiration) until resistance is met or patient coughs; then pull back 1 cm.	Application of suction pressure while introducing catheter into trachea increases risk of damage to tracheal mucosa, as well as increased hypoxia related to removal of entrained oxygen present in airways. Pulling back stimulates cough and removes catheter from mucosal wall.

STEPS	RATIONALE
(4) Apply suction either intermittently or continuously. Continuous suction may retrieve more secretions but increases volume of gas suctioned. Intermittent suction can be applied by placing and releasing non-dominant thumb over vent of catheter. Intermittent suction is recommended if catheter is in contact with tracheal walls and not in lumen of the tracheostomy tube. Slowly withdraw catheter while rotating it back and forth between dominant thumb and forefinger (Pierce 2007). Encourage patient to cough. Watch for respiratory distress.	Rotation of catheter exposes inlet of catheter to an increased surface area to retrieve more secretions.

Critical decision point: If patient develops respiratory distress during the suction procedure, immediately withdraw catheter and supply additional oxygen and breaths as needed. Oxygen can be administered directly through the catheter in an emergency. Disconnect suction and attach oxygen at prescribed flow rate through the catheter.

(5) Close swivel adapter or replace oxygen delivery device. Encourage patient to deep-breathe, if able.	Re-oxygenates and re-expands alveoli. Suctioning can cause hypoxaemia and atelectasis.
(6) Rinse catheter and connecting tubing with Normal saline until clear. Use continuous suction.	Removes catheter secretions. Secretions left in tubing decrease suction and provide environment for microorganism growth. Secretions left in connecting tube decrease suctioning efficiency.
(7) Assess patient's cardiopulmonary status for secretion clearance and complications. Repeat Steps (1) to (6) once or twice more to clear secretions. If more than one suction pass is needed (and closed system suction is not in situ), use a new suction catheter for each pass. Allow adequate time (at least 1 full minute) between suction passes for ventilation and re-oxygenation. Replace oxygen delivery device during rest times.	Suctioning can induce arrhythmias, hypoxia and bronchospasm and impair cerebral circulation or adversely affect haemodynamics. Repeated passes with suction catheter clear airway of excessive secretions and promote improved oxygenation.
(8) Perform nasopharyngeal and oropharyngeal suctioning. After nasopharyngeal and oropharyngeal suctioning is performed, catheter is contaminated; do not reinsert into tracheostomy tube.	Removes upper airway secretions.
16. When suctioning is completed, roll catheter around fingers of dominant hand. Pull glove off inside out so that catheter remains coiled in glove. Pull off other glove over first glove in same way to seal in contaminants. Discard in contaminated waste receptacle. Turn off suction device.	Reduces transmission of microorganisms.

STEPS	RATIONALE
17. Remove towel, place in appropriate receptacle and reposition patient as indicated by patient's condition. Nurse may need to wear clean gloves for personal care.	Reduces transmission of microorganisms. Promotes comfort. Sims' position encourages drainage and reduces risk of aspiration.
18. If indicated, readjust oxygen to original level because patient's blood oxygen level should have returned to baseline.	Prevents absorption atelectasis and oxygen toxicity while allowing patient time to re-oxygenate blood.
19. Discard remainder of Normal saline into appropriate receptacle. If basin is disposable, place into appropriate receptacle. If basin is reusable, rinse and place in soiled utility room.	Reduces transmission of microorganisms.
20. Remove goggles and mask or face shield. Discard disposable items and perform hand hygiene.	
21. Place unopened suction kit on suction machine or at head of bed according to institution preference.	Provides immediate access to suction catheter.
22. Compare patient's respiratory assessments before and after suctioning.	Identifies physiological effects of suction procedure to restore airway patency.
23. Ask patient if breathing is easier and if congestion is decreased.	Provides subjective confirmation that airway obstruction is relieved with suctioning procedure.
24. Observe airway secretions.	Provides data to document presence or absence of respiratory tract infection.

RECORDING AND REPORTING

- Record amount, consistency, colour and odour of secretions and patient's response to procedure; document patient's presuctioning and postsuctioning respiratory status.

HOME CARE CONSIDERATIONS

- In an emergency, Normal saline can be made at home by adding 2 teaspoons of table salt to 1 litre of boiled water. This solution should be freshly made and not stored.

displacement of the tongue into the oropharynx (Figure 35-17). The Guedel airway extends from the teeth to the oropharynx, maintaining the tongue in the normal position. The correct-size airway must be used. Proper Guedel airway size is determined by measuring the distance from the corner of the mouth to the angle of the jaw just below the ear. The length is equal to the distance from the flange of the airway to the tip. If the airway is too small, the tongue is not held in the anterior portion of the mouth; if the airway is too large, it may force the tongue towards the epiglottis and obstruct the airway.

The airway is inserted by turning the curve of the airway towards the hard palate, placing it over the tongue and inserting until the soft palate is reached. The airway is then rotated so that the opening points downwards, following the curvature of the tongue. Correctly placed, the airway moves the tongue forwards away from the oropharynx; and the flange, the flat portion of the airway, rests against the patient's teeth. Incorrect

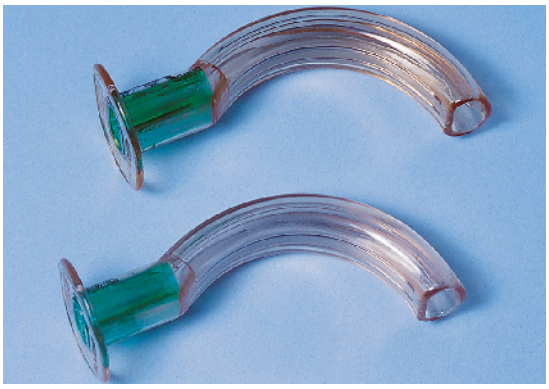


Figure 35-17 Guedel airways.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

insertion merely forces the tongue back into the oropharynx (Pierce 2007).

Nasopharyngeal airway This airway is a flexible tube that is inserted through one nostril and into the oropharynx. It is used when there is severe trauma to the mouth, or the mouth cannot be used for an oral airway (e.g. jaws wired, severe stomatitis). As for the Guedel airway, the correct-size airway must be used. Proper size is determined by measuring from the nostril to the angle of the jaw. A too-short airway will not maintain the airway, while a too-long airway risks entry into the oesophagus and inflation of the stomach, leading to vomiting and potential aspiration of gastric contents. This airway permits suctioning and a patent airway; it is never used in the patient with a suspected or actual fractured base of skull (Pierce 2007).

Tracheal airway Tracheal airways include endotracheal, nasotracheal and tracheostomy tubes. These allow easy access to the patient's trachea for deep tracheal suctioning. Because of the presence of the artificial airway, the patient no longer has normal humidification of the tracheal mucosa. Nurses should ensure that humidity is supplied to the airway through nebulisation or with the oxygen delivery system. This humidification is protective and helps reduce the risk of airway plugging.

The 'Mini Trach' is a narrow-bore tracheal access device to facilitate pulmonary hygiene in patients who are unable to cough and expectorate secretions from the lower airways. It remains capped between the requirements of pulmonary hygiene. It is inserted as for a tracheostomy tube but offers limited capacity for oxygen delivery.

Maintenance or promotion of lung expansion

Nursing interventions to maintain or promote lung expansion include non-invasive techniques. This includes positioning, procedures using equipment such as incentive spirometry and invasive procedures such as management of a chest tube.

POSITIONING In the healthy, completely mobile person, adequate ventilation and oxygenation are maintained by frequent position changes during daily activities. However, when a person's illness or injury restricts mobility, there is an increased risk of respiratory impairment. Frequent changes of position are simple and cost-effective methods for reducing the risks of stasis of pulmonary secretions and decreased chest wall expansion.

The most effective position for patients with cardiopulmonary diseases is the 45-degree semi-Fowler's position, using gravity to assist in lung expansion and reduce pressure from the abdomen on the diaphragm. Nurses need to ensure that the patient in this position does not slide down in bed, which could reduce lung expansion. A patient with unilateral lung disease, such as pneumothorax, atelectasis, pneumonia, thoracotomy and multiple trauma affecting one lung, should be positioned with the 'good lung down'. This promotes better perfusion of the healthy lung due to gravity, and gas is preferentially distributed to the better lung due to enhanced compliance. Hence, oxygenation is improved. In the presence of pulmonary abscess or haemorrhage, the patient should be placed with the affected lung down to prevent drainage towards the healthy lung (Pierce 2007).

INCENTIVE SPIROMETRY is a method of encouraging voluntary deep-breathing by providing visual feedback to patients about inspiratory volume. It is used to promote deep-breathing to prevent or treat atelectasis in the postoperative patient. Studies have, however, shown no respiratory benefit to postoperative incentive spirometry when compared with deep-breathing and early ambulation (Freitas et al 2007, Guimarães et al 2009).

- Flow-oriented incentive spirometers consist of one or more plastic chambers that contain freely moving coloured balls. The patient inhales slowly and with an even flow to elevate the balls and to keep them floating as long as possible, to ensure a maximally sustained inhalation.
- Volume-oriented incentive spirometry devices have a bellows that is raised to a predetermined volume by an inhaled breath (Figure 35-18). An achievement light or counter is used to provide feedback. Some devices are constructed so that the light will not turn on unless the bellows is held at a minimum desired volume for a specified period to enhance lung expansion.

Incentive spirometry encourages patients to breathe to their normal inspiratory capacities. A postoperative inspiratory capacity half to three-quarters of the preoperative volume is acceptable because of postoperative pain. Administration of pain medications before incentive spirometry will help the patient achieve deep-breathing by reducing pain and splinting (see Chapter 36).

CHEST TUBES Chest tubes, also termed intercostal catheters, are inserted to remove air and fluids from the pleural space to prevent air or fluid from re-entering the pleural space and to re-establish normal intrapleural and intrapulmonic pressures. A **chest tube** is a catheter inserted through the thorax to remove fluid or air. Chest tubes are used after chest surgery and chest trauma and for pneumothorax or haemothorax to promote lung re-expansion. They are sutured in place (Skill 35-4).

PNEUMOTHORAX A **pneumothorax** is a collection of air in the pleural space, between the visceral and parietal pleurae. The loss of negative intrapleural pressure causes the lung to

Figure 35-18 Volume-oriented spirometer.

SKILL 35-4

Care of patients with chest tubes

Delegation considerations

This task requires the problem-solving and knowledge-application abilities of a professional nurse and should not be delegated. Nurse assistants may help with positioning.

- Instruct care provider in the proper positioning of a patient with chest tubes to facilitate drainage.
- Explain to care provider the appropriate set-up of drainage equipment for the type of system to be used.
- Instruct care provider to inform nurse of any changes in the vital signs, chest tube drainage or excessive bubbling (air loss) in water-seal chamber.

Equipment

- Chest drainage system (bottles or disposable system)
- Suction source and set-up (wall canister or portable)
- Non-sterile gloves
- Sterile irrigation saline or sterile water (500 mL bottle)
- Tape (5 cm width)
- Sterile gauze sponges
- Two artery forceps

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess patient for respiratory distress and chest pain, breath sounds over affected lung area and stable vital signs (see Chapter 24).	Signs and symptoms reflect improvement in respiratory distress and chest pain after insertion of chest tube.
2. Observe for increased respiratory distress.	Signs and symptoms of increased respiratory distress and/or chest pain, decrease in breath sounds over the affected and non-affected lungs, marked cyanosis, asymmetrical chest movements, presence of subcutaneous emphysema around tube insertion site or neck, hypotension and tachycardia. Notify medical staff immediately.
3. Observe:	
a. Chest tube dressing.	Ensures that tubing is patent.
b. Tubing for kinks, dependent loops or clots.	Maintains a patent, freely draining system, preventing fluid accumulation in chest cavity.
c. Chest drainage system, which should be upright and below level of tube insertion.	System must be in this position to function properly and prevent air or water flowing back into the pleural cavity.

STEPS	RATIONALE
4. Provide two artery forceps for each chest tube, attached to top of patient's bed with adhesive tape. Chest tubes are clamped only under specific circumstances. Double-clamp close to the patient's chest only in the following circumstances: a. To assess air leak. b. To quickly empty or change collection bottle or chamber; performed by nurse who has received training in procedure. c. To change disposable systems; have new system ready to be connected before clamping tube so that transfer can be rapid and drainage system re-established. d. To change a broken water-seal bottle in the event that no sterile solution container is available. e. To assess if patient is ready to have chest tube removed (which is done by medical order); the nurse must monitor patient for re-accumulation of pneumothorax.	Artery forceps have a covering to prevent forceps from perforating chest tube.
5. Position patient:	
a. Semi-Fowler's position to evacuate air (pneumothorax).	Permits optimal drainage of air. Air rises to highest point in chest. Pneumothorax tubes are usually placed on anterior aspect at mid clavicular line, second or third intercostal space.
b. High-Fowler's position to drain fluid (haemothorax).	Permits optimal drainage of fluid. Posterior tubes are placed on mid axillary line, eighth or ninth intercostal space.
6. Maintain tube connection between chest and drainage tubes intact and taped. Connections should be taped longitudinally not circumferentially.	Secures chest tube to drainage system and reduces risk of air leak causing breaks in airtight system. Inadvertent loosening of connections beneath the tape of circumferential taping may go unnoticed as tape covers the join completely.
a. Water-seal vent must be without occlusion.	Permits displaced air to pass into atmosphere.
b. Suction-control chamber vent must be without occlusion when suction is used.	Provides safety factor of releasing excess negative pressure into atmosphere.
7. Coil excess tubing on mattress next to patient. Secure with rubber band and safety pin or system's clamp.	Prevents excess tubing from hanging over edge of mattress in dependent loop. Drainage could collect in loop and occlude drainage system.
8. Adjust tubing to hang in straight line from top of mattress to drainage chamber. If chest tube is draining fluid, indicate time (e.g. 0900) that drainage was begun on drainage bottle's adhesive tape or on write-on surface of disposable commercial system.	Provides a baseline for continuous assessment of type and quality of drainage.

STEPS	RATIONALE
9. Passively drain any fluid in the tubing into the collection chamber. Strip or milk chest tube only if indicated: a. Postoperative mediastinal chest tubes are manipulated if nursing assessment indicates obstruction of drainage secondary to clots or debris in tubing. b. Postoperative assessment is done every 15 minutes for the first 2 hours. This assessment interval then changes based on patient's status.	Stripping is controversial and should be performed only if hospital policy permits it and there is a medical prescription. Stripping creates a high degree of negative pressure and has potential to pull lung tissue or pleura into drainage holes of chest tube (Pierce 2007).

■ **Critical decision point: Review agency policy before milking or stripping chest tubes. In almost all instances this is contraindicated and not undertaken.**

10. Perform hand hygiene.	Reduces transmission of infection.
11. Observe:	
a. Chest tube dressing, tubing and chest tube drainage system, which should be upright and below level of tube insertion.	Ensures that tube is patent, and notes any drainage. Maintains tubing free of kinks and dependent loops. Note presence of clots or debris in tubing.
b. Water seal for fluctuations with patient's inspiration and expiration.	Fluid should rise in water seal with inspiration and fall with expiration, indicating that system is functioning properly.
c. Bubbling (air loss) in water-seal bottle or chamber (see Table 35-9).	When system is initially connected to patient, bubbles are expected in the underwater seal chamber from air that was present in system and in patient's intrapleural space. After a short period, bubbling will stop. Fluid will continue to fluctuate in water seal on inspiration and expiration until lung is re-expanded or system becomes occluded. It is important that the correct chamber is visualised to record the bubbling of air loss, i.e. underwater seal chamber and NOT the suction control chamber.
d. Type and amount of fluid drainage. Nurse should note colour and amount of drainage, patient's vital signs and skin colour.	Sudden gush of drainage may be retained blood and not active bleeding. Increase in drainage can be result of patient position.
(1) Less than 50–300 mL/h immediately postoperative in mediastinal chest tube; approximately 500 mL in first 24 hours; dark-red drainage is expected early in postoperative period, turning serous with time.	Re-expansion of lungs forces drainage into tube. Coughing can also cause large gushes of drainage.
(2) Between 100 and 300 mL of fluid may drain in posterior chest tube during first 2 hours after insertion; rate will decrease after 2 hours; 500–1000 mL can be expected in first 24 hours; drainage will be grossly bloody during first several hours after surgery and then change to serous.	Excessive amounts and/or continued presence of frank, bloody drainage after first several hours of surgery should be reported to the senior nurse or medical staff, along with patient's vital signs and respiratory status.

STEPS	RATIONALE
e. Bubbling in the suction-control chamber (when suction is being used) (see Table 35-9).	Suction-control chamber has constant, gentle bubbling. Tubing to suction source should be free of obstruction, and suction source should be turned on to appropriate setting.

RECORDING AND REPORTING

- Record in nurses' notes patency of chest tubes, presence of drainage, presence of fluctuations, patient's vital signs, chest dressing status, type of suction and level of comfort.

HOME CARE CONSIDERATIONS

- If patient goes home with chest tube (i.e. empyema), teach patient and family to care for chest tube and drainage bottle.

collapse. There are a number of causes of pneumothorax. It may occur spontaneously or as a result of chest trauma, such as a stabbing or the chest striking the steering wheel in a car accident. A pneumothorax may result from the rupture of an emphysematous bleb on the surface of the lung (a large bulla resulting from the destruction caused by emphysema) or from an invasive procedure such as insertion of a subclavian central venous catheter (CVC) line.

A patient with a pneumothorax usually feels pain as atmospheric air irritates the parietal pleura. The pain may be sharp and pleuritic. Dyspnoea is common and worsens as the size of the pneumothorax increases.

HAEMOTHORAX A **haemothorax** is an accumulation of blood and fluid in the pleural cavity between the parietal and visceral pleurae, usually as a result of trauma. It produces a counter-pressure and prevents the lung from full expansion. A haemothorax can also be caused by rupture of small blood vessels from inflammatory processes, such as pneumonia or tuberculosis. As well as pain and dyspnoea, symptoms of shock can develop if blood loss is severe.

Chest tube drainage systems

- The *one-bottle system* is the simplest closed drainage system because the single bottle serves as a collector and a water seal (Figure 35-19A). During normal respiration the fluid should ascend with inspiration and descend with expiration. The one-bottle system is used for smaller amounts of drainage, such as an empyema, which is a collection of infected fluid or pus in the pleural space.
- A *two-bottle system* permits the liquid to flow into the collection bottle as air flows into the water-seal bottle (Figure 35-19B). Fluctuations in the water-seal tube are still expected. The two-bottle system allows for more-accurate measurement of chest drainage and is used when larger amounts of drainage are expected.
- A *three-bottle system* is used to evacuate any volume of air or fluid with controlled suction (Figure 35-17C). The suction-control bottle contains a long tube, submerged under water and vented to the atmosphere. There are two short tubes: one tube connects bottles 2 and 3, and the second tube is connected to an external suction source. The suction pressure causes gentle, continuous bubbling in bottle 3. Suction pressure is measured in centimetres of water, and is equated with the length of the long tube submerged in water in bottle 3 and not to the level of pressure on the suction gauge. Usually 15–20 cm of water is used for adults. This means that the long tube is submerged in 15–20 cm of water. Children require lesser amounts of pressure.

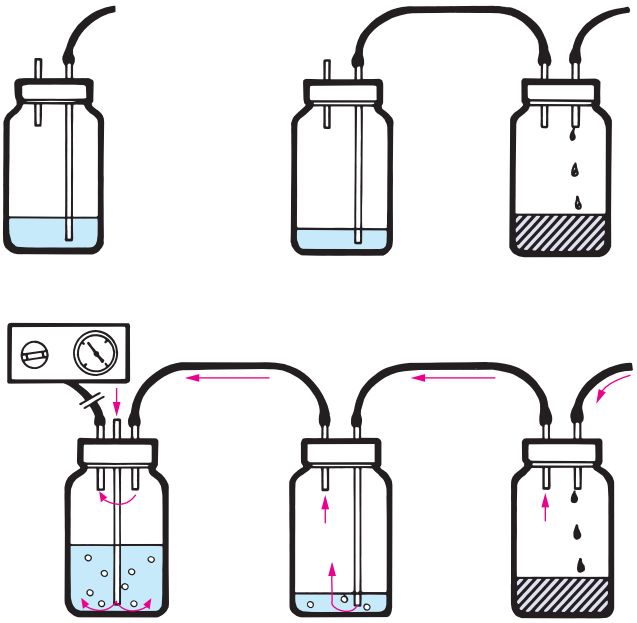

Figure 35-19 Chest tube drainage.

A, One-bottle system. B, Two-bottle system. C, Three-bottle system with suction.

Potter PA, Perry AG 2004 Fundamentals of nursing, 6th edn. Mosby, St Louis.

Disposable systems, such as the Thora Seal or Pleur-Evac chest drainage systems, are commercially available one-piece moulded plastic units that duplicate the three-bottle system (Figure 35-20). The disposable units appear to be the system of choice because they are cost-effective and some facilitate autotransfusion, a common practice in open-heart surgeries. Knowledge of the basics of chest tube management and

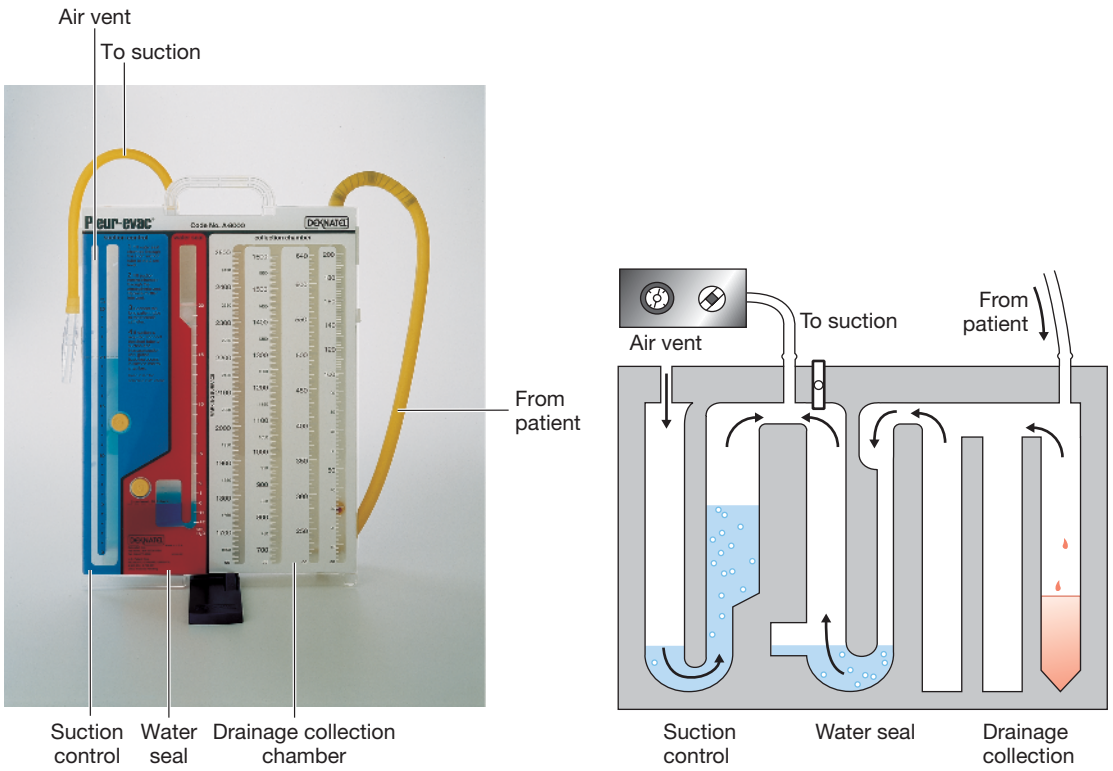

Figure 35-20 Chest drainage devices.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

troubleshooting manoeuvres reduces the patient's risk of complications (Table 35-9).

SPECIAL CONSIDERATIONS Clamping chest tubes is contraindicated. Nurses should handle the chest drainage unit or bottles carefully and maintain the drainage device below the patient's chest. If the tubing disconnects from the unit or bottles, the nurse should instruct the patient to exhale as much as possible and to cough. This manoeuvre rids the pleural space of as much air as possible. The nurse needs to clean the tips of the tubing and reconnect them to the bottles quickly. If a glass bottle is used and the bottle breaks, the end of the tubing can be quickly submerged in a container of sterile water to re-establish the seal. Clamping the chest tube may result in a tension pneumothorax, which is life-threatening.

Removal of chest tubes requires patient preparation. Patients report sensations during chest tube removal, the most common of which include burning, pain and pulling.

Maintenance and promotion of oxygenation

Promotion of lung expansion, mobilisation of secretions and maintenance of a patent airway help the patient meet oxygenation needs. Some patients, however, also require oxygen therapy to keep a healthy level of tissue oxygenation.

GOALS OF OXYGEN THERAPY The goal of oxygen therapy is to prevent or relieve hypoxia. Any patient with impaired tissue oxygenation can benefit from controlled oxygen administration. Oxygen is not a substitute for other treatment, however, and should be used only when indicated. Oxygen should be treated as a drug – it has dangerous side effects. As with any drug, the dosage or concentration of oxygen should be continuously monitored. Oxygen can be initiated by nurses in emergency situations when a patient experiences desaturation or becomes acutely dyspnoeic. Oxygen should be administered to achieve an oxygen saturation level of 88–92% for the COPD patient (Austin et al 2010, Beasley et al 2011) and approximately 95% for most other patients (Pierce 2007). Follow-up with the medical or nurse practitioner should occur as soon as possible. Nurses should routinely check the prescription to verify that the patient is receiving the prescribed oxygen concentration. The seven rights of medication administration also pertain to oxygen administration (see Chapter 27).

SAFETY PRECAUTIONS WITH OXYGEN THERAPY Oxygen supports combustion, which means that although it will not spontaneously burn or cause an explosion, it can easily cause a fire in a patient's room if it contacts a spark from an open flame or electrical equipment. Oxygen in high concentrations has a great combustible potential and readily fuels fire. With increasing use of home oxygen therapy, patients and healthcare professionals must be aware of the dangers of combustion. The nurse should promote safety by using the following measures:

- No smoking in the environment is strictly monitored.
- Nurses determine that all electrical equipment in the room is functioning correctly and is properly grounded. An electrical spark in the presence of oxygen can result in a serious fire.
- Nurses should know the fire procedures and the location of the closest fire extinguisher.

TABLE 35-9 Problem-solving with chest tubes

Problem	Solution
Leaks	
Air leak is present	Locate leak
Continuous bubbling is seen in water-seal bottle/chamber, indicating that leak is between patient and water seal	Tighten loose connections between patient and water seal; loose connections cause air to enter system Leaks are corrected when constant bubbling stops
Bubbling continues, indicating that air leak has not been corrected	Cross-clamp chest tube close to patient's chest. If bubbling stops, air leak is inside patient's thorax or at chest tube insertion site. Unclamp tube and notify medical staff immediately. Reinforce chest dressing. Leaving chest tube clamped causes a tension pneumothorax and mediastinal shift
Bubbling continues, indicating that leak is not in patient's chest or at insertion site	Gradually move clamps down drainage tubing away from patient and towards suction-control chamber, moving one clamp at a time. When bubbling stops, leak is in section of tubing or connection distal to clamp. Replace tubing or secure connection and release clamp
Bubbling continues, indicating that leak is not in tubing	Leak is in drainage system. Change drainage system
Patient symptoms	
• Tension pneumothorax is present • Severe respiratory distress • Chest pain • Absence of breath sounds on affected side • Hyper resonance on affected side • Mediastinal shift to unaffected side • Tracheal shift to unaffected side • Hypotension • Tachycardia	Determine that chest tubes are not clamped, kinked or occluded. Obstructed chest tubes trap air in intrapleural space when air leak originates within patient. Notify medical staff immediately. Prepare immediately for another chest tube insertion; obtain a flutter (Heimlich) valve or large-gauge needle for short-term emergency release of air in intrapleural space; have emergency equipment (e.g. oxygen and resuscitation trolley) near patient
Other	
Dependent loops of drainage tubing have trapped fluid	Passively drain tubing contents into drainage bottle by gravity. Coil excess tubing on mattress and secure in place
Water seal is disconnected	Connect water seal and tape connection
Water-seal bottle is broken	Insert distal end of water-seal tube into sterile solution so that tip is 2 cm below surface and set up new water-seal bottle. If no sterile solution is available, double-clamp chest tube while preparing new bottle
Water-seal tube is no longer submerged in sterile fluid	Add sterile solution to water-seal bottle until distal tip is 2 cm under surface or set water-seal bottle upright so that tip is submerged

- Nurses should always check the oxygen level of portable cylinders before transporting to ensure that there is enough oxygen remaining in the cylinder.
- Oxygen cylinders should be stored in a purpose-designed holder to avoid being knocked over and breaking the valve, which can potentially release the oxygen under pressure.

SUPPLY OF OXYGEN Oxygen is supplied to the patient's bedside generally through a permanent wall-piped system, but in some instances by oxygen cylinders. Oxygen cylinders are transported on carriers that allow the cylinder to be placed upright at the bedside. Regulators are used to control the amount of oxygen delivered. One common type is an upright flow meter with a flow adjustment valve at the top. A second type is a cylinder indicator with a flow adjustment handle.

In the hospital or home, oxygen cylinders are delivered with the regulator in place. Home care vendors are usually responsible for connecting the oxygen cylinder to the regulator for home use.

METHODS OF OXYGEN DELIVERY Oxygen can be delivered to the patient by nasal cannula, nasal catheter, face mask or mechanical ventilator.

Nasal cannula A nasal cannula is a simple, comfortable device (Figure 35-21). The two cannulas, about 1.5 cm long, protrude from the centre of a disposable tube and are inserted into the nares (Skill 35-5). Oxygen is delivered via the cannulas with a flow rate of up to 6 L/min. Flow rates greater than 4 L/min are not often used because of the drying effect on the mucosa and the relatively little increase in delivered oxygen concentration. Nurses must know what flow rate produces a given percentage of inspired oxygen concentration (FiO_2). Room air has an FiO_2 of

21% (Table 35-10). Nurses must also be alert for skin breakdown over the ears and in the nares from too tight an application of the nasal cannula.

Nasal catheter Nasal catheters are used infrequently, but they are not obsolete. The procedure involves inserting an oxygen catheter into the nose to the nasopharynx. Because securing the catheter can cause pressure on the nostril, the catheter must be changed at least every 8 hours and inserted into the other nostril each time. For this reason, the nasal catheter is a less desirable method because the patient may have pain when the catheter is passed into the nasopharynx and because trauma can occur to the nasal mucosa.

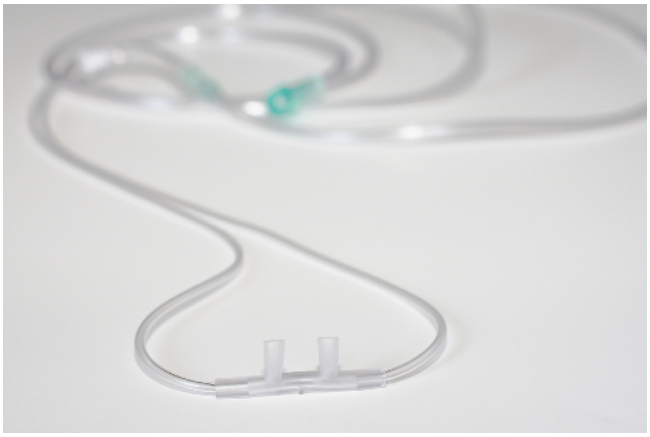

Figure 35-21 Nasal cannula.

Dreamstime/Susy56.

Oxygen masks An oxygen mask is a device used to administer oxygen, humidity or heated humidity. It is shaped to fit snugly over the mouth and nose and is secured in place with a strap. There are two main types of oxygen masks: those delivering

TABLE 35-10 Approximate fraction of inspired oxygen (FiO_2) with different delivery devices

Litre flow (L/min)	Approximate FiO_2 (%)	Delivery device
1	24	Nasal cannula
2	28	Nasal cannula
3	32	Nasal cannula
4	36	Nasal cannula

SKILL 35-5

Applying a nasal cannula or oxygen mask

Delegation considerations

This task can be delegated to appropriately trained nurse assistants. The nurse is responsible for assessing and checking the device set-up and the patient.

- Instruct care provider in the proper way to set up and apply the nasal cannula or oxygen mask.
- Instruct caregiver in unexpected outcomes associated with the oxygen delivery device and the need to inform the nurse if any occur.

Equipment

- Nasal cannula (see Figure 35-21) or oxygen mask
- Oxygen tubing
- Humidifier, if indicated
- Sterile water for humidification, if indicated
- Oxygen source
- Oxygen flow meter
- Appropriate room signs – oxygen in use, no smoking

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Inspect patient for signs and symptoms associated with hypoxia and presence of airway secretions.	Left untreated, hypoxia can produce cardiac arrhythmias and death. Presence of airway secretions decreases effectiveness of oxygen delivery.

■ **Critical decision point: Patients with sudden changes in their vital signs, level of consciousness or behaviour may be experiencing profound hypoxia. Patients who demonstrate subtle changes over time may have worsening of a chronic or existing condition or a new medical condition.**

2. Explain to patient and family what the procedure entails and the purpose of oxygen therapy.	Decreases patient's anxiety, which reduces oxygen consumption and increases patient cooperation.
3. Perform hand hygiene.	Reduces transmission of microorganisms.
4. Attach nasal cannula to oxygen tubing and attach to humidified oxygen source adjusted to prescribed flow rate.	Prevents drying of nasal and oral mucous membranes and airway secretions.
5. Place tips of cannula into patient's nares (see illustration) and adjust elastic headband or plastic slide until cannula fits snugly and comfortably (see illustration).	Directs flow of oxygen into patient's upper respiratory tract. Patient is more likely to keep cannula in place if it fits comfortably.

Step 5 Inserting cannula tips into patient's nares and adjusting plastic slide.

6. Maintain sufficient slack on oxygen tubing and secure to patient's clothes.	Allows patient to turn head without dislodging cannula and reduces pressure on tips of nares.
7. Check cannula every 8 hours and keep humidification jar filled at all times.	Ensures patency of cannula and oxygen flow. Prevents inhalation of dehumidified oxygen.
8. Observe patient's nares and superior surface of both ears for skin breakdown.	Oxygen therapy can cause drying of nasal mucosa. Pressure on ears from cannula tubing or elastic can cause skin irritation.

STEPS	RATIONALE
9. Check oxygen flow rate and prescriptions every 8 hours (see illustration).	Ensures delivery of prescribed oxygen flow rate and patency of cannula.
10. Wash hands.	Reduces transmission of microorganisms.
11. Inspect patient for relief of symptoms associated with hypoxia.	Indicates that hypoxia is corrected or reduced.

■ **Critical decision point: Note whether current oxygen therapy is meeting patient's oxygenation needs. Determine what factors have changed, resulting in new assessment findings.**

Step 9 Check oxygen flow rate.

RECORDING AND REPORTING

- Document oxygen delivery device and litre flow in medical record.
- Document patient and family education.
- Report oxygen delivery device, litre flow and response to changes in therapy to oncoming shift.

HOME CARE CONSIDERATIONS

- If patient is to have home oxygen therapy, teach patient and family how to use the oxygen equipment and properly apply the oxygen delivery device (see Skill 35-4).

low concentrations of oxygen, and those delivering high concentrations.

- The simple face mask (Figure 35-22) is used for short-term oxygen therapy. It fits loosely and delivers oxygen concentrations from 30% to 60%. The mask is contraindicated for patients with carbon dioxide retention because retention can be worsened.
- A plastic face mask with a reservoir bag (Figure 35-23) and a Venturi mask (Figure 35-24) are capable of delivering higher concentrations of oxygen.
  - When used as a non-rebreather, the plastic face mask with reservoir bag can deliver from 80% to 90% oxygen (70% when used as a rebreather) with a flow rate of at least 10 L/min. This oxygen mask maintains a high-concentration oxygen supply in the reservoir bag. The

Figure 35-22 Simple face mask.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

nurse should inspect the bag often to make sure it is inflated. If it is deflated, the patient may be breathing large amounts of exhaled carbon dioxide.

The Venturi mask can be used to deliver oxygen concentrations of 24% to 55% with oxygen flow rates of 2–14 L/min, depending on which flow-control meter is selected (Table 35-10).

HOME OXYGEN THERAPY Indications for home oxygen therapy include an arterial oxygen partial pressure (PaO_2) of 55 mmHg or less or an arterial oxygen saturation (SaO_2) of 88% or less on room air at rest, on exertion or with exercise. Patients with a PaO_2 of 56–59 mmHg may also receive oxygen if there is also evidence of corpulmonale, pulmonary hypertension, erythrocytosis, central nervous system dysfunction, impaired mental status or increasing hypoxaemia with exertion.

When home oxygen is required, it is usually delivered by nasal cannula. When a patient has a permanent tracheostomy, however, a T tube or tracheostomy collar is necessary. Three types of oxygen are used: compressed oxygen, liquid oxygen and oxygen concentrators. The advantages and disadvantages (Table 35-11) of each type are assessed, along with the patient's needs and community resources, before placing a delivery system in the home. In the home the major consideration is the oxygen delivery source.

Patients requiring home oxygen need extensive teaching to be able to continue oxygen therapy at home efficiently and safely (Skill 35-6). This includes oxygen safety, regulation of the amount of oxygen and how to use the prescribed home oxygen delivery system. Nurses coordinate the efforts of the patient

Figure 35-23 Plastic face mask with reservoir bag.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

TABLE 35-11 Home oxygen systems

System type	Primary use	Advantages	Disadvantages
Compressed gas cylinder	Intermittent therapy when oxygen is required only for short periods, such as for exercise or sleep only	100% oxygen, relatively inexpensive, no loss of gas during storage, relatively portable, delivery of high-volume flows of up to 15 L/min	Bulky, possibly unsightly, frequent refilling necessary with continuous use
Liquid oxygen system	High-volume flows and active patients	100% oxygen, conveniently portable, portable units refilled at home, delivery of up to 6 L/min; cost varies according to cylinder size; supply oxygen on inspiration only via nasal cannula – this increases life of cylinder by a factor of 5, depending on size of cylinder and flow rate during use	Usually weekly delivery necessary for refill, evaporates if not used, potential for frostbite at connections and if liquid is spilled
Concentrator	Moderate volume flows and patients with limited mobility inside or outside home	Delivers 96–98% oxygen; funding may be available to subsidise cost through various agencies – Veterans' Affairs, Palliative Care, Extended Aged Care at Home Packages; minimal interruption of household by supplier, no refills of 'main cylinder', most units with delivery of up to 4 or 5 L/min	Oxygen concentration decreases as litre flow increases (usually 85–90%), power supply necessary, second system for portability necessary (usually gas cylinders); can be noisy; tubing length for concentrators is recommended to be less than 13 m – this means concentrator needs to be placed in central area in most homes

SKILL 35-6

Using home liquid oxygen equipment

Delegation considerations

This task can be delegated to appropriately trained nurse assistants. The nurse is responsible for assessing and checking the device set-up and the patient.

- Instruct care provider in the proper way to set up and use home oxygen equipment.
- Instruct care provider in unexpected outcomes associated with use of home oxygen and the need to inform the nurse if any occur.

Equipment

- Nasal cannula equipment (see Skill 35-5)
- Primary and portable liquid oxygen source for mobility (see Figure 35-25)

STEPS	RATIONALE
1. Assess:	
a. Patient for need for home oxygen therapy.	Candidates for home oxygen have an arterial partial pressure of oxygen (PaO_2) of 55 mmHg or an oxygen saturation of 88% on room air, or a PaO_2 of 55–59 mmHg or an oxygen saturation of 86–89% with evidence of right heart failure, corpulmonale or polycythaemia.
b. Patient's or family's ability to use oxygen equipment properly, or for appropriate use of oxygen equipment in home setting.	Physical or cognitive impairments may require instructing family members or significant others on how to operate home oxygen equipment.
c. Patient's and family's ability to observe for signs and symptoms of hypoxia: apprehension, anxiety, decreased ability to concentrate, decreased level of consciousness, increased fatigue, dizziness, behavioural changes, increased pulse, increased respiratory rate, pallor or cyanosis of the mucous membranes.	Hypoxia can occur at home despite use of oxygen therapy. It can be caused by worsening of patient's physical condition or another underlying condition, such as a change in the respiratory status.
2. Explain procedure to patient and family.	Reinforces information given to patient and family; allows opportunity to ask questions.
3. Perform hand hygiene.	Reduces transmission of infection.
4. Demonstrate steps for preparation and completion of oxygen therapy.	Teaches psychomotor skill and enables patient to ask questions.
5. Prepare primary and portable oxygen.	
a. Place primary oxygen source in clutter-free environment.	Primary oxygen source replaces compressed oxygen cylinders.
b. Check oxygen levels of both sources by reading gauge on top (see illustrations).	Ensures adequate amount of oxygen available for use and timely refills of primary source.
c. Refill portable source by placing on top of primary source and pressing down firmly. Check oxygen gauge to determine fullness of portable source (see illustration).	Provides secure connection and prevents leakage of oxygen into room. If not seated securely, the cold liquid oxygen will leak out, creating a snow-like precipitate.

STEPS	RATIONALE
d. Select prescribed rate.	Ensures delivery of prescribed amount of oxygen.
e. Connect nasal cannula and oxygen tubing to oxygen source.	Connects oxygen source to delivery method.

Step 5 Check oxygen levels of both primary (left) and portable (right) oxygen sources.

6. Have patient and family perform each step with guidance from the nurse.	Allows nurse to correct for errors in technique and discuss their implications.

■ **Critical decision point: Discuss signs and symptoms of respiratory tract infection: fever; increased sputum production; change in colour, consistency or smell of sputum; difficulty clearing secretions; or shortness of breath.**

RECORDING AND REPORTING

- Record patient's and family's ability to safely use the home oxygen equipment.
- If multiple care providers are in the home, report the type of equipment, patient's and family's understanding and any concerns to the other care providers.

and family, community care nurse, home physiotherapist and home oxygen equipment vendor. During discharge planning, nurses usually help to arrange for the community care nurse and oxygen vendor. Nurses must help the patient and family learn about home oxygen and ensure their ability to maintain the oxygen delivery system.

Restoration of cardiopulmonary functioning

If a patient's hypoxia is severe and prolonged, cardiac arrest may result. A cardiac arrest is a sudden cessation of cardiac output and circulation. When this occurs, oxygen is not delivered to tissues, carbon dioxide is not transported from tissues, tissue metabolism becomes anaerobic and metabolic and respiratory

acidosis occurs. Permanent heart, brain and other tissue damage occurs within 4–6 minutes.

CARDIOPULMONARY RESUSCITATION Cardiac arrest is characterised by an absence of pulse and respiration. If nurses determine that the patient has cardiac arrest, cardiopulmonary resuscitation (CPR) must be initiated. CPR is a basic emergency procedure of expired air resuscitation (EAR) and manual external cardiac massage (Skill 35-7). Nursing students are required to have successfully completed a CPR course before their clinical experiences.

Cardiopulmonary resuscitation should follow the acronym 'DRSABCD' – check for *Danger*, then for *Responsiveness*, *Send for help*, open the *Airway*, check for *Breathing*, start *CPR* and finally attach a *Defibrillator* when available. If breathing is absent when checked (look, listen, feel), then chest compressions and rescue breathing are to be initiated in a ratio of 30 : 2, commencing with compressions. CPR no longer commences with three rescue breaths followed by checking for a pulse, as this has been shown to delay initiation of effective resuscitation (Australian Resuscitation Council 2010). It is paramount to circulate

SKILL 35-7

Cardiopulmonary resuscitation – basic life support

Delegation considerations

- Cardiopulmonary resuscitation (CPR) can be performed by trained staff.
- Review procedures for opening the airway if the patient has any risk of cervical neck trauma.
- Caution care provider regarding differences between infants, children and adults.

Equipment

- Ambu-bag, if available
- CPR pocket mask or barrier device, if available
- Chest compression board, if available and required. Hospital beds have a sufficiently firm base to perform compressions.
- Gloves, if available
- Resuscitation trolley, if available
- Face shield, if available

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. **Danger** Check for danger, e.g. potential electrical hazard.	Protects operator from potential injury.
2. **Responsiveness** Determine whether patient is unconscious by gently shaking patient and speaking loudly, giving simple commands such as 'Open your eyes, squeeze my hand'. If no response, grasp 2.5–5 cm of the trapezius muscle close to where the shoulder meets the neck. Squeeze and twist.	Confirms that patient is unconscious as opposed to intoxicated, sleeping or hearing-impaired.
3. **Send for help** Activate emergency medical services. Know telephone numbers for emergency services, both in the community and in the hospital.	The majority of adult victims are in ventricular fibrillation and need defibrillation and antiarrhythmic drugs as soon as possible.
4. **Suction oropharynx** or turn victim's head to one side, unless contraindicated.	Suction before opening airway minimises risk of aspiration of vomitus.

STEPS	RATIONALE
5. Open airway	
a. If no head or neck trauma, use head tilt/chin lift method (see illustration).	The tongue is the most common cause of airway obstruction in an unconscious patient. Airway obstruction from the tongue is relieved. If necessary, remove foreign body.
b. Jaw-thrust manoeuvre (see illustration) can be used by healthcare professionals but is not taught to the general public. Grasp angles of victim's lower jaw and lift with both hands, displacing mandible forwards while tilting head backwards.	When head and/or neck trauma is suspected, this manoeuvre opens the airway while maintaining proper head and neck alignment, thus reducing the risk of further damage to the neck.
c. If readily available, insert oral airway.	
d. Repeat suctioning procedure if necessary.	Secretions may have previously moved further down the airway.

Step 5a Head tilt/chin lift method of opening airway.

Step 5b Jaw-thrust manoeuvre.

6. Breathing Assess for breathing. Look and feel for movement of upper abdomen or chest. Listen for air leaving nose or mouth. If breathing absent, proceed straight to compressions.	
7. Cardiopulmonary resuscitation (CPR) Place victim on hard surface such as floor, ground or backboard. Victim must be flat. If necessary, logroll victim to flat, supine position using spine precautions. Initiate cardiopulmonary resuscitation in the ratio of 30 compressions followed by 2 breaths, commencing with compressions (as outlined below).	External compression of heart is facilitated. Heart is compressed between sternum and spinal vertebrae, which must be on a hard and firm surface. Ventilation is provided.
a. Assume correct and comfortable position.	Nurse may be administering CPR for extended period, particularly in community setting. Correct, comfortable position decreases skeletal muscle fatigue and promotes more effective compressions.
A. One-person rescue	
Position to face victim, on knees, parallel to victim's sternum.	Allows rescuer to quickly move back and forth from victim's mouth to sternum.

STEPS	RATIONALE
B. Two-person rescue	
One person faces victim, kneeling parallel to victim's head. Second person moves to opposite side and faces victim, kneeling parallel to victim's sternum.	Allows one rescuer to maintain breathing while other maintains circulation, without getting in each other's way.
b. If available, put on gloves and face shield.	Reduces transmission of microorganisms.
Critical decision point: It is important to avoid compressing below the lower limit of the sternum which may result in damage to the xiphoid process or internal organs and cause regurgitation of gastric contents.	
c. The appropriate site for chest compressions is the lower half of the sternum regardless of infant, child or adult.	Insufficient evidence exists for a specific site for chest compressions.
Adult (1) Place hands on the lower half of the sternum. Keep hands parallel to chest and fingers above chest. Interlocking fingers is helpful. Keep fingers off chest wall. Extend arms and lock elbows. Maintain arms straight and shoulders directly over victim's sternum.	 Step 7c(1) To keep hands off the xiphoid process, mark that area with two fingers of one hand and place the heel of the other hand next to them. The hand marking the xiphoid process can then be moved and placed on top of the other hand.
Child (2) Place heel of one hand on the lower half of the sternum (see illustration). Maintain head tilt with other hand, if possible, to maintain patent airway.	 Step 7c(2) Placement of hands for CPR of child.

STEPS	RATIONALE
Infant (3) Place two fingers on the lower half of the sternum (see illustration). Maintain head tilt with other hand, if possible, to maintain patent airway.	 Step 7c(3) Placement of fingers and hand for CPR of infant.
d. Compress sternum to one third of the depth of the chest and then release pressure, maintaining contact with skin to ensure ongoing proper placement of hands. Do not rock, but transmit weight vertically down. One third of the depth of the chest is approximately: (1) Adult: greater than 5 cm (see illustration). (2) Child: approx. 5 cm. (3) Infant: 4 cm.	Compression occurs only on sternum and is meant to squeeze the heart between the sternum and spine. Pressure necessary for external compression is created by nurse's upper arm muscle strength and upper body. When compression is released, the heart fills.  Step 7d(1) Compression for an adult.
e. Maintain proper rate of compression of 100/min regardless of age.	Proper number of compressions per minute should be delivered to ensure adequate cardiac output. Compression quality, particularly depth of compressions, deteriorates after a time.
f. Palpate for carotid or femoral pulse with chest compressions. If pulse is not palpable, compressions are not deep enough or hand position is incorrect.	Assessment of pulse validates that adequate stroke volume is achieved with each compression.

STEPS	RATIONALE
g. Mouth to mouth/mask is used for adults and older children (see illustration). Pinch the victim's nose with thumb and index fingers, and place the rescuer's mouth over the slightly open mouth of the victim or use CPR pocket mask. Maintain head tilt/chin lift while administering breaths so air enters lungs and not stomach. Each breath should last approximately 1 second and be of sufficient volume to raise the chest. Allow passive exhalation.	Provides adequate ventilation to excrete waste gas and supply adequate blood oxygen levels.  Step 7g Mouth-to-mouth position for an older child.
h. Mouth to nose is used for adult victims whose jaw remains clenched, or for infants and small children. Keep victim's head tilted with one hand on forehead. Use other hand to lift jaw and close mouth. Seal operator's lips around the victim's nose and blow. Allow passive exhalation.	
i. Ambu-bag; adult and child For ambu-bag resuscitation use proper size face mask and apply it under chin, up and over victim's mouth and nose.	Airtight seal is formed; as bag is compressed, oxygen enters patient.
j. For all forms of ventilation, observe for rise and fall of chest wall with each respiration (see illustration). Listen for air escaping during exhalation, and feel for flow of air. If lungs do not inflate, reposition head and neck and check for visible airway obstruction such as vomitus.	 Step 7j Listen and observe for respiration commencing independently.
8. Defibrillator Attach an automated external defibrillator (AED) as soon as one is available.	Time to defibrillation is the primary factor in patient survival.

STEPS	RATIONALE
a. Pads should be placed on bare skin of chest: one pad in anterior position, one pad in lateral position. Ensure good skin contact. This may require shaving chest hair. Adult pads are suitable for children over age 8 years. Paediatric pads should be used for children aged 1–8 years. Note that diagrams of appropriate placement are provided on pad packaging.	Appropriate pad placement ensures effective conduction and delivery of shock.
b. Switch AED on and follow the prompts.	
c. Do not touch the victim during delivery of the shock.	
d. Safety: avoid wet areas; remove oxygen from patient for delivery of shock.	

Australian Resuscitation Council (ARC) 2010 Guideline 4, Airway; Guideline 5, Breathing; Guideline 6, Compressions; Guideline 7, External automated defibrillation in basic life support; Guideline 8, Cardiopulmonary resuscitation. ARC, Melbourne. Online. Available: www.resus.org.au; accessed 1 April 2016.

RECORDING AND REPORTING

- Immediately report arrest, indicating exact location of victim. In hospital setting, follow hospital policy. In community setting, call emergency services.
- Record in medical record and appropriate code sheet onset of arrest, medication and other treatments given, procedures performed and victim's response.

HOME CARE CONSIDERATIONS

- Assess home environment to determine presence of a suitable backboard and patient's room to determine whether there is sufficient room to pull patient to the floor, if necessary, to perform CPR.
- A mouthpiece for CPR should be kept handy during all home health visits, and family should be advised to obtain mouthpieces when appropriate.
- If patient is at high risk of cardiopulmonary arrest, family or caregivers should be instructed and certified in CPR.
- Patient and family should keep emergency numbers taped to the phone. These numbers may include fire department, ambulance, hospital and doctor. Instruct patient and family on whom to call.

oxygenated blood to the brain to attempt to prevent permanent damage.

Restorative and extended care may emphasise cardiopulmonary reconditioning as a structured rehabilitation program. **Cardiopulmonary rehabilitation** is actively helping the patient to achieve and maintain the best possible level of health through controlled physical exercise; nutrition counselling; relaxation and stress management techniques; prescribed medications and oxygen; and adherence. As physical reconditioning occurs, the patient's complaints of dyspnoea, chest pain, fatigue and activity intolerance should decrease. The patient's anxiety, depression or somatic concerns also often decrease. The patient and the rehabilitation team together define goals of rehabilitation (Australian Lung Foundation 2009, National Heart Foundation of Australia 2004).

INSPIRATORY MUSCLE TRAINING improves muscle strength and endurance, resulting in improved activity tolerance. Inspiratory muscle training may prevent respiratory failure in patients with COPD (Australian Lung Foundation 2009).

One method of inspiratory muscle training is the **incentive spirometer resistive breathing device (ISRBD)**. Resistive breathing is achieved by placing a resistive breathing device into a volume-dependent incentive spirometer. Muscle training is achieved when the patient uses the ISRBD on a scheduled routine (e.g. twice a day for 15 minutes).

BREATHING EXERCISES include techniques to improve ventilation and oxygenation. The three basic techniques are deep-breathing and coughing exercises, pursed-lip breathing and diaphragmatic breathing. Deep-breathing and coughing exercises are routine interventions for postoperative patients (see Chapter 39).

Pursed-lip breathing involves deep inspiration and prolonged expiration through pursed lips to prevent alveolar collapse. While sitting up, the patient is instructed to take a deep breath

and to exhale slowly through pursed lips, as if blowing through a straw. The patient can also blow through a straw into a glass of water to learn the technique. Patients need to gain control of the exhalation phase so that it is longer than inhalation. The patient is usually able to perfect this technique by counting the inhalation time and gradually increasing the count during exhalation. In studies using pulse oximetry as a feedback tool, patients have been able to demonstrate an increase in their arterial oxygen saturation during pursed-lip breathing.

Diaphragmatic breathing is more difficult and requires the patient to relax the intercostals and accessory respiratory muscles while taking deep inspirations. The patient concentrates on expanding the diaphragm during controlled inspiration, and is taught to place one hand flat below the breastbone above the waist and the other hand 2–3 cm below the first hand. The patient inhales while the lower hand moves outwards during inspiration. The patient observes for inward movement as the diaphragm ascends. These exercises are initially taught with the patient in the supine position and then practised while the patient sits and stands. The exercise is often used with the pursed-lip breathing technique.

Diaphragmatic breathing is also useful for patients with pulmonary disease, for postoperative patients and for women in labour to promote relaxation and provide pain control. The exercise improves efficiency of breathing by decreasing air trapping and reducing the work of breathing.

EVALUATING IMPACTS AND OUTCOMES

Reflect on process and new learning

Nursing interventions and therapies are evaluated by comparing the patient's progress with the goals and expected outcomes of the nursing care plan. Patient care evaluates the actual care given to the patient by the healthcare team based on the expected outcomes (Figure 35-25). Patient expectations evaluate the care from the patient's perspective.

Patient care

Patients are the only ones who can evaluate their degree of breathlessness. They should be asked to rate their breathlessness using a validated dyspnoea assessment tool such as the MMRC Dyspnoea Scale or the Modified Borg Scale (Australian Lung Foundation 2009). Evaluation of arterial blood gases, pulmonary function tests, vital signs, ECG tracings and physical assessment data provide nurses with objective measurements of the success of therapies and treatments. Outcomes are compared with expected outcomes to determine a patient's health status. Continuous evaluation allows nurses to determine whether new or revised therapies are required and whether new problems have developed and require a new plan of care. When nursing measures directed to improve oxygenation are unsuccessful, the nurse must immediately modify the nursing care plan. Nurses should not hesitate to notify medical staff about a patient's deteriorating oxygenation status. Prompt notification can avoid an emergency situation or even the need for CPR. Continuous evaluation allows nurses to determine whether new or revised therapies are required and whether new problems have developed and require a new plan of care.

Patient expectations

If nurses have successfully developed a good relationship with a patient, the patient will be more willing to share their satisfaction. It is important for nurses to ask the patient if their expectations of care have been met. For example, the nurse can ask the patient 'Do you feel as though you will be able to

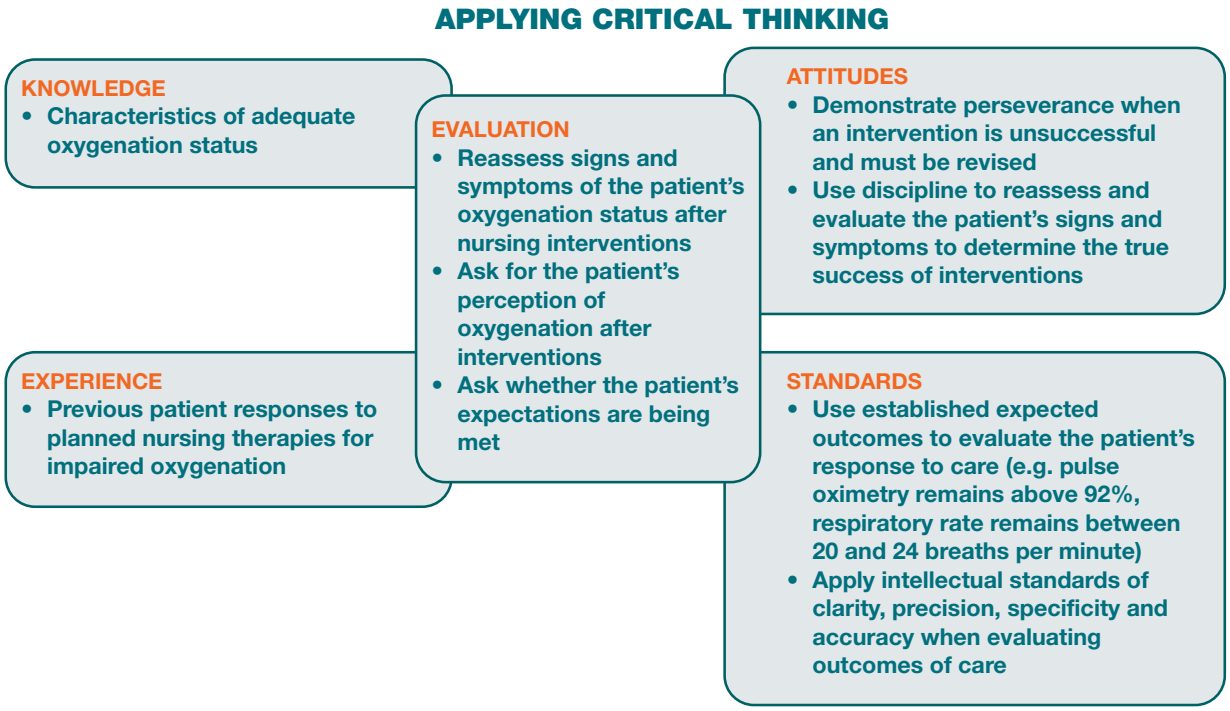

Figure 35-25 **Critical thinking associated with the evaluation phase for oxygenation.**

use the breathing techniques at home that we have practised?' If the patient says that this may not work at home, then the patient's expectations for care management have not been met. Nurses should ask the patient whether all questions and needs have been met. If not, nurses need to spend more time understanding what the patient wants and needs to meet the expectations. Working closely with the patient will enable nurses to redefine those patient expectations that can be realistically met within the limitations of the patient's condition and treatment.

• CRITICAL REFLECTION POINT

Mrs Arwae, a 55-year-old Torres Strait Islander, asks your advice on preventive strategies for reducing her husband's risk of contracting another chest infection this year. As a nurse at the family practice clinic, what advice could you offer Mrs Arwae?

Key concepts

- The main function of the heart is to deliver deoxygenated blood to the lungs for oxygenation and to deliver oxygen and nutrients to the tissues.
- Preload, afterload, contractility and heart rate alter cardiac output.
- Cardiac arrhythmias are classified by site of impulse origin and mechanism of the cardiac response.
- The main function of the lungs is to transfer oxygen from the atmosphere into the alveoli and to transfer carbon dioxide out of the body as a waste product.
- Ventilation is the process of providing adequate oxygenation from the alveoli to the blood.
- Compliance, or the ability of the lungs to expand and contract, depends on the function of musculoskeletal and neurological systems and on other physiological factors.
- The process of inspiration (active process) and expiration (passive process) is caused by changes in intrapleural and intra-alveolar pressures and lung volumes.
- Respiration is controlled by the central nervous system and by chemicals within the blood.
- Decreased haemoglobin levels alter the patient's ability to transport oxygen.
- Impaired chest wall movement reduces the level of tissue oxygenation.
- The nursing assessment includes information about the patient's cough, dyspnoea, fatigue, wheezing, chest pain, environmental exposures, respiratory infection, cardiopulmonary risk factors, use of medications and physical functioning.
- Diagnostic and laboratory tests may be needed to complete the database for a patient with decreased oxygenation and/or perfusion.
- Coughing and suctioning techniques are used to maintain a patent airway.
- Oxygen therapy is used to improve levels of tissue oxygenation and is delivered by a nasal cannula, nasal catheter or oxygen mask.
- Cardiac arrest requires the use of cardiopulmonary resuscitation.

Managing pain

Anthony Schoenwald and Clint Douglas

KEY TERMS

Acute pain, p. 1321
Adjuvants, p. 1337
Analgesic pain ladder, p. 1344
Biopsychosocial model of pain, p. 1324
Chronic pain, p. 1322
Epidural analgesia, p. 1348
Gate control theory of pain, p. 1323
Local anaesthetic, p. 1353
Modulation, p. 1327
Multimodal analgesia, p. 1344
Neuropathic pain, p. 1322
Nociception, p. 1324
Nociceptive pain, p. 1322
Opioids, p. 1346
Patient-controlled analgesia, p. 1348
Perception, p. 1327
Transduction, p. 1327
Transmission, p. 1327

Learning outcomes

Mastery of content will enable you to:

- demonstrate a comprehensive understanding of the concepts related to pain
- explain influential models of pain, including the gate control theory
- identify the importance of providing person-centred care by adopting a biopsychosocial approach when caring for patients with pain
- perform a comprehensive pain assessment and advocate for appropriate care by accepting and acting on the patient's report of pain
- explain the pharmacology of the three analgesic groups in pain management and the concept of multimodal analgesia
- develop nurse-initiated and collaborative interventions for preventing and treating opioid-related side effects
- describe the role of the nurse in providing safe and effective pain management for patients receiving patient-controlled analgesia, epidural or intrathecal analgesia, or peripheral nerve blocks
- describe commonly used non-drug interventions for acute pain
- engage in the clinical reasoning process for pain management, following a cycle of assessment, intervention and reassessment.

Introduction

Pain is a key consideration in all patient-care situations and nurses play a critical role in pain management. This chapter aims to provide an introduction to some key concepts in pain management and to encourage you to reflect on some of your assumptions about pain. It presents evidence-based information to help you assess and manage pain successfully in collaboration with other healthcare providers.

Nurses are uniquely positioned to improve patient outcomes through effective pain assessment and management, and yet there is ample evidence, gathered over several decades, of poor pain assessment and undertreatment of patients in pain (Pasero & McCaffery 2011). Despite the rapidly evolving scientific knowledge base for pain management, the evidence suggests that patients are at risk of inadequate pain control (e.g. Gerbershagen et al 2013). Why might this be so? Read the following *Clinical example* and identify barriers to adequate acute pain control in this situation. What knowledge and skills did the RN use to advocate for appropriate pain relief?

CLINICAL EXAMPLE

'A real pain' by Paola Scamperle, RN

As a neurosurgical nurse I've got plenty to do, including helping patients with some of the things some doctors don't do well – one of which is effectively managing patients' pain. Let me give you an example. I recently took care of a patient whose surgeon insisted that he didn't need much nursing care. The patient had been operated on for a herniated disc and had only been out of surgery for 1 day. Interestingly, the patient himself was a senior doctor, a gastroenterologist who'd come to our hospital and unit because of the spine surgeon's reputation.

As soon as I began to take care of him, the patient–doctor asked me to tell him about the normal course of postoperative recovery for this kind of operation. I told him we usually discharged patients 2 days after their surgery and that we gave them a prescription for pain medication. He was very concerned about pain meds because he'd been in unbearable pain before his surgery and took pain pills daily. After the operation he continued to take these pills, but was still complaining about his pain. Plus, he had a lot of pain that we hadn't expected from the wound site.

When his well-respected surgeon came in to do a quick exam, the patient told him that he was in pain. Although this surgeon is very competent and self-confident, pain management is not one of his strengths. He just doesn't understand that pain is an exquisitely personal experience and that each patient experiences it differently.

So what was the doctor's response to this particular patient? He insisted the patient was somehow 'imagining' his pain, not really having it. The surgeon told the patient that he'd checked on his surgery, all was well, and he should no longer be in pain. So even though I spoke with him about the patient's pain, he didn't come up with a different pain management strategy.

Not surprisingly, when it came time for his discharge 2 days later, the patient was still in so much pain that he couldn't leave the hospital. When the surgeon and a medical student made their rounds that day, the patient again asked them about his pain. Once again, they insisted that the patient's pain could not be as severe as he said it was.

By now, I'd been with the patient over several days. I watched how he walked and knew how uncomfortable he was. I knew I had to do something to manage his pain and recognised that ordinary painkillers just wouldn't work.

The first thing I did was talk to the patient. In a careful tone, I said: 'Look, Dr X, your surgeon is very knowledgeable and competent. Most of the time patients don't have a lot of pain. But I know from experience that the kind of inflammatory pain you're having doesn't resolve within the first day or two. What you need is some cortisone prescribed in a single dose in the morning for a few days. I have seen this work in other cases with worse pain than yours.'

The patient–doctor thought about this. He thanked me for the suggestion and asked me to talk to the surgeon and suggest that he order the medication. I waited until the surgeon was out of the operating room and talked with him. He'd become so frustrated with the patient that he quickly agreed. He ordered the medication, and I gave the cortisone to the patient. Pretty soon the patient was comfortable and appeared not only relaxed but serene.

He approached me in the hall and said, 'I want to thank you so much for your patience, your availability and, most of all, your competence and professional attitude you showed me these past days. If it hadn't been for you, I would still be in pain. I would have been suffering the same pain that made my life intolerable and led me to have this surgery in the first place. I want to thank you for dealing with this and all the needs I've had since I came to the hospital.'

Nurses do these kinds of things every day. Isn't it about time we advertised them?

Defining pain

Pain is often defined according to the International Association for the Study of Pain (IASP) as:

> **An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.**

This definition underscores the subjectivity of pain and acknowledges the importance of emotional as well as sensory factors in the pain experience. It also highlights

that although pain is usually considered a warning signal of actual or potential tissue damage, pain can occur in the absence of tissue damage, even though the experience may be described as if the damage has occurred.

The most widely accepted and clinically useful definition of pain, however, was developed by a leading nursing expert on pain, Margo McCaffery (1968:95):

> **Pain is whatever the experiencing person says it is, existing whenever he or she says it does.**

This definition reflects an understanding that the patient is the authority on their pain and the only one who can describe the experience. Nurses who approach pain from this perspective (like the neurosurgical nurse in the *Clinical example* above) can help the patient achieve effective management by advocating for proper control. If the patient cannot provide a self-report, a variety of other methods, such as observation of behavioural indicators, are used to assess the pain.

• CRITICAL REFLECTION POINT

Take a minute to think about McCaffery's clinical definition of pain. Do you agree with this definition? Who is the authority on the patient's pain? Whose pain is it?

Acute pain

In evolutionary terms, **acute pain** can be understood as an important biological protective mechanism to warn the body of injury or disease. Acute pain directs immediate attention to the situation, promotes reflexive withdrawal and fosters other actions that prevent further damage and enhance healing. Acute pain usually stops long before healing has occurred, which may take days or a few weeks.

Clinically, poorly controlled acute pain can lead to serious adverse outcomes for patients and their families. Acute postoperative pain delays healing and leads to systemic complications (see Table 36-1). Rehabilitation may be delayed and hospitalisation prolonged if acute pain is not controlled. Uncontrolled acute pain can also lead to the development of chronic pain problems.

• CRITICAL REFLECTION POINT

You are caring for a patient admitted to a surgical ward after a fall that has resulted in multiple rib fractures. He has an intercostal catheter to correct a pneumothorax. His respirations are shallow and he cannot cough effectively due to pain. His body temperature is 39°C. What complications could poorly controlled acute pain cause in this situation?

TABLE 36-1 The harmful effects of unrelieved pain

Domains affected	Specific responses to pain
Endocrine	↑ Adrenocorticotrophic hormone (ACTH), ↑ cortisol, ↑ antidiuretic hormone (ADH), ↑ adrenaline, ↑ noradrenaline, ↑ growth hormone (GH), ↑ catecholamines, ↑ renin, ↑ angiotensin II, ↑ aldosterone, ↑ glucagon, ↑ interleukin-1, ↓ insulin, ↓ testosterone
Metabolic	Gluconeogenesis, hepatic glycogenolysis, hyperglycaemia, glucose intolerance, insulin resistance, muscle protein catabolism, ↑ lipolysis
Cardiovascular	↑ Heart rate, ↑ cardiac workload, ↑ peripheral vascular resistance, hypertension, ↑ myocardial oxygen consumption, deep-vein thrombosis
Respiratory	↓ Lung volumes, atelectasis, hypoxaemia, ↓ cough, sputum retention, infection
Genitourinary	↓ Urinary retention
Gastrointestinal	↓ Gastric and bowel motility
Musculoskeletal	Muscle spasm, impaired muscle function, fatigue, immobility
Cognitive	Reduction in cognitive function, mental confusion
Immune	Depression of immune response
Developmental	↑ Behavioural and physiological responses to pain, altered temperaments, higher somatisation, infant distress behaviour; possible altered development of the pain system, ↑ vulnerability to stress disorders, addictive behaviour and anxiety states
Future pain	Debilitating chronic pain syndromes: chronic post-surgical pain, neuropathic pain
Psychological	Sleeplessness, anxiety, fear, helplessness, ↑ thoughts of suicide

↓ = decreased; ↑ = increased.

Pasero C, McCaffery M 2011 Pain assessment and pharmacologic management. Mosby, St Louis, p. 11. Data from Cousins M 1994 Acute postoperative pain. In Wall PD, Melzack R (eds), Textbook of pain, 3rd edn. Churchill Livingstone, New York; Kehlet H 1998 Modification of responses to surgery by neural blockade. In Cousins MJ, Bridenbaugh PO (eds), Neural blockade. Lippincott-Raven, Philadelphia; Macintyre P, Schug S 2015 Acute pain management: a practical guide, 4th edn. CRC Press, Boca Raton.

Chronic pain

In contrast to acute pain, **chronic pain** persists constantly or intermittently past the normal time of healing and serves no biological purpose. Chronic pain is clearly not a warning to prevent injury or disease – it is a disease in its own right (Siddall & Cousins 2004). Chronic pain can occur after injury or surgery, with chronic disease and disability, and sometimes the exact cause of persistent pain is unknown. While this chapter focuses on acute pain management, Douglas (2014) provides a discussion of chronic pain management from a nursing perspective. Table 36-2 compares some important clinical aspects of acute and chronic pain.

Nociceptive pain

Another common way to categorise pain problems is by their underlying clinical mechanisms. **Nociceptive (physiological) pain** is sustained by activation of the sensory systems that process noxious stimuli. It is the result of damage to somatic or visceral tissues sufficient to activate the normal pain transmission system. Examples include pain associated with trauma, surgery, burns and tumour growth.

Neuropathic pain

Neuropathic (pathophysiological) pain is sustained by injury or dysfunction of the peripheral and/or central nervous system (CNS). In contrast to nociceptive pain, which is caused by activation of essentially normal neural systems, neuropathic pain is caused by the abnormal processing of stimuli. Neuropathic pain problems are common in diseases affecting the nervous system, such as diabetes mellitus, herpes zoster and multiple sclerosis. It may also result from surgery and/or trauma to nervous tissue.

TABLE 36-2 Comparison of acute and chronic pain

Acute pain	Chronic pain
Short duration and resolves with healing	Persists for months beyond the time of healing
Responds to reasonable doses of analgesics	Poor response to conventional analgesics
Rapid rehabilitation and return to normal social roles	Disability, diminished social roles and poor quality of life
Poor management and emotional distress may lead to chronic pain	Anxiety and depression are common features
Mostly nociceptive in origin	Associated with features of neuropathic pain
Usually located to the area of trauma or disease	Radicular components away from the original site of injury or disease
Simple management plan with multimodal approach	Management plan is complex and involves adjunctive drugs and a multidisciplinary approach

Evolution of pain theories

Early pain theories

Historically, acute pain has been understood using a biomedical model. The basic ideas of this view of pain are most often attributed to the work of 17th-century philosopher René Descartes (1596–1650). Descartes attempted to explain pain in purely mechanistic terms using the analogy of a foot coming into contact with fire (Figure 36-1). This conception of pain was a straight-through channel from the skin to the brain. It assumed a direct and one-to-one relationship between the amount of tissue damage and perceived pain.

While there were key developments in scientific thinking about pain over the 19th and early 20th centuries, the *biomedical model of pain* was widely accepted and often taught as fact rather than theory. Following this model, medical assessment and treatment of pain were concerned only with the underlying tissue damage or injury. Psychological and social factors were thought to play a secondary role and were viewed as simply responses to pain itself (Keefe 2009).

Figure 36-1 Descartes' model of pain.

• CRITICAL REFLECTION POINT

It is easy to assume that pain severity is closely tied to the amount of tissue damage based on our personal experiences of pain, but can you think of exceptions to this idea? Can you identify any examples of injury without pain, or vice versa? What factors might explain the highly individual and variable responses to pain after surgery?

Gate control theory of pain

Although the biomedical model has been very influential in understanding and treating acute pain, its failure to explain why pain is not always proportional to the amount of tissue damage or injury spurred interest in alternative theories of pain. One of the most influential of these theories was Melzack and Wall's (1965) **gate control theory of pain**. The main hypothesis of the gate control theory is that there is a neural gating system in the dorsal horn of the spinal cord which modulates the transmission of noxious signals from the periphery to the brain based on the peripheral input (i.e. relative balance of large diameter and small diameter fibre input), as well as the dynamic action of brain processes (Figure 36-2).

The gate control theory proposes that under certain circumstances (e.g. exposure to danger, use of adaptive coping skills, or high levels of social support) higher brain centres are activated to 'close the gate' in the spinal cord and inhibit transmission of noxious signals to the brain. Under other circumstances (e.g. when preoccupied with pain, depressed, or exposed to interpersonal stress), neural processes in the brain are activated in a way that 'opens the gate' and facilitates transmission of noxious signals to the brain. It was this radical shift in thinking about the role of psychological factors in pain perception that is perhaps the most important contribution of the gate control theory. The theory underscores that, through its influence on spinal gating mechanisms, the brain plays a crucial role in pain inhibition and facilitation (Keefe 2009). Some non-pharmacological therapies can be explained using the gate control theory. For example, it is thought that massage or cutaneous stimulation can activate large fibre impulses (touch) that close the pain gate.

• CRITICAL REFLECTION POINT

Use the gate control theory to explain why rubbing an injury helps to reduce pain or how a sportsperson can continue a game after serious injury yet report no pain?

Shortly after it was introduced, Melzack and Casey (1968) expanded the gate control theory to describe the neural systems beyond the gate in the spinal cord. Three brain systems were hypothesised to interact to create the subjective experience of pain. According to Melzack, the sensory–discriminative dimension of pain refers to the sensory processing of location, intensity and quality of pain. The motivational–affective dimension is the emotional response to pain. The cognitive–evaluative dimension involves the appraisal of pain in terms of attention, meaning and past experience.

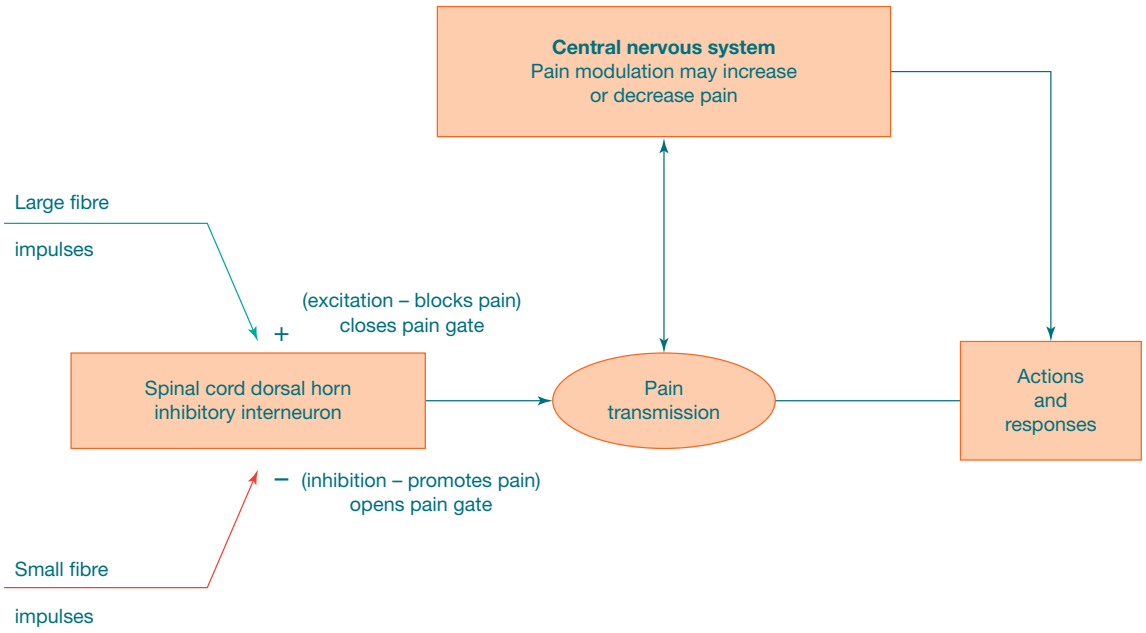

Figure 36-2 **Gate control theory of pain.**

SE Huether, KL McCance 2008 Understanding pathophysiology, 4th edn, Mosby, St Louis.

Post-gate control theories

The gate control theory stimulated a great amount of laboratory and clinical pain research in the decades that followed. In contrast to the biomedical model, the gate control theory did not view psychosocial factors as simply responses to pain, but rather as an integral component of pain processing (Keefe 2009). Although the theory made an important contribution to our understanding of pain, Melzack (1999) points out that the gate control theory still fails to explain certain pain problems, such as phantom limb pain. Melzack's most recent work has been to shift the focus of pain theory from the peripheries and spinal mechanisms to understand how the brain creates the experience of pain in the proposed *neuromatrix theory of pain*.

Person-centred care: working from a biopsychosocial perspective

Biopsychosocial model of pain

The most useful contemporary model for nursing practice which brings together much of what we know about pain is the **biopsychosocial model of pain** (Gatchel et al 2007). The biopsychosocial model highlights the multidimensional nature of pain, and builds on the gate control theory by emphasising the role of psychosocial factors (Douglas 2014). The conceptual view of the biopsychosocial model of pain is presented in Figure 36-3. In this onion skin model we see that biomedical factors may initiate and maintain nociceptive input, psychological factors influence the appraisal and perception of pain, and social factors shape the person's behavioural responses. All of these factors interact to shape an individual's response to pain (Douglas 2014).

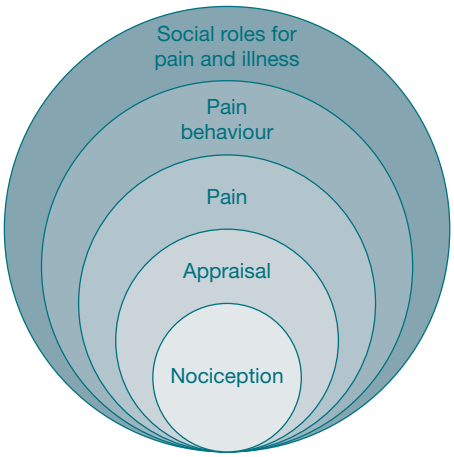

Figure 36-3 Biopsychosocial model of pain.

Turk DC, Burwinkle TM 2006 Coping with chronic pain. In Carr A, McNulty M (eds), The handbook of adult clinical psychology: an evidence-based practice approach. Reproduced with permission of Taylor & Franics Books UK.

The biopsychosocial model makes clear the important distinction between nociception and pain (Gatchel et al 2007). **Nociception** is a physiologic process which involves activation of nerves by tissue damage or inflammation that convey information to the brain. In contrast, pain is the subjective perception that always involves conscious awareness, emotional and cognitive appraisals (Gatchel et al 2007). Pain is a private and personal experience.

Pain behaviours are overt manifestations of pain and suffering, such as grimacing, moaning or protecting a body part. In acute pain, 'fight-or-flight' responses may occur, such as increased vital signs, sweating and dilated pupils. However, the response to pain is highly individual, is shaped by social and cultural factors, and humans quickly adapt physiologically and behaviourally to pain. Be careful not to expect certain responses when assessing any type of pain. The absence of pain behaviours does not mean the absence of pain.

Working from a biopsychosocial perspective challenges nurses and other clinicians to accept that it is the *person* in pain, rather than the underlying disease process, that is the focus of assessment and management. The person in pain is the expert and most accurate source of information about their pain. The person in pain is also the expert on the effectiveness of pain therapies and interventions. This means taking the time to understand the physical, psychological and social dimensions of pain from the patient's perspective and tailoring treatment based on their individual needs and priorities.

Although administering analgesics may be the cornerstone of acute pain management, there are very practical applications of a biopsychosocial approach to pain using fundamental nursing skills. Using skilled communication to determine the patient's needs may uncover other physical factors contributing to discomfort, such as uncomfortable position, thirst, or the need to urinate (Wells, Pasero & McCaffery 2008). Psychosocial factors contributing to pain can be elicited by building trust and listening to the patient's concerns or fears, seeking the patient's understanding of their condition and their need to be informed, and respecting and safely involving the patient and significant others in their care. Addressing these needs will improve patient comfort and communicate your desire to promote comfort. McCaffery (2002) argues that a short time spent with the patient to communicate concern and caring may go a long way to providing patient comfort. The content of this 5-minute conversation may include the following:

- Listening to patient concerns.
- Communicating the desire to help the patient become more comfortable.
- Determining strategies that might achieve more comfort.

Consistent with the Fundamentals of Care Framework discussed in Chapter 2, a biopsychosocial way of thinking about pain puts the person at the centre of their care. The large variation in patient reports of pain and responses to treatment becomes more understandable if we accept that pain is a subjective, individual experience that is shaped by a range of biological, psychological and social factors. Following this model, we will first discuss the physiologic basis of pain and then important psychosocial contributors to the pain experience.

Physiology of pain

The sensory experience of acute pain is mediated by a specialised system, called the *nociceptive system*. Between the stimulus of tissue injury and the subjective experience of pain is a series of complex electrical and chemical events. To understand this, it is useful to conceptualise four key physiological processes involved: transduction, transmission, perception and modulation (Figure 36-4).

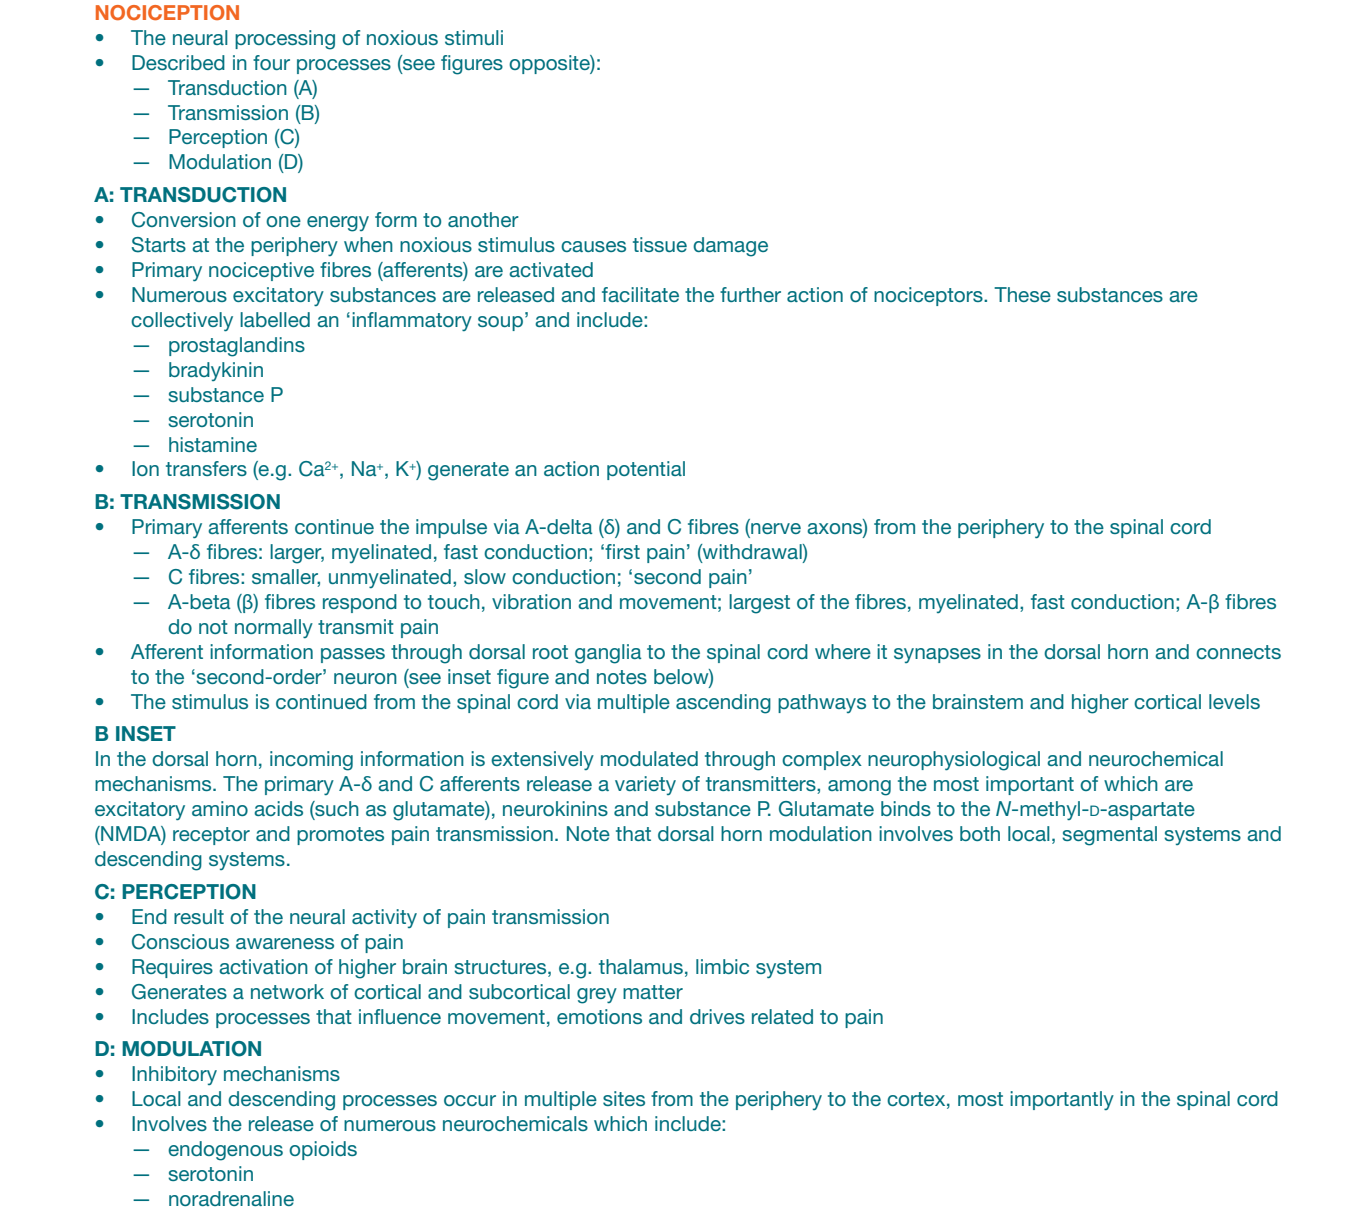

Figure 36-4 Nociception: 'normal' pain transmission.

Pasero C, McCaffery M (eds) 2011 Pain assessment and pharmacologic management. Mosby, St. Louis.

continued

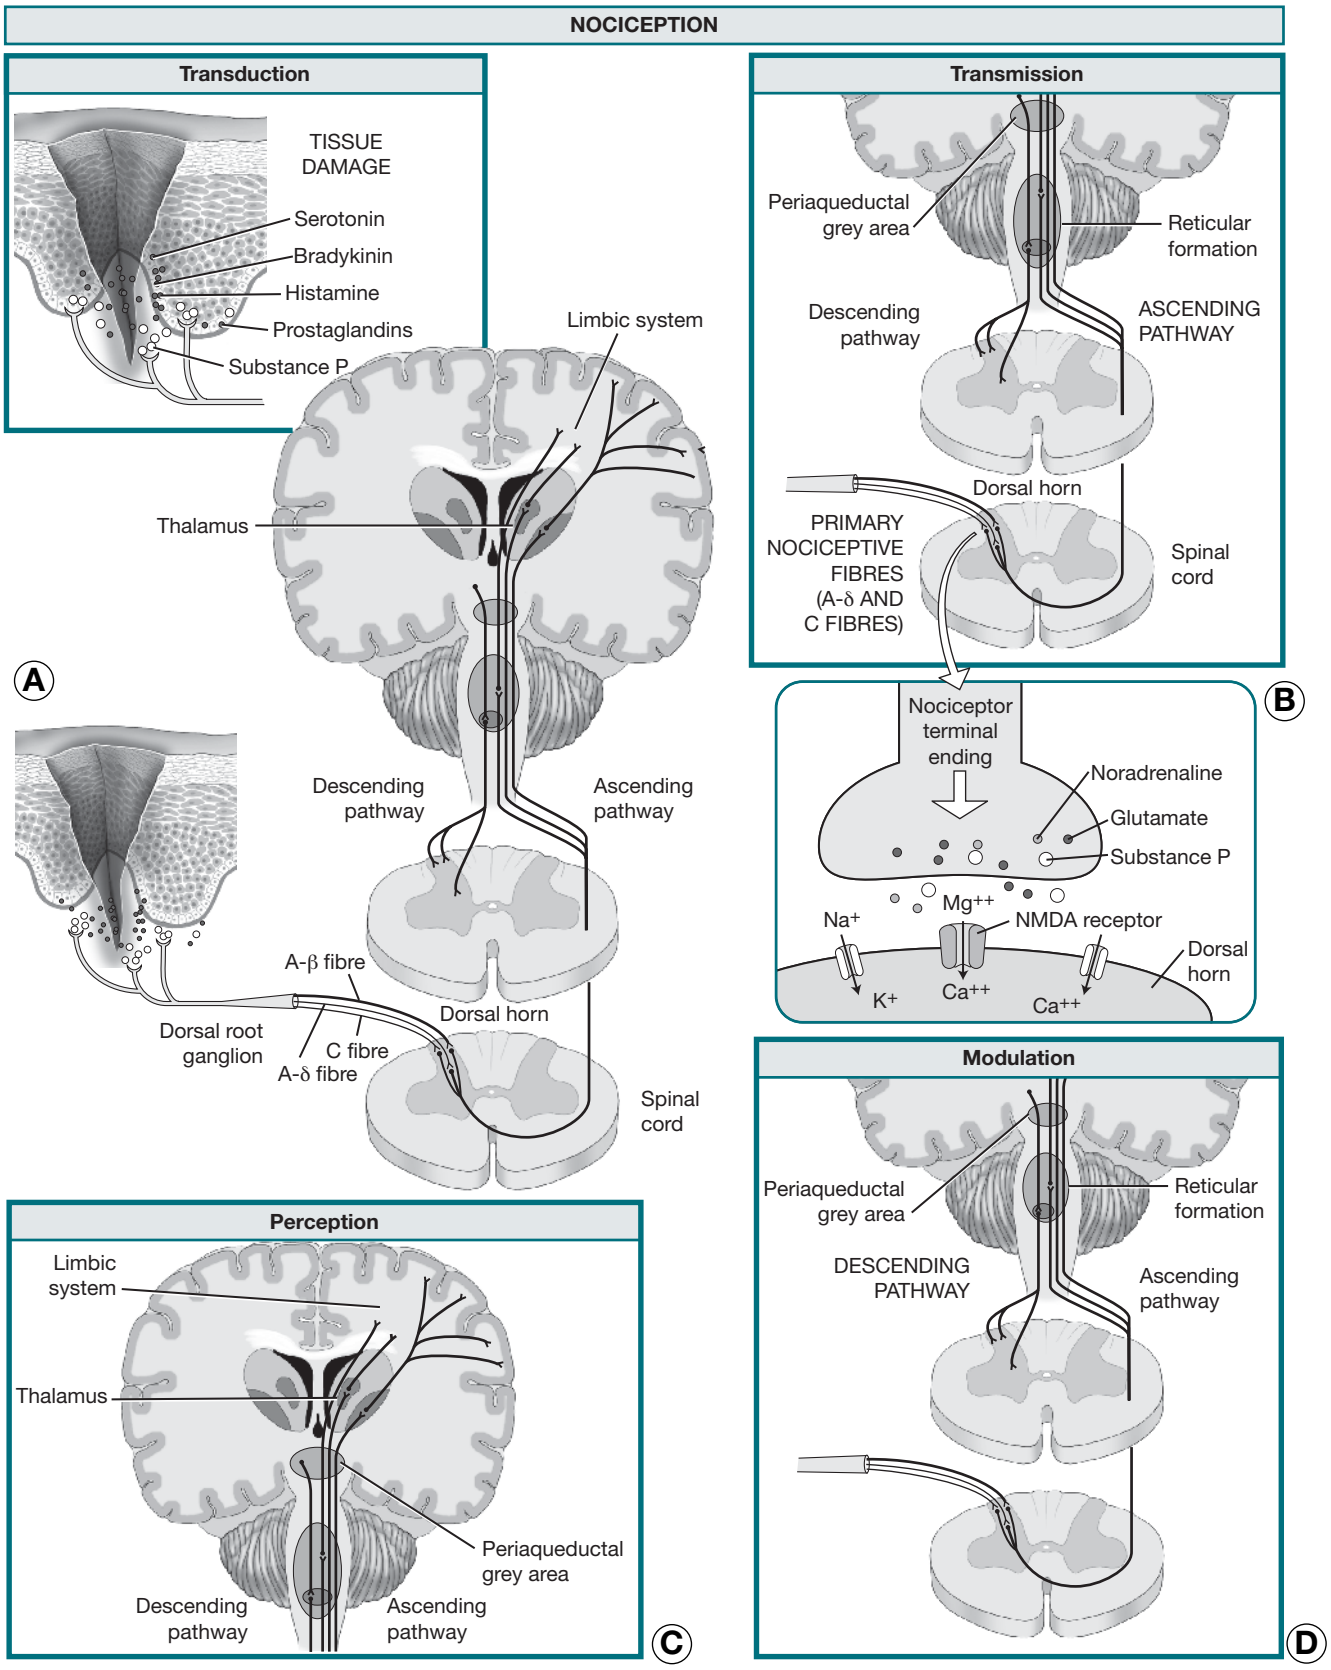

Figure 36-4 ***continued***

Transduction

Transduction refers to the processes by which noxious stimuli activate nociceptors, which are primary afferent neurons that exist throughout the body (skin, subcutaneous tissue and visceral or somatic structures). Nociceptors have free nerve endings which respond selectively to mechanical (e.g. incision, tumour growth), thermal (e.g. burn, frostbite) or chemical (e.g. toxins, chemotherapy) stimuli, which are then converted into a neuronal action potential.

Tissue damage and inflammation also cause the release of chemical mediators from injured cells, inflammatory cells (e.g. mast cells, lymphocytes) and primary afferent neurons which lower the excitability threshold of nociceptors and sensitise them to further sensory input. A partial list of these chemicals includes bradykinin, prostaglandins, serotonin, histamine and substance P, known collectively as the 'inflammatory soup'. These chemicals stimulate or sensitise the nociceptors to send impulses to the spinal cord.

Transmission

Transmission of action potentials generated from effective transduction occurs along two types of nociceptor fibres towards the CNS. *A-delta fibres* are thinly myelinated, large-diameter, fast-conducting fibres (5–30 metres/second), which transmit well-localised sensations of sharp pain. *C fibres* are unmyelinated, small-diameter, slow-conducting fibres (0.5–2 metres/second), which transmit pain that is poorly localised, dull and aching. Other types of sensory fibres, such as *A-beta fibres*, do not usually transmit nociceptive information, but respond to touch, movement and vibration.

For example, after spraining an ankle a person initially feels a sharp, localised pain, related to A-delta fibre transmission. Within a few seconds, the pain becomes more diffuse and widespread, until the whole foot aches, which is related to C-fibre activation. The C fibres remain exposed to the chemicals released when cells are damaged.

Transmission continues along the primary afferent fibres until they synapse in the dorsal horn of the spinal cord. Within the dorsal horn, neurotransmitters (such as glutamate, neurokinins and substance P) are released, causing a synaptic transmission from the primary afferent neurons to second-order neurons in the spinal cord which project to the brainstem and thalamus via multiple ascending pathways. Of these pathways, the spinothalamic and spinoreticular tracts are particularly important. These second-order fibres cross the midline and ascend in the anterolateral quadrant of the spinal cord.

Perception

Perception is the point at which a person is consciously aware of pain. It requires the activation of higher brain structures, including the thalamus and cortex. It involves both awareness and related cognitions and the occurrence of emotions and drives associated with pain (Pasero & Portenoy 2011). From the thalamus, third-order neurons transmit impulses to various areas of the brain. Figure 36-5 identifies the major cortical structures involved in pain perception.

Modulation

Modulation (inhibition or facilitation) of afferent input can also occur anywhere along nociceptive pathways, particularly in the spinal cord, as suggested by the gate control theory discussed earlier. When activated, descending efferent pathways originating in the brain release a number of chemicals capable of altering the processing of nociceptive input. Of the descending inhibition systems, the periaqueductal grey (PAG) region is particularly important; this projects to the dorsal horn of the spinal cord.

These descending pathways release substances such as endogenous opioids (endorphins and encephalin), serotonin and noradrenaline, which can inhibit the transmission of noxious stimuli and produce analgesia. For example, when released in the spinal dorsal horn these substances can bind to receptors to prevent the release of neurotransmitters from primary afferent nociceptors such as substance P to second-order neurons, thus blocking transmission of the impulse. Activation of these descending pathways by drug therapy or positive thoughts can produce analgesia (Voscopoulos & Lema 2010).

• CRITICAL REFLECTION POINT

The discussion so far has been about the normal physiological processes involved in nociceptive pain. But what mechanisms can explain the development of pathophysiological pain problems such as chronic inflammatory and neuropathic pain? A key development in our understanding of pain mechanisms is the concept of *neuroplasticity* of the nervous system, which refers to the ability of neurons throughout the peripheral and central nervous systems to change their structure and function because of nociceptive input. Explore what the terms *peripheral sensitisation* and *central sensitisation* mean and how they might contribute to the pathophysiology of acute and chronic pain problems.

Psychosocial factors influencing pain

Psychological and social factors play a central role in the experience of acute pain (Keefe 2009). Together they shape the way an individual makes sense of and gives

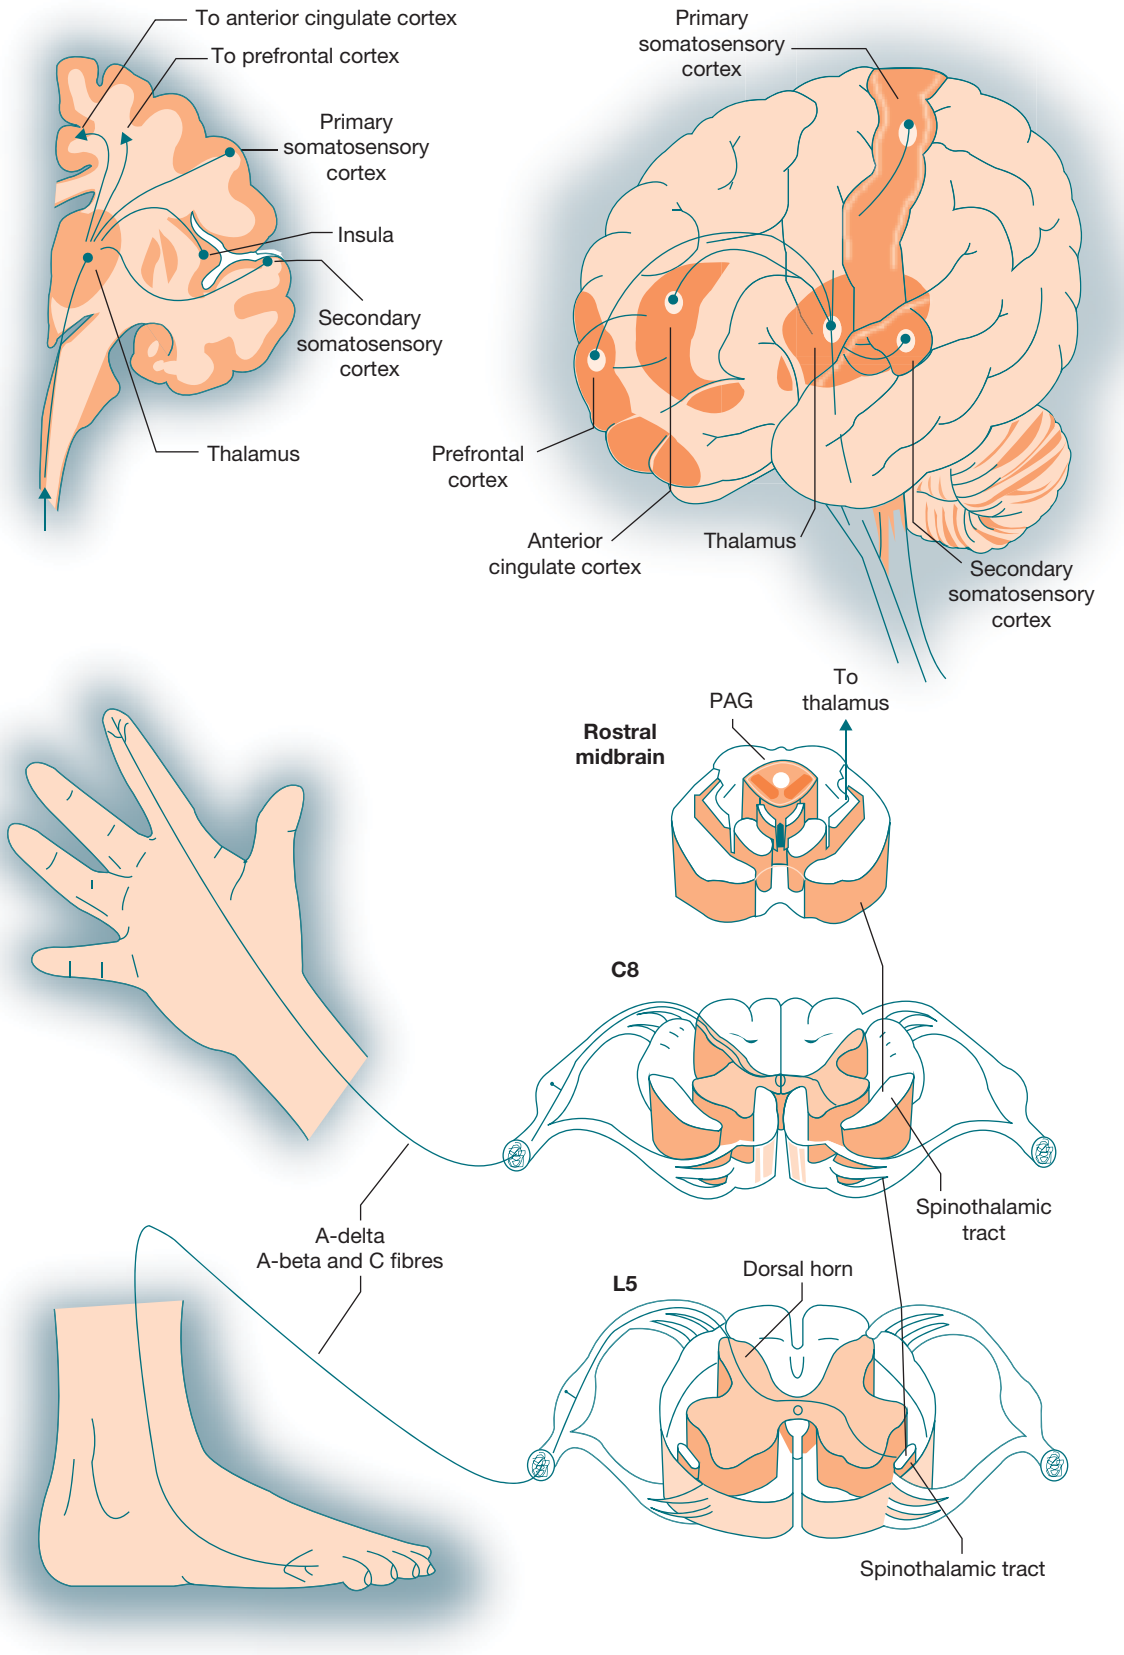

Figure 36-5 Structures involved in pain perception.

Jensen MP 2010 A neuropsychological model of pain: research and clinical implications. The Journal of Pain 11(1):3.

meaning to pain. They also influence the way in which the individual will cope with pain and the extent to which it will interfere with recovery.

• CRITICAL REFLECTION POINT

'Here is perhaps the most difficult thought to accept about pain. We experience pain only and entirely as we interpret it. It seizes us as if with an unseen hand, sometimes stopping us in mid-sentence or mid-motion, but we too capture and reshape it' (Morris 1991:29).

Anxiety and depression

The relationship between pain and psychological disturbance is complex. Anxiety and depression often increase the perception of pain, but pain may also cause feelings of anxiety and may even lead to depression (Keefe 2009). It is important that patients are screened for these feelings, especially prior to hospital admission. In this way, patients at risk of having poor pain control can be identified and pre-emptive strategies undertaken.

Perceived control

People develop underlying beliefs and attitudes to make sense of their pain. These include beliefs about the cause, meaning and appropriate treatment of pain, as well as perceptions of control over pain and personal coping efficacy (Thorn 2004). A greater sense of control over the pain management plan leads to better analgesia and patient outcomes. Offering patients more information and discussing choices regarding their admission and pain management are useful strategies. Taking a person-centred approach means respecting patient preferences, values and beliefs regarding pain and its management.

Catastrophising

Pain catastrophising has been defined as the tendency to ruminate on and magnify pain and to feel helpless when confronted with pain (Sullivan 2009). It has been found to be one of the most important psychosocial predictors of pain and adjustment to pain (Keefe 2009). In the early postoperative period, anxiety, depression and catastrophising are linked to higher pain severity and/or opioid requirements, and greater risk for developing chronic pain after surgery. The relationship between pain catastrophising, anxiety and depression and their effects in the postoperative context is presented in Figure 36-6.

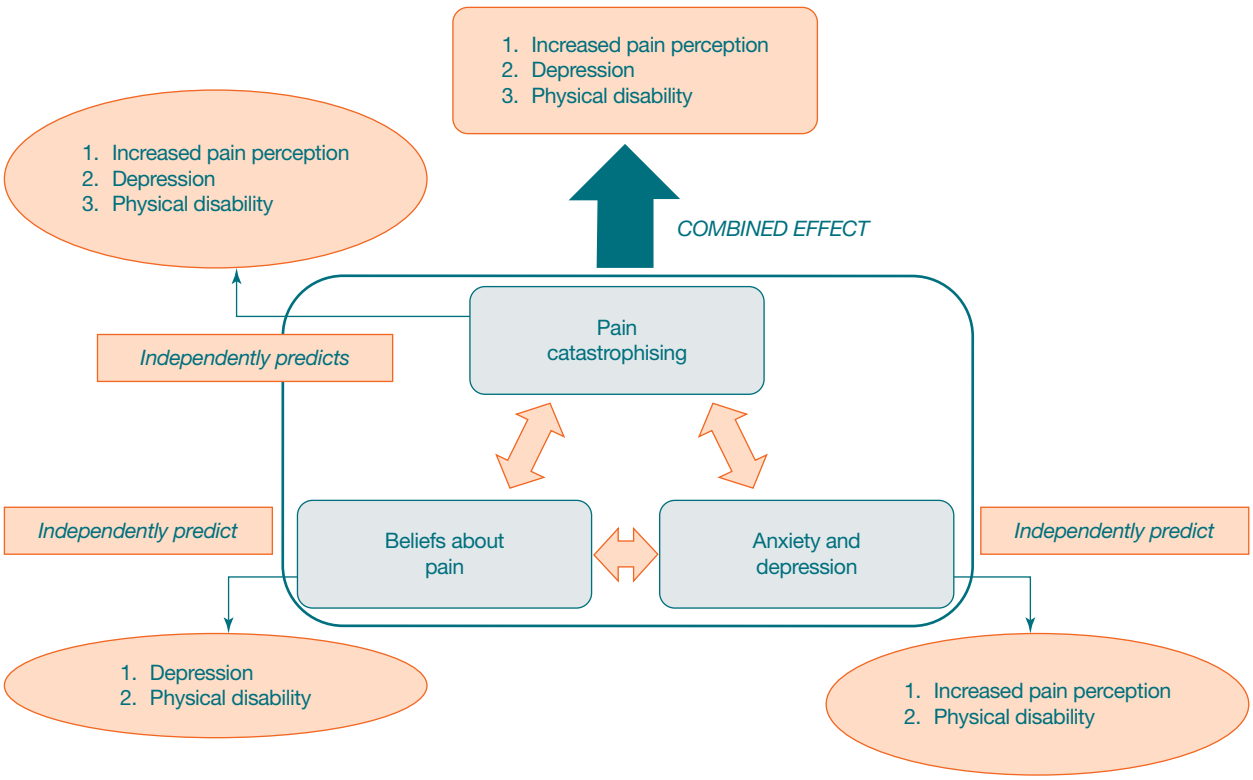

Figure 36-6 Association of catastrophising with other psychological factors and their effects on acute pain.

Khan RS et al 2011 Catastrophizing: a predictive factor for postoperative pain. The American Journal of Surgery 201(1):123.

Age

Children and older adults are at risk for inadequate pain management because of common misconceptions about pain perception, appropriate pain assessment and effective and safe use of analgesics (see Table 36-3).

Young children may have difficulty describing and expressing pain to parents or caregivers. Developmentally, toddlers and preschoolers are unable to recall explanations about pain, or associate pain with experiences that can occur in various situations. With these considerations in mind, you should adapt approaches for assessing a child's pain (including what to ask and the behaviours to observe for) and how to prepare a child for a painful procedure.

When older people have pain, there can be serious impairment of functional status. Mobility, activities of daily living, social activities outside the home and activity tolerance can all be reduced. The presence of pain in the older adult requires aggressive assessment, diagnosis and careful management that is safe and effective.

Chronic pain is a problem for many elderly people presenting to hospital with other illnesses or living in both community and residential aged care facilities. When they are admitted to hospital they often have acute pain superimposed on chronic pain problems. There are also many myths about pain in older adults that need to be corrected in order to provide effective nursing care (see Table 36-4).

WORKING WITH DIVERSITY

The multicultural nature of the Australian and New Zealand population means that you will encounter a variety of responses to pain. It is important to note that observed cultural differences are more likely to concern the way in which pain is regarded and the extent to which a person is permitted to express pain and under what conditions. These differences in pain behaviour are not evidence of differences in pain threshold and tolerance. They signify differences in the way people from different cultures have learned to behave when they are in pain.

Implications for practice

While it is important that you are aware of cultural differences in response to pain, you should be careful not to stereotype patients based on their ethnicity. Although an individual may identify with a cultural group, there is also diversity within each culture.

Providing culturally safe care means being aware of your own cultural values and beliefs about pain and reflecting on how this might influence practice (see Chapter 14).

The nurse, patient and family must work together to facilitate communication about assessment and management of pain. Finding a common assessment tool and communicating that tool to other healthcare providers is important.

TABLE 36-3 Pain in infants

Misconception	Correction
Infants are incapable of feeling pain	Infants have developed the anatomy and physiology for pain processing by mid to late gestation
Infants are less sensitive to pain than older children and adults	Full-term neonates are as sensitive to pain as older infants and children Preterm neonates may be more sensitive to pain than full-term neonates or older infants
Infants are incapable of expressing pain	Although infants cannot verbalise pain, they demonstrate it with observable cues, both behavioural and physiological
Infants must learn about pain from previous painful experiences	Pain requires no prior experience; it need not be learned from earlier painful experience. Pain is present from the first injury
Pain cannot be accurately assessed in infants	Behavioural cues (i.e. facial expressions, crying, body movements) and physiological indicators of pain can be reliably and validly assessed either alone (univariate approach) or in combination (multivariate approach). The most valid univariate approach is facial expression. The most valid multivariate approach is through the use of a composite pain measure
Infants are incapable of remembering pain	Studies have shown that infants who are exposed to painful stimuli at an early age respond more vigorously to subsequent painful stimuli
Analgesics and anaesthetics cannot be safely given to infants and neonates because of their immature capacity to metabolise and eliminate drugs and their sensitivity to opioid-induced respiratory depression	Infants older than 1 month of age metabolise drugs in the same manner as older infants and children. Careful selection of the agent, dosage, administration route and time, frequent monitoring for desired and undesired effects and drug titration and weaning can minimise the adverse effects of opioids and non-opioids for pain management in neonates

TABLE 36-4 Pain in older adults

Misconception	Correction
Pain is a natural outcome of growing old	Although older adults are at greater risk of developing painful conditions, pain is not an inevitable result of ageing
Pain perception, or sensitivity, decreases with age	This assumption is unsafe. Although older adults often demonstrate less emotional suffering with pain, there is no evidence that they perceive it any differently from younger people
If the elderly patient does not report pain, he or she does not have pain	Elderly patients commonly under-report pain. Reasons include expecting to have pain with increasing age; not wanting to alarm loved ones; being fearful of losing their independence; not wanting to distract, anger or bother caregivers; and believing caregivers know they have pain and are doing all that can be done to relieve it The absence of a report of pain does not mean the absence of pain
If the elderly patient appears to be occupied, asleep or otherwise distracted from pain, he or she does not have pain	Assumptions about the presence or absence of pain cannot be made solely on the basis of a patient's behaviour. They may be using pain-related coping strategies such as distraction. Sleep may also indicate exhaustion, not pain relief
The potential side effects of opioids make them too dangerous to use to relieve pain in the elderly	Opioids may be used safely in the elderly. Although the opioid-naïve elderly may be more sensitive to opioids, this does not justify withholding them in the management of pain in this population The key to the use of opioids in the elderly is to 'start low and go slow'. Potentially dangerous opioid-related side effects can be prevented with slow titration; regular, frequent monitoring and assessment of the patient's response; and adjustment of dose and interval between doses when side effects are detected
Patients with dementia or cognitive impairment do not feel pain, and their reports of pain are most likely invalid	No evidence exists that the cognitively impaired elderly experience less pain or that their reports of pain are less valid than those of individuals with intact cognitive function Assessment of pain in these patients is challenging but possible. The best approach is to accept the patient's report of pain and treat the pain as it would be treated in an individual with intact cognitive function

Adapted from McCaffery M, Pasero C 1999 Pain: clinical manual, 2nd edn. Mosby, St Louis.

The ability of older patients to interpret pain can be complicated by the presence of multiple diseases with vague symptoms that may affect similar parts of the body. It is important to take enough time to complete a thorough assessment of pain and pain-related concerns.

• CRITICAL REFLECTION POINT

Smithy is a 55-year-old Indigenous Australian who has a fractured femur resulting from the impact of a cow in the cattle yards. He is a long way from home and family members. As his female RN, you are having difficulty assessing his pain and he avoids eye contact with you. What issues might you consider in terms of ensuring cultural safety and a positive nurse–patient relationship?

Family and social support

Perceived social support is another critical factor influencing pain perception. People in pain often depend on family members or close friends for support, assistance or protection. Although pain still exists, the presence of a loved one can minimise loneliness and fear. An absence of family or friends can often make the pain experience more stressful. The presence of parents is especially important for children experiencing pain and parents can contribute to pain assessment and treatment. Partners and caregivers are often interested in helping their loved one manage acute pain but uncertain what role they can play.

CLINICAL REASONING PROCESS

Making sound clinical judgements requires you to anticipate what assessment data is needed, critically analyse the data and make appropriate decisions regarding patient care (see Chapter 4). In the case of pain management, a scientific knowledge base of pain and evidence-based approaches to assessment and management allow you to safely and effectively intervene. Previous experience in caring for patients with pain will also sharpen your assessment skills and ability to choose effective therapies.

This clinical knowledge and judgement that underpins nursing practice is not always obvious to others – in fact, it is often invisible – and so others often attribute this work to the medical practitioner instead. Consider the typical scenario described by Buresh and Gordon (2006:26) in the *Clinical example* overleaf.

Buresh and Gordon (2006) argue that telling the patient that the medical practitioner 'ordered' her morphine would conceal the nurse's contribution. She couldn't tell the patient that she had fought with the medical officer to get the morphine, but she could have negotiated the dilemma by saying: 'I've

CLINICAL EXAMPLE

A nurse working on the oncology floor at a major teaching hospital spends hours trying to get a medical intern to write an order for an opioid for a patient suffering from pancreatic cancer. The nurse has informed the intern that the patient is in excruciating pain. Far more familiar with cancer patients and their pain management than the intern, she recommends a course of intravenous (IV) morphine.

The intern refuses to order the opioid. He simply will not listen to the nurse. Over a period of several hours, she repeatedly engages with him, trying, to no avail, to teach him about cancer pain management. Finally, she corners a more senior resident who agrees with her and directs the intern to write the order. In the patient's chart – the contemporary and historical record of the case – the nurse's struggle with the young doctor is absent. Reading the chart, one would never know that the nurse was responsible for easing the patient's pain and that the intern resisted her attempts to provide appropriate care. In this chart the new doctor is 'credited' with taking the action that reduced the patient's suffering.

Not surprisingly, the patient and her family believe the doctor was her saviour. Several days later, the patient writes letters thanking her caregivers. She expresses her heartfelt gratitude to her attending doctor who, during her hospitalisation, rarely saw her when she was awake. She specifically thanked the intern whom she thought brought her relief. She did not thank her primary and associate nurses by name. She included only a general thank you to 'the nurses'.

consulted with the medical practitioner, and she agreed with my recommendation to give you IV morphine. I will make sure it's effective.'

The same process can occur as a student nurse – what may have seemed like a brief interaction between the RN and patient before giving a dose of IV morphine was in fact a complex assessment of the patient, including their pain rating, level of sedation, vital signs and other assessment cues. This can be an invisible process to the student unless they take an active part in learning.

Making the most of clinical placements by seeking opportunities to develop pain assessment and management skills is important in the transition from student nurse to beginning practitioner. Use every opportunity on clinical placement to ask RNs how they make clinical judgements about pain management. What assessments did they perform to make decisions about patient care? What was the reasoning behind their decision?

GATHERING RELEVANT INFORMATION AND DATA

Before reading on, work through the clinical scenarios about pain assessment in Box 36-1 opposite.

The foundation of pain assessment: accepting the patient's report of pain

Probably the most challenging aspect of caring for the patient with pain is to accept that pain is completely subjective. No objective measures of pain exist. Pain cannot be proved or disproved. While nurses sometimes may not believe what the patient says about their pain, they have an ethical and professional responsibility to accept and act on it (Pasero & McCaffery 2011). All reports of pain should be taken seriously. Yet, nurses and other healthcare professionals often have trouble accepting the patient's report of pain.

A patient's self-report of pain is the single most reliable indicator of the existence and intensity of pain (Schug et al 2015). Thus, the gold standard for assessing the existence and intensity of pain is the person's self-report, not the nurse's opinion. No other source of information has ever been shown to be more accurate or reliable than what the patient says. Behaviours and vital signs, the opinions of staff delivering care and the family's estimates are not as reliable as the patient's report of pain.

The 'Andrew–Robert' scenario presented in Box 36-1 has been developed to demonstrate the necessity of accepting reports of pain as the standard for assessment. Everything about the patients in the vignettes is the same except for their behaviour. If we accept that the patient is the expert on their pain, then the correct answer is to record a pain rating of 8 for both patients in their charts. Also, given the information that the previous dose of morphine 2 mg IV was safe but ineffective, the correct answer is to administer morphine 3 mg IV for both patients. What we find when this survey is administered to students and RNs reflects the reality of clinical practice – nurses' pain assessment and management decisions are often based on their personal opinions and biases rather than the patient's self-report.

A summary of findings of the 'Andrew–Robert' vignette administered to RNs between 1990 and 2006 have been published by the developers of the survey (McCaffery et al 2007). These data show that while there has been a significant improvement over time, some nurses have not been taught or have not accepted that only the patient's own pain rating should be recorded when a self-report pain scale is used (see Table 36-5). Unfortunately, this trend towards improved pain assessment has not translated into providing an appropriate analgesic dose to patients with severe pain, and suggests that nurses may still base their choices about opioid dose on the assumption that patients in pain should look like they are in pain. In the 2006 survey, approximately half of the nurses would allow a smiling patient to remain in severe pain by failing to increase the dose and about a third of nurses would under-treat a grimacing patient.

• CRITICAL REFLECTION POINT

You are caring for 17-year-old Mark Lang, who has had surgery for incision and drainage of an arm abscess and requires a dressing change. When you attempt to change the dressing, he screams in pain and refuses to allow you to proceed. You call the resident medical officer to organise analgesia, who cites the patient's history of intravenous drug use and simply suggests paracetamol. Other nursing staff avoid the patient or attempt to control his expressions of pain with statements such as 'Try to take control of yourself', or 'You're going to have to learn to handle this yourself.' How would you respond to this situation?

BOX 36-1 Survey – assessment and use of analgesics: 'Andrew – Robert'

Andrew is 25 years old, and this is his first day after abdominal surgery. As you enter his room, he smiles at you and continues talking and joking with his visitor. Your assessment reveals the following information: BP = 120/80, HR = 80, RR = 18 and on a scale of 0–10 (0 = no pain/discomfort, 10 = worst pain/discomfort) he rates his pain as 8.

1. On the patient's hospital chart you must record his pain intensity on the scale below. Circle the number that you will record:

   0 1 2 3 4 5 6 7 8 9 10

   No pain Worst pain

2. Your assessment, above, is made 2 hours after he received morphine 2 mg IV. Half-hourly pain ratings following the injection ranged from 6–8, and he had no clinically significant respiratory depression, sedation or other untoward side effects. He has identified 2 or less as an acceptable level of pain relief. His doctor's order for analgesia is 'morphine IV 1–3 mg q1h prn pain relief'. Mark the action you will take at this time:

   ____No morphine now____1 mg IV now

   ____2 mg IV now____3 mg IV now

Robert is 25 years old, and this is his first day after abdominal surgery. As you enter his room, he is lying quietly in bed and grimaces as he turns in bed. Your assessment reveals the following information: BP = 120/80, HR = 80, RR = 18 and on a scale of 0–10 (0 = no pain/discomfort, 10 = worst pain/discomfort) he rates his pain as 8.

1. On the patient's hospital chart you must record his pain intensity on the scale below. Circle the number that you will record:

   0 1 2 3 4 5 6 7 8 9 10

   No pain Worst pain

2. Your assessment, above, is made 2 hours after he received morphine 2 mg IV. Half-hourly pain ratings following the injection ranged from 6–8, and he had no clinically significant respiratory depression, sedation or other untoward side effects. He has identified 2 or less as an acceptable level of pain relief. His doctor's order for analgesia is 'morphine IV 1–3 mg q1h prn pain relief'. Mark the action you will take at this time:

   ____No morphine now____1 mg IV now

   ____2 mg IV now____3 mg IV now

BP = blood pressure (mmHg), HR = heart rate (beats per minute), IV = intravenous, q1h prn = every hour as needed; RR = respiratory rate (breaths per minute).

McCaffery M, Pasero C 1999 Pain: clinical manual, 2nd edn, Mosby, St Louis.

TABLE 36-5 'Andrew–Robert': comparison of RNs' responses from 1990 through 2006*

	Andrew – smiling				Robert – grimacing			
	1990	1995	1998	2006	1990	1995	1998	2006
Nurses recorded same as patient's pain rating (%)	40.7	73.8	85.8	86	71.6	87.1	90	94.6
Nurses increased opioid dose (%)	32.8	51.5	47.3	50.6	54	71.3	62.5	64.3

* In the first two surveys, meperidine (pethidine) IM was used instead of morphine IV because at that time many nurses were not familiar with the dosing of morphine. 1990: n = 465; 1995: n = 450; 1998: n = 615; 2006: n = 615.

McCaffery M, Pasero C, Ferrell BR 2007 Nurses' decisions about opioid dose. Am J Nurs 107(12):35–9. © Margo McCaffery, Betty Farrell, Chris Pasero.

Accepting and acting upon the patient's report of pain is difficult if you doubt their credibility, which may happen on occasion. Since pain cannot be proven, healthcare professionals are vulnerable to being fooled by patients who lie about pain. Yet, as Pasero and McCaffery (2011) cogently argue, although accepting and responding to the patient's report of pain will occasionally result in analgesics being given to some patients who are addicted or malingering, it ensures that everyone who has pain receives the best possible pain management. Healthcare professionals do not have the right to deprive a patient of appropriate assessment and treatment simply because they believe the patient is lying.

You are required to accept the patient's report of pain, convey this acceptance to the patient and take the appropriate action. Doubts and opinions may persist, but they cannot be allowed to interfere with appropriate care. Pasero and McCaffery (2011) offer some excellent strategies, listed in Box 36-2, that you could use when difficulties arise with accepting the patient's self-report of pain.

Even when the patient's report of pain is sought by nurses, this process can be undermined by misconceptions that hamper the assessment and subsequent treatment of pain. Take the time to carefully review these common misconceptions in Table 36-6 and reflect on whether you hold any of these beliefs about pain.

Performing a pain assessment

The key to effective pain management is adequate pain assessment. Just as it is necessary to regularly monitor patients'

BOX 36-2 Strategies when the patient's report of pain is not accepted

What do we do if the healthcare team does not respond positively to the patient's report of pain?

1. Acknowledge that everyone is entitled to a personal opinion, but personal opinion does not form the basis for professional practice.
2. Clarify that pain is subjective and cannot be proved or disproved.
3. Quote recommendations from clinical practice guidelines and research.
4. Ask: 'Why is it so difficult to believe that this person hurts?'

Pasero C, McCaffery M 2011 Pain assessment and pharmacologic management. Mosby, St Louis.

vital signs, pain should be considered a core assessment skill, along with others such as temperature, pulse, respirations and blood pressure. In some institutions, initiatives to treat pain as the fifth vital sign were developed to encourage routine pain assessment.

A pain problem should prompt a focused pain assessment (see Skill 36-1, p. 1341) as well as the need to assess its potential impact on the patient's physical and psychosocial functioning. In doing so, you should incorporate standardised and evidence-based assessment tools to obtain complete and reliable information.

The frequency of pain assessment and amount of information collected is determined by the patient's situation. For example, on admission to the post-anaesthesia care unit (PACU) a patient may only be able to tell you that their pain is 'severe' and further assessment may not be possible until they are more awake and pain has begun to be controlled with IV analgesia.

New-onset or increasing pain should always indicate the need for a focused physical assessment of the region or body systems

TABLE 36-6 Misconceptions: barriers to the assessment and treatment of pain

Misconception	Correction
The best judges of the existence and severity of patients' pain are the doctors and nurses caring for the patients	Patients are the authorities on their pain. Patients' self-reports are the most reliable indicators of the existence and intensity of pain
Clinicians should use their personal opinions and beliefs about the truthfulness of patients to determine patients' true pain status	Allowing each clinician to act on personal beliefs presents the potential for different pain assessments by different clinicians, leading to different interventions by each clinician. This results in inconsistent and often inadequate pain management. It is essential to establish the patients' self-reports of pain as the standard for pain assessment
Clinicians must believe what patients say about pain	Clinicians need not believe the patients' reports of pain, but clinicians must accept and respect patients' reports of pain and proceed with appropriate assessment and treatment. Clinicians are always entitled to their personal opinions, but those opinions cannot be allowed to guide professional practice
Comparable noxious stimuli produce comparable pain in different people. The pain threshold is uniform	Findings from numerous studies have failed to support the notion of a uniform pain threshold. Comparable stimuli do not result in the same pain in different people. After similar injuries, one person may suffer moderate pain and the other severe pain
There is no reason for patients to hurt when no physical cause for pain can be found	Pain is a new and inexact science, and it would be foolish of us to think that we will be able to determine the cause of all the pains that patients report
Patients should not receive analgesics until the cause of pain is diagnosed	Pain is no longer the primary diagnostic tool of clinicians. Symptomatic relief of pain should be provided while the investigation of cause proceeds. Early use of analgesics is now advocated for patients with acute abdominal pain
Visible signs, either physiological or behavioural, accompany pain and can be used to verify its existence and severity	Even with severe pain, periods of physiological and behavioural adaptation occur, leading to periods of minimal or no signs of pain. Lack of pain expression does not necessarily mean lack of pain
When it is time to reassess patients' pain following an analgesic and the patients are sleeping, it is not necessary to awaken them	Sleep does not mean the absence of pain, and not all patients who appear to be sleeping are actually sleeping. Until patients' responses to analgesics are established as being effective and safe, patients should be awakened to obtain a pain rating. This should be explained to patients However, if the same analgesic dose has been administered before and has produced effective pain relief, and patients are not aroused by simple stimuli such as calling their names in a normal tone of voice, patients with acceptable respiratory status may be allowed to sleep If patients' pain is relatively constant and the analgesic effect is known to wear off after a certain time, e.g. 4 hours, consider awakening patients for the next dose before pain awakens the patients. Discuss this option with the patients

continued

TABLE 36-6 ***continued***

Misconception	Correction
Anxiety makes pain worse	Anxiety is often associated with pain, but the cause-and-effect relationship has not been established. Pain often causes anxiety, but it is not clear that anxiety necessarily makes pain more intense
Patients who are knowledgeable about opioid analgesics and who make regular efforts to obtain them are drug-seeking (addicted)	Patients with pain should be knowledgeable about their medications; use of opioids for pain relief is not addiction. When patients are accused of drug-seeking, it may be helpful to ask, 'What else could this behaviour mean? Might these patients be in pain?'
When patients report pain relief after a placebo, it means that the patients are malingerers or that the pain is psychogenic	About one-third of patients who have obvious physical stimuli for pain (e.g. surgery) report pain relief after a placebo injection. Therefore, placebos cannot be used to diagnose malingering, psychogenic pain, or any psychological problem. Sometimes placebos relieve pain, but why this happens remains unclear
The pain-rating scale preferred for use in daily clinical practice is the Visual Analogue Scale (VAS)	For patients who are verbal and can count from 0 to 10, the Numerical Rating Scale (NRS) is preferred for adult patients. It is easy to explain, measure and record, and it provides numbers for setting pain-management goals. The VAS is a straight line with anchors at each end and no numbers or adjectives in between
Cognitively impaired older patients are unable to use pain-rating scales	When an appropriate pain-rating scale (e.g. 0 to 5) is used and patients are given sufficient time to process information and respond, many cognitively impaired elderly people can use a pain-rating scale
Cognitively impaired patients, especially those who are unable to self-report, do not experience as much pain as those who are cognitively intact	Recent studies examining mechanisms and differences in pain transmission and perception in older adults with dementia document that the pain transmission process is unaltered, but these adults may respond with behaviours that are different from those of cognitively intact adults. In other words, cognitive impairment may result in less pain being reported, but there is no evidence that cognitive impairment reduces the ability to feel painful stimuli
Critically ill patients, especially those who appear to be unconscious or have received a neuromuscular blocking agent, do not feel pain and do not recall painful episodes in intensive care units (ICUs)	Levels of consciousness are difficult to determine, and patients who are thought to be unconsciousness in the ICU often recall moderate to severe pain. Patients under the influence of neuromuscular blocking agents may still be fairly alert and able to feel pain. Patients with endotracheal tubes are unable to self-report verbally but may be able to provide self-reports if attempts are made, such as establishing head nod, pointing or eye blink in response to questions about pain
Persons with intellectual disabilities (IDs) or mental retardation are either insensitive to pain or have greater tolerance for it	This perception appears to be based on observations that behaviour following a potentially painful event is delayed or unconventional. These observations are often valid but do not necessarily indicate insensitivity to pain or indifference to it. Measurements of sensitivity to pain using heat-pain thresholds indicated greater sensitivity to pain than is experienced by normal controls. Behavioural responses to pain may not occur in some individuals with IDs because of physical disabilities such as cerebral palsy
Schizophrenic patients' reports of pain are commonly expressions of the mental illness	For some time, decreased reactivity to pain in some patients with schizophrenia has caused clinicians to believe they were experiencing insensitivity to pain. Some patients with schizophrenia fail to report pain until it becomes severe. As a result, these patients seek medical care at a later stage of the physical disease and may suffer complications as a consequence. Postoperative pain is a risk factor for postoperative confusion and should be treated with analgesics The appearance of insensitivity to pain by schizophrenic patients is poorly understood, but may be the result of abnormal processing of sensory input. In one study of experimental pain, it was noted that individuals with schizophrenia had difficulty focusing on their pain. Furthermore, pain is rarely a hallucination. Recently, studies have suggested that absence of pain reactivity does not mean absence of pain sensitivity
Patients with post-traumatic stress disorder (PTSD) show low sensitivity to acute pain and rarely have chronic pain	Although a few studies have shown that patients with PTSD are less sensitive to very brief painful stimuli, chronic pain is commonly present in patients with PTSD and, conversely, patients with chronic pain often have PTSD, although both of these co-occurrences are underdiagnosed

Pasero C, McCaffery M 2011 Pain assessment and pharmacologic management. Mosby, St. Louis.

BOX 36-3 Mnemonic for pain assessment: PQRSTU

- **P** *Provoking/Palliative factors* – What makes the pain better or worse?
- **Q** *Quality* – Describe what the pain feels like in your own words.
- **R** *Region and radiation* – Where is it? Does it radiate? Does it occur anywhere else? Have the patient point to the body area that is painful.
- **S** *Severity* – Have the patient rate their pain intensity using a pain-rating scale. How much pain do you have at rest? How much pain do you have with movement/coughing?
- **T** *Time of onset/duration* – When did the pain begin? How long does the pain last?
- **U** *Patient's understanding* – What is the patient's understanding of the cause of pain? What treatments have they tried to relieve it?

involved. For example, surgical or other complications need to be ruled out for a postoperative patient with severe pain despite analgesia. Review by an acute pain service should also be considered.

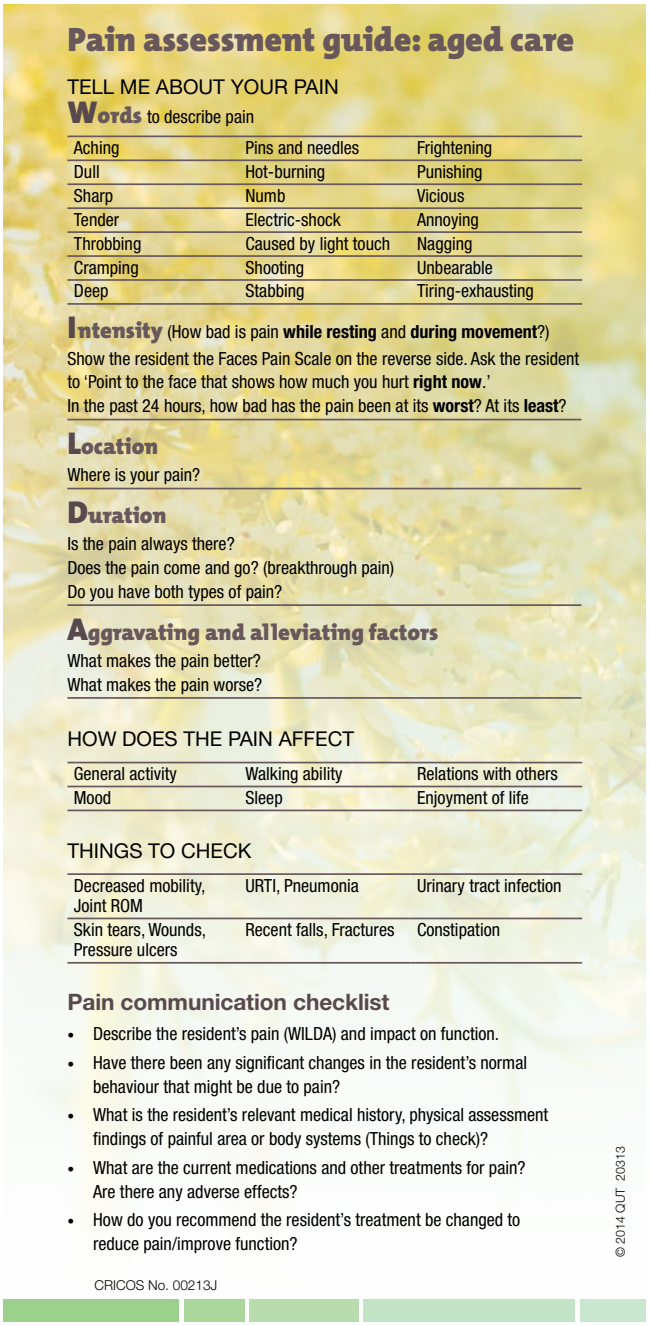
It is helpful to use a mnemonic to remember the key components of a basic pain assessment, such as the PQRSTU approach described in Box 36-3 or the WILDA example in Figure 36-7. More-comprehensive assessment of the person in pain is required for chronic and complex pain problems, which is beyond the scope of this chapter (see Douglas 2014).

Intensity

Pain intensity – a quantitative estimate of the severity or magnitude of perceived pain – is without a doubt the most salient dimension of pain, and a variety of pain-rating scales have been developed to measure it. Most of these tools are highly correlated with each other and therefore they can be used in most situations (Jensen & Karoly 2011). What is important is that you select the tool based on the patient's individual needs (e.g. developmental, cognitive, language and cultural factors) with consideration of the particular strengths and weaknesses of each tool. Where possible, the same tool should be used throughout the admission.

Although acute postoperative pain is often assessed when patients are resting, the effectiveness of analgesia is better determined by assessment of pain during functional activity required for recovery. *For the acute care patient, this means you should record pain intensity ratings for both static (e.g. pain at rest) and dynamic (e.g. pain on coughing, deep breathing or movement) pain* (Schug et al 2015).

The numerical rating scale (NRS) is the most widely used measure of pain intensity in clinical practice (see Figure 36-7). An NRS asks the patient to rate their pain from 0 to 10 (an 11-point scale) or 0 to 100 (a 101-point scale), with the understanding that the 0 represents one end of the pain intensity continuum ('no pain') and the 10 or 100 represents the other extreme of pain intensity ('pain as bad as it can be'). Patients simply state or circle the number on written versions of the scale that best represents their pain intensity by answering the question: 'On a scale of 0 to 10, with 0 being no pain and 10 being the worst possible pain you could imagine, where would you rate the pain you are experiencing right now?' The reliability and validity of the NRS is well established (Jensen & Karoly 2011) and is easily administered.



Pain assessment guide: aged care

TELL ME ABOUT YOUR PAIN

Words to describe pain

Aching	Pins and needles	Frightening
Dull	Hot-burning	Punishing
Sharp	Numb	Vicious
Tender	Electric-shock	Annoying
Throbbing	Caused by light touch	Nagging
Cramping	Shooting	Unbearable
Deep	Stabbing	Tiring-exhausting

Intensity (How bad is pain **while resting** and **during movement**?)

Show the resident the Faces Pain Scale on the reverse side. Ask the resident to 'Point to the face that shows how much you hurt **right now**.'

In the past 24 hours, how bad has the pain been at its **worst**? At its **least**?

Location

Where is your pain?

Duration

Is the pain always there?

Does the pain come and go? (breakthrough pain)

Do you have both types of pain?

Aggravating and alleviating factors

What makes the pain better?

What makes the pain worse?

HOW DOES THE PAIN AFFECT

General activity	Walking ability	Relations with others
Mood	Sleep	Enjoyment of life

THINGS TO CHECK

Decreased mobility, Joint ROM	URTI, Pneumonia	Urinary tract infection
Skin tears, Wounds, Pressure ulcers	Recent falls, Fractures	Constipation

Pain communication checklist

- Describe the resident's pain (WILDA) and impact on function.
- Have there been any significant changes in the resident's normal behaviour that might be due to pain?
- What is the resident's relevant medical history, physical assessment findings of painful area or body systems (Things to check)?
- What are the current medications and other treatments for pain? Are there any adverse effects?
- How do you recommend the resident's treatment be changed to reduce pain/improve function?

Figure 36-7 An example of the WILDA pain assessment tool for aged care staff.

Queensland University of Technology, Faculty of Health, School of Nursing http://eprints.qut.edu.au/86745/12/86745(e).pdf

A *verbal descriptor scale (VDS)* simply consists of a list of adjectives describing different levels of pain intensity. Patients are asked to read over the list of descriptors and choose the word that best describes their pain intensity on the scale. A simple and clinically useful example is 'no pain', 'mild pain', 'moderate pain' and 'severe pain' (scored numerically from 0 to 3).

The *visual analogue scale (VAS)* consists of a 10 cm horizontal line representing a continuum of pain intensity, with verbal descriptors at each end (e.g. 'no pain' to 'pain as bad as it can be' or 'worst possible pain'). The patient is asked to indicate which point along the line best represents their pain intensity. The distance measured from the 'no pain' end to the mark made by the patient is the pain intensity score. The VAS is commonly used in research as a measure of pain intensity.

The *faces pain scale* is another tool that was originally developed for children but has been found to be useful and popular among adults, especially those with cognitive or communication difficulties. Faces pain scales include cartoon faces (e.g. Wong-Baker FACES Pain Rating Scale; Wong & Baker 1988), hand-drawn realistic depictions (e.g. The Faces Pain Scale – Revised; Hicks et al 2001) and photographs of actual children in distress (e.g. Oucher Scale; Beyer et al 1992). The *Wong-Baker FACES pain rating scale*, for example, contains six cartoon faces and is recommended for persons aged 3 years and older (see Figure 36-8). Instructions are read to the patient and they are asked to choose the face that best describes their pain intensity.

• CRITICAL REFLECTION POINT

How would you assess pain intensity in non-verbal patients who are unable to use a pain-rating scale?

Whenever possible, the existence and intensity of pain is measured by the patient's self-report. Unfortunately, some patients cannot provide a self-report of pain verbally, in writing or by other means such as blinking their eyes to answer 'yes' or 'no' questions. These groups can include older adults with advanced dementia, infants and pre-verbal toddlers and intubated and/or unconscious patients. In such cases a suggested hierarchy of importance of basic measures of pain intensity is recommended (see Box 36-4; see also Herr et al 2011).

Use of a *behavioural pain assessment tool* may assist in recognition of pain in these challenging populations (see *Research highlight*). For example, the FLACC (Face, Legs, Activity, Cry and Consolability) scale was developed to assess acute (postoperative) pain in young children (see www0.health.nsw.gov.au/policies/gl/2016/pdf/GL2016_009.pdf). A comprehensive review and copies of existing pain assessment tools for non-verbal older adults are available at http://prc.coh.org/PAIN-NOA.htm.

Quality

Unidimensional measures of pain intensity alone do not capture the other qualitative aspects of pain. Asking the patient to describe the *quality* of their pain using their own words is important. Providing a list of possible descriptors can sometimes be helpful if patients find it difficult to do this. You may also gain valuable information about the underlying pain mechanisms from the types of words chosen. For example, neuropathic pain is characterised by descriptors, such as 'burning', 'cold', 'numb', 'electric' or 'shooting' pain. Features of neuropathic pain may not respond to conventional analgesics like opioids. Often, **adjuvant** analgesics are required, such as anticonvulsants (pregabalin) or tricyclic antidepressants (amitriptyline). Registered nurses are in

BOX 36-4 Hierarchy of pain assessment techniques

1. Attempt first to elicit a self-report of pain from patient. If patient is unable to give a self-report, explain why and proceed with the following steps.
2. Identify pathological conditions and common problems or procedures that may cause pain.
3. Observe for behaviours recognised as pain-related. A behavioural assessment tool may be used.
4. Solicit information about possible indicators of pain from caregivers and others knowledgeable about the patient.
5. Attempt an analgesic trial and observe changes in the patient's behaviour.

Figure 36-8 Wong-Baker FACES scale.

Explain to the person that each face is for a person who has no pain (hurt) or some, or a lot of pain. Face 0 doesn't hurt at all. Face 2 hurts just a little bit. Face 4 hurts a little bit more. Face 6 hurts even more. Face 8 hurts a whole lot. Face 10 hurts as much as you can imagine, although you don't have to be crying to have this worst pain.

RESEARCH HIGHLIGHT

Research focus

Practical strategies are needed to improve pain awareness among aged care staff and promote a systematic approach to pain identification using evidence-based tools. The purpose of this study was to evaluate a pain identification tool for use by nursing and non-professional staff in residential aged care facilities (RACFs).

Research abstract

Intervention

The research team developed the 'Identify Pain: Ask, Observe, Report' tool based on current best practice guidelines. This was supported by a range of practical implementation strategies such as a pain education booklet, plastic lanyard cards, pocket-sized pain assessment guides, A3- and A4-sized posters and pain communication checklists as clinical reminders and practice prompts. Pain workshops were also conducted over a 3-month period to improve knowledge, skills and confidence for pain assessment among all staff.

Methods

To evaluate the effectiveness of the intervention, it was implemented with staff in five nursing homes at one RACF, with four nursing homes at a second RACF serving as the control group. Participants under control conditions received usual staff development activities and provided standard care to residents. Before and after the intervention period, the primary outcomes of staff knowledge, skills and confidence were measured by survey. The secondary outcomes of frequency of pain assessments and use of pain interventions were also examined with chart audits. Residents' perceptions of the quality of their pain management were measured by self-report survey among cognitively intact residents.

Research findings

The intervention group showed significant improvement in routine pain assessment and use of non-drug pain interventions. Among homes allocated to the intervention, the proportion of residents with a documented routine pain review increased from below half (48.4%) at baseline to approximately three-quarters (73.8%) at 3-month follow-up. Overall, staff believed the intervention was clinically useful and fostered a team approach to pain assessment.

Evidence-based practice

- The introduction of simple pain identification resources with implementation strategies to support frontline staff created a more responsive and team-based approach to treating pain among residents.
- Translating evidence into practice to improve pain care deserves much greater attention in aged care settings.
- You can freely access the pain assessment resources used in this study at: http://eprints.qut.edu.au/86745/

a prime position to detect neuropathic pain and collaborate to provide the correct treatment for the patient.

Onset and duration

You should ask questions to determine the onset, duration and pattern of pain. When did the pain begin? How long has it lasted? Does it occur at the same time each day? How often does it recur? Is it intermittent or constant?

Location

To assess pain location, ask the patient to describe or point to all areas of discomfort. Pain sites can be documented on a body diagram (see Figure 36-9). A pain drawing consists of outline drawings of the human body, front and back, on which the participant indicates the location of pain by shading the painful area. When describing pain location, use anatomical landmarks and descriptive terminology (e.g. 'abdominal pain localised to the right upper quadrant'). Pain, classified by location, may be *superficial* or *cutaneous*, *deep* or *visceral*, or *referred* or *radiating* (see Box 36-5).

Precipitating factors

It helps to assess specific events or conditions that precipitate or aggravate pain. Ask the patient to describe activities that cause pain, such as physical movement or position, certain activities or environmental factors. For example, with a herniated intervertebral disc, the low back pain and radiation down the leg is usually aggravated by bending over or lifting objects. Swallowing and talking often aggravate the pain of pharyngitis. When precipitating or aggravating factors are identified, it is easier to plan interventions to prevent pain from occurring or worsening.

Alleviating factors

It is useful to know whether the patient has found effective ways of relieving pain, including drug and non-drug pain management techniques. These strategies can be incorporated into the plan of care if appropriate.

Associated symptoms

Associated symptoms are those that often occur with pain (e.g. nausea, dizziness). Certain types of pain have predictable accompanying symptoms. For example, severe rectal pain often results in constipation. The pain of an inflamed gallbladder or a kidney stone often causes nausea and vomiting.

Impact of pain on functioning

The ability of patients to function is a key outcome of effective acute pain therapy. The Victorian Quality Council (2007) recommends that all patients are to have a *Functional Activity*

Brief Pain Inventory

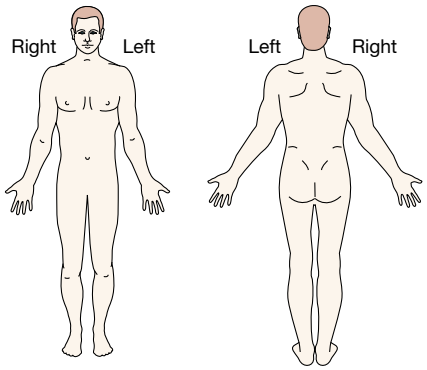
Date: _____ / _____ / _____ Time: _____

Name: _____ _____ _____
Last First Middle Initial

1) Throughout our lives, most of us have had pain from time to time (such as minor headaches, sprains and toothaches). Have you had pain other than these everyday kinds of pain today?

1. Yes 2. No

2) On the diagram, shade in the areas where you feel pain. Put an X on the area that hurts the most.



3) Please rate your pain by circling the one number that best describes your pain at its **worst** in the past 24 hours.

0 1 2 3 4 5 6 7 8 9 10
No pain — Pain as bad as you can imagine

4) Please rate your pain by circling the one number that best describes your pain at its **least** in the past 24 hours.

0 1 2 3 4 5 6 7 8 9 10
No pain — Pain as bad as you can imagine

5) Please rate your pain by circling the one number that best describes your pain on the **average**.

0 1 2 3 4 5 6 7 8 9 10
No pain — Pain as bad as you can imagine

6) Please rate your pain by circling the one number that tells how much pain you have **right now**.

0 1 2 3 4 5 6 7 8 9 10
No pain — Pain as bad as you can imagine

7) What treatments or medications are you receiving for your pain?

_____

_____

8) In the past 24 hours, how much **relief** have pain treatments or medications provided? Please circle the percentage that most shows how much relief you have received.

0% 10 20 30 40 50 60 70 80 90 100
No relief — Complete relief

9) Circle the one number that describes how, during the past 24 hours, pain has **intefered** with your:

A. General activity

0 1 2 3 4 5 6 7 8 9 10
Does not interfere — Completely interferes

B. Mood

0 1 2 3 4 5 6 7 8 9 10
Does not interfere — Completely interferes

C. Walking ability

0 1 2 3 4 5 6 7 8 9 10
Does not interfere — Completely interferes

D. Normal work (includes both outside the home and housework)

0 1 2 3 4 5 6 7 8 9 10
Does not interfere — Completely interferes

E. Relations with other people

0 1 2 3 4 5 6 7 8 9 10
Does not interfere — Completely interferes

F. Sleep

0 1 2 3 4 5 6 7 8 9 10
Does not interfere — Completely interferes

G. Enjoyment of life

0 1 2 3 4 5 6 7 8 9 10
Does not interfere — Completely interferes

Figure 36-9 Brief Pain Inventory.

Pasero C, McCaffery M (eds) 2011 Pain assessment and pharmacologic management. Mosby, St Louis, p. 53.

Score in addition to pain ratings. This is an activity-related score. The patient is asked to perform a task appropriate to their painful injury or rehabilitation requirements and is rated on how pain affects their ability to perform this task (i.e. no, mild or severe limitation). For example, asking the patient to deep-breathe and cough after abdominal surgery, or move the affected leg for lower limb pain. You should observe the patient during the activity and note the level of limitation because of pain (see Table 36-7). Severe limitation should trigger a review of the patient by the acute pain team. Assess the impact of acute pain on the patient's functional ability.

Other simple tools such as the *Brief Pain Inventory (BPI)* scale assess the extent to which pain interferes with mood, walking, general activity, relationships with other people, sleep, and enjoyment of life (see Figure 36-9). The tool can be adapted to measure pain interference on coughing, breathing and mobilising for acute pain management. Using evidence-based, brief screening tools such as the BPI is useful for identifying problems which can then be more comprehensively assessed by nursing and/or referred for specialist assessment and management.

BOX 36-5 Understanding referred pain

Referred pain occurs when a patient locates a painful region that does not correspond to the area of injury or surgery. For example, a patient may experience pain in the shoulder after abdominal surgery or locate pain from gallstones at the tip of the right shoulder blade or scapula.

The physiological basis for this lies in the dorsal horn of the spinal cord where wide dynamic range (WDR) neurons receive input from skin, muscle and viscera. Referred pain may occur because the area shares the same spinal cord branches as the area of injury. For example, trapped air from surgery may irritate the diaphragm, which shares the same cervical nerve branch as the shoulder tip (Hughes 2008).

Hughes J 2008 Pain management: from basics to clinical practice. Elsevier, London.

TABLE 36-7 Functional activity scale

A No limitation	The patient is able to undertake the activity without limitation due to pain
B Mild limitation	The patient is able to undertake the activity but experiences moderate to severe pain
C Significant limitation	The patient is unable to complete the activity due to pain, or pain treatment-related side effects, independent of pain intensity scores.

Victorian Quality Council 2007 Guidelines, acute pain management toolkit. Victorian Government Department of Human Services, Melbourne.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

After assessing pain you need to make sense of the data and make a clinical judgement about the person's needs, concerns, or health problems (see Chapter 5). For example, severe acute postoperative pain might be identified as a priority problem, but it might also indicate a surgical complication that needs immediate action. By systematically collecting data you can make safe and appropriate clinical decisions about the nature and possible causes of the person's pain problem.

Common clinical problems in acute pain management

Acute pain management is not only about the patient's pain! This chapter so far has highlighted the benefits of adequate analgesia and the important link between pain management and rehabilitation from injury, disease or trauma. Therefore, the assessment of pain needs to take into account a whole range of physical, psychological and social variables that contribute to the patient's outcome. Table 36-8 (p. 1343) describes some examples of the complex decisions RNs make in the acute pain management setting.

SETTING PRIORITIES AND ESTABLISHING GOALS

Priorities of care

When developing a plan of care, you need to establish priorities based on the patient's level of pain and its effect on their condition. For acute, severe pain, it is important to provide relief as soon as possible. Analgesics can provide relatively rapid relief and lessen the chance of pain worsening. After a patient gains some relief from the pain, you can plan other interventions such as relaxation or the application of non-pharmacological interventions to enhance the effect of analgesics.

Goals and outcomes

In an acute care setting, setting a *comfort-function goal* with the patient can be useful. This consists of the pain rating identified by the individual patient above which the patient experiences interference with function and quality of life, that is, activities that the patient needs or wishes to perform (Pasero & McCaffery 2004). For example, you might ask a patient having cardiac surgery: 'What pain rating would make it easy for you to use your incentive spirometer frequently?' The patient might answer that a 3 (on a 0–10 numeric pain scale) would be manageable. This sets a goal for treatment, and pain ratings above this goal should then trigger additional interventions.

Plan to collect evaluation data that is specific and relevant to the patient. Following the example of the patient having cardiac surgery, relevant evaluation criteria for pain management may include:

- Patient verbalises pain intensity at rest, while coughing or deep breathing, and with movement as ≤ 3 on a 0–10 numerical pain-rating scale.
- Vital signs within normal limits including heart rate, blood pressure, oxygen saturation, rate and quality of respiration.
- Patient reports no pain interference with sleep, mood and overall functioning.
- Advises nursing staff if analgesic side effects are experienced.

PREPARING FOR AND TAKING ACTION

Nurses are usually the most important member of the healthcare team in initiating and providing pain-relief interventions. You are an important member of the multidisciplinary pain management team. You provide input into the assessment and reassessment of pain (Skill 36-1). You help in planning and implementing treatments, including education, advocacy, and support of the patient and family. Because patients in any care setting can experience pain, you must be knowledgeable about current therapies and flexible in trying new approaches to pain management.

Together with the patient, develop a pain treatment plan that describes the patient's comfort-function goal and how pain will be assessed and controlled. The plan should ensure that pain will be treated based on the patient's perception and report of pain. The success of these actions depends on your ability to establish a trusting relationship with the patient and caregiver and to address their concerns regarding pain and its treatment. Pain interventions require an individualised approach. The nurse, patient and often the family must be partners in pain management.

SKILL 36-1

Focused pain assessment

Delegation and other considerations

Initial pain assessment is the basis for the development of the nursing care plan and therefore should not be delegated by the registered nurse.

Ongoing pain assessment may be delegated to an enrolled nurse who should report any abnormal findings.

Equipment

- Pain assessment tools (e.g. Numerical Rating Scale, Wong-Baker Faces Scale, FLACC tool for children < 7 years)

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
Critical decision point: The essential message about pain assessment is simple: 'Ask patients about their pain; accept and respect what they say; intervene to relieve their pain according to their pain management goals; and, once intervention has been implemented, ask them again about their pain to evaluate the intervention. It is a circle of assessment, intervention, and reassessment' (Pasero & McCaffery 2011:161).	
1. Routinely ask about the presence of pain or discomfort on admission and with all regularly scheduled nursing assessments.	Regular assessment of pain leads to improved acute pain management (Schug et al 2015). Treat pain intensity as the fifth vital sign, as it may also indicate clinical deterioration.
2. Use a validated pain assessment tool such as the Initial Pain Assessment Tool (Pasero & McCaffery 2011) or the Brief Pain Inventory (see Figure 36-9) to organise the pain interview. Ensure that the selection of the assessment tool is developmentally and clinically appropriate.	The pain measurement tool chosen should be appropriate to the individual patient: developmental, cognitive, emotional, language and cultural factors should be considered (Schug et al 2015). Age and cognitive impairment may present significant barriers to effective pain assessment.
3. Conduct a pain history assessing each of the key characteristics of pain using the PQRSTU mnemonic.	The gold standard for assessing the existence and intensity of pain is the patient's self-report. Self-reporting of pain should be used whenever possible (Schug et al 2015).
a. Provoking/Palliative factors – ask: What makes the pain better or worse?	Helpful to determine the cause of pain and inform the management plan. Known triggers can be avoided or additional analgesia given at those times. The patient may also know which medications and doses are helpful and may have found some non-drug methods helpful. If appropriate, these methods should be part of the care plan.

STEPS	RATIONALE
b. Quality – ask the patient to describe what the pain feels like in their own words. (1) If the patient has difficulty describing pain, ask about the appropriateness of possible descriptors (e.g. throbbing, shooting, sharp, cramping, aching, tender, pricking, burning). (2) If necessary, ask: What could you do to me to make me feel the pain you have?	This information is helpful in diagnosing the underlying pain mechanism (e.g. nociceptive or neuropathic) and may have direct implications for the type of pain treatment chosen.
c. Region and radiation – ask: Where is it? Does it radiate? Does it occur anywhere else? (1) Ask the patient to mark the location on a pain drawing or have them point to the body area that is painful.	The location(s) and sensory distribution of pain are also helpful in determining the pain mechanism.
(2) If there is more than one site of pain, letters (A, B, C, etc) may be used to distinguish the various sites.	
d. Severity – have the patient rate their pain intensity using a pain-rating scale. Ask: How much pain do you have at rest? How much pain do you have with movement/coughing?	Pain-rating scales are used to identify the intensity of pain over time for the purpose of evaluating the effectiveness of interventions to relieve pain.
(1) Pain intensity can be scored for present pain, worst and least pain felt, and comfort–function goals (pain ratings that will not interfere with necessary or desired functioning, such as ambulation or decreased anxiety). (2) If the patient has more than one pain site, ask them to report the pain intensity for each site and record using the letter system above.	Scoring should incorporate different components of pain, including the functional capacity of the patient. In the postoperative patient this should include static (rest) and dynamic (e.g. pain on sitting, coughing) pain (Schug et al 2015).

■ **Critical decision point: Always assess pain on movement and/or coughing, as well as at rest.**

e. Time of onset, duration and pattern – ask: When did the pain begin? How long does the pain last? Is the pain constant? If not, how often does it occur?	This information has diagnostic importance and may also alert to a new or worsening problem.
(1) To detect variations and rhythms, ask the patient: Is the pain better or worse at certain times, certain hours of the day or night or certain times of the month?	These questions help screen for the presence of breakthrough pain.
f. Patient's understanding – ask about the patient's understanding of the cause of pain. What treatments have they tried to relieve it?	Determines the success of other pain interventions.

STEPS	RATIONALE
4. Assess the impact of pain. a. Determine the impact on physical functioning and recovery. Assessment tools are available such as the Functional Activity Score (FAS). b. Assess for important psychosocial factors related to pain (e.g. culture, previous pain events, beliefs, mood and ability to cope). c. Assess for pain interference with daily activities and impact on quality of life.	Information about the impact of pain should inform the pain management plan and trigger referral to specialist advice and treatment if needed.
5. Conduct a focused physical examination of the relevant body region or systems (e.g. neurological or musculoskeletal exam).	Assess for potential causes of pain using a structured approach. Uncontrolled or unexpected pain requires a reassessment of the diagnosis and consideration of alternative causes for the pain (e.g. new surgical/medical diagnosis, neuropathic pain) (Schug et al 2015).

RECORDING AND REPORTING

- Always accept and record what the patient says about their pain.
- Record assessment findings in patient's healthcare record following local hospital policy and protocols.
- Report any abnormal data following comprehensive assessment to the senior nurse, acute pain service or another appropriate medical officer.

HOME CARE CONSIDERATIONS

- Has a discharge pain management plan been created?
- Has the patient received information about the ongoing plan and follow-up arrangements?
- Do the family or significant others have concerns or need information to help with the plan?

TABLE 36-8 Example clinical situations and decision-making relating to pain

Clinical setting	Situation	Nursing judgement and decision-making
Post-anaesthesia care unit	The patient reports severe pain but appears sedated and comfortable based on observations	The PACU nurse carries out a thorough physical assessment. There is a wound haemorrhage and the surgical team is engaged to return to the operating suite
Post-delivery ward	A woman has delivered her baby by caesarean and requests some ibuprofen for her pain	The nurse discovers that the woman has preeclampsia and collaborates to cease the drug as it may affect kidney function
Medical ward	A patient admitted for respiratory distress complains of nausea, insomnia, abdominal cramping and sweating	The nurse undertakes a health history. The patient is withdrawing from opioids because the usual oral oxycodone dose for cancer pain has not been prescribed since admission 4 days ago
Surgical ward	The patient's pain score is 7/10 at rest after a total abdominal hysterectomy. She is prescribed PRN oxycodone 5 mg and it has been administered	A decision is made that the pain management plan is inadequate. The RN calls the acute pain service and the nurse practitioner orders patient-controlled analgesia

Pain resources for registered nurses

Many hospitals have acute pain teams that contribute to improved management and outcomes for hospitalised patients. Acute pain services are a source of advice and support for RNs caring for patients with pain problems. These services are led by advanced practice nurses who also provide education on pain management as part of their roles. For example, a nurse practitioner (NP) specialising in acute pain management has expertise regarding pharmacological and non-pharmacological interventions that are most effective for acute pain, whereas a palliative care NP may be more appropriate for cancer pain management. Some hospitals also have specialist staff to give

advice on the management of chronic pain, although acute pain services are usually the only resource available.

There are many external organisations that support the management of patients with pain. For example, the International Association for the Study of Pain has clinical resources that are freely available (see *Online resources* at the end of the chapter).

Acute pain management

Acute pain management requires thorough patient assessment and a logical plan that will prevent the complications of inadequate pain relief, ensure patient safety and promote wellbeing. Analgesics are usually administered using a step-wise approach in line with the severity of the pain. Non-drug interventions (discussed later) and paracetamol are the foundation layers of any acute pain management plan alongside non-steroidal anti-inflammatory agents if appropriate. The **analgesic pain ladder** in Figure 36-10 portrays this approach to acute pain management. Opioids are higher up the ladder if pain is still poorly controlled on the foundation interventions.

Multimodal analgesia

Multimodal analgesia is a key principle for effective pain management that involves using two or more classes of analgesics to target different pain mechanisms in the nervous system (Pasero & Portenoy 2011). A multimodal approach can maximise pain relief and prevent analgesic gaps while using lower doses of each drug. This can achieve better pain control and lessen the potential for side effects that may occur if only one type of analgesic is used in higher doses to achieve a desired effect (Pasero & Portenoy 2011). For example, paracetamol provides analgesia centrally and non-steroidal anti-inflammatory drugs reduce inflammatory mediators at peripheral nociceptors. Both classes of drugs may be administered at the same time without adverse consequences because they work differently. Figure 36-11 shows that specific analgesics work at different sites along the nociceptive pathways to reduce pain perception.

In clinical practice, analgesics may be divided into three groups: non-opioids, opioids and adjuvant analgesics. We provide only an introduction to these three analgesic groups and we encourage you to consult other excellent resources (Macintyre & Schug 2015, Pasero & McCaffery 2011) for a comprehensive review of pharmacologic pain management.

• CRITICAL REFLECTION POINT

Mrs Egbert is an 89-year-old woman awaiting surgery to repair a fractured neck of femur. She has dementia and pain assessment is difficult, although she is groaning and grimacing. Over the last 2 days she has received 3 doses of oral paracetamol as required and 10 mg of subcutaneous morphine. What would be your response to this situation? Can you suggest an alternative pain management plan?

Pharmacology of analgesics

The experience of pain is always part of a broader health context and it is important to consider the risks

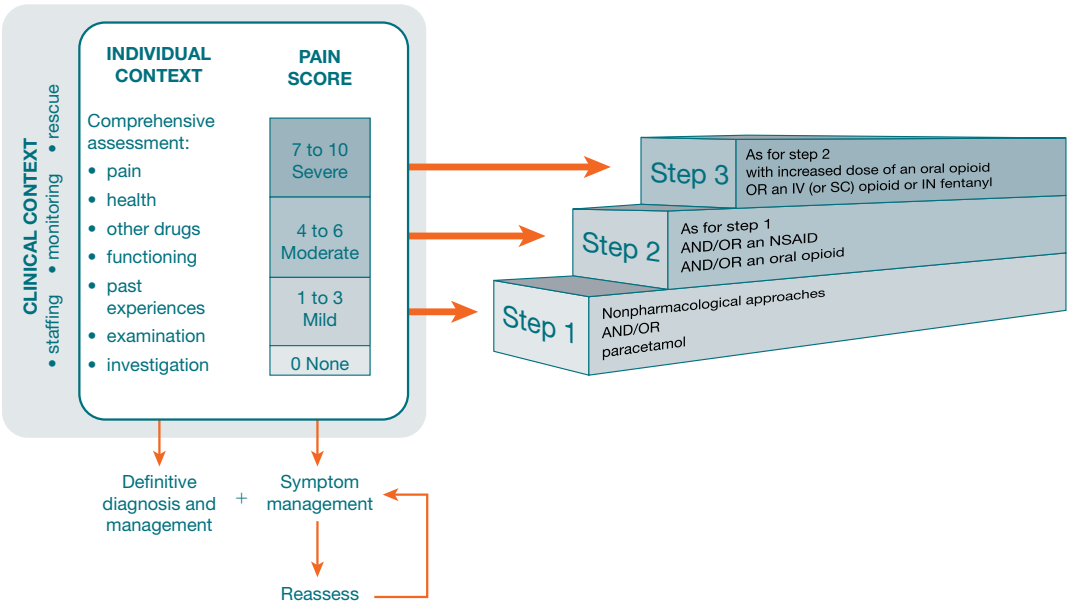


Figure 36-10 Analgesic ladder for acute pain management.

Therapeutic guidelines: Analgesic 2012 Deciding where to start when prescribing analgesics for new-onset acute pain, version 6. Therapeutic Guidelines Limited.

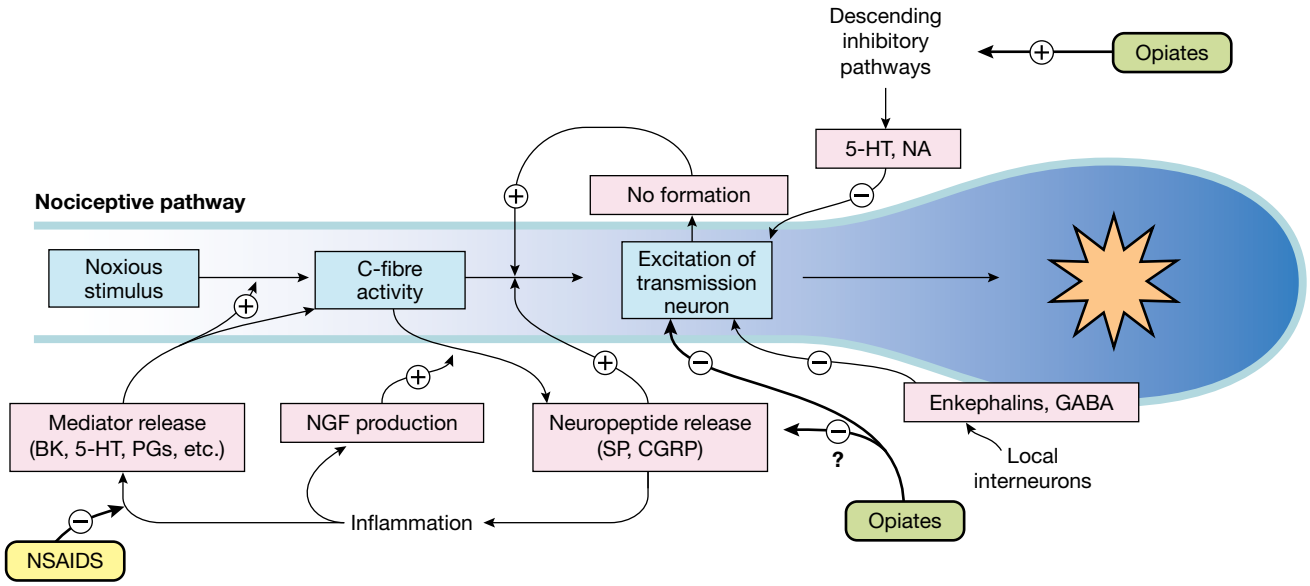

Figure 36-11 Summary of modulatory mechanisms in the nociceptive pathway.

5-HT = 5-hydroxytryptamine; BK = bradykinin; CGRP = calcitonin gene-related peptide; NA = noradrenaline; NGF = normal growth factor; NO = nitric oxide; NSAID = non-steroidal anti-inflammatory drug; PG = prostaglandin; SP = substance P.

Redrawn from Rang HP, Dale MM, Ritter JM et al 2007 Rang and Dale's Pharmacology, 3rd edn. Elsevier, London.

that analgesics might pose for patients (Boxes 36-6 and 36-7). Box 36-7 identifies some of the common situations encountered in clinical practice. Although most nurses do not prescribe analgesics, it is essential to apply principles of pharmacology to safely and effectively administer and evaluate patient responses to treatment (see

BOX 36-6 Principles for administering analgesics

Know the patient's previous response to analgesics

- Determine whether relief was obtained from various analgesics.
- Identify previous and current use of analgesics.
- Determine whether the patient has allergies or has experienced adverse effects from specific analgesics.

Administer medications as appropriate based on clinical reasoning

- Use regular doses of paracetamol as a foundation analgesic layer that limits the need for opioid drugs.
- Consider a non-steroidal anti-inflammatory drug (NSAID) if appropriate to further limit the need for opioids and improve pain relief.
- Avoid multiple opioid analgesics.
- Know that intravenous medications act more quickly and can relieve severe, acute pain within 10–20 minutes and that oral medication may take as long as 1 hour to relieve pain.
- Patients who are opioid-tolerant may require increased doses.
- Always assess response to treatment by documenting pain and sedation scores with all other observations.
- Increasing sedation is the primary indicator of impending respiratory depression.
- Always consider non-pharmacological interventions such as ice, transcutaneous electrical nerve stimulation (TENS), relaxation and distraction.
- For chronic pain, administer the patient's usual regimen, including opioids, and add acute analgesics for acute pain situations.

Know the accurate dosage

- For adults, opioid doses are calculated based on age and not weight.
- Adjust doses, as appropriate, for children (weight) and older patients at a reduced dose for opioids.

Assess the right time and interval for administration

- Prevent pain where possible. Administer analgesics as soon as pain occurs and before it increases in severity.
- Give analgesics before pain-producing procedures or activities.
- Know the average duration of action for a drug and the time of administration so that the peak effect occurs when the pain is most intense.

BOX 36-7 Risk associated with the administration of various analgesics

- Adverse drug reactions
- Potential drug interactions (e.g. tramadol and antidepressants)
- Renal impairment or poor urine output leading to increased drug concentrations
- Pregnancy and lactation
- Liver impairment and impaired drug metabolism
- Opioid tolerance
- Obstructive sleep apnoea and opioid risks
- Broncospasm in some asthmatic patients with non-steroidal anti-inflammatory drugs (NSAIDs)
- Elderly and paediatric patients
- Haemodynamic instability and additive effects of opioids.

Chapter 27). For example, controlled-release oxycodone will take almost 3 hours to reach peak effect, whereas an immediate-release dose of the same drug has a time to maximum concentration of about 1 hour. Sedation and other opioid effects, such as nausea and respiratory depression, are related to the *pharmacodynamic* effects of the drug. Key terms are defined in Table 36-9; the basic pharmacology of some common analgesics is summarised in Table 36-10.

Non-opioid analgesics

Paracetamol

Paracetamol has a central analgesic action that may be associated with an anti-inflammatory action on central cyclooxygenase. An intravenous preparation is available and allows for around-the-clock dosing when oral administration is not possible. It is important to note that paracetamol remains the foundation starting point for an analgesic plan and should continue around the clock when other drugs are added to the plan. Regular dosing with paracetamol results in a 20% decrease in the patient's requirement for opioid analgesics (opioid sparing effect) that may reduce adverse effects such as sedation, nausea and constipation (Therapeutic Guidelines 2012). Paracetamol administration should not be taken lightly, especially in acute care situations. In normal doses administered over several days, toxicity can occur and liver damage may be the result. It is recommended that the patient's liver function be reviewed in hospital.

Non-steroidal anti-inflammatory drugs (NSAIDs)

The analgesic effects of NSAIDs (e.g. ibuprofen, diclofenac, ketorolac, parecoxib, celecoxib) are the result of decreased synthesis of cyclooxygenase at the peripheral and central nervous systems, producing an opioid-sparing effect of 20–40% (Macintyre & Schug 2015). These drugs are noted for having a high efficacy in terms of analgesic effects (see *Research highlight*). However, the adverse effects of NSAIDs are well known and include upper gastrointestinal ulceration, postoperative bleeding, asthma in susceptible patients and renal failure in patients at risk such as the elderly and those on some antihypertensive medications. Pasero and McCaffery (2011) suggested that patients should be placed on gastroprotective therapy, such as ranitidine or omeprazole, while receiving regular doses of NSAIDs.

Opioids

All drugs that act like morphine are called **opioids** (e.g. morphine, fentanyl, oxycodone, codeine, tramadol, hydromorphone). They produce their effects by acting on opioid receptors (namely, mu (μ), delta (d) and kappa (k) receptors) in the peripheral and central nervous systems, and may produce analgesia, sedation, respiratory depression, nausea and constipation (Macintyre & Schug 2015). Common oral opioids include oxycodone

TABLE 36-9 Definitions and application of key pharmacological terms

Term	Definition	Example applications
Pharmacodynamics	'What the drug does to the body' and events caused by the interaction of a drug with a receptor	Opioids may cause respiratory depression, sedation, nausea, pruritus and constipation
Pharmacokinetics	'What the body does to the drug' and concerns relating to drug absorption, metabolism, distribution and elimination	An intravenous injection of morphine peaks in 15–20 minutes in plasma. This is the time to maximum concentration or t_{max}
Half-life	The time it takes for plasma concentration of a drug to decrease by 50%	The half-life or $t_{½}$ of morphine is 2–3 hours

Rang HP et al 2007 Rang and Dale's pharmacology, 3rd edn. Elsevier, London.

TABLE 36-10 Pharmacodynamic and pharmacokinetic aspects of common analgesics expressed as t_{max} (time to maximum concentration) and $t_{½}$ (half-life)

Drug	Action (pharmacodynamics)	t_{max}	Half-life	Comments
Celecoxib (Celebrex)	COX-2 selective NSAID	2–3 hours	4–15 hours	Claimed to be less risk of GIT bleeding
Codeine	Pro-drug of morphine	1–2 hours	2–4 hours	Some patients lack the liver enzyme that converts codeine to morphine Not recommended for lactating mothers
Diclofenac (Voltaren, Fenac)	Non-selective NSAID Acts on both COX-1 and COX-2 enzymes to decrease prostaglandin synthesis	2 hours 30–40 minutes for suppository	1–2 hours	More selective for COX-2
Fentanyl (Sublimaze)	Opioid agonist on opioid receptors	7 minutes	3–5 hours	No active metabolites
Ibuprofen (Brufen, Nurofen, Rafen)	Non-selective NSAID Acts on both COX-1 and COX-2 enzymes to decrease prostaglandin synthesis	1–3 hours	2 hours	20–40% opioid-sparing May be administered without food temporarily for acute pain episodes Proton-pump inhibitor drugs may be co-administered to prevent gastrointestinal side effects
Ketorolac (Toradol)	Intramuscular NSAID	50 minutes	5–6 hours	Increased risk of serious GIT bleeding Not recommended in elderly patients
Morphine sulfate	Opioid agonist on opioid receptors	20 minutes (intravenous) 30–90 minutes (subcutaneous)	2–3 hours	Active metabolite M-6-G and not recommended in renal impairment
Oxycodone IR (Endone, Oxynorm)	Opioid agonist	Less than 1 hour	2–3 hours	Most popular oral opioid used for acute pain
Paracetamol (Panadol, Panamax, Perfalgan IV)	Possible anti-inflammatory effects within the central nervous system	Less than 1 hour if given orally 15 minutes for intravenous dose	1–3 hours	20% opioid-sparing Reduce dose in liver disease or poor nutritional status
Parecoxib (Dynastat)	COX-2 selective NSAID given intravenously	30 minutes	8 hours	Used extensively for perioperative patients Oral NSAID may be commenced at least 12 hours after the dose of parecoxib
Tramadol IR (Tramal, Zydol)	Opioid plus enhanced serotonin and noradrenaline	2 hours	5–7 hours	Claimed as safer with obstructive sleep apnoea Many drug interactions
Tapentadol	Opioid agonist plus noradrenaline reuptake inhibition	3–6 hours	4 hours	New drug for chronic pain
Transdermal buprenorphine (Norspan)	Partial opioid agonist	17 hours	12 hours after patch removal	Not recommended for acute pain management
Transdermal fentanyl (Durogesic)	Opioid agonist on opioid receptors	24–72 hours	22–25 hours after patch removal	Not recommended for acute pain management
Buprenorphine (Temgesic)	Opioid agonist at smaller doses 200–400 micrograms sublingual administration	2–4 hours	5 hours	Not in conjunction with benzodiazepines

GIT = gastrointestinal tract, IR = immediate-release, IV = intravenous, NSAID = non-steroidal anti-inflammatory drug.

RESEARCH HIGHLIGHT

Research focus

A Cochrane systematic review examined the effectiveness of single-dose oral analgesics for relief of acute postoperative pain in terms of the number needed to treat (NNT) for a single or combination analgesic dose. For example, for every 2.5 people receiving 400 mg of oral ibuprofen, at least one of these patients will experience at least 50% pain relief. The NNT value for ibuprofen is 2.5 for postsurgical pain relief. The NNT for other common analgesics include: paracetamol 1000 mg (NNT = 3.6), paracetamol 1000 mg + codeine 60 mg (NNT = 2.2), paracetamol 1000 mg + oxycodone 10 mg (NNT = 1.8).

The full range of reliable NNTs can be located at: http://onlinelibrary.wiley.com/doi/10.1002/14651858.CD008659.pub2/abstract

(e.g. Endone, Oxynorm), codeine and tramadol. Morphine is the intravenous opioid of choice due to its long history of clinical experience, although it is not recommended in renal impairment due to the accumulation of its metabolite morphine-6-glucuronide. This metabolite is active and may cause respiratory depression, and so fentanyl is recommended in susceptible patients (Rang et al 2007). All other opioids may be compared with 10 mg of morphine in terms of their equianalgesic dose, as shown in Table 36-11. Pethidine is no longer recommended as a systemic opioid due to its potential for seizures, especially in neonates. However, it is sometimes used in patient-controlled **epidural analgesia** in the obstetric environment.

Patient-controlled analgesia

Intravenous **patient-controlled analgesia (PCA)** involves the administration of intravenous drugs to treat acute pain. The patient controls the administration of drug by pressing a button attached to a pain-management pump. PCA is more likely to maintain a constant blood concentration of the drug and to overcome the wide inter-patient variation in opioid requirements (Macintyre & Schug 2015). This may be represented by the *analgesic corridor* concept in Figure 36-12, which shows the pharmacokinetics of PCA in terms of blood plasma concentration over time.

Check the IV line and ensure that a one-way valve exists above the point where opioids enter the maintenance fluid line. The insertion site and PCA program must also be regularly checked to ensure patient safety and that effective analgesia is obtained. Document the cumulative opioid dose, pain score and sedation score with all other routine observations at intervals stated on specific organisational policy documents (see Figure 36-13). It is recommended that standardisation of local hospital protocols occurs

TABLE 36-11 Equianalgesic doses and half-lives of some commonly used opioids

Opioid	Intramuscular or intravenous dose (mg)	Oral dose (mg)	Half-life (hours)
Morphine	10	30	2–3
Alfentanil	0.75–1.5	–	1–2
Buprenorphine	0.4	0.8 (sublingual)	3–5
Codeine	130	200	2–4
Fentanyl	0.15–0.2	–	3–5
Hydromorphone	1.5–2	6–7	3–4
Methadone	10	10–20	8–60
Oxycodone	10	20	2–3
Pethidine	75–100	300	3–4
Tramadol	100	150	5–7
Tapentadol	–	100	4

in order to prevent error with PCA. These should cover standard infusion concentrations, equipment used, PCA doses, lockout times, monitoring and documentation. Examples of standard PCA programs are shown in Table 36-12.

• CRITICAL REFLECTION POINT

Dawn Osborne is a 62-year-old woman who returned to the unit 3 hours ago after bowel resection for colorectal cancer. She reports 7/10 pain on movement and 4/10 pain 'if I lie completely still'. She has an intravenous morphine PCA and her cumulative dose is 2 mg (order: 1 mg morphine, lockout 5 minutes). On questioning, she says, 'I do not want to become addicted' and 'I might need to use more if the pain gets worse.' How would you respond to this situation?

Your role in patient education across the patient journey from pre-admission to discharge from hospital is critical for safe and effective use of PCA (Box 36-8 and Figure 36-14). Patients must be able to understand the use of the equipment and be physically able to locate and press the button to deliver the dose. Key points to include are:

- Reassurance that addiction is extremely unlikely
- The lockout function on the pump protects from overdose
- Nurses are monitoring patients' pain ratings and use of the PCA
- Explanation of analgesics used and side effects
- Rationale for other analgesics such as paracetamol used to improve analgesia (multimodal approach)
- Importance of pain management for effective postoperative recovery (e.g. respiration and mobility)
- Likely treatment duration and plan after PCA is ceased.

Prevention and management of opioid-induced adverse effects

Common side effects of opioids include constipation, nausea and vomiting, sedation and itching (pruritus). Most adverse effects are dose dependent, which is why an effective and practical approach to treatment of these is to administer the lowest effective opioid dose. With continued use, many side effects diminish; the exception is constipation.

Postoperative nausea and vomiting remains a significant clinical problem that distresses patients and prolongs recovery from surgery and anaesthesia. The serotonin (5HT-3) antagonist drugs are the most effective antiemetics, and these include ondansetron. Dexamethasone, droperidol and promethazine are effective. Opioid-induced itching (pruritus) may also be treated with ondansetron, but antihistamines or naloxone may be more effective.

Stimulation of the P6 acupuncture point may be also used by nurses as a complementary intervention in a multimodal approach. The P6 (neiguan) point can be found three finger-breadths above the skin fold of the wrist joint (Schultz et al 2003). The direct-pressure digital stimulation technique can be maintained by applying pressure for at least 6 seconds at a time (Ming et al 2002, Shin et al 2007).

Recommended Minimum Monitoring Requirements for PCA

As per hospital policy for routine post operative observations AND/OR PCA specific observations:

HOURLY for 8 hours then 2 HOURLY for 16 hours then 4 HOURLY thereafter.

A Program and Connection/Line Check must be performed:

- At the commencement of each shift
- Upon return from another ward/department
- At each bag/syringe change

Refer to Intravenous PCA and Epidural/Regional Analgesia Monitoring form for details

Observations are to be recorded on the *PCA and Epidural/Regional Analgesia MONITORING form*. Any observations listed in the ASSESSMENT/INTERVENTION GUIDELINES (page 1 of monitoring form) must be reported to the contact person and required interventions completed.

Naloxone Protocol

If sedation score = 2 and respiratory rate less than 8/minute OR if sedation score = 3 a Registered Nurse/Midwife is hereby authorised to:

1) Dilute naloxone 400 mcg (1 ampoule) to 4 mL with normal saline (100 mcg/mL)
2) Give naloxone 100 mcg (1 mL) every minute until sedation score less than 2 or a maximum dose of 400 mcg has been given
3) Ensure contact person has been notified. Continue monitoring every 10 minutes for a further half an hour, then every hour for a further 2 hours. If sedation score returns to greater than or equal to 2, follow recommended intervention (as on monitoring form) and repeat steps 1-3.

Any administered doses must be recorded on the front page of the patient's Medication Chart under Nurse Initiated Medicines

Oxygen Prescription *(medical officer to tick appropriate option)* **If not completed, use option (A) as default**

Give oxygen: ❑ **(A) *overnight*** at a *minimum* of 2 L/min via nasal prongs or 6 L/min via Hudson Mask (*ensure oxygen saturation is equal to or greater than 93%*). Notify contact person if the *required* flow rate exceeds 6 L/min via Hudson Mask OR oxygen saturation falls below 93% for more than 1 minute.

❑ **(B) *at all times*** to maintain a *minimum* oxygen saturation of 93%
Notify contact person if oxygen flow rate exceeds ..... L/min via Hudson Mask

❑ **(C) *at all times*** to maintain a range of ..... to ..... %
Notify contact person if oxygen flow rate exceeds ..... L/min via Hudson Mask

Available: www.rch.org.au/anaes/pain/index.cfm?doc_id=845#Prescription_and_program_of_PCA; accessed 9 March 2016.

Constipation may be prevented by adequate mobility, fluid intake and diet, but additional measures may be required when on opioid therapy. Pasero and McCaffery (2011) suggested regular dosing with docusate and senna, or with an osmotic laxative available if this is not adequate. They also recommended that chewing gum may be beneficial. For cancer patients, an opioid antagonist (methylnaltrexone) is available for treating opioid-induced constipation. It increases bowel movements without decreasing analgesia (National Prescribing Service 2010).

BOX 36-8 **Patient teaching and preparation for patient-controlled analgesia (PCA)**

Objectives

- Patient will be able to explain purpose of PCA in managing pain.
- Patient will use the PCA device correctly.
- Patient achieves pain control and desired functional outcome.

Teaching strategies

- Teach the use of PCA before any procedure so that patients can understand how to use it after waking from anaesthesia or sedation. Reinforce as needed.
- Teach patient about the purpose of PCA, emphasising that the patient controls medication delivery.
- Explain that the pump prevents the risk of overdose.
- Tell family members or friends that they should not operate the PCA device for the patient.
- Have the patient demonstrate use of the PCA delivery button.

Evaluation

- Ask patient to tell you the purpose of the PCA device.
- Observe the patient administering a dose.
- Evaluate the severity of the patient's pain 15–20 minutes after use of the PCA device and with all other routine observations.

Respiratory depression is the most feared, yet an uncommon side effect of opioid treatment (Dahan et al 2010). You should routinely monitor sedation score (SS) and respiratory rate during patient assessment for indications of respiratory depression. Monitoring sedation levels using a sedation scale is the most effective way to prevent opioid-induced respiratory depression. The Victorian Quality Council (2007) recommends that a sedation score (Table 36-13) of ≥ 2 and a respiratory rate of < 10 breaths per minute should be reported immediately and further intervention considered. If the patient is difficult to rouse (SS = 3) and respiratory rate is less than 8 breaths per minute, most organisations have a standard order to administer intravenous naloxone to reverse the effects of the opioid.

Adjuvants

An adjuvant is a drug that is not primarily indicated for pain but has analgesic benefits for some conditions and situations. Certain agents such as ketamine or antidepressant drugs may be helpful in acute, chronic and cancer pain problems (Pasero & McCaffery 2011).

TABLE 36-13 Sedation score scale

Sedation score	Level of sedation (Wake patient to assess sedation score)
0	Awake
1	Mild; occasionally drowsy, easy to rouse
2	Moderate; rousable but unable to remain awake (e.g. falls asleep during conversation)
3	Severe; difficult to rouse or unrousable

Adapted from Victorian Quality Council 2007 Acute pain management measurement toolkit. Victorian Quality Council, Melbourne. Online. Available: www.health.vic.gov.au/qualitycouncil/downloads/apmm_toolkit.pdf; accessed 9 March 2016.

Ketamine

The main action of ketamine is to block the N-methyl-d-aspartate (NMDA) receptor that is involved with central sensitisation. Ketamine has been very useful for acute pain states where opioids have failed (Kapur 2008). In this context, it has been used most effectively as an intravenous infusion at sub-anaesthetic doses so as to avoid its well-known psychotropic effects such as hallucinations. It is usually administered as a separate intravenous infusion in conjunction with PCA with an opioid.

Clonidine

Clonidine is an alpha-2 adrenergic agonist that seems to work synergistically with morphine to produce analgesia (Kapur 2008). It has been added to intravenous PCA in the acute pain setting to improve analgesia and decrease opioid requirements, although it may contribute to hypotension (Macintyre & Schug 2015).

Antidepressants

Antidepressants (e.g. amitriptyline, venlafaxine, duloxetine, mirtazapine) have been used in a variety of chronic pain problems including neuropathic pain. They have multiple receptor actions and so have many side effects and potential drug interactions (Macintyre & Schug 2015, Pasero & McCaffery 2011). Because of their ability to enhance central serotonin levels, antidepressants should be avoided in patients receiving tramadol.

Anticonvulsants

Anticonvulsants (e.g. gabapentin, pregabalin) decrease the firing rate of neurons and mimic the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) (Kapur 2008). These agents may be beneficial in the perioperative setting and should always be considered as first-line therapy for neuropathic pain if an antidepressant is contraindicated or ineffective (Pasero & McCaffery 2011).

Local anaesthesia and peripheral nerve blocks

Local anaesthetic agents may be used while suturing a wound and performing simple surgery (see Table 36-14). They can be applied topically on skin and mucous membranes, injected to anaesthetise a body part or infused to provide postoperative analgesia. The drugs produce temporary loss of sensation by inhibiting sodium channels to prevent transmission of impulses. They may also block motor and autonomic functions when administered as nerve blocks. Smaller sensory nerve fibres are more sensitive to local anaesthetics than are large motor fibres. As a result, the patient loses sensation before losing motor function and, conversely, motor activity returns before sensation.

TABLE 36-14 Local anaesthesia techniques

Type	Area of injection	Area affected	Indications for use
Epidural	Epidural space	Dermatomes related to level of injection	Obstetrics and major surgery
Infiltration	In superficial area under skin or mucous membranes	Small peripheral nerves to area infiltrated	Small incisions of skin, insertion of sutures to close cuts or wounds, minor dental repairs
Peripheral nerve block (e.g. femoral, sciatic, interscalene)	In area surrounding large peripheral nerve at point above bifurcation of nerve	Wider area than with infiltration, numbing entire body part (e.g. hand, upper gums, foot)	Major dental repairs, manipulation or reduction of extremity fractures, minor hand and foot surgery
Spinal nerve block	Subarachnoid space surrounding spinal cord	Lower trunk and extremities	Major surgery to lower trunk and extremities, patients at risk with general anaesthesia

After administration of a local anaesthetic, protect the patient from injury until full sensory and motor function return. Until a local anaesthetic is absorbed and metabolised, the patient must be careful with using an affected body part. Patients can easily injure themselves without knowing it. For example, after an injection around a nerve that supplies a limb, warn the patient to avoid using the limb until function returns. For patients with local regional anaesthesia, avoid applying heat or cold to numb areas. After spinal anaesthesia the patient stays in bed until sensory and motor function return. Assist the patient to *slowly* get out of bed during the first time to reduce the risk of falling.

Epidural and intrathecal analgesia

Neuraxial analgesia may be described as the administration of agents into the epidural or subarachnoid space (spinal) to provide pain relief. The potential benefits for patients include better pain relief than parenteral opioid administration; increased oxygen levels; decreased incidence of pulmonary infections and complications when compared with systemic opioid drugs; improved bowel recovery after abdominal surgery; and reduced incidence of postoperative myocardial infarction (Schug et al 2015).

The anatomical difference between spinal and epidural drug administration can be seen in Figure 36-15, which provides a sagittal-section view of the spinal cord and associated structures that shows the target drug areas of the epidural and subarachnoid space.

Standard equipment for epidural insertion includes an epidural needle with a catheter that can be passed through it into the epidural space (see Figure 36-16). A filter is attached after insertion and this is designed to prevent infection of the infusion and patient. A spinal needle is visible on the right, and this is used for a single-shot spinal injection into the subarachnoid space, usually for surgery on the lower abdomen or limbs.

The medical practitioner inserts a blunt-tip needle into the level of the vertebral interspace nearest to the area requiring analgesia. When the needle reaches the space, drugs may be freely injected and small catheters may be passed into it. Once a catheter is advanced into the epidural space and the needle is removed, the remainder of the catheter is secured with a dressing and taped up the back of the patient.

Once the catheter is connected to a bacterial–viral filter, it is connected to an epidural giving set and is secured along the spine and over the patient's shoulder. The end of the catheter can then be placed on the patient's chest for the nurse's access. The catheter is connected to a continuous epidural infusion pump, a port or reservoir, or is capped off for bolus injections. To reduce the risk of accidental epidural injection of drugs intended for IV use, the catheter should be clearly labelled 'epidural catheter'. Continuous infusions must be administered through electronic infusion devices for accurate control.

Most labour and postoperative epidural regimens include a background local anaesthetic and opioid infusion rate. The most common opioid used is fentanyl

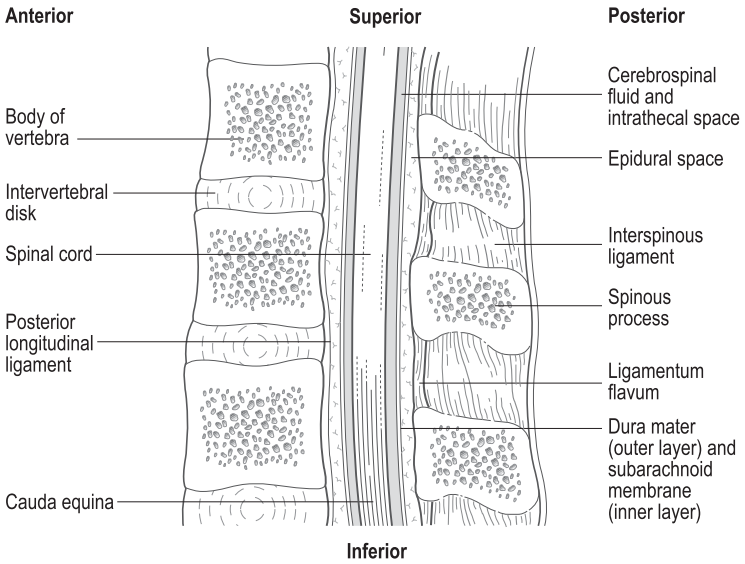

Figure 36-15 Anatomy of the spinal cord.

Macintyre P, Schug S 2007 Acute pain management: a practical guide, 4th edn. CRC Press, Boca Raton.

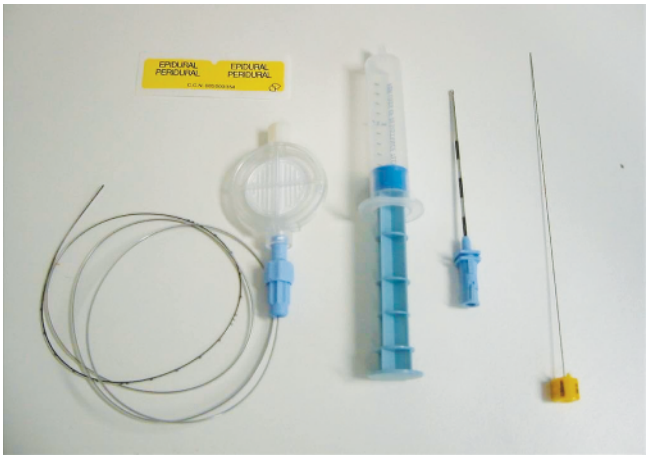

Figure 36-16 **Epidural needle, syringe, catheter and filter with a spinal needle on the right.**

at 2–5 micrograms/mL and a local anaesthetic concentration of 0.125%. Available infusions include bupivacaine (e.g. Marcain), levo-bupivacaine (e.g. Chirocaine) and ropivacaine 0.2% (e.g. Naropin). A patient-controlled epidural bolus (PCEA) may also be programmed. In some settings, newer techniques like patient intermittent epidural bolus (PIEB) automatically infuse larger volumes of local anaesthetic at programmed intervals to maintain adequate spread of the infusion in the epidural space. It can also be used with PCEA which combines the benefits of better analgesia with patient control.

Nursing care of epidural analgesia

Because of the risk of epidural abscess and spinal cord compression, strict surgical asepsis is needed to prevent a serious and potentially fatal infection. Thorough nursing care is needed during hygiene procedures to keep the catheter system clean and dry. The responsible clinicians are notified immediately of any signs or symptoms of infection or pain at the insertion site. Peripheral sensory and motor dysfunction may also occur and denote a medical emergency. A summary of nursing care for epidural analgesia is provided in Table 36-15.

Assessment of motor and sensory blockade is a requirement for standard monitoring of patients receiving neuraxial analgesia (Victorian Quality Council 2007). The Bromage Score must be documented in the patient's record; this ascertains the degree of motor blockade in the lower extremities as a score ranging from 0 to 3 (Figure 36-17).

TABLE 36-15 Nursing care for patients with epidural infusions

Goal	Actions
Identify neurological disturbance	Assess dermatome levels for the anaesthetic block to ensure adequate analgesia or blocks that are too high Perform motor block assessment (Bromage Score) and report any motor block with epidural therapy
Prevent epidural catheter displacement	Secure catheter (if not connected to implanted reservoir) carefully to skin and warn patient of movements that may dislodge the catheter from its original position and render analgesia ineffective
Maintain epidural catheter function	Use transparent adhesive dressing to aid inspection Inspect catheter for breaks or kinks
Prevent infection and its neurological complications	Inspect insertion site every 4–8 hours and report signs of infection Record body temperature with observations Use strict aseptic technique when caring for an epidural catheter (see Chapter 25) Do not routinely change dressing over site Change infusion tubing every 24 hours Immediately report increasing pain at the site, fever, unresolved headaches, motor/sensory dysfunction that is unexpected, bladder or bowel dysfunction
Monitor for respiratory depression	Monitor vital signs and oxygen saturation Document respirations and sedation score as per policy
Prevent adverse drug reactions	Monitor for signs of local anaesthetic toxicity Monitor for hypotension and be aware of organisational protocols for treatment Assess for pruritus (itching) and nausea and vomiting Administer antiemetics as required
Maintain urinary and bowel function	Monitor intake and output Assess for bladder and bowel distension Assess for discomfort, frequency and urgency

INTRAVENOUS PATIENT CONTROLLED ANALGESIA (PCA) AND EPIDURAL/REGIONAL ANALGESIA MONITORING

(Affix patient identification label here)

URN:

Family name:

Given names:

Date of birth: Sex: ❑ M ❑ F

Recommended Minimum Monitoring Requirements

PCA	Epidural/Regional	Epidural: Obstetric Labour Epidural Patients
As per hospital policy for routine post-operative observations and/or monitoring HOURLY for 8 hours then 2 HOURLY for 16 hours then 4 HOURLY thereafter.	1. As per hospital policy for routine post-operative observations and/or monitoring HOURLY for 8 hours then 2 HOURLY for 16 hours then 4 HOURLY thereafter. 2. Monitor Bromage (motor block check) 4 HOURLY and continue for 24 hours after removal of epidural/regional catheter. 3. Dermatome check 4 HOURLY (if hospital policy). 4. After a clinician dose monitor every 5 minutes for the first 20 minutes. Then continue as per routine epidural/regional observations.	1. After a clinician dose monitor every 5 minutes for the first 20 minutes, then every 10 minutes for 20 minutes then HALF HOURLY thereafter. 2. Monitor Bromage (motor block check) 4 HOURLY and continue for 24 hours after removal of epidural/regional catheter. 3. Dermatome check 4 HOURLY (if hospital policy).

The following must also be checked for ALL patients:

1. At the commencement of each shift 2. Upon return from another ward/department 3. At each bag/syringe change

Program Check:
(Check that the following are within parameters of current prescription)
- Medication being administered
- Infusion rate
- Bolus dose
- Lockout time

Connection/Line Check:
- Between pump and line
- Between line and infusion bag/syringe
- Between line and patient
- Line not kinked
- Correct line type
- Catheter site/dressing (Epidural/Regional)
- Clamp(s) open
- Identification via yellow labels/lines (Epidural/Regional)

Assessment/Intervention Guidelines

Any observations as below must be reported to the **CONTACT PERSON** (as specified on **PCA** or **EPIDURAL/REGIONAL ANALGESIA order form**

	Observation	Assessment	Intervention
	Sedation Score (SS)	• Sedation score 2	Stop infusion/removal patient bolus button. Assess respiratory rate. Ensure patient receives oxygen and monitor oxygen saturation. Return to hourly observation for 2 hours.
		• Sedation score 3	Stop infusion/remove patient bolus button. Notify contact person immediately. Ensure patient receives oxygen and monitor oxygen saturation. Give **naloxone** as per protocol (see PCA or Epidural/Regional Analgesia Order form).
	Respiratory Rate (RR)	• Respiratory rate less than 8/min	Ensure patient receives oxygen and monitor oxygen saturation. Give **naloxone** as per protocol if sedation score is greater than 1 (see PCA or Epidural/Regional Analgesia Order form). Notify contact person.
	Oxygen Saturation (SpO_2)	• Less than 93% for more than 1 min	Administer **oxygen** as per prescription (see PCA or Epidural/Regional Analgesia Order form).
Pain	Pain Score 0–10 / Functional Activity Score (FAS)	• A pain score at rest of greater than 4/10 or • A FAS of C (severe irritation)	Encourage patient bolus/increase infusion rate (if ordered/give clinician dose (if ordered) Notify contact person if no improvement.
EPIDURAL/REGIONAL ANALGESIA ONLY	**Hypotension** (BP)	• Systolic blood pressure less than 90 mm Hg or equal to or greater than 40 mm Hg drop from baseline	Manage as per **fluid bolus** protocol (see Epidural/Regional Analgesia Order form).
	Motor Deficit	• Initial Bromage score of 2 or 3 that does not decrease to less than 1 in FOUR hours following spinal anaesthetic or • Bromage score of greater than zero at any other time	Stop infusion/remove patient bolus button. Notify contact person immediately.
	High Blockade	• Tingling/numbness in fingers or • Weakness in arms or • Respiratory difficulties	Stop infusion/remove patient bolus button. Notify contact person immediately.
	Back Pain	• Unexpected or new pain or • Tingling, numbness or weakness in limb(s) or • New urinary or faecal incontinence	Notify contact person immediately—**THIS COULD BE A MEDICAL EMERGENCY**.
		• Breakdown of dressing cover site or • Temperature greater than 38.5°C or • Pain, inflammation or swelling at epidural/regional catheter insertion site	Reinforce cover site. Notify contact person.
	Local Anaesthetic Toxicity	• CNS: agitation, anxiety, tingling around mouth, drowsiness, convulsions or • CVS: hypotension, cardiac arrythmia	Stop infusion/remove patient bolus button. Administer oxygen and provide basic life support. Notify contact person immediately.
	Post Operative Nausea and Vomiting (PONV)	• PONV score 2 or 3	Administer prescribed antiemetics. Notify contact person *if no improvement.*
	Pruritus	• If patient requests treatment	Notify contact person.

NB: No other sedating medications should be given to patients (e.g. antihistamines such as promethazine, benzodiazepines such as temazepam, other opiates) without contact persons review.

INTRAVENOUS PCA AND EPIDURAL/REGIONAL ANALGESIA MONITORING

Keys

Sedation Score (SS)

S = Normal sleep
0 = Awake
1 = Mild (occasionally drowsy)
2 = Moderate (rousable but not able to stay awake)
3 = Severe (difficult to rouse or unrousable)

Pain Score

R = Rest
M = Movement
0 = No pain
10 = Worst pain

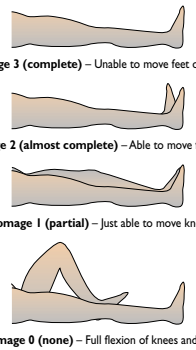
Functional Activity Score (FAS)

A = Activity unlimited by pain
B = Activity mild to moderately limited by pain
C = Activity severely limited by pain

Post Operative Nausea and Vomiting (PONV) Score

0 = No nausea or vomiting
1 = Mild nausea or vomiting
2 = Moderate nausea or vomiting
3 = Severe/persistent nausea or vomiting

Bromage



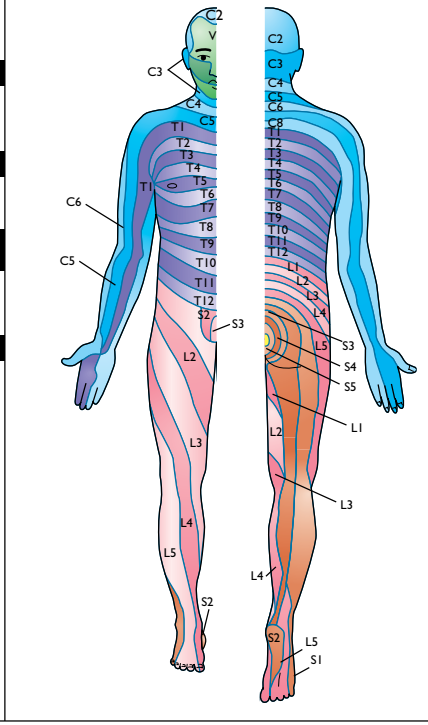
Bromage 3 (complete) – Unable to move feet or knees

Bromage 2 (almost complete) – Able to move feet only

Bromage 1 (partial) – Just able to move knees

Bromage 0 (none) – Full flexion of knees and feet

Dermatomes



Other Observations for Post-Operative Patients *(if required)*

Neurovascular Circulation

Score	*Colour (C)*	*Warmth (W)*	*Movement (M)*	*Sensation (S)*	*Capillary (CR)*
1	Usual colour	Warm	Flexion/Extension	No numbness/Tingling	Brisk ≤ 2 secs
2	Dusky	Cool	Restricted	Slight numbness/Tingling	Sluggish ≥ 3 secs
3	Mottled	Cold	Nil	Numb	Poor ≥ 4 secs

See keys on back page for explanation of** SS, Pain score, FAS, PONV score, Bromage, Dermatomes **and other observations

The goal of analgesia is a score of zero, which represents the absence of motor blockade. Any changes from this level must be reported immediately.

Evaluating the level of sensory block in a patient with an epidural infusion is standard procedure every 4 hours (Figure 36-16). The skin covering the entire body is supplied by peripheral spinal nerves. These segments are known as *dermatomes* – areas of skin supplied by afferent nerves that come together to form a dorsal nerve root. Loss of temperature sensation occurs in those dermatomes affected by the local anaesthetic agent. Applying ice to the skin, or an alcohol swab, can help ascertain the extent of sensory fibre blockade. A bilateral assessment is made to determine the extent of local anaesthetic blockade at the surgical incision. A normal block distribution would be 2–3 dermatomes above and below the epidural catheter level of insertion. Numbness around the incision dermatomes is normal. Numbness or weakness in the legs or arms must be reported.

Removal of epidural catheters is often performed by registered nurses and midwives and is a simple process, although there are risks such as catheter breakage and epidural haematoma. The risk of haematoma is increased if the patient has been administered anticoagulant medication such as heparin, enoxaparin (e.g. Clexane) or rivaroxaban. The use of epidural analgesia in conjunction with the oral anti-coagulant rivaroxaban is not recommended at present, but there are recommendations made for removal of epidural catheters with the subcutaneous anticoagulant drugs (Schug et al 2015). In general, catheters can be removed 6 hours after prophylactic doses of heparin and at least 12 hours after enoxaparin. Another dose of either drug should not be administered for at least 2 hours after the removal of the epidural catheter.

A prescription to remove the catheter must be documented in the patient record with an exact date and time for removal. The authority for removal only exists with the individual or team specialising in epidural analgesia. Check that the tip of the catheter is present after removal and that the procedure is accurately recorded in the patient record. The epidural site should be inspected after removal, and Bromage Score needs to be documented for at least another 24 hours in order to assess for haematoma or abscess development.

Despite the benefits of neuraxial analgesia, there are many risks and the suggested responses to these are summarised in Table 36-16.

Part of your role is to provide patient education about epidural analgesia in terms of the action of the medication and its advantages and disadvantages. Patients should know about the potential for side effects and should be instructed to notify a healthcare provider if signs of complications develop.

Non-drug pain management interventions

Non-pharmacological interventions should always be considered when formulating a pain management plan for patients. There are two main categories of non-pharmacological interventions for pain management: physical and cognitive–behavioural interventions. There is a variety of evidenced-based opinions on the effectiveness of non-drug therapies for pain management (see Schug et al 2015), but if something works well for a patient and/or they express a preference, an intervention may be appropriate.

Physical interventions

Massage

Cutaneous stimulation is the stimulation of the skin to relieve pain. A massage, warm bath or ice bag are simple ways to reduce pain perception. The gate control theory suggests that cutaneous stimulation works by activating larger, faster-transmitting A-beta sensory fibres. This decreases nociceptive transmission through small-diameter A-delta and C fibres by 'closing the gate' and blocking the transmission of nociceptive impulses at the spinal cord.

An advantage of cutaneous stimulation is that the measures can be used in the home, giving patients and families some control over pain and treatment. The proper use of cutaneous stimulation can reduce pain perception and help to reduce muscle tension that might otherwise increase pain.

When using cutaneous stimulation methods, it is useful to eliminate sources of environmental noise, help the patient to assume a comfortable position and explain the purpose of the therapy. Cutaneous stimulation should not be used directly on damaged skin areas (e.g. burns, bruises, skin rashes, inflammation and underlying bone fractures).

Cold and heat

Cold and heat applications may also relieve pain and promote healing. The selection of heat versus cold interventions varies with each patient's condition. For example, moist heat can help relieve the pain from a tension headache and cold applications can reduce acute pain from inflamed joints. When using any form of heat or cold application, teach the patient to avoid injury to the skin by checking the temperature and avoiding direct application of the cold or hot surface to the skin. Patients especially at risk include those with spinal cord or other neurological injury, older adults and confused patients.

TABLE 36-16 Potential complications associated with epidural analgesia and management

Complication	Description	Nursing actions
Local anaesthetic toxicity	Light-headedness, numbness of mouth and tongue, tinnitus/visual disturbances, muscular twitching, drowsiness, convulsions, coma, respiratory and cardiac arrest	Contact medical officer Turn off infusion Prepare for emergency intubation and other interventions
Hypotension	Decrease in blood pressure (BP) caused by sympathetic blockade Sustained BP < 90 mmHg (systolic)	Cease epidural infusion Contact medical officer Increase monitoring Consider fluid bolus Don't position head down
Urinary retention	Inability to pass urine	Ideal to have indwelling urinary catheter (IDC)
Post-dural-puncture headache	Epidural has punctured the dura mater causing leaking of cerebrospinal fluid (CSF) Headache better when supine	Notify medical officer Medical treatment may be a blood patch for headache
Haematoma	Increasing back pain, sensory/motor changes in lower extremities Medical emergency	Contact medical officer Medical treatment is magnetic resonance imaging (MRI) scan and decompression
Infection/abscess	Meningitis or epidural abscess Increasing back pain, sensory/motor changes May have local swelling at epidural site Medical emergency	Contact medical officer Commence neurological observations Medical treatment antibiotics and surgical decompression
Respiratory depression	Peak time for epidural morphine is 8–10 hours after the initial dose Sedation score ≥ 2 Respiratory rate < 10	Notify medical officer Prepare naloxone 400 micrograms in 4 mL Normal saline Give 100 micrograms every 2–3 minutes until respiratory rate is > 10
Epidural catheter migration	Rarely, catheter may migrate into subarachnoid space and large doses of local anaesthetics may be delivered into the CSF	Call medical officer and emergency Support vital signs Turn off infusion Monitor Give oxygen
Motor weakness	Loss of power in lower extremities May be caused by local anaesthetic concentration or serious side effects, such as abscess or haematoma	Call medical officer for any neurological deficit Increase frequency of patient monitoring
Inadequate analgesia	Pain is unrelieved	Increase infusion rate Call medical officer if problem persists
High block	Respiratory distress Upper/lower limb weakness Hypotension Sensory block at or above T4 after ice test	Contact medical officer Cease infusion Administer oxygen Intravenous fluid order Increase frequency of observations Sit patient up if appropriate
Epidural catheter disconnection	May accidentally occur due to physical tension on the catheter May be prevented by a secure catheter and filter dressing	Call medical officer

Ice massage and application of cold packs are two types of cold therapy that are particularly effective for pain relief. Ice massage involves the use of a large ice cube or a small paper cup filled with water and frozen (the water rises out of the cup as it freezes to create a smooth surface of ice for massage). The massage is simple. You or the patient can apply the ice with firm pressure to the skin, followed by a slow, steady, circular massage over the area. It takes 5–10 minutes to apply cold and each patient responds differently to the site of application that is most effective. Application near the actual site of pain tends to work best. A patient feels cold, burning and aching sensations and numbness. When numbness occurs, the ice should be removed. Cold is particularly effective for tooth or mouth pain when ice is placed on the web of the hand between the thumb and index finger. This point on the hand is an acupuncture point that apparently influences nerve pathways to the face and head. Cold applications are also effective before invasive needle punctures.

Cognitive–behavioural interventions

Relaxation and guided imagery

Patients can alter affective–motivational and cognitive–evaluative dimensions of pain perception through relaxation and guided imagery. *Relaxation* is mental and physical freedom from tension or stress. Relaxation techniques provide individuals with self-control when discomfort or pain occurs, reversing the physical and emotional stress of pain. Relaxation techniques can be used at any phase of health or illness.

Patients who use relaxation techniques successfully experience several physiological and behavioural changes (Box 36-9). Relaxation techniques include meditation, yoga, Zen, guided imagery and progressive relaxation exercises.

For effective relaxation, the individual's participation and cooperation are needed. Relaxation techniques are taught only when the patient is not in acute discomfort, because the inability to concentrate during severe pain makes the learning exercise ineffective. Explain the technique in detail and describe common sensations the patient may experience (e.g. a decrease in temperature or numbness of a body part). The patient should use these sensations as feedback.

Act as a coach, guiding the patient slowly through steps of the exercise. The environment should be free of noise or other irritating stimuli. The patient may sit in a comfortable chair or lie in bed (Box 36-10). The patient may use guided imagery and relaxation exercises together or separately.

In *guided imagery* the patient creates an image in the mind, concentrates on that image and gradually becomes less aware of pain. Coach the patient in forming the image and concentrating on the sensory experience. Initially ask the patient to think of a pleasant scene or experience that promotes the use of all the senses. Use specific information given by the patient and keep to the patient's image. The following is an example of a portion of a guided imagery exercise:

> **Imagine yourself lying on cool grass with the sound of rushing water from a nearby stream. It's a beautiful day. You turn to see a patch of yellow wildflowers in bloom and can smell their fragrance.**

Sit close enough to the patient to be heard, without being intrusive. Using a calm, soft voice helps the patient focus more completely on the suggested image. While relaxing, the patient focuses on the image, and it becomes unnecessary to speak continuously. If the patient shows signs of agitation, restlessness or discomfort, stop the exercise and begin later when the patient is more at ease. Progressive relaxation of the entire body takes about 15 minutes. The patient pays attention to the body, noting areas of tension. Tense areas are replaced with warmth

BOX 36-9 Effects of relaxation

Decreased pulse, blood pressure and respirations
Decreased oxygen consumption
Decreased muscle tension
Lowered metabolic rate
Heightened global awareness
Lack of attention to environmental stimuli
No voluntary change of position
Sense of peace and wellbeing
Deep, wakeful, restful period of alertness

BOX 36-10 Body positions for relaxation

Sitting

- Sit with entire back resting against back of chair.
- Place feet flat on floor.
- Keep legs separated.
- Hang arms at the side or rest on chair arms.
- Keep head aligned with spine.

Lying

- Keep legs separated with toes pointed slightly outwards.
- Rest arms at sides without touching sides of body.
- Keep head aligned with spine.
- Use thin, small pillow under head.

and relaxation. Some patients relax better with their eyes closed. Soft background music can help.

Progressive relaxation exercise involves a combination of controlled breathing exercises and a series of contractions and relaxation of muscle groups. The patient begins by breathing slowly and diaphragmatically, allowing the abdomen to rise slowly and the chest to expand fully. When the patient establishes a regular breathing pattern, coach the patient to locate any area of muscular tension, to think about how it feels, to tense muscles fully and then to completely relax them. This creates the sensation of removing all discomfort and stress. Gradually the patient can relax the muscles without first tensing them. When full relaxation is achieved, pain perception is lowered and anxiety about the pain experience becomes minimal. The following is an example of how you might coach a patient to use this technique:

> **Let's begin by finding as comfortable a position as possible. Arms at your side, legs uncrossed. Move until you feel at ease. Take a deep breath. Feel your stomach and chest slowly rise. Relax. Now breathe out slowly … slowly … and relax.**
>
> **Count to 4, inhaling on 1 and 2, exhaling on 3 and 4. Continue to breathe slowly. Your body is beginning to relax. Think 'relax' … feel the parts of your body. Notice any tension in your muscles. Continue to breathe slowly … and relax.**
>
> **Concentrate on your face … your jaws … your neck. Notice any tightness. Breathe in warmth and relaxation.**
>
> **Concentrate on any tension in your hands. Notice how it feels. Now make a fist, a tight fist. As you begin to exhale, relax your fist. Notice how your hand feels. Think 'relax'. Your hand feels warm … heavy or light. Just relax more … and more.**
>
> **Now focus on your forearms. Notice any tension. Relax your arms. Feel your body relaxing. Let the feelings of relaxation spread from your fingers and hands through to the muscles of your arms.**

If the patient seems to have difficulty relaxing any part of the body, slow the progression of the exercise and concentrate on the tensed body part. Let the patient know at the beginning that the exercise can be stopped at any time. With practice the patient can soon perform relaxation exercises independently.

Distraction

With meaningful sensory stimuli, a person can ignore or become unaware of pain. Pleasurable stimuli cause the release of endorphins. People who are bored or in isolation have only their pain to think about and thus perceive it more acutely. *Distraction* directs a patient's attention to something else and thus can reduce the awareness of pain and even increase tolerance. Distraction may work best for short, intense pain lasting a few minutes, such as during an invasive procedure or while waiting for an analgesic to work.

Identify activities enjoyed by the patient that may act as distractions. These might include listening to music and playing games. Most distractions can be used in a hospital, home or residential aged care facility.

One effective distraction is *music*, which decreases pain, stress and anxiety by diverting the person's attention and creating a relaxation response. You can use music creatively in many clinical situations. Music that initially matches a person's mood is usually best. Classical, popular and non-traditional music (music with no vocals, periods of silence) is used in music therapy. Popular music does not usually produce a deep level of relaxation because it is short with a steady beat and words. In an acute care setting, listening to music has been shown to provide a small reduction in postoperative pain and opioid requirement (Schug et al 2015). Some considerations when using music for pain relief are presented in Box 36-11.

EVALUATING IMPACTS AND OUTCOMES

The essential message about pain assessment and management is easy to summarise: Ask patients about their pain; accept and respect what they say; take action to relieve pain according to their pain management goals; and, after actions have been put in place, ask them again about their pain to determine the outcomes of care. It is a circle of assessment, intervention and reassessment (McCaffery et al 2011).

The patient is the best judge of whether a pain intervention is effective. Therefore, communicating with the patient is the most effective way to determine the outcomes of care. Evaluation criteria are formulated based on the type of pain, the intervention, the timing of the interventions, the nature of the injury or disease and the patient's previous responses. If a patient continues to have discomfort after an intervention, it may be necessary to try a different approach. For example, if an

BOX 36-11 Using music to control pain

- Match musical selections to the patient's taste. Consider age and background.
- Use earphones to avoid annoying other patients or staff and help patient to concentrate on music.
- Have family members bring music from home.
- If pain is acute, increase the volume of the music. As pain decreases, reduce the volume.
- If background music is provided, select general types suited to the patient's preferences.
- Have the patient concentrate on the music and emphasise rhythm by tapping fingers or patting the thigh.
- Avoid interruptions by dimming lights and closing the curtains or door.
- Leave patients alone as they listen to the music.

analgesic provides only partial relief, you might add relaxation exercises or guided-imagery exercises. It may be useful to consult with the medical or nurse practitioner about increasing the dosage, decreasing the interval between doses or trying different analgesics or adjuvant drugs. Communicating with the patient is the most effective form of evaluation. The patient's perceptions of the effectiveness of interventions should guide their use. The patient may help decide the best times to attempt a treatment. In essence, the patient is the best judge of whether an intervention works.

Effective communication of a patient's assessment of pain and their response to intervention is facilitated by accurate and thorough documentation. This information must be communicated from nurse to nurse, shift to shift and from nurses to other healthcare providers. It is your professional responsibility to report what has been effective for managing a patient's pain.

Key concepts

- Pain is whatever the experiencing person says it is, existing whenever he or she says it does.
- Working from a biopsychosocial, patient-centred perspective means taking the time to understand the physical, psychological and social dimensions of pain from the patient's perspective and tailoring treatment based on their individual needs and priorities.
- Normal pain processing involves four key processes: (1) transduction, the conversion of noxious stimuli into nerve impulses; (2) transmission, the conduction of nerve impulses from the periphery to the spinal cord and then to the brain; (3) perception, the process by which pain becomes a conscious experience; and (4) modulation, the process by which the brain dampens or facilitates ascending pain impulses.
- Key psychosocial factors shaping the acute pain experience include fear, anxiety and depression, perceived control over pain, pain catastrophising, and perceived social support.
- While nurses sometimes may not *believe* what the patient says about their pain, they have an ethical and professional responsibility to *accept* and act on it.
- Routinely perform and document pain assessment including pain intensity, quality, onset and duration, location, aggravating and relieving factors, associated symptoms, and the impact of pain on functioning.
- Assess acute postoperative pain intensity both *at rest* and *on movement* (e.g. sitting, coughing, moving the affected part) to determine whether pain control is adequate for recovery.
- Analgesia is the cornerstone of acute pain management, so RNs need to develop a working knowledge of the pharmacology of the three major groups of analgesics: (1) non-opioids, (2) opioids, and (3) adjuvants.
- Multimodal analgesia is the recommended approach for successfully managing all types of pain. Multimodal analgesia combines different drugs with different underlying mechanisms of action to produce more effective pain relief with fewer adverse effects.
- The nursing role is critical for patient safety including assessing pain, administering treatment, monitoring for side effects, and teaching patients and caregivers.
- You can initiate and support patients to use appropriate non-drug therapies in conjunction with analgesia to increase the overall effectiveness of therapy and enhance patient coping and perceived control over pain.

Managing stress and adaptation

Patricia Barkway

Learning outcomes

Mastery of content will enable you to:

- discuss the limitations of homeostatic control
- compare four models of stress as they relate to nursing practice
- describe how adaptation occurs in each of the six dimensions of a person's functioning
- describe two forms of physiological adaptation
- describe the three phases of the general adaptation syndrome
- list and discuss behaviours that are responses to stress
- list and discuss the most common ego-defence mechanisms that are responses to stress
- discuss the effects of prolonged stress on each of the six dimensions of a person's functioning
- describe stress-management techniques that nurses can use and help clients to use
- discuss techniques of crisis intervention.

KEY TERMS

Adaptation, p. 1365
Burnout, p. 1384

Severe stress situations, p. 1375
Situational crisis, p. 1382
Stress, p. 1365
Stressors, p. 1365
Task-oriented behaviours, p. 1372

Every person experiences some stress throughout life. Stress can provide the stimulus for change and growth. Some stress is positive and even necessary (Moskowitz et al 2012). However, too much stress can result in poor judgement, physical illness and inability to cope (Folkman 2008). Several studies have proposed a relationship between stressful life events and a wide variety of physical and psychiatric disorders (Koutentaki et al 2014, Papadiamantopoulou et al 2010).

Claude Bernard, in 1867, was one of the first physiologists to recognise the consequences of stress. He proposed that changes in the internal and external environments disrupted the functioning of an organism and that it was essential for an organism to adapt to a stressor to survive. In 1920, Walter Cannon studied physiological responses to emotional arousal and emphasised the adaptive functions of the 'fight-or-flight' reaction. Cannon also noted that these responses were the result of the influence of the emotional state on the body and that the subsequent responses were adaptive and physiological (Cannon 1932).

Hans Selye (1946) developed a biochemical model of stress known as the **general adaptation syndrome (GAS)**, which described physiological events during a stress response. Selye also introduced the concept of stressors, which are internal or external stimuli that cause stress (Selye 1976a, 1976b). Selye's classic research into stress and stressors has contributed important knowledge for healthcare professionals, and current research in many disciplines focuses on a variety of stress and stress-related concepts.

Subsequently, research in this area has not only focused on identifying and understanding stress and stressors, but also on how individuals cope with and adapt to stress. Lazarus and Folkman (1984) described stress as a transaction between the individual and the environment, in which the individual makes a cognitive assessment as to whether an event is stressful or not, and whether or not they have the resources to manage or cope with the stressor. Unlike earlier stress research which focused on negative emotions and outcomes, Folkman emphasises the co-occurrence of positive and negative emotions and experiences during stressful times (Folkman 2008, Moskowitz et al 2012).

Stress and stressors

Everyone experiences stress from time to time and normally a person is able to adapt to long-term stress, or cope with short-term stress until it passes. Nevertheless, stress can place heavy demands on a person and if the person is unable to adapt, illness can result.

Stress is any situation in which a non-specific demand requires an individual to respond or take action (Selye 1976b). Stress involves both physiological and psychological responses and can lead to negative thoughts, feelings and behaviours that may threaten emotional and physical wellbeing. Stress can threaten the way a person normally perceives reality, solves problems and thinks in general. Stress can threaten a person's relationships and sense of belonging and lead to coping or maladaptive behaviour. Stress can also threaten a person's general outlook on life and health status.

A person's perception or experience of a major change may initiate the stress response. The stimuli preceding or precipitating the change are called stressors. **Stressors** represent an unmet need and may be physiological, psychological, social, environmental, developmental, spiritual or cultural. Stressors can be classified as internal or external. **Internal stressors** originate inside a person (e.g. having a fever, living with a chronic illness, experiencing an emotion such as guilt). **External stressors** originate outside a person (e.g. a marked change in environmental temperature, a change in family or social role, peer pressure, loss).

Physiological adaptation

Physiological adaptation to stress is the body's ability to maintain a state of relative balance. This adaptive ability is a dynamic form of equilibrium in the body's internal environment. The internal environment constantly changes, and the body's adaptive mechanisms continually function to adjust to these changes and maintain equilibrium, or homeostasis.

Homeostasis is maintained by physiological mechanisms that control body functions and monitor body organs. For the most part, these mechanisms are controlled by the nervous and endocrine systems and do not involve conscious behaviour. The body makes adjustments in heart rate, respiratory rate, blood pressure, temperature, fluid and electrolyte balances, hormone secretions and level of consciousness – all directed at maintaining **adaptation**.

Mechanisms of physiological adaptation

When a person becomes aware of an unmet physiological need, such as hunger or cold, deliberate actions (such as eating or putting on more clothes) can meet the need. For the most part, however, adaptation involves adjustments that the body makes automatically to maintain equilibrium. These homeostatic mechanisms are self-regulatory; in other words, they are automatic. In a person with an

illness or injury, however, the mechanisms may not be able to maintain and sustain homeostasis.

Physiological mechanisms of adaptation function through *negative feedback*, a process by which the controlling mechanism senses an abnormal state, such as lowered body temperature, and makes an adaptive response, such as initiating shivering to generate body heat. Three of the major control mechanisms used in adapting to a stressor are the medulla oblongata, the reticular formation and the pituitary gland.

Medulla oblongata

The **medulla oblongata** controls vital functions necessary for survival, including heart rate, blood pressure and respiration. Impulses travelling to and from the medulla oblongata can increase or decrease these vital functions. For example, regulation of the heartbeat is the result of sympathetic or parasympathetic nervous system impulses travelling from the medulla oblongata to the heart. The heart rate increases in response to impulses from sympathetic fibres and decreases with impulses from parasympathetic fibres.

Reticular formation

The **reticular formation** is a small cluster of neurons in the brainstem and spinal cord. In addition to adapting to stress, the reticular formation also controls vital functions and continuously monitors the physiological status of the body through connections with sensory and motor tracts. For example, certain cells within the reticular formation can cause a sleeping person to regain consciousness or increase the level of consciousness when a need arises.

Pituitary gland

The **pituitary gland**, a small gland attached to the hypothalamus, supplies hormones that control vital functions. It produces hormones necessary for adaptation to stress, and regulates the secretion of thyroid, gonadal and parathyroid hormones. Hormone secretion, like other homeostatic mechanisms, is normally regulated by a feedback mechanism that continuously monitors hormone levels in the blood. When hormone levels drop, the pituitary gland receives a message to increase hormone secretion. When hormone levels rise, the pituitary gland decreases hormone production.

Limitations of physiological mechanisms of adaptation

Physiological mechanisms of adaptation work together through complex relationships in the nervous, endocrine and other body systems to maintain a relative constancy within the body (homeostasis). In a healthy person, these mechanisms affect physiological balance and the body's day-to-day needs are met. However, physiological mechanisms of adaptation can provide only short-term control over the body's equilibrium. They cannot adapt to long-term changes in hormone secretion or vital functions. Therefore illness, injury or prolonged stress can decrease the body's adaptive capacity. Decreased functioning can result in continued but inadequate homeostatic control, or breakdown of the feedback mechanism that allows control. Either form of decreased function can result in further illness or death.

In severe stress situations, for example, the pituitary gland supplies the body with the necessary hormones for adaptation. However, these hormones may be insufficient in quantity to provide the physiological requirements necessary for coping. In such a case, the person's condition deteriorates and functioning declines.

Models of stress

The origins and effects of stress can be examined in terms of biomedical and cognitive-behavioural theoretical models. Stress models are used to identify the stressors for a particular individual and to predict that person's responses to them. Each model emphasises a different aspect of stress. Understanding stress models will enable you as a nurse to assist clients to cope with excessive stressors and to recognise and manage their possible unhealthy or non-productive responses to stressors. Stress models can therefore inform the delivery of individualised and person-centred nursing care.

Response-based model

The response-based model is concerned with specifying the particular response or pattern of responses to a stressor. Walter Cannon was a physiologist and an early stress researcher who first described the **fight-or-flight response** (a primitive inborn protective mechanism to defend the organism against harm). This is a physical reaction by an organism (including humans) to a perceived threat (Cannon 1932). Cannon observed that the organism's endocrine and sympathetic nervous systems were aroused when threatened – leading to the release of catecholamines by the adrenal gland (particularly adrenaline and noradrenaline). Hormones (aldosterone and cortisol) and neurotransmitters (dopamine and seratonin) also influence the organism's response (Figure 37.1). This prepares the organism to respond to the anticipated danger by either reacting with aggression (*fight*) or by escaping (*flight*).

The fight-or-flight response is adaptive when arousal enables the individual to take immediate action – to either

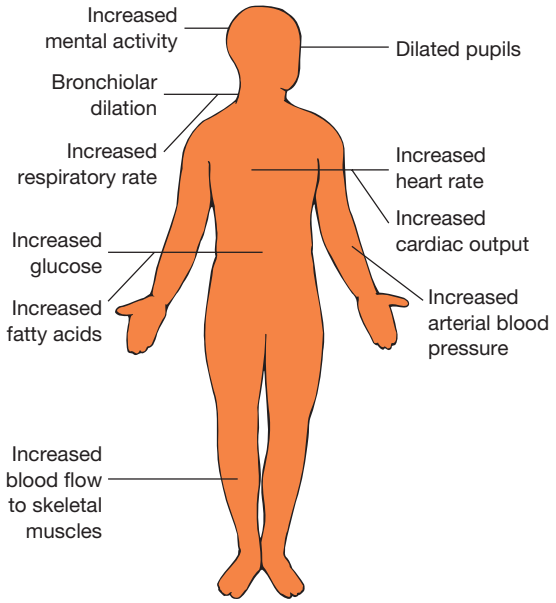

Figure 37-1 **Fight-or-flight response.**

confront or escape the threat (see Figure 37-1). However, prolonged, unrelenting arousal, for which adaptation does not occur, is potentially harmful and can lead to long-term health consequences. For example, for the client who lives in a domestic violence situation, neither fight nor flight is an adaptive response because a longer-term solution is required.

Selye's (1976a) model defines stress as a non-specific response of the body to any demand made upon it. Stress is demonstrated by a specific physiological reaction of the whole body, involving the autonomic nervous system and the endocrine system. The response of a person to stress is therefore considered purely physiological by this model, and not influenced by cognitive processes (Selye 1976a).

A limitation of the response-based model is that it does not consider individual differences in response patterns. For instance, one individual may see the same stressor, such as starting a new job, as a welcome challenge while another may perceive it as a threat (Barkway 2013).

Adaptation model

The adaptation model is based on the understanding that people experience anxiety and increased stress when they are unprepared to cope with stressful situations.

The adaptation model proposes that four factors determine whether a situation is stressful (McAlpine & Mechanic 2010, Mechanic 1962). The ability to cope with stress, the first factor, usually depends on the person's experience with similar stressors, support network and overall perception of the stressor. The second factor deals with the practices and norms of the person's peer group. If the peer group considers it normal to talk about a particular stressor, the client may respond by complaining about it or discussing it. This response may help with adaptation to the stress, or the client may respond in this way simply to conform to peer group behaviour. The third factor is the impact of the social environment in helping a person to adapt to a stressor. For example, a homeless woman may seek assistance by attending an emergency department for an acute pelvic infection. The woman may be assessed and antibiotic therapy instituted. The ED and the healthcare professionals involved are resources for the client to reduce the severity of a stressor. The last factor involves the resources that can be used to deal with the stressor. In this case, the client needs transport to the hospital and financial arrangements that will provide for her care. Both these factors will influence how she can access the resources within the hospital to help her cope with the physiological stressor.

Stimulus-based model

The stimulus-based model focuses on disturbing or disruptive events within the environment. The seminal research of Holmes and Rahe (1967) identified stress as a stimulus and resulted in the eventual development of the Social Readjustment Rating Scale, which measures the effects of major life events on illness. Alternatively, the stimulus may be an accumulation of minor life events or hassles, as described by Kanner and colleagues (1981) in a study that compared the stress from daily hassles and 'uplifts', with stress produced by major life events. In another study of 110 Swiss couples, Falconier and collegues (2014) found that the stress from daily hassles had a negative impact on the individual's psychological and physical health as well as the couple's relationship. However, as with the response-based model, the stimulus-based model does not allow for individual differences in perception and response to stressors.

Transaction-based model

The transaction-based (process) model was first proposed by Lazarus and Folkman (1984). This model views the person and environment as being in a dynamic, reciprocal, interactive relationship. The person's reaction to a stressor is viewed as an individual perceptual response (cognitive appraisal) rooted in psychological and cognitive processes. Distress is experienced when the person perceives an imbalance between demands and resources. The individual's appraisal is influenced by personal factors such as beliefs, perception of control and uncertainty.

This model focuses on stress-related processes, such as cognitive appraisal and coping (Folkman 2008, Moskowitz

et al 2012). Stress originates from the relationship between the person and the environment. Distress is experienced when the person perceives that the stressor exceeds the resources available to respond to the stressor. Alternatively, coping occurs when the person perceives that their resources are sufficient to deal with the stressor.

Factors influencing response to stressors

The response to any stressor depends on physiological functioning, personality and behavioural characteristics, as well as the nature of the stressor (Box 37-1). Each factor influences the response to a stressor. A person may perceive the intensity or magnitude of a stressor as *minimal*, *moderate* or *severe* – the greater the magnitude of the stressor, the greater the stress response. Similarly, the scope of a stressor can be described as *limited*, *medium* or *extensive* – the greater the scope of a stressor, the greater the response of the client to it (Lazarus & Folkman 1984).

Adaptation to stressors

Adaptation is the process by which the physiological or psychosocial dimensions change in response to stress. There are many forms of adaptation. Physiological adaptations make physiological homeostasis possible. A similar process of adaptation, however, may occur in the psychosocial and other dimensions. For example, health promotion activities can focus on a person, a family or a community's adaptation to stress.

Adaptation is an attempt to maintain optimal functioning. Adaptation involves *reflexes*, automatic body mechanisms for protection, and coping mechanisms. Ideally, adaptation can lead to adjustment or mastery of a situation (Selye 1976a). A stressor that stimulates adaptation may be short term, such as a fever, or long term, such as paralysis of a limb. To function optimally, a person must be able to respond to such stressors and adapt to the required demands or changes. Adaptation requires an active response from the whole person.

Similar to an individual's response, a whole family or group may need to adapt to a stressor. *Family adaptation* is the process by which a family maintains balance so that it can fulfil its purposes and tasks, deal with stress and promote the growth of individual members. In a study investigating the functioning of families in which one partner was employed in the fly-in fly-out (FIFO) workforce (where workers are flown into an often remote employment site for a number of days before returning to their family for a rest period), effective communication skills, cohesive relationships and an ability to be flexible with change and access to community resources were found to be predictive of family coping (Taylor & Simmonds 2009).

• CRITICAL REFLECTION POINT

Sarah Jenkins, who is 10 weeks pregnant, presented with vaginal bleeding and abdominal pain to emergency department of the hospital where you work. Her partner Neil accompanied her. Their baby was conceived following three unsuccessful in-vitro fertilisation treatments.

1. **Identify potential stressors for Sarah.**
2. **Identify potential stressors for Neil.**

Dimensions of adaptation

Stress can affect the physical, psychological/emotional, developmental, intellectual, social and spiritual dimensions of a person. Adaptive resources exist in each of these dimensions. Therefore, when assessing a client's adaptation to stress, it is important to consider the whole person. Table 37-1 highlights adaptive resources found in each dimension and gives examples of positive and negative outcomes of stressors.

Response to stress

The whole person is involved in responding and adapting to stress. However, most research into stress responses focuses on single psychological, emotional or physiological responses. In reality, these dimensions not only overlap but also interact with other dimensions.

When stress occurs, a person uses physiological and psychological energy to respond and adapt. The amount of energy required and the effectiveness of the attempt to adapt depends on the intensity, scope and duration of the stressor and the number of other stressors occurring at the same time. The stress response is adaptive and protective,

TABLE 37-1 Dimensions of adaptation

Dimension	Adaptive resources	Example of stressor	Example of unsuccessful outcome	Example of successful outcome
Developmental	Successful coping in past development task/stages Successful adaptation to past stressors	Retirement	Depression	Role functions altered to other meaningful activities
Emotional	Psychological defence mechanisms Individual personality strengths	Rape	Irrational fear of men	Integration of traumatic memory Serves as advocate for others at rape crisis centre
Intellectual	Formal education Ability to problem-solve Communication skills Realistic perception of stressor Conscious mobilisation of past positive coping strategies	Diagnosis of cancer	Denies presence of cancer and forgoes any treatment	Uses an active problem-solving approach to make decisions about care
Physical	Local adaptation syndrome General adaptation syndrome	Fever	Death	Infection resolved
Social	Social network that provides support Others who may direct person to needed resources	Family member using heroin	Person with the drug problem withdrawing from family and other social contacts	Active participation of all family members in Narcotics Anonymous support groups
Spiritual	Prayer groups; support from spiritual adviser	Ill family member feeling abandoned by God	Withdraws from attending church, won't talk with church members or minister	Begins to seek out friends in the church, volunteers for church-related activities

and the characteristics of this response are the result of integrated neuroendocrine responses (Box 37-2).

As a nurse you are constantly challenged by a variety of stress responses when providing care to clients and in managing your own stress responses. In delivering care, the physiological underpinnings, psychological issues, developmental and intellectual factors and the person's social and spiritual world need to be considered.

Physiological response

In his seminal research, Selye (1946, 1976a, 1976b) identified two physiological responses to stress: the **local adaptation syndrome (LAS)** and the general adaptation syndrome (GAS). The LAS is the response of a body tissue, organ or part to the stress of trauma, illness or other physiological change. The GAS is a defence response of the whole body to stress.

Local adaptation syndrome

The body produces many localised responses to stress. These include blood clotting, wound healing, accommoda-

BOX 37-2 Characteristics of the stress response

- Stress response is natural, protective and adaptive.
- There are normal responses to stressors; stressors encountered in everyday circumstances increase catecholamine excretion, which causes an increase in heart rate and blood pressure.
- Physical and emotional stressors trigger similar responses; magnitude and patterns may differ.
- There are limits in ability to compensate.
- Magnitude and duration of stressors may be so great that homeostatic mechanisms for adjustment fail, leading to health problems and in extreme cases death.
- Repeated exposure to stimuli results in adaptive changes; that is, tissue levels of the enzyme tyrosine hydrolase increase, which increases capacity for the body to produce adrenaline and noradrenaline.
- There are individual differences in response to same stressors.

Modified from Carrieri-Kohlman V, Lindsey AM, West CM 2003 Pathophysiological phenomena in nursing: human response to illness, 3rd edn. Saunders, St Louis.

tion of the eye to light, and response to pressure. All forms of the LAS share the following characteristics:

- the response is *localised*; it does not involve entire body systems
- the response is *adaptive*, meaning that a stressor is necessary to stimulate it
- the response is *short term*; it does not persist indefinitely
- the response is *restorative*, meaning that the LAS helps restore homeostasis to the body region or part.

Two localised responses, the reflex pain response and the inflammatory response, are described here as examples of the LAS. As a nurse you will encounter these responses frequently.

Reflex pain response

The reflex pain response is a localised response of the central nervous system to pain (see Chapter 36). This is an adaptive response to protecting tissue from further damage. The reflex pain response involves a sensory receptor, a sensory nerve to the spinal cord, a connector neuron within the spinal cord, a motor nerve from the spinal cord and an effector muscle. Examples of reflex pain responses are the unconscious, reflex removal of the hand from a hot surface, and a muscle cramp.

Inflammatory response

The inflammatory response is stimulated by trauma or infection. This response localises the inflammation, thereby preventing its spread, and promotes healing. The inflammatory response may produce localised pain, swelling, heat, redness and changes in functioning. The inflammatory response occurs in three phases:

1. The first phase involves changes in cells and the circulatory system. Initially, narrowing of blood vessels occurs at the injury to control bleeding. Then histamine is released at the injury, increasing blood flow to the area and increasing the number of white blood cells to combat infection. Almost simultaneously, kinins are released to increase capillary permeability to permit the flow of proteins, fluid and leucocytes to the injury. At this point the localised blood flow decreases, keeping leucocytes in the area to fight infection.
2. The second phase is characterised by release of exudate from the wound. Exudate is a combination of fluid, cells and other substances produced in the area of injury, which may be a cut, laceration or surgical incision. The type and amount of exudate vary from injury to injury and from person to person.
3. The last phase is repair of tissue by regeneration or scar formation. Regeneration replaces damaged cells with identical or similar cells. Scar formation replaces original tissue that is not functional.

The inflammatory response indicates that the body is adapting to a local injury. During adaptation, the inflammatory response protects the body from infection and promotes healing.

General adaptation syndrome

The GAS is a physiological response of the whole body to stress. It involves several body systems, mainly the autonomic nervous system and the endocrine system. Some texts refer to the GAS as the *neuroendocrine response*. The GAS consists of the alarm reaction, the resistance stage and the exhaustion stage (Figure 37-2).

Alarm reaction

The alarm reaction involves the mobilisation of the defence mechanisms of the body to cope with the stressor. Hormone levels rise to increase blood volume and thereby prepare the person to act. Cortisol is released to increase blood glucose levels to make energy available for adaptation. Increased levels of other hormones – adrenaline and noradrenaline – result in an increased heart rate, increased blood flow to muscles, increased oxygen intake and greater mental alertness.

This extensive hormonal activity prepares the person for the fight-or-flight response. Cardiac output, oxygen intake and respiratory rate increase; the pupils of the eyes dilate to produce a greater visual field; and the heart rate increases for more energy. Other changes occur to prepare the person to act (Figure 37-1). With this increased mental energy and alertness, the person is prepared to fight or flee the stressor.

During the alarm reaction, the person is faced with a specific stressor. The person's physiological response is extensive, involving major systems of the body, and may last from a minute to many hours. If the stressor is extreme or remains for a long time, there may be a threat to life. If the stressor is still present after the initial alarm reaction, the person progresses to the second (resistance) phase of the GAS.

Resistance stage

In the resistance stage the body stabilises and hormone levels, heart rate, blood pressure and cardiac output return to normal – the person is attempting to adapt to the stressor. If the stress can be resolved, the body repairs any damage that may have occurred and homeostasis is regained. However, if the stressor remains present, as in

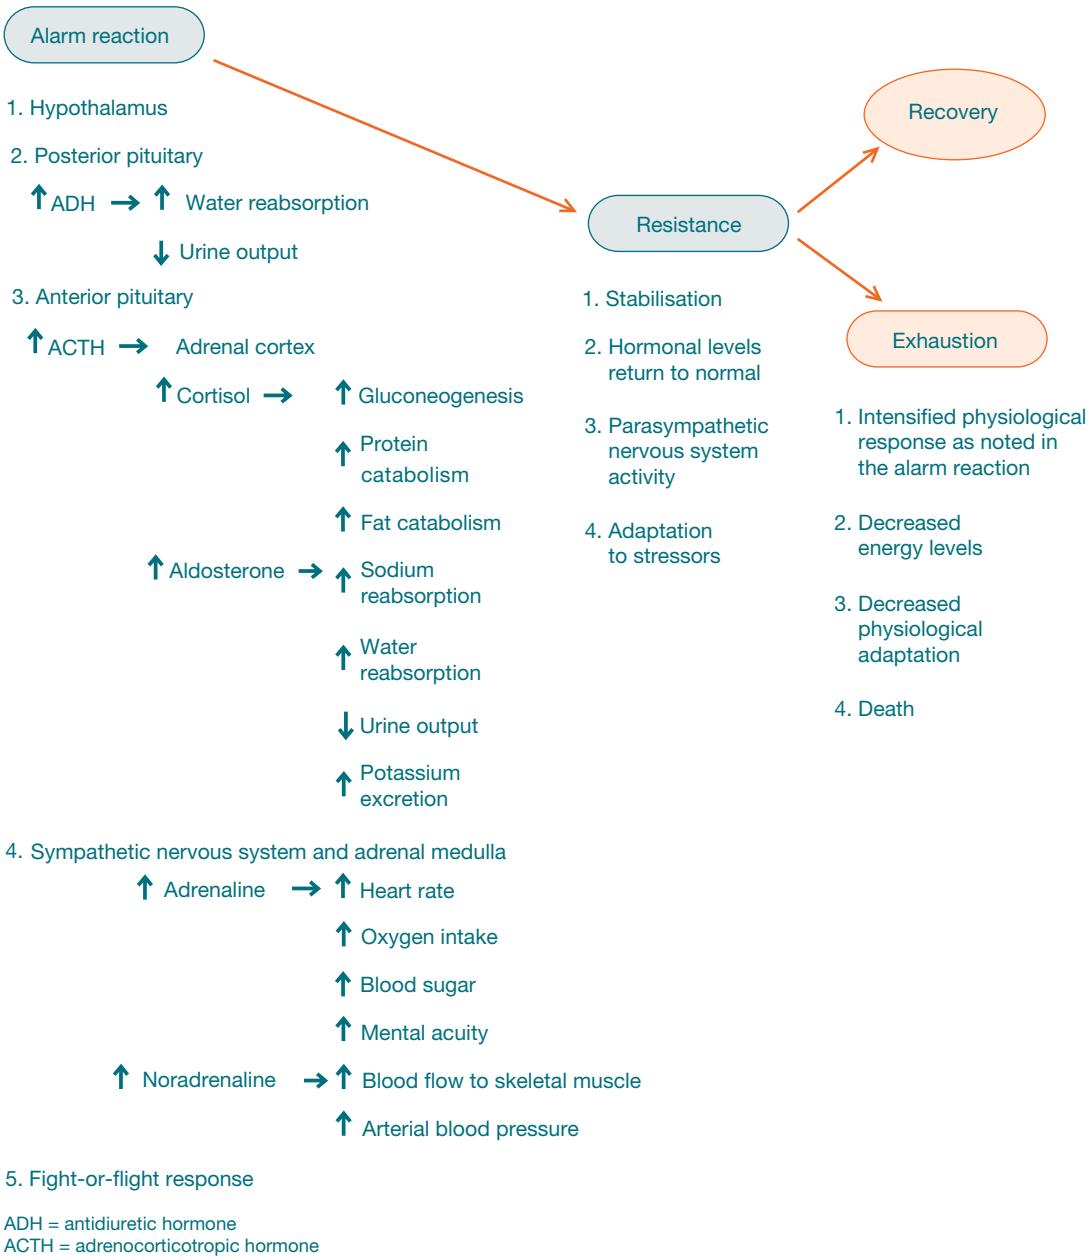

Figure 37-2 **General adaptation syndrome.**

examples of continued blood loss, debilitating disease, or ongoing severe mental illness, adaptation fails and the person enters the third (exhaustion) phase of the GAS.

Exhaustion stage

The exhaustion stage occurs when the body can no longer resist stress and when the energy necessary to maintain adaptation is depleted. The physiological response is intensified, but the person's energy level is compromised and adaptation to the stressor diminishes. The body is unable to defend itself against the impact of the stressor, physiological regulation diminishes and, if the stress continues, illness or even death may result.

• CRITICAL REFLECTION POINT

John Morgan, aged 52 years, who has no family history of heart disease, had a myocardial infarction 3 days ago, and has just been transferred from the coronary care unit to the medical ward where you work.

1. **What risk assessments do you undertake?**
2. **What questions will you ask John to identify his stressors?**
3. **What lifestyle issues need to be assessed?**

Psychological response

Psychological adaptive behaviours influence how a person copes with stress. These behaviours are directed at stress management and are acquired through learning and experience as a person identifies acceptable and successful behaviours throughout the life span.

Psychological adaptive behaviours can be constructive or harmful. *Constructive behaviours* help a person accept the challenge to resolve conflict. Even anxiety can be constructive; it can signal that a threat is present so that a person can take measures to reduce the impact of the threat, for example, the person who is worried about frequent headaches and consults his or her GP to have the headaches investigated. *Harmful behaviours*, on the other hand, do not help a person cope with a stressor. Harmful behaviours affect reality orientation, problem-solving abilities, personality and, in severe circumstances, the ability to function. The use of alcohol or drugs, for example, may alleviate immediate distress, but in the longer term hamper a person's ability to deal with stress.

Psychological adaptive behaviours are also referred to as *coping mechanisms*. Such mechanisms can be problem-focused, involving the use of direct problem-solving techniques to cope with threats; or emotion-focused, involving the use of strategies to manage one's emotional response to the stressor.

Problem-focused coping behaviours involve using cognitive abilities to reduce stress, solve problems and resolve conflicts. **Task-oriented behaviours** enable a person to cope realistically with the demands of a stressor. The three general types of task-oriented behaviour are attack behaviour, withdrawal behaviour and compromise (Box 37-3).

Emotion-focused coping behaviours can be intentional, for example, seeking support from friends; or they may involve the use of unconscious processes like ego-defence mechanisms – the purpose of which is to regulate emotional distress and give a person protection from anxiety and stress. **Ego-defence mechanisms**, first described by Sigmund Freud and later elaborated on by his daughter Anna (Freud 1966), are unconscious behaviours that offer psychological protection from a stressful event. They are used by everyone and help protect against feelings of distress and anxiety. Occasionally, a defence mechanism can become distorted and is no longer able to help the person adapt to a stressor. There are many ego-defence mechanisms (Box 37-3). They are often activated by short-term stressors and do not usually result in psychiatric disorders.

BOX 37-3 Psychological adaptive behaviours

Task-oriented behaviours (problem-focused)

- *Taking action* to remove or overcome a stressor or to satisfy a need.
- *Withdrawal behaviour* is removing the self physically or emotionally from the stressor.
- *Compromise behaviour* is changing the usual method of operating, substituting goals or omitting the satisfaction of needs to meet other needs or to avoid stress.

Examples of ego-defence mechanisms (emotion-focused)

- *Compensation* is making up for a deficiency in one aspect of self-image by strongly emphasising a feature considered an asset.
- *Conversion* is unconsciously repressing an anxiety-producing emotional conflict and transforming it into physical symptoms.
- *Denial* is avoiding emotional conflicts by refusing to consciously acknowledge anything that might cause intolerable emotional pain.
- *Displacement* is transferring emotions, ideas or wishes from a stressful situation to a less-anxiety-producing substitute.
- *Identification* is patterning behaviour after that of another person and assuming that person's qualities, characteristics and actions.
- *Regression* is coping with a stressor through actions and behaviours associated with an earlier developmental period.

Psychological/emotional reactions

Individual personality involves a complex relationship between many factors. The emotional reaction to prolonged stress is determined by examining the person's current lifestyle and stressors, previous experience with stressors, past successful coping mechanisms, role functions, self-concept and hardiness. **Hardiness** is a combination of three personality characteristics thought to militate against stress – sense of control over life events, commitment to meaningful activities, and anticipation of challenge as an opportunity for growth. Hardy individuals adapt more readily to stress because of the more positive ways they appraise stressful situations and utilise more effective coping responses (Cash & Gardner 2011).

Developmental factors

Prolonged stress can affect a person's ability to complete developmental tasks. In any developmental stage, a person normally encounters tasks and engages in

behaviours characteristic of the stage (Santrock 2014) (see Chapters 16–18). In extreme forms, repeated stress can lead to maturational crisis. For example, if parents or the environment prevent a young child from developing a sense of autonomy (see Chapter 16), the child may experience stress, which is indicated by excessive dependence on others or passive inactive behaviour (Erikson 1963).

Intellectual factors

Studies have shown that repeated stress can have consequences for brain function, including learning and memory processes (Schwabe et al 2012). A person's ability to acquire new knowledge or skills may also be impaired by stress. This is especially important information for nurses who are involved daily in the delivery of nursing care, and are partners in health decisions and health education. The person may not be able to learn new skills about an illness process, or its management, until prolonged stressors have been resolved or alternative forms of coping have been found. It may be necessary to provide information to the person on repeated occasions and in writing so that they can refer to it later if necessary.

Social determinants

The social determinants of health include the physical environment, family, lifestyle, and cultural and political issues. The word 'family' means different things to different people (see Chapter 15) and family is not necessarily static. In Western cultures, single parent families, same gender parent families, blended families and families with alternative patterns of relationships now exist alongside the nuclear family model that predominated during the 1950s. In non-Western cultures, family is viewed as extending beyond the parent/child dyad to also include grandparents, aunts, uncles and cousins.

Each individual has their own perception of the role and importance of family. Western cultures have an individualistic perspective, and attribute the responsibility of health, for example, to the individual. Collective cultures, on the other hand, emphasise the role that family and community play in the health of group members (Sawrikar & Katz 2008). New Zealand Māori, for example, believe that health is influenced by four domains: mind, spirit, family (extended) and the physical world (Ministry of Health 2015). It is therefore important to be cautious when applying theories about stress and health which are derived from Western cultures to people from collectivist societies, such as Australian Aboriginal or Torres Strait Islander people, New Zealand Māori and immigrants and refugees from collectivist cultures.

The family unit itself can be a cause of stress. Single parents can face the burden of caring for children on their own while working and running a home. Teenage parents, single parents and same-sex couples with children may face the added stress of discrimination. Economic concerns, homelessness, violence and illness are all factors that can increase stress within a family. Poor communication habits and maladaptive behaviours among family members can create crises within a family structure and limit capacity for adaptation (World Health Organization 2008).

Lifestyle decisions can also be important factors that influence stress. A father may know that smoking can lead to cardiovascular disease or cancer. However, he may continue to smoke because it helps him cope with an unsatisfactory job situation. His children may then ask him to stop smoking. If he is unable or unwilling to quit, he may feel like a failure, thereby precipitating more stress. If he is successful at quitting smoking, he may then feel positive about himself and replace smoking with a daily exercise regimen. His children may also feel affirmed because their father listened to their concerns.

Each social and cultural group has its own views regarding stress. Education, poverty, spirituality, support systems and accepted coping mechanisms all influence these beliefs. Social instability can also play a role in stress and adaptation. For example, the impact of colonisation on Indigenous populations (see Chapter 14) has imposed considerable stress resulting in significantly poorer health outcomes, both physically and mentally (Central Australian Aboriginal Congress 2011, Ministry of Health 2011).

Spiritual considerations

Spirituality begins early in life and is influenced by culture, beliefs and life experiences (see Chapters 14 and 22). Just as the concept of family is unique to each person, spirituality is also highly individual. While the concepts of religion and spirituality are often used interchangeably, they are not the same. Religion is a system of organised beliefs, emotions and worship (Cochran 2014). Spirituality is a human experience, which demonstrates a unique capacity for love, joy, caring, compassion and for finding meaning in life's difficult experiences (Emmons 2005).

During times of stress, some clients may rely on their faith, whereas others may abandon their religious practices out of disillusionment and anger. Although spirituality can be a difficult subject for nurses to approach, it is an essential part of the person's health and wellbeing.

CLINICAL REASONING PROCESS

Successful clinical reasoning and critical reflection requires a synthesis of professional knowledge and experience, information and data gathered from clients and their family, and professional standards for practice informing decisions.

Clinical judgements require you to anticipate or access the required information, analyse the data and make decisions regarding care. During assessment of a patient or client (Figure 37-3) you will consider all elements that build towards making a relevant assessment in order to prioritise, plan and evaluate appropriate nursing care.

In the case of stress and adaptation, it is important to integrate the knowledge and research of many disciplines, the client's previous experiences, and information gathered from clients, to understand stress and its impact on the person and their family or community. In addition, the use of critical thinking and perseverance are needed to form a plan of care to provide appropriate stress management. To fully understand how stress has affected the client, complete and accurate data collection is required. Physical, emotional, social, cultural and developmental state information are all part of the assessment, using a broad knowledge base to ensure that the person's needs are accurately identified.

GATHERING RELEVANT INFORMATION AND DATA

Nurses care for individuals in various settings and are able to assess reactions to stress. The nursing assessment is directed towards gathering relevant information and data on indicators of stress (and coping) in all dimensions of adaptation, and facilitating the synthesis of that information (Figure 37-3). Your knowledge, experience and attitudes are especially important during the assessment phase as each individual has their own unique perceptions and responses to stress. This presents a complex picture influenced by beliefs and norms, life experiences and patterns, environmental factors, family structure and function, developmental stage, past experiences with stress, and coping mechanisms. Because nurses spend a great deal of time with clients and their families or friends, they are well positioned to critically analyse coping responses and to recommend professional counselling when indicated. The identification of stress-response behaviours, both verbal and non-verbal, is part of nursing assessment.

Physiological indicators

Physiological indicators of stress are objective and are therefore more readily identifiable, observable and measurable (Box 37-4). However, physiological indicators are not always present in all people experiencing stress, and can vary among individuals. Vital signs (pulse, respirations, blood pressure) are usually elevated during stress, and the person may appear restless and unable to concentrate. These indicators can appear at any stage of the stress response.

The duration and intensity of stress symptoms are directly related to the perceived duration and intensity of the stressor. Physiological indicators arise from a variety of systems; therefore, the assessment of stress involves collecting data from all of these systems. The link between psychological stress and disease is often called the *mind–body interaction*. Research has shown that psychosocial stress in children can adversely affect their rates of infection and immune function (Shonkoff & Garmer 2012).

During any stage of the stress reaction there may be physical symptoms such as nausea, vomiting, diarrhoea or headache. Physical appearance can be changed, posture may be slumped, hygiene and grooming may deteriorate and style of dress may differ. Prolonged stress has been linked with cardiovascular and gastrointestinal diseases. Some cancers and immunological disorders, migraine headaches, infertility, burnout and irritability are associated with prolonged, unresolved stressors. In addition, stress is known to exacerbate neurological conditions such as Parkinson's disease (Fitzpatrick et al 2010).

Mild stress situations are a type of stressor that everyone encounters regularly, such as oversleeping, traffic jams, a flat tyre, or criticism from a supervisor. Mild stress situations do not usually produce chronic physiological damage. Such situations usually last from a few minutes to a few hours. By

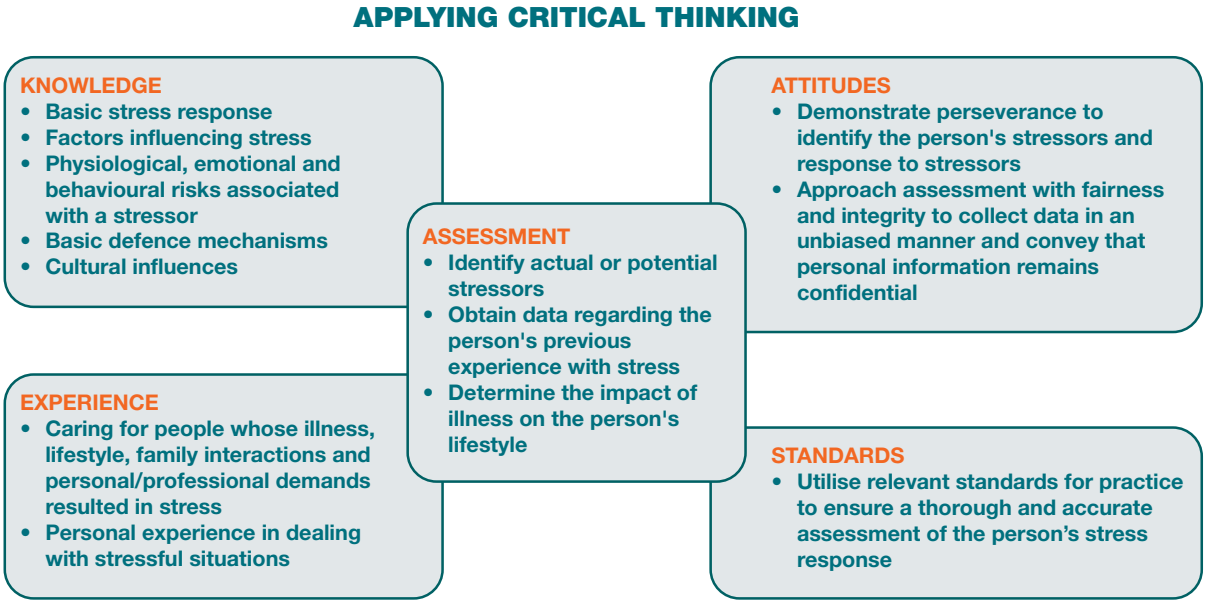

Figure 37-3 **Critical thinking associated with the assessment phase for managing stress and adaptation.**

BOX 37-4 Physiological indicators of stress

Elevated blood pressure
Increased muscle tension in neck, shoulders, back
Elevated pulse and increased respiration
Sweaty palms
Cold hands and feet
Slumped posture
Fatigue
Tension headache
Upset stomach
Higher-pitched voice
Nausea, vomiting, diarrhoea
Change in appetite
Change in weight
Change in urinary frequency
Abnormal laboratory findings: elevated adrenocorticotropic hormone, cortisol and catecholamine levels, and hyperglycaemia
Restlessness: difficulty falling asleep or frequent awakening
Dilated pupils

themselves, these stressors are not significant risks of symptom development. However, multiple mild stressors over a short time can increase the risk of illness. The stimulus may be an accumulation of minor life events as described by Kanner and colleagues in a study referred to earlier, which compared the stress from everyday hassles and 'uplifts' with the stress produced by major life events (Kanner et al 1981).

Moderate stress situations last longer, from several hours to days. These may be, for example, an unresolved disagreement with a co-worker, caring for a sick child or the prolonged absence of a family member. Moderate stress situations may create an increased risk of illness or the worsening of an existing chronic illness.

Severe stress situations are chronic situations that may last several weeks to several years, such as continual relationship problems, prolonged financial difficulties or long-term physical illness. The more frequent and longer duration of the stress situation, the higher the health risk (Shonkoff & Garmer 2012, Holmes & Rahe 1967).

The development of stress-related disease can be examined in terms of the health–illness continuum (Figure 37-4). As a person's stress increases, stress behaviours gradually increase. This decreases energy and adaptive responses. Identifying the mind–body interaction is crucial for predicting the risk of stress-related illness. A critical assessment of the person's perception of stressors is important. What may seem a trivial or mild stress situation to you may be extremely disturbing to another individual.

Major life events

The theory that major life events are a stimulus for stress emerged from the research of Holmes and Rahe in the 1960s, who hypothesised that major or frequent changes in one's life predispose the individual to illness due to the cumulative effect of life stressors. These researchers observed that tuberculosis (TB) infection commonly followed a major life crisis or multiple life crises and they subsequently developed a tool to measure the impact of life changes on health and to predict individual vulnerability to illness – the Social Readjustment Rating Scale (SRRS) (Holmes & Rahe 1967, Rahe et al 2000).

The SRRS consists of 43 items, of which 17 are rated as *desirable* (e.g. going on vacation) and 18 are rated as *undesirable* (e.g. death of a close friend). The remaining 8 are classified as *neutral*, for example, 'major change in responsibilities at work'. Such a change might be the consequence of a promotion, which is desirable; but it could also be the result of a restructuring and reduction of staff at a person's workplace, which would be undesirable as there would be fewer people to undertake the workload.

Items in the SRRS are given a weighting to reflect the magnitude of the stressful stimulus. For example, the death of a spouse

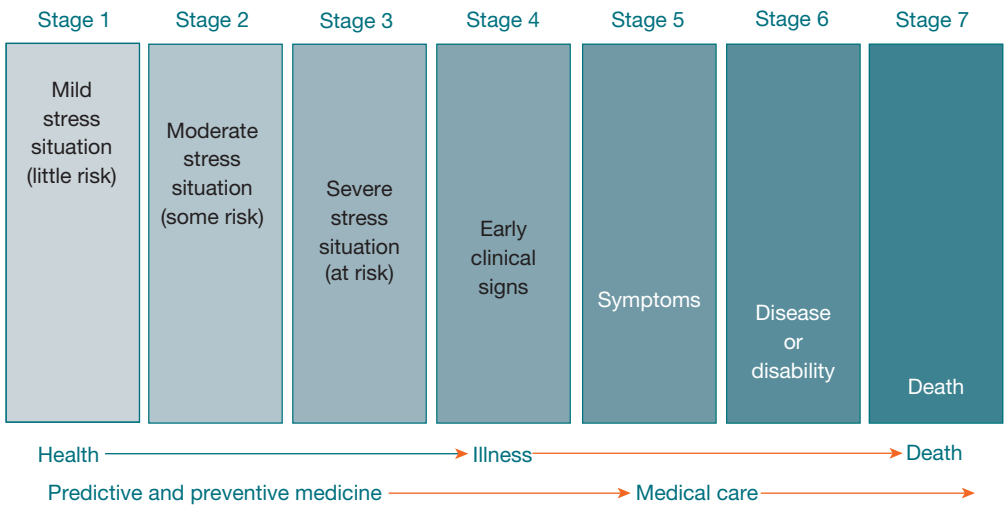

Figure 37-4 Stages of illness development in stress-related diseases.

was found to be the most stressful life event. This is given a score of 100. Using the SRRS, a total score of 150–299 for events occurring over the preceding year places the individual at 'moderate risk' for illness, whereas a total score of 300 in the preceding 6 months (or more than 500 in the preceding year) places the individual at 'high risk' of developing a stress-related illness.

Since its development 50 years ago, the Holmes–Rahe SRRS continues to be one of the most widely used and cited measurement tools in stress research. Scully and colleagues re-examined the usefulness of the tool as an indicator of health risk in the 1990s and found that the relative weightings and rank order of the selected life events remained valid. They concluded that the SRRS continues to be 'a robust instrument for identifying the potential for the occurrences of stress-related outcomes' (Scully et al 2000:875).

Psychological indicators

Exposure to a stressor results in physiological and psychological adaptive responses. As stated earlier, psychological adaptive behaviours increase a person's ability to cope with stressors. When conducting a health assessment, observe the person for maladaptive behaviours that do not facilitate coping with a stressor. Conversion, denial and displacement are examples of maladaptive ego-defence mechanisms. An example of denial is a person addicted to cocaine who says he or she could quit taking drugs whenever he or she chooses. To some, the abuse of alcohol or other drugs may seem to be an adaptive behaviour. In reality, it increases rather than decreases stress.

Developmental indicators

Erikson's psychosocial theory describes the developmental stages that occur through the life span (see Chapters 16 and 17). At each stage the individual attempts to resolve a conflict, for example, trust versus mistrust in infancy (Erikson 1963). Failure to achieve the developmental task of a particular stage in the life span hinders psychological growth and produces stress.

Infants or young children encounter stressors within their home or in out-of-home care situations. When nurtured in responsive, empathetic environments, they are able to develop healthy self-esteem and self-identity (see Chapter 20) and ultimately learn healthy adaptive coping responses. However, the absence of parents or caring figures, or their failure to provide the security needed to develop a sense of trust, can be stressors. In later life there may be chronic distrust, resulting in withdrawal and dysfunctional interpersonal relationships (Santrock 2014).

School-age children normally develop a sense of adequacy. They begin to realise that accumulation of knowledge and mastery of skills can help them accomplish goals. Self-esteem develops through friendships and sharing with peers. At this stage of development, an indicator of stress may be the inability or unwillingness to develop friendships.

Adolescents normally develop a strong sense of identity, but at the same time need to be accepted by peers. Adolescents with strong social support systems report an increased ability to adjust to stressors, but adolescents without social support systems often report increased psychosocial problems. In a study conducted by Rueger and colleagues (2010), adolescents with poor parental and peer support were found to have more depressive symptoms, anxiety, self-esteem and academic adjustment problems than young people who reported strong family and social support. There are many stressors in this age group, including conflicts involving sexual drive and expected standards of behaviour (see Chapters 16 and 17). Prolonged conflict may present as indecision and confusion, rebellion, depression or anxiety.

Young adults are in transition from youthful experiences to adult responsibilities. They must prepare for careers, living alone, forming intimate relationships and, perhaps, starting families. Conflicts between work, study, relationships and family responsibilities may be a source of stress during this developmental period (see Chapter 17).

Middle-aged adults are usually involved in family building, creating stable careers and perhaps caring for older parents. They are generally able to control desires, and in some cases, place the needs of partners, children or parents ahead of their own. Stress can result, however, if they feel that too many responsibilities have been placed on them. Several studies have looked at the impact of stressors on the family carer's role. Middle-aged adults have been called the 'sandwich generation' (see Chapter 17) because they are often responsible for ageing parents while raising their own families. Because of the stressors involved, carers have reported increases in fatigue, minor illnesses (e.g. colds and influenza), depression and dissatisfaction with family interaction (Gallagher-Thompson & Coon 2007).

Older adults are commonly faced with adapting to changes in family structure and perhaps to the death of partners or long-time friends (see Chapter 18). Older adults must also adjust to changes in physical appearance and physiological functioning (see *Working with diversity*). Major life changes, such as retirement, can also be stressful. A small number of older adults will also need to adjust to relocation, or to some form of institutionalised living. Moving to a nursing home or assisted accommodation can be made less stressful for an older person if social support is provided by family, staff and other residents during the transition from home (Lee 2010).

Emotional behavioural indicators

Emotions are sometimes assessed directly or indirectly by observing the person's behaviour. Stress affects emotional wellbeing in many ways (Box 37-5). Because stress affects each person differently, it is important to establish rapport with the person before assessing their emotional status. The person may or may not be aware of their behavioural responses. Non-verbal cues such as anger or a sad affect are extremely important. Include open-ended questions in your assessment that address the person's sense of self, their support network, current lifestyle, and current and previous experience with stressors.

Cognitive indicators

Prolonged stress can manifest itself in the cognitive dimension and have observable indicators. A person's ability to acquire new knowledge or skills may be impaired. A person's cognitive appraisal of a situation may also be inaccurate and frequently negative. Stress can impede communication between the person and others. A shortened attention span, inability to think clearly and the tendency to focus narrowly may render the person unable to solve problems and resolve conflicts. There may be increased dependence on others, as the person feels unable to cope with everyday life.

WORKING WITH DIVERSITY

Focus on older adults

- Ageing is often associated with declines in functional abilities due to the normal ageing process. Although this may be true, evidence suggests that coping and adaptation functions are surprisingly well preserved throughout the entire life span (Young et al 2009).
- Health problems are common among the elderly and can be a cause of stress.
- Since many older adults are on a fixed income, the cost of medical care can be a huge stressor. Other disciplines such as social workers may need to be involved to help the individual to access services.
- Loneliness and isolation can be a major stressor for the elderly. Studies have suggested that older people's perceptions of stress are less likely to lead to depression if high social resources are present (Schwarzbach et al 2014).
- Older adults effectively use religious coping in response to medical illness and disasters (Levin & Chatters 2008).
- Before scheduling a doctor's appointment or a needed test, explore the transport needs of the older person. Dependency can be a significant stressor for an older person, and necessary steps should be taken to avoid this issue.

Social determinants

The social determinants approach to understanding health argues that the biomedical model is insufficient to explain health and illness. This approach proposes that the attributes of a society, such as inequalities or injustices, and government policies dealing with these inequalities, are important indicators of the health of populations (Parry & Willis 2013).

Family

It is important to recognise that nursing interventions planned for an individual can affect the entire family. For this reason, assessment of the whole family and knowledge of the role of its members is essential. Culture, structure and concepts within the family are also important to understand when assessing how a family will cope with stress. Major life events should be explored. Job instability, death or illness of a family member and housing relocation are examples of significant family stressors. Stressors on the family may create dysfunction that affects the individual and the family as a whole (Sawrikar & Katz 2008). Relevant information and data may also include the person's perception as to whether or not effective emotional support is provided by their family.

BOX 37-5 Behavioural and emotional indicators of stress

Anxiety
Depression
Burnout
Increased use of chemical substances
Change in eating habits, sleep and activity pattern
Mental exhaustion
Feelings of inadequacy
Loss of self-esteem
Increased irritability
Loss of motivation
Emotional outbursts and crying
Decreased productivity and quality of job performance
Tendency to make mistakes (i.e. poor judgement)
Forgetfulness and blocking
Diminished attention to detail
Preoccupation (i.e. daydreaming or 'spacing out')
Inability to concentrate on tasks
Increased absenteeism and illness
Lethargy
Loss of interest
Prone to accidents

Lifestyle

Up until the mid-20th century, infectious diseases were the leading causes of death in Western countries. Since then, antibiotics and public health initiatives, such as improved living conditions, access to nutritious food and better sanitation, have lowered the death rate from infection. Now, the leading causes of death are diseases involving lifestyle stressors such as cardiovascular disease (AIHW 2014). There are a variety of lifestyle choices that can create physical and/or psychological stress in an individual and a health assessment examines both positive and negative factors related to stress. Smoking, overeating, insufficient physical activity, alcohol or drug abuse and chronic sleep deprivation are examples. Other examples include lifestyle choices such as unprotected sex with multiple partners posing a stressor in the form of exposure to sexually transmitted diseases (STDs). Regular exercise, adequate rest and a nutritious diet are positive lifestyle options that can reduce stress. Exercising regularly also facilitates both physical and mental health.

Sociocultural factors

Assessing stressors and coping resources in the social dimension involves exploring with the person the amount, type and quality of social interactions present in their life. Cultural differences in health beliefs or family stress responses may influence the individual's health behaviours and coping mechanisms. For example, Asian–Australian clients may prefer to seek social support from family members rather than from healthcare professionals (Sawrikar & Katz 2008). Further, it is known that South Asian immigrants in Western countries have continually

lower screening rates for cancer and other conditions than the wider population (Crawford et al 2015) (see *Working with diversity*).

Spiritual indicators

Spirituality refers to how the individual understands their place in the world (society and the environment). This includes their relationship with family, friends and others, the meaning they ascribe to their life, and their beliefs regarding an after-life. People use spiritual resources to adapt to stress in many ways, but stress can also manifest itself in the spiritual dimension. Severe stress may result in anger at a supreme being, or the person may view the stressor as punishment for a perceived wrongdoing. Stressors, such as acute illness or the death of a loved one, may threaten a person's meaning of life and can lead to depression. When providing care, it is important for the nurse to seek an understanding of the meaning of the spiritual experience from the person's perspective.

Client expectations

It is important to remember that every person perceives and reacts differently to stress. Culture, life experiences and family belief systems all play a part. Pang and Suen (2008) found that nurses rated experiences in the intensive care unit (ICU) to be more stressful than the patients did, and nurses tended to over-emphasise the stressful nature of the ICU environment. Complete and accurate assessment of the patient and their support networks is essential in tailoring care to the individual's needs. Asking the patient what is stressful for them, and how they suggest stressors could be reduced, assists in the setting of achievable goals and the identification of interventions. The very best quit-smoking program will achieve nothing if the person does not recognise their smoking as a problem. Therefore, planning care requires an awareness of your own value systems, as well as those of the person for whom you are planning care, and a critical synthesis of all available information in order to make appropriate judgements and decisions.

• CRITICAL REFLECTION POINT

You are a nurse working at a community health expo. A man stops by your health assessment booth and tells you he has been feeling apathetic and lethargic since he lost his job 2 months ago. He tells you he has been drinking heavily (more than 10 standard drinks) every evening, and his wife is constantly angry with him.

1. **What additional areas will you assess?**
2. **What questions will you ask?**
3. **What information will you seek?**
4. **What resources and social supports would be available in your community for him?**

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Stress can be observed in multiple ways: physical (e.g. elevated blood pressure), emotional (e.g. sad mood), cognitive (e.g. forgetfulness), social (e.g. feelings of isolation), behavioural (e.g. use of illicit drugs) and spiritual (e.g. feelings of despair). Using a critical reflection framework, the nurse synthesises all available information from the above domains (physiological, psychological, cognitive, behavioural, sociocultural and spiritual) to make decisions and plan appropriate person-centred nursing care for individuals experiencing stress or stress-related issues. The nursing assessment of these domains is supported with objective measures and/or subjective descriptors of stress and its consequences. For example, the person appears anxious, as evidenced by constant hand wringing during the interview.

WORKING WITH DIVERSITY

Focus on cultural care

The contrast between Chinese or other traditional medicines and Western approaches to health may be a source of stress for immigrants to Western countries. Western medicine is very technical and has a strong biological base. Chinese culture, including Chinese medicine, is strongly linked to religious and social beliefs. Therefore newly migrated and first-generation Chinese–Australians/New Zealanders may experience conflict and stress in seeking health support from Western medicine. Recently migrated Chinese have been shown to prefer the treatment of minor or chronic illness with Chinese medical services (herbal remedies, acupuncture, massage therapy and skin scraping) and will seek Western medical services only for acute or serious problems (Jette & Vertinsky 2010). Hence, some Chinese immigrants may be acutely ill when they first seek medical attention.

Cultural factors can also influence how individuals engage in health care. Crawford and colleagues (2105) undertook a literature review of 70 articles published between 1994 and 2014 which investigated the cancer screening behaviour of South Asian immigrants in the UK, USA and Canada. The researchers found that this population had lower screening rates for breast, cervical and colo-rectal cancer than the wider population in these countries. Four contributing factors for the low cancer screening rates were identified: 1) beliefs and attitudes about health and family (the central role of family and the primary source of health information); 2) lack of knowledge regarding cancer causes and screening; 3) personal and structural barriers to accessing services; and 4) there were gender differences in screening uptake (more men than women sought screening for colo-rectal cancer). The authors concluded that the findings identify areas that need to be addressed to increase cancer screening uptake in this immigrant population.

The review and interpretation of assessment information and data will enable you to identify potential or actual stressors and observe the person's response to these. Using your nursing knowledge and experience leads to the identification of problems, and the making of appropriate judgements and decisions; for example, changes in appetite, sleeping patterns and an increased number of headaches are frequently observed in individuals experiencing stress.

CLINICAL EXAMPLE: LU CHEN

Lu Chen is a 25-year-old Chinese-born woman who is hospitalised following a car accident. Lu immigrated to New Zealand 6 months ago and does not speak English. Her husband Feng, who has lived and worked in New Zealand for 10 years, accompanies her. Feng speaks English and is Lu's only relative in New Zealand. He is acting as her translator. Lu's provisional diagnosis is a possible concussion and a broken arm. Feng reports that Lu is very concerned about her arm because she has recently been working on a farm picking vegetables. Lu does not want to lose this job because she has made friends with other migrant workers, and they need the money that she earns to pay the mortgage on the house that she and Feng recently purchased.

• CRITICAL REFLECTION POINT

1. **What cultural factors might increase Lu's stress?**
2. **What can you, as the nurse, do to help alleviate some of that stress?**

SETTING PRIORITIES AND ESTABLISHING GOALS

Planning nursing care by using critical reflection, clinical reasoning and incorporating a research evidence base ensures that the person's care is appropriate to achieve the set goals. During planning, information from relevant multiple sources (Figure 37-5) is synthesised to set relevant priorities and goals for the individual and their family,

Goals should be individualised and realistic with measurable outcomes. Sensitivity to specific cultural issues and expressions of adaptation will also promote a sense in the person of feeling well cared for. It is important to focus on coping strategies that are both realistic and appropriate to the individual's needs. Goal planning should also involve the person and their family, if possible, to ensure that all views are considered. Research has shown that the perceptions of the client, family and nurse are not always the same (Wåhlin et al 2009) (see *Research highlight*).

Stress-management techniques are designed to match the client's actual and potential stressors. The general goals for clients who require stress management include:

- reduction in frequency of stress-inducing situations
- decreased physiological response to stress
- improved behavioural responses to stress
- improved psychological (cognitive and affective) responses to stress
- increased knowledge about the cause of stress and coping with stress.

PREPARING FOR AND TAKING ACTION

Stress management may be seen as a health promoting activity or an intervention that modifies a response to illness. The focus depends on the purpose of the nursing interventions, and is based on the individual's needs.

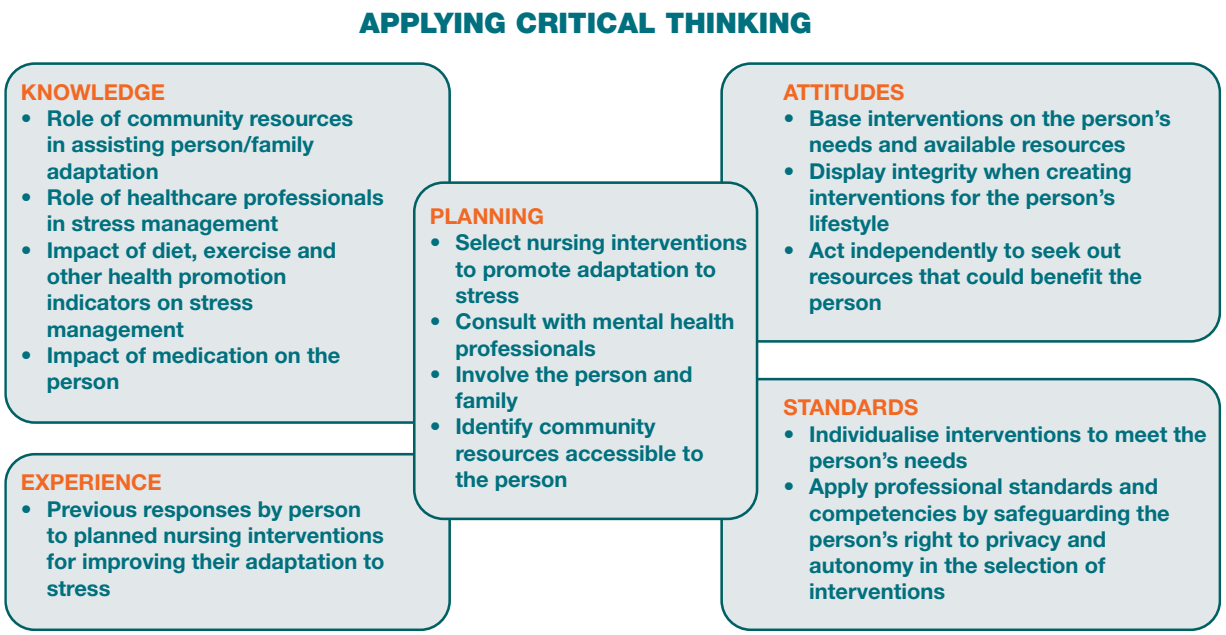

Figure 37-5 **Critical thinking associated with the planning phase for managing stress and adaptation.**

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant information and data*

When Janet Rich, RN, first visits Carl at his home she finds it in slight disarray. The lawn is overgrown, there are dirty dishes in the sink, and an empty soup can is sitting on the kitchen bench. Carl is standing in the living room folding laundry, while Evelyn, his wife, is sitting in a chair watching TV. Evelyn has recently been diagnosed with Alzheimer's dementia. Carl appears very **tired** and **depressed**. He continues to fold clothes during the visit, stating, 'There's so much to do that I don't even know where to begin.' Carl states that he has lost **9 kilograms in the past 6 months** and that his **appetite has been poor**. Until recently, Evelyn cooked all of their meals. Carl describes being awakened three to four times a night to find Evelyn wandering around the house. He states that he no longer has any activities outside the home because he is fearful of leaving Evelyn by herself. Their children live interstate. Carl does have a couple of close friends who live nearby, but he is unaware of any community resources.

** important data to cluster in setting priorities in bold.*

Priority problem(s)

Strain associated with being primary caregiver for partner with dementia

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Carl will: • appear more rested • maintain a stable weight • state that he has resumed one outside activity	Carl will: • report waking up less frequently during the night • state approaches used to involve others in his wife's caregiving activities. • re-establish normal eating patterns • report a balanced routine that incorporates time for his own rest or relaxation
Preparing for and taking action	**Rationale**
Carer's support • Help Carl establish a consistent care routine for his wife. • Discuss ways to simplify care routine, such as hiring a lawn mowing service, having groceries delivered, engaging a house cleaning service. • Identify sources of informal respite care by encouraging Carl to identify friends who can help with caregiving. • Explore formal community resources, such as home healthcare, adult day care and meals on wheels with Carl.	Routines can help tasks be simplified and more time-efficient. Creates free time for the client and may help decrease feelings of being overwhelmed. Supporting the carer of a person with dementia may delay or prevent the admission of the person to a nursing home (Brown & Abdelhafiz 2011, Podgorski & King 2009). Feelings of burden have been found to be lower among caregivers with informal and formal supports (Podgorski & King 2009).
Client support • Teach Carl stress-management techniques. • Set up monthly health checks for Carl that include vital sign and weight checks.	Stress and anxiety can precipitate physical illness (Lutgendorf & Anderson 2015).

Evaluating impacts and outcomes

- Observe for signs of fatigue.
- Review new care routines. Ask Carl what other modifications may need to be made.
- Ask Carl about how community and additional family support is helping to relieve stress.
- Ask Carl to compare past and present energy levels.
- Weigh Carl regularly.
- Ask Carl about recent food intake.

RESEARCH HIGHLIGHT

Research focus

Experiences of critically ill patients are an important aspect of the quality of care in intensive care units (ICUs). If next-of-kin and staff try to empower the patient, this is probably performed in accordance with their beliefs about what patients experience as empowering. As ICU patients often have difficulties communicating, staff and next-of-kin need to interpret their wishes, but there is limited knowledge about how correct a picture next-of-kin and staff have of the intensive care patient's experiences.

Research abstract

The aim of this study was to compare ICU patients' experiences of empowerment with next-of-kin and staff beliefs. Interviews with 11 ICU patients, 12 next-of-kin and 12 staff were conducted and analysed using a content analysis method.

Research findings

The findings showed that the main content is quite similar between patient experiences, next-of-kin beliefs and staff beliefs, but a number of important differences were identified. Some of these differences related to how joy of life and the will to fight were generated, the character of relationships, teamwork, humour, hope and spiritual experiences. Staff and next-of-kin seemed to regard the patient as more unconscious than the patient did.

Promoting health and wellness

Lifestyle decisions can have a dramatic impact on the stress experienced in everyday life. Regular exercise, good nutrition, adequate rest, effective time management, interactions with positive support systems and humour are all examples of habits that can positively affect physical and mental health. Nurses are in an excellent position to work with clients and their families towards health promoting strategies for reducing stress. Attempting to eliminate all stressors is unrealistic, but helping individuals and families to understand their particular stress response, and its probable causes, can be a significant step forward in stress reduction. However, there are some stressors that can be reduced and thereby provide the person with a greater sense of control. Several methods that may help in stress reduction are outlined below.

Time management

People who use time efficiently generally experience less stress because they feel more in control of their lives. Helping clients set priorities if they are feeling overwhelmed or are immobilised, and attempting to control or at least minimise the demands of others, is essential for effective time management. Few people are able to meet all requests made by others. It is important to learn to recognise which requests can be realistically met, which need to be negotiated or delegated, and which can be assertively declined. Defining a period of time in which to meet specific goals also reduces a sense of urgency and increases feelings of control.

Regular exercise

A regular exercise program improves muscle tone and posture, controls weight, reduces tension and promotes relaxation. In addition, exercise reduces the risk of cardiovascular disease and improves cardiopulmonary functioning. In general, for a fitness program to have positive physical effects, a person should exercise at least three times a week for 30–40 minutes. However, there is also evidence that exercise can be equally useful in smaller slices, for example, in periods of 10 minutes at a time, with a goal of accumulating 30–40 minutes each day (Gingerich 2007, Kahn 2007).

Everyone should use warm-up exercises before vigorous exercise such as jogging, aerobic dancing or tennis. Warm-up exercises stimulate blood flow to the muscles and increase flexibility. They reduce the risk of damage to the musculoskeletal system during exercise. Similarly, after vigorous exercise, people should do cool-down exercises rather than stopping abruptly. For example, after jogging or aerobic dancing, people should walk around at a moderate pace, gradually slowing and stopping. Cool-down exercises allow the cardiovascular, pulmonary, musculoskeletal and metabolic systems to gradually return to their resting states.

Exercise programs are effective in decreasing the severity of stress-related conditions such as hypertension, obesity, tension headaches, fatigue, mental exhaustion, irritability and depression (Smith & Blumenthal 2015). Exercise also promotes release of endogenous opioids that create a feeling of wellbeing (Boecker & Dishman 2015). Persons with a history of chronic illness, or those at risk of developing an illness, should consult their doctor or health professional to ensure that appropriate physical exercise programs are commenced.

Nutrition and diet

Nutrition and exercise are closely related. Food provides the fuel for activity and exercise, which improves the circulation and delivery of nutrients to body tissues. Everyone is encouraged to maintain their weight according to standard ranges for gender, age and body type. In addition to avoiding over-eating or under-eating, people should be aware of the nutritional quality of foods. Too much fat, caffeine, salt or sugar can upset the body's metabolic functioning; deficiencies in vitamins, minerals and nutrients can also cause metabolic problems. Poor dietary habits can worsen a stress response and make a person irritable, hyperactive and anxious, impairing their ability to meet personal, family and role responsibilities. Nursing strategies for helping a client meet nutritional needs are detailed in Chapter 31.

Rest

An established and regular pattern of sufficient rest and sleep is also important. People experiencing stress should be encouraged to allow ample time for rest and sleep. Sleep not only refreshes the body, but also helps a person become mentally relaxed. A client may need specific help in learning relaxation techniques to fall asleep.

Support networks

A support network of family, friends and colleagues who will listen and offer emotional support and advice is beneficial to a person experiencing stress (Barkway 2013). Therapeutic communication is a nursing tool that you can use to assist individuals to identify the social resources and support networks available to them. Or, if stress is the result of social isolation or exclusion, nursing interventions will be aimed at helping the person to develop new social networks.

Crisis intervention

Crisis intervention is a therapeutic technique for helping a client to resolve a particular, immediate stress-related problem. Crisis intervention does not involve an in-depth analysis of a situation, but tackles the immediate, urgent need for stress reduction. The goal of crisis intervention is to restore the person to the pre-crisis level of functioning as quickly as possible. A **crisis** occurs when people encounter problems or stress situations with which they are unable to cope in usual ways. A crisis does not necessarily denote the occurrence of a traumatic event. However, even if this happens, the event can be an opportunity for personal growth and development if the crisis is successfully mastered (Findler et al 2014).

Clients and nurses are at risk of two types of crises: situational and developmental. A **situational crisis** arises suddenly in response to an external event or conflict involving a specific circumstance. Symptoms associated with situational crises are transient, and the episode is usually brief. Situational crises include giving birth; major role changes; acute physical illness; physical or sexual assault; family changes such as remarriage or the death of a family member; and unexpected unemployment. A **developmental crisis** occurs when a person is unable to complete the developmental tasks of a psychosocial stage (Erikson 1963) and is therefore unable to continue developing. For example, an adolescent who develops anorexia nervosa may be unable to complete some of the developmental tasks associated with this phase in the life span, such as identity development. A developmental crisis can occur at any point in life, and wherever the circumstances prevent a person from meeting the challenge of a particular stage.

If nursing assessment determines that the individual is experiencing a crisis, you can plan and implement specific measures to immediately assist the person to resolve it, and refer the person to professional counselling if indicated. Aguilera (1998) has developed an approach that can be used as an intervention in both situational and developmental crises (Figure 37-6). This approach provides an understanding of how a stressful event has led to a state of crisis. Resolution of the crisis depends on the person's realistic perception of the stressful event, use of adequate coping mechanisms and the availability of social support. If the crisis has arisen because perception of the event is distorted, you can assist the person to perceive the stressful event more realistically. If the crisis has arisen because of a lack of situational support or coping mechanisms, the person can be referred to suitable community resources and support. This is followed by an evaluation of the effectiveness of the interventions to assess whether the personal crisis has been resolved.

Restorative care

There are many ways to encourage clients to make lifestyle choices that are healthy and stress-reducing. Appropriate use of humour, spirituality and stress-management techniques are examples of these options. Although the following are presented with respect to restorative care, these techniques can be used in many healthcare settings.

Humour

Using humour or laughter as therapy was first popularised in the lay literature by Norman Cousins (1979). The ability to perceive fun and to laugh, alleviates stress. The physiological hypothesis is that laughter releases endorphins into the circulation and feelings of stress are relieved. Laughter has been shown to increase immune and cardiac system functioning (Bennett & Lengacher 2008), lower blood pressure, neutralise adrenaline and increase energy and fertility (Hull-Rodgers 2007). Nurses can initiate therapeutic activities by encouraging clients to relate past humorous anecdotes or to develop a 'humour scrapbook' (Figure 37-7). It is important, though, to critically examine the client's receptivity to humour first, to ensure it is not demeaning or ill-timed in relation to the stressful event.

Enhancing self-esteem and self-efficacy

Improvement in a client's self-esteem is a positive stress-reduction strategy. When clients identify their positive characteristics, it helps them see what resources they can draw upon to cope with the stressor.

Self-efficacy is the personal belief that one is capable of achieving desired or required outcomes. According to Bandura (Bandura 2001, 2008), the thoughts and beliefs (self-talk) that the person has about a particular circumstance or event are predictive of the outcome. Positive self-talk enables the person to rehearse a positive outcome, while negative self-talk produces stress and may become a self-fulfilling prophecy – that is, the anticipated negative outcome will result. For example, the student who believes they are capable of passing an exam is more likely to engage in helpful behaviours, such as studying, than the student who does not view themselves as capable of passing. The latter student is less likely to study and, therefore, more likely to fail.

Cognitive restructuring is a cognitive-based intervention that can modify stress responses. This is a technique in which the nurse and client analyse the person's appraisals of a stressor. If these are unrealistic or focus only on negative outcomes, the person is helped to restructure their thinking to more realistic, positive patterns (Seligman 2002, 2011). This may be accomplished by encouraging the person to consider how realistic their thinking is, and challenging perceptions that are negative. For example, consider a person who is about to sit an exam whose self-talk is 'If I fail this exam I will let my parents down'. It is likely that the person will be highly anxious, which in turn will reduce their performance. Restructuring the person's self-talk to 'I have prepared for the exam and will do my best' is a more realistic and less stress-producing thought. As a nurse you can assist clients to restructure their negative cognitions by asking questions such

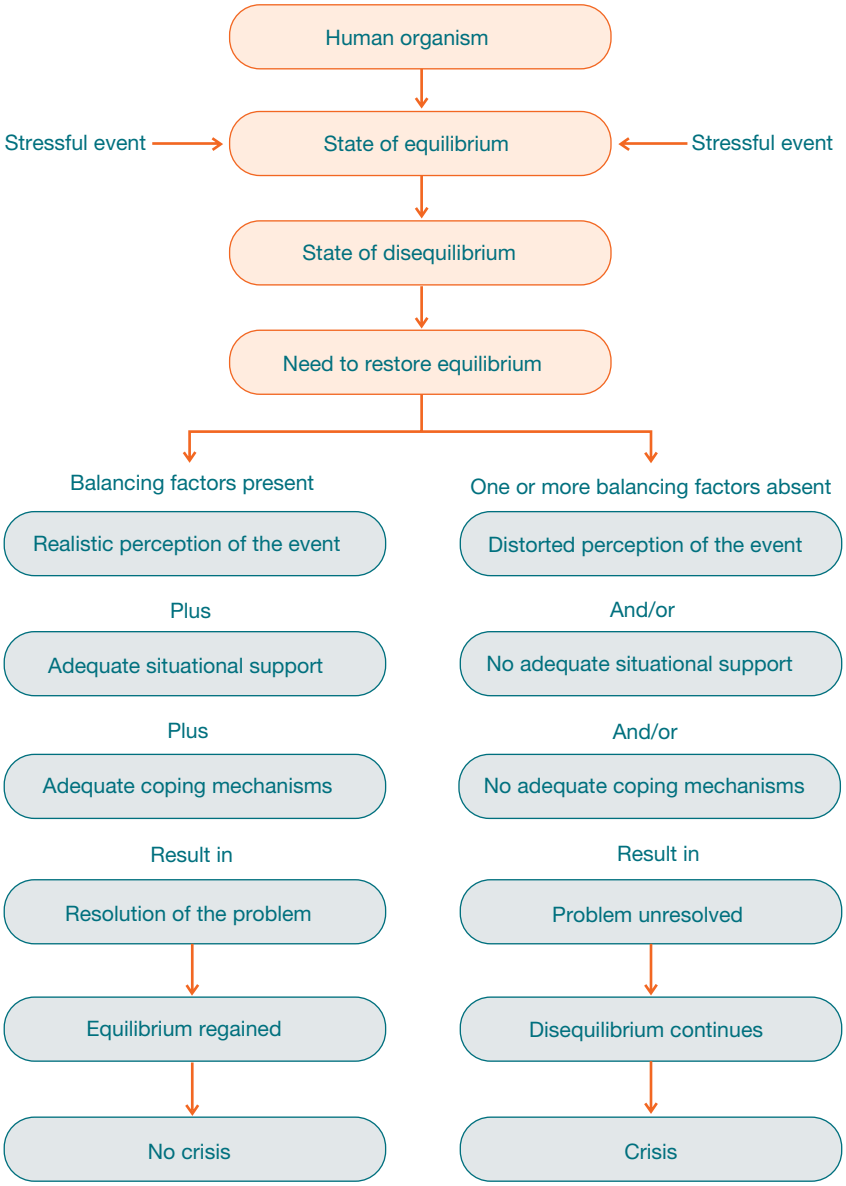

Figure 37-6 Crisis intervention model.

Redrawn from Aguilera DC 1998 Crisis intervention: theory and methodology, 8th edn. Mosby, St Louis.

Figure 37-7 Sharing a joke or laughing with clients can help reduce stress and support a therapeutic relationship.

Potter PA, Perry AG 2013 Fundamentals of nursing, 8th edn. Mosby, St Louis.

as: 'How likely is the negative outcome?', 'What else might happen?' or 'If the worst does happen, what personal or other resources do you have available to respond to the challenge?'

Another useful cognitive strategy is the use of *mindfulness*, whereby the individual focuses on the present through conscious awareness of their current experience, utilising openness and acceptance. Mindfulness is a Western psychological therapy which has its origins in Eastern philosophies including Taoism, Buddhism and yoga (Harris 2009). Najvani et al (2015) found that Acceptance and Commitment Therapy, which included mindfulness, was an effective treatment for depression in women with breast cancer.

Relaxation techniques

Progressive relaxation with and without muscle tension and imagery techniques reduces the physiological and emotional

BOX 37-6 Changes resulting from practising relaxation techniques

Lowered blood pressure (baseline)
Lowered heart rate (baseline)
Decreased cardiac dysrhythmias
Decreased oxygen demands and oxygen consumption
Decreased muscle tension
Lowered metabolic rate
Increased alpha brain waves, which occur when the client is awake, non-attentive and relaxed
Increased restfulness
Improved concentration
Improved ability to cope with stressors

components of stress. Relaxation techniques are learned behaviours and require training and practice sessions. When a person is skilled in these techniques, tension is reduced and physiological parameters are changed (Box 37-6).

Examples of relaxation techniques are guided imagery and visualisation, progressive muscle relaxation, meditation and biofeedback. In clinical practice, two or more of these techniques will often be used concurrently. Cutshall and colleagues (2011) found that biofeedback and meditation was effective in helping hospital nurses to reduce stress and anxiety levels. It is important to note that relaxation techniques such as biofeedback and hypnosis should only be implemented by those health professionals who are trained and experienced to provide these services.

Spirituality

Spiritual activities can also have a positive effect on decreasing stress. Practices such as prayer, meditation or reading religious material may have a meaningful impact on some clients. According to Levin and Chatters (2008), religious constructs are determinants of numerous psychosocial, health and wellbeing outcomes in older adults, who use religious coping in response to medical illness and disasters.

CLINICAL EXAMPLE: DANNY

You are a nurse working in the children's ward of a major metropolitan hospital. Danny Parker is a 7-year-old Indigenous boy from a remote community who is admitted to your ward with the diagnosis of type 1 diabetes mellitus, following recent weight loss and feeling unwell for several weeks. His blood sugar level on arrival was 25 and he appeared to be slightly dehydrated. This is the first time Danny has ever left his community, which is 500 km away. His mother, Penny, has accompanied him. Penny expresses concern for her son. She and several of their relatives have diabetes mellitus type 2, and she is well aware of the potential problems, such as kidney disease and vision problems. Danny appears bewildered and clings to his mother during your assessment.

CRITICAL REFLECTION POINT

1. **Identify potential stressors for Danny.**
2. **Identify potential stressors for Danny's mother.**
3. **Suggest ways in which these stressors might be alleviated.**

Stress management in the workplace

Workplace or **job stress** is a major contributor to work being identified as an emerging occupational hazard. According to the World Health Organization Commission Report on the Social Determinants of Health, stress at work is associated with a 50% increased risk of coronary heart disease. Furthermore, high job demand, low control, and effort–reward imbalance were found to be risk factors for mental and physical health problems in workers (WHO 2008).

Most nurses experience stress in their work environments. Specific stressors can include heavy workload, shift work, bullying, institutional policies, conflict with co-workers, dealing with death or dying and loss, conflict within the multidisciplinary team and inadequate preparation for dealing with the emotional needs of clients and families. For example, research conducted by Laschinger and Nosko (2015) found that nurses who were exposed to frequent workplace bullying were at risk of developing symptoms of post-traumatic stress disorder.

Reaction to a job-related stressor depends on the nurse's personality, health status, previous experiences with stress, personal support systems and coping mechanisms. Nevertheless, while excessive stress can be harmful, Landa and colleagues' (2008) study of 180 Spanish nurses found that having high levels of *emotional intelligence* (a personal perception of one's ability to identify, assess and manage one's own emotions and those of others) was protective against stress. The researchers concluded that stress effects could be moderated if healthcare professionals were given suitable training and development.

Extreme job stress may result in a condition called **burnout**, which is characterised by emotional exhaustion, cynicism and a sense of professional ineffectiveness (Leiter & Maslach 2009). Burnout may result from prolonged chronic workplace stress which is unresolved (Maslach 2003). The job or profession no longer has positive rewards for the person, who may experience anger or apathy. Pan and colleagues' (2010) study of Chinese nurses working in an emergency department (ED) found that nurses who were exposed to violence in the ED experienced increased levels of psychological distress and were more vulnerable to burnout.

According to Maslach (2003), anyone who works with people in need of care is potentially at risk of burnout. Hence, nurses and other healthcare workers may benefit from using the same stress-management techniques that they teach to clients. It is important to identify specific stressors at work and strive to eliminate or reduce them. It is also helpful to gain social support from other nurses to maintain a caring attitude towards clients, their families or communities (Hurley 2007).

Clinical supervision is a professional development activity designed to enable reflection on practice with the support of an experienced clinician who has received specialist training in this

technique. The outcomes of clinical supervision include reduced stress and burnout (Hyrkäs 2005, Hyrkäs et al 2006).

EVALUATING IMPACTS AND OUTCOMES

Because clients' perceptions of stress differ, so do their perceptions of the effectiveness of stress reduction. Therefore, evaluation of nursing interventions directed at stress management must consider whether the person's perception is that the stress has reduced, whether the person is able to control factors that contribute to the stress and whether the person is able to independently develop and maintain stress-reduction strategies into the future (Figure 37-8).

To evaluate interventions directed at stress management, it is important to objectively measure the reduced frequency of stressful situations, decreased physiological responses to stress and improved behavioural and emotional responses to stress. Reports from the individual and their family, as well as nursing observations, are important indicators.

It is important to refer the person to appropriate resources for continuity of care. Lifestyle changes and developing new patterns of coping with stress can be difficult and may take some time to adopt. It is also very easy for individuals to fall back into old stress-producing habits if adequate, continued support is not provided.

Client expectations

Clients who experience prolonged stress often have a loss of self-esteem and a reduced sense of control over their lives. These feelings can be reduced by maintaining an open line of communication and working in partnership with the individual and their family. Provided the client has consented, family members should be given opportunities to be involved in all aspects of the person's care. Open communication between clients and healthcare professionals will facilitate an environment in which the person feels comfortable providing relevant information about whether interventions are successful or not, and will enable the person to become more involved in the self-management of their health condition. Open communication is essential to empowering individuals to become engaged, informed, collaborative, committed and tolerant of uncertainty as they navigate an increasingly complicated and demanding healthcare system (Johnson 2011). Importantly, open communication can avoid the situation in which the person may conform to the 'good patient' role – that is, does not disagree or complain for fear of being perceived as a complainer (Hart 2010).

The evaluation process should be ongoing to ensure that the person has an appropriate care plan and that the plan is frequently reviewed. Collaboration between the individual, family, nurse and the interdisciplinary team involved in providing care is essential to meeting client expectations.

Conclusion

Stress and stressors are a part of everyday life. However, excessive or prolonged stress can lead to physical and psychological health consequences, exacerbate an existing illness or delay recovery. An understanding of the causes and consequences of stress ensures that stress prevention and management strategies can be incorporated into the planning of care with clients and their families to provide holistic care.

Key concepts

- Physiological adaptive mechanisms are controlled by the medulla oblongata, reticular formation and pituitary gland.
- Stress is physiological or psychological tension that can affect a person in any or all human dimensions.

APPLYING CRITICAL THINKING

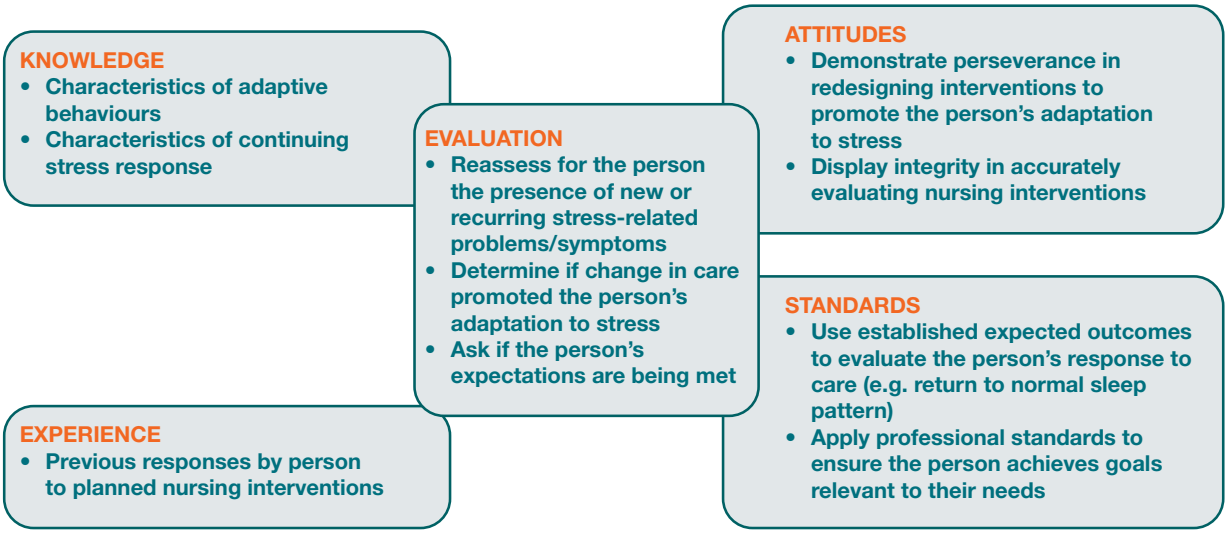

Figure 37-8 **Critical thinking associated with the evaluation phase for managing stress and adaptation.**

- Stressors necessitate change or adaptation so that a state of equilibrium can be maintained.
- A person's response to stress is influenced by the intensity, duration and scope of the stressor, by the number of stressors present at one time, predictability, level of personal control, feelings of competence, cognitive appraisal and availability of social supports.
- A person adapts to stress by using resources in the physical, psychological/emotional, developmental, intellectual, social and spiritual dimensions.
- The local adaptation syndrome involves several specific responses to stress, including the reflex pain response and the inflammatory response.
- The general adaptation syndrome (fight/flight) involves a multisystem physiological response to stress.
- Psychological responses to stress include problem-focused (task-oriented) and emotion-focused behaviours, and the use of ego-defence mechanisms.
- Stress has an impact on the onset, course and outcome of illness.
- Prolonged stress decreases the ability to adapt to the stress and affects the person in all six dimensions of health (physical, social, mental, emotional, spiritual and environmental).
- Stress-management techniques include health-enhancing habits, crisis intervention and methods of reducing situational stress, for example, job stress.

Learning outcomes

Mastery of content will enable you to:

- critically discuss the impacts of population ageing for Australian and New Zealand societies
- analyse and compare the policy approaches taken by Australian and New Zealand governments in response to the changing patterns of ageing
- examine and evaluate models of primary healthcare for the older person across the health continuum
- recognise the impact of inequity in community healthcare services for older Indigenous Australians, New Zealand Māori and Pacific peoples and discuss proactive health care to minimise their ill-effects
- evaluate the impact of formal and informal primary healthcare systems for the older person, their family and society
- recognise the complex scope of Australian and New Zealand community nursing care services for an ageing population
- identify the key principles and responsibilities of culturally competent community nursing practice in the care of the older person
- consider future directions of community nursing services for the older person and their family.

Health care for older people is currently one of the major challenges facing developed countries and will be even more of a challenge in future decades. In most countries the chronological age of 65 years signals the start of old age, but there is no universally accepted criterion (World Health Organization (WHO) 2011). An estimated 20% of the population of developed countries is now over the age of 60 years, and by 2050 that age group is predicted to make up a third of the population in those countries (United Nations Population Fund 2010). Ageing baby boomers, declining fertility and ever-improving health treatments and technologies have created a population bulge of older people who are healthier and living longer than their parents did, but often live with a chronic illness. Health care for the older person is therefore integral to nursing care in all clinical settings and especially so in the community, because that is where the vast majority of older people live (Australian Bureau of Statistics (ABS) 2013a). Nurses are at the 'front-line' of community-based care and their role is of the utmost importance in health promotion, disease prevention and ongoing care for those living with a chronic illness.

In this chapter, factors that influence the health of older people are explored, including the effects of health problems on their lives and the health care that supports them to live as well as possible. The chapter also covers an overview of legal, policy, governance and conceptual perspectives of older person health. Healthcare systems and nursing roles and competencies that best support the health of older people are presented for critique. Models and frameworks will be used throughout the chapter to illustrate aspects of older person health, using triangular diagrams, which show how aspects of care intersect. Community-based care for younger adults and adolescents is covered in Chapter 20 of this textbook.

Health support for older people in Australia and New Zealand

Ageing population profile

Along with many developed countries, Australia and New Zealand have growing populations over the age of 65 years. The most recent census of the Australian population, taken on 30 June 2011, counted just over 3 million people over the age of 65, about 14.0% of the population (ABS 2012). In the next 15 years, this population will nearly double as the 'baby-boomer' generation ages. There were approximately 4.1 million people aged 60 years and older, with the number expected to rise from the current 13.5% of the total population to 22% (17.1 million) in 10 years' time (ABS 2013b). An issue for aged care service providers is that the number of Australians aged 70 and older, currently 9.7% of the total population, is expected to almost double between 2010 and 2030, from 2.1 million to 4.1 million. This is three times faster than the growth in the total population (Productivity Commission 2011). An even more startling picture is that over the next 20 years, the number of Australians 85 years and older (those most likely to need aged care services) will grow from 1.9% (365,000) to 2.8% (802,000) of the total population (ABS 2013b).

Women are living longer than men; the number of women aged 80 years and over is predicted to be almost double that of men in 2016. The trend is a continuation of decades of decreasing birth rates and lengthening life expectancies. Both of these phenomena have health and economic policy implications, with government estimates suggesting a fourfold increase in the number of people needing aged care services in the community (Access Economics 2010, Australian Treasury 2010). The Organisation for Economic Cooperation and Development (OECD) predicts that until 2025, both Australia and New Zealand will have continuing growth in demand for expenditure on community aged care services, greater than for the United States, Canada and Europe combined (OECD 2015). According to the *Intergenerational Report* published by the Australian Treasury, Australian government spending on aged care is expected to grow from 0.8% of GDP in 2010–11 (around $7 billion) to around 1.8% of GDP by 2049–50 (approximately $15.75 billion in current dollars) (Aged Care Financial Authority 2014).

New Zealand has a younger population than Australia, but a similar rate of growth in people over the age of 65 years (14.3% of the total population), which is expected to double to 1.2 million by 2036 (23% of the population). The 2013 census indicated that there were 73,000 people 85 years and over, 64.3% of whom were female, a 29.4% increase since 2006 (Statistics New Zealand 2014). Unlike the steady growth in the small number of older Indigenous Australians (ABS 2013b), increases in New Zealand's older **Māori** and **Pacific peoples** will be particularly significant over the next 50 years (Statistics New Zealand 2014). There is an expected 270% increase in the proportion of Māori aged 65 years and over, and a more than 400% increase in the proportion of Pasifika people aged 65 years and over. Other ethnic minority populations, while relatively young, are also projected to increase significantly, especially those from Asian countries (Statistics New Zealand 2014).

While the ageing process is experienced and understood by older people, their families and cultural

communities in many different ways, most Australians and New Zealanders aged 65 years or over are relatively fit and healthy. However, the burden of morbidity and mortality among **Indigenous Australians** is significantly worse than that of non-Indigenous Australians and of other 'Anglo-settler societies' like New Zealand (Hunter 2007). The majority of older non-Indigenous Australians are well enough to live independently in private dwellings: 80% of 60- to 79-year-olds and 34% of those aged 80 years and over. About 6% of these older people live in more than 2000 retirement villages across Australia. The Department of Social Services (DSS) report that of the small number of older people living in non-private dwellings, the majority (54%) live in some sort of care accommodation, including nursing homes or aged care hostels (50%) and hospitals (3.0%) (DSS 2014a).

In the 2011 Australian Census, about one-fifth (570,000) of Australians 65 years or older reported needing assistance with core activities of living (Crisp et al 2013a). A minority of this group were frail and vulnerable and required high levels of care and disability services, usually during the last few years of their lives, or as a result of chronic illness or disability that may have been present for many years. The proportion of people living in cared accommodation increases with age and illness, rising from 1.1% of all 60- to 79-year-olds to 15% of people aged 80 years and above (ABS 2013b). If current trends continue, nearly 300,000 Australians will require cared accommodation by 2030 (Department of Health and Ageing (DOHA) 2011).

The ageing of the population has impacts on different community members and systems, mainly the family. Estimates from the ABS (2013b) show that, of the 1.2 million people aged 65 years or older (80%) who need assistance living at home, close to three-quarters use unpaid, informal support, mainly provided by family members. Access Economics (2010) has estimated that around 60% of Australians with dementia are living in the community, with the majority being supported by 6.2 million informal carers (Australian Institute of Health and Welfare (AIHW) 2011a) (Figure 38-1). Over 113,000 people aged 65 years and above are the primary carer for an older person (i.e. providing the most assistance in terms of help or supervision) or a disabled care recipient (ABS 2013b). The number of Australians receiving unpaid home-based care has remained fairly constant over the last 10 years, despite the number of older people increasing by over 20%. The percentage receiving unpaid care has actually decreased, largely due to an increase in the mix of government and non-government community-based services. Together these services help the older person to maintain their connections to family and community and to exercise a choice of services if they require a higher level of care.

Figure 38-1 The level of care required by older people varies from individual to individual.

iStockphoto/Guven Demir.

People are now healthier for longer than in past generations, but the rapid growth of the number of chronic illnesses that tend to occur in older age will inevitably increase pressure on health funding. A New Zealand Ministry of Health paper (Johnston & Teasdale 1999) projected that, based on 2000–01 patterns, health expenditure would need to grow by an average of 3.6% per year over the next 50 years to meet increased demand for existing services (Ministry of Social Development 2001). Unless there are significant changes in the disability trajectory, more people will live with prolonged periods of needing health and supportive services and there will be fewer people to pay for these services. The actual rate of increase is difficult to predict; however, because of the impact of other factors, such as changes in the availability of informal carers, technological advances, rising expectations for more and better services and changing rates of disability among older populations, future funding pressures are likely. Australian and New Zealand governments have responded to the challenge of age-related chronic illness by establishing policies to support active, healthy ageing so as to reduce the prevalence of disability, and to enable older people to remain in their home longer with formal service support (DOHA 2011a, Ministry for Social Development 2001).

• CRITICAL REFLECTION POINT

Spend a couple of minutes now thinking about how future changes in the age profile of the population might affect the community you live in.

- **What activities do you know of that are popular with active older people?**

- **Explain what needs to happen for public facilities to meet the needs of a growing older population.**
- **What effect would there be on general practice services?**
- **What other health services might be affected by an older but healthier population?**

Policy contexts

Australia

Australian **aged care policy** is laid out in the Aged Care Act 1997 (Cth). Amendments to the Act in 2012 were, in part, a response to the Productivity Commission's *Caring for Older Australians* report (2011). These amendments built on earlier reforms found in the 2010 Council on Australian Governments' National Health Reform Agreement (COAG) 2011, and include:

- consumer-directed care initiatives that mark new directions in community and residential care
- informed consumer choice through My Aged Care website, which aims to inform consumer choice
- strengthening policy with the Aged Care Quality Agency and the Aged Care Financial Authority
- care/support needs being determined by local aged care assessment teams, while Centrelink administers means testing
- increased user charges for both community and residential care, with more account being taken in the means tests of the value of owner-occupied housing
- state government influence on the provision of public and community housing programs, land-use regulations, and fair trading regulations
- responsibility of the Australian Government for all aged care services (DSS 2014b).

Along with the state and territory governments, the Australian Government has undertaken a number of significant recent reforms that influence the way the older person and their family experience the aged care system. Under the 2010 COAG National Health Reform agreement, starting July 2012, the Australian Government took full responsibility (funding, policy, management and delivery) for the aged care system across the country, including home care and residential care. One particularly relevant component of this agreement is that the Home and Community Care Program (HACC), which was formerly the jurisdiction of state and territory governments, became an Australian government responsibility. In exchange, the state and territory governments became fully responsible for funding support services for people with disabilities under the age of 65. In 2012–13, Australian government expenditures on the aged care system reached $12.9 billion: 71% of spending was on the residential aged care program, 22% on Home and Community Care (HACC), Community Aged Care Packages (CACP), Extended Aged Care at Home (EACH), Extended Aged Care at Home–Dementia (EACH–D) and 7% on other programs, such as respite and the multidisciplinary aged care assessment program (DSS 2013).

As part of the **'Living Longer Living Better' (LLLB) aged care reform package**, the Australian Government also removed the distinction between low- and high-level residential care from 2014, thereby increasing the ability of residents to age in place (DOHA 2012). Although some residential care facilities specialise in either high or low care, many of these facilities broadened their service offerings to include the full continuum of care, which allows older people to stay in the same facility as their care needs increase. About 71% of the funding for residential aged care comes from the Australian Government, 25% from private contributions and 4% from accommodation payments (DSS 2014c).

It is proposed that the consolidation of aged care funding for these levels of aged care service will result in a nationally consistent and better-integrated aged care system (AIHW 2013). This consolidated system will also have strong links to health and hospital services, the logical next step in progressing integrated aged care in Australia, which aims to provide a more streamlined and positive care experience for older Australians. The COAG agreement also included the introduction of a national information line in July 2011, which was the first step to make it easier for people to access information about aged care services.

Fundamental to the reform process is a **consumer-directed care (CDC) system**, which is a significant shift in how aged care services have operated to date and how consumers have experienced the service system. The critical elements in this change are individualised budgets, consumer choice about which provider they receive services from, a home care agreement and a care plan, which together indicate the level of involvement the user wishes to have in decision-making and management of services (DSS 2014b). Since July 2015 all CDC Home Care Packages are now delivered in a consumer-directed way. In the longer term, CDC will be introduced into residential care.

Governance by Aboriginal boards of management will continue to support the rights of Indigenous Australians to attain good quality of life in older age, through self-determined community-based health programs. For Australian Indigenous communities, the health of their older members is not just about individual physical

wellbeing. Health incorporates all aspects of a person's life, including control over the physical environment, maintaining personal and community dignity, and self-esteem and justice. Health includes the social, emotional and cultural wellbeing of the whole community, which is directly associated with the community's relationship to the land of their ancestors. This is a whole-of-life view and also includes the cyclical concept of life–death–life (Anderson et al 2006).

Optimal **primary healthcare** for older Indigenous Australians will, therefore, provide a wide range of health-related community support services to achieve whole-community health. These may cover a variety of services; for example, community development work; advocacy for legal, public housing, Centrelink and disability support; cultural promotion activities; and transport to medical appointments (AIHW 2011b). Services to rural and remote areas are provided through regional primary health services (RPHS), which consolidate a range of these existing programs in a flexible way. As an example of flexible community health programs for Indigenous people that will affect the whole community, in December 2011 the Minister for Australian and Torres Strait Islander Health launched toolkits for health workers, including nurses, to tackle the high rates of smoking and chronic disease, such as type 2 diabetes and smoking-related deaths in these communities. In 1997, the National Aboriginal Community Controlled Health Organisation (NACCHO) was created as the national peak body for Aboriginal health in Australia. This organisation works with over 150 Aboriginal Community Controlled Health Services (ACCHS); examples of the range of programs and their impact on Aboriginal health can be found on the NACCHO website, listed at the end of this chapter.

New Zealand

The 'Health of Older People Strategy' is a key plank of the New Zealand Positive Ageing Strategy (Ministry of Social Development 2001). The policy emphasis on 'ageing in place' is intended to reflect the personal preferences of older people themselves, who prize their autonomy and independence (Davey 2006). Ageing 'baby boomers' are expected to be living longer and healthier, have higher levels of education and work experience, and women will have greater financial independence and literacy than did their mothers and grandmothers (Davey 2006). Therefore, the strategy focuses on older people's health and wellbeing through coordinated and responsive health and disability support programs. Development of the strategy was guided by the aims and principles of the New Zealand Health Strategy (Ministry of Health 2000), New Zealand Disability Strategy (Minister for Disability Issues 2001) and the Māori Health Strategy He Korowai Oranga (King & Turia 2002). The **Health of Older People Strategy** sets out a comprehensive framework for planning, funding and providing services. It includes a work program for the Ministry of Health on a national framework for implementing the strategy, and identifies the steps to be taken by district health boards (DHBs) to develop an integrated approach to service provision in their own districts. Implementing the strategy requires the Ministry of Health and DHBs to systematically review and refocus services to better meet the needs of older people now and in the future, by reallocating available resources between services.

New Zealand's Ministry of Social Development (2013) gave assurances that positive ageing principles would direct all relevant policy to:

- empower older people to make choices that enable them to live a satisfying life and lead a healthy lifestyle
- provide opportunities for older people to participate in and contribute to family, whānau and community
- reflect positive attitudes to older people
- recognise the diversity of older people and ageing as a normal part of the life cycle
- affirm the values and strengthen the capabilities of older Māori and their whānau
- recognise the diversity and strengthen the capabilities of older Pacific people
- appreciate the diverse cultural identity of older people living in New Zealand
- recognise the different issues facing men and women
- ensure older people, in both rural and urban areas, live with confidence in a secure environment and receive the services they need to do so
- enable older people to take responsibility for their personal growth and development through changing circumstances.

Services and programs within the jurisdiction of New Zealand's Positive Ageing Strategy include health promotion, preventive care, specialist medical and psychiatric care, hospital care, rehabilitation, community support services, equipment, respite care and residential care. All health services are older-person focused, the wellness model is promoted, and services are coordinated and responsive to needs; the family's, whānau and carers' needs are also considered and, where appropriate, there is information-sharing and a smooth transition between services. Planning and funding arrangements support integration. Employing an integrated continuum of care approach means that the older person is able to access

needed services at the *right time*, in the *right place* and from the *right provider* (Ministry for Social Development 2001).

Additionally, **Whānau Ora** is a policy direction and funding stream that has been developed to more adequately address the health and social needs of all New Zealand families, in a way that is designed to be consistent with Māori values. Whānau Ora, therefore, pays attention to the particular needs and place in society of older adults. Government agencies are required to work cooperatively to empower whānau (families) collectively, rather than individuals separately, in ways that enhance self-management, healthy lifestyles, active participation in society and te ao Māori (the Māori world). Support also fosters economic security and family cohesion and resilience. Specialist Whānau Ora providers offer comprehensive services tailored to the needs of whānau through the development of a 'whānau plan' that maximises access to health and social services (Durie 2013).

• CRITICAL REFLECTION POINT

Take some time now to reflect on the policies and strategies that guide health services for older adults in Australia and New Zealand.

1. **What values and beliefs of society are reflected in the intentions of these policies and strategies?**
2. **How are the interests of older people prioritised and served in your community?**
3. **To what extent do the health policy documents for older person health in Australia and New Zealand reflect a holistic view of health, especially with regard to Māori and Australian Indigenous peoples?**
4. **Make a list of the ways that older people are supported in the community in which you live. What facilities are especially user-friendly for them?**
5. **What improvements do you think could be made to better cater for their needs?**
6. **What may be some future options for housing older people?**

Health care for populations as well as individuals

Older people are members of many different communities – social, cultural, recreational, spiritual and political. Policies to support their health and wellbeing, therefore, focus on improving the health of individuals, families, communities and systems by modifying the social determinants of health (Box 38-1).

There are five characteristics of population health (Keller et al 2002). First, there is a focus on entire populations (those possessing similar health concerns or characteristics, such as the older person with a chronic illness); second, population-based practice is based on thorough community-involved health assessment to establish priorities and planning; third, population-based care includes the range of the determinants of health: social, economic, spiritual, physical and psychological. The fourth element is that all levels of prevention are employed. Primary prevention helps to maintain and/or improve health before a problem has occurred, and secondary prevention reduces risk factors or early symptoms and continues on to disease management and chronic care. Finally, population-based practice employs interventions for populations, communities, families and individuals. These practices emphasise population health outcomes to reduce **health inequity**, through the delivery of health care that portrays the features of primary healthcare. In their community-based practice, nurses work in a variety of ways to provide care for individuals and also for populations (McKillop et al 2011). The nature of their practice is described later in this chapter.

Population health supports care for people at all life stages and levels of health need. Systems are required for identifying health inequity in a population, planning health improvement initiatives in collaboration with the community and accessing local services that can contribute to health gain. Mechanisms are required to establish cooperative, integrated care, improve access to health care, collect and manage health information and monitor health gain indicators against population health targets (Coster & Gribben 1999). These mechanisms are evident

BOX 38-1 The features of a population health approach

- A culture across the organisation that places the same emphasis on promoting health and preventing disease as on treating illness.
- Investment in activities that influence the determinants of health.
- Operational commitment to reducing inequalities.
- Inter-sectorial and intra-sectorial collaboration on local initiatives so that there are working partnerships and alliances with a range of community groups.
- Genuine community participation.
- Support for sustainable community development.
- Data collection that is comprehensive and considers ethnicity, deprivation and outcomes.
- Workforce development to support this wider population health approach.

Poore M 2004 Would you recognise a population health approach if it passed you in the street? Ministry of Health, Wellington.

in the Aboriginal Community Controlled Health Services governance system for Indigenous people established by the Australian Government (AIHW 2011b) and the New Zealand Government's Māori Health Strategy (King & Turia 2002). Population-based health care:

> focuses on entire populations, is grounded in community assessment, considers all health determinants, emphasises prevention and intervenes at multiple levels (Keller et al 2004).

Population-based primary healthcare for the older person is provided at three levels simultaneously. The treatment of the biophysical effects of disease, such as type 2 diabetes, characterises a 'short-term, problem-specific, individual-based "downstream' approach"' (Cypress 2004:249). Midstream health care includes early risk detection and reduction of the factors giving rise to lifestyle-influenced diabetes, through a partnership approach (McKinlay & Marceau 2000). Upstream actions aim to strengthen the structural determinants affecting a person with a health condition like type 2 diabetes, which can include education, employment, housing, transport, nutrition, income and working conditions (Keller et al 2004, Kleffel 1991, Sharpe 2006). A population health approach is fundamental to the 'new' primary healthcare.

Primary healthcare

Modern-day primary healthcare has its origins in the global primary healthcare strategy conceived by nations attending the WHO conference at Alma-Ata in South Eastern Russia in 1978, where they collectively called for 'Health for all by the year 2000' and vowed to embrace the principles of the Declaration of Alma-Ata:

1. Health as a basic human right
2. Inequity as politically, socially and economically unacceptable, and
3. Health as a reflection of the social and economic conditions affecting people's lives (World Health Organization 1978).

These three principles heralded a turnaround from the view of health as a biological state, directed at individuals, experienced and modified by individuals and separated from the socioeconomic and political environment in which people reside. While the year 2000 is long gone and universal health remains an aspiration, the Declaration of Alma-Ata was a turning point for primary healthcare towards more actively addressing persistent inequity, injustice and general lack of fairness in the delivery of health care (Salmond 2008).

A fundamental shift in the provision of primary healthcare was required to reach the goals agreed to at Alma-Ata, a shift that continues today (McKillop et al 2012). Nurse leaders in New Zealand have defined primary healthcare nursing as:

> ... practical and research-based. Employing socially and culturally acceptable practices, nurses make care accessible to people in the places they live and work. Primary health care nurses aim to reduce inequity in the health status of the population, in particular for Māori, Pacific and other underserved populations. A population health approach is required, alongside work to assist individuals to make decisions about their own health and independence (Primary Health Care Nursing Expert Advisory Group 2008).

Traditionally, primary healthcare has been delivered in Australia and New Zealand from general practice clinics, which were originally set up for illness treatment rather than wellness support. When a health service is geared for treatment of sporadic, one-off illness episodes, or for regular chronic illness management, health promotion and assessment of illness risk are more likely to be neglected (McKillop et al 2012). More recently, health policy and funding have targeted health care along the continuum from health promotion to illness care, but changes in the way primary healthcare is organised are required to enable new approaches to primary healthcare.

An effective 'continuum of care' system is one where a complete array of health and health-related support services are offered, and mechanisms are in place that organise and track these services over time, in a way that is client-oriented. Older clients often have to move between providers as their care needs change (DOHA 2012). The motivation for reform on integrated packages of aged care services is particularly strong for the large and growing numbers of people with complex and/or ongoing health and social needs. The Australian aged care reforms represent significant improvements in the potential for service integration. The New South Wales state government, for example, has recently released details of an integrated care strategy that could provide a substantial framework for greater collaboration across the health system (O'Keeffe 2014). The framework encourages health organisations to work together and to form partnerships between hospitals and community-based services. The NSW state government will provide $120 million over 4 years to facilitate the integrated service package, whose goal is seamless or connected health care, which would particularly benefit older people who currently struggle to navigate the disjointed health system.

As well, the Australian Government instituted a new approach to primary healthcare to help improve the health and wellbeing of Australian Aboriginal and Torres Strait Islander peoples (AIHW 2011b). While comprehensive primary healthcare includes access to nurses, Aboriginal health workers and other healthcare professionals, it also

includes access to social and emotional wellbeing services. These programs help individuals to reunite with their kinship networks, and include the 'Bringing Them Home' and 'Link Up' programs and counselling services associated with family and community reconnection. The 'Bringing Them Home' and 'Link Up' counsellors help individuals (many of whom are now over 55 years of age), families and communities affected by past practices of the forced removal of children from Aboriginal and Torres Strait Islander families, to reunite with their families, culture and community, and to restore their social and emotional wellbeing. The Bringing Them Home counsellor program provides counselling and related services to individuals and families, while the Link Up services support people in tracing, locating and reuniting with their families. Access to these primary healthcare services is critical for preventing ill-health, effectively managing stress-related chronic disease and improving health outcomes, to help close the gap in life expectancy between Indigenous and non-Indigenous Australians (AIHW 2011b). Comparisons between 'old' and 'new' primary healthcare are presented in Table 38-1.

• CRITICAL REFLECTION POINT

Using the new primary healthcare column in Table 38-1, identify at least one example of how each of these aspects of health care would be played out in community-based care for older person health.

TABLE 38-1 The differences between 'old' and 'new' primary healthcare

Old primary healthcare	New primary healthcare
Focuses on individuals	Looks at health of populations as well
Provider-focused	Community and people-focused
Emphasis on treatment	Education and prevention important too
Doctors are principal providers	Teamwork – nursing and community outreach crucial
Fee-for-service	Needs-based funding for population care
Service delivery is monocultural	Attention paid to cultural competence
Providers tend to work alone	Connected to other health and non-health agencies

Ministry of Health 2001 Implementing the primary health strategy. Ministry of Health, Wellington.

Community and people-focused health care

Community engagement is a prerequisite for consumer and community involvement in the planning and delivery of health care for older people. There are various layers of healthcare governance, and each should include community representatives so that the voices of service users and/or their advocates are included in health decisions (Coney 2004). As previously identified, the concept of 'community' has many meanings. Five core elements were derived from a narrative review of 154 definitions of community: its location, sharing common interests and perspectives, joint action as a source of cohesion and identity, a foundation of social ties and that some diversity is expected and accepted since all people are unique (McQueen et al 2001).

The location of a community is not just where older people live, but other places where they come together; for example, where they socialise. In 2013, the Australian Institute of Health and Welfare (AIHW 2013) reported on the 'desire to age in place' among the vast majority of older Australians. Intentions to stay in current accommodation were highest among public tenants and homeowners and lowest among private renters, which signifies the role that income plays in this aspiration (DSS 2014a). Much of the desire to age in place is related to emotional and social attachment to the locale rather than to the dwelling. This highlights the need to create sustainable communities which provide enabling environments for older people and opportunities for social interaction, and which promote integration with local communities. Age-friendly communities incorporate social and physical structures that support healthy ageing (WHO 2007). This includes consideration of outdoor spaces, transportation, appropriate housing and public attitudes that encourage healthy ageing (Plouffe & Kalache 2010).

Where the older person lives and the availability of health infrastructure in that location will influence the way that nurses are able to engage with different rural communities. Rural people are more likely to have greater restrictions to accessing health care from their home in the community, especially for those living in remote and inhospitable locations. When community support systems are not available in rural areas, necessitating the move to a regional centre, older people can experience feelings of loneliness and isolation, which drastically lower their life expectancy (Bernoth et al 2012). The realities of rural and remote Aboriginal health, in particular, are distinguished by 'hardship, sufferance and invisibility' (Hunter 2007). Many Indigenous people have high levels of unrecognised

and untreated illnesses. One of the reasons for this is the failure of mainstream health services staff to understand and acknowledge the extreme difficulties that Indigenous people experience in seeking culturally sensitive health care in rural and remote locations.

Issues that will continue to impact on **community nursing** services relate to the changing social and political climate associated with an ageing population. Future needs for housing and support in later life will increase substantially with the decline in home ownership and continuing hardship for private tenants as rental costs rise (DSS 2014a). The gap between available income and the cost of formal services will continue to be an issue for older Australians and New Zealanders. In Australia, the majority of older people rely on a government pension for income support. Full superannuation coverage of older people is not expected for another decade (Chomik & MacLennan 2014a). As well, the availability of informal carers who provide the bulk of support for older people is projected to decline (Nepal et al 2011). Similarly, in New Zealand, most people over the age of 65 receive a fortnightly payment of 66% of the net national average wage adjusted annually, although the age for eligibility is under scrutiny. Income support will continue to be an issue as ageing baby boomers bring increased expectations for independent living and increasing diversity in lifestyles and service requirements (Beer & Faulkner 2009). To provide an effective community health service, nurses will need to gain a good understanding of the issues impacting on service access, in light of the changing health perspectives and needs of different communities of older people (Crisp et al 2013b).

Integrated community health services

As previously discussed, the purpose and focus of primary healthcare involves not only care for individuals with health problems, but also health promotion and preventative care. In their health promotion and preventative care work, and in light of ever-increasing rationing of health resources, nurses are challenged to provide older people and their families with the most appropriate education and support to improve the social determinants of health (Sharpe & O'Sullivan 2006). **Effective primary healthcare** involves expanded nursing services, community outreach and multidisciplinary team collaboration in providing health care across the continuum of care, as identified in the Australian and New Zealand aged care policies (Finlayson et al 2008, Ministry of Health 2001, 2003, Productivity Commission 2012, Wagner et al 2001).

Primary healthcare and social service providers that are well integrated with each other can provide a seamless service for their clients (Sheridan 2005). Nurses need to work with other services to improve access and to improve the social determinants of health, including housing, education and a range of social services. Not least, care that is integrated across primary and secondary services can avoid gaps and overlaps in health services. A discussion document published by the Australian Primary Health Care Advisory Council (PHCAC) suggests that future primary healthcare organisations, whatever form they take, 'will need to define together what the glue will be that will hold them together' (PHCAC 2009:4). Exploring the implementation of the PHCAC guidelines may reveal the 'glue' that integrates services. The way that services are arranged and connected with each other is represented in the model of health care on which they are based.

Appropriate community-based nursing, therefore, will be individualised to suit the client and their family, have a population health focus (Sheridan 2005) and rely on continuing relationships with other health services (Wagner et al 2001). This approach requires a reorienting of health services across the health continuum, not just in the primary healthcare sector (Bodenheimer et al 2002a). In particular, integrated care for the older adult requires coordination and collaboration within and across primary, secondary and tertiary healthcare providers to ensure continuity and relevance of care, in which nurses play a pivotal role. Key components of person-centred integrated care include coordination within and across care teams and community resources, relationships that enhance familiarity with patients across time, continuous proactive and responsive actions between visits, and shared responsibility (Singer 2011).

Six interlinked components are essential to the effective integration of care (Wagner et al 2001, Bodenheimer et al 2002b):

- *community resources* – mobilising community resources to meet the needs of people with long-term conditions
- *healthcare organisation* – creating a culture, organisation and mechanisms that promote safe, high-quality care
- *self-management support* – empowering and preparing people to manage their health and health care
- *delivery system design* – delivering effective, efficient care and self-management support
- *decision support* – promoting care that is consistent with research evidence and patient preferences
- *clinical information systems* – organising patient and population data to facilitate efficient and effective care (Wagner 1999).

Future areas of focus in improving integrated aged care services in Australia will be in designing information systems, supporting care management processes and developing a system of finance that creates the appropriate incentives to promote changes to the balance, or mix, of services and behaviour change (Daley et al 2014).

Community-based services for older Australians and New Zealanders

The six components listed above are essential to an effective integrated healthcare system for older people and their families. For example, in 2013–14 over one million older Australians and their family carers accessed government-subsidised integrated community-based services from the programs listed in Figure 38-2.

Australian aged care services

The service components of a continuum of aged care have grown and developed in Australia over three decades. Since 1963, the government has funded residential care at 'high' and 'low' levels. Residential care also includes respite services. In addition, the government has supported two major types of community care programs: the **Home and Community Care (HACC) program** and the **community package programs** (Community Aged Care Packages (CACP), Extended Aged Care at Home (EACH) and EACH for dementia clients (EACH-D)). As previously identified, these service offerings have recently been upgraded to consumer-directed (CDC) home care packages. The demographic pressure of an ageing population and an increase in the number of Australians living with significant disability increases the number who

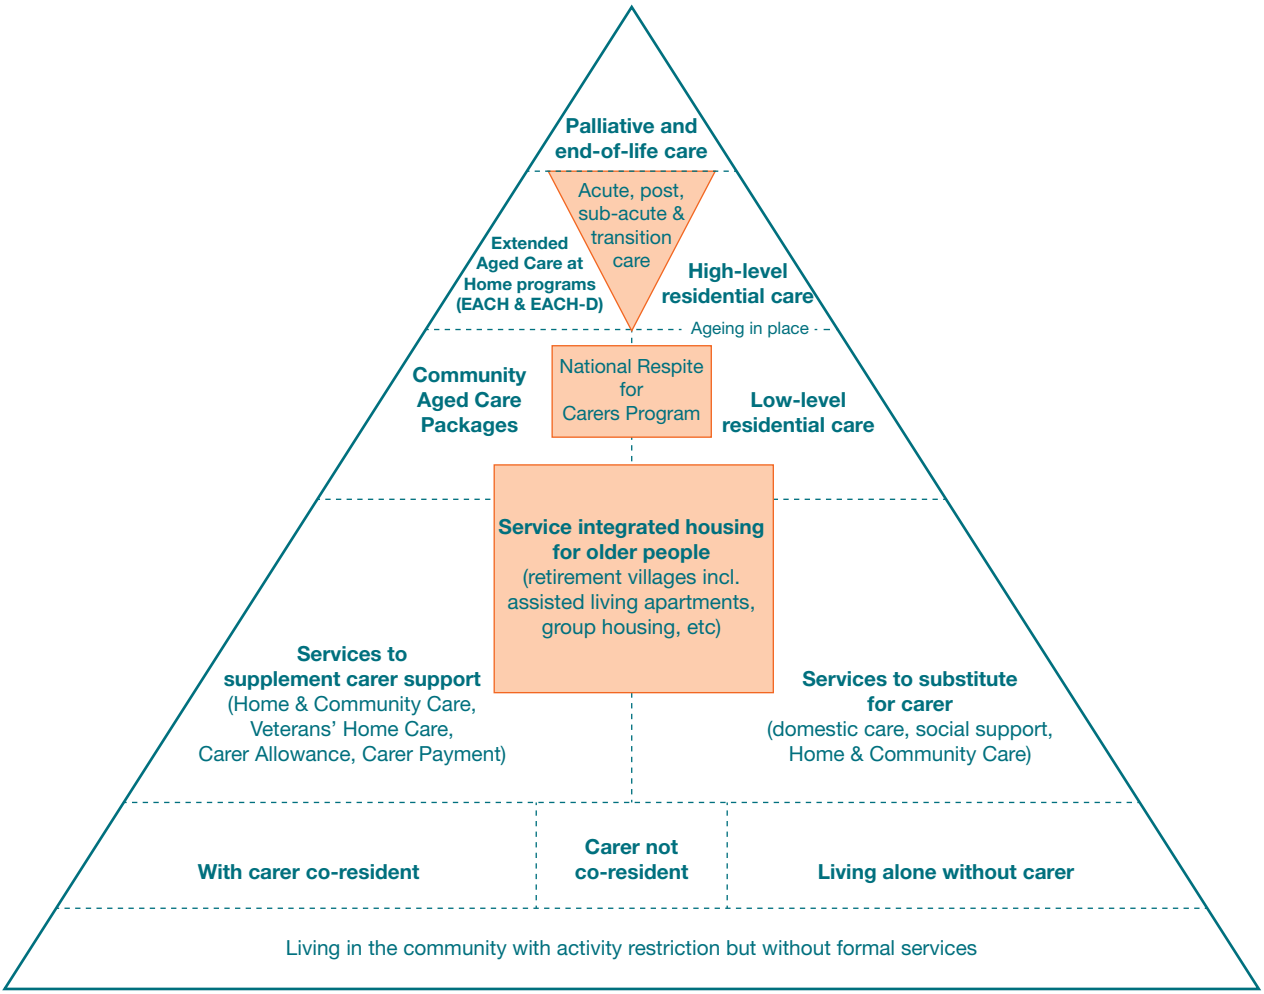

Figure 38-2 Services to support older people across the continuum of care.

Productivity Commission 2011 Caring for older Australians: overview. Inquiry report no. 53. Productivity Commission, Canberra, p. XXIV. © Commonwealth of Australia, Productivity Commission.

need government-subsidised aged care services. Ensuring that access to aged care services is both sufficient and appropriate to meet the needs of the population is an important governmental planning function (DSS 2014B).

To ensure that future needs are met, each year the Australian Government creates new residential and community aged care places to be allocated in each Australian state and territory, in relation to benchmark ratios for people aged 70 and above, set separately for high- and low-level residential care and for community care. The current target ratios are: 25 community care places, 44 low-level residential care places and 44 high-level residential care places per 1000 people aged 70 years and older (DSS 2014c), notwithstanding that the 'ageing in place' policy has removed the distinction between low- and high-care places. By employing a ratio of aged care places to those likely to use care (i.e. persons 70 years and older), the government hopes to ensure that the availability of care keeps pace with the ageing population.

Eligibility for community care packages is determined by an Aged Care Assessment Team (ACAT), which assesses general health, health conditions and ability to attend to activities of daily living (DSS 2014a). Altogether, community package programs served almost 83,000 older people living in the community in 2013–14. The CACP program provided the majority – with more than 63,000 recipients in 2012–13 (DSS 2013), while the EACH program served about 13,000 recipients, with almost 6500 of these receiving EACH-D packages in 2013. Funding is allocated largely based on demand and services are provided at the discretion of providers. Services included transport, nursing, home maintenance, counselling and personal care, and delivers services to people with a range of disabilities, regardless of whether that disability is related to an acquired condition or injury (DOHA 2014). The program also supported Indigenous health by improving access to community services in rural and remote Australia (DSS 2013).

RESEARCH HIGHLIGHT

Research focus

Issues and solutions for improving transitions from acute to community care for older people with dementia.

Research abstract

The aim of the research was to examine the literature on the impact of the discharge experience of patients with dementia and their continuity of care.

Peer-reviewed and grey literature published in the English language between 1995 and 2014 were systematically searched using Medline, CINAHL, PubMed, PsycINFO and Cochrane library databases, using a combination of the search terms: dementia, caregivers, integrated healthcare systems, managed care, patient discharge. Also reviewed were Department of Health and Ageing and Alzheimer's Australia research reports between 2000 and 2014.

Research findings

The review found a wide range of studies that raise concerns in relation to the quality of care provided to people with dementia during hospital discharge and in transitional care.

Conclusion

Discharge planning and transitional care for patients with dementia are not adequate and are likely to lead to re-admission and other poor health outcomes.

Evidence-based practice

It is clear from the research literature review that hospitalisation and discharge have a significant impact on the person with dementia and their carers and that these processes are not generally well managed. A need for further investment in training, improvement of discharge planning and referral pathways, and improved access to transitional care services for people with dementia who are leaving hospital have been identified. The case for beginning discharge planning on admission to hospital, in consultation with families and community health personnel, is also strong. These improvements are generally seen as leading to a reduction in re-admission rates. Various models of comprehensive discharge and follow-up support with more collaborative primary care also demonstrate reduced hospitalisations. Effective Australian models include: the Transitional Behavioural Assessment and Intervention Service (T-BASIS); the Behaviour Assessment Management Service (BAMS) established in 2013 under the aegis of Specialist Mental Health Services for Older People; and the Transition Care Program (TCP), a 12-week discharge package providing vulnerable patients with continuing care and optimising functionality through a range of support services in the community.

Chenoweth L, Kable A, Pond D 2015 Research in hospital discharge procedures addresses gaps in care continuity in the community, but leaves gaping holes for people with dementia – a review of the Literature. Australasian Journal on Ageing 34(1):9–14.

Aged care reforms in 2014–15 have significantly increased the amount of home care available, with four levels of Home Care Packages that support people with basic care needs, through to high care needs. The new Home Care Packages are a *coordinated* package of services tailored to meet the consumer's specific care needs. A home care provider coordinates a package, with funding provided by the Australian Government (DSS 2013).

Other community-based programs funded by the Australian Government include the Veterans Home Care program, which serves 70,000 mostly aged war veterans and their widows, or widowers, as well as Innovative Care, Multi-Purpose Services and Transition Care Services. Aided by funding by the Australian Government, for some older Indigenous Australians the Aboriginal Community Controlled Health Organisations (ACCHOs) contribute to primary healthcare services through Aboriginal-led locally elected boards of management (AIHW 2011b).

New Zealand aged care services

Home support services give older people the ability to make choices in later life about where they want to live, and to receive the support they need to do that. The New Zealand Ministry of Health is responsible for the development of home and community support services for older people. A continuum-of-care approach is taken for older people's support services, which emphasises home- and community-based services (Ministry of Social Development 2001). Consistent with a 'restorative' model of home support that maximises an older person's independence, District Health Boards provide for specialist assessment by a Needs Assessment Service Coordination (NASC) agency, many using the internationally validated inteRAI tool to effectively identify needs and guide integrated care plan development (Mello et al 2015), so each person can remain in his/her own home safely for longer (Ministry of Social Development 2013). New Zealand government agencies collaborate to fund services including health care, housing, transport and income support. Funding for equipment or housing and vehicle modifications is also available as required to enhance safety and independence.

Older people are also supported through church-based services such as:

- *Enliven* – a service offered by Presbyterian support organisations throughout New Zealand that enables older New Zealanders to stay in their own homes and to remain in control of their own destiny
- *Wesley Community Action* – a Methodist organisation with experience in working alongside older people in the community to help maintain their independence and quality of life
- *Selwyn Centres* – parish-based drop-in centres for older people hosted by the Anglican Selwyn Foundation. They offer older people in their communities a morning program, which includes gentle exercise, social time and activities, for a nominal fee.

Aged residential-care services are available for older people (usually aged 65 years and over) who need more support than can be made available to them in their own homes (Figures 38-3 and 38-4). Options include a range of private and public residential home-care facilities and specialist hospital facilities. In addition, a range of services and resources are provided by Age Concern, the Alzheimer's Society, Arthritis New Zealand, the Cancer Society, Diabetes New Zealand, the Hearing Association, Hospice New Zealand, the Mental Health Foundation, the National Heart Foundation, the National Foundation for the Deaf, the Parkinsonism Society of New Zealand,

the Public Health Association, the Royal New Zealand Foundation for the Blind and the Stroke Foundation.

Strengths-based approach

Both Australian and New Zealand aged care services support a primary healthcare, strengths-based approach that strives to meet older people's holistic needs by:

- being consumer-directed, allowing older people and their families choice and control over their lives
- being easy to navigate, by helping older people and families know what care and support is available and how to access those services
- promoting independence and wellness in older people and their continuing contribution to society
- ensuring access to person-centred services that can change as the older person's needs change
- treating older people with dignity and respect
- assisting informal carers and family to perform their caring role
- being affordable for older people requiring care and for society more generally and
- providing incentives to ensure the efficient use of resources devoted to the caring role and broadly equitable contributions between generations.

• CRITICAL REFLECTION POINT

Pause now to consider how nurses can best support the continuing optimal health of older people.

1. **How would you summarise a strengths-based approach to community-based nursing?**
2. **Make a list of what this would mean to the recipients of such care.**
3. **How would they be included in decisions about their care?**

The older person with chronic illness

Ageing is a natural part of life and there is great diversity in the health and wellbeing of older people. Two-thirds of older Australians who report having 'good', 'very good' or 'excellent' health attribute their health status to continued participation in the wider community and to lifestyle choice (AIHW 2013). The 2009–10 Family Characteristics Survey (ABS 2011) found that while the number of Australian grandparent families has decreased since 2003, there remained 17,000 grandparent families in which the grandparents were guardians or main carers of resident children aged 0–17 years, and approximately 43% of people over 65 years of age were actively involved in caring roles and/or volunteer work outside their home

Figure 38-5 Older people are commonly engaged in carer roles within the family.

(Figure 38-5). As well, in 2011 at least half of all Australians aged over 65 years (54%; 2.9 million older people) engaged in some sporting or exercise program on a regular basis, and regularly walked for fitness (ABS 2013b). On the other hand, in vulnerable populations like Australian Aborigines, social disadvantage and ill-health over the life span can lead to younger-onset chronic illness (COAG 2011).

'Chronic disease' is an umbrella term used to describe a diverse array of medical conditions, both communicable and non-communicable, that are most prevalent in people over 65 years of age. The Australian Institute of Health and Welfare (AIHW 2010) and the 'National Chronic Disease Strategy' (National Health Priority Action Council 2005) have broadly described chronic diseases as being:

- complex and multi-factorial in causation
- gradual in onset with variation in symptoms experienced, from acute or sudden onset of symptoms through to symptom-free periods
- persistent and long-term in nature, leading to gradual deterioration of health more prevalent with older age; but, like asthma and renal disease, can occur throughout the life span
- compromising to an individual's quality of life through physical limitations and disability
- not immediately life-threatening, but eventually leads to premature mortality.

In Australia, 77% of the population has at least one chronic condition and 80% of the burden of disease and injury is attributable to chronic diseases. In 2011, deaths due to these illnesses/conditions accounted for 77% of all underlying causes of death and were either associated with, or the underlying cause of, 90% of deaths (ABS 2013b). Data on 9156 patients attending general medical

practitioners in 2009 (Family Medicine Research Centre 2010) revealed that the incidence of chronic disease is on the rise, involving one or more of the following conditions: vascular, musculoskeletal, psychological, asthma, upper gastrointestinal diseases, cardiac, diabetes, cerebrovascular and malignant neoplasms. Australia's national health priority areas focus on chronic diseases and conditions that are generally occurring in older age: arthritis and musculoskeletal conditions, cancer, cardiovascular health, diabetes mellitus, injury prevention and control, mental health, including dementia, and obesity.

Chronic physical disease and mental illness often co-exist in Australians over 65 years of age (Grealish et al 2013). In the 2007 National Survey of Mental Health and Wellbeing, 20.0% of the population aged 16–85 years reported a mental health disorder in the past 12 months and nearly half the same population (45.5%) had experienced an anxiety, affective or substance use disorder at some time in their life (Slade et al 2009). Depression is an independent risk factor for cardiovascular disease in older Australians (Brunner et al 2014, Davidson et al 2001). Increased rates of complications of diabetes (up to fourfold) occur in older adults with both depression and diabetes, and a twofold mortality rate with co-existing myocardial infarction and an anxiety disorder (AIHW 2012a, 2014, Scherrer et al 2010).

Chronic illness is the main cause of disability. The prevalence of disability rises steeply with advancing age. Only about 11% of Australians aged 65–74 were severely disabled in 2009, but that proportion rose to 54% for people aged 85 and over (ABS 2013b). Alzheimer's disease, osteoporosis, heart disease and stroke predominate among the many diseases that cause chronic disability in older age (ABS 2013b). The leading cause of chronic-illness-related deaths in Australia and New Zealand alike is cardiovascular disease (40%). The proportion of deaths attributed to stroke has decreased from 9.6% of deaths in 1998 to 8.0% of deaths in 2010, although there was no such decrease among Indigenous people. Diabetes remains the underlying cause of 6.7% of deaths in Indigenous people, compared with 2.7% of deaths of non-Indigenous people (AIHW 2010). Within the next 20 years, dementia will account for the highest number of chronic diseases in people over 65 years of age (Alzheimer's Australia 2011).

In 2009, 48% of older Australians reported having a disability: 36% of people aged 60–64 years, 48% aged 70–74 years and 88% aged 90 years and over (Australian Indigenous Health Bulletin 2014). In the 60- to 79-years age group, the disability rate is higher among those living alone (49%) than it is for those living with others (40%). For people aged 80 years and above, the disability rates for living alone and with others is the same (68%). For older people living in a non-private dwelling, nearly four-fifths (79%) had a reported disability, with those living in cared accommodation being much more likely to have a disability (97%) (ABS 2012). Thirty-seven per cent of older people (48% for people aged over 85 years) report the need for assistance with at least one activity, including property maintenance (21%), health care (19%) and household chores (16%), because of a chronic-illness-related disability. The fastest growing age group in the population, those aged 85 and over, is also the group most likely to need long-term care for one or more chronic illnesses. Largely because women live longer than men, older people with disabilities are disproportionately very old women (ABS 2013b).

Many older people with one or more chronic illness are susceptible to developing *geriatric syndromes*. These syndromes are a group of connected symptoms with multi-factorial etiology which limit the person's functionality, independence and quality of life. They can include pressure ulcers, incontinence, falls, functional decline, delirium, malnutrition, eating and sleeping problems, dizziness and syncope, and self-neglect. Cognitive deficits, including changed behaviour, combined sensory loss and mal-adaption to changed abilities, distinguish other geriatric syndromes. Cognitive impairment, including confusion and memory loss, is also a side effect of medicines that can cross the blood–brain barrier (e.g. dopamine, glutamate, serotonin and acetylcholine) and those which alter mood (e.g. antihistamines and hypnotics). Concurrent administration of some medicines, such as benzodiazepines and antipsychotics, also reduce certain cognitive abilities (Bushhardt et al 2008).

Since there are multi-factorial causes for geriatric syndromes, each can be defined by isolating shared risk factors (Brown-O'Hara 2013). For example, hypo-mobility syndrome is distinguished by deconditioning and muscular weakness, which can arise from neurological impairment, depression, anxiety and fear of falling, shortness of breath, fatigue, pain, claudication, and environmental obstacles. As the person reduces their movement, atrophy of skeletal muscles occurs, leading to reduced ability to mobilise independently. With total loss of mobility there is a high risk of pressure and venous ulcers, urinary incontinence and constipation. Besides leading to increased mortality and disability, decreased financial and personal resources, and longer hospitalisations, geriatric syndromes can substantially diminish the older person's quality of life.

Impact of chronic illness

Age alone is not the key factor in determining the need for healthcare services, but rather ill-health, a change

in functional capacity and a reduction in informal support networks. It is predicted that nearly two-thirds of the Australian and New Zealand governments' health expenditures will be consumed by people 65 years and older by 2050, generally peaking in the last two years of life (Access Economics 2010, New Zealand Treasury 2013). This represents a 17.1% growth in service need over the past 5 years (ABS 2011). In Australian acute care services alone, people aged 65 years and over accounted for 38% of all hospital admissions and 51% of all inpatient days in 2011, with those aged over 85 years being more than five times as likely to be admitted to hospital, mainly as a result of chronic illness (ABS 2011).

Dementia is the second leading cause of overall burden of disease and the leading cause of disability burden, accounting for one-sixth of the total disability burden in older Australians (AIHW 2012b). People with dementia are at risk of developing diabetes and heart disease, and have a higher risk of sustaining injury from falls. They have higher hospitalisation rates than older Australians without dementia and when admitted for more than an overnight stay, people with dementia need to stay twice as long (18.3 days vs 9.1 days) (AIHW 2012b).

Increasing rates of chronic disease in Australia and New Zealand are, therefore, placing increasing pressure on health expenditure, as well as reduced future labour force participation rates and productivity. Diabetes, for example, is projected to increase from around 5% of the total burden of disease in 2003 to 9% by 2023, primarily due to increasing obesity rates (Access Economics 2010). Current data on the management of chronic diseases indicate that the current health system works best for individuals with specific, time-limited health needs (ABS 2012). Those with more complex needs who require ongoing services and management involving collaboration between health, community and aged care sectors tend to fare worse.

Older people with a chronic illness need access to services in order to maintain their independence, function and wellbeing over the longer term. This increases their chances of remaining at home longer and of avoiding premature admission to residential care and/or re-admission to hospital (ABS 2011). With the incidence of dementia rising, there are profound implications for community nursing provision (de Bruin 2012). Karmel et al (2012) found that timely access to community nursing care could be important in reducing the rate of entry to residential care after hospitalisation for people with dementia. It is essential that people with dementia have access to appropriate mental health and psychogeriatric services to minimise the need for unplanned acute health services, primarily through stronger, better-resourced community-based health care (AIHW 2010).

Without community healthcare support, family carer stress can lead to abuse and/or neglect of the older person (Aged Rights Advocacy Service (ARAS) 2013, Brown-O'Hara 2013, WHO 2008). The impact of chronic illness is known to predispose older people to elder abuse because of their increased likelihood of requiring support with activities of daily living (Collins 2014). Other risk factors include living alone, cognitive impairment, challenging behaviours and substance dependence. According to Age Concern New Zealand (Peri et al 2008), the main forms of elder abuse are:

- physical abuse: physical pain and injury or use of force
- psychological/emotional abuse: behaviours that cause anguish, stress or fear
- financial abuse: exploitation and illegal/unethical use of funds and other resources
- sexual abuse: threats, forced sexual activity or exploitation because of reduced ability to consent.

Unfortunately, those most likely to abuse older people are family members (73%) and friends or neighbours (10%), often because the person being abused is relatively powerless and dependent on them to some degree (Collins 2014). The older person may not complain for fear that the abuse will get worse. An essential aspect of community-based nursing for older adults is recognition of risk factors and the signs of abuse, and to respond and follow up by referring the older person to appropriate agencies to assist, for example, elder abuse and neglect prevention coordinators. Protective factors include supportive family and friends and skilled monitoring by all professionals in contact with the older person.

If nurses are concerned that elder abuse is occurring to an older client, they can access elder abuse support services to discuss their concerns and gain advice on procedures for reporting and obtaining help for the client. In New Zealand, Age Concern's Elder Abuse and Neglect Prevention (EANP) services provide advocacy, consultation and liaison with police, social care and support for more than 2000 referrals for older people who may be facing elder abuse (Collins 2014). The Australian Network for the Prevention of Elder Abuse (ANPEA) and each Australian state and territory provide information about elder abuse, abuse prevention and useful contacts.

There are many challenges that community nursing will need to address in relation to:

- the significant increase in the number of people aged 85 years and over with one or more chronic illnesses over the next few decades (United Nations Population Fund 2010)

- the growing number of older people who require complex care for a chronic illness, including dementia, as well as geriatric syndromes and palliative care
- the relative decline in the availability of informal carers, reducing the ability of some older people to receive home-based care
- the increasing cultural and social diversity among older people in their preferences and expectations, including a greater desire for independent living and culturally relevant care
- the declining community and aged care workforce, and 'age-induced' tightening of the overall labour market, alongside the expected relative decline in family support and informal carers and strong demand for healthcare workers from other parts of the health system
- the growing disparity in available and culturally sensitive health services for rural, remote and urban aged populations, especially for Indigenous older people
- the extent to which communities can support the values associated with ageing in place by enabling healthy, active ageing in an appropriate and supportive environment, including access to effective social and family support, improved lifestyle, enhanced health, affordable housing and housing security.

Evidence-based chronic illness models

When considering the best fit of health service support for older people with a chronic illness, Leutz (1999) divided them into three groups:

- the majority of people with mild to moderate but stable conditions and having high capacity for self-direction and/or strong informal networks who require a select few routine care services
- people with a moderate level of need
- the small percentage of older people with long-term, severe, unstable conditions who frequently require urgent intervention from various sectors and who have limited capacity for self-direction.

Leutz (1999) argued that the first group of people would likely be sufficiently served by relatively simple systematic linkage of different systems, as long as healthcare providers are aware of, and understand how to access, the range of services offered by other providers. The group with moderate health support needs would also operate mainly through existing health and social systems, but would require additional explicit structures and processes to maintain their health and prevent disability. This would require mechanisms for routinely sharing client information and collaborative discharge planning, case management and coordinated care across various sectors. It is the group with long-term, severe, unstable conditions that is likely to benefit most from a high level of service integration of different service domains. A fully integrated system would assume responsibility for all services, resources and funding, which might be subsumed into one managed structure (Leutz 1999).

Kaiser Permanente, a US health-maintenance organisation for older people with chronic illnesses, is a good example of a successfully integrated primary healthcare system which successfully provides three different levels of community health services at different levels of need, such as those described by Leutz (1999) (Bodenheimer et al 2002b). Another influential chronic illness primary healthcare model, also originating in the United States, is the Evercare model, the primary aim of which is to combine preventative and responsive health care for older people at high risk of health deterioration, mainly through case management (Boaden et al 2006). The program uses risk-stratification tools to assess the level of care required and to inform the development of an individualised care plan for older people living in the community, coordinated and monitored by an advanced practice nurse acting as a case manager. The Chronic Care Model (Wagner et al 1999, 2001) aims to provide a comprehensive framework for the organisation of health care for people with chronic conditions via four interacting system components: self-management support, delivery system design, decision support, and clinical information systems. The cornerstone of the productive interactions between the healthcare staff and the person in effectively managing the chronic illness is having an 'informed activated patient' and a 'prepared proactive health team'. The role of nurses in chronic care is pivotal to helping people navigate the health service by being 'informed and activated'.

The Chronic Care Model (Wagner et al 1999, 2001) has been influential in informing chronic-care policies in a number of countries (Glasgow et al 2001). In Australia, the NSW Department of Health has embraced the model, spearheaded by the Greater Metropolitan Clinical Taskforce (GMCT) Aged Care Health Network, a multidisciplinary peak-body advisory group to the director-general of NSW on matters relating to the health care of older people. One of the goals of the GMCT is to make illness prevention 'everybody's business' by strengthening primary healthcare and continuing care in the community, building community-based health partners to improve the healthcare opportunities and

experiences for older people and their families and promoting and evaluating evidence-based chronic illness care models in all health settings.

Meeting the complex needs of an increasing number of older adults with multiple chronic conditions has challenged community-based healthcare teams to offer innovative approaches to integrated, person-centred care. Integrated models of such care are comprehensive, person-oriented, health promoting, strengths-based, do not have a singular disease focus, and address inequity. Innovative models of integrated community-based primary healthcare have been implemented internationally (Beland et al 2006a, 2006b, Hébert et al 2009) and in New Zealand (Parsons et al 2012). These models have demonstrated better health outcomes and reductions in costly and often inappropriate hospital and residential long-term care.

• CRITICAL REFLECTION POINT

Pause here to consider:

1. **In their practice with older people who have chronic conditions, how would nurses help them to become 'informed and activated'?**
2. **What do nurses need to consider if they are to contribute to 'prepared and proactive health teams'?**

The changing scope of community nursing practice

The older person is now the core business of the whole healthcare system for those with rapid-response needs, short-term care needs and chronic disease long-term care needs. Consequently, in meeting these different healthcare needs the range of services provided and/or coordinated in the community include: telehealth; social enterprise; disability care; aged and dementia care and rehabilitation; chronic disease management; personal care and support; palliative care and respite; and specialist consultancies (DSS 2013, Ministry of Health 2001). With the reduced capacity of the acute care sector to meet the demands of older people with a chronic illness, and to reduce risks associated with hospitalisation, the Australian and New Zealand governments fund subacute and post-acute in-home projects for this population group (AIHW 2011a, Ministry of Health 2001). Palliative care in the community is also subsidised for those wishing to die at home, which not only improves care options but also provides palliative-care career pathways for community nurses (Kralik & van Loon 2011, Ministry of Health 2001).

Since the majority of older people choose to 'age in place' at home in the community (DOHA 2012, Ministry of Social Development 2001), the major work of community nurses is the care of older people with one or more chronic illnesses. Community nurses need to employ different strategies to support older people within a range of new services being offered by government and non-government agencies (Ellis et al 2010). In 2009–10, the Australian Government's budget extended access to the Medical Benefit Scheme (MBS) and the Pharmaceutical Benefit Scheme (PBS) for nurse practitioners (NPs). While nurse practitioners make up only a small proportion of the total community-based nursing workforce, this initiative represents a significant step forwards in recognising the knowledge, skills and expertise that nursing brings to the provision of primary healthcare services (Commonwealth of Australia 2009).

The scope of community nursing is expanding to take account of: the nursing context; the nurse's professional education, qualifications and competency levels; client health needs; and service provider policies (Kralik & van Loon 2011). Nevertheless, the community nursing role remains weighted towards community health and wellness, based on primary healthcare principles and their focus on strengthening community reserves (Griffiths 2008) and accommodating the complex factors associated with the older person's and family's life transitions (Heath & Phair 2009). Figure 38-6 illustrates some of the work that community nurses engage in: health-promoting activities that enable the older person to optimise health, wellbeing and independence in later life; curative and rehabilitative dimensions that focus on functional and psychological recovery from illness or injury; facilitating self-care and enabling effective management of chronic conditions; providing care for those who become frail and have limited self-care capacity; and palliative and end-of-life care (Tolson et al 2011). In each of these roles the community nurse, the older person and their carer/support network work as a team, being focused on the older person's needs and self-determined goals, not the nurse's goals (Meltzer et al 2010).

Advanced community nursing

The vignettes below identify the range of services provided by NPs, ones which rely on a great deal of initiative as well as collaboration with other healthcare providers, and culturally sensitive partnerships with health consumers and the community, to provide the very best healthcare services possible with limited resources.

Vignette 1 – a nurse practitioner in rural New Zealand

I see my role first and foremost to empower people in my community to have the best health possible. The most important support for this work comes from developing

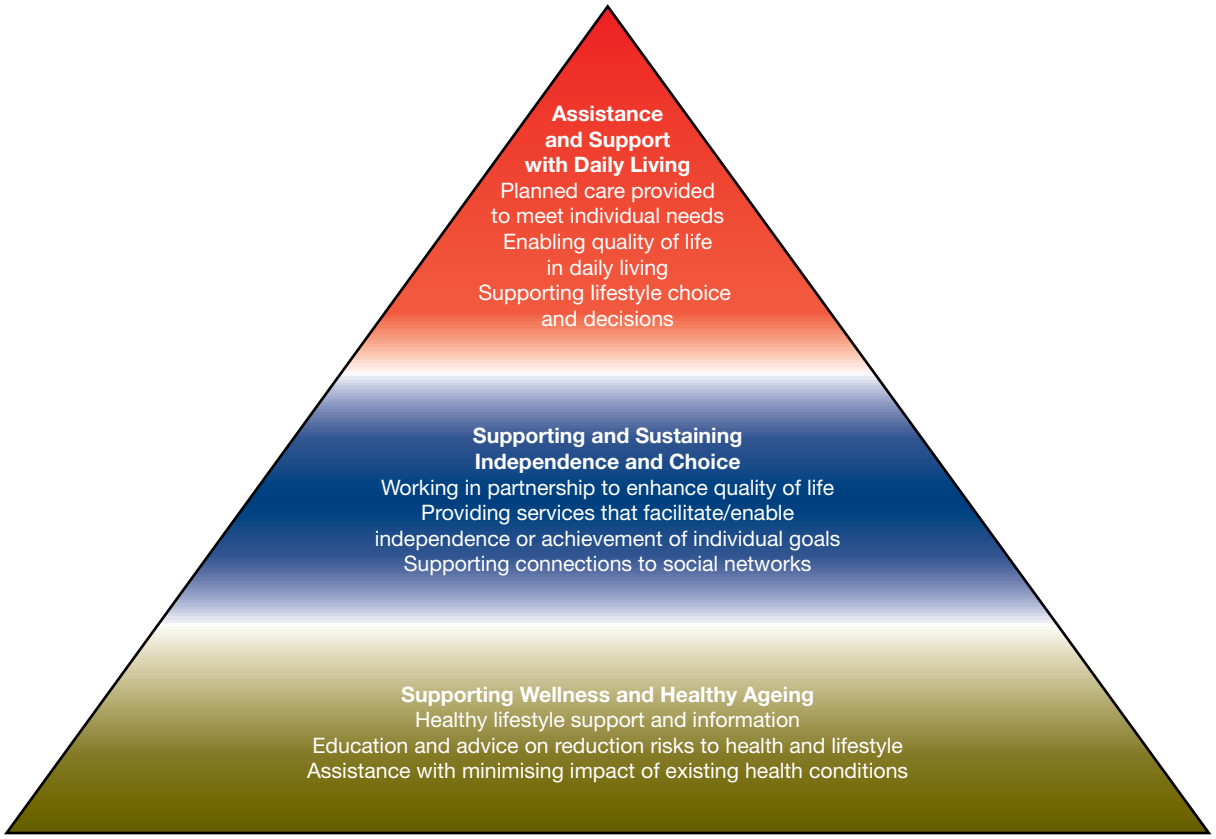

Figure 38-6 **Aspects of community nursing work.**

and maintaining good relationships with others, because they are essential to all aspects of my role – including community outreach clinics, home visits, connecting with people at community meeting places, preschools, seeing patients at medical clinics and as part of a multidisciplinary team. I provide primary healthcare to the whole community with a special focus on reducing health inequity and, as a Māori NP, I have a special connection to our Māori population and familiarity with how traditional values and beliefs influence our lives.

I don't really have a typical day as such, but here is what a day might involve. I would usually begin at 8 am or earlier, depending on how far I have to travel to my first appointment. Before heading off I have lab results to review and follow-up actions from previous patient visits. Usually the morning then involves providing outreach clinics at a medical centre, schools, preschools, community centres, marae [Māori meeting houses] or home visits. I have to be very well prepared for my day ahead to allow for travelling long distances, coping with bad weather that can cause flooding and road damage and being flexible enough to respond to a whole range of health needs I could encounter at any time. My afternoons typically involve more outreach visits into rural communities providing screening for health risks, support for self-management of chronic illness and wellness support for community groups. If I'm not doing outreach, I'll be holding clinics at a medical centre where I see patients, usually individually, for ongoing chronic illness support or with acute health problems. Also, I meet with nurses, either one-to-one for clinical supervision [mentoring] or case management discussions, and consult regularly with GPs for case reviews, advice and clinical supervision. All of this work depends on good communication, established networks and careful planning ahead.

My skills and knowledge have to be broad-based because of the wide age range of people I see, some with multiple health problems and needs. My clinical judgement relies on competent assessment of health needs for individuals and communities, efficient laboratory diagnostic services, access to good evidence for practice and effective collegial relationships, including other healthcare providers, social services and pharmacists. Most of all, though, it is engagement with my community that enables me to empower people to make health gains and to build strong networks across the region that keeps me informed of opportunities to work with groups and individuals and to know how best to support them.

Vignette 2 – an aged care nurse practitioner in urban Australia

I have been working as a nurse practitioner, aged care (cognition) within the metropolitan region for the ARV Retirement Villages for the last 5 years. ARV has approximately 5000 clients spread across all regions of central and wider Sydney, living in the general community receiving 'care packages', in independent living units or within 19 residential aged care facilities. My initial brief was to develop an organisational strategy that would address the growing incidence of dementia. The key elements included raising awareness of dementia, reducing the stigma, highlighting risk factors, promoting better health strategies, achieving early identification, supporting care and enhancing staff skills. In order to do this, we established our service, known as BrightMinds©, which initially consisted of two pilot sites. Since starting, the service has grown and is now an organisational-wide strategy, with an additional clinical nurse consultant (CNC) and clinical nurse specialist (CNS) to assist with service delivery.

My usual day includes not only team support, which can be direct, online or over the phone, but also direct clinical consultations. Those experiencing difficulty with memory, their families, friends, staff, community groups, or other healthcare professionals, frequently call upon our services. A clinical consultation includes compiling a detailed health and lifestyle history, reviewing pathology and medication and completing cognitive testing. Dependent on the outcome, liaising with the GP and often a specialist is required to facilitate access to first-line treatment, which usually includes acetyl cholinesterase inhibitors. As an NP working in cognition, I am constantly searching for underlying causes of cognitive decline, and it is rewarding to find a reversible delirium or a treatable depression, and know you have made a difference. When it is dementia I can still help, sometimes with practical tips, carer support or advice regarding treatment regimens. Most weeks involve presenting to a forum or group to discuss recent advances in research, novel treatment options or behavioural interventions. It is an exciting role that is continuing to grow and offers new and exciting opportunities, particularly in the field of research. Hopefully, we will have a major breakthrough soon, and our team is ready and prepared for paving the way.

Competencies for community nursing

While the competencies of all nurses are consistent, no matter where they work, the roles of nurses in community settings overlap, and are different from, the roles of nurses in acute secondary care settings. The most outstanding difference of community nursing is the focus on populations as clients, rather than individuals, which requires additional skills in population-focused interventions (Bigbee & Issel 2012). In shifting towards population-based practice, primary healthcare nursing emphasises the social determinants of health, focuses on primary prevention and health promotion, and addresses social injustice (Marmot & Allen 2014, Bigbee & Issel 2012). Primary healthcare nursing in New Zealand aims to reduce health and social inequity, in particular for Māori, Pacific peoples and other underserved populations, by adopting a population health approach (Sheridan et al 2009). Promoting health behaviours can sometimes require the community nurse to help the person and their carer to overcome barriers arising from the person's social situation, such as low social opportunities and levels of emotional support and poor access to some health services. In planning support services, the community nurse needs to consider the person's educational and employment backgrounds, their income availability, food supplies and access to social services (National Ageing Research Institute 2006). These issues are particularly relevant in community nursing support for Australian Indigenous people. It is, therefore, essential that the community nurse appreciates the client's and family's unique needs and circumstances, and is competent in all dealings with individuals and groups requiring their support (Garside & Nhemachena 2013, King et al 2012).

The WHO (WHO 2010a) has proposed that nurses need to change the discourse of clinical practice, so that public health and promoting health are central to their practice. The gains to individuals, society and national budgets will be immense with such changes, because a recalibration of nursing clinical practice has the potential to achieve

> **… fewer disabilities and loss of functional ability associated with diseases of old age; more people participating actively as they age in all aspects of society including paid and unpaid roles and in their families and in social, political and cultural life; and more people experiencing a high quality life as they age (WHO 2010a).**

Changes in community nursing practice as described above will be the most effective way of achieving lower costs related to health care, because it will minimise the need for medical treatments and hospital stays and social care to meet dependency needs.

As advocates of public health, **community nurse competencies** need to occur at three levels: the healthcare system; the health organisation and services; and the client

and family carer/support network (Australian Nursing Federation 2009). Capturing the complexity of practice in this setting was the catalyst for a large project in Minnesota (USA) that produced the Wheel of Public Health Nursing Interventions (the Wheel) (Keller et al 2004, Minnesota Department of Health 2001). In the United States, nursing that takes place in the community is known as public health nursing, which in Australia and New Zealand would be known as primary healthcare nursing, district nursing or community nursing. The Wheel model specifies the key interventions that community-based nurses generally use at the individual and family, community or systems levels. The Wheel has been identified as one of the primary conceptual models for public health nursing in the United States (Bigbee & Issel 2012), and has been found useful in an Australian setting (Woods 2010), in Ireland (McDonald et al 2015) and as an overarching framework for primary healthcare nursing in New Zealand (Sheridan 2005).

TABLE 38-2 Definitions of 17 public health interventions

Intervention	Definition
Surveillance	Describes and monitors health events through ongoing and systematic collection, analysis and interpretation of health data for planning, implementing and evaluating public health interventions
Disease and health event investigation	Systematically gathers and analyses data regarding threats to the health of populations, ascertains the source of the threat, identifies cases and others at risk, and determines control measures
Outreach	Locates populations-of-interest or populations-at-risk and provides information about the nature of the concern, what can be done about it, and how services can be obtained
Screening	Identifies individuals with unrecognised health risk factors or asymptomatic disease conditions in populations
Case-finding	Locates individuals and families with identified risk factors and connects them with resources
Referral and follow-up	Assists individuals, families, groups, organisations and/or communities to identify and access necessary resources to prevent or resolve problems or concerns
Case management	Optimises self-care capabilities of individuals and families and the capacity of systems and communities to coordinate and provide services
Delegated functions	Direct care tasks that a registered professional nurse carries out under the authority of a healthcare practitioner as allowed by law. Delegated functions also include direct care tasks entrusted by a registered nurse to be performed by other appropriate personnel
Health teaching	Communicates facts, ideas and skills that change knowledge, attitudes, values, beliefs, behaviours and the practices of individuals/families, systems, communities
Counselling	Establishes an interpersonal relationship with a community, a system, family or individual intended to increase or enhance their capacity for self-care and coping. Counselling engages the community, system, family or individual at an emotional level
Consultation	Seeks information and generates optional solutions to perceived problems or issues through interactive problem-solving with a community, system, family or individual. The community, system, family or individual selects and acts on the option best meeting the circumstances
Collaboration	Commits two or more persons or organisations to achieve a common goal through enhancing the capacity of one or more of the members to promote and protect health
Coalition building	Promotes and develops alliances among organisations or constituencies for a common purpose. It builds linkages, solves problems and enhances local leadership to address health concerns
Community organising	Helps community groups to identify common problems or goals, mobilise resources, and develop and implement strategies for reaching the goals they have agreed upon
Advocacy	Pleads someone's cause or acts on someone's behalf, with a focus on developing the community, system, individual or family's capacity to plead their own cause or act on their own behalf
Social marketing	Utilises commercial marketing principles and technologies for programs designed to influence the knowledge, attitudes, values, beliefs, behaviours and practices of the population-of-interest
Policy development and enforcement	Places health issues on decision-makers' agendas, acquires a plan of resolution, and determines resources. Policy development results in laws, rules, regulations, ordinances and policies. Policy enforcement compels others to comply with the laws, rules, regulations, ordinances and policies

Keller L et al 2004 Population-based public health interventions: practice-based and evidence-supported, Part 1. Public Health Nurs 21(5):453–68.

The Wheel represents a range of interventions, three levels of practice (individual and family, community, and systems), and the population health foundations characteristic of primary healthcare. Population-based practice is determined by five criteria: focusing on entire populations (with no limits or restrictions); informed by community health assessment (to identify risk factors, protective factors, and assets that impact health status, so that priorities are needs-based, and interventions are planned, implemented and evaluated); addressing determinants of health, such as income, poverty, education, housing, culture, and ethnicity (that impact health status); emphasising all levels of prevention, in particular primary prevention, promoting health and preventing problems before they occur; and directed at all levels of practice, often simultaneously (entire communities, a whole health system and/or individuals and families within populations known to be at risk) (Keller et al 2002, 2004).

Each of the interventions (surveillance, disease and health event investigation, outreach, screening, case-finding, referral and follow-up, case management, delegated functions, health teaching, counselling, consultation, collaboration, coalition building, community organising, advocacy, social marketing, policy development and enforcement) can be implemented at all three levels, with the exceptions of case finding, which occurs only at the individual level, and coalition building and community organising, which occurs only at the community and systems levels. Related interventions are grouped into 'wedges' and the sequencing reflects their relationship (Figure 38-7); surveillance is located at the top of the Wheel because it is where most public health work begins (Keller et al 2002, 2004).

The 17 interventions contribute to the overall goal of improving population health status at all three levels. Population-based practice aimed at individuals and families intends to change knowledge, attitudes, beliefs, practices, and the behaviours of individuals. However, interventions aimed at communities and systems can be a more effective and sustainable way of impacting population health (Keller et al 2002). At the community level, interventions can be aimed at all members or a specific group and success is measured in terms of changes

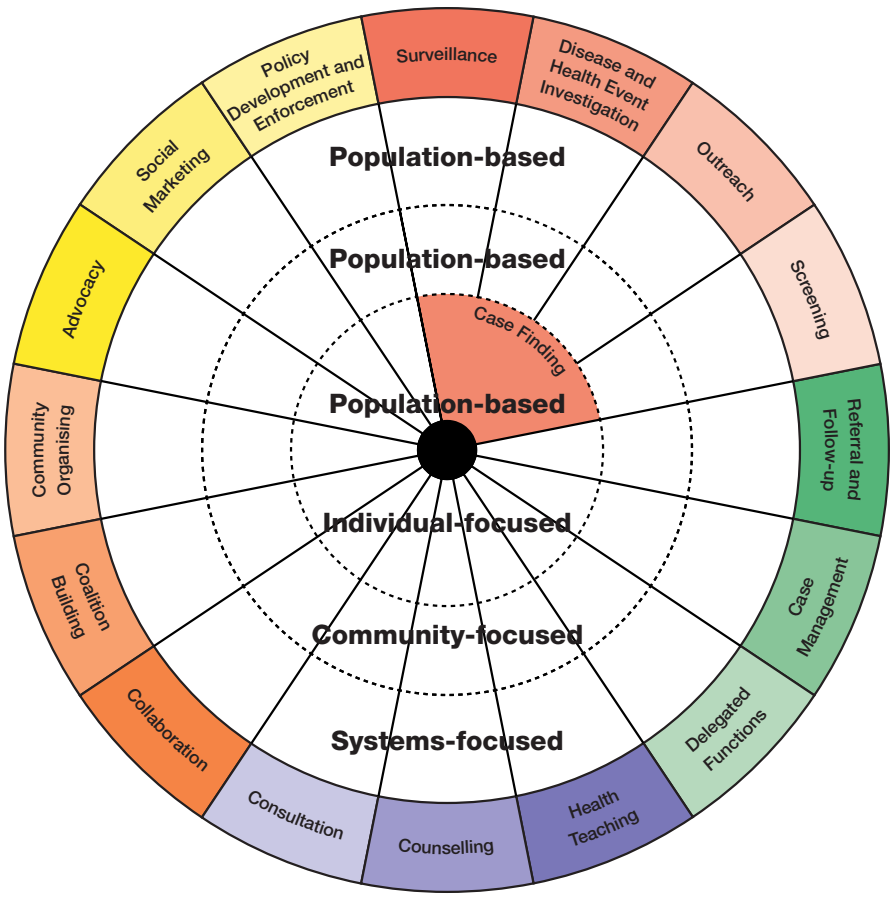

Figure 38-7 The Public Health Interventions Wheel.

Public Health Nursing Section: Public Health Interventions – Applications for Public Health Nursing Practice. St. Paul: Minnesota Department of Health, 2001.

in health status, community awareness, and community attitudes and behaviours.

• CRITICAL REFLECTION POINT

Thinking about primary healthcare nursing work, take an example of community-based care for older adults and consider each of the 17 public health interventions in turn. Can you identify a) the interventions that were being employed in your practice example? and b) the level at which the interventions were being used?

Cultural competence

As population mobility has increased the cultural diversity of populations worldwide, healthcare services have been more aware of the need to employ culturally competent staff (Omeri & Raymond 2009). Nurses work with people who hold a variety of beliefs about health, illness and treatment and who will also have different thresholds for seeking health care in older age (Chomik & MacLennan 2014b). Even though health outcomes research has been lacking in this respect, education for cultural competence in healthcare staff is expected to reduce health disparities and improve healthcare effectiveness (Callister 2005). From a Māori client's point of view, health care that has been designed to be culturally appropriate, affordable and accessible gains a high level of client satisfaction (Maniapoto & Gribben 2003). Cultural competence is vitally important in primary healthcare and has special meaning in New Zealand in light of the Treaty of Waitangi and health inequity for Māori.

Primary healthcare involves effective and meaningful relationships between clients/families and clinicians which are reliant on cultural competence. Clients judge the extent to which health care is culturally safe, based on individual experiences. Nurses are at the front-line of primary healthcare where cultural safety is pivotal to clients' experience of health care (Wilson & Grant 2008). The Treaty of Waitangi acknowledges the special status of Māori in New Zealand and is embedded into health law, whereby culturally safe care is required to be consistent with the principles of partnership, participation and protection. The application of partnership, participation and protection in health care requires the knowledge, skills and attitudes of cultural safety. Cultural safety denounces the uncritical aggregation of clients of similar cultures into groups with common values, customs, beliefs and behaviours (Carrillo et al 1999). Culturally safe nursing practice is informed by an analysis of the politics inherent in the systematic mechanisms of marginalisation, poverty and inequity for different community groups (Ramsden 2002).

Providing culturally safe health care is particularly relevant for the many individuals who access the Australian primary healthcare system, which services more than 200 different cultural and language health populations (ABS 2012), and for the growing number of international refugees living in Australia. This is an area requiring considerable improvement in the broad spectrum of Australian health services. Culturally competent nursing care is similarly essential in the care of older Indigenous Australians, given the unique needs and circumstances of the many hundreds of Indigenous nations, with their own languages, cultural mores and community structures. Developing nursing services that are attuned to local Indigenous circumstances and customs will demand more than simply enabling access to the full spectrum of health interventions; it requires nurses to work effectively with an expanded Indigenous workforce (Congress of Aboriginal and Torres Strait Islander Nurses (CATSIN) 2013). Culturally sensitive Indigenous nursing services require broad, health-affirming approaches which are attuned to the circumstances and priorities of each community, initiatives that support empowerment at individual, family and community levels, and the willingness of nurses to recognise and challenge underlying social disadvantage and injustice experienced by their Indigenous clients and families (Hunter 2007, Omeri & Raymond 2009).

• CRITICAL REFLECTION POINT

Work with a learning partner to consider what is meant by 'effective and meaningful relationships between client/families and clinicians that are reliant on cultural competence'.

1. **Who is the best judge of cultural competence?**
2. **How would a nurse know how culturally safe a client felt as a result of their healthcare experience?**

Nursing competencies for integrated care

Wolff and Boult (2005) have identified nine components that constitute a comprehensive system of community care service, one that is ideally suited to the community nurse role. This system includes: client and carer evaluation; individual care planning; evidence-based decision-making; consumer empowerment through joint decision-making; promotion of healthy lifestyles; coordination across multiple conditions, coordination across provider settings, carer support and education; and facilitating consumer access to health resources. In order to fulfil this comprehensive role, community nurses must arm themselves with the right sets of knowledge and skills.

Community nurses must be able to coordinate services at the micro level (nurses, other healthcare staff and client/carer), meso level (services and organisations) and macro level (healthcare system) (Davies et al 2006). Across these levels, the nurse must focus on processes to facilitate coordination (e.g. communication strategies, support for service providers and consumers) and focus on building structures for coordinating activities (e.g. shared information systems, referral proforma, care plans and decision support systems) (Rosenthal et al 2006). A proven strategy for improving client and carer outcomes involves strengthening the relationships between the community service, GP services and acute care services, and employing a shared client care plan and records tools to actively support coordination (Davies et al 2006).

As previously identified, the community nurse must recognise the broader context of health from one that focuses on the biological cause of illness, to one that enables the older person and their family/support networks to become actively involved in a range of health maintenance processes. This requires the nurse to have excellent assessment skills and a high capacity for communicating knowledge across the healthcare continuum. This will be especially important when needing to negotiate competing value systems in the provision of professional, equitable and ethical care to members of different generations, multiple cultures and broadly ranging socioeconomic backgrounds (CATSIN 2013, National Ageing Research Institute 2006).

Having a good knowledge of the available range of community-based services and developing effective partnerships with healthcare consumers and service providers is required for a number of key community nursing roles. These roles include: referral procedures; brokering services for older persons and carers; providing short- and long-term case management; and working with the older person and their carer to develop care plans aimed at self-management. Partner services will include mental health, ageing, palliative and disability services; continence, wound and stoma care services; drug, alcohol and sexual health services; carer respite and community support services; and specialist treatment services (Kralik & van Loon 2011).

In order to provide safe and effective care, the community nurse requires a good working knowledge of the unique healthcare changes experienced by the older person and the impact of these on the person's physical, psychological and social functioning. In the first instance the nurse must learn to recognise and pay attention to the key features of altered clinical presentation that can occur in the older person, such as the disease, multiple pathology, frailty, geriatric syndromes and cascading responses to physical, social or emotional factors that can lead to severe illness or even death (National Ageing Research Institute 2006). Common, potentially serious and debilitating conditions in older age, such as delirium, falls, pain, urinary incontinence and constipation, low body mass index and sensory impairment are examples of geriatric syndromes that lead to poor outcomes (Tolson et al 2011). These syndromes are indicative of a change in health status, but frequently do not represent the specific disease condition/s causing that change.

For this reason the community nurse requires an advanced knowledge to identify the 'atypical' signs of illness that are complicated by multiple pathology in the older person and even conditions that are relatively minor but debilitating, such as painful feet. Unless the community nurse pays attention to these early signs of illness, they can have a cumulative effect on the older person's overall condition, to the extent that the person can rapidly lose functional and cognitive capacity (Edvardsson & Nay 2009). As well, the community nurse must acknowledge that for each separate condition the older person might be prescribed different medicines. The resulting polypharmacy can lead to toxic drug reactions and interactions, which can lead to further loss of functional and cognitive capacity (Tolson et al 2011).

The Hartford Institute for Geriatric Nursing website offers many educational resources to assist nurses in developing a strengths-based plan of care for older people with complex health issues (Brown-O'Hara 2013). Evidence-based care protocols have been developed by Care Excellence for Seniors (ACES) in partnership with the National League for Nursing (NLN) and the Community College of Philadelphia with funding from the John A. Hartford Foundation, Laerdal Medical, and the Independence Foundation, USA. The website introduces ACES as essential nursing actions to improve quality of life for older adults, coordinate care, decrease caregiver stress, and promote shared decision-making (see *Online resources*).

Given the complex factors involved in chronic illness prevention, assessment and management, the community nurse has a major role to play in assessing the health risks of their older clients, helping them to develop self-efficacy (confidence) for self-management (Chenoweth et al 2015), while supporting the older person's dignity, autonomy and quality of life. This can be facilitated by providing education and supervision in self-management support and treatments, helping the person to set self-care goals and helping them to gain support from others with similar chronic illnesses through links to support and self-help groups (Wertenberger et al 2006).

In this respect the community nurse must provide strong leadership in pursuing a strengths-based approach to their practice, where the emphasis is on fostering confidence in self-management; building trust and positive relationships between the person, their support network and the nurse; facilitating the older person's and their carer's access to relevant services; and using evidence to inform the health consumer, rather than to control them (WHO 2010a, 2010b). The leadership qualities of an effective community nurse cover four main domains: personal values and character traits; responses and actions befitting a respected leader; high-level tacit and applied knowledge; and client-/colleague-centred professional behaviour (Kralik & van Loon 2011). Such leadership qualities are values-based, visionary, creative and inspiring (Stanley 2006).

• CRITICAL REFLECTION POINT

Discuss with a learning partner what you would consider to be positive indicators of these four domains of nursing leadership:

- **personal values and character traits**
- **responses and actions befitting a respected leader**
- **high-level tacit and applied knowledge**
- **client-/colleague-centred professional behaviour.**

Quality community nursing services for older people

Challenges for community nurses

The challenge for community nurses is how to support positive healthcare outcomes for older people within a resource-pressured healthcare system. Community nurses need to reconceptualise the way they provide care for older people who generally have one or more chronic illnesses and/or a geriatric syndrome, with high health service needs and expectations. As previously identified, policies aimed at shorter hospital episodes of care, including an increasing number of day-surgery procedures, means that at discharge older people require greater and more-complex care from community nurses (AIHW 2011c). In addition, some treatment and nursing care that has traditionally been provided in a hospital setting for people with a chronic illness is increasingly being provided in the community (e.g. dialysis and chemotherapy). Other factors over the last two decades, such as changes to mental health services, have increased the demand on community nursing services to support people with complex health needs (WHO 2010a).

Growing knowledge of what constitutes best-practice care, at both the consumer and the healthcare provider level, combined with new technologies that can change the way services are provided, have meant that expectations regarding health and the healthcare system have risen. Consumer demand is having more impact than ever on the community healthcare sector (AIHW 2011a, Ministry of Health 2004). Australian and New Zealand governments are grappling with how best to address these growing consumer needs and demands.

Given the projected health expenditure trends associated with population ageing, an important goal for healthcare reform in both countries is the long-term financial sustainability of a comprehensive primary healthcare system. One noticeable impact on community healthcare services is the ageing of the healthcare workforce, including nurses, and an exponential rise in retirement numbers in recent years. The average age of people employed in healthcare occupations in 2012 was 45 years, three years older than other people in the workforce (ABS 2012). Combined with rising consumer need and expectations, the loss of experienced nurses from the workforce leads to growing pressure on existing services, and leaves more healthcare consumers with gaps in care.

Older people with one or more chronic illnesses can miss out on necessary community care in a complex and fragmented healthcare system where access depends on the availability of services, the geographical location of suitable services and an individual's level of health insurance cover and ability to pay for services (Commonwealth of Australia 2009, Ministry of Health 2003). In some respects, fragmentation in health service provision occurs because of the variety of funding mechanisms and lack of integration, coordination and collaboration between different healthcare systems, including community nursing and acute care nursing services (Grealish et al 2013). As well, the traditional organisation of community-based health care, which separates general practice medical care and more-specialised health services, does not always meet healthcare consumer needs (Gray et al 2012).

Diabetes, for example, has been identified as a typical condition that requires the services of a wide range of healthcare practitioners, such as GPs, nurses, diabetes educators and specialist health staff such as podiatrists, endocrinologists, dietitians, nephrologists, neurologists, pharmacists and cardiologists (Lorig et al 2001). All these services are needed to ensure the best possible health outcomes for the person with diabetes; however, the person may not have access to all these services, especially in rural and remote areas, and health service providers may not be aware of the scope and range of services the person is accessing (AIHW 2011c).

Similarly, effective support for people living with dementia must include a range of community-based services: health care; family counselling and education; home support; respite care; and specialist services. This need is highlighted in people with younger-onset dementia, which occurs in an estimated 16,000 people under the age of 65 years, approximately 6.2% of the total population with dementia (Alzheimer's Australia 2011). Children of people with younger-onset dementia may be at greater risk as the family tries to cope with the condition, and relationships come under stress. Community-based support, education, respite and psychological services, therefore, need to be available for children and teenagers to help them cope with the effect of dementia on their parent (Alzheimer's Australia 2011).

The weaknesses of the current primary healthcare system affect not only older healthcare consumers through delays in care assessments and subsequent limits on the number of care packages and community nursing services available to them, but also on the work of community nurses, especially during times of staff shortages (Grealish et al 2013, National Health and Hospitals Reform Commission 2009).

Overcoming community nursing challenges

In Australia and New Zealand a number of strategies have been implemented to increase the quality of community health services, including using the healthcare workforce more effectively and broadening the current roles and responsibilities of this workforce (Finlayson et al 2009, Nepal et al 2011). Increasing the roles and responsibilities of the community nurse workforce, such as through NPs and practice nurses, provides opportunities for new models of care and collaborative partnerships (Australian Nursing Federation 2009). Improved collaboration among nurses and other healthcare professionals has required a reduction/eradication of some structural barriers, such as legislating for NP-authorised medicines and repeat prescriptions. This strategy has freed up resources, enabling more effective service delivery within the community sector. As well, community nurses have been employed in alternative primary healthcare service delivery models for older people with chronic illnesses, such as 'hub and spoke' arrangements and the 'Healthdirect' inbound/outbound call centre networks in Australia (Commonwealth of Australia 2009) and Care Plus in New Zealand (Ministry of Health 2004).

To address some of the health challenges associated with the ageing population, increasing numbers of people with chronic illnesses and reduced numbers of skilled healthcare workers, the 2010 report *Primary health care (now more than ever)* (WHO 2010a) calls for a return to primary healthcare to help align healthcare systems to deliver better performance, efficiency and equity. The report found that where countries at the same level of economic development were compared, those that were organised around the tenets of primary healthcare produced a higher level of population health for the same investment, in light of the growing burden of disease associated with chronic illness. Well-coordinated primary healthcare systems are also more efficient, have lower rates of hospitalisation and reduced lengths of hospital stay, fewer health inequalities and better health outcomes, including lower mortality, than those that do not, especially for managing chronic illness care (Gray et al 2012, WHO 2010b). Increasingly, there is also recognition that strengthening and improving the way in which community health care is provided is vital in determining how well the healthcare system responds to current and emerging pressures (Frenk 2011, Meltzer et al 2010, WHO 2010a).

However, increasing the level and scope of community-based health services will require a shift in current healthcare workforce allocations and reorientation of staff towards primary healthcare. The primary healthcare model will require greater partnerships between community nurses, healthcare consumers and other community-based services to manage the risks, symptoms and impacts of chronic disease, rather than focusing mainly on treatment of chronic conditions (Garside & Nhemachena 2013, Swerissen & Taylor 2008, WHO 2010b).

Summary

This chapter has emphasised that health care for older people is one of the major challenges facing nursing and other healthcare services now, and will be even greater in the future. The changes we can expect in the older population profiles of Australia and New Zealand over the next few decades will place health care for older people centre-stage, not only for healthcare funders and service providers, but also for community-based nursing services. Operating from a strengths-based approach to nursing care will require innovative, high-quality support and collaboration with the healthcare team and a range of support agencies, so that older people are able to exercise lifestyle choices that best suit their needs. Nursing roles and competencies that best support community-based care and older person health have been presented for critique, and learning exercises have been included throughout to develop critical thinking. The various knowledge bases and competencies required for nursing in the community were explored and have revealed both the rewards and the

challenges of this work. Primary healthcare, community-based nursing and the health care of older people are areas of specialty practice that have steadily grown in scope and are well recognised for the opportunities they offer for nurses to make a real contribution to health gains for what is becoming an even larger proportion of the population.

Key concepts

- Primary healthcare refers to healthcare services that are provided outside the hospital. Modern-day primary healthcare has its origins in the global primary healthcare strategy conceived by nations attending the WHO conference at Alma-Ata in South Eastern Russia in 1978, where they collectively called for 'Health for all by the year 2000' and vowed to embrace the principles of the Declaration of Alma-Ata: health as a basic human right; inequity as politically, socially and economically unacceptable; and health as a reflection of the social and economic conditions affecting people's lives.
- The health–illness continuum illustrates the process of change, in which individuals experience various states of health and illness (ranging from extremely good health to death) that fluctuate day to day and throughout their lives.
- Health equity is the absence of differences in health between groups with differential exposure to those social and economic policies and practices that create barriers to opportunity.
- The social determinants of health are the conditions in which people are born, grow, live, work and age, and receive services, including healthcare systems. Conditions across these domains are shaped by the distribution of money, power and resources, which are influenced by global, national and local policies. The social determinants of health are mostly responsible for health inequities – the unfair and avoidable differences in health status.
- Older person health refers to the relationship between increasing age and long-term health conditions, higher rates of disability and poorer reported health status. Population ageing, and the health of older people, is likely to have impacts on the overall health status of Australian and New Zealand communities.
- The role of local, state and national government agencies is to deliver programs and services that build the health and wellbeing of our community.
- Community-based nursing takes place where the clients live, work and play. It may be a school, work site or home; no matter where it is, however, the nursing care provided is individualised to suit the client and their family, and has a population health focus.

CHAPTER

39

Working in acute care environments

Nicole M Phillips and Debbie Massey

KEY TERMS

Acute care, p. 1421
Acute-on-chronic, p. 1421
Antiembolism stockings, p. 1449
Atelectasis, p. 1432
Clinical deterioration, p. 1422
Coughing exercises, p. 1439
Deep vein thrombosis (DVT), p. 1437
Diaphragmatic breathing, p. 1439
Leg exercises, p. 1445
Paralytic ileus, p. 1457
Post-anaesthetic care unit (PACU), p. 1452
Postoperative, p. 1452
Preoperative education, p. 1437
Same-day surgery, p. 1435
Surgical site infection (SSI), p. 1448
Venous thromboembolism (VTE), p. 1439

Learning outcomes

Mastery of content will enable you to:

- identify reasons for a patient being admitted to the acute care environment
- explain the acute care nurse's role in keeping patients safe, including patient identification and procedure matching, recognising and responding to patient deterioration, and providing a safe clinical handover
- perform a preoperative assessment of a surgical patient
- demonstrate postoperative exercises: diaphragmatic breathing, coughing, turning and leg exercises
- discuss the interventions to prevent venous thromboembolism in medical and surgical patients in the acute care setting
- prepare a patient for surgery
- explain the rationale for specific nursing interventions designed to prevent postoperative complications
- identify specific evaluation criteria to determine the effectiveness of postoperative nursing care.

Introduction

The World Health Organization (WHO) acknowledges that as populations continue to grow and age, there will be increasing demand for acute curative services (Hirshon et al 2013). This chapter will focus on the specific knowledge and skills required of nurses in general acute care settings. Discussion of advanced practice areas within the acute care setting, such as the intensive care unit (ICU), coronary care unit (CCU) and operating theatre (OT), are beyond the scope of this chapter. These are areas where specialty nursing knowledge and skill are demanded. In this chapter, we draw on WHO to define acute care. Second, we explore the role of the nurse in establishing and maintaining patient safety in the acute care setting. The clinical reasoning process (see Chapter 4) then provides a framework to discuss the nursing management of an acute care patient.

Defining acute care

Acute care nursing is complex and challenging. Working in an acute care setting requires: multidisciplinary teamwork; effective and therapeutic communication and collaboration with the patient and their family/significant others; accurate assessment; problem identification, implementation of priority nursing interventions and the ability to evaluate their effectiveness; and advocacy for the patient and their significant others. **Acute care** can be defined as 'the health system components, or care delivery platforms, used to treat sudden, often unexpected, urgent or emergent episodes of injury and illness that can lead to death or disability without rapid intervention' (Hirshon et al 2013:386). Acute care is a broad term that encompasses a range of clinical healthcare domains (Figure 39-1), including emergency medicine, trauma care, pre-hospital emergency care, acute care surgery, critical care, urgent care and short-term inpatient stabilisation (Hirshon et al 2013).

Acute care encompasses public or private acute hospital settings, large teaching hospitals and smaller ambulatory-care facilities. A person may enter the acute care setting due to a medical illness, need for surgery or for diagnostic purposes. Persons may be admitted to an acute care setting for a variety of reasons: an emergency or unplanned admission (e.g. injured in a car accident, chest pain, loss of consciousness), for elective planned surgery or treatment (e.g. total hip replacement, chemotherapy, day surgery), for review (e.g. in outpatients) or for ongoing treatment in their own home (hospital in the home). Many persons in the acute setting have complex illnesses and are seriously ill. They may be treated in the emergency department (ED), a medical or surgical unit,

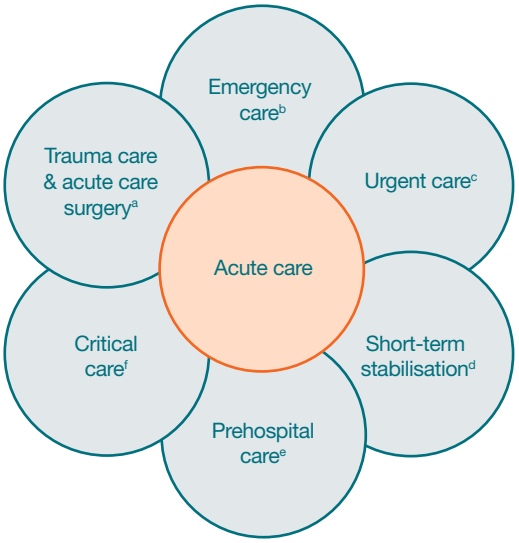

Figure 39-1 Domains in acute care.

Hirshon JM et al 2013 Health systems and services: The role of acute care. Bulletin of the World Health Organization 91:386–88.

a day-care or short-stay unit or an ICU. Large public and private hospitals have specialised medical and surgical units, such as a respiratory unit or cardiac unit, while smaller hospitals tend to have more generalised medical and surgical units. Although the specific acute care setting may differ, the fundamental knowledge and skills required of RNs practising in acute areas in Australia and New Zealand are transferable.

A person may be admitted for an acute medical reason, or for treatment of an **acute-on-chronic** condition (see Figure 39-2). An acute illness is generally recognised to be an illness that lasts for less than 3 months. For example, an older person admitted with pneumonia or a teenager having an appendicectomy (removal of the appendix) would be considered to have an acute illness. In contrast, a chronic illness is one that lasts for more than 3 months (e.g. asthma, emphysema, diabetes). When a person is admitted with an exacerbation of a chronic illness this is referred to as an acute-on-chronic admission. An exacerbation refers to an increase in severity of the signs and symptoms of a disease or the worsening of a disease (e.g. acute exacerbation of chronic obstructive pulmonary disease). The condition has worsened to the extent that it requires clinical management in the acute care setting.

• CRITICAL REFLECTION POINT

Reflect on the reasons people you have cared for were admitted to an acute care setting. Was it for surgical, medical or diagnostic purposes? Make a judgement as to whether each individual's admission was due to an acute, chronic or acute-on-chronic health problem.

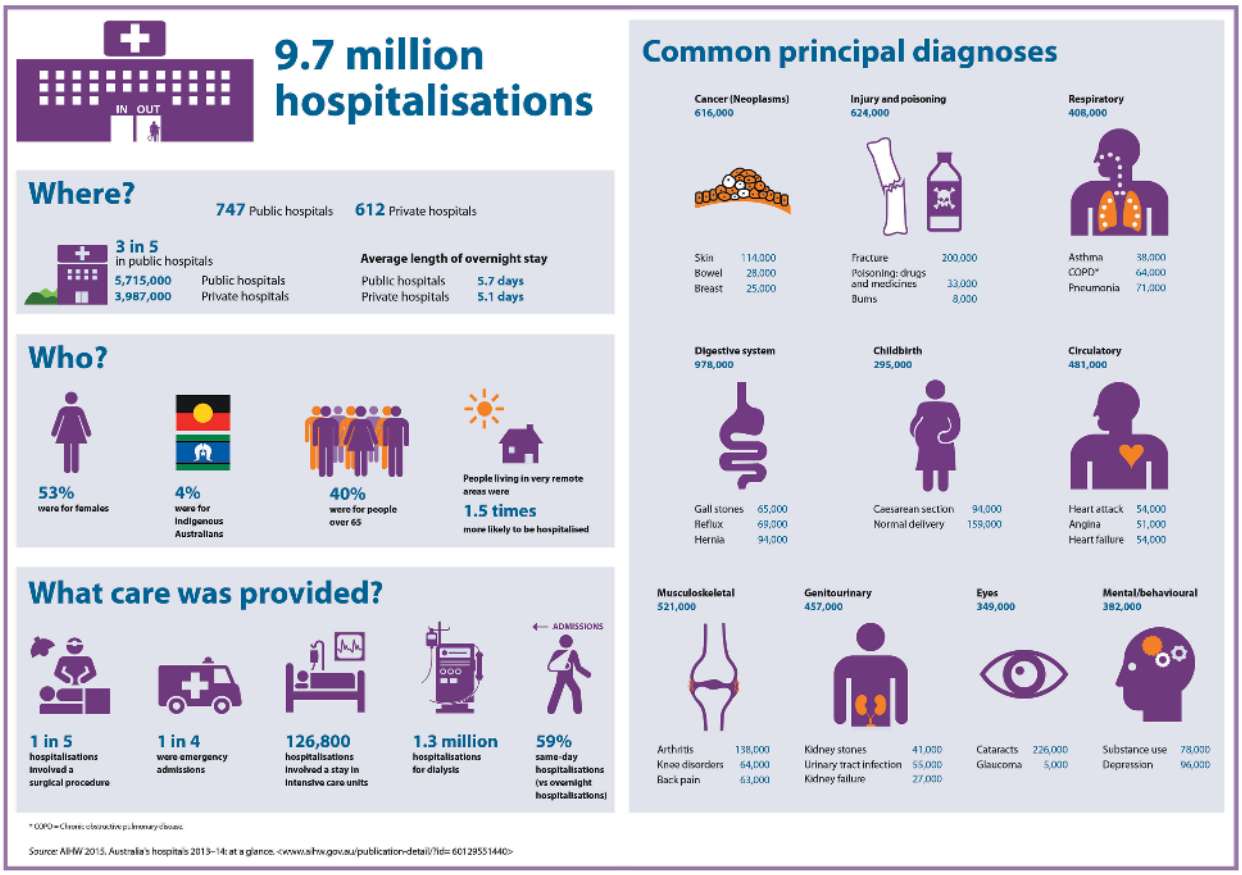

Figure 39-2 **Australian hospitalisation data infographic.**

AIHW, 2015. Available: www.aihw.gov.au/WorkArea/DownloadAsset.aspx?id=60129551486.

Promoting patient safety in the acute care setting

Recognising and responding to patient deterioration

Acute hospitals have an increasing number of patients with complex or high acuity care needs, who are at risk of **clinical deterioration**. Technological developments, an ageing population and economic rationalisation are all factors contributing to increasing *patient acuity* on hospital wards. Several studies have demonstrated that patients who deteriorate on hospital wards exhibit early signs of physical decline many hours before clinical deterioration (Bingham et al 2015). Failure to recognise and respond to patients at risk of clinical deterioration contributes to negative patient outcomes (Massey et al 2014). Delays in care may be explained by a number of factors. For example, clinical staff may lack the knowledge and skills required to safely and effectively manage the deteriorating patient; they may not have access to the appropriate resources; there may be inefficient systems for accessing appropriate help and support; or there may be a lack of appropriate supervision. Whatever the reasons, failure to recognise and respond to patient deterioration care can have devastating consequences: it may lead to death, increased length of hospital stay; or decreased quality of life, together with a significant increase in healthcare costs (Aranaz-Andres et al 2011, Jha et al 2013).

In response to this recognised threat to safe high-quality care, a number of safety systems have been developed and implemented. The most well known is the rapid response system (RRS). An RRS is a safety initiative aimed at improving the care and management of the deteriorating patient in an acute ward (Massey et al 2010). An RRS provides a safety net for patients who deteriorate suddenly, and develop complex clinical care needs that may be outside the scope of clinical staff knowledge and skills (Hillman et al 2014). At a minimum, RRSs must have an afferent limb (detection of deterioration) and an efferent limb (response to deterioration). Detection of patient deterioration (the afferent limb) utilises a set of predetermined criteria that involve the assessment, measurement and documentation of patients' vital signs

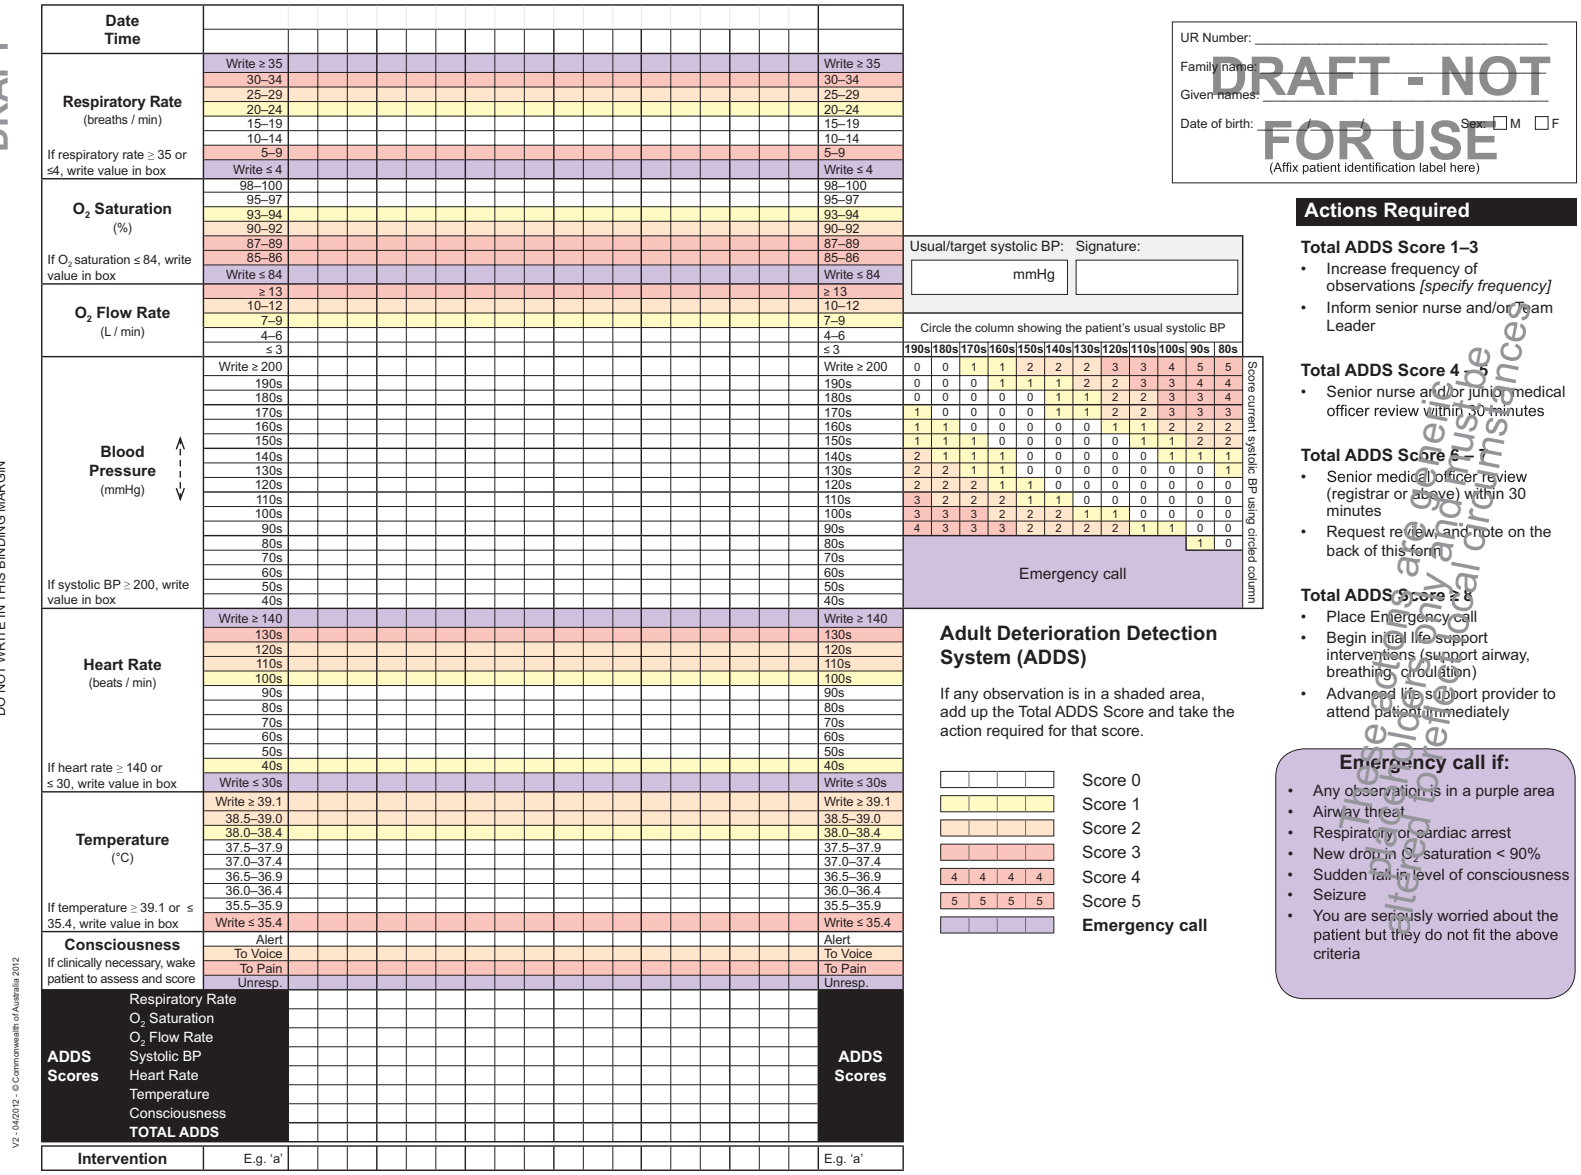

Figure 39-3 Adult Deterioration Detection System (ADDS).

The Australian Commission on Safety and Quality in Health Care, Adult Deterioration Detection System (ADDS) chart with blood pressure table 2012. ACSQHC, Sydney. Available: www.safetyandquality.gov.au/wp-content/uploads/2010/01/ADDS-chart-with-blood-pressure-table-2012.pdf

(DeVita et al 2006, Jansen et al 2010). These criteria are increasingly referred to as track and trigger systems (Jansen et al 2010). An example of the criteria used is displayed in the adult deterioration detection system chart in Figure 39-3.

The efferent limb of an RRS directs response to the deteriorating patient. The medical emergency team (MET), critical care outreach team, intensive care liaison nurse, and after-hours advanced practice nurse service are all examples of an RRS. The key aims of an RRS are to improve the care and management of the deteriorating patient by averting admission to critical care units, facilitating discharge from a critical care facility and sharing critical care skills throughout the hospital (Hillman et al 2015).

The ability of nurses to recognise and respond to signs of patient deterioration is an important predictor in improving patient outcomes (Purling & King 2012) and preventing adverse events (AEs). The past decade has seen an increased focus on recognising and responding to deteriorating hospitalised patients (Preece et al 2010). Much of this interest has been prompted by findings that demonstrated patient deterioration is often not recognised, or responded to, in a timely manner (Jones et al 2013). Failure to recognise and respond to patient deterioration and escalate care has led to an increased risk of AEs in hospitalised patients that may have been avoided if patient deterioration had been recognised and responded to earlier (Massey et al 2014).

Recognising and responding to patient deterioration in the acute care setting is primarily a nursing responsibility. It is important that nurses working in the acute care setting understand the importance of patient assessment and the clinical reasoning process when recognising and responding to patient deterioration. A deteriorating patient is defined by Jones et al (2013:1031) as:

> **A patient who moves from one clinical state to a worse clinical state which increases their individual risk of morbidity, including organ dysfunction, protracted hospital stay, disability, or death.**

Accurate assessment is the key to early recognition and response to patient deterioration. Nurses rely on assessment findings to guide their decision about nursing care and, when necessary, escalate care (Massey et al 2014). Managing a deteriorating patient in the ward environment can be complex and challenging and the successful rescue of a deteriorating patient depends on assessment skills (see Chapters 23 and 24). While patient assessment is a fundamental part of nursing practice, it is by no means a basic skill; it requires knowledge of the patient, the disease processes (pathophysiology) and integration of this knowledge into clinical practice. In the following section we identify the nursing priorities in recognising and responding to patient deterioration and the use of assessment skills (Skill 39-1).

SKILL 39-1

Assessment and management of the deteriorating patient (ABCDE)

Delegation and other considerations

Clinical assessment and judgement about patient status should not be delegated by the registered nurse (RN). The RN who is providing direct care for the patient should provide handover to the treating team or medical emergency team (MET).

Equipment

- Patient bedside folder or charts
  - Vital signs (and other relevant documents, e.g. neurovascular chart)
  - Intravenous fluid chart
  - Medication chart
  - Fluid balance chart
- Equipment for physical examination

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
Critical decision point: Inform the nurse-in-charge, senior nurse or another member of the team that you are concerned about the safety of your patient as early as possible.	
1. Identify and confirm that you have the correct patient. Review the patient's observation charts to ensure that you have all of the available information and that the data you will be referring to is accurate and up to date.	To prevent errors used a minimum of three (3) identifiers for each patient when handing over (South Australia Health 2012). Ensure that all patient documentation is up to date with the current information about the patient.
2. Assess the patient using the primary survey ABCDE approach. Commence the process for monitoring vital signs, attach ECG monitoring (if available), blood pressure cuff and the pulse oximeter probe.	Assessing the patient with simple questions such as 'How are you?', can provide you with valuable information. How the patient answers may alert you to an underlying medical condition. The pulse oximeter probe should not be placed on extremities if the patient is hypothermic or peripherally compromised. Instead, consider using a probe that attaches to the patient's ear or nose (Thim et al 2012).
Critical decision point: Treat an airway obstruction as a medical emergency. This constitutes the highest level of medical intervention and the initiation of the rapid response team, or Code Blue, and takes precedence over any medical condition or injury including suspected spinal injuries.	
Airway (A) 1. Identify any signs that there may be an airway obstruction. 2. If present, treat as a medical emergency. a. Alert senior nursing and medical team members that you need assistance. b. Attempt to remove or dislodge the object (chin-thrust, airway suction, back thrust or insertion of a nasopharyngeal airway). c. Apply supplemental O_2 if deemed necessary (high concentration via a non-rebreather mask).	Foreign bodies may lead to laryngeal spasms which may result in partial or total airway obstruction. An obstruction of the upper airway is often accompanied by loud abnormal breath sounds (stridor) (Australian Resuscitation Council & New Zealand Resuscitation Council 2016a).
Breathing (B) 1. Identify signs of respiratory distress or impairment (cyanosis, increased work of breathing, use of accessory muscles). 2. Check position of trachea (should be located in the suprasternal notch). 3. Count respiratory rate. a. Note rate, rhythm or patterns, and if the chest rise is symmetric. b. Identify any physiological deformities that could identify cause or other medical conditions (e.g. flail chest). 4. Auscultate the chest (bilaterally). a. Identify lung sounds (wheeze, stridor, crackles or creps). b. Compare lung sounds (left and right lung sounds may vary).	Breathing is essential for life. If the patient's breathing is absent or impaired, this identifies the need for resuscitation (Australian Resuscitation Council & New Zealand Resuscitation Council 2016b). The effectiveness of inspiration can be assessed by the depth and duration of each breath. Assessment of the function of the lungs identifies the function of the respiratory system and allows for the identification of potential obstructions and the relative amount of air, liquid or solid mass in the lungs.

STEPS	RATIONALE
5. Palpate and percuss the chest. a. Identify chest sounds (hyper-resonance sounds, surgical emphysema or crepitus). 6. Record oxygen %, SaO_2 – identify if oxygen concentration is sufficient.	
Circulation (C) 1. Identify signs of circulatory impairment (cyanosis, tachycardia, cool peripheries and low blood pressure). 2. Check patient appearance (colour, warmth – centrally and peripherally). 3. Count pulse rate. a. Note rate, rhythm or patterns, and if pulse rates are present and equal. b. Identify any physiological deformities that could identify cause or other medical conditions. 4. Measure blood pressure. 5. Measure capillary refill time. 6. Auscultate heart sounds. 7. Palpate pulses peripheral to central. a. Note rate, rhythm or patterns, and if pulse rates are present and equal (Note: radial pulse may be absent in patients post coronary arterial bypass graft surgery [CABGS]). b. Identify any physiological deformities that could identify cause or other medical conditions.	Hypovolaemic shock is a common cause of altered cardiac physiology and should be considered in presentations without an obvious cardiac cause. When assessing the rate and quality of the patient's pulse, never use your thumb; this is a 'false' pulse and impacts on the accurate measurement of the heart rate. Certain medical conditions such as renal disease, diabetes, acute or chronic pain, can affect blood pressure levels. Impaired or absent pulses may indicate peripheral vascular disease, which can affect the vascularisation to the limbs and surrounding tissue. Never palpate the carotid arteries simultaneously; this can occlude the supply of blood to the brain and surrounding areas.

■ **Critical decision point: Hypoglycaemia can mimic the signs and symptoms of a stroke. Therefore, it is important that a blood sugar level (BSL) is completed as part of assessing the level of consciousness.**

Disability (D) 1. Identify the level of consciousness and potential causes for the altered conscious state. 2. Assess conscious state (AVPU or Glasgow Coma Score). AVPU a. (A) – Alert b. (V) – Voice responsive c. (P) – Pain responsive OR d. (U) – Pain unresponsive Glasgow Coma Score (GCS) a. (E) – Best eye opening b. (V) – Best verbal response c. (M) – Best motor response 3 Assess pupils. a. Note response and size and if both pupils are equal. 4. Measure blood glucose levels.	Identifying level of consciousness in your patient can identify the patient's alertness, cognitive abilities and other medical conditions (e.g. raised intracranial pressure). GCS scores range from 3–15: never zero. Sluggish or unresponsive pupils may be a sign of head injury or raised intracranial pressure or a pre-existing medical condition, e.g. glaucoma.

STEPS	RATIONALE
Critical point: Remember when exposing the bodies of potentially at-risk patients (e.g. children, elderly), they will lose body heat quickly. Only expose the areas that are required for assessment or assess the patient in stages to avoid a long period of time where the patient's body is exposed.	
Exposure (E)	
1. Perform head-to-toe scan. Identify areas of the patient's body that will be exposed. a. Remember to cover patient once assessment has been completed. 2. Ensure patient confidentiality and dignity. 3. Document your findings at the conclusion of the ABCDE assessment.	Changing the patient into a hospital gown will allow you to assess your patient and may highlight injuries that may be hidden by the patient's clothing.
Critical decision point: The medical emergency team (MET) may be called by any member of the healthcare team (including student nurses). Rapid response team, or Code Blue or may be initiated by phone or by an emergency button on the wall or beside the patient's bed.	
If assessment findings are abnormal or within the reportable parameters for the patient, consider calling for the medical emergency team (MET).	Always be aware of emergency policies and phone numbers (MET call, Code Blue, Code Grey, etc), as they may be different depending on the hospital's policy. Criteria for activation of the MET: a. A member of staff is very worried about a patient. b. Acute change in conscious state. c. Acute change in respiratory rate < 8 to > 30. d. Acute change in oxygen saturation < 90% despite high flow oxygen. e. Acute change in heart rate to < 40 or > 130 beats per minute. f. Acute change in systolic blood pressure to < 90 mmHg. g. Acute change in urine output to < 50 mL over 4 hours. (Austin Health 2016)

RECORDING AND REPORTING

- Record assessment findings in patient's healthcare record following local hospital policy and protocols.
- Report any abnormal data following comprehensive assessment to the senior nurse, acute pain service or another appropriate medical officer.

HOME CARE CONSIDERATIONS

- Has a discharge plan been created?
- Has the client received information about the ongoing plan and follow-up arrangements?
- Do the family or significant others have concerns or need information to help with the plan?

All patients in the acute care setting should have a comprehensive nursing assessment at the time of admission (Osborne et al 2015). This assessment should include physical assessment, collection of essential biographical data, and brief history of the presenting signs and symptoms. Nursing assessment involves gathering and synthesising clinical data, recording this information, communicating within the multidisciplinary team and acting on abnormalities. It is an ongoing dynamic process that requires clinical reasoning. A high degree of knowledge application and translation is required. Knowledge of normal physiological parameters is important, but, used in isolation, can be of limited value. It is of greater value to know what is normal for that particular patient. Two

or more abnormal vital signs is a significant predictor of deterioration (Hodgetts et al 2002, Jacques et al 2006). The ABCDE primary survey framework discussed in Chapters 23 and 24 is useful in performing a systematic clinical assessment. It ensures that acutely ill patients are assessed and managed in a logical manner.

Communicating your assessment findings

Effective communication about patient deterioration is important to ensure the situation is escalated in a timely and appropriate way and resultant management is appropriate to prevent AEs and promote positive outcomes. The SBAR (situation, background, assessment, recommendation) framework is an easy-to-remember communication tool that you can use to frame conversations, especially critical ones that require a clinician's immediate attention and action (see Chapter 12). It enables you to clarify what information should be communicated between members of the team, and how. It can also help you to develop teamwork and foster a culture of safety. The example in Box 39-1 shows how SBAR can be used to communicate

CLINICAL EXAMPLE

Harry Summers, a 73-year-old man, is admitted to the ED by ambulance following a fall at home. He lives alone, but his daughter lives with her family in the next suburb. Your nursing assessment on presentation reveals:

Airway	Patent
Breathing	Respiratory rate 22 breaths/minute SpO_2 99% on room air
Circulation	Heart rate 90 beats/minute and regular Blood pressure 145/92 mmHg
Disability	Alert. Pain in his right leg and hip
Exposure	Temperature 36.9°C
	Some bruising and skin discolouration to his right upper thigh. His right leg was externally rotated and slightly shorter than the left

Focused neurovascular assessment

	Right leg	Left leg
Colour	Pale	Pink
Temperature	Cool	Warm
Capillary refill	> 2 seconds	< 2 seconds
Distal pulses	Present	Present
Oedema	Yes, to hip	Nil

X-ray confirms a fractured right neck of femur and transfer to the orthopaedic ward is arranged.

BOX 39-1 SBAR tool

S: Situation

- Identify yourself – the site/unit you are calling from.
- Identify the patient by name and the reason for your report.
- Describe your concern.

An example of a script would be:

> **This is Dee Smith, an RN in CCU. I am contacting you about Miss Singh in bed 11. She has become suddenly short of breath.**

B: Background

- Give the patient's reason for admission.
- Explain significant medical history.
- Outline the patient's background: admitting diagnosis, date of admission, prior procedures, current medications, allergies, pertinent laboratory results and other relevant diagnostic results. For example:

> **Miss Singh is 29, admitted yesterday with bilateral deep vein thrombosis following a long haul flight 2 weeks ago. Her care has been complicated by a pulmonary embolism. She has been on strict bed rest since admission and is on a heparin infusion at 1.2 mL an hour. Since admission she has been tachycardic and tachypnoic.**

A: Assessment

- Vital signs and patient assessment findings
- Clinical impressions, concerns

You need to think critically when informing the person listening to your assessment of the situation. This means that you have considered what might be the underlying reason for your patient's condition.

> **Her oxygen saturation has dropped to 89% on room air, her respiration rate is 30 per minute, her heart rate is 120 and her blood pressure is 90/50. Her work of breathing is increased; she is anxious, short of breath on minimal exertion and on auscultation has bilateral crackles.**

R: Recommendation

- Explain what you need; be specific about request and timeframe.
- Clarify expectations.

What is your recommendation? That is, what would you like to happen by the end of the conversation? Any order that is given on the phone needs to be repeated back to ensure accuracy:

> **I think she is deteriorating. I would like you to come and review her immediately and outline a clear management plan.**

Chaboyer W, McMurray A, Wallis M 2010 Bedside nursing handover: a case study. International Journal of Nursing Practice 16(1):27–34.

your concerns about a deteriorating patient. If you have not used the SBAR framework in your clinical practice, try using it and see if it helps your communication skills and patient care.

• CRITICAL REFLECTION POINT

Review the important and relevant information provided in the *Clinical example* on the previous page. Apply the information provided using the SBAR framework for handover of the patient to the orthopaedic ward.

Patient identification and procedure matching

Ensuring patients are correctly identified is a nursing responsibility required to reduce the risk of misidentification and possible harm as a result. The Australian Commission on Safety and Quality in Health Care (ACSQHC) developed The National Safety and Quality Health Service (NSQHS) Standards. The purpose of these standards is to improve the quality of health care and protect the public from harm (ACSQHC 2012). Standard 5 relates to patient identification and procedure matching (Box 39-2) to ensure that patients are always correctly identified and matched to their intended treatment (ACSQHC 2012).

• CRITICAL REFLECTION POINT

Reflect on why a patient's bed and room number are not approved patient identifiers under Standard 5. Consider also why is it imperative that patients in the acute care setting wear an identification band, such as a wristband? Think about these from a patient safety perspective.

BOX 39-2 Standard 5 – Patient identification and procedure matching

In the acute care setting you will need to formally verify a patient's identification on numerous occasions throughout a shift, for example at handover, each time medications are administered, prior to transfer, and prior to any procedure. When identifying an individual patient, for example, as part of assessing the 'right patient' prior to medication administration, at least *three* patient identifiers must be used (ACSQHC 2012). The ACSQHC specifies that an identification band, such as a wristband, be worn by patients in hospital (Box 39-3). Identifiers such as room or bed numbers are not to be used. Health service organisations must have clear policies governing patient identification practices within the health service and the ACQSHC requires this as part of accreditation of the services.

Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012 National Safety and Quality Health Service Standards. ACSQHC, Sydney.

BOX 39-3 Approved patient identifiers: Items of information

Accepted for use in patient identification, includes: patient name (family and given names), date of birth, gender, address, medical record number and/or Individual Healthcare Identifier.

Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012 National Safety and Quality Health Service Standards. ACSQHC, Sydney.

The essentials of safe and quality care for patients undergoing a procedure or surgery

All nurses in the acute care setting need to be skilled to manage patients before surgery (preoperatively) and after surgery (postoperatively). Pre- and postoperative care may take place in a hospital, a surgical centre attached to a hospital, a free-standing day-surgery or an ambulatory-care centre. A number of invasive procedures are conducted in acute care settings and nurses have responsibilities in relation to pre- and post-procedure care.

Anticipating surgery or a procedure may lead to fear and anxiety for patients and their families/significant others. For example, surgery may be associated with pain, possible disfigurement, loss of independence and perhaps even death. An upcoming procedure may cause concerns around the implications of the procedure and recovery afterwards. The ability to quickly establish rapport with patients and really listen to them, so that their concerns can be discussed and addressed, is important. The continuing care of the patient after some surgeries/procedures has shifted from hospital-based rehabilitation to home-based rehabilitation, with resultant increased responsibility for the patient and/or family and significant others. As the length of hospital stay decreases, the educational needs of the patient undergoing a surgery or procedure increase. Patients are discharged home with complex conditions

CLINICAL EXAMPLE

Mr Summers is admitted to the orthopaedic ward from the ED with a diagnosis of fractured right neck of femur. He has 4 kg of straight leg traction in place and is booked for theatre for open reduction and internal fixation (ORIF) of the right femur the following day.

that require both education and follow-up by nurses. Appropriate patient education is essential to ensure a positive overall patient experience and optimal outcomes (Hamlin et al 2009).

• CRITICAL REFLECTION POINT

Review the important and relevant information provided in the *Clinical example* on the previous page; for example, the handover report. What new information do you need to collect?

CLINICAL REASONING PROCESS: THE PREOPERATIVE PHASE

In the preoperative or pre-procedure phase, your role centres on 1) gathering relevant information and data; 2) making appropriate judgements and decisions; 3) setting priorities and establishing goals; 4) preparing for and taking action; and 5) evaluating impacts and outcomes. Nurses are involved in preparing the patient both physically and emotionally for the surgery or procedure, and providing relevant education relating to preventing complications, assuming self-care, or the provision of ongoing care for patients requiring extended observation and interventions.

Patients enter the acute care setting in different stages of health and with different levels of preparedness. A patient may enter the hospital or surgical unit on a predetermined day being relatively healthy, or with a significant medical history that may affect the surgery and subsequent recovery, and feel prepared to undergo elective surgery. In contrast, an individual involved in a motor vehicle accident facing emergency surgery will feel totally unprepared for such an event. The ability to quickly establish and develop rapport with the patient and maintain a professional relationship is an essential component of the preop phase.

The patient may undergo tests and procedures to establish baseline measurement of relevant body systems. Testing may be performed on the day of or several days before surgery. Testing performed on the day of surgery or procedure is usually limited to such areas as glucose monitoring for a patient with a history of diabetes. You should become familiar with these tests, their purpose and be able to interpret the results.

During an acute care admission, the patient meets many healthcare professionals other than nurses. This team includes surgeons, anaesthetists and relevant allied health professionals, such as a physiotherapist, dietitian and occupational therapist. All play a role in the patient's care and recovery. While family members and significant others attempt to provide support through their presence, they are often as stressed as the patient. Effective communication with the patient and family is critical because the nurse–patient relationship is the foundation of care (see Chapters 2 and 3). The nurse assesses the patient's physical and psychosocial status, recognises the degree of surgical risk, gathers results of diagnostic tests, identifies the patient's priority problems and interventions and establishes outcomes in collaboration with the patient and the patient's family. Pertinent data and the plan of care are communicated to the surgical team.

GATHERING RELEVANT INFORMATION AND DATA

Assessment of the preoperative patient can be extensive. Same-day procedure/surgery can provide challenges in gathering a complete assessment within a limited timeframe. A multidisciplinary team approach is essential. Patients are admitted only hours before surgery/procedure, so nurses gather relevant data and information to inform the clinical reasoning process and ensure safe and quality patient care. It has become common practice for patients to be admitted on the day of surgery, even for major procedures such as open heart surgery or craniotomy. The majority of assessments begin before admission for surgery in the medical practitioner's office, pre-admission clinic, anaesthesia clinic or by telephone. Patients may answer a self-report checklist, the nurse may conduct a physical examination, laboratory tests may be required, education is commenced, patient questions are answered and documentation is initiated. This streamlines the care required by the patient on the day of surgery. Nurses in the immediate preoperative period are well positioned to assess the patient's understanding of previous education and individualise patient and family care.

For patients undergoing elective surgery, a comprehensive history and physical examination are usually performed by a medical practitioner prior to admission, with follow-up by the pre-admission or admitting nurse. In this case you need to review findings of assessments and testing. Focus on key assessments for all body systems to ensure that no obvious priorities are overlooked, and clarify that the patient has understood education previously provided. Even though the surgeon will screen the patient before scheduling surgery, preoperative assessment occasionally reveals an abnormality that delays or cancels the procedure/surgery. For example, the patient may have a cough and low-grade fever on admission. This may indicate the onset of infection, and the surgeon will need to be notified. Further education regarding the procedure and related care may also be required if the patient demonstrates a knowledge deficit.

The goal of the assessment of the preoperative patient is the same, no matter what the setting. The intent is to establish the patient's normal preoperative function to assist the nurse in preventing and recognising possible postoperative complications, thereby minimising risk and assisting the patient to return to their previous functional status.

CLINICAL EXAMPLE

Mr Summers is retired and depends on the pension for his income. He is self-sufficient and prides himself on his independence. He makes all his own meals, cleans his house and cares for the garden himself. As you continue your assessment, Mr Summers discloses a past medical history of osteoarthritis, high cholesterol and type 2 diabetes controlled by diet, diagnosed 10 years ago. His blood glucose levels are normally between 11–14 mmol/L. His cholesterol is well controlled with atorvastatin 20 mg daily.

Patient history

Conduct an initial interview to collect a patient history similar to that described in Chapter 5. If a patient is unable to provide all of the necessary information, rely on family members, caregivers or significant others as resources. Various conditions and factors increase a person's risk for surgery and some procedures. Knowledge of risk factors enables you to take the necessary precautions to make appropriate decisions and plan effective and individualised care.

Past medical history

A review of the patient's medical history should include the main reason for seeking health care and any illnesses. The patient's healthcare record provides this information and is an excellent resource, as are the healthcare records from any previous hospitalisations in partner hospitals.

Pre-existing illnesses and lifestyle behaviours can influence the choice of anaesthetic agents used, as well as the patient's ability to tolerate surgery or certain procedures and reach full recovery (Table 39-1). Preoperative and pre-procedure patients must be carefully screened for medical conditions that may increase the risk of complications during or after the surgery or procedure. For example, a patient with a history of heart failure may experience a further decline in cardiac function both intraoperatively and postoperatively. Intravenous fluids may need to be administered at a slower rate, or a diuretic may need to be given after a blood transfusion.

Perceptions and understanding

The surgical experience affects not only the patient, but also the family and/or significant others. It is therefore important to prepare both the patient and their significant other(s) regarding the experience. Identification of the patient's and family's knowledge, expectations and perceptions allows you to plan education and to provide the appropriate support.

Each patient brings certain fears to the acute setting. Some are due to past hospital experiences, family and friends' experiences, events they might have seen on television or a lack of knowledge. During the assessment, ask for a description of the patient's understanding of the planned procedure/surgery and its implications. Sample questions include: 'Explain what you know about the surgery you are having' or 'What do you think will happen after the procedure?' Contact the surgeon if the patient has an inaccurate perception or knowledge of the surgical procedure, before the patient is transported to the theatre suite.

TABLE 39-1 Medical conditions that increase the risks of surgery

Type of condition	Reason for risk
Bleeding disorders (thrombocytopenia, haemophilia)	Disorders increase risk of haemorrhaging during and after surgery
Diabetes mellitus	Diabetes increases susceptibility to infection and may impair wound healing from altered glucose metabolism and associated circulatory impairment Fluctuating blood levels may cause central nervous system malfunction during anaesthesia Stress of surgery may cause increases in blood glucose levels
Heart disease (recent myocardial infarction, dysrhythmias, heart failure) and peripheral vascular disease	Stress of surgery causes increased demands on myocardium to maintain cardiac output General anaesthetic agents depress cardiac function
Upper respiratory infection	Infection increases risk of respiratory complications during anaesthesia (e.g. pneumonia and spasm of laryngeal muscles)
Liver disease	Liver disease alters metabolism and elimination of drugs administered during surgery and impairs wound healing and clotting time because of alterations in protein metabolism
Fever	Fever predisposes patient to fluid and electrolyte imbalances and may indicate underlying infection
Chronic respiratory disease (emphysema, bronchitis, asthma)	Respiratory disease reduces ability to compensate for acid–base alterations Anaesthetic agents reduce respiratory function, increasing risk of severe hypoventilation
Immunological disorders (leukaemia, acquired immune deficiency syndrome, bone marrow depression and use of chemotherapeutic drugs)	Immunological disorders increase risk of infection and delay wound healing after surgery
Recreational IV drug use	Persons using recreational IV drugs may have underlying disease (HIV/hepatitis), which affects healing
Chronic pain	Regular use of pain medications may result in higher tolerance. Increased doses of opioids/analgesics may be required to achieve postoperative pain control

Medication history

If a patient regularly uses prescription or over-the-counter medicines, the surgeon or anaesthetist may temporarily discontinue the medicines or adjust the dosages. Certain medicines may have implications for the patient, creating greater risk for complications. For example, anticoagulants alter normal clotting times and therefore increase the risk of bleeding. Aspirin is a commonly used medication that can alter clotting mechanisms and is usually discontinued for at least 48 hours prior to surgery and some procedures. Some patients who usually administer insulin for diabetes may need a reduced dose following surgery because of a reduced nutritional intake; others may need an increased dose due to the stress response and intravenous infusion of glucose solutions during surgery.

Patients should also be specifically asked if they use any herbal preparations, since many patients do not view herbs as medications and may omit them from their medication history. There are herbs that may interfere with the action of other medicines (consult the pharmacist).

Allergies

To minimise risk, it is critical to ask the patient if they have known allergies to any medicines, latex, food and possible contact allergies (e.g. to tapes, ointments or solutions). If the patient identifies any allergy, you should follow the institution's policy and procedures regarding documenting and alerting other healthcare professionals to the patient's allergy.

Smoking habits

The patient who smokes is at greater risk of postoperative pulmonary complications. Someone who has smoked chronically already has an increased amount and thickness of secretions in the lungs. General anaesthetics increase airway irritation and stimulate pulmonary secretions, which are retained as a result of reduction in ciliary activity during anaesthesia. After surgery the patient who smokes has greater difficulty clearing the airways of mucous secretions, and the importance of postoperative deep-breathing and coughing must be emphasised (see Chapter 35).

Alcohol and substance use

Alcohol and substance misuse can affect the choice of anaesthetic agents and post-procedure pain management. Patients who use alcohol excessively are at risk of acute alcohol withdrawal and delirium postoperatively (Rudolph & Marcantonio 2011). Use of prescription opioids or barbiturates and abuse of recreational drugs may affect the level and amount of anaesthesia/sedation required, as well as impact on the level of pain experienced, and its management, post-surgery/procedure.

Obesity

Obesity increases risk. A person who is obese is more likely to have associated hypertension, heart disease, type 2 diabetes mellitus, metabolic syndrome, and/or sleep apnoea (Mayo Clinic 2015). Respiratory postoperative complications including pulmonary embolus and **atelectasis** (collapse of alveoli) are also more-frequent postoperative complications in patients with obesity (Poirier et al 2009). The patient may have difficulty resuming normal physical activity after surgery. Patients who are obese are more susceptible to delayed wound healing and wound infection because of the structure of fatty tissue, which contains a poor blood supply. This slows delivery of essential nutrients, antibodies and enzymes needed for wound healing (see Chapter 26 on surgical wounds).

Fluid and electrolyte balance

The body responds to surgery as a form of trauma. As a result of the adrenocortical stress response, hormonal reactions cause sodium and water retention and potassium loss within the first 2–5 days after surgery. Severe protein breakdown causes a negative nitrogen balance. The severity of the stress response influences the degree of fluid and electrolyte imbalance. The more extensive the surgery, the more severe the stress. A patient who is hypovolaemic or who has serious preoperative electrolyte alterations is at significant risk during and after surgery. For example, an excess or depletion of potassium increases the chance of arrhythmia during or after surgery. If the patient has pre-existing renal, gastrointestinal or cardiovascular abnormalities, the risk of fluid and electrolyte alterations is even greater.

Level of support

It is important to determine the extent of support from the patient's family members or significant others. Surgery often results in a temporary or permanently altered functional status that requires understanding, support and assistance to manage effectively during recovery. Often patients cannot immediately assume the same level of physical activity experienced before surgery or the illness that resulted in the surgery. Patients may return home with a dressing, exercises to perform or with certain restrictions to adhere to. Involvement of support persons in preoperative and postoperative education is an important strategy to assist and encourage the patient in implementing the education.

Pain

Manipulation of tissues, treatments and positioning during surgery or some procedures usually results in some degree of pain for the patient following the procedure. Pain is a very personal experience and requires an individualised plan of care. It is a nursing responsibility to collect information about the patient's expectations regarding pain management following surgery. Preoperative education should emphasise the need for the patient to report their pain and the importance of adequate pain control for their recovery. Refer to Chapter 36 for a discussion of acute pain management.

Body image

Surgical removal of any diseased body part often leaves permanent disfigurement, alteration in body function or concern over mutilation. Loss of certain body functions (e.g. with a colostomy or urostomy) compounds a patient's fears. Assessment of a patient's perceived body image alterations is important. Sometimes surgery changes the physical or psychological aspects of a patient's sexuality. Excision of breast tissue, colostomy, ureterostomy, hysterectomy or prostatectomy may affect patients' perceptions of their sexuality. Patients may have to refrain temporarily from sexual intercourse until they return to normal physical activity after some surgery.

Patients should be encouraged to express their concerns about sexuality (see Chapter 21). The patient facing even temporary sexual dysfunction requires understanding and support. Ideally, discussions about the patient's sexuality should be

held with the patient's sexual partner, so that they can gain a shared understanding of how to cope with limitations in sexual function.

Coping resources

It is important to ask the patient about coping strategies and past stress management. If the patient has had previous surgery, successful coping strategies can be determined and incorporated into the care plan if appropriate. Relaxation exercises can also be taught to help control anxiety (see Chapter 20).

Culture

Patients come from diverse backgrounds, cultures and religions. The way a patient perceives their experience related to surgery is affected by their background. If potential cultural, ethnic and religious implications are not acknowledged and planned for, desired surgical outcomes may not be achieved. Although it is important to recognise and plan for cultural differences, it is also necessary to recognise that members of the same culture are individuals and may not hold the same beliefs. A culturally safe approach is needed that respects and seeks to understand the implications of acute illness from the patient and family's perspective (see Chapter 14).

• CRITICAL REFLECTION POINT

Reflect on the *Clinical example* on p. 1430. How could the additional information provided to you by Mr Summers be of use to you in your decision-making relating to his care?

Physical assessment

A focused physical assessment is undertaken, based on the patient's condition and the surgery or procedure. Chapters 23 and 24 describe the techniques used in physical assessment. Assessment focuses on findings related to the patient's medical history and on the body systems that are likely to be affected by the surgery/procedure. It is important to establish a baseline of information and to identify any actual alterations or potential complications (see Figure 39-4).

General survey and baseline vital signs

Observe the patient's general appearance, including their skin colour and moisture, facial expression, gait and height and weight. These are all important cues that may be indicators of underlying disease and an alteration in status and function. Weight is usually recorded to ascertain baseline data and may be required information for accurate medication dosages.

Preoperative assessment of vital signs provides important *baseline data* with which to compare alterations that occur during and after surgery/procedure (see Chapter 23). Anxiety and fear commonly cause elevations in heart rate and blood pressure. Anaesthetic agents typically depress all vital functions. As the effects of the anaesthesia diminish after surgery, the nurse closely monitors vital signs and compares findings with the preoperative baseline. Vital signs are considered in the discharge or transfer of the patient from the post-anaesthetic care unit (PACU) back to the ward environment or to home.

Preoperative assessment of vital signs is also important to rule out fluid and electrolyte abnormalities before surgery commences (see Chapter 23). An elevated heart rate may result from a fluid volume deficit, potassium deficit or sodium excess. If the pulse is full and bounding, a fluid volume excess may be the cause. Cardiac arrhythmias are commonly caused by electrolyte imbalances, especially potassium, magnesium and calcium.

An elevated body temperature before surgery is a cause for concern. If the patient has an underlying infection, it may be necessary to postpone surgery until the infection has been treated.

Head and neck

Assessment of oral mucous membranes reveals data about hydration status. A patient who is dehydrated is at risk of developing serious fluid and electrolyte imbalances during surgery. Excess fluid within the circulatory system or failure of the heart to contract efficiently may lead to jugular vein distension and reveal a risk of cardiovascular complications during surgery.

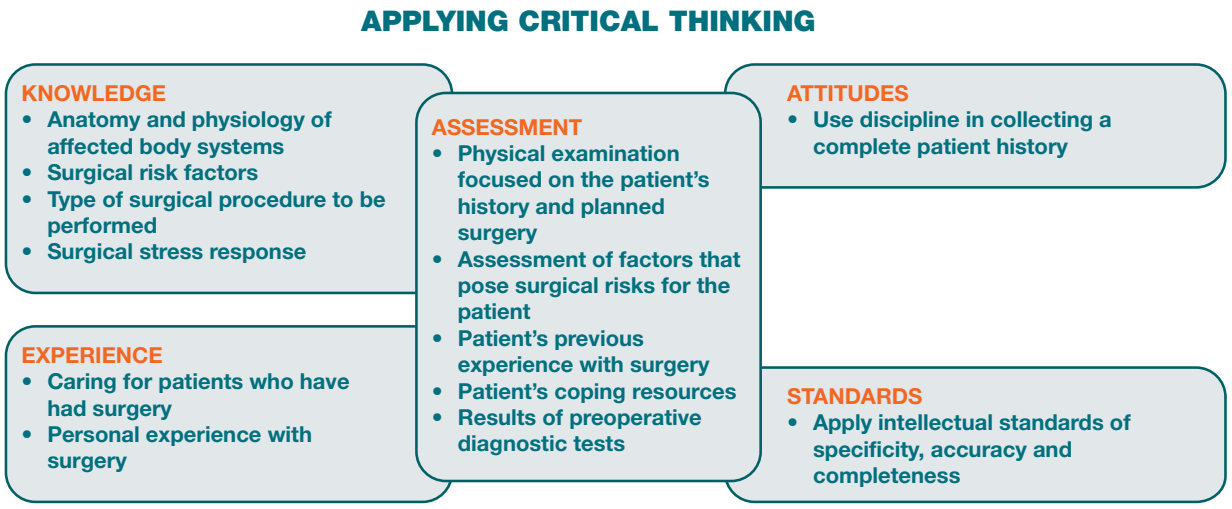

Figure 39-4 Critical thinking associated with the assessment phase for the surgical patient.

Thorax and lungs

Assessment of the patient's respiratory rate, breathing pattern and chest movement helps assess ventilatory capacity. Patients are encouraged to deep-breathe and cough postoperatively. A decline in ventilatory function may place the patient at risk of respiratory complications. Auscultation of lung sounds will indicate whether there is pulmonary congestion or narrowing of airways. Existing atelectasis or moisture in the airways will be aggravated during surgery. Serious pulmonary congestion may cause postponement of the surgery. Certain anaesthetics can cause bronchospasm; thus if you auscultate a wheeze preoperatively, the patient is at risk of further airway narrowing during surgery and after extubation (removal of the endotracheal tube).

Heart and vascular system

Anaesthetic agents, alterations in fluid and electrolyte balance, and stimulation from the surgical stress response can cause cardiac arrhythmias. Depending on the type of surgery/procedure and the patient's past history, assessment of peripheral pulses, capillary refill time and the colour and temperature of extremities may be conducted. If peripheral pulses are not palpable, a Doppler ultrasound should be used for assessment of their presence and their position marked with a pen. Measurement of capillary refill and assessment of peripheral pulses are particularly important for patients having vascular surgery or for those who may have casts or constricting bandages applied to the extremities after surgery.

Abdomen

The abdomen is assessed for size, shape and symmetry. If the patient is having abdominal surgery, the nurse will be frequently assessing the abdominal incision dressing site postoperatively and will compare with preoperative data. Abdominal distension may indicate postoperative alterations in gastrointestinal function, or possible abdominal bleeding. Assessment of preoperative bowel sounds may be useful to use for postoperative comparison. If the surgery requires manipulation of the bowel or if a general anaesthetic is used, normal peristalsis and bowel sounds will be absent or diminished for several days after surgery.

Neurological status

Preoperative assessment of neurological status is imperative for all patients receiving general anaesthesia. Baseline assessment aids the assessment of the patient when recovering from anaesthesia. During the health history and physical assessment, observe the patient's alertness, orientation and speech, noting whether the patient answers questions appropriately and can recall recent and past events. Level of consciousness changes as a result of general anaesthesia. However, after the effects of anaesthesia resolve, the patient should return to the preoperative level of responsiveness.

If the patient is having a spinal anaesthesia, preoperative assessment of gross motor function and strength is important. Spinal anaesthesia causes temporary paralysis of the lower extremities (see Chapter 36).

Integument

It is important to carefully inspect the skin, paying particular attention to bony prominences, such as the heels, elbows, sacrum and scapula. During surgery in particular, a patient must lie in a fixed position, often for several hours, which makes them susceptible to pressure injuries (see Chapter 26), especially if the skin is thin and dry. An older person is often at high risk for an alteration in skin integrity related to positioning and sliding on the operating room table, causing shear and pressure. In addition, skin turgor is an indicator of hydration status.

CLINICAL EXAMPLE

Mr Summers' diagnostic test results include: FBC haemoglobin 13.0 g/dL and normal WBC count. Blood chemistry within normal limits.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

Cluster patterns of assessment data identified during assessment, to identify relevant patient needs, concerns or clinical problems (Box 39-4). The acute care patient with pre-existing health problems is likely to have a variety of risks for complications (Box 39-5). For example, a patient with pre-existing chronic bronchitis who has abnormal breath sounds and a productive cough will be *at risk of having difficulty clearing their airway*. The nature of the surgery and the patient's health status provide defining characteristics for a number of problem statements. For example, a patient who undergoes a surgical procedure is at risk of developing infection at either the surgical site, the IV site or in the bloodstream (sepsis). The *risk of infection* will need to be addressed by nurses from admission to rehabilitation.

Clinical priorities identified preoperatively may also focus on the potential risks a patient will face after surgery (e.g. risk for chest infection). Preventive care is essential so that the surgical patient can be managed effectively and risk be reduced.

BOX 39-4 Examples of priority problems associated with surgery

- Anxiety
- Airway clearance, ineffective
- Breathing pattern, ineffective
- Constipation, risk of
- Coping, family: potential for growth
- Fear
- Fluid volume deficit, risk of
- Infection, risk of
- Knowledge deficit (specify)
- Latex allergy response, risk of
- Management of therapeutic regimen, individual: effective
- Mobility, impaired physical
- Pain
- Powerlessness
- Skin integrity, impaired, risk of
- Surgical recovery, delayed

BOX 39-5 Example of clinical reasoning process

Patient facing surgery

Assessment activities	Clustered data	Nursing priority problem
Ask patient to describe any previous surgical experiences. Ask patient about their knowledge relating to preoperative education/ preparation before admission. Observe patient's non-verbal behaviour. Assess vital signs.	States they feel apprehensive. Identifies fear of surgery. Unaware of preoperative testing that will take place. Tense – wringing hands, slight rocking, speech speeds up when talking of feeling scared. Elevated heart rate (> 96 beats/ minute).	Fear related to knowledge deficit and previous surgical experience.

SETTING PRIORITIES AND ESTABLISHING GOALS

Develop an individualised plan of care for each patient problem (see *Sample student nursing care plan*). The nurse and patient set realistic individualised goals for care with realistic measurable outcomes. Successful application of the clinical reasoning process requires the involvement of the patient and family. Involving the patient early on when identifying the priorities can minimise risks and postoperative complications. A patient informed about the surgical experience is likely to be less fearful and can prepare to participate in the postoperative recovery phase so that outcomes can be met.

For **same-day surgery** patients and patients admitted the day of their scheduled surgery, preoperative planning occurs (ideally) days before admission to the hospital or surgical centre. Often, preoperative education begins in the doctor's surgery, continues during the scheduled pre-admission testing visit and is reinforced by the nurse on the day of admission. Preoperative information and instructions may include follow-up telephone calls, mailings from the clinic or hospital, or the use of videos or patient pathways (Figure 39-5). Preoperative instruction gives the patient time to think about the surgical experience, make necessary physical preparations (e.g. altering diet or discontinuing medication use) and ask questions about postoperative procedures. Well-planned preoperative care ensures that the patient is well informed and able to be an active participant during recovery. The family/significant others can also play an active supportive role.

Establishing priorities and setting goals preoperatively is individualised for the patient. However, there are broad goals that are relevant to the majority of patients undergoing a procedure or surgery. These are:

- understanding physiological and psychological responses to the procedure/surgery
- understanding reasons for postoperative care
- achieving emotional comfort and relaxation
- achieving return of normal physiological function after the surgery
- maintaining fluid and electrolyte balance
- achieving comfort and rest
- remaining free of wound infection
- remaining safe from harm during the acute care admission.

• CRITICAL REFLECTION POINT

Reflect on the *Clinical example* on p. 1434. Can you identify at least four priority nursing problems and goals for Mr Summers' preoperative phase of hospitalisation?

PREPARING FOR AND TAKING ACTION

Nursing actions include providing the patient with an understanding of the procedure or surgery and prepare the patient physically and psychologically for the intervention. Actions implemented by the RN are always focused on providing safe and effective patient care, to reduce risk and ensure optimal patient outcomes.

Informed consent

An important responsibility when caring for a patient before surgery or a procedure is ensuring that patient consent has been obtained. You should be aware of the requirements of a valid consent and of who may provide consent if the patient is unable to do so because of an altered mental state, illness or emergency situation. In Australia and New Zealand it is common practice that patients are expected to complete a written consent form prior to surgery. For the patient's consent to be valid, all the elements that constitute consent must be fulfilled (see Chapters 10 and 11). The signed consent form is evidence that consent has been given. The healthcare professional undertaking the procedure or surgery is responsible for obtaining the patient's consent.

A patient can revoke consent at any time. This can be done verbally or by writing on the consent form. There are also times when patients alter the written form. If this occurs, the treating medical practitioner needs to be informed and the patient should be asked to initial the alteration, consistent with hospital policy. Likewise, if the patient asks specific questions regarding the procedure when the nurse is admitting or preparing the patient, it is important that the nurse practises within their scope of practice. The nurse should inform the treating medical officer of the patient's specific concerns and document this in the patient's file.

There is no clear life span of a written consent form, so many agencies will have policies that stipulate an acceptable timeframe (e.g. 30 days). The older the form, the greater the potential risk that the patient's condition or cognitive status may

SAMPLE STUDENT NURSING CARE PLAN

Gathering relevant data and information*

Mr Molosky is 78 years of age and is scheduled to be admitted in 5 days for elective bowel resection. Anne Holloway, RN, is responsible for preparing Mr Molosky for surgery. During Anne's initial discussion with Mr Molosky, she ascertains that Mr Molosky is alert and oriented. Mr Molosky wears glasses for reading and is able to hear Anne's questions. Mr Molosky last had **surgery over 25 years ago**. He says to Anne, **'It is my understanding that I will probably be in the hospital for quite a while.'** Anne clarifies that hospitalisation for surgery is shorter than what was expected 25 years ago. After further questioning, Anne learns that Mr Molosky **has not received instruction on the surgical procedure and the care relating to effective postoperative recovery**. Mr Molosky **shows interest in Anne's questions and asks what to expect following surgery.**

** Important data to cluster in setting priorities in bold.*

Priority problem(s)

Knowledge deficit regarding preoperative and post-operative care requirements.

Making appropriate judgements and decisions

Setting priorities and establishing goals	Expected outcomes
Mr Molosky will demonstrate the ability to perform deep-breathing and coughing exercises and leg exercises by the day before surgery. Mr Molosky will be able to discuss a clear understanding of the postoperative routines related to surgical care by the day before surgery.	Mr Molosky will accurately perform leg exercises and breathing and coughing exercises by the day before the surgery. Mr Molosky will discuss monitoring routines following surgery by the day before surgery. Mr Molosky will be able to describe the importance of postoperative exercises by the day before surgery. Mr Molosky will be able to describe his schedule for activity and nutritional management following surgery by the day before surgery.
Preparing for and taking action†	**Rationale**
Teaching: preoperative • Provide educational written information (e.g. pamphlet). Make a follow-up call to give Mr Molosky the opportunity to ask questions, clarify any information and voice concerns. • On admission to hospital, ask Mr Molosky to demonstrate performance of the expected postoperative exercises. • Explain sensations to be expected postoperatively (e.g. incisional pain, IV, nasogastric tube, wound care solutions). • Ask Mr Molosky to discuss their expectations and correct any unrealistic expectations relating to the surgery.	It is beneficial to give the patient written material and audiovisual material that they can listen to repeatedly if necessary. The patient has the opportunity to clarify anything they do not understand clearly. The nurse can rectify any misinterpreted information prior to admission, so that the patient can participate in their care effectively. Preoperative education can assist in reducing postoperative anxiety. The patient can obtain feedback on their performance. The nurse can ascertain accuracy and correct any misunderstanding. It is important to educate about sensory aspects, so the patient is adequately prepared and doesn't become alarmed after surgery. Unrealistic expectations, when unmet, can contribute to the patient's anxiety.

Evaluating impacts and outcomes

- Ask Mr Molosky to describe typical monitoring and care activities following surgery.
- Observe Mr Molosky's demonstration of post-operative exercises.
- Ask Mr Molosky to express any remaining fears or concerns.

APPLYING CRITICAL THINKING

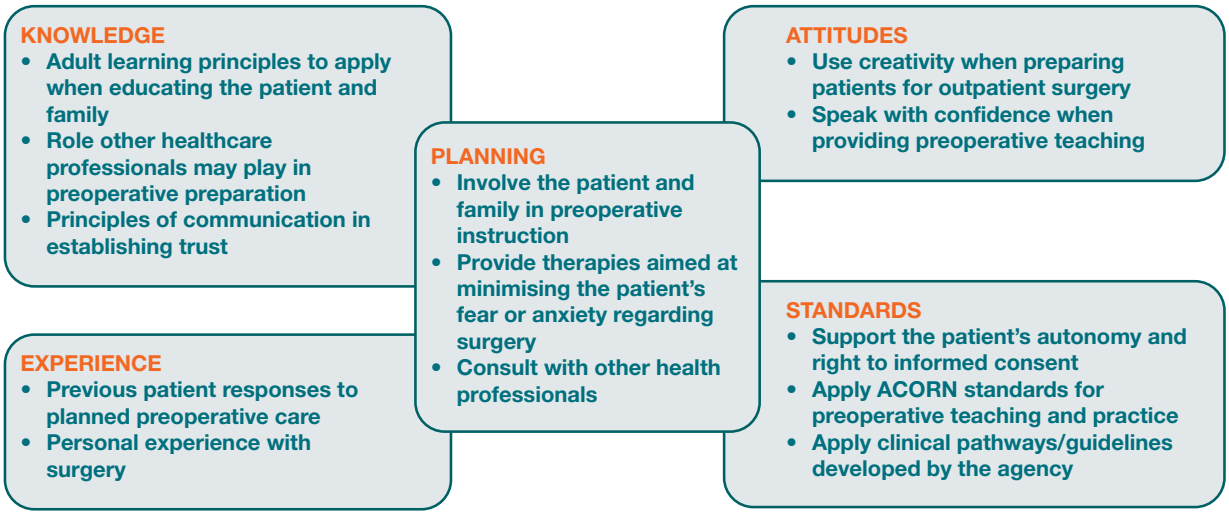

Figure 39-5 **Critical thinking associated with the planning phase for the surgical patient.**

have changed. If a consent form is used, it is filed in the patient's record; the record accompanies the patient to surgery.

Although healthcare professionals can witness a patient's signature, the precise role of the witness remains unclear. In general terms, a witnessed signature merely attests that the witness actually saw the patient sign the form. It is policy in some agencies for the witness to write 'witness to signature' next to their signature, if not already documented on the form. However, in the healthcare context, questions can also be raised in relation to the information given and the specifics of the discussion between the parties. For this reason, it is preferred that the person explaining the procedure, the medical practitioner, signs as the witness.

Preoperative patient education

Preoperative education concerning a patient's expected postoperative experience, provided in a systematic and structured format underpinned by teaching and learning principles, can have a positive influence on the patient's recovery. The ACORN (2014) asserts that the competence of the nurse conducting the preoperative assessment and providing education can influence the patient's surgical outcome.

Structured preoperative education can influence postoperative factors such as the following:

- *Lung function*. Explaining and demonstrating the technique of deep-breathing and coughing while the patient is pain-free helps the patient learn and perform these exercises postoperatively.
- *Physical functional capacity*. Teaching feet and leg exercises helps to reduce the incidence of postoperative **deep vein thrombosis (DVT)**. These exercises and teaching turning assist to improve the patient's ability to walk and resume activities of daily living.
- *Sense of wellbeing*. Patients who are adequately prepared for surgery often experience less anxiety and report a greater sense of psychological wellbeing.
- *Pain control*. Patients who are involved in learning about pain and ways to relieve it may be less anxious about it and more inclined to ask for what they need.

For preoperative education to be effective, it is important for it to be planned so that the appropriate information is covered, but also for it to have a person-centred approach. It needs to be individualised and tailored to the patient; some patients will want only minimal information and may experience increased levels of anxiety with too much detail, while others will want very detailed and involved information. This is highly individual and, as such, you need to be able to adequately assess the needs of the patient, their existing knowledge in relation to the surgery and identify the specific knowledge gaps.

Detailed discussion and demonstration of postoperative exercises are vital to reduce the risks associated with postoperative recovery. If the patient understands why these exercises are important to postoperative recovery and knows how to perform them correctly, the recovery period will be less complicated. However, despite the education provided to patients, patient retention of information following discharge is often poor. To counteract this, education before admission that is reinforced during the hospital stay and after discharge is important. Frequently, day-surgery centres conduct follow-up telephone interviews with patients after they have been discharged. One of the reasons for this is to ascertain any knowledge gaps and to reinforce previous education provided regarding postoperative care.

Including the patient's family, significant others and/or carer in the perioperative preparation is advised, and the benefits of this should be discussed with the patient. For example, when the patient returns from surgery, a family member may take on the role of 'coach' in relation to the postoperative exercises. If anxious relatives do not understand routine postoperative events, it is likely that their anxiety will heighten the patient's fears and concerns. To minimise anxiety and misunderstanding, preoperative preparation of carers, family and significant others should occur before surgery. It is optimal to also include written

UR No…… **Name:** ……

CRITICAL PATH	ON ADMISSION / PRE-OP DATE:	AM	PM	ND	AM
PSYCHOSOCIAL / SPIRITUAL	• Patient/family/carer informed of and verbalise understanding of procedures • Patient/family/carer designate a person for Surgeon to contact post-op – contact number clearly visible within clipboard that goes to theatre				

NURSING ASSESSMENT	**NB MAY HAVE BEEN COMPLETED AT PRE-ADMISSION**
	• Admission medical / nursing history reviewed in consultation with patient
	• Relevant nursing risk factors discussed with patient / next of kin
	  • Documented as a variance and followed up with relevant clinician
	• Dementia, acute brain syndrome / impulsive behaviours
	  • Nil risk identified ☐
	  • At risk ☐ (documented on MR 050)
	• Bariatric assessment
	  • Notify bookings / Theatre if patient > 100 kgs				

NUTRITION / HYDRATION	• NBM from: ……				
HYGIENE	• Self care – Betadine shower night before and am of op • After second shower – dress in hospital gown and hat, clean sheets to bed				
ELIMINATION	• Normal function. Date of last bowel action……				

SKIN / WOUNDS	• Full shave as per cardiac surgery clinical guidelines (MCC 5.1)
	• Skin integrity intact
	• All jewellery removed prior to surgery, including wedding band/s (tick relevant)
	  • Sent home with next of kin ☐
	  • Placed in Hospital safe ☐				

PAIN / COMFORT / SLEEP	• Patient pain free, comfortable, night sedation offered • Patient educated and verbalises understanding of pain management plan-post-op				
RISK ASSESSMENT	Falls Risk – Screening score _____ if > 65 years or at risk If score > 2 complete Falls Risk Assessment Tool MR 048				
	Skin / Pressure Risk – Complete Braden Risk Assessment Tool MR 047 if > 65 years and LOS > 4 days or at risk.

Figure 39-6 ***continued***

material. Many hospitals will also provide video information aimed at both the patient and the key people who support them.

Provide patients with information about sensations typically experienced after surgery/procedure. Preparatory information helps patients anticipate the steps of a procedure and thus helps them form realistic images of the surgical experience. When events occur as predicted, patients are better able to cope with the experiences. Sensations that the nurse may cover include the expected pain at the surgical site, tightness of dressings, dryness of the mouth or the sensation of a sore throat resulting from an endotracheal tube.

Anxiety and fear are barriers to learning, and both emotions may be heightened. The patient's readiness and ability to learn must be assessed. If the patient is capable of and receptive to learning, the nurse presents information in a logical sequence, beginning with preoperative events and proceeding to postoperative routines. If possible, the family or significant others should be present during teaching.

The following can be used to guide discussions and facilitate demonstration of patient understanding of the surgical experience.

Patient cites reasons for instructions and exercises

Given a rationale for pre- and post-procedures, the patient is better prepared to participate in care. For example, a preoperative education program may include explanation and demonstration of postoperative exercises: diaphragmatic breathing, incentive spirometry, positive expiratory pressure (PEP) therapy, coughing, turning and leg exercises. These exercises are designed to prevent postoperative complications (Skill 39-2).

When a patient is under general anaesthesia, the lungs do not ventilate fully. After surgery the patient has a reduced lung volume and needs greater effort to breathe. **Diaphragmatic breathing** improves lung expansion and oxygen delivery without using excess energy. The patient learns to use the diaphragm during deep-breathing to take slow, deep, relaxed breaths. The goal is to inhale slowly and deeply through the nose, hold the breath for a few seconds and then exhale slowly and completely through the mouth. Eventually the patient's lung volume improves. Deep-breathing also helps clear out anaesthetic gases that remain in the airways. To facilitate deep-breathing, the patient may use an *incentive spirometer*, which encourages effective deep-breathing through sustained maximal inspiration (see Chapter 35).

Patients undergoing cardiothoracic procedures or who may have pre-existing lung disease may use *PEP therapy* postoperatively, such as using a blow-bottle device to reduce atelectasis and improve respiratory function. After use of the device, the patient inhales deeply, holds for 3 seconds, and exhales in short, rapid, forced exhalations ('huff' coughing). **Coughing exercises** help move respiratory secretions to larger airways for expectoration. A deep, productive cough is more beneficial than merely clearing the throat. Nebulised treatments with bronchodilators, such as salbutamol (Ventolin) and ipratropium (Atrovent), may also be prescribed to help with sputum expectoration. Postoperative incisional pain makes coughing difficult. Aggressively manage acute pain and demonstrate methods for splinting the incision to minimise pain during coughing. Encourage patients to cough and breathe deeply every 1–2 hours while awake.

Stasis of circulation may lead to thrombi or clots. A clot that breaks off is referred to as an embolus. An embolus from the leg usually lodges in the lungs (pulmonary embolism), but may also lodge in the heart or brain. Emboli are potentially fatal complications. According to the National Health and Medical Research Council (NHMRC 2011), the incidence of **venous thromboembolism (VTE)** is more than 100 times greater in hospitalised patients than in the community. VTE includes DVT and pulmonary embolus (PE). The cause of 10% of all deaths in hospitals is a PE. The prevention of VTE has been identified

SKILL 39-2

Demonstrating postoperative exercises

Delegation considerations

This task requires the problem-solving and knowledge-application skills of a registered nurse. For this reason, delegation of this task to nurse assistants is inappropriate. The registered nurse can teach assistants to encourage patients to practise exercises regularly following instruction.

Equipment

- Pillow or wrapped towel (optional)
- Incentive spirometer
- Positive expiratory pressure (PEP) device

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Assess patient's risk of postoperative respiratory complications. Review medical history to identify presence of chronic pulmonary conditions (e.g. emphysema, asthma), any condition that affects chest wall movement, history of smoking and presence of reduced haemoglobin.	General anaesthesia predisposes patient to respiratory problems because lungs are not fully inflated during surgery; cough reflex is suppressed, so secretions collect within airway passages. After surgery, patient may have reduced lung volume and require greater efforts to cough and deep-breathe; inadequate lung expansion can lead to atelectasis and pneumonia. Patient is at greater risk of developing respiratory complications if other chronic lung conditions are present. Smoking damages ciliary clearance and increases mucous secretion. Reduced haemoglobin level can lead to inadequate oxygenation.
2. Assess ability to cough and deep-breathe by having patient take deep breath and observing movement of shoulders and chest wall. Measure chest excursion during deep breath. Ask patient to cough after taking deep breath.	Reveals maximum potential for chest expansion and ability to cough forcefully; serves as baseline to measure ability to perform exercises after surgery.
3. Assess risk for postoperative thrombus formation (see Figure 39-6). Observe for calf pain, redness, warmth, swelling or vein distension.	General anaesthesia and immobilisation results in decreased muscular contraction in lower extremities, which promotes venous stasis.
4. Explain postoperative exercises to patient, including their importance to recovery and physiological benefits.	Information allows patient to attend and can motivate learning. People tend to learn new skills when benefits can be gained.

STEPS	RATIONALE
5. Demonstrate exercises. **A. Diaphragmatic breathing**	
(1) Help patient into comfortable sitting or standing position. If patient chooses to sit, help to side of bed or to upright position in chair.	Upright position facilitates diaphragmatic excursion.
(2) Stand or sit facing patient.	Allows patient to observe breathing exercise.
(3) Ask the patient to place palms of hands across from each other, down and along lower borders of anterior rib cage. Place tips of third fingers lightly together (see illustration). Demonstrate for patient.	Position of hands allows patient to feel movement of chest and abdomen as diaphragm descends and lungs expand.

Step 5A(3) Demonstrating placement of hands on upper abdomen.

(4) Have patient take slow, deep breaths, inhaling through nose. Tell patient to feel middle fingers separate during inhalation. Demonstrate.	Taking slow, deep breaths prevents panting or hyperventilation. Inhaling through nose warms, humidifies and filters air.
(5) Explain that patient will feel normal downward movement of diaphragm during inspiration. Explain that abdominal organs descend and chest wall expands.	Explanation and demonstration focus on normal ventilatory movement of chest wall. Patient develops understanding of how diaphragmatic breathing feels.
(6) Avoid using chest and shoulders while inhaling and instruct patient in same manner.	Using auxiliary chest and shoulder muscles increases useless energy expenditure.
(7) Have patient hold slow, deep breath for count of 3 and slowly exhale through mouth. Tell patient middle fingertips will touch as chest wall contracts.	Allows for gradual expulsion of all air.

STEPS	RATIONALE
(8) Repeat breathing exercise 3–5 times.	Allows patient to observe slow, rhythmic breathing pattern.
(9) Have patient practise exercise. Instruct patient to take 10 slow, deep breaths every 2 hours while awake during postoperative period until mobile.	Repetition of exercise reinforces learning. Regular deep-breathing prevents postoperative complications.
B. Incentive spirometry	
(1) Wash hands.	Reduces transmission of microorganisms.
(2) Ask the patient to assume semi-Fowler's or high-Fowler's position.	Promotes optimal lung expansion during respiratory manoeuvre.
(3) Either set or indicate to patient on the device scale the volume level to be attained with each breath.	Establishes volume level necessary for lung expansion.
(4) Demonstrate to patient how to place mouthpiece of spirometer so that lips completely cover mouthpiece (see illustration).	Demonstration is a reliable technique for teaching psychomotor skill and enables the patient to ask questions.
(5) Teach the patient to inhale slowly and maintain constant flow through unit. When maximal inspiration is reached, patient should hold breath for 2–3 seconds and then exhale slowly. Number of breaths should not exceed 10–12/minute.	Maintains maximal inspiration and reduces risk of progressive collapse of individual alveoli. Slow breath prevents or minimises pain from sudden pressure changes in chest.

Step 5B(4) Patient learning incentive spirometry.

(6) Ask the patient to breathe normally for short period.	Prevents hyperventilation and fatigue.

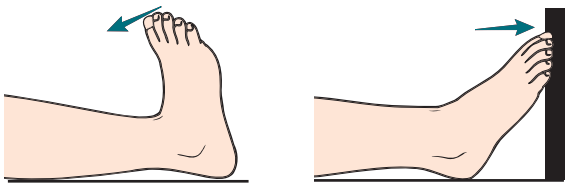
STEPS	RATIONALE
(7) Have patient repeat manoeuvre until volume goals are achieved.	Ensures correct use of spirometer.
(8) Wash hands.	Reduces transmission of microorganisms.
C. Positive expiratory pressure therapy and 'huff' coughing	
(1) Wash hands.	Reduces transmission of microorganisms.
(2) Assemble appropriate PEP device, e.g. blow-bottle.	
(3) Ask the patient to assume semi-Fowler's or high-Fowler's position.	Promotes optimal lung expansion and expectoration of secretions.
(4) Have patient place lips around tubing. Patient should take a full breath and then exhale 2–3 times longer than inhalation. Pattern should be repeated for 10–20 breaths.	Ensures that all breathing is done through the mouth and that the device is used properly.
(5) Remove device from mouth and have patient take a slow, deep breath and hold for 3 seconds.	Promotes lung expansion before coughing.
(6) Teach the patient to exhale in quick, short, forced exhalations.	'Huff' coughing, or forced expiratory technique, promotes bronchial hygiene by increased expectoration of secretions.
D. Controlled coughing	
(1) Explain importance of maintaining upright position.	Position facilitates diaphragm excursion and enhances thorax expansion.
(2) Demonstrate coughing. Take two slow, deep breaths, inhaling through nose and exhaling through mouth.	Deep breaths expand lungs fully so that air moves behind mucous and facilitates effects of coughing.
(3) Inhale deeply third time and hold breath to count of three. Cough fully for two or three consecutive coughs without inhaling between coughs. (Tell patient to push all air out of lungs.)	Consecutive coughs help remove mucous more effectively and completely than one forceful cough.
(4) Caution patient against just clearing throat instead of coughing.	Clearing throat does not remove mucous from deep in airways.
(5) If surgical incision will be abdominal or thoracic, teach patient to place one hand over incisional area and other hand on top of first. During breathing and coughing exercises, patient presses gently against incisional area to splint or support it. Pillow over incision is optional (see illustration).	Surgical incision cuts through muscles, tissues and nerve endings. Deep-breathing and coughing exercises place additional stress on suture line and cause discomfort. Splinting incision with hands provides firm support and reduces incisional pulling. (Some patients prefer to have a pillow to place over incision.)

STEPS	RATIONALE

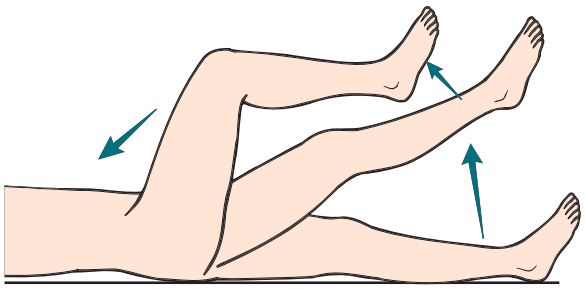
Step 5D(5) Techniques for splinting incision.

(6) Patient continues to practise coughing exercises, splinting imaginary incision. Teach the patient to cough 2–3 times every 2 hours while awake.	Value of deep coughing with splinting is stressed to effectively expectorate secretions with minimal discomfort.
(7) Teach the patient to examine sputum for consistency, amount and colour changes.	Sputum consistency, amount and colour changes may indicate presence of pulmonary complication, such as pneumonia.
E. Turning	
(1) Ask the patient to assume supine position to the right side of bed if permitted by surgery. Side rails on both sides of bed should be in up position.	Positioning begins on right side of bed so that turning to left side will not cause patient to roll towards bed's edge.
(2) Have the patient place their left hand over the incisional area to splint it.	Supports and minimises pulling on suture line during turning.
(3) Ask the patient to keep the left leg straight and flex the right knee up and over the left leg (if back surgery was performed, patient will need to logroll).	Straight leg stabilises patient's position. Flexed right leg shifts weight for easier turning.
(4) Have the patient grab the left side rail with the right hand, pull towards the left and roll onto their left side.	Pulling towards side rail reduces effort needed for turning.
(5) Teach the patient to turn every 2 hours while awake.	Reduces risk of vascular and pulmonary complications.
F. Leg exercises	
(1) Have patient assume supine position in bed. Demonstrate leg exercises by performing passive range-of-motion exercises and simultaneously explaining exercise.	Provides normal anatomical position of lower extremities.
(2) Rotate each ankle in complete circle. Instruct patient to draw imaginary circles with big toe. Repeat 5 times.	Leg exercises maintain joint mobility and promote venous return to prevent thrombi.
(3) Alternate dorsiflexion and plantar flexion of both feet. Direct patient to feel calf muscles contract and relax alternately (see illustration). Repeat 5 times.	Stretches and contracts gastrocnemius muscles.

STEPS	RATIONALE
(4) Have patient alternately raise each leg straight up from bed surface, keeping legs straight. Repeat 5 times.	Promotes contraction and relaxation of quadriceps muscles.
(5) Have patient continue leg exercises by alternately flexing and extending knees. Repeat 5 times (see illustration).	Contracts muscles of upper legs and maintains knee mobility.



Step 5F(3) Alternate dorsiflexion and plantar flexion of foot.



Step 5F(4 & 5) Hip and knee movements.

6. Have the patient practise exercises at least every 2 hours while awake. Teach the patient to coordinate turning and leg exercises with diaphragmatic breathing, incentive spirometry and coughing exercises.	Repetition of sequence reinforces learning. Establishes routine for exercises that develops habit for performance. Sequence of exercises should be leg exercises, turning, breathing, incentive spirometry and coughing.
7. Observe the patient's ability to perform all exercises independently.	Ensures that patient has learnt correct technique.
8. Record exercises demonstrated and the patient's ability to perform them independently.	Documents patient's education and provides data for instructional follow-up.

as a national and international priority area for improving patient safety (NHMRC 2011). Effective prophylactic measures include wearing compression stockings, performing feet and leg exercises while in bed, using a compression pump on the lower legs and anticoagulants (NHMRC 2008). A summary of the current Australian evidence-based guidelines for thromboprophylaxis for both medical and surgical patients admitted to hospital is presented in Figure 39-7.

Leg exercises and mobilisation improve venous return from the extremities and thus reduce stasis. Contraction of lower leg muscles promotes venous return, reducing the risk for clot formation. Encourage the patient to perform leg exercises 10–12 times at least every 1–2 hours while awake if not ambulant. If the patient is measured for elastic compression stockings or pneumatic compression devices, they must be educated about the purposes and nursing care that will be required following application (see Chapter 28).

Each exercise needs to be explained and demonstrated. The nurse acts as a coach, guiding the patient through each one. For example, assess whether the patient is sitting properly and help them place the hands in the proper position during breathing. It is important to evaluate the effectiveness of the education session and the patient's ability to perform the exercises correctly. The patient should be given time for independent practice and you need to re-evaluate the overall effectiveness of the patient performing the exercises before surgery.

Patient states the unit location and location of the family during procedure/surgery and immediate recovery period

The unit to which the patient is admitted before the procedure/surgery may be different from the unit afterwards. The family needs to know where the patient will be. Explain where the family can wait. If the patient is to be taken to a special unit after surgery, for example, it helps to orient the patient and family to the unit's environment before surgery.

Prevention of Venous Thromboembolism (VTE) in Patients Admitted to Australian Hospitals: Guideline Summary

This summary and full guideline available from **www.nhmrc.gov.au**

Steps in selecting thromboprophylaxis

STEP 1: If the patient is admitted for any of the following surgical procedures or injury, the procedures carry a high risk of VTE and some form of thromboprophylaxis is warranted (as per page 2 of this guideline summary):

- any surgical procedure, but especially abdominal, pelvic, thoracic or orthopaedic surgery. Major joint surgery and curative surgery for cancer carry very high VTE risk
- leg injury requiring surgery or prolonged immobilisation
- prolonged surgery and/or prolonged immobilisation.

Prior to selecting an appropriate method, consider other VTE risk factors (STEP 2), patient preference and possible pharmacological (STEP 3) or mechanical (STEP 4) contraindications and then refer to page 2 for advice on recommended VTE prophylactic options based on the type of surgery or injury.

STEP 2: Assess other VTE risk factors (patient and condition based).
Presence of any of these risk factors or conditions may warrant VTE prophylaxis for any hospital admission.

VTE risk is increased with:
- previous VTE
- active cancer
- age (incidence of VTE rises with each decade over age 40)
- prolonged severe immobility (prolonged bed rest, immobilisation in a plaster cast/brace or prolonged travel with limited movement and venous stasis)
- pregnancy and the puerperium
- marked obesity
- oestrogen-containing hormone replacement therapy (HRT) or oral contraceptive
- certain types of thrombophilia
- general anaesthesia (versus regional anaesthesia).

VTE risk is increased with the following medical conditions:
- acute/acute-on-chronic chest infection
- heart failure
- myocardial infarction
- ischaemic stroke with immobility
- some forms of cancer chemotherapy
- acute inflammatory bowel disease.

STEP 3: Assess the risk of bleeding/contraindications to pharmacological prophylaxis. Presence of any of the following factors may contraindicate pharmacological prophylaxis. If pharmacological prophylaxis is contraindicated, consider mechanical prophylaxis, if appropriate (STEP 4).

Consider:
- significant renal impairment (reduced creatinine clearance for renally excreted anticoagulants)
- current active major bleeding (i.e. at least 2 units of blood/blood products transfused in 24 hours)
- current chronic, clinically significant and measurable bleeding over 48 hours
- inherited or acquired bleeding disorders, e.g. haemophilia or other coagulation factor abnormality, coagulopathy or disseminated intravascular coagulation (DIC)
- severe platelet function disorder or thrombocytopenia (pharmacological prophylaxis not recommended with platelet count <50,000/μL)
- recent central nervous system (CNS) bleeding
- intracranial or spinal lesion
- recent major surgical procedure of high bleeding risk
- active peptic ulcer or active ulcerative gastrointestinal disease
- liver failure or prolonged obstructive jaundice
- concomitant use of medications that may affect clotting (e.g. anticoagulants, antiplatelet agents, selective/non-selective nonsteroidal anti-inflammatory drugs—NSAIDs)
- neuraxial block or recent lumbar puncture.

STEP 4: Assess any contraindications to mechanical prophylaxis.

- Graduated compression stockings may cause reduced blood flow, pressure ulcers or increase the risk of falls, so are contraindicated with:
  - any factor that prevents correct fitting of stockings (e.g. morbid obesity)
  - inflammatory conditions of the lower leg
  - severe peripheral arterial disease
  - diabetic neuropathy
  - severe oedema of the legs
  - severe lower limb deformity or inability to correctly fit stockings.
- Intermittent pneumatic compression (IPC) or foot pumps can exacerbate peripheral arterial disease or arterial ulcers.

STEP 5: Select appropriate thromboprophylaxis.

Consult with patient to ensure support for, and adherence to, VTE prophylaxis measures.

continued

Thromboprophylaxis for admitted surgical patients

Anaesthesia	• Consider neuraxial block as an alternative to general anaesthesia if feasible. If neuraxial block is used, there is a risk of developing an epidural haematoma (A) • To minimise this risk with neuraxial block, timing of pharmacological thromboprophylaxis should be carefully planned and discussed in advance with the anaesthetist (GPP)

Type of surgery	Recommendations (and grade of recommendations)	
	Pharmacological options	**Mechanical options**
Total hip replacement	*Use either:* • LMWH (A) or • Fondaparinux (B) or • Rivaroxaban (B) or • Dabigatran etexilate (B) *For up to 35 days*	• Use GCS or IPC or foot pump (B) whether or not pharmacological prophylaxis is used • If pharmacological prophylaxis is contra-indicated, use GCS and foot pump (B) *Use until fully mobile*
Hip fracture surgery	*Use either:* • Fondaparinux (B) or • LMWH (B). If using LMWH, consider adding low dose aspirin (B) *For up to 35 days*	• If pharmacological prophylaxis is contra-indicated, use foot pump or IPC (C) *Use until fully mobile*
Total knee replacement	*Use either:* • LMWH (A) or • Fondaparinux (B) or • Rivaroxaban (B) or • Dabigatran etexilate (B) *For up to 14 days*	• Use foot pump or IPC (C) whether or not pharmacological prophylaxis is used *Use until fully mobile*
Knee arthroscopy	• Thromboprophylaxis is not recommended unless the patient has additional VTE risk factors (see Step 2, page 1) (C)	• Insufficient evidence; unable to make a recommendation
Lower leg fractures/ injuries with immobilisation in a brace or plaster cast	• LMWH (A) *For the entire period of immobilisation*	• Insufficient evidence; unable to make a recommendation
General surgery	*Use either:* • LMWH (B) or • UFH (B) *For up to one week or until fully mobile*	• Use GCS, whether or not pharmacological prophylaxis is used (B) *Use until fully mobile*
Urological surgery	• Consider thromboprophylaxis based on assessment of the patient's risk of VTE and of bleeding (GPP)	• Inconclusive evidence; unable to make a recommendation
Gynaecological surgery	*Use either:* • LMWH (B) or • UFH (B) *For up to one week or until fully mobile*	• Consider using GCS or other mechanical options, especially if pharmacological prophylaxis is contraindicated (GPP) *Use until fully mobile*
Abdominal surgery	• Use LMWH (B) *For 5–9 days*	• Use GCS, whether or not pharmacological prophylaxis is used (B) *Use until fully mobile*
Cardiac, thoracic and vascular surgery	*Use either:* • LMWH (B) or • UFH (B) *For up to one week or until fully mobile*	• Use GCS or IPC, whether or not pharmacological prophylaxis is used (C) *Use until fully mobile*
Neurosurgery	• Due to high risk of bleeding, use thromboprophylaxis with extreme caution (GPP) • If appropriate and not contraindicated, use LMWH or UFH (B)	• Use IPC, whether or not pharmacological prophylaxis is used (A) • Consider use of GCS (C) *Use until fully mobile*
Trauma and spinal surgery	• Use LMWH, starting 5 days after admission (C) • Do not start thromboprophylaxis until primary haemostasis has been established (GPP) *Use until fully mobile*	• In addition to pharmacological prophylaxis, use foot pump for trauma surgery patients, from admission (C) *Use until fully mobile*
Cancer patients having general, abdominal, pelvic or neurosurgery (see also next category)	• Use LMWH or UFH. In particular, consider risk of bleeding (GPP) *For at least 7–10 days post surgery* • Consider extending the duration of LMWH to 28 days for patients having major abdominal or pelvic surgery for cancer, especially if obese, slow to mobilise or with past history of VTE (GPP)	• Use GCS, if pharmacological prophylaxis is contraindicated (GPP) *Use until fully mobile*
Head and neck cancer patients having head and neck surgery	• Unless other significant VTE risk factors are present (see Step 2, page 1), thromboprophylaxis is **not recommended** (GPP)	• Insufficient evidence; unable to make a recommendation
Caesarean section	• Mobilise promptly post caesarean (GPP) • Use LMWH after caesarean delivery *for 5–7 days post caesarean or until fully mobile* (GPP) • For women with additional risk factors (see Step 2, page 1), extend LMWH or adjusted therapeutic dose warfarin *to six weeks* (GPP)	• Consider using IPC *during and 24 hours after caesarean* (GPP) • Consider using GCS if pharmacological prophylaxis is contraindicated (GPP)

Thromboprophylaxis for admitted medical patients

Medical condition	Recommendations (and grade of recommendations)	
	Pharmacological options	**Mechanical options**
Ischaemic stroke	• Consider LMWH, based on degree of immobility and risk of bleeding (B) • If LMWH is contraindicated or not available, use UFH (B)	• Inconclusive evidence; unable to make a recommendation
Haemorrhagic stroke	• **Do not use** any pharmacological prophylaxis due to the risk of intracranial bleeding (GPP)	• Inconclusive evidence; unable to make a recommendation
Myocardial infarction	• UFH (C), only when full anticoagulation is not in use	• Insufficient evidence; unable to make a recommendation
General medical: **• acute/ acute-on-chronic chest infection** **• heart failure** **• myocardial infarction** **• stroke with immobility** **• some forms of cancer chemo-therapy** **• acute inflammatory bowel disease**	*Use either:* • LMWH or UFH, based on assessment of patient's risk of VTE and bleeding (B)	• Insufficient evidence; unable to make a recommendation
Cancer (non-surgical)	• Use LMWH or UFH (GPP) *From admission until discharge*	• Use GCS, if pharmacological prophylaxis is contraindicated (GPP)
Pregnancy and childbirth (not caesarean – see surgical recommendations)	• Minimise immobilisation and ensure adequate hydration during pregnancy, labour and the puerperium (GPP) • For women with additional VTE risk factors (see Step 2, page 1), use LMWH or adjusted dose warfarin *for six weeks post vaginal delivery* (GPP)	• Consider using GCS if pharmacological prophylaxis is contraindicated or not used (GPP)

NHMRC grading of recommendations

A	Body of evidence can be trusted to guide practice
B	Body of evidence can be trusted to guide practice in most situations
C	Body of evidence provides some support for recommendation(s) but care should be taken in its application
D	Body of evidence is weak and recommendation must be applied with caution
GPP	Good practice point – consensus-based recommendations

Key

LMWH	Low molecular weight heparin
UFH	Unfractionated heparin
GCS	Graduated compression stockings
IPC	Intermittent pneumatic compression

This summary is based on the National Health and Medical Research Council's *Clinical Practice Guideline for the Prevention of Venous Thromboembolism in Patients Admitted to Australian Hospitals.*

Figure 39-7 ***continued***

Patient discusses anticipated postoperative monitoring and therapies

The patient and family want to know about post-procedure and postoperative events. If they understand the frequency of vital sign monitoring before surgery occurs, they will be less apprehensive when nurses regularly assess vital signs. The nurse can also explain whether the patient is likely to have IV lines, monitoring lines, dressings or drainage tubes.

Patient describes surgical procedures and postoperative treatment

After the surgeon has explained the basic purpose of a surgical procedure, the patient may ask additional questions to clarify misunderstandings. Pre-established teaching standards, such as those integrated in clinical pathways for preoperative and postoperative care (Figures 39-6 and 39-11), give the nurse an excellent guide for instruction. One way to avoid problems is to first ask what the patient has been told.

Patient describes activity resumption after the procedure/surgery

The specific surgery or procedure a patient undergoes affects the speed with which normal physical activity and regular eating habits can be resumed. Explain that it is normal to progress gradually in activity and eating. If the patient tolerates activity and diet well, activity levels will progress more quickly.

Patient has understanding of expected pain management

One of the patient's greatest fears is pain. The family is also concerned for the patient's comfort. Acute pain after surgery and some procedures should be aggressively treated and prevented where possible. Inform the patient and family of interventions available for pain relief (e.g. analgesics, positioning, splinting and relaxation exercises) and determine the patient's comfort–function goal (see Chapter 36). The patient needs to know about the use of analgesics, the route of administration and their effects.

Some patients avoid taking analgesics because of prevalent myths and misconceptions, such as the fear of becoming addicted to opioids. You should dispel any misconceptions about pain management and encourage the patient to use analgesics as needed (see Chapter 36). Uncontrolled pain leads to prolonged recovery time and postoperative complications.

The patient should be encouraged to inform nurses as soon as they experience pain or discomfort. If a patient waits until pain becomes severe, pain-relief interventions are less effective. Patients who will have patient-controlled analgesia (PCA) after surgery should know how to use the machine to prevent pain and understand that use of PCA will not cause overdose. Regional analgesia (see Chapter 36) is also commonly used for postoperative pain control. The use of a pain scale can help the patient to express the intensity and presence of pain, as well as assisting the nurse in evaluating effectiveness of pain-control interventions. Information from preoperative pain assessment will be helpful to the nurse when educating about pain-relief measures.

Physical preparation

The degree of physical preparation depends on the patient's health status, the surgery or procedure to be performed and sometimes surgeon preferences. An acutely ill patient will receive more supportive care in the form of medication, IV therapy and monitoring than the patient having a minor elective procedure.

Maintenance of fluid and electrolyte balance

The patient having surgery and some procedures is vulnerable to fluid and electrolyte imbalances as a result of inadequate preoperative intake or excessive fluid losses during surgery. It is relatively common practice for the patient to be ordered to fast or take nil by mouth (NBM) prior to surgery. The timeframe varies depending on the type of surgery and/or procedure. Fasting is required to reduce the risk associated with general anaesthesia for aspiration of gastric contents during and after surgery. Medical staff will also consider the patient's usual medications and, if indicated, may prescribe necessary medications to be taken with 30 mL of water (e.g. antihypertensive and anticonvulsant medications).

The Australian and New Zealand College of Anaesthetists (2010) recommends the following guidelines for preoperative fasting for patients selected for day-care surgery, unless otherwise specifically prescribed by the anaesthetist, or where other institution guidelines apply:

- For healthy adults having an elective procedure, limited solid food may be taken up to 6 hours prior to anaesthesia and clear fluids totalling not more than 200 mL per hour may be taken up to 2 hours prior to anaesthesia.
- For healthy children over 6 weeks of age having an elective procedure, limited solid food and formula milk may be given up to 6 hours, breast milk may be given up to 4 hours and clear fluids up to 2 hours prior to anaesthesia.
- For healthy infants under 6 weeks of age having an elective procedure, formula or breast milk may be given up to 4 hours and clear fluids up to 2 hours prior to anaesthesia.
- Only medications with a little water if required as prescribed by the anaesthetist should be taken less than 2 hours prior to anaesthesia.
- A proton-pump inhibitor or other appropriate agent should be considered for patients with an increased risk of gastric regurgitation.

It is the nurse's responsibility to educate the patient, significant others and family about fasting time and to ensure they understand the importance of fasting. All fluids and foods should be removed from the patient's bedside and a sign posted over the bed to alert all hospital personnel and family members of the fasting restrictions.

As patients may experience thirst and dryness in the mouth while fasting, it is important to assist the patient with mouth care, rinsing the mouth with water or mouthwash and/or brushing teeth. If the patient eats or drinks anything during the fasting period, notify the surgeon. An IV route for fluid replacement may be commenced if indicated.

Reduction of risk of surgical site infection

Infection of the surgical wound is a risk associated with having surgery. A **surgical site infection (SSI)** is not only a potentially serious complication which can cause morbidity and possible mortality; it can also lengthen hospital stay for the patient and results in increased healthcare-related costs (ACORN 2014, Webster & Osborne 2015). The skin is a site for microorganisms to grow and multiply. Skin preparation is used in the operating

room, immediately prior to making the incision and, depending on the type of surgery, the patient may be required to bath or shower before the operation using an antiseptic wash. According to recent evidence-based standards (ACORN 2014), the antiseptic must be registered with the Therapeutic Goods Administration and is used to remove contamination and reduce skin microbial counts.

Hair removal is needed only if the hair has the potential to interfere with exposure, closure or dressing of the surgical site. Hair removal can damage and cause breaks in the patient's skin integrity, which puts the patient at risk for infection due to microorganism entry. The ACORN (2014) standards recommend: the skin at, and surrounding, the operative site should be assessed for integrity and inflammatory reactions to depilatory creams and antiseptic washes (if used); if hair removal is to be performed, it should be as close to the time of surgery as practical; hair removal should be undertaken outside of the operating room where the surgery is to be conducted; hair clippers with disposable blades are to be used to preserve skin integrity.

Short hospital stays are known to reduce the chance of a nosocomial infection. SSIs and respiratory infections can all be acquired during hospitalisation. This is one advantage of having same-day surgery, since the patient usually returns home on the day of surgery, reducing the time spent in hospital.

Bowel and urinary elimination

If the patient's surgery or procedure involves the GI tract, they may be ordered to receive bowel preparation prior to the procedure. What this specifically involves depends on the type of surgery or procedure. For example, prior to a colonoscopy procedure, the patient will be ordered an oral prepkit that entails taking medication to induce loose and frequent stools and following a specific diet 1–2 days before the colonoscopy. This is to assist in the success of the colonoscopy and to ensure clear visualisation.

Manipulation of parts of the GI tract during surgery results in reduced peristalsis for 24 hours and sometimes longer. Enemas and cathartics cleanse the GI tract to prevent intraoperative incontinence and postoperative constipation. An empty bowel reduces risk of injury to the intestines and prevents contamination of the operative wound in case a part of the bowel is incised or opened accidentally, or if colon surgery is planned.

In relation to urinary elimination, ask the patient to void just before administering any ordered preoperative medications and/or leaving for the operating room. An empty bladder reduces the risk of urinary incontinence during surgery and is also important for abdominal surgery, when it may be necessary for the surgeon to manipulate the bladder. An empty bladder also makes abdominal organs more accessible during surgery. An indwelling urinary catheter (IDC) may be inserted in the operating room to maintain an empty bladder.

Promotion of rest and comfort

Rest is essential for normal healing. Anxiety about surgery can easily interfere with the ability to relax or sleep. The underlying condition requiring surgery may be painful, further impairing rest. Attempts should be made to ensure that the patient's environment is quiet and comfortable. The surgeon may order a sedative–hypnotic or antianxiety agent before the surgery.

An advantage of same-day surgery is that the patient is able to sleep at home the night before. The patient is likely to get more rest in a familiar and usually quieter environment than a hospital. The non-hospitalised patient may also have medication ordered if apprehension about surgery is likely to interfere with their sleep pattern.

Preparation on the day of surgery or procedure

On the day the nurse completes a number of activities before transferring the patient to the operating theatre or procedure room. These activities are conducted as part of risk-management strategies for patients undergoing surgery and a checklist must often be completed by the nurse; see example in Figure 39-8 of a preoperative checklist. Examples of requirements on the checklist are: patient wearing patient identifiers, completed consent form, and medication chart and diagnostic test results to accompany the patient.

The nurse makes a final preoperative assessment of vital signs. The anaesthetist uses these values as a baseline for intraoperative/during procedure vital signs. If the baseline vital signs are abnormal for the patient, the surgery or procedure may be postponed. In addition to assessing vital signs, it is important that the patient enters the operating suite clean. If the patient is unwilling or unable to independently meet their own hygiene needs, assist the patient to have a shower, bath, or bed-bath. A clean hospital gown is provided. The patient's mouth may be dry due to fasting and it is important that mouth care is addressed. The patient should be cautioned not to swallow any water. No make-up (lipstick, powder, blusher, nail polish) is to be worn which can interfere with skin and mucous membrane assessment to determine the patient's level of oxygenation and circulation both during and after the procedure/surgery. Therefore all make-up should be removed to expose normal skin and nail colouring. Nail polish is generally removed too as some colours (e.g. black and brown) may affect peripheral pulse-oximetry readings (Chan et al 2013).

If a patient has any valuables (e.g. money, jewellery), with permission of the patient, give these to a family member/significant other in the first instance, or secure them for safekeeping. Many hospitals require patients to sign a release form to free the institution of responsibility for lost valuables. There may be a facility for securely storing valuables in a designated location. Often patients are reluctant to remove wedding rings or religious medals. A wedding ring can be taped in place. However, if there is a risk that the patient will experience swelling of the hand or fingers (e.g. hand surgery, mastectomy, fluid shifts), the ring should be removed.

VTE is a major cause of death among hospitalised adults. To prevent DVT, **antiembolism stockings** or sequential compression devices (SCDs) are commonly used. Antiembolism stockings are designed to support the lower extremities and maintain compression of small veins and capillaries. The constant compression forces blood into larger vessels, thus promoting venous return and preventing circulatory stasis. When correctly sized and properly applied, antiembolism stockings can reduce the risk of thrombi. SCDs may be applied to the lower extremities for the same purpose. These devices promote circulation by sequentially compressing the legs from the ankle upwards, promoting venous return. Application may be ordered preoperatively, intraoperatively (especially for long surgery) or postoperatively

All checks need to be read out loud at time of confirmation

Sign in - Before anaesthesia or equivalent

1. Patient has confirmed:
- ☐ Identity AND
- ☐ Site / Side AND
- ☐ Procedure AND
- ☐ Consent

2. Site marked:
- ☐ Yes OR
- ☐ Not applicable

3. Anaesthesia safety check completed:
- ☐ Yes

4. Appropriate equipment / assistance available for managing a difficult airway / aspiration risk:
- ☐ Yes

5. Known allergy(ies):
- ☐ Yes OR
- ☐ No

6. Known alert(s):
- ☐ Yes OR
- ☐ No

7. Risk of blood loss of > 500mL (7mL/kg in children):
- ☐ Yes, and adequate planning for intravenous access and fluids OR
- ☐ No

8. Prosthesis (or special equipment) has been checked and confirmed:
- ☐ Yes OR
- ☐ Not applicable

9. Plan for antibiotic prophylaxis has been made:
- ☐ Yes OR
- ☐ Not applicable

10. Thromboprophylaxis:

Mechanical:
- ☐ Implemented OR
- ☐ Not indicated

Mechanical:
- ☐ Ordered OR
- ☐ Not indicated

11. Essential imaging:
- ☐ Checked with patient ID AND
- ☐ Available in theatre and viewed by operator AND
- ☐ Cross-checked against planned procedure OR
- ☐ Not applicable

Time out - Before operative procedure or equivalent commences

12. Confirm all team members have:
- ☐ Introduced themselves by name and role OR
- ☐ Already know each other by name and role

13. Surgeon, Anaesthetist and Nurse confirm:
- ☐ Patient AND
- ☐ Site / Side AND
- ☐ Procedure

14. Antibiotic prophylaxis has been given:
- ☐ Yes OR
- ☐ Not applicable

15. Pressure injury prevention plan implemented:
- ☐ Yes

16. Anticipated critical events:

Surgical team review:
- ☐ Confirm the critical or non-routine steps

Anaesthesia team review:
- ☐ Confirm any patient-specific concerns

Nursing team review:
- ☐ Confirm sterility (including indicator results) AND
- ☐ Confirm all equipment available

Sign out - Before patient leaves operating room

17. Nurse confirms with the team:
- ☐ The name of the procedure documented AND
- ☐ Accountable items count correct

18. Specimens are correctly labelled:
- ☐ Yes OR
- ☐ Not applicable

19. Equipment problems to be addressed:
- ☐ Yes OR
- ☐ Not applicable

20. Specific concerns for post operative care including pressure injury prevention:
- ☐ Surgical team AND
- ☐ Anaesthetic team AND
- ☐ Nursing team

Figure 39-8 ***continued***

according to agency policy and the procedure manual. Documentation of application, capillary refill and patient tolerance should be in the patient chart.

Performing special procedures

The patient may be prescribed pre-anaesthetic medication ('on-call medication', 'pre-med', 'preop med') for a number of reasons, including to reduce patient anxiety, the amount of anaesthetic required, and the risk of nausea and vomiting (Table 39-2). Prior to administering the medication, all other nursing care measures are completed. The consent form must have been signed before administration and the patient should have been assisted to the toilet (if able) to void. As some medication may cause sedation, the patient is advised not to leave the bed or trolley. The call bell is left within the patient's reach and the patient is advised to call for assistance if required. If the patient asks to go to the toilet after premedication is administered and it has a sedating effect, the patient is given a pan or urinal in the bed.

EVALUATING IMPACTS AND OUTCOMES

The admitting nurse or the nurse caring for the patient preoperatively will evaluate patient preoperative outcomes (Figure 39-9). With regard to the preoperative patient's plan of care, there may be limited time to evaluate the outcomes, for example in the case of immediate, emergency surgery and same-day surgery. To determine the effectiveness of preoperative interventions, ask the patient to discuss their understanding of the surgical procedure and their expectations after the surgery. This will assist in determining the patient's knowledge level and identify any gaps that should be addressed. Skilled observation and interaction with the patient will assist in identifying the presence of fear or anxiety, which can then be investigated further and addressed appropriately with reassurance, information and/or possibly medication. Evaluate the patient's knowledge of postoperative care, which may include use of patient-controlled analgesia, exercises and use of a pain scale. The patient's status is compared with expected outcomes to determine whether new or revised interventions need to be implemented and/or priorities of care identified.

TABLE 39-2 Preoperative medications and their purpose

Medication	Purpose
Antacids	Decrease gastric acidity
Antibiotics	Minimise risk of wound infection
Anticholinergics Atropine Hyoscine Glycopyrrolate	Dry secretions and decrease risk of aspiration and airway irritability
Antiemetics Ranitidine (Zantac) Cimetidine (Tagamet) Famotidine (Pepcidine) Metoclopramide (Maxolon)	Increase gastric pH and/or promote gastric emptying (decreasing risk of aspiration)
Barbiturates Secobarbital Pentobarbitone	Provide sedation with minimal cardiopulmonary depressant effects
Benzodiazepines Midazolam (Hypnovel) Diazepam (Valium) Lorazepam (Ativan)	Reduce anxiety and/or provide sedation
Opioids	Decrease intraoperative anaesthesia requirements and facilitate induction

The essentials of safe and quality care post-procedure/surgery

After surgery or some procedures a patient's care can become complex as a result of physiological changes that may occur. Patients who have undergone general anaesthesia (GA) are more likely to face complications than those who have had only local anaesthesia. The patient who requires GA has usually undergone extensive surgery as well. In contrast, a same-day surgery patient who has had local anaesthesia with no sedation and has stable vital signs may be immediately discharged. A patient who has undergone regional anaesthesia or GA is usually transferred to a high-dependency area in the operating suite called the post-anaesthesia care unit (PACU; also referred to as the **post-anaesthetic recovery unit (PARU)** in a number of settings) to be stabilised before discharge, whereas a patient who has had local anaesthesia may go directly to the nursing unit or back to the same-day surgery centre.

A patient's **postoperative** course involves two phases: the immediate recovery period (in PACU) and post-operative rehabilitation. For a same-day surgery patient, recovery normally lasts only 1–2 hours, and rehabilitation takes place at home. For a hospitalised patient, recovery may last a few hours, and rehabilitation takes 1 or more days, depending on the extent of surgery and the patient's response.

Immediate postoperative recovery

Immediately following surgery the patient is usually transferred to the PACU to allow close observation to identify and/or prevent complications and adverse events (Street et al 2015). The patient may ask the PACU nurse what the surgeon specifically did during the operation. It is the surgeon's responsibility to describe the patient's status, the results of surgery and any complications that may have been encountered.

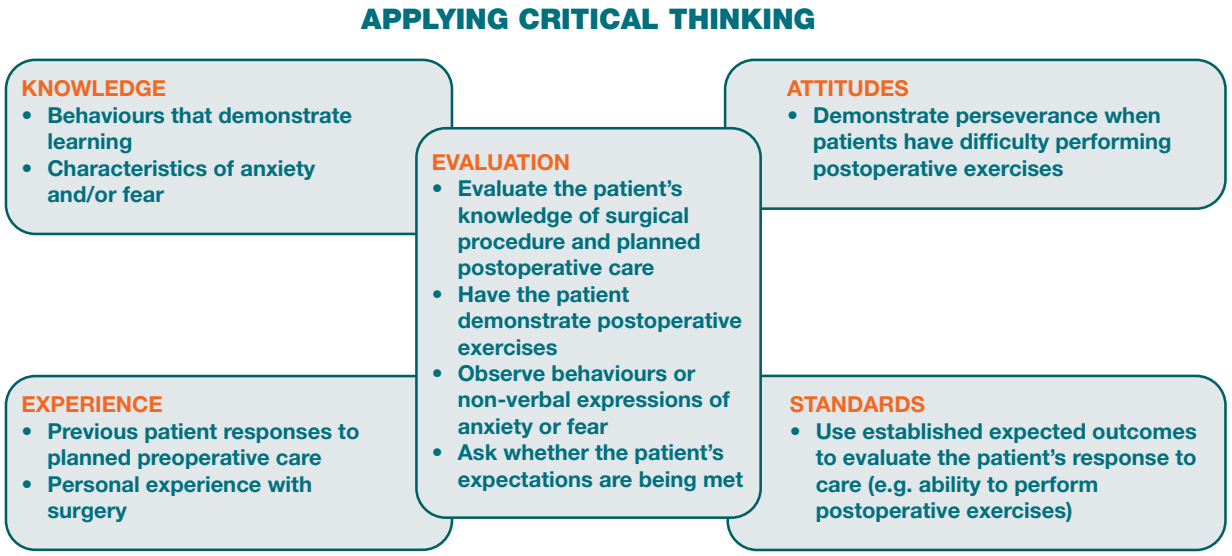

Figure 39-9 **Critical thinking model associated with the evaluation phase for the surgical patient.**

Discharge from the PACU

The recovery nurse evaluates patient readiness for discharge from the PACU on the basis of several factors, including preoperative status, surgical procedure, anaesthetic, level of conscious state, level of pain, nausea and vomiting, and vital sign stability (Phillips et al 2011). Other outcomes for discharge include absence of complications, controlled wound drainage and adequate urine output. Patients with more-extensive surgery requiring anaesthesia of longer duration usually recover more slowly.

When the patient has been assessed as ready to be discharged from the PACU, the recovery nurse calls the acute care unit. The nurse from the unit attends the post-anaesthetic unit and receives a handover from the PACU nurse. The comprehensive handover includes specifics regarding the surgery performed and type of anaesthesia, and a report of vital signs, blood loss, level of consciousness, general physical condition, presence of IV lines, drainage tubes or catheters and any specific documented postoperative orders. The PACU nurse's report helps the nurse in the acute care area to anticipate special patient needs and obtain necessary equipment. The patient is usually returned to the surgical unit on a trolley. Nurses in the surgical unit assist to safely transfer the patient to a bed.

Recovery in same-day surgery

The thoroughness and extent of postoperative assessment depends on the same-day surgery patient's condition, type of surgery and anaesthesia. In many cases, the assessment is identical to that conducted for hospitalised patients. However, if the patient has undergone minor surgery (e.g. cosmetic removal of a mole), the postoperative recovery phase requires minimal assessment.

The time that a patient spends in recovery depends on several factors. Outpatient anaesthesia is gauged to provide a quick recovery time, few after-effects and a speedy return to daily routines. Patients are encouraged to gradually sit up on the trolley or bed and begin to take ice chips or sips of water while regaining full alertness. Some patients who have undergone minor surgery may be transferred directly to a room equipped with medical recliner chairs, side tables and foot rests. Kitchen facilities for preparing light snacks and beverages are usually located in the area, along with bathrooms. Considerations for discharge for ambulatory patients include condition of the dressing, intensity and location of pain, ability to stand and walk, tolerance of oral fluids and/or food and ability to urinate spontaneously (Herrera et al 2007). Nurses review postoperative education and instructions with the patient and their support person (Box 39-6).

Postoperative rehabilitation

Same-day surgery patients are discharged to home when they meet certain criteria; for example, they are alert and oriented, have minimal nausea/vomiting, minimal postoperative pain and no excess bleeding or drainage, are able to void (if applicable) and walk, they have received written postoperative instructions and prescriptions, they understand these instructions and they are being discharged to a responsible adult.

BOX 39-6 Client teaching of postoperative instructions for ambulatory surgical client

Objectives

- Client will list resources to contact for assistance.
- Client will describe signs and symptoms of postoperative problems.
- Client will list the name and dose of medications.
- Client will describe guidelines related to specific surgery.

Teaching strategies

- Give instruction sheet with centre's number and follow-up appointment date and time. Allow client and family to ask questions.
- Explain to family member the signs and symptoms of infection or other relevant complications to watch for.
- Explain name, dose, schedule and purpose of medications. Provide drug information leaflets.
- Explain activity restrictions, diet progression and any special wound care related to specific surgery. Provide instruction sheet with clear, focused explanations.

Evaluation

- To confirm the client's understanding after teaching, have the client 'teach back' discharge information to you (e.g. 'What are you going to do when you get home?')
- Client is able to explain when to call healthcare provider with problems.
- Client is able to state date for follow-up appointment.
- Client and family member describe signs and symptoms of infection or other relevant complications.
- Client able to state name of drug/s, dose and when to take.
- Client demonstrates appropriate activity/movement and wound care.

CLINICAL REASONING PROCESS: THE POSTOPERATIVE PHASE

Nursing care in the PACU focuses on careful monitoring and maintenance of the patient's airway, breathing, circulation and neurological status, as well as the management of acute pain and other postoperative complications. Other important factors to assess include temperature, skin and incision/wound status, fluid and electrolyte balance and genitourinary and GI function. These factors are not, however, unique to the PARU setting. The nurse in the acute care area continues assessment of these critical factors on a less-intensive and less-frequent basis until the patient's discharge from the acute care facility.

GATHERING RELEVANT INFORMATION AND DATA

After the patient is transferred from the PACU to the acute care area, an initial assessment is conducted by the nurse accepting responsibility for the patient. This focused body systems assessment is based on the nature of the surgery/procedure, type of anaesthetic given and the postoperative plan of care. An important component of monitoring to detect complications is the assessment of vital signs (see Chapter 23) (Phillips et al 2014). Vital sign assessment is often conducted every 30 minutes for 2–4 hours initially, and if the patient's condition is stable the frequency is reduced as per the institution policy and the patient's condition. The postoperative orders usually specify criteria for when vital sign changes are to be reported. However, you must carefully monitor the patient as their condition can change rapidly, especially during the postoperative period.

Document the initial assessment, including vital signs, level of consciousness, condition of dressings and drains, pain level, IV fluid status and urinary output measurements. Patient data can be entered on flow sheets, a computerised patient record or progress notes; this is specific to the institution. The preoperative findings are used as a baseline for comparing postoperative changes.

After the first assessment is completed in the acute care area and immediate needs are attended to, the family/significant others may visit. The purpose of postoperative procedures or equipment and the patient's condition may need to be explained to them.

Airway and breathing

If the patient has an altered conscious state and is extremely drowsy, and there is difficulty rousing the patient, consideration needs to be given regarding the ability of the patient to maintain a patent airway, especially if there is any vomiting or secretions. The patient may not be able to clear their own secretions and suction may be required. In the post-anaesthetic patient, the tongue causes the majority of airway obstructions.

Certain anaesthetic agents and opioid analgesics may cause respiratory depression. The first and most important clinical indicator of opioid-induced respiratory depression is increasing level of sedation (see Chapter 36). Be alert for shallow, slow breathing and a weak cough. Regularly assess sedation score, respiratory rate, rhythm, depth, symmetry of chest wall movement, breath sounds, and colour of mucous membranes. If breathing is unusually shallow, placement of the hand over the patient's face or mouth allows you to feel exhaled air. Pulse oximetry is also used to monitor the patient's oxygen saturation (Phillips et al 2014).

It is important after the immediate postoperative period that the nurse providing ongoing care in the acute environment continues respiratory assessments, especially auscultation of lung sounds. Older patients and those with a history of respiratory disease or smoking are more prone to developing complications, such as atelectasis or pneumonia. The patient should also be assessed for signs of shortness of breath or difficulty breathing on exertion (e.g. when showering). A pulmonary infection caused by aspiration in the operating room or PACU setting may not be evident until several days later. Patients should also be instructed to report any symptoms to their medical practitioner after discharge, since the length of stay in acute care may be quite short.

Circulation

The patient is at risk of cardiovascular complications resulting from blood loss from the wound site, side effects of anaesthesia,

electrolyte imbalances and depression of normal circulatory regulating mechanisms. Careful assessment of heart rate and rhythm, along with blood pressure, reveals the patient's cardiovascular status. An ECG may be performed if, for example, the patient has a cardiac history.

Assess peripheral perfusion by palpating pulses and noting colour, warmth, movement, sensation, and capillary refill time for the nail beds and skin. If the patient has had vascular surgery or has casts or constricting devices that may impair circulation, assess peripheral pulses distal to the site of surgery. For example, after surgery to the femoral artery, assess posterior tibial and dorsalis pedis pulses. Compare pulses in the affected extremity with those in the non-affected extremity. Redness, pain and swelling, especially in a lower extremity, could be an indication of a DVT.

A common early circulatory problem is *haemorrhage*. Blood loss may occur externally through a drain or incision or internally within the surgical wound. Haemorrhaging may result in an elevated heart and respiratory rate; thready pulse; cool, clammy, pale skin; restlessness; and with progressive shock, decreased blood pressure. If haemorrhage is external, the nurse observes increased bloody drainage on dressings or through drains. Sometimes, the blood can ooze down the patient's side and collect in a pool under the patient. *It is important to always check under the patient for drainage, even if the dressing is not saturated.* When haemorrhage is internal, the operation site becomes swollen and tight. For example, if a patient bleeds within the abdomen, the abdomen becomes tight and distended. The first signs of suspected haemorrhaging should be reported to the surgeon immediately. The nurse maintains IV fluids and monitors the patient's vital signs every 15 minutes or more frequently until the patient's condition stabilises. Oxygen may be initiated and the patient's legs and head slightly elevated to promote venous return and increase the volume of blood available for supplying oxygen and nutrients to vital organ systems. Further medications and IV volume replacement, such as blood products, may be ordered.

If the patient is on prolonged bed rest or has reduced mobility, anticoagulants may be ordered in addition to the use of pneumatic compression stockings. This is to prevent the formation of a DVT. The risk of DVT decreases when the patient begins to mobilise.

Because of the surgical patient's risk of fluid and electrolyte abnormalities, assess hydration status and monitor cardiac and neurological function for signs of electrolyte alterations (see Chapter 34). Fluids are especially important as the patient recovers from regional anaesthesia. Laboratory values will be monitored and compared with the patient's baseline values.

An important responsibility is assessment of the patient's IV site for signs and symptoms of infiltration and phlebitis. The patient's only source of fluid intake immediately after surgery may be through an IV.

To ensure adequate fluid intake, administer the infusion as ordered. If assessments indicate a fluid volume deficit or a fluid volume excess, notify the medical officer of the data and the infusion and/or rate may be changed. As the patient begins to commence oral fluids, the ordered IV rate will usually be decreased. When the patient no longer requires a continuous IV infusion, the IV line may be capped ('bunged off') and Normal saline flushes ordered to ensure IV cannula patency for medication administration (e.g. antibiotics). The patient may also be ordered to receive blood products after surgery, depending on blood loss during surgery.

Accurate recording of fluid intake and output assists with assessment of renal and circulatory function. You may need to document input and output on a fluid balance chart. This is dependent on the surgery, patient's past history, patient condition and whether the patient has an IV, drains and other interventions such as an IDC or NGT. Measure all sources of output, including urine, drains, gastric drainage via emesis or NGT and drainage from wounds, and note any insensible loss from diaphoresis.

Disability

A patient will have been orientated to the environment before being discharged from the PACU, and the nurse from the acute area should ensure that the patient is rousable prior to agreeing to accept the patient from the PARU. If a patient has had surgery involving a part of the neurological system, conduct a thorough neurological assessment. For example, if the patient has had lower back surgery, assess leg movement, sensation and strength. Patients with regional anaesthesia begin to experience a return in motor function before tactile sensation returns. Dermatome (a segmental skin area innervated by segments of spinal cord) assessment of the spinal nerves is performed (Figure 39-10). Typically, the level of sensory block is assessed by testing the dermatome level at which the patient reports a

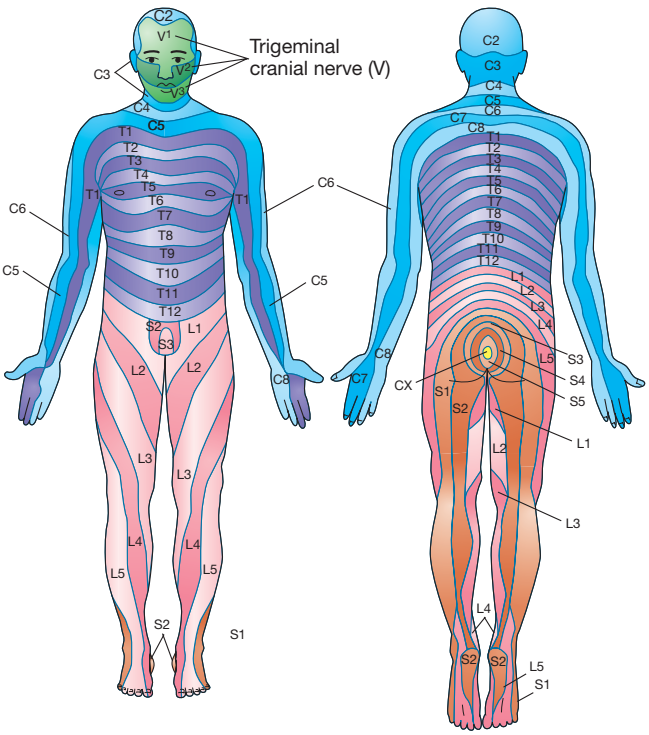

Figure 39-10 Segmental dermatome distribution of spinal nerves.

Modified from Thibodeau GA, Patton KT 2002 Anthony's textbook of anatomy and physiology, 17th edn. Mosby, St Louis.

WORKING WITH DIVERSITY

Focus on older adults

Acute delirium is common in older people following surgery, occurring in up to 30% of elderly patients. Delirium can be caused by many physiological problems, including metabolic imbalances, infection, dehydration and malnutrition. Nurses need to be alert to rapid changes in a patient's mental state which may include disorganised thinking, incoherent speech and restless, agitated behaviour. A focused nursing assessment is necessary to determine the cause of delirium, which is often reversible.

Reference

Poole J, Mott S 2003 Agitated older patients: nurses' perceptions and reality. Int J Nurs Pract 9(5):306.

change in temperature sensation when ice or alcohol is applied to the skin.

Orientation to the environment is important in maintaining the patient's alertness. You may need to re-orientate the patient to the ward, explain that the surgery is completed and describe the nursing measures being carried out. The patient who was properly prepared before surgery is likely to be less anxious when nurses begin their care.

Unless the patient has undergone neurological surgery, the focus of nursing assessment will be a basic neurological examination. Of primary importance is the patient's level of consciousness. An altered level of alertness may be an indicator that patient condition is deteriorating. Although the patient may still be drowsy from anaesthesia, you should be able to assess the patient's ability to follow commands and answer questions assessing their orientation. Extremity strength assessment is important if spinal or epidural anaesthesia has been administered.

Exposure

The operating room and PACU environments are extremely cool. The patient's anaesthetically depressed level of body function results in a lowering of metabolism and a fall in body temperature. When patients begin to wake, they often complain of feeling cold. The length of time spent in the operating room and laminar flow rooms contributes to heat loss. Surgeries that require an open body cavity also contribute to heat loss. Older adults and paediatric patients are at higher risk of developing problems associated with hypothermia.

Measure the patient's body temperature and provide warmed blankets if required. Shivering may not be a sign of hypothermia, but rather a side effect of certain anaesthetic agents. Deep-breathing and coughing help expel retained anaesthetic gases. If the patient's temperature is 35.6°C or below, a warming device may be used. Increasing body warmth causes the patient's metabolism to rise and circulatory and respiratory functions to improve.

In rare instances, malignant hyperthermia can develop, a life-threatening complication of some anaesthetic drugs. Malignant hyperthermia causes tachypnoea, tachycardia, unstable blood pressure, cyanosis, skin mottling and muscular rigidity. Despite the name, an elevated temperature is a late sign. Although it is often seen during the induction phase of anaesthesia, symptoms may recur 24–72 hours postoperatively. Without proper treatment, it can be fatal.

Temperature is monitored relatively closely when a patient who has had surgery is in the acute care area. An elevated temperature may be the first indication of an infection. If the patient's temperature is elevated, the nurse assesses the patient for a potential source of infection, including the IV site (if present), the surgical incision/wound, the respiratory system (potential for chest infection) and the urinary system (potential for urinary tract infection). The medical officer must be notified, as further assessments may be ordered, including blood collection (e.g. blood cultures), sputum specimen and urinary specimen.

Comfort

As patients regain consciousness from general anaesthesia, the perception of pain becomes prominent. Pain can be perceived before full consciousness is regained. Acute incisional pain causes patients to become restless and may be responsible for changes in vital signs. It is difficult for patients to begin deep-breathing and coughing exercises when they experience pain. This is of particular significance for patients who have had abdominal, back or chest surgery, as the pain experienced will impede their ability to effectively perform these exercises, placing them at greater risk for chest infection. The patient who has had regional or local anaesthesia usually does not experience pain initially, because the incision area is still anaesthetised.

Thorough assessment of the patient's pain and evaluation of pain-relief therapies are essential. Pain scales are an effective way for nurses to assess the severity of postoperative pain, evaluate response to analgesics and objectively document pain severity (see Chapter 36). Using preoperative pain assessments as a baseline, evaluate the effectiveness of interventions throughout the patient's recovery.

It is common to administer opioid analgesics immediately after surgery for pain relief and to maximise the patient's ability to perform respiratory exercises, such as deep-breathing and coughing. Initial analgesic doses are usually given IV in the PARU and titrated to patient comfort. Patient-controlled analgesia (PCA) may also be commenced. Many patients receive epidural analgesia, which may be continued throughout the recovery period (see Chapter 36).

If the patient has a PCA and is making attempts to use it more frequently than it is programmed for (the number of patient demands is displayed on the machine) or pain is uncontrolled, the nurse should contact the acute pain team to change the order. The amount of medication the patient can receive may be increased, the lockout period decreased or other medication may be commenced. As oral intake is tolerated, and dependent on the pain assessment, the patient's analgesia will usually be changed from IV to oral administration. Non-pharmacological interventions should also be implemented. An example is to lower the head of the bed and use a pillow for incisional splinting while turning a patient with recent abdominal surgery.

Gastrointestinal function

Anaesthetics slow GI motility and may cause nausea. Normally, during the immediate recovery phase faint or absent bowel sounds can be auscultated in all four quadrants. Inspection of the abdomen rules out distension which may be caused by accumulation of gas. In a patient who has had abdominal surgery, distension will develop if internal bleeding occurs.

Distension may also occur in the patient who develops a **paralytic ileus** from handling of the bowel in surgery. This paralysis of intestines with distension and symptoms of acute obstruction may also be related to the administration of anticholinergic drugs. This usually does not occur for 24 hours. Be aware of the risk for paralytic ileus and observe for abdominal distension and reduction in bowel sounds.

The level of nausea should be regularly assessed, as well as the effect of any interventions (e.g. administration of antiemetics). Because stomach-emptying slows with the patient under anaesthesia, the accumulated contents cannot escape, and nausea and vomiting develop. Normally a patient does not receive fluids to drink in the PARU because of bowel sluggishness, with the risk of nausea and vomiting, and because of grogginess from GA. If the patient has an NGT on free drainage, the nurse assesses the output for amount and colour.

The patient is likely to begin taking ice chips or sips of fluids when arriving in the acute care unit. If these are tolerated, diet can usually be commenced. In the case of some abdominal surgery, the bowel may need to be rested, and commencement of oral intake will not be indicated for several days.

Skin integrity

After surgery, most surgical wounds are covered with a dressing that protects the wound site and absorbs drainage. Observe the dressing for drainage: colour, amount (marking around the ooze with a permanent pen, including date and time), consistency and odour. Some smaller wounds are covered with a transparent dressing only, facilitating ongoing assessment of the wound. The dressing is left intact, thereby reducing the risk for infection from dressing changes.

Some surgeons prefer to assess the incision and surrounding skin the first time the dressing is removed, or 'taken down'. The nurse in the acute care area assesses the wound site and documents the assessment and any related interventions (see Chapter 30). The first assessment is important as it forms the baseline for continued wound evaluation during the patient's hospital stay.

It is also important to consider the patient's mobility level. If the patient is unable or unwilling to turn, they are at increased risk for pressure injury. Follow institutional policy regarding assessment of patient risk for pressure injury (e.g. use of the Braden Scale). Appropriate preventive measures can then be implemented to manage the risk (see Chapter 30).

Assess the condition of the patient's skin, noting rashes, abrasions, bruising or burns. A rash may indicate a drug sensitivity or allergy. Abrasions or bruising may result from inappropriate positioning during surgery. A burn may indicate that an electrical cautery grounding pad was incorrectly placed on the patient's skin during surgery. Burns or serious injury to the skin should be documented following institutional policy (e.g. completion of an incident report and entry into the risk-management system).

Genitourinary function

Depending on the surgery or procedure, a patient may not regain voluntary control over urinary function for 6–8 hours after anaesthesia. An epidural or spinal anaesthetic may prevent the patient from feeling bladder fullness or distension. Palpate and percuss the lower abdomen just above the symphysis pubis for bladder distension. Patients may need an intervention to void if their bladder becomes distended. If an IDC is inserted, the expected minimum urine output is 0.5–1 mL per kg per hour (0.5–1 mL/kg/h) in adults. Assess urine colour and odour. A urinalysis may be conducted to ascertain specific gravity if fluid volume deficit is suspected.

Surgery involving portions of the urinary tract normally cause bloody urine for at least 12–24 hours, depending on the type of surgery. If the patient has an IDC, the goal should be to have it removed as soon as possible. Patients with an IDC are at high risk of developing a healthcare-associated bladder or urinary tract infection. This will contribute to patient discomfort, increased costs and possible increase in length of hospitalisation.

CLINICAL EXAMPLE

You go to the PACU to retrieve Mr Summers, who has had an open reduction and internal fixation (ORIF) of the right femur. He has recovered satisfactorily postoperatively. His vital signs in the PACU are:

Heart rate	110 beats/minute and regular
Blood pressure	156/96 mmHg
Respiratory rate	10 breaths/minute, shallow
SpO_2	94% on Hudson mask at 6 L/minute oxygen
Temperature	37.1°C
Conscious state	drowsy but rousable
Pain score	4/10

Dressing dry and intact. IDC in situ with minimal drainage.

He required supplemental oxygen to maintain oxygen saturations above 95%. Pain was managed with a morphine patient-controlled analgesia (PCA), 1 mg bolus dose with 5 minute lockout. The PACU nurse is keen for you to take him back to the ward.

• CRITICAL REFLECTION POINT

Using the ABCDE mnemonic to assess Mr Summers' situation described in the *Clinical example* above, would you agree to take Mr Summers back to the ward? Justify your decision based on scientific rationale and evidence-based literature.

MAKING APPROPRIATE JUDGEMENTS AND DECISIONS

The nurse evaluates the status of any priorities identified from the preoperative assessment and gathers new relevant data and information to ascertain if the priorities and goals are still relevant postoperatively, modify if relevant, or identify new ones. Previously defined priorities, such as *impaired skin integrity*, may continue as a postoperative problem (e.g. if the patient has an incisional wound, then they clearly have impaired skin integrity). The nurse may also identify new risk factors leading to identification of new priorities (Box 39-7). For example, an older patient who has undergone major

BOX 39-7 Examples of postoperative priority problems

Difficulty clearing airway related to:
- Retained secretions
- Bronchospasm
- Acute pain with movement/coughing
- Decreased level of consciousness

Risk of impaired skin integrity related to:
- Exposure to wound drainage
- Altered fluid status
- Altered sensation
- Altered nutritional status

abdominal surgery and who has a pre-existing problem of reduced hip mobility resulting from arthritis will have the problem and thus priority of *impaired physical mobility*. The surgery or procedure itself may add risk factors for the patient. Consider the needs of a patient's family when identifying priorities. For example, the inability of the family to cope with the patient's condition requires intervention.

SETTING PRIORITIES AND ESTABLISHING GOALS

When a patient is recovering from surgery or a procedure, the nurse has a great deal of assessment data and information to inform making appropriate judgements and decisions to plan patient care. The preoperative history, postoperative assessment data and the postoperative orders all inform the nurse to plan specific patient-centred nursing interventions. Box 39-8 presents a sample of typical postoperative orders. Typical postoperative orders include the following:

Multidisciplinary clinical pathways are commonly used to plan care for the surgical patient, although these must be individualised for each patient based on the RN's assessment and clinical judgement (see Figure 39-11). The nurse considers the effects of the stress of surgery and the limitations it produces when establishing expected outcomes and interventions for the individual patient. Measurable outcomes help to facilitate the evaluation of appropriate recovery from surgery. For example, the patient with impaired mobility should have specific outcomes selected, which may include walking at least 20 metres four times a day, performing range-of-movement exercises (as taught) on the relevant joint every 2 hours while awake, a pain level no greater than 3 (on a scale of 0–10), wound edges approximated and absence of wound infection, performing deep-breathing and coughing exercises correctly every 1–2 hours when awake. Outcomes can then be evaluated as to whether they were met and whether any modifications need to be made.

Typical broad goals of postoperative care include:
- demonstrating return or maintenance of normal physiological function, including respiratory, circulatory, elimination and nutritional status
- demonstrating absence of postoperative surgical wound infection
- achieving rest and comfort
- maintaining or enhancing self-concept.

BOX 39-8 Typical postoperative orders

- Frequency of vital sign monitoring and any focused assessments (e.g. related to drain tubes, NGTs, IDCs)
- IV fluids and rates of infusion
- postoperative medications (especially those for pain and nausea)
- fluids and food allowed by mouth
- level of activity the patient is allowed to resume
- position the patient is to maintain while in bed
- intake and output recording
- laboratory tests and X-rays
- special directions relevant to the surgery performed.

WORKING WITH DIVERSITY

Focus on older adults

Being aware of older adults' special needs and addressing them early can reduce the incidence of postoperative complications.
- *Hearing and vision loss* – ensure that the patient uses their hearing aid and/or glasses. Miscommunication has the potential to have serious adverse consequences. For example, hearing and vision losses may lead to confusion, increased anxiety and non-adherence to plan of care, based on misunderstanding.
- *Comorbidities* – older adults may present with vague symptoms that mask serious underlying conditions. Be aware of the likelihood of cardiovascular, respiratory, renal and central nervous system disorders.
- *Polypharmacy* – older adults may be prescribed multiple medications. It is essential that all current medications are noted during the admission assessment. For elective surgery, patient should be asked to bring all medications in with them.
- *Hypothermia* – older people are more vulnerable to hypothermia than other age groups. Hypothermia can result in serious physical and psychological consequences: renal concentrating ability, drug clearance, wound healing and tissue oxygenation requirements can all be seriously impaired by hypothermia. The older patient must be kept warm by using warm blankets, patient-controlled warming gowns, warmed infusion fluids and/or heated, humidified inspired gases.

• CRITICAL REFLECTION POINT

Reflect on the *Clinical example* on p. 1457. Outline your postoperative assessment of Harry Summers, focusing on immediate postoperative recovery issues. Identify the immediate nursing priority goals and interventions based on scientific rationale and the evidence.

PREPARING FOR AND TAKING ACTION

The principal causes of postoperative complications are a surgical wound, the effects of prolonged immobility during surgery and recovery rehabilitation and the influence of anaesthesia and analgesics. Nursing management is directed at preventing complications so that the patient returns to the highest level of functioning possible. Failure of the patient to become actively involved in recovery adds to the risk of complications (Table 39-3). Virtually any body system can be

TABLE 39-3 Postoperative complications

Complication	Cause
Respiratory system	
Atelectasis is collapse of alveoli Signs and symptoms include elevated respiratory rate, dyspnoea, fever, crackles auscultated over involved lobes of lungs and productive cough	Atelectasis is caused by inadequate lung expansion. Anaesthesia, analgesia and immobilised position prevent full lung expansion. There is greater risk in patients with upper abdominal surgery who have pain during inspiration and repress deep-breathing
Pneumonia is inflammation and consolidation of alveoli caused by infectious process. It may involve one or several lobes of lung. Development of pneumonia in lower dependent lobes of lung is common in immobilised surgical patient Signs and symptoms include fever, chills, productive cough, chest pain, purulent sputum and dyspnoea	Pneumonia is caused by poor lung expansion with retained secretions. Common resident bacterium in respiratory tract is *Diplococcus pneumoniae*
Hypoxaemia is inadequate concentration of oxygen in arterial blood Signs and symptoms include restlessness, dyspnoea, high blood pressure, tachycardia, diaphoresis and cyanosis	Respirations are depressed by anaesthetics or analgesics. Increased retention of secretions with impaired ventilation occurs because of pain or poor positioning
Pulmonary embolism is caused by an embolus blocking a pulmonary artery and disrupting blood flow to one or more lobes of lung Signs and symptoms include dyspnoea, sudden chest pain, cyanosis, tachycardia and drop in blood pressure	Immobilised surgical patients with pre-existing circulatory or coagulation disorders are at risk
Circulatory system	
Haemorrhage is loss of large amount of blood externally or internally in short period of time Signs and symptoms are same as for hypovolaemic shock	Haemorrhage is caused by slipping of suture or dislodged clot at incisional site. Patients with coagulation disorders are at greater risk

continued

TABLE 39-3 ***continued***

Complication	Cause
Hypovolaemic shock is inadequate oxygenation and perfusion of tissues and cells from loss of circulatory fluid volume Signs and symptoms include hypotension, weak and rapid pulse, cool and clammy skin, rapid breathing, restlessness and reduced urine output and hypertension	In surgical patient, hypovolaemic shock is usually caused by haemorrhage
Thrombophlebitis is inflammation of vein often accompanied by clot formation. Veins in legs are most commonly affected Signs and symptoms include swelling and inflammation of involved site and aching or cramping pain. Vein feels hard, cord-like and sensitive to touch. Pain in calf may occur when patient walks or dorsiflexes foot (Homans' sign)	Venous stasis is aggravated by prolonged sitting or immobilisation. Trauma to vessel wall and hypercoagulability of blood increase risk of vessel inflammation
Thrombus is formation of clot attached to interior wall of a vein or artery, which can occlude the vessel lumen	Thrombus is caused by venous stasis (see thrombophlebitis) and vessel trauma. Venous injury is common after surgery of legs, abdomen, pelvis and major vessels
Embolus is piece of thrombus that has dislodged and circulates in bloodstream until it lodges in another vessel, commonly lungs, heart or brain	Thrombi also form from increased coagulability of blood (e.g. polycythaemia and use of contraceptives containing oestrogen)
Gastrointestinal system	
Abdominal distension is increased abdominal girth and tympanic percussion over abdominal quadrants. Patient complains of fullness and 'gas pains'	Distension is caused by slowed peristalsis from anaesthesia, bowel manipulation or immobilisation
Constipation is infrequent passage of stools. It should not be an immediate concern after surgery, especially if patient has preoperative bowel preparation. After patient resumes solid diet, failure to pass stool within 48 hours is cause for concern	Slowed peristalsis (see causes of distension) and delay in resuming normal diet cause constipation
Nausea and vomiting are symptoms of improper gastric emptying or chemical stimulation of vomiting centre Patient complains of gagging or feeling full or sick in stomach	Nausea and vomiting are caused by severe pain, abdominal distension, fear, medications, eating or drinking before peristalsis returns and initiation of gag reflex
Genitourinary system	
Urinary retention is involuntary accumulation of urine in bladder as result of loss of muscle tone Signs and symptoms include inability to void, restlessness, abdominal pain and bladder distension. It appears 6–8 hours after surgery	Retention is caused by effects of anaesthesia and opioid analgesics. Local manipulation of tissues surrounding bladder and oedema interfere with bladder tone. Poor positioning of patient impairs voiding reflexes
Integumentary system	
Wound infection is an invasion of deep or superficial wound tissues by pathogenic microorganisms Signs and symptoms include warm, red and tender skin around incision. Patient may have fever and chills. Purulent material may exit from drains or from separated wound edges. It appears 3–6 days after surgery	Infection is caused by poor aseptic technique and contaminated wound before surgical exploration
Wound dehiscence is separation of wound edges at suture line Signs and symptoms include increased drainage and appearance of underlying tissues. It usually occurs 6–8 days after surgery	Malnutrition, obesity, preoperative radiation to surgical site, old age, poor circulation to tissues and unusual strain on suture line from coughing cause dehiscence
Wound evisceration is protrusion of internal organs and tissues through incision. It usually occurs 6–8 days after surgery	See *Wound dehiscence*. Patient with dehiscence is at risk of developing evisceration
Nervous system	
Uncontrolled acute pain	Severe pain despite adequate analgesia may have a surgical cause

affected. The nurse must consider the interrelationship of all systems and therapies provided.

Maintaining respiratory function

To manage risk and prevent respiratory complications, begin aggressive pulmonary measures preoperatively. The benefits of thorough preoperative education are realised when patients are able to participate actively. Skill 39-2 (p. 1440) outlines postoperative exercises to prevent respiratory complications postoperatively. The following measures promote expansion of the lungs:

- Encourage diaphragmatic breathing exercises at least every 2 hours while patient is awake. Maximal inspirations lasting 3–5 seconds open up alveoli.
- Instruct patients to use an incentive spirometer for maximum inspiration.
- Encourage early ambulation. Walking means that patients assume a position that does not restrict chest wall expansion and stimulates an increased respiratory rate.
- Assist patients who are restricted to bed to turn on their sides every 1–2 hours while awake and to sit when possible. Turning permits expansion of the lungs. Sitting causes lowering of abdominal organs, thus facilitating diaphragmatic movement and lung expansion.
- Keep the patient comfortable. A patient who is comfortable will be able to participate in the postoperative regimen. Assess, document, treat and evaluate the patient's pain and nausea levels.

The following measures promote removal of pulmonary secretions if they are present:

- Encourage coughing exercises every 1–2 hours while the patient is awake and effectively manage pain to promote a deep, productive cough. Note that for patients who have had eye, intracranial or spinal surgery, coughing may be contraindicated because of the potential increase in intraocular or intracranial pressure.
- Maintain adequate hydration (e.g. with IV or oral fluids as tolerated) and provide oral hygiene to help thin and expectorate secretions. Secretions become thick and tenacious and the oral mucosa becomes dry when patients are NBM or are placed on limited fluid intake.
- Initiate orotracheal or nasotracheal suction for patients who are too weak or are unable to cough (see Chapter 35).

Maintain circulatory function

Nursing interventions aimed at preventing the risk of circulatory complications need to be implemented. Some patients are at greater risk of venous stasis because of the nature of their surgery and/or postoperative care. The following measures promote venous return and circulatory blood flow.

- Remind the patient to perform leg exercises at least every hour while awake. Exercise may be contraindicated in an affected extremity involving vascular repair or realignment of fractured bones and torn cartilage.
- Apply antiembolism stockings as ordered. The stockings should be removed every 8 hours and left off for 1 hour (see Chapter 28).
- Apply pneumatic compression stockings as prescribed. Each stocking wraps around a patient's leg and is kept in place with a Velcro attachment. Compressed air inflates the padded plastic stocking systematically from ankle to calf to thigh, and then deflates. The alternating inflation and deflation of the stocking reduces venous stasis.
- Encourage early ambulation. Most patients are expected to walk the evening of surgery, depending on the severity of the surgery and their condition. Even if a patient has an epidural catheter or PCA device, walking should be encouraged. The degree of activity allowed progresses as the patient's condition improves. Before walking, assess the patient's vital signs. Abnormalities may contraindicate walking. If vital signs are normal, assist the patient to sit on the side of the bed and encourage them to wiggle their toes. Dizziness may be a sign of postural hypotension. Recheck blood pressure to determine whether walking is safe. Ensure that the patient is steady when they first stand and walk by the patient's side. Evaluate exercise tolerance.
- Avoid positioning patients in a manner that interrupts blood flow to the extremities. While in bed, patients should not have pillows or rolled blankets placed under the knees, as compression of the popliteal vessels can cause thrombi.
- Administer anticoagulant medication as prescribed. Anticoagulants, such as heparin, are often ordered for patients at risk of thrombus formation.
- Assess for adequate fluid intake, and when able to commence oral fluids encourage intake. Adequate hydration prevents concentrated build-up of formed blood elements, such as platelets and red blood cells. When the plasma volume is low, these elements may gather and form small clots within blood vessels.

Promoting elimination and adequate nutrition

Interventions for preventing GI complications promote return of normal elimination and faster return of normal nutritional intake. It may take several days for a patient who has had surgery on GI structures (e.g. a colon resection) to resume a normal diet. Normal peristalsis may not return for 2–3 days. In contrast, the patient whose GI tract is unaffected directly by surgery can resume dietary intake after recovering from the effects of anaesthesia. The following measures promote return of normal elimination:

- Dependent on the surgery, the nurse may be required to assess for return of peristalsis. This involves auscultation of the abdomen to detect bowel sounds; 5–30 gurgles per minute over each quadrant indicate normal bowel sounds. Asking whether the patient has passed flatus also indicates that peristalsis is returning. Abdominal distension should be reported to the medical officer.
- Maintain a gradual progression in dietary intake. A patient having day-surgery may be able to eat and drink as soon as they wake from the anaesthetic. Some patients may receive only IV fluids for the first few hours after surgery. Once oral fluids and food can be commenced, it is sensible to encourage the patient to start with water, progressing to clear fluids and a light diet (e.g. soup and sandwiches), as overloading with large amounts of fluids may lead to nausea and vomiting. Patients who have had abdominal surgery with interference to the bowel or GI tract are usually NBM for the first 24–48 hours. As peristalsis returns, clear fluids only may be ordered, followed by free fluids, then light food diet, and finally a regular diet.

- Promote walking and exercise. Physical activity stimulates a return of peristalsis. The patient who suffers abdominal distension and 'gas pain' will often obtain relief while walking.
- Maintain an adequate fluid intake. Patients who have had surgery are often at a higher risk for constipation due to the side effects of pain medication and reduced mobility. Fluids keep faecal material soft for easy passage. Administer stool softeners and enemas as prescribed.

The following measures assist in maintaining an adequate dietary intake:

- Remove sources of noxious odours which may deter the patient from eating.
- Assist the patient into a comfortable position at meal-times. The patient should sit if possible.
- Assist the patient in selecting desired servings of food. For example, a patient may be more willing to face the first meal when servings are small.
- Provide oral hygiene. Adequate hydration and cleansing of the oral cavity diminish dryness and bad tastes.
- Provide meals when the patient is rested and free from pain. Often a patient loses interest in eating if meal-time has been preceded by exhausting activities, such as walking, coughing and deep-breathing exercises or extensive dressing changes. When a patient has pain, there may be associated nausea which will often cause a loss of appetite.

Promoting urinary elimination

The depressant effects of anaesthetics and analgesics impair the sensation of bladder fullness and can cause urinary retention. If bladder tone is reduced, the patient has difficulty voiding. However, patients should void within 8–12 hours after surgery. Patients who undergo surgery of the urinary system often have an IDC inserted to maintain free urinary flow until voluntary control of micturition returns. The following measures promote normal urinary elimination:

- If possible, considering the patient's medical condition, assist the patient to assume their normal position when voiding. A male patient may prefer to stand to void. A bed pan can make voiding difficult and a female patient may prefer to use a toilet or bedside commode.
- Assess the patient for the need to void. A surgical patient restricted to bed needs assistance to handle and use bed pans or urinals. Often the patient acquires a sudden feeling of bladder fullness and urgency to void and will need help quickly.
- Assess for bladder distension by palpating the lower abdomen above the symphysis pubis. A bladder scanner may be used to assess the volume of urine in the bladder. If a patient does not void within 8 hours of surgery or bladder distension is present, it may be necessary to insert a urinary catheter so you need to notify the medical officer.
- Monitor intake and output. An accepted level of urinary output is at least 0.5–1 mL/kg/h for adults. If the urine is dark, concentrated and low in volume (< 30–60 mL per hour), the medical officer should be notified. A patient can easily become dehydrated as a result of fluid loss from the surgical wound or a lengthy fasting preoperative period. Measure intake and output for several days after surgery until normal fluid intake and urinary output are achieved.

Promoting wound healing

A number of factors may affect surgical wound healing and place the patient at risk for delayed healing, such as inadequate nutrition, impaired circulation and metabolic alterations (see Chapter 26). A wound may also undergo considerable physical stress. Strain on sutures from coughing, vomiting, distension and movement of body parts can disrupt the wound layers. The nurse has a role in promoting wound healing. If a wound becomes infected, the infection usually establishes itself 3–6 days after surgery. A clean surgical wound usually does not regain strength against normal stress for 15–20 days after surgery. The nurse uses aseptic non-touch technique during dressing changes and wound care (see Chapter 25). Surgical drains must remain patent so that accumulated secretions can escape from the wound bed. Assessment of the wound identifies early signs and symptoms of infection.

Achieving rest and comfort

A surgical patient's pain usually increases as the anaesthesia wears off. The incisional area may be only one source of pain. Irritation from drainage tubes, tight dressings or casts and the muscular strains caused from positioning on the operating-room table can make the patient feel uncomfortable. As such, do not assume that expression of pain is only related to the incision.

Pain can significantly slow recovery. The patient becomes reluctant to cough, breathe deeply, turn, walk or perform necessary exercises. The nurse assesses the patient's pain thoroughly (see Chapter 36) and ensures that interventions and therapies are adequate. If they are not, the nurse needs to collaborate with the acute pain service or medical staff to obtain more-effective pain relief. The nurse should also independently implement non-pharmacological interventions to promote pain relief, such as appropriate positioning that aids the patient's comfort, gentle back massage and use of hot or cold packs (if appropriate).

Epidural infusion of local anaesthetic and opioids, such as morphine or fentanyl via patient-controlled epidural analgesia (PCEA), is another common method for administering effective postoperative analgesia for many surgical patients. These medications may be delivered as a continuous infusion or a pre-programmed bolus dose or interval, or both. Epidural opioids relieve severe pain, often without the central nervous system depression that can occur with systemic opioids. Recognising potential complications and what to do if they occur is an important role for the postoperative nurse (see Chapter 36 on preventing and managing complications of epidural analgesia).

Maintaining/enhancing self-concept

The appearance of wounds, bulky dressings, bruising, extruding drains and tubes affects a patient's self-concept. The effects of surgery, such as disfiguring scars, may create permanent changes for the patient's body image. If surgery leads to impairment in body function, the patient's role within the family can change significantly.

The nurse observes patients for alterations in self-concept. Patients may show revulsion towards their appearance by refusing to look at incisions, carefully covering dressings with

bedclothes or refusing to get out of bed because of tubes and devices. The fear of not being able to return to a functional role in their families may even cause patients to avoid participating in their plan of care.

The family and significant others are important to improving the patient's self-concept. The nurse explains the patient's appearance to the family in a way that avoids non-verbal expressions of revulsion or surprise. The family needs to accept the patient's needs and still encourage the patient's independence. If the condition is permanent, the family learns to help the patient through the grieving process so that the patient can reach a stage of acceptance. The following measures maintain the patient's self-concept:

- Offer opportunities for the patient to discuss feelings about appearance. A patient who avoids looking at an incision may need to discuss fears or concerns. Many patients may worry about permanent scarring. When the patient chooses to look at an incision for the first time, the area should be clean. If necessary, the patient should eventually be able to care for the incision site by applying simple dressings or bathing the affected area.
- Provide privacy during dressing changes or inspection of the wound and appropriately drape the patient so that only the dressing or incisional area is exposed.
- Maintain the patient's hygiene. Wound drainage and antiseptic solutions from the surgical skin preparation dry on the skin's surface and cause irritation. A bed bath following surgery facilitates patient wellbeing. When the gown becomes soiled by wound drainage, offer a clean gown and washcloth. Keep the patient's hair neatly combed and offer frequent oral hygiene, especially for the patient who is NBM. Room deodorisers may be useful if the odour from drainage seems particularly troublesome to the patient and family.
- The patient sometimes becomes preoccupied with observing the drains and gradual collection of drainage. Drains can leak if they become too full; change or empty the drains as per institution policy.
- Maintain an environment conducive to recovery. Self-concept is heightened by being in pleasant, comfortable surroundings. Often the room of a surgical patient becomes cluttered with extra dressings, rolls of tape and bottles of antiseptic solution. If the patient requires frequent dressing changes, the room may take on the appearance of a supply room. Store or remove unused supplies and keep the patient's bedside and room orderly and clean.
- Provide the family and significant others with opportunities to discuss ways to promote the patient's self-concept. Encouraging independence can be difficult for a family member who has a strong desire to help the patient in any way. By knowing about the appearance of a wound or incision, family members can be supportive during dressing changes. The topic or tone of a conversation can also help family members distract a patient from dwelling on fears and concerns. Family members should not avoid discussing the future. However, they need help to know when it is appropriate to discuss future plans. This makes it possible for the patient and family to work together to discuss realistic plans for the patient's return home.

CLINICAL EXAMPLE

Mr Summers is now 2 days post-surgery and you are the RN caring for him today. At the beginning of your shift you collect the following assessment data:

Heart rate	108 beats/minute and regular
Blood pressure	165/98 mmHg
Respiratory rate	28 breaths/minute, deep and laboured
Chest	Appears to be some intercostal muscle recession. Air entry diminished to both bases and crackles present in right base.
SpO_2	89% on Hudson mask at 6 L/minute oxygen
Temperature	38.5°C

When assessing his pain, you note that he has utilised the PCA only once in the last 3 hours. He reports his pain is currently at 5 at rest on a 0–10 numerical rating scale. He is reluctant to move and, on questioning, states that he has not used the PCA much as he does not want to become addicted to the drugs.

Mr Summers is reviewed by the resident medical officer. A chest X-ray shows right-sided basal consolidation and collapse and he is diagnosed with right-sided pneumonia.

CRITICAL REFLECTION POINT

1. **From the *Clinical example* above, explain the most likely cause for Mr Summers' postoperative respiratory complication. What postoperative nursing interventions might have prevented this complication?**
2. **Using the primary survey as a framework to prioritise, identify the priority interventions for Mr Summers' postoperative respiratory compromise. Ensure that you can justify your priority interventions with scientific rationales and evidence-based literature.**
3. **For each intervention you have selected, outline two specific evaluation criteria that would indicate to you that this intervention is having the desired effect.**

EVALUATING IMPACTS AND OUTCOMES

The nurse evaluates the effectiveness of care provided to the patient on the basis of expected outcomes of nursing interventions. In all acute settings, the nurse consults with the patient, family and significant others to determine outcomes and review processes. The nurse can evaluate the same-day surgery patient's outcomes by making a telephone call to the patient's home to follow up on the patient's recovery and see whether the patient understands restrictions or medications. The call is usually placed 24 hours after surgery, which allows the nurse to evaluate the progress of recovery.

In an acute care setting, the evaluation of a surgical patient is ongoing. If a patient fails to progress as expected, the nurse revises the patient's plan of care based on the priorities of the

patient's needs. Every effort is made to assist the patient to return to an optimal functional status.

Part of the nurse's evaluation is determining the extent to which the patient and family have learnt self-care measures. A patient often has to continue wound-dressing care, follow activity restrictions, continue medication therapy and observe for signs and symptoms of complications on returning home. Patients who are unable to perform self-care activities and who lack support may be referred to home healthcare agencies, or admitted to rehabilitation facilities. A comprehensive discharge summary should be provided to ensure continuity of care. Ensuring that discharge plans are in place facilitates that process and enhances the patient's satisfaction with care.

Key concepts

- Patients are admitted to the acute care setting for a range of reasons, including treatment of medical conditions, for surgery and for diagnostic tests. These can be acute, chronic or acute-on-chronic illnesses.
- Nurses play a crucial role in ensuring and promoting patient safety in the acute setting.
- Nurses are integral to recognising and responding to patient deterioration: early identification of patient deterioration saves lives.
- There are approved patient identifiers to be used for patient identification and procedure matching as specified by the Australian Commission for Quality and Safety in Health Care.
- Acute care nurses play a key role in managing health problems and preventing complications. For example, the prevention of venous thromboembolism has been identified as a national and international priority area for improving patient safety in the acute care setting.
- Previous illnesses, past surgeries and the nature of nursing care provided influence the patient's ability to tolerate surgery and/or procedures.
- Family members and/or significant others are important in helping patients with any physical limitations and in providing emotional support during recovery.
- Preoperative/preprocedure assessment of vital signs and physical examination findings provide an important baseline with which to compare postoperative assessment data.
- Primary responsibility for informed consent rests with the patient's doctor.
- Structured preoperative education has a positive influence on postoperative recovery.

CHAPTER

40

Meeting the mental health needs of individuals and their carers

Anthony O'Brien

Learning outcomes

Mastery of content will enable you to:

- define the mental health nursing scope of practice
- discuss the concept of recovery in mental healthcare
- discuss the role of assessment in mental health nursing
- identify the range of practice contexts for mental health nursing
- discuss common treatment modalities used in mental healthcare
- discuss the role of mental health legislation
- discuss mental health promotion
- name Australian and New Zealand professional organisations in mental health nursing.

Mental health issues within acute nursing contexts

Mental health is an integral aspect of the holistic care provided by nurses. Nurses encounter people with mental health problems in all clinical settings, from primary care through to medical and surgical settings, emergency departments, residential care facilities and prisons. If we think of mental health problems as including not only problems of mood, perception or cognition (for example), but also the hazardous use of substances, such as alcohol and drugs, they are very common indeed. For some people, mental health issues will be a temporary adjustment to a difficult period in their life, such as the stress of illness and hospitalisation. For others, mental health problems can be lifelong. Many people in the community live with **mental illness** and are able to make the adjustments necessary to successfully manage their lives with minimal professional support. Others might seek support from health professionals, social agencies and specialist mental health services. Because mental health issues are common in our communities, programs of nursing education include a focus on mental health problems encountered in day-to-day life, as well as more severe mental health problems, including mental illness.

Knowledge of mental health issues, and skills in responding to patients' mental health needs, are among the core competencies of every nurse. The person with diabetes or heart disease may also have low mood or suffer from depression. Having a long-term physical illness may be a challenge to the person's coping skills, and may in turn lead to low mood. Also, a person with a serious mental illness such as bipolar disorder or schizophrenia may attend primary care or be admitted to hospital for a physical illness not related to their mental illness. The co-occurrence of mental and physical illness is called comorbidity and is very common. Nurses need to be able to respond to the full range of needs that patients present with, including physical and mental health needs.

There is a lot a nurse can do to incorporate mental health responses into the care of patients in various health settings. Mental health issues do not always require a specialist response. Helpful responses can include acknowledging and validating the mental health issues experienced by a patient, inquiring about any care preferences related to their mental health, and incorporating reference to mental health issues into routine care. Addressing mental health needs does not have to be something that takes place after attending to other needs. Providing mental healthcare can be part of the routine practice of nursing in every healthcare setting (O'Brien 2014). In order to incorporate responses to mental health needs into routine nursing practice, it is helpful to have an understanding of the broader area of mental health and mental healthcare. These issues are the focus of this chapter. The purpose of the chapter is to outline the scope of practice of mental health nursing, to describe key aspects of mental health nursing practice and to discuss some current issues in mental healthcare. As you read the chapter, keep in mind that the information presented is to inform your practice and assist you in the development of holistic nursing skills. It is not intended, by itself, to prepare you for the specialist practice of mental health nursing.

The mental health service system

Mental health nursing is a specialist area of nursing practice concerned with caring for people with mental distress and illness, and with the promotion of mental health. While every registered nurse responds to clients' mental health needs, mental health nurses specialise in this area of practice and work specifically within health services for people with mental illness. In response to the global prevalence of mental health problems, the World Health Organization (WHO) has developed a Mental Health Action Plan (WHO 2013) aimed at providing better mental healthcare internationally. Both Australia and New Zealand have mental health strategies, which set priority areas for service provision (Commonwealth of Australia 2009, Ministry of Health 2005). In both countries mental healthcare has seen the 'deinstitutionalisation' of public mental health services, with the closure of the old institutions in favour of care provided in community settings. An understanding of the mental health service system, common clinical syndromes and available treatments is therefore important for nursing practice.

• CRITICAL REFLECTION POINT

How do you think you might respond to the mental health needs of people in your nursing practice?

As you read through this chapter, keep asking yourself: what would I need to think about if I was providing care for a person with this mental illness within an acute care setting?

Mental health scope of practice

Mental health nursing is an area of specialty practice that is concerned with providing care for people with mental distress and illness and with the promotion of mental health. A definition of the mental health scope

BOX 40-1 Mental health nursing scope of practice

A mental health nurse is a registered nurse who holds a recognised specialist qualification in mental health [nursing]. Taking a holistic approach, guided by evidence, the mental health nurse works in collaboration with people who have mental health issues, their family and community, towards recovery as defined by the individual (Australian College of Mental Health Nurses 2013).

of practice provided by the Australian College of Mental Health Nurses is given in Box 40-1. Mental health nurses are registered nurses who are graduates of degree nursing programs or from the former hospital programs. They are educationally prepared to provide physical and mental healthcare. New graduates will usually undertake postgraduate study in the specialty of mental health nursing in their first year of employment.

There are approximately 19,000 mental health nurses in Australia (MHSA 2015) and 4300 in New Zealand (NCNZ 2014). Mental health nurses are employed in clinical, teaching, research, administration and service management. Roles include staff nurse, community mental health nurse, nurse educator, nurse specialist, nurse advisor and nurse practitioner. Areas of clinical practice include community mental health services, inpatient units, specialist mental health services such as eating disorders, liaison psychiatry and home-based treatment, forensic services, child and youth, old age, alcohol and drug services, and primary healthcare.

Mental health nursing can be defined as a caring process whereby the nurse forms a therapeutic relationship with a client, and uses that relationship as the basis for assessment, identification of problems, formulation of a plan of care and evaluation of that care. Although mental health nurses practise within a healthcare system based on medicine, the practice of mental health nursing is underpinned by nursing philosophy, values and theory.

History of mental health nursing

As with other nursing specialties, mental health nursing has its history in the caring practices of religious orders of the Middle Ages. Until the 18th century there was little organised care for people with mental illness (Shorter 1997), although the Bethlem asylum in England first opened in 1247 and received people with mental illness from 1376 (Andrews et al 1997). Most institutions of the 18th century were small in scale, and were known as 'madhouses'. Some were private houses with accommodation for people with mental illness. The madhouses of the 18th century employed staff referred to as 'keepers', who performed custodial and caregiving functions. Some keepers were doctors who took clients into their homes, where they administered the medical treatments of the time, such as bloodletting and purging. In many cases, 'treatment' involved physical punishment and harsh living conditions. From the late 18th century, larger asylums were provided, and in the 19th century the number and size of asylums grew considerably in England, Europe, the United States and the British colonies. The first asylum in Australia was opened in 1811 (Dax 1989) and in New Zealand in 1852 (Brunton 2005). In the asylums, attendants were employed to provide care, most of which was custodial in nature. As the medical discipline of psychiatry became organised in the late 19th century, attendants began training as nurses (Sands 2009).

The first specialist training as asylum (later 'psychiatric') nurses was provided in psychiatric hospitals, which were the almost exclusive site of public mental healthcare. Registration of Australian and New Zealand psychiatric nurses began early in the 20th century (Prebble 2008/09, Sands 2009), soon after registration for general nurses. The psychiatric hospital served as the sole location for nursing training until the last half of the 20th century, when nursing education moved into the tertiary education sector (Happell 2009, Prebble 2001). Mental health nurses now receive their undergraduate education in university or polytechnic degree programs and specialise in mental health following graduation. Since its asylum beginnings, mental health nursing has expanded to include a diverse range of practice settings and roles. Practice settings have expanded beyond psychiatric hospital sites to include community clinics, general hospitals, courts and prisons, and service users'[1] homes.

Hildegard Peplau and interpersonal care

The first recognised theorist of mental health nursing was Hildegard Peplau (1909–1999), whose theory of interpersonal relations in nursing was first published in 1952 (Peplau 1952/1988). Peplau was influenced by the principles of psychodynamic psychiatry which have their origins in the psychoanalytical theories of Sigmund Freud. These ideas were introduced into American psychiatry by Harry Stack Sullivan and Frieda Fromm-Reichmann, who were early influences on Peplau's work. Peplau's interpersonal theory was developed at a time when care and treatment in the 'mental' hospitals was predominantly custodial and physical. Sullivan, Peplau and colleagues

reasoned that through therapeutic relationships, people with mental illness could develop more-adaptive patterns of living and more satisfying interpersonal relationships (D'Antonio 2014).

Peplau identified three core elements of mental health nursing: the patient, the nurse and the interaction between patient and nurse. Her interpersonal theory described mental health nursing as a negotiated relationship which developed in four sequential phases: orientation, identification, exploitation and resolution. By working with people through these four phases, nurses were able to act as a 'maturing force' to assist people towards health. Interpersonal relationships subsequently came to form the theoretical basis for nursing generally (Olson 1996). Today, interpersonal practice remains a core skill for nurses in every clinical setting. Current models of mental health nursing continue to emphasise Peplau's interpersonal theory (e.g. Barker & Buchanan-Barker 2005), although nurses are also encouraged to develop skills in specific forms of therapy such as cognitive therapy (Turner 2010) and brief solution focused therapy (Wand 2010). These and other forms of psychological therapy are based on the development of a therapeutic relationship between client and therapist (Hill 2005).

Recovery and mental health

Recovery is not a new concept in health care, but it has been given new meaning in mental healthcare as service users have advocated for models of care and service delivery that place service users' experience, rather than clinicians' perceptions, at the centre of mental healthcare (Anthony 1993). The current concept of recovery does not mean 'cure' as it does in other healthcare contexts. Recovery refers to *living with* mental health problems. The Scottish Recovery Network (2015) provides the following definition of recovery:

> **Recovery is being able to live a meaningful and satisfying life, as defined by each person, in the presence or absence of symptoms. It is about having control over and input into your own life. Each individual's recovery, like his or her experience of the mental health problems or illness, is a unique and deeply personal process.**

The reason for this change in the concept of recovery is that some service users' mental health problems are of long standing, and the concept of recovery as 'cure' can lead to a sense of pessimism about the future. The concept of *hope* is central to recovery, based on the belief that hope can sustain people through times of distress and illness and will support the individual in maintaining their personal life goals. Recovery is included in the mental health scope-of-practice statement of the Australian College of Mental Health Nurses, provided in Box 40-1, and is referenced in contemporary mental health policy documents.

• CRITICAL REFLECTION POINT

1. **In which clinical settings do you expect to encounter people with mental illness?**
2. **How can the attitudes and beliefs of nurses influence the care of a person with mental illness?**
3. **How might a chronic illness such as diabetes affect a person's mental health?**

Mental illness

Everyone can expect to experience mental health issues at some point in their lives, such as in life crises or life transitions. For some individuals, mental health issues become severe or prolonged, and may develop into mental illness. Illnesses such as diabetes and heart disease are more common in people with mental illness and are associated with worse health outcomes. Mental illnesses are disturbances in emotional state, thinking and social functioning which occur in recognisable patterns and which reach a threshold of severity in comparison with common life experiences such as stress and sadness. Mental illnesses include disturbances in mood, such as depression and bipolar disorder; disturbances in reality testing, such as schizophrenia, the manic phase of bipolar disorder and delirium; disturbances in arousal and thinking, such as panic and anxiety; and disturbances in cognition, such as the dementias. Addiction is a form of mental illness that involves persistent harmful use of alcohol or other substances, usually over a long period. In most cases of mental illness there will be disruption in more than one area of functioning. Mental illnesses are sometimes classified as *organic* (having a demonstrated biological cause, such as delirium and the dementias) and *non-organic* (where there is no identifiable organic cause, such as schizophrenia). The term *psychosis* is used to refer to mental illness in which the person is thought to be out of touch with reality, with abnormal sensory perceptions (*hallucinations*) or fixed false ideas about the nature of reality (*delusions*). Psychosis may be temporary or enduring and will cause disturbance in personal and social functioning. A description of the most common mental illnesses is provided in Box 40-2.

The causes of mental illness are not fully understood. They include adverse early life experiences, interpersonal stress, trauma and adverse social environments. While there is a presumed biological basis to some mental illnesses, this does not explain all cases, and so is considered to be only a partial explanation of cause. The multiple causal factors at work give rise to the *biopsychosocial model*, which recognises that many factors play a part in mental illness as they also do in physical illness.

BOX 40-2 Common mental illnesses

Anxiety

Anxiety is a common experience in response to stress, but becomes a disorder if the response is maintained for a long period or if it is out of proportion to the stressor. Anxiety disorders can occur in all age groups, from children through to older people. They may take the form of prolonged and excessive concern about situations such as social encounters, leading to avoidance; or may be specific to situations such as closed or open spaces. Anxiety may lead to *panic*, a state of acutely increased physical and psychological arousal. Anxiety can be treated with psychological therapy, in some cases with supportive pharmacological treatment.

Bipolar disorder

Bipolar disorder is a mental illness which is characterised by disturbances of mood leading to episodes of either mania or depression. Bipolar disorder typically follows a cyclical pattern with episodes of mood disturbance followed by periods of normal mood (*euthymia*) and good social functioning. Treatment with a mood stabiliser will help to prevent extremes of mood, and psychological treatment will help maintain social functioning and prevent or minimise extremes of mood.

Delirium

Delirium is an organic disorder which is most commonly acute in onset and involves marked change in thinking and perception, often with heightened arousal and confusion. The cause of delirium is interference with brain functioning as the result of a physiological disturbance. There are many possible sources of physiological disturbance, including illness, fever, prescribed pharmacological agents and anaesthesia. Although older people are more vulnerable to developing delirium, it can also occur in young people. Delirium is common in general hospital patients. Nursing care involves reducing confusion by providing a safe, predictable environment, treating the underlying cause if it is known and pharmacological treatment to reduce confusion and arousal.

Dementia

Dementia is an organic syndrome in which brain function is impaired by a degenerative or disease process, leading to impairment in cognitive functioning. Memory is usually most markedly affected. Dementia most commonly affects older people, but can also occur in young adults. The course is progressive, although variable. Assessment is important to establish the extent of impaired functioning and to assist the person to maintain existing functioning. Although there are some pharmacological agents available, treatment is usually supportive and aimed at preserving cognitive and social functioning as long as possible.

Depression

Depression is a disorder of mood in which the person's mood is lowered for a prolonged period with resulting disruption to personal and social functioning. Depression affects all age groups and may be precipitated by stressful events, especially those involving loss, such as bereavement. Physical illness is associated with a higher incidence of depression, and low mood can make adjustment to physical illness difficult. Especially in its milder forms, depression may respond to psychological interventions such as cognitive therapy, or to interventions such as exercise or social support. In some cases people with depression will also benefit from pharmacological treatment.

Schizophrenia

Schizophrenia is a disorder of thinking and perception which also causes disruption to social functioning and performance of social roles. People with schizophrenia may experience hallucinations and/or delusions, and impaired social functioning. Schizophrenia most frequently manifests in young adults, although the symptoms and impaired social functioning may be enduring. Psychological and pharmacological treatment and social support can help reduce the symptoms of schizophrenia.

For a more comprehensive description of common mental illnesses, see Elder R, Evans K, Nizette D 2016 Psychiatric and mental health nursing. Elsevier, Sydney.

For a full list of mental disorders, with diagnostic criteria, see American Psychiatric Association (APA) 2013 Diagnostic and Statistical Manual of Mental Disorders (DSM-5), 5th edn. APA, Washington.

Mental illness is relatively common, especially in the clinical populations nurses will encounter in various healthcare settings. It is estimated that almost half (45%) of the Australian population will experience a mental illness in their lifetime and that 20% of the adult population (18–65 years) will have experienced a mental disorder in the past 12 months (ABS 2008). While most people who seek help for mental illness will consult their general practitioner, those with more severe illness will be referred to specialist mental health services, where they will be assessed by a psychiatrist or another clinical specialist such as a mental health nurse.

Mental illness and personality disorders

Personality disorders are lifelong patterns of thinking, emotional response, impulse control and interpersonal functioning that are problematic for the individual because they disrupt social role performance and relationships.

Personality disorders are thought to result from problems in early development, and for that reason are often marked by stable but dysfunctional patterns of relating and behaviour rather than changes from the person's own established patterns. In cases where patterns of relating and behaviour influence the person's personality but without causing major disruption to personal and social functioning, these patterns are referred to as personality *traits*, rather than disorders. Personality disorders are not regarded as mental illnesses, although their effects may be equally disabling. Distinguishing between mental disorder and personality disorder can be quite difficult as the two types of disorder share a lot of common characteristics and the presenting features can be quite similar. In most cases it is after thorough exploration of the person's clinical and social history that a distinction can be made. Individuals may be diagnosed with both a mental disorder and a personality disorder.

Three clusters of personality disorder have been recognised (American Psychiatric Association 2013). The *odd or eccentric* cluster (cluster A) refers to personality disorders marked by prominent difficulty in relationships, either through excessive concern with what others think or indifference to others. The *dramatic, erratic and emotional* cluster (cluster B) includes those disorders in which the person is considered to show excessive self-regard, usually at the expense of empathy with others. Despite their excessive self-regard, people with cluster B personality disorders are unusually vulnerable to criticism or perceived rejection from others, and may act on these perceptions in ways that arouse the concern of others, such as self-harm or other behaviour that attracts attention. The final cluster of personality disorders (cluster C) is the *anxious and fearful* type. People with cluster C personality disorders may be avoidant of contact with others, or may be either excessively dependent or controlling in social relationships.

People with personality disorders may seek health care in unusual ways, may avoid health care altogether and may not share healthcare professionals' views of their needs for health care. Often the problems experienced in personal relationships will be re-created within the healthcare context, and nurses may find themselves drawn into conflict with these individuals. An important aspect of mental health nursing practice is for nurses to maintain awareness of their own emotional responses to service users who do not share, or even reject, nurses' attempts to engage or to help. It is important to remember that personality patterns that healthcare professionals find challenging may result from adverse developmental experiences such as trauma, which offers some opportunities for treatment and change (Bowen 2013). Having clear goals of care is important, and it is important for nurses to manage their own emotional responses through peer support and clinical supervision (Deans & Meocevic 2006).

Substance use

Substance use and addiction form an important part of the mental health scope of practice, for two reasons. First, use of substances is prevalent in Australian and New Zealand society (AIHW 2005, Ministry of Health 2010), and extends from the use of prescription medications (sometimes illegally obtained) to illegal substances (such as marijuana and methamphetamine) and legal substances (such as alcohol and tobacco). Second, mental illness and substance use frequently occur together, either in the form of comorbid disorders (where a person may have both a substance-use disorder and a mental illness) or where substance use complicates a mental illness (such as the contribution of alcohol consumption to depression and self-harm). Nurses will encounter individuals with substance-use and addiction problems in every clinical setting, including primary care, medical and surgical settings, older adult services and specialist mental health and addiction services.

With the exception of tobacco, the most commonly used substance is alcohol, which is unsurprising as the use of alcohol has a long history in Australia and New Zealand and is deeply embedded in cultural norms. Other substances used are methamphetamine, cocaine, benzodiazepines, ecstasy (MDMA), LSD, marijuana and opiates. While most substances are taken orally or by smoking, some users take substances by intravenous injection, a practice which carries the additional risks of blood-borne infection with hepatitis C or human immunodeficiency virus (HIV). In addition, injecting substance users run the risk of accidental overdose or of injecting impure drugs. Some individuals will use more than one substance, and may combine prescription drugs such as benzodiazepines or opiates with illegal substances such as methamphetamine.

Substance-use problems range from acute intoxication to physical dependence. Understanding the nature and severity of the person's problems involves taking a comprehensive personal and substance-use history, and considering the possibility of a comorbid mental disorder such as anxiety or depression. Key terms related to substance use are explained in Box 40-3. Assessment should also include a physical examination and health history because of the high rate of physical comorbidity associated with substance use and the risks to health posed by various substances. Substance users may avoid

BOX 40-3 Key terms related to substance use

Addiction

Addiction is the state of continuing substance use despite the presence of behavioural, psychological, physical or social problems caused by the substance use. Addiction may be characterised by the use of increasing amounts of a substance, or by a stable pattern of problematic use. A person who is addicted will experience withdrawal symptoms on cessation, usually leading to further substance use.

Dependence

Dependence on a substance occurs when the individual needs to take a substance in order to be able to function. Dependence can be physical or psychological and is usually marked by signs and symptoms of withdrawal when the substance is not available.

Harmful use

Harmful substance use describes a pattern of use that results in disruption to psychological, physical or social functioning. While there are established thresholds for harmful use of substances such as alcohol, some individuals are more vulnerable than others and the effects of the substance use need to be individually assessed.

Hazardous use

Hazardous use of substances occurs when the level of use is such that future harm can be predicted on the basis of the current pattern of use. Harm may not be occurring currently, but can be predicted on the basis of cumulative effects of substance use and any increase in use.

Intoxication

Intoxication refers to altered physiological or psychological functioning as a result of substance use. Intoxication can be mild, such as the effect of a single alcoholic drink or a small amount of marijuana, or severe, such as intoxication associated with a drinking binge. Intoxication is reversible, with the time involved dependent on the half-life and metabolism of the substance.

Tolerance

Tolerance refers to physiological and behavioural adaptation to the presence of a substance. Increasing tolerance can mask the harmful effects of substances such as tobacco and alcohol, for example, lung and liver damage. With increasing tolerance, individuals will use more of the substance to achieve the same psychological effects.

Withdrawal

Withdrawal is a syndrome of central nervous system arousal which occurs in individuals who have become dependent on a substance and who stop taking that substance. People experience withdrawal from nicotine soon after cessation, although with other substances withdrawal takes longer to begin. Withdrawal symptoms can be relatively mild, for example a slight feeling of anxiety, to the severe and dangerous syndrome of delirium tremens.

health care because they wish to avoid health messages about cessation or moderation, or because they prefer to apply their financial resources to purchasing substances.

Intervention in substance use will often involve a harm-reduction approach rather than aiming for cessation. The advantage of the harm-reduction approach is that it allows the substance user to engage in health care and to work towards minimising the harmful effects of their substance use. This can mean moderating the amount of substances used, avoiding additional risks such as driving, learning safe injection practices and avoiding substance use that places the person at personal risk of assault or exploitation. Harm-reduction approaches are especially helpful for individuals with a pattern of relapse, or who are unable to commit to cessation of substance use. Because of the long-term nature of substance-use problems, many services use a philosophical model such as the Wheel of Change (Prochaska et al 1994), which recognises that recovery may be marked by several relapses. Motivational interviewing, an intervention that focuses on identifying the client's goals for change, is another commonly used strategy in the treatment of people with substance-use problems.

While most people with harmful patterns of substance use are seen in primary care, those who seek professional help will be referred to specialist substance-use and addiction services. Symptoms of low mood, anxiety and sleep disturbance, which frequently occur in this population, will be treated concurrently and are likely to significantly reduce as use of substances diminishes. Substance use is associated with a high incidence of thoughts of self-harm, **self-harming behaviour and suicide attempts**, meaning that treatment of substance use also involves treatment of accompanying thoughts of self-harm. In cases of acute withdrawal from addictive drugs such as alcohol or benzodiazepines, inpatient admission might be necessary in order to provide treatment in a safe environment and provide the necessary supportive physical care. Such treatment is usually short term and may be followed by residential rehabilitation or engagement in a community-based rehabilitation program. For many people, inpatient admission is not necessary, and the entire treatment program can be provided as a community-based service. For people with long-term substance-use problems, recovery is a lifelong process and may be marked by recurrent relapses.

Intellectual disability

The term 'intellectual disability' refers to people whose intellectual functioning is less than average and who also have impaired social and adaptive functioning. Intellectual disability may result from hereditary factors such as genetic disorders; developmental factors such as exposure to alcohol or other toxins in pregnancy; sensory deprivation during early years; or damage to the brain from impaired oxygen supply, infection or other medical conditions. Intellectual disability may be accompanied by impaired physical functioning, sensory loss, impaired neuromuscular development or complications of medical disorders. The term 'dual disability' is used when a person has both an intellectual disability and a physical disability.

As with mental health, services for people with intellectual disability are predominantly provided in community settings. The principle of 'normalisation' was articulated in 1972 by Wolfensberger as a means of advocating for social inclusion and the opportunity for people with intellectual disability to fully develop their talents and abilities (Jugessur & Iles 2009). Within the normalisation model, people with intellectual disability are seen as possessing the full range of human rights, including the right to participate in society. Society is seen as having an obligation to provide the services necessary for the realisation of human rights.

People with intellectual disabilities have high rates of physical illness and so are seen in a wide range of health settings. Nurses need to be aware of the many issues facing people with intellectual disabilities in order to ensure the best outcomes of care (Temple & Mordoch 2012). Treatment for intellectual disability includes medical treatment for any physical health problems, pharmacological treatment for problems with emotional regulation and impulse control, and occupational programs aimed at developing social and living skills and providing meaningful occupation. Nursing skills used with people with intellectual disability include assessment, with an emphasis on assessment of cognitive functioning; and communication, care planning and goal setting.

• CRITICAL REFLECTION POINT

1. **What personal experience have you had with people with mental illness, personality disorder, addictions or developmental disability?**
2. **What personal attributes do you think a nurse would need in order to provide effective care for people experiencing mental illness?**

Self-harm and suicide

Self-harm and suicide are related mental health problems that affect people in a wide range of health settings from primary care through to specialist mental health services. Self-harm can involve cutting, taking harmful amounts of prescribed or illicit drugs and risk-taking behaviour. While people who self-harm are at high risk of suicide, some people who self-harm do not do so with the intent to commit suicide but rather as a means of communicating or reducing distress. Individuals who self-harm or attempt suicide may present to emergency departments for treatment of injuries or toxic states, for example, the effects of overdose of prescribed or over-the-counter medications. Although people who self-harm or attempt suicide are more likely to have a mental illness, these problems are not confined to those with mental illness. Common means of suicide are overdose of medication, jumping, poisoning and firearms. Suicide is internationally recognised as a mental health issue, and both Australia and New Zealand have national suicide prevention strategies (Associate Minister of Health 2006, Commonwealth of Australia 2008).

Risk factors for suicide include male gender, substance use, depression, alcohol use and the presence of multiple stressors. Nurses working with individuals who have self-harmed or are suicidal will assess suicide risk as part of their nursing assessment, and will work with the individual to develop a safety plan. This can involve identifying and including friends or family members in the safety plan, distraction, utilising support systems, avoiding stressful situations, limiting use of alcohol and calling crisis or support services. For people with depression or other mental illness, treatment with medication may be part of a longer-term plan to reduce suicide risk.

Psychiatric diagnosis

Psychiatric diagnosis is the practice of assigning a category of mental illness following history-taking and assessment. In Australia and New Zealand, the most widely used system of psychiatric diagnosis is the Diagnostic and Statistical Manual of Mental Disorders (the DSM) (American Psychiatric Association 2013). The current version of the DSM, the DSM-5, lists over 400 mental disorders, although in practice only a limited number of those disorders are diagnosed. The DSM provides a set of criteria for each diagnosis. Criteria include subjective symptoms, severity of symptoms and duration of symptoms. Criteria also list disorders which must be excluded before a diagnosis can be made. For example, for the diagnosis of major depressive episode, the possibility

of substance-induced mood disorder must be excluded. Some symptoms of mental illness are common to many disorders; for example, sleep disturbance, anxiety, agitation and changes in energy levels. In some cases, such as post-traumatic stress disorder, a diagnosis cannot be made for a number of weeks following the precipitating event. In the case of a major depressive disorder, the person's symptoms must be present for a minimum of 2 weeks. Duration of symptoms is also considered in diagnosis. Psychiatric diagnosis requires comprehensive assessment, including a history of the presenting problem, mental health history and assessment of the person's current mental state.

Diagnosis may be uncertain due to lack of a clear history, or uncertainty about the nature of subjective experiences, and may be provisional, or even deferred, until the person's presentation is better understood. Diagnosis should be made with caution, as the treatment for different disorders, especially pharmacological treatment, is different. Diagnosis may also create expectations for the person's prognosis and future, and so needs to be reviewed regularly as part of the person's care. Psychiatric diagnosis is not formally part of most nurses' practice, although all nurses need to be aware of how diagnoses are made, the diagnostic criteria of the more common disorders and the sometimes uncertain nature of psychiatric diagnosis. The full diagnostic criteria for each disorder are contained in the DSM (American Psychiatric Association, 2013).

Mental health assessment in nursing

Assessment is the process of gaining an understanding of the issues and problems faced by the person with mental illness, and of engaging with that person in a plan of intervention. Assessment involves a structured conversation in which the person is invited to discuss their concerns and what forms of support or intervention they would find helpful. The role of the nurse in mental health assessment is to listen, validate and explore concerns, ask key questions about the person's problems, observe, and offer an interpretation. The process of assessment in mental health nursing focuses on the client's presenting problems, clinical symptoms, mental health history, current mental state, risk, strengths and protective factors, physical health strengths and protective factors, and other aspects of psychosocial functioning.

Assessment will usually begin with a statement of the client's presenting problem, followed by exploration of that problem so that the client is able to relate their unique experience of stress, distress, or change in functioning or coping. Changes might have begun recently, or be of long duration. During the assessment the nurse adopts an empathic listening role, using key questions to enable the client to talk freely. As the client describes their concerns they are validated by the nurse using empathic communication. Some areas, such as thoughts of self-harm or of harming others, may require direct questions, but often these can be integrated into an assessment interview. The assessment interview is allowed to develop according to the concerns expressed by the client, and to the client's level of distress and ability to communicate. In some cases a complete assessment may take more than one interview. Initial assessment ends with careful documentation of all aspects of the client's history and presenting problems. However, assessment continues throughout the process of care and will need to be revised as the person's needs change.

There are many different tools and models of mental health assessment, including conversational interview (Brown 1995), history-taking, systems review and use of validated assessment instruments. Examples of validated instruments include the Alcohol Use Disorders Identification Test (AUDIT) for assessment of alcohol use (Saunders et al 1993); the Mini Mental State Examination (MMSE) for assessment of cognitive function (Folstein et al 1975); the Beck Depression Inventory (BDI) for assessment of mood (Beck et al 1961); and the Liverpool University Neuroleptic Side Effect Rating Scale (LUNSERS) for assessment of side effects of medication (Morrison et al 2000).

Mental state assessment

Mental state assessment is a core mental health nursing skill, and involves assessment of behaviour, mood, thoughts, perception, cognition and judgement (Skill 40 1). Assessment of mental state is integrated into an overall mental health assessment, which includes history-taking and inquiry about symptoms and relevant experiences. Many aspects of mental state assessment can be incorporated into everyday nursing practice, such as bedside care or a clinic review. The mental state assessment focuses on the service user's mental state at the time of the assessment, not on historical information. Nurses sometimes find it helpful to use a mnemonic for recording the mental state assessment, as this allows the assessment to be recorded in a consistent manner and ensures that no important areas of mental state are omitted. An example of a mnemonic, BATOMI, is outlined in Box 40-4, which also illustrates how the observations in a mental state assessment are recorded.

The assessment of mental state is usually documented towards the end of an overall assessment, once all the aspects of personal and clinical history have been recorded. Mental state assessment will be undertaken at several points during an episode of care, with the initial assessment providing a baseline against which to measure response to care and treatment.

SKILL 40-1

Mental state assessment

Mental state assessment is a key nursing skill and provides a structured set of observations about the patient's cognitive and emotional state at a specific point in time.

Delegation and other considerations

The mental state assessment can be conducted without supervision. Most aspects of the mental state assessment can be carried out as part of routine nursing care, that is, they can be integrated into other nursing procedures.

Before proceeding:

- review the categories of mental state assessment, and communication skills
- revise the structured format for mental state assessment (BATOMI) (see Box 40-5).

Equipment

- Mental health assessment uses communication skills and the therapeutic use of self.
- Consider privacy and appropriateness of setting

Therapeutic relationship and patient considerations

- Confirms patient identity
- Gains patient consent
- Initiates communication by introductions and clarification of patient's immediate needs and problems
- Identifies how the skill will affect the patient
- Discusses procedure with the patient to clarify understanding
- Provides reassurance
- Assesses patient knowledge and expectations and ensures patient understanding
- Where necessary, provides further clarification
- Explains actions and potential discomfort at all stages of procedure

STEPS	RATIONALE
1. Determine the need to assess mental state of patient.	Mental state is changeable, and is influenced by a range of biological, psychological and emotional factors.
2. **Focused mental health history** a. Consider the patient's usual mental state, and how mental state may be affected by illness. b. Consider the presence of factors that may affect mental state: • pain/discomfort • sedative or other effects of medication • tiredness • anxiety about health/hospitalisation • sensory loss or impairment • nausea or other symptoms • any history of mental illness • alcohol or drug use.	The focused mental health history provides insight into the links between a patient's general health and their cognitive and emotional functioning.
Procedure (1) Initiate communication by introductions, clarification of the patient's immediate needs and problems. (2) Consider positioning of nurse and patient to assist communication, that is, by enabling eye contact. (3) Ideally sit at the same level as the patient. (4) Continue with assessment using guidelines below to assess mental state.	Promotes rapport and psychological comfort during assessment.

STEPS	RATIONALE
3. Assess mental state	Appearance provides an initial set of clues to the patient's mental state.
A. Assessment of appearance – includes both expected and unusual aspects of appearance.	
Observe for:	
(1) Gross appearance (stature, state of dress, appropriateness of dress for current situation).	Expected and unusual aspects of appearance are equally important.
(2) Patient's apparent age compared with recorded age.	
(3) Position during assessment (sitting, lying).	
(4) Grooming and evidence of self-care or neglect.	
(5) Jewellery, make-up.	
(6) Distinguishing features (complexion, marks on skin, any observable disabilities).	
(7) Facial expressions.	
B. Assessment of behaviour – includes all observable behaviour.	Many changes in mental state are apparent from observations of behaviour.
Observe for:	
(1) Physical signs of anxiety or distress (handwringing, nervous mannerisms, plucking at clothes/hair, clutching objects such as purse or personal items).	
(2) Changes in behaviour in response to assessment.	Changes in behaviour can provide an indication of concerns and anxieties.
(3) Any tremor or involuntary movements.	
(4) Gestures with hands, eyes, head.	
(5) Crying, laughing or other behavioural indicators of mood.	
(6) Eye contact with interviewer (observe for constant, intermittent, intense or absent eye contact).	
(7) Motor activity (settled/relaxed, changes of position, restlessness).	
C. Assessment of affect and mood – includes direct and indirect observations of emotional state.	Assessment of mood includes both the nurse's assessment and the patient's statements about their mood.
(1) Emotional responsiveness (warm, engaging, distant, aloof).	
(2) Responses to topics of discussion.	
(3) Crying, smiling, laughing and other behavioural indicators of emotional state.	Affect may change throughout an interview or procedure; changes can be as important as overall mood.
(4) Conversational triggers to emotional responses.	
(5) Congruence between emotional response and content of conversation.	
(6) Irritability/anger.	
(7) Indications of anxiety.	
(8) Patient's self-rating of mood (1 = lowest ever; 10 = best ever).	

STEPS	RATIONALE
D. Assessment of thought and speech – includes directly observed speech and underlying thought processes. Make allowances for age, culture, language. Observe for: (1) Rate of speech (slowed, normal, accelerated, pressured). (2) Themes of thought and speech (preoccupations, guilt, depressive themes, dominant concerns). (3) Reduced/absent speech. (4) Organisation of speech (coherent, logical, complete sentences, goal oriented). (5) Evidence of ideas that are out of context (i.e. paranoid ideas, delusions). (6) Evidence of unexplained perceptions (voices, visual hallucinations). Patients can also be asked to describe their thoughts.	Patterns of thought are assessed by attending to speech.
E. Assessment of orientation (1) Aspects of orientation are: • Time • Place • Person (2) Orientation is assessed by asking specific questions or interpreting conversational cues to orientation (e.g. names, time, place of assessment).	Orientation provides important clues to organic or functional confusional states as well as additional information about problems of mood, thinking and perception.
F. Assessment of memory – includes all retention of information, whether short or long term. (1) Observe for: • attention/concentration/registration • short-term memory loss • long-term memory loss. (2) Ask specific questions if you need to test different aspects of memory, that is, can the patient remember: • events that just occurred (registration) • events that occurred 5 minutes ago (short-term memory) • events that occurred on the previous day (long-term memory). Memory can be further tested by giving the names of three unrelated items (ball, flag, tree) and asking the patient to repeat (registration) and then recall after 5 minutes' conversation.	Memory can be disrupted in many illnesses and when emotional and cognitive functioning is impaired. General assessment conversation can provide important information about memory.

STEPS	RATIONALE
G. Assessment of insight and judgement – assesses and records the patient's understanding of their current: (1) realistic perception of current health problems (2) realistic perception of any need for treatment (3) awareness of consequences of own choices.	Insight is important in order to engage patient in a plan of care. Impaired cognitive and emotional functioning can lead to reduced insight. Assessment of judgement can be an important indicator of safety.

■ **Critical decision point: Routine mental state assessment may show or confirm changes in cognitive or emotional state that require amendment of the plan of care, and possibly further assessment or referral. For example, if the mental state assessment shows a developing confusional state the patient may need more intensive nursing care and closer observation.**

RECORDING AND REPORTING

- Mental state assessment is recorded in a narrative style using a structured format with headings for each component of assessment (see Box 40-5). Issues of concern such as low mood or anxiety should be discussed with a senior colleague or supervisor.
- Each mental state assessment should be compared with the patient's baseline assessment.

HOME CARE CONSIDERATIONS

- Mental state assessment can be undertaken in the home as part of the routine nursing care.
- The assessment may need to be abridged if there is not sufficient privacy.

BOX 40-4 Mental state assessment using BATOMI mnemonic

The following assessment records the mental state of a woman assessed following an overdose of over-the-counter medication and medical treatment in the emergency department. The mental state assessment is one component of a complete mental health assessment, which would also include taking a history and formulating a diagnosis and problem list.

Behaviour and appearance

45-year-old Caucasian woman who attends well to interview. Looks older than her chronological age. Casually dressed in jeans and T-shirt. Is well groomed and appears well cared for. No unusual movements or mannerisms. Maintains good eye contact. Tearful at times.

Affect and mood

Affect is predominantly sad, with occasional brightening in response to questions. Mood is objectively depressed. She describes her mood as low, rates it at 3 on 1–10 scale where 1 is the lowest it has been.

Thought and speech

Thoughts focus on recent stressors, especially loss of a significant relationship. States she is currently unable to see a future without her partner. Is unable to focus on problem-solving about employment or other issues. There is a depressive theme to her thoughts. Thoughts are slowed. No delusional ideas expressed. No unusual perceptions. Has occasional thoughts of suicide but stresses she would not act on these. Has no specific plan. Gives concern for her children as a preventive factor.

Orientation

Oriented to time, place and person. Knows her whereabouts, the date and time of day. Accurately identifies staff by role or name.

Memory

Both short- and long-term memory are intact. She remembers events of the past few days, and more distant. Able to recall new information presented during interview.

Insight and judgement

Identifies that her mood is currently low and has been low prior to her recent separation. Accepts that professional care will help raise her mood and resolve current difficulties. Is willing to consider a review of current antidepressant medication. Judgement is unimpaired.

Practice contexts

Mental health nurses practise in a range of clinical contexts where they provide direct care either to individuals or to groups. Practice contexts include community and inpatient mental health and addiction services. Community mental health settings can include visits to service users' homes and care provided in clinic visits. Mental health nurses usually work as members of multidisciplinary teams which consist of a psychiatrist, registered nurse, social worker, psychologist, occupational therapist and other healthcare professionals. Teams might also include non-professional support workers. Mental health teams liaise with service users' primary healthcare providers, with social agencies and in some cases with housing and other welfare services. Other clinical roles include therapist roles for nurses with specific postgraduate education, liaison psychiatry in general hospitals, court and police liaison roles and others. An outline of some of the more common contexts in which mental health nursing is practised is listed in Box 40-5.

BOX 40-5 Mental health practice contexts

Addiction services

Nurses working in addiction services may provide direct care to clients with addiction or substance dependence, or may work in inpatient settings which provide either detoxification services or a period of inpatient care prior to discharge to community care. Some nurses practise in long-term care settings where clients may be admitted for weeks or even months of rehabilitation. Although nurses working in alcohol and drug services may administer prescribed treatments such as medications, they will also use psychological treatment strategies such as motivational interviewing and problem-solving.

Child and youth services

Many of the mental health needs of children and youth are specific to their age group or developmental stage, and require nurses and clinical practitioners responsive to the unique needs of this population group. Mental health nurses may work in inpatient settings providing 24-hour care as well as participating in a range of therapeutic activities including family meetings, liaison with school or other guidance counsellors, individual therapy, medication and group therapy. Child and youth services are also provided in community settings, including mobile mental health teams and outpatient clinics. Some mental health nurses practise in roles that involve liaison with schools and social agencies where mental health problems might first become apparent.

Community mental health services

These include adult community mental health teams and specialist mental health services based in the community. Nurses may work as case managers for a group of clients with long-term mental health problems, crisis workers providing triage and assessment of people presenting in mental health crisis, and home-based treatment teams, providing intensive support for individuals and their families in their homes as an alternative to hospital admission.

Forensic services

Forensic mental health services provide care and treatment for service users whose mental illness has brought them before a court on criminal charges. If the behaviour leading to the criminal charge is thought to be due to mental illness, the court may order that the service user is admitted to an inpatient forensic service rather than face the possibility of conviction and a jail sentence. Forensic mental health services also provide community follow-up for service users discharged from inpatient forensic services, usually with the objective that the service user will later be transferred to the care of adult community mental health services.

Inpatient care

This practice context involves care for service users who have been admitted to hospital usually because their mental health problems are especially acute and cannot be managed in a community setting. Inpatient care may be necessary for service users with acute depression or psychosis, especially if the clinical severity is associated with significant risk to self or others. In inpatient settings nurses provide 24-hour care, including liaison with families, community mental health services and other health or social agencies. Inpatient care may be voluntary or may be compulsory under mental health legislation.

Liaison psychiatry

Liaison psychiatry is an area of specialty practice that provides assessment and treatment for people presenting to general hospitals with self-harm or suicide attempts or with medical consequences of overdose or drug use. Clients also include those with mental distress or illness related to a physical health problem or with alcohol and substance-use issues. Nurses in liaison psychiatry roles may provide initial assessment, brief intervention and referral to follow-up services on discharge.

Older adult mental health services

Older adult mental health services provide inpatient and community services for older people, usually for those aged 65 years and over. Some mental health problems are markedly more common in old age, such as the dementias and others take on specific characteristics in the older adult population, such as depression and schizophrenia. Substance use and addiction are also prevalent in the older adult age group. Older people may have co-existing physical health problems such as heart disease, diabetes and impaired renal and liver function that exacerbate mental illness and make treatment more complex.

continued

Primary care

Primary care is a relatively new mental health nursing role and involves nursing in primary care clinics where nurses assess patients, develop plans of care, provide psychological interventions and in some cases prescribe pharmacological agents. Mental health nurses working in primary care liaise closely with general practitioners and may make referrals to specialist mental health services.

Treatment modalities

Treatments provided in mental healthcare vary, from group and individual psychotherapy, to specific psychological therapies, such as cognitive therapy and dialectical behaviour therapy, to inpatient admission, community case management, pharmacological treatments, electroconvulsive treatment, and a range of others. Different treatments may be provided together, such as psychological and pharmacological treatment for depression. Some of the more commonly used psychological treatments are described below.

Individual psychotherapy

Individual psychotherapy is a form of one-to-one psychological intervention in which a clinician (or therapist) meets with an individual client to talk about emotional problems. There are many models of individual psychotherapy, such as interpersonal psychotherapy, brief focused psychotherapy, cognitive therapy and others. Individual psychotherapy may be goal-focused with an agreement to work towards a particular objective; solution-focused in which the aim is to solve a specific problem; or open-ended where there is no specific aim but a commitment to exploration and change on the part of the client. Components of individual psychotherapy have been integrated into mental health nursing practice, although nurses may also practise individual psychotherapy as a structured form of clinical intervention. Individual psychotherapy will usually involve regular individual appointments for a set period of time.

Cognitive therapy

Cognitive therapy (or cognitive behaviour therapy) is a form of individual or group psychotherapy in which a nurse will assist a client to reflect on their habitual patterns of thoughts and beliefs and how those patterns affect their emotional state, decision-making and responses to others. Cognitive therapy is based on the theory that emotions and behaviour are influenced by thoughts (cognitions) and that if we consciously change our habitual patterns of thought, emotions and behaviour will change as a result. Cognitive therapy has been found to be effective in the treatment of depression and anxiety (see *Research highlight*) and in helping clients develop adaptive responses to physical illness and trauma.

Dialectical behaviour therapy

Dialectical behaviour therapy (DBT) is a form of individual or group therapy specifically developed for people who have difficulty managing painful emotional states, and who tend to self-harm as a form of emotional regulation. DBT was developed as a means of assisting this group of people to manage emotional distress without

RESEARCH HIGHLIGHT

Research focus

Depression is common in people with diabetes, and has an adverse effect on physical and mental health. Psychological interventions such as cognitive therapy are effective interventions for depression in the general population, as well as in people with chronic illness.

Research abstract

The study was a randomised controlled trial in which 94 people with type 1 or type 2 diabetes and depression were assigned to individual mindfulness cognitive behavioural therapy (MCBT, 31), individual cognitive behavioural therapy (CBT, 32) or a wait list (31).

Evidence-based practice

- Following the intervention, people receiving MBCT and CBT showed significantly greater reductions in depressive symptoms compared with those on the wait list. There was no significant difference in HbA1c (glycosylated haemoglobin test).
- In people with type 1 or type 2 diabetes mindfulness cognitive behavioural therapy and cognitive behavioural therapy are effective in reducing depressive symptoms.
- Both interventions could be implemented to improve psychological care for depressed patients with diabetes.

Reference

Tovote et al 2014 Individual mindfulness-based cognitive therapy and cognitive behaviour therapy for treating depressive symptoms in patients with diabetes: Results of a randomized controlled trial. Diabetes Care 37(9):2427–34.

direct intervention from nurses or other therapists. However, the skills of DBT need to be learnt and practised with professional support before they can be implemented independently. Components of DBT include mindfulness, self-soothing, problem-solving, distraction and asking for help. An important aspect of DBT is helping the client to manage painful emotions without resorting to self-harm. DBT has been found to be effective in people with borderline personality disorder.

Acceptance and commitment therapy

Acceptance and commitment therapy (ACT) is a relatively new form of psychological therapy, which attempts to blend influences of traditional Western models of psychotherapy with the Eastern-inspired idea of mindfulness. ACT is different to other psychotherapies, as it does not focus directly on symptoms, but rather on helping people to live a rich and satisfying life while accepting that pain, in the form of psychological discomfort, is an inevitable part of life. In addition to acceptance of the pain of life, ACT involves a commitment to taking steps that will help to achieve a valued life. The core skill of mindfulness has four components. These are: acceptance; cognitive diffusion; contact with the present moment; and the observing self. ACT has been found to be effective in a number of clinical conditions such as anxiety, depression and schizophrenia, as well as with psychological problems such as smoking cessation, stress, pain, and coping with physical illnesses such as diabetes.

Group therapy

Group therapy is a form of psychological intervention in which people are treated in small or large groups. Many of the techniques used in group therapy are also used in individual psychotherapy, with the added aspect that fellow clients participate in the therapy. Group therapy has many applications, including inpatient care, addictions, bipolar disorder and schizophrenia. Groups are a powerful means of intervention when problem-solving is important to treatment, as the experience and resources of group members can be used to generate strategies and validate individuals' efforts to manage problems. Nurses working in therapeutic groups will encourage clients to develop a sense of belonging to the group and will attempt to use that sense of belonging to help motivate the client to change. Groups may be open (accepting new members on a regular basis) or closed (not open to new members once they have formed). They may run for a predetermined number of meetings, or they may have no set endpoint. On joining a group, a new member will be asked to commit to a set of rules covering issues such as attendance, participation, confidentiality, and norms of behaviour while in the group. Groups may also have rules about what topics are acceptable for discussion, and about contact between members between group meetings.

Pharmacological treatments

There are many pharmacological treatments used in mental healthcare. These include anxiolytics, antidepressants, antipsychotics, hypnotics and mood stabilisers. Nurses may be involved in administering medication, educating service users about its effects and side effects and discussing with service users the place of **pharmacological treatment** in their recovery.

Anxiolytics

These agents are used for the treatment of anxiety. Examples are lorazepam, diazepam and midazolam, all of the benzodiazepine group. Long-term treatment with anxiolytics is not recommended because of the possibility of dependence. However, the anxiolytics have an important role in the treatment of acute anxiety for people with anxiety disorders, and also for the acute anxiety that frequently accompanies psychosis. Because of their sedative effect, anxiolytics are sometimes used to assist sleep and to help service users achieve behavioural control.

Antidepressants

As the name suggests, antidepressants are used in the treatment of depression. Antidepressants are considered to work by increasing available serotonin at key sites in the brain, and thus elevating the person's mood. They are most effective in cases of severe depression. The effects may not be apparent for up to 3 weeks, and the treatment will then need to be continued for several months to achieve a sustained lift in mood. Antidepressant agents work well in combination with psychological approaches. Some individuals report an initial increase in anxiety on antidepressant medication, and this needs to be carefully managed as anxiety is also a feature of depression. An initial increase in anxiety will usually decrease over the first few weeks of treatment. Antidepressant medication is not addictive, but people notice a 'rebound effect' if treatment is discontinued suddenly. Examples of commonly used antidepressants are citalopram, fluoxetine, amitriptyline and paroxetine.

Antipsychotic agents

Antipsychotic agents are those given for the treatment of psychosis, especially schizophrenia and mania. These agents are considered to work on dopamine receptors at

various sites in the brain. Because of their effect in reducing the intensity of negative perceptions, antipsychotic agents may also be used in the treatment of severe depression, delirium and dementia. Antipsychotic agents have variable sedative effects, and so the right agent and dose will need to be carefully considered for each individual. Antipsychotic agents can be given orally, intramuscularly and sub-lingually. Some intramuscular forms of antipsychotic agents are stored in muscle and released slowly, meaning that they only need to be administered at 2-weekly or even monthly intervals. Antipsychotic agents can cause muscular side effects, such as rigidity and tremor, and in some cases long-term involuntary movements. Some antipsychotic agents are associated with the metabolic syndrome, type 2 diabetes, and cardiovascular side effects. Because of their potential for significant side effects and adverse effects clients should have a full health assessment prior to commencing treatment. Antipsychotic agents need to be chosen carefully and closely monitored. Examples of antipsychotic agents are haloperidol, chlorpromazine, risperidone, olanzapine and clozapine.

Mood stabilisers

Mood stabilisers are used in the treatment of bipolar disorder and other illnesses in which there is marked mood instability. The most commonly used mood stabiliser is lithium carbonate, which is used in the treatment of bipolar disorder. Other examples are carbamazepine, lamotrigine, and sodium valproate. Mood stabilisers are prescribed as maintenance treatment rather than as treatment for acute episodes of psychosis. They are most effective at preventing further acute episodes and helping the individual maintain a steady mood state. In some cases people will be prescribed an additional antipsychotic agent, especially in the early stages of recovery from an acute episode. Blood levels of mood stabilisers need to be regularly monitored to prevent toxicity. Clients should also have liver and renal function monitored regularly.

Hypnotics

Hypnotics are pharmacological agents prescribed to enhance sleep. Sleep disturbance is a common health problem, and is a feature of mental illness. Poor sleep also impedes recovery by limiting the individual's ability to benefit from the recuperative powers of sleep. Some antidepressant and antipsychotic agents have a hypnotic effect which can be enhanced by taking the medication close to retiring to bed. In other cases the individual will benefit from an additional hypnotic. Most hypnotic agents are benzodiazepines and have the potential for addiction, so use of hypnotics needs to be limited to periods of acute sleep disturbance, with sleep hygiene measures used as a longer-term strategy. Examples of hypnotics are zopiclone, triazolam and temazepam.

Electroconvulsive therapy

Electroconvulsive therapy (ECT) is a form of treatment for severe depression and mood disorder. ECT consists of passing an electrical current through the temples into the brain, sufficient to induce a tonic–clonic seizure. The procedure is carried out under a short-acting general anaesthetic, and the muscular effects of the seizure are controlled by the use of a muscle-relaxant drug such as methohexital (brevital sodium). A typical course of ECT is usually six to eight treatments with a day between each one. The service user's mental state, especially mood, is assessed following each treatment. ECT has a controversial history, as it is associated with excessive and punitive use in the past and is associated with memory loss. However, ECT is also considered to be an effective treatment for severe depression and catatonia. In current mental healthcare, ECT is usually subject to specific consent processes, unlike most medical treatments. In the case of individuals considered to lack competence to consent, a court-appointed guardian may be asked to consent.

• CRITICAL REFLECTION POINT

1. **If you or a family member were being treated for mental illness, what choices of therapy would you want to be offered?**
2. **Are there any forms of therapy you would not want for yourself or a family member?**
3. **What further learning do you feel you need about treatment of mental illness?**

Culture and mental illness

Although disturbances in thinking, emotional state and social relationships occur in every **culture**, the forms they take are in some cases specific to those contexts. For example, the experience of *whakamaa* (shame, self-abasement, shyness, excessive modesty and withdrawal describe some aspects of this concept) is only seen in the Māori culture (Hirini et al 2005). Vukic et al (2010) have described the culturally specific understandings of mental health among Australian Aboriginals. The concept of 'mental illness' is a construct of Western societies and so represents Western ideas of the individual and the relationship between the individual and society. The increasing ethnic and cultural diversity of Western societies means that individuals attend Western health services with presentations influenced

by cultural beliefs and practices different to those of clinicians trained in Western models. Nurses respond to this diversity by developing an understanding of the diversity of cultures in their own societies, and by developing cross-cultural communication skills (O'Brien et al 2009). Services also attempt to provide clinicians from the cultural group of the service user, and in some cases develop specialty services based on a culturally specific model of treatment.

Stigma

A continuing issue facing people with mental illness is **stigma** (Fitzpatrick 2015). Stigma is a complex issue that has historical origins in the perception of people with mental illness as dangerous, bizarre and unreasonable. Social responses to mental illness, including the conditions of the former asylums, have also contributed to stigma towards mental illness. The perceptions of others may become internalised so that individuals with mental illness come to accept negative views of themselves, a concept known as *self-stigma* (MacInnes & Lewis 2008). The causes and expressions of stigma vary across different cultural groups and can result in people from cultural minorities avoiding mainstream services because they feel they will not be understood by service providers (Choudhury & Chopra 2011) (see Chapter 14). The effects of stigma are that people may not seek intervention for mental illness, may be socially excluded and may be ostracised from family and friends. People with mental illness also encounter stigma in health services, and in some cases have difficulties in accessing care (Horsfall et al 2010). In recent times concerted efforts have been made to counter the stigma of mental illness, including campaigns such as the Australian beyondblue depression initiative (Pike 2010) and the New Zealand Like Minds, Like Mine project (Thornicroft et al 2014). These campaigns have had some impact in improving public perceptions of mental illness. One focus of these campaigns is to inform the public of the prevalence of mental illness, and to use well-known public figures to talk about their experience of mental illness. An example of an intervention to reduce self-stigma is outlined in the following *Research highlight*.

Hearing voices

As discussed in the section on mental illness above, some people with mental illness experience *hallucinations*, often in the form of **hearing voices**. While hearing voices has traditionally been viewed as a symptom of illness, recent approaches have drawn attention to hearing voices as a common human experience and one which is not necessarily symptomatic of illness (Jones & Coffey 2012). Many people report hearing the voice of a deceased family member and others report hearing voices that become part of their life and are not experienced as negative or adverse. In addition, people

RESEARCH HIGHLIGHT

Research focus

Stigma towards people with mental illness involves negative perceptions, including perceptions of the person with mental illness as different, dangerous, bizarre or unreasonable. One effect of stigma is that individuals with mental illness come to share these negative perceptions and apply them to themselves, a concept known as self-stigma.

Research abstract

The researchers conducted a 6-week trial of a program designed to reduce self-stigma in a group of service users with severe and enduring mental illness. Twenty male participants were recruited to the study and assessed for self-stigma using a 12-item standardised measure of devaluation–discrimination. Additional measurements were made of self-esteem, self-acceptance and psychological wellbeing. The study used a 'before and after' design, and the intervention used a cognitive therapy approach in addition to psychoeducational strategies. The intervention was delivered to groups of six to eight participants. Following the intervention, there was a significant reduction in self-stigma using the devaluation–discrimination measure, but no changes in the measures of self-esteem, self-acceptance and psychological wellbeing.

Evidence-based practice

- Structured group interventions can be effective in reducing self-stigma in people with severe and enduring mental illness.
- Self-stigma appears to be distinct from self-esteem, self-acceptance and psychological wellbeing.
- Further research is needed to test these findings with other forms of stigma about mental illness and with female participants.

Reference

who hear unpleasant voices can learn to limit the effects of these voices, and to manage their responses using a range of skills and strategies. Managing responses to hearing voices is part of dialectical behaviour therapy and other forms of self-management.

Mental health nurses work with service users who hear voices by exploring the nature of the voices, acknowledging the sometimes distressing nature of the voices, helping service users identify patterns in the voices heard and assisting service users to develop their own management strategies. Strategies include blocking out voices with alternative auditory stimuli (such as earphones), talking back to voices that make derogatory comments, and recognising the situations in which the voices occur. Service users may be offered medication if that is something they find helpful.

• CRITICAL REFLECTION POINT

1. **Do you or anyone you know have the experience of hearing voices?**
2. **After reading the section above, do you think people who hear voices are always mentally ill?**
3. **What actions can you take to reduce stigma about mental illness?**

Mental health legislation

A characteristic that is almost unique to mental healthcare is the existence of legislation which compels people with mental illness to accept treatment without consent and to remain in hospital for the purposes of treatment. Treatment without consent is considered unethical under most circumstances, and is specifically forbidden under professional codes of practice and human rights legislation. In mental health services, however, specific legislation allows clinicians to provide treatment without consent (in specific circumstances). Why is this so? Mental illness can impair a person's judgement so that their actions pose a risk to themselves or other people. This might include an impulse to attempt suicide in the case of a person with depression, or might include thoughts of harming others in the case of someone who is hearing voices telling them someone is intent on harming them. These are exceptional circumstances, and the purpose of **mental health legislation** is both to protect the individual from self-harm and to protect others from impulses to harm arising from mental illness.

The process of applying mental health legislation is known as *committal*, or *civil commitment*, and usually involves a period of treatment without consent in a hospital or mental health unit. Under the principle of least-restrictive care, committal should be for the briefest period necessary to contain the risk of harm, and should be aimed at returning the person to their former level of autonomy. In many cases, people placed in hospital under mental health legislation will be discharged under a community treatment order. A community treatment order allows the person to live in the community while at the same time receiving compulsory treatment for mental illness. People placed under civil commitment have rights to consult a lawyer or advocate and to appeal their legal status. Legislation will usually specify the period of treatment necessary and will also require periodic formal reviews of the need for compulsory treatment.

Clinical supervision in mental health nursing

Mental health nursing is known to be a stressful occupation that places significant psychological and emotional demands on practitioners. These demands arise because of the nature of service users' clinical problems and the emotional responses of nurses. Other sources of stress include relationships with peers and senior nurses, and the organisational demands of health service providers such as shift work, staff shortages and requirements for continuous professional development. The stress arising from clinical practice is an addition to stresses arising in the nurse's personal life. The effects of multiple stressors can affect nurses' mental health and their enjoyment of clinical practice, leading to disengagement, emotional distancing and a reduced sense of optimism. In extreme cases this can lead to *burnout*, a state in which the nurse is no longer able to manage the emotional and psychological demands of nursing (Kravits et al 2010).

Clinical supervision is used by nurses as a way to help manage stress, address professional and clinical issues and to seek support and validation for their clinical work (Brunero & Stein-Parbury 2008). Clinical supervision has a long history in psychology, counselling and social work, but has only recently been introduced into nursing. Different models of supervision have been described (Te Pou 2009), and nurses engaging in supervision will identify a supervisor who utilises a model that meets the developmental needs of the supervisee. Standards of mental health nursing practice in Australia and New Zealand require that mental health nurses are actively involved in clinical supervision (Australian College of Mental Health Nurses 2013, Te Ao Maramatanga 2012).

Typically, a nurse will negotiate a supervision contract with a more experienced nurse, who, in addition to having a depth of clinical experience, will themselves be engaged in clinical supervision and will have undertaken training in providing supervision. For supervision to work effectively,

it is important that the relationship between nurse and supervisor is one of trust. The supervisee needs to find the process safe and supportive. Within the supervision relationship the supervisor will encourage the supervisee to reflect on their practice and identify ways in which practice can be improved. Other issues that can be a focus of discussion in supervision are the political and social context of nursing and health care, and the supervisee's professional and career development plans. Supervision discussions should be confidential between the nurse and supervisor, although an employer might require evidence that the nurse is participating in supervision. The issues discussed in the supervision relationship can be quite personal, but it is essential that supervision does not become counselling or psychotherapy. Supervision should also be distinguished from line management. Establishing clear guidelines for supervision can help maintain the focus on professional support.

Benefits of supervision are reduced sense of burden, greater enthusiasm for clinical practice and an increased sense of optimism about patients and about the nurse's own professional development (Koivu 2011). Supervision also helps to maintain a safe and healthy workplace by providing nurses with an opportunity to manage issues that might otherwise result in impaired performance and conflict with colleagues. Clinical supervision can play an important supportive role in maintaining mental health by helping the nurse identify strategies for coping with clinical work, providing an opportunity to identify problems before they become overwhelming, and validating the nurse's clinical practice.

Mental health promotion

The focus of this chapter so far has been on mental illness, assessment and treatment, and on the variety of specialist mental health services available. The focus has therefore been on what nurses need to know to provide care for people whose mental health problems have reached a significant level of severity. **Mental health promotion** is aimed at the prevention of such problems, and in creating conditions in which serious mental health problems are less likely to occur.

Mental health promotion involves nurses and other healthcare practitioners in activities that promote mental health for individuals, as well as advocating for social changes that support mental health. The focus of mental health promotion is promoting wellbeing in the context of people's everyday lives. Through mental health promotion, people are enabled to develop personal coping skills and resources, to establish and maintain supportive relationships and to make positive lifestyle choices.

In addition to focusing on the mental health of individuals, mental health promotion is concerned with community development (O'Brien 2013). Strategies include participation in development of policy, contributing to local and national debates about social issues, and advocating for services and amenities that will enhance mental health. Mental health promotion initiatives involve the health sector, but also extend to other agencies such as education, social services, housing and transport.

Nurses employed in every clinical setting can use principles of mental health promotion to help clients improve their mental health, manage the stresses of their lives and identify support systems that can help promote positive mental health. This can include providing health information and identifying those who might benefit from referral to specialist mental health services.

Professional organisations in mental health nursing

In both Australia and New Zealand, colleges of mental health nursing represent the professional interests of mental health nurses through developing standards of practice, formulating position statements on professional and public issues relevant to mental health and liaising with policy makers and other professional groups. Colleges in both Australia and New Zealand have developed credentialling processes which enable nurses to gain professional recognition for their specialty status. Both colleges hold regular conferences and the Australian college produces a peer-reviewed journal, the *International Journal of Mental Health Nursing*. As with other nursing specialties, having a professional voice is an important aspect of professional practice. A brief summary of the roles of both colleges is provided in Box 40-6.

Summary

In summary, mental health nursing is an area of specialist nursing practice concerned with people with mental distress and illness in a wide range of clinical contexts. Mental health nurses practise in inpatient and community settings, and usually work as members of multidisciplinary mental health teams. Mental health nursing is underpinned by the interpersonal theory first developed by Hildegard Peplau and subsequently by more recent mental health nursing theorists. Interpersonal theory places the relationship between service user and nurse at the centre of mental healthcare, and seeks to utilise that relationship to assist the service user to reach their health goals. The concept of recovery has recently been advocated as a means of focusing mental healthcare

BOX 40-6 Colleges of mental health nursing

Australian College of Mental Health Nurses

The Australian College of Mental Health Nurses Inc (ACMHN) was established in 1974, and is a nursing body representing the professional interests of mental health nurses in Australia. Members of the College work in a variety of settings throughout the public and private healthcare and education sectors. The majority of members work in clinical practice in hospital or community services. The College produces the quarterly *International Journal of Mental Health Nursing*. Website: www.acmhn.org

Te Ao Maramatanga (New Zealand College of Mental Health Nurses)

Te Ao Maramatanga (New Zealand College of Mental Health Nurses, NZCMHN) was established in 1993 as a branch of the Australian college, and as a separate college since 2004. Te Ao Maramatanga is a nursing body representing the professional interests of mental health nurses in New Zealand. Members practise in community and inpatient clinical settings, in education, management and research. The College has a bicultural governance structure reflected in the office of Kaiwhakahaere (chair) and through a caucus of Māori members. Website: www.nzcmhn.org.nz.

Elder R, Evans K, Nizette D 2016 Psychiatric and mental health nursing Elsevier, Sydney.

on the experience of the person receiving services, and of maintaining hope in the face of mental distress and illness. Clinical practice occurs in a range of practice settings and includes care of people with mental illness, **developmental disability** and substance-use problems.

Mental health nursing is based on comprehensive health assessment with a special focus on social and developmental history, and on current mental state. Treatments are both interpersonal and pharmacological, sometimes a combination of both. The emotional demands of mental health nursing make clinical supervision an important part of professional practice in order for nurses to maintain their own mental health, and to manage the emotional needs of service users. In addition to direct clinical care, mental health nurses may be involved in mental health promotion which seeks to promote positive mental health for individuals and communities. Professional colleges provide support to mental health nurses by articulating standards of clinical practice and through a range of professional activities. Current challenges facing mental health nursing are the continued devolvement of mental healthcare into the primary care sector and the need to integrate clinical interventions into a recovery-focused philosophy of care.

Key concepts

- Mental health nursing is a specialist branch of nursing aimed at supporting and assisting people with mental distress or illness.
- Nurses will encounter people with mental illness in every practice setting.
- The therapeutic relationship is a concept introduced into mental health nursing by theorist Hildegard Peplau. Therapeutic relationships are considered fundamental to nursing practice and provide the basis for nursing intervention and psychological therapies.
- Recovery in mental health refers to living well in the presence or absence of illness. It does not refer to cure. Recovery is aimed at assisting people with mental illness to maintain hope and an optimistic sense of their future.
- The terms mental distress and mental illness are often used together because it can be difficult to establish when the distress of life should be regarded as an illness to be treated by a healthcare professional. Mental illnesses are categorised in the American Psychiatric Association's Diagnostic and Statistical Manual (DSM).
- A personality disorder is an enduring pattern of thinking and behaviour that is problematic because it adversely affects interpersonal relationships and social role performance.
- Substance use refers to the problematic use of substances that affect psychological, physical and social functioning. Although numerous substances are used problematically, the most common substance used in Australia and New Zealand is alcohol. Substance-use problems occur across a continuum from intoxication to addiction.
- Mental health assessment refers to the process of taking a mental health history, conducting a mental state assessment and arriving at a statement of problems that can be the focus of nursing intervention.
- A mental state assessment is an assessment of a person's present cognitive, emotional and perceptual functioning.
- A psychiatric diagnosis is a category of mental illness assigned on the basis of a person's history and presenting symptoms.
- Mental health and addiction services are specialist services for people with significant mental health and/or addiction problems. Nurses working in specialist services have usually undertaken postgraduate study in the mental health or addictions specialties.
- Mental health treatment refers to the range of interventions provided by mental healthcare professionals. These include psychological therapy and pharmacological therapy.
- Mental health legislation refers to Acts of Parliament that give mental healthcare professionals, under defined

circumstances, the legal power to detain people who are mentally ill and present a significant risk of harm to themselves or others, and to treat people detained without consent.

- Clinical supervision is the process of engaging in structured discussion about professional practice with the aims of improving practice, supporting the nurse and helping to develop strategies of professional development.

Note

1. The term 'service user' is sometimes used in mental health to refer to people who are receiving mental health services. Other terms used are 'consumer', 'client' and 'patient'.

Caring for the cancer survivor

Patsy Yates

Learning outcomes

Mastery of content will enable you to:

- discuss the concept of cancer survivorship
- describe the influence of cancer survivorship on clients' quality of life
- discuss the effects cancer has on the family
- explain the nursing implications related to cancer survivorship
- discuss the essential components of survivorship care.

KEY TERMS

Biological response modifiers (biotherapy), p. 1493
Cancer-related fatigue (CRF), p. 1493
Cancer survivor, p. 1491
Chemotherapy, p. 1493
Hormone therapy, p. 1491
Neuropathy, p. 1493
Post-traumatic stress disorder (PTSD), p. 1495
Radiation therapy, p. 1491

Introduction

There exists a population of clients that has not been recognised for the extent and nature of health problems that it experiences. At the end of 2009, a total of 370,470 people in Australia had been diagnosed with cancer at some time during the previous 5 years, representing 1.7% of the population. The 28-year prevalence of cancer was 861,057 (AIHWl 2014). Cancer survivors' healthcare problems have largely been ignored or misunderstood because of the belief that for those who receive treatment, survive and are given a 'clean bill of health', their health problems are over. Such is not the case. There are many different trajectories or courses for cancer survival (see Box 41-1). With the advances made in diagnosis and treatment, more clients are becoming long-term survivors of cancer, whereas others with cancers such as lymphoma control their disease with ongoing or periodic treatment. The major forms of cancer therapy – surgery, chemotherapy, **hormone therapy**, biotherapy and **radiation therapy** – often create unwanted, long-term effects on tissues and organ systems that impair a person's health and quality of life in small and large ways (Hewitt et al 2006). Thus, cancer survivorship has enormous implications for the way these individuals monitor and manage their health throughout their lives. As a nurse, you will care for these clients when they seek care for their cancer as well as when they seek care for other medical conditions.

A **cancer survivor** is defined as someone who is living with or beyond their cancer (Department of Health, Macmillan Cancer Support and NHS Improvement 2013). In Australia, the term cancer survivor is generally used to refer to people who have completed initial cancer treatments, who are apparently free from cancer (Jefford 2009). Consider that family members and friends are also survivors, because they experience the effects cancer has on their loved ones. Cancer truly is a life-changing event. Evidence shows that there is a neglected phase of cancer care: the period following first diagnosis and initial treatment and before the development of a recurrence of the initial cancer or death (Hewitt et al 2006, Lofti-Jam et al 2009). In this phase of their disease, survivors do not necessarily have consistent healthcare follow-up. Frequent contact with a cancer care provider often suddenly stops, and survivors' unique psychosocial needs often go unnoticed or untreated. Despite the incredible advances made in cancer care, there are many long-term survivors who suffer unnecessarily and experience increased morbidity or mortality from treatment-related chronic disease. Cancer survivors can also live knowing that their disease could recur.

As nurses, we have the responsibility to better understand the needs of cancer survivors and to provide the most current evidence-based approaches for managing late and long-term effects of cancer and cancer treatment. It is also important to understand disparities in survivorship outcomes. For example, 5-year prevalence rates are significantly lower among Indigenous Australians compared to non-Indigenous Australians (AIHW 2013). There are limited data on the needs of Aboriginal and Torres Strait Islander cancer survivors in Australia, although studies of adult cancer patients indicate that Aboriginal cancer patients have high levels of unmet supportive care needs especially in areas of psychological support and practical assistance (Garvey et al 2012). Studies from the United States similarly suggest that survivors among racial and ethnic minorities and other underserved populations have more post-treatment symptoms and poorer treatment outcomes than Caucasians (Centers for Disease Control and Prevention 2004). These disparities in health among ethnic groups are related to a complex interplay of economic, social and cultural factors, with poverty being a key factor (Hewitt et al 2006). Being able to provide comprehensive care to a cancer survivor begins with recognising the effects of cancer and its treatment and learning about the survivor's own meaning of health.

BOX 41-1 The seasons of cancer survival

Acute survival – starts with the diagnosis of cancer. Diagnostic and therapeutic efforts dominate. Fear and anxiety are constant elements of this phase.

Extended survival – period during which a client goes into remission or has ended the basic, rigorous course of treatment and enters a phase of watchful waiting. Client will undergo periodic examinations and/or intermittent therapy. Psychologically, the fear of recurrence is common. This is usually a period of physical limitations. Diminished strength, fatigue, pain, nausea, reduced tolerance for exercise or hair loss often occur in the acute phase, but clients now have to deal with cancer in the home, community and workplace.

Permanent survival – this phase is roughly equated with 'cure', but the experience permanently affects the survivor. Problems with employment and insurance are common. The long-term secondary effects of cancer treatment on health represent an area in which permanent survivors are at risk.

Adapted from Hewitt M, Greenfield S, Stoval E (eds) 2006 From cancer client to cancer survivor: lost in transition. Institute of Medicine and National Research Council. National Academies Press, Washington DC; Mullan F 1985 Seasons of survival: reflections of a physician with cancer. New Engl J Med 313(4):270–3.

The effects of cancer on quality of life

As people live longer after diagnosis and treatment for cancer, it becomes important to understand the types of distress many survivors experience and how it affects their quality of life (see Figure 41-1). Evidence shows that cancer survivors have a range of unmet health needs (see *Research highlight*). Cancer survivors often report a heightened sense of vulnerability, loneliness, worries about their health, concerns about burdening their loved ones and anxiety about the possibility of cancer recurrence (Boyes et al 2012). Quality of life in cancer survivorship means having a balance between the experience of increased dependence while seeking both independence and interdependence. Of course, there are always exceptions with regard to the level of distress survivors face. For some, cancer becomes an experience

RESEARCH HIGHLIGHT

Research focus

A group of researchers wanted to learn about the supportive care needs of cancer survivors. They studied more than 1323 cancer survivors from the New South Wales cancer registry. The study assessed unmet needs using a 34-item supportive care needs survey. The results of the study showed that 37% of cancer survivors had at least one 'moderate to high' level unmet need. The most commonly reported unmet needs were in psychological (25%) and physical aspects of daily living domains (20%). The most frequently reported unmet needs included worries of those close to them, fears about the cancer spreading, not being able to do the things they used to do, uncertainty about the future and lack of energy/tiredness.

Evidence-based practice

- As a nurse, learn to assess the many ways in which cancer affects the lives of clients who are survivors.
- Interventions which focus on reducing fears of recurrence and uncertainty are critical. These interventions need to consider the needs of family members.
- Support to address impacts on daily living and assist people to return to optimal functioning is needed.

Reference

that provides self-reflection and an enhanced sense of what life is about. Regardless of each survivor's journey with cancer, having cancer affects each person's physical, social, psychological and spiritual wellbeing.

Physical wellbeing and symptoms

Cancer survivors are at increased risk for cancer (either a recurrence of the cancer for which they were treated, or a second cancer) and for a wide range of treatment-related problems (Jefford 2009). The increased risk for developing a second cancer is due to cancer treatment, genetic or other susceptibility or an interaction between treatment and susceptibility. The risk for treatment-related problems is associated with the complexity of the cancer itself (e.g. type of tumour and stage of disease); the type, variety and intensity of treatments used; and the age and underlying health status of the client.

To respond effectively to cancer survivors' needs, it is important to appreciate the varying experiences and impacts on a person's health. The Australian Cancer Survivorship Centre website presents a number of stories from cancer survivors who come from a range of social and demographic backgrounds (see *Online resources*). An example of one survivor's story is provided below to illustrate how a cancer survivor's physical health problems can be complex and burdensome.

CLINICAL EXAMPLE

Susan was an army nurse, who learned 7 months after discharge from the army that she had Hodgkin's disease, a malignancy of lymphoid tissue. Susan received an aggressive course of treatment, including surgery, 6 months of chemotherapy and 3 months of total lymph-node irradiation. It took many months for her bone marrow to heal and blood values to return to normal. After a few years she had bilateral mastectomies for treatment-related breast cancer. She also received 3 years of immunotherapy for cancer in situ (tumour not metastasised) of the bladder. She continues to experience many non-cancer conditions: premature menopause, early osteoporosis, hypothyroidism, lung fibrosis and atrophy of neck and upper chest muscles.

Leigh S 2006 Cancer survivorship: a first-person perspective. Am J Nurs 106(3 suppl):12.

Stories like these highlight the long disease course some cancer survivors face. There are a number of tissues and body systems that are impaired as a result of cancer and its treatment (see Table 41-1). Late effects of **chemotherapy** include osteoporosis, congestive heart failure, diabetes, amenorrhea in women, sterility in men and women, gastrointestinal motility problems, abnormal liver function, impaired immune function, paraesthesias, hearing loss and problems with thinking and memory (Hewitt et al 2006). Treatment for cancer or the cancer itself often induces pain and **neuropathy** (Boyes, Hodkinson, Alderidge 2009). **Cancer-related fatigue (CRF)** and associated sleep disturbances are also frequent and disturbing complaints of people with cancer (Boyes, Hodkinson, Alderidge 2009). Certain conditions resolve over time, but irreversible tissue damage causes some conditions to progress and persist indefinitely. Healthcare professionals do not always recognise these conditions as delayed problems. Often conditions such as osteoporosis, hearing loss or change in memory are instead considered to be age-related. The problem is that, for many survivors, these conditions go undiagnosed and are never treated.

TABLE 41-1 Examples of late effects of surgery among adult cancer survivors

Procedure	Late effect
Any procedure	Pain, psychosocial distress, impaired wound healing
Surgery involving brain or spinal cord	Impaired cognitive function, motor sensory alterations, altered vision, swallowing, language, bowel and bladder control
Head and neck surgery	Difficulties with communication, swallowing and breathing
Abdominal surgery	Risk of intestinal obstruction, hernia, altered bowel function
Lung resection	Difficulty breathing, fatigue, generalised weakness
Prostatectomy	Urinary incontinence, sexual dysfunction, poor body image

Adapted from Hewitt M, Greenfield S, Stovall E (eds) 2006 From cancer client to cancer survivor: lost in transition. Committee on Cancer Survivorship: improving care and quality of life. Institute of Medicine and National Research Council. National Academies Press, Washington DC.

Cognitive changes are a set of physical symptoms that occur in some survivors as a result of their disease, treatment, the complications of treatment, underlying medical conditions and psychological responses to the diagnosis of cancer (Ahles et al 2012). Cognitive changes can occur during all phases of the cancer experience, from small deficits in information processing to acute delirium. Some survivors report attention problems, loss of memory and difficulty in recognising and solving problems. Studies show that when clients receive systemic cancer treatment, including chemotherapy or **biological response modifiers (biotherapy)**, there is a generalised, subtle effect on cognitive function. In addition, systemic treatment causes both short-term and persistent cognitive impairment in

a variety of cognitive domains. Researchers do not yet understand the effects of specific cognitive changes on survivors' daily lives (Correa & Ahles 2008), although impairments in memory, attention and concentration, speed of processing, and executive functioning are most common (Von Ah 2015).

Data from the Australian Institute of Health and Welfare (AIHW) indicate that most cancer survivors (54%) are over the age of 65 years (AIHW 2014). The most common cancers for this age group include cancer of the colon, breast, pancreas, prostate and lung. Often, healthcare providers wrongly attribute the symptoms of cancer or the symptoms from the side effects of treatment to ageing. This often leads to late diagnosis or a failure to provide aggressive and effective treatment of symptoms.

Cancer is a chronic disease because of the serious consequences and the persistent nature of some of cancer's late effects (Phillips & Currow 2010). Cancer survivors therefore also face many of the same health issues experienced by individuals with other chronic conditions. There is great diversity in the range of effects clients suffer. For example, a 41-year-old woman with early-stage melanoma on the right arm undergoes successful surgery and only has the effect of an inconspicuous scar. In contrast, Susan, the army nurse diagnosed with Hodgkin's disease, underwent intensive chemotherapy followed by an extended course of radiation. She faced serious and substantial long-term health problems from her treatment. Cancer clients present significant variations in the type of conditions they develop and the length of time the conditions persist.

There are numerous factors that contribute to survivors not receiving timely and appropriate treatment for the effects of their disease or treatment. Survivors can be reluctant to report symptoms because of a fear of cancer recurrence (Boyes, Hodkinson, Alderidge 2009). Survivors are not always aware that painful conditions or syndromes are common and believe that pain relief is not possible (see Box 41-2). Healthcare providers can have limited awareness of the prevalence and incidence of pain and other symptoms among survivors, and many have limited education in symptom management. Guidelines for managing pain during survivorship released by the National Comprehensive Cancer Network also highlight that there are a limited number of clinical trials for pain management in this population other than for neuropathy and phantom limb pain (Glare et al 2014). There are few healthcare settings that track the health-related quality of life and symptomatology of clients over time. Work to improve survivorship care in Australia is gaining momentum; however, efforts remain patchy (Jefford et al 2013). Thus there is limited evidence about the long-term patterns of symptoms most commonly associated with certain forms of cancer and its treatment.

BOX 41-2 Examples of chronic pain syndromes associated with cancer treatments

Postoperative pain syndromes
- Post-mastectomy syndrome
- Post-radical neck dissection pain
- Post-amputation pain

Post-radiation pain syndromes
- Myelopathy
- Enteritis or proctitis
- Lymphoedema
- Brachial or lumbosacral plexopathy

Post-chemotherapy pain syndromes
- Peripheral neuropathy
- Osteonecrosis
- Arthralgia

Hormonal therapy
- Arthralgia
- Muscle cramps/spasms
- Carpal tunnel syndrome

Adapted from Glare P et al 2014 Pain in cancer survivors. J Clin Oncol Jun 1,1739–47.

Many of the issues experienced by cancer survivors, such as fatigue and fear of recurrence, are common to all cancers; other concerns are tumour-specific. Research involving breast cancer survivors is extensive. Women with a history of breast cancer are the largest group of cancer survivors (Hewitt et al 2006). After their primary treatment for breast cancer, women can experience significant physical impairments, such as fatigue, pain, postsurgical and persistent upper-quadrant issues, chemotherapy-induced peripheral neuropathy, lymphedema, cardiotoxic effects of chemotherapy and radiotherapy, weight gain, bone health challenges, and arthralgias (Schmitz et al 2012). An Australian study of 5332 colorectal cancer patients with an ostomy identified that painful or irritated peristomal skin and odour and noise from the appliance were the most commonly reported stoma-related difficulties for this group of survivors (Lynch et al 2008).

Psychological wellbeing

The physical effects of cancer and its treatment sometimes extend to cause serious psychological distress (see Chapter 37). In the context of cancer, *distress* is defined

as a multifactorial unpleasant emotional experience of a psychological, social and/or spiritual nature (see Chapter 25) that interferes with the ability to cope effectively with cancer, its symptoms and its treatment (National Comprehensive Cancer Network 2013). Survivors' feelings of distress range along a continuum from sadness to disabling depression (Vachon 2006). Estimates of the prevalence of psychological morbidity experienced by cancer survivors vary; however, distress is most common in the acute survival phase and declines over time from diagnosis (Boyes, Hodkinson, Alderidge 2009). One Australian study indicated that long-term survivors of cancer have levels of psychological wellbeing that match or exceed population levels (Boyes, Girgis, Zucca 2009).

Another psychological problem for some survivors is **post-traumatic stress disorder (PTSD)**. PTSD is a psychiatric disorder characterised by an acute emotional response to a traumatic event or situation. Cancer survivors experience symptoms of PTSD (e.g. grief, nightmares, panic attacks or fear). One recent study of non-Hodgkin's lymphoma survivors who were a median of 12.9 years following treatment identified that more than one-third (37%) reported persistent or worsening of PTSD symptoms over 5 years (Smith et al 2011). Being female, younger, less educated and having a lower income and less social and emotional support increases the risk for PTSD. Studies of clients with PTSD suggest that the stress response of the hypothalamus–pituitary–adrenal system is abnormal (see Chapter 42). This same negative feedback inhibition of cortisol resulting in cortisol alterations also occurs in cancer (Yehuda 2003).

The disabling effects of chronic cancer symptoms disrupt family and personal relationships, impair individuals' work performance and often isolate survivors from normal social activities. Such changes in lifestyle create serious implications for a survivor's psychological wellbeing. When cancer changes a client's body image or alters sexual function, the survivor frequently experiences significant anxiety and depression in interpersonal relationships. In the case of breast cancer survivors, studies show that poorer self-ratings of quality of life are associated with poor body image, coping strategies and a lack of social support (Hewitt et al 2006).

The risk for a cancer survivor having psychological problems is high because of a complex set of factors. Anderson et al (1993) developed a model for predicting the psychological wellbeing in women with gynaecological cancer (see Figure 41-2). The model has applications for

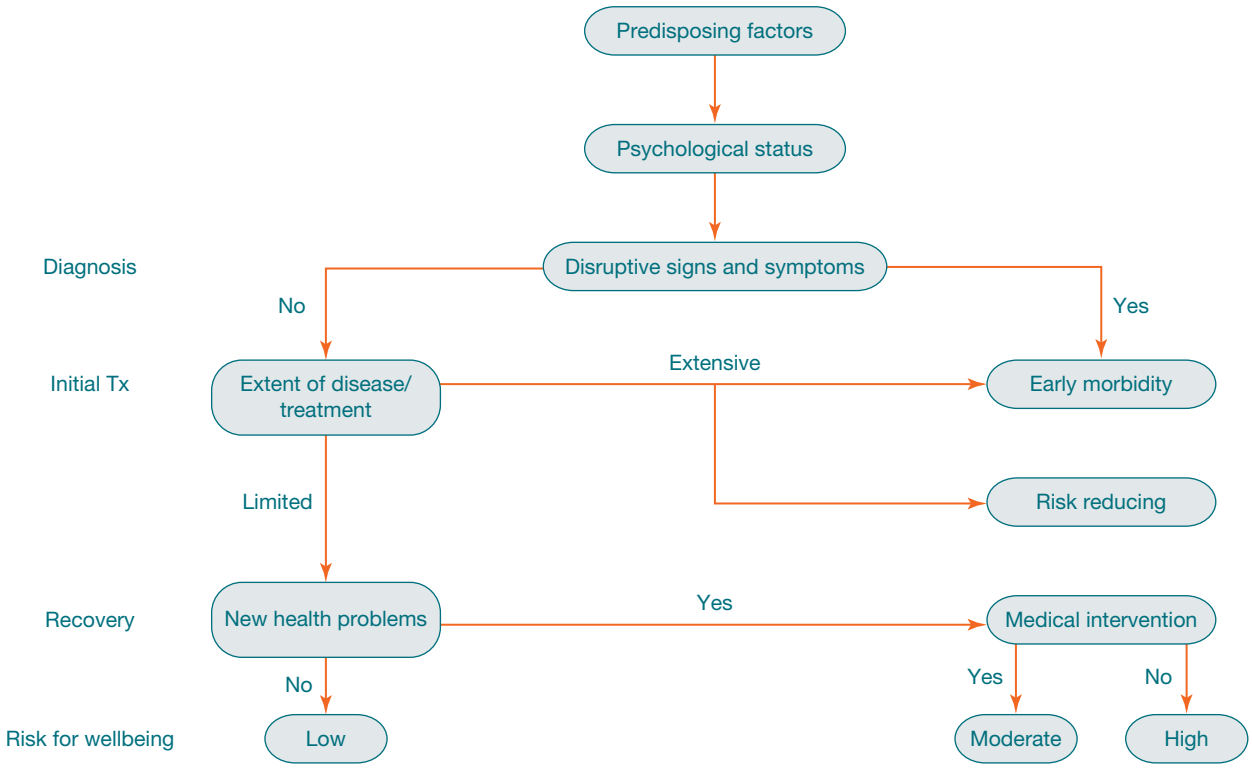

Figure 41-2 Predicting psychological wellbeing.

Modified from Andersen BL 1993 Predicting sexual and psychologic morbidity and improving the quality of life for women with gynaecologic cancer. Cancer 71(4 suppl):1678. © 1996 American Cancer Society. This material is reproduced with permission of Wiley Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

other client groups as well. How well a survivor adapts to the cancer experience depends upon predisposing factors (e.g. age, gender, race, income, prior psychiatric disorder, marital status, coping style and social support), their current psychological status and the presence of disruptive signs and symptoms. When a client has few disruptive signs and symptoms and the cancer is less extensive, the risk of poor psychological wellbeing is low. In contrast, the risk of psychological distress is high in a client who has numerous disruptive signs and symptoms, an advanced stage of cancer, and other health problems.

There are factors that help ease the psychological stress associated with having cancer. A survivor's appraisal of the cancer experience makes a difference. A survivor who sees cancer as a challenging experience and a controllable threat will have less stress (Jacobsen 2006). Clients who use problem-oriented, active and emotionally expressive coping processes also manage stress well (see Chapter 37). Survivors who have social and emotional support systems and maintain open communication with their treatment providers are also likely to have less psychological distress (Jacobsen 2006).

Social wellbeing

Cancer affects any age group (see Figure 41-3). The developmental effects of cancer are perhaps best seen in the social impact that occurs across the life span. For adolescents and young adults, cancer seriously alters a young person's social skills, sexual development, body image and the ability to think about and plan for the future. Cancer interrupts their lives, causing young survivors to either feel out of touch with the interests of their peers or to perceive interests as superficial (Blum 2006). In addition, because cancer makes them feel different, young survivors, out of fear of rejection, have problems developing new relationships. Often the course of cancer or its treatment causes young adults to delay leaving their parents. The natural separation that occurs when young adults finish school and look to start their careers is postponed or stopped. Often a young adult then feels ill-equipped to take on the real world. As a result of these impacts on social wellbeing, adolescent and young adult cancer survivors are more likely to have worse or impaired quality of life compared with the general population, regardless of other demographic factors (Quinn et al 2015).

Adults (ages 30–59 years) who have cancer also experience significant changes in their families. Once a member of the family is diagnosed with cancer, every family member's role, plans and abilities change (Blum 2006). The healthy spouse often takes on added job responsibilities to provide additional income for the family. A spouse, sibling, grandparent or child often has to assume caregiving responsibilities for the cancer client. Clients who experience changes in sexuality, intimacy and fertility will see their marriages affected, too often resulting in divorce.

Studies in the United States and Australia suggest that a history of cancer significantly affects employment opportunities and the ability of a survivor to obtain and retain health and life insurance (Hewitt et al 2006, Knott et al 2014). Often a survivor experiences health-related work limitations (see Table 41-2) that require a reduced work schedule or a complete change in employment. However, most cancer survivors who worked before their diagnosis return to work following their treatment. The problem is that employers and supervisors often assume that people with cancer are not able to perform job

Figure 41-3 A family representing young and old.

responsibilities as well as they did before their diagnosis or co-workers may not know how to provide support. Cancer survivors report problems in the workplace, including dismissal, failure to hire, demotion and denial of promotion. The Cancer Council Australia has developed a resource *Working with cancer* in association with employers and with people diagnosed with cancer to provide guidance for employers and co-workers of people who have been treated for cancer (Cancer Council Australia 2015).

The economic burden of cancer is enormous. If a survivor's illness affects their ability to work, less income goes to the individual and family. Also, there is likely to be an increase in out-of-pocket expenses for prescription drugs and medical devices and supplies. Older adults face numerous social concerns as a result of cancer. The disease can cause a survivor to retire prematurely. Older adults also face a high level of disability as a result of cancer and cancer treatment. Older adults with cancer report a higher incidence of limitations in activities of daily living (ADLs) than older adults without cancer (Hewitt et al 2006). As a result, many older cancer survivors require ongoing caregiving support from either family members or professional caregivers.

Spiritual wellbeing

The experience of cancer challenges a person's spiritual wellbeing (see Chapter 14). Key features of spiritual wellbeing include a harmonious interconnectedness, creative energy and a faith in a higher power or life force (Brown-Saltzman 2006). Cancer and its treatment create physical and psychological changes that cause survivors to question 'Why me?' and to wonder if perhaps their disease is some form of punishment. Survivors often experience a level of spiritual distress, a disruption in a person's spirit or life principle. Survivors most at risk for spiritual distress are those with energy-consuming anxiety, an inability to forgive, low self-esteem, maturational losses and mental illness (Brown-Saltzman 2006). Additional risk factors include poor relationships and situational losses (see Chapter 14).

Relationships are critical for cancer survivors: relationships with a god, a higher power, nature, family or community. Cancer can threaten relationships because it makes it difficult for survivors to maintain a connection and a sense of belonging with what is important to them. Cancer can isolate survivors from meaningful interaction and support, which then threatens their ability to maintain hope. The long courses of treatment, the recurrence of cancer and the lingering side effects of treatment all create a level of uncertainty for survivors.

Cancer and families

A survivor's family takes different forms: the traditional nuclear family, extended family, single-parent family, close friends and blended families (see Chapter 18). Once cancer affects a member of the family, it affects all other members as well. It is usually a member of the family who becomes the client's caregiver. Family caregiving is a stressful experience, depending on the relationship between client and caregiver and the nature and extent of the client's disease. For members of the 'sandwich generation', caregivers who are 30–50 years old are often caught in the middle of caring for their own immediate family as well as a parent with cancer. The demands are many, from providing ongoing encouragement and support and assisting with household chores to providing hands-on physical care (e.g. bathing, assisting with toileting or changing a dressing) when cancer is advanced. Caregiving also involves the psychological demands of communicating, problem-solving and decision-making; social demands of remaining active in the community and work; and economic demands of meeting financial obligations.

Family distress

Relationships between cancer survivors and family members can become difficult to maintain because family members often do not know, do not understand or report not having the skills or confidence to support the survivor's reactions to cancer. Differing priorities can result in tensions in relationships, with the cancer survivor being expected to 'move forward' and to 'get back to normal' (Boyes, Hodkinson, Alderidge 2009). These responses can also reflect the family member's desire to avoid contemplating an uncertain future (Boyes, Hodkinson, Alderidge 2009).

Mellon et al (2006) interviewed cancer survivors and their family caregivers, finding that among the strongest predictors for cancer survivors' quality of life were family stressors and social support. In their study, family caregivers reported a lower quality of life than that of their family members. The researchers also noted that ongoing concerns and problems facing survivors and their family are important determinants of adjustment and quality of life. Families generally find themselves ill-prepared to deal with cancer. Cancer survivorship has not yet become a distinct phase of cancer care; thus professional caregivers often fail to inform and educate clients and their families about what to expect during the cancer experience.

Couples who experience the acute phase of breast cancer treatment often function in a survival mode, during

which time-competing demands from jobs or other family members distract them from attending to each other's needs, thoughts and feelings (Lewis 2006). Often couples struggle with interpersonal problem-solving because they do not have the communication or problem-solving skills to understand one another's views, concerns or fears. We know less about what happens to family relationships in long-term survivorship. Lewis (2006) suggests two possible outcomes: benefit-finding behaviour (identifying positive aspects in the cancer experience) or heightened interpersonal tension.

Families struggle to maintain core functions when one of their members is a cancer survivor. Core family functions include maintaining an emotionally and physically safe environment, interpreting and reducing the threat of stressful events (including the cancer) for family members and nurturing and supporting the development of individual family members (Lewis 2006). In childrearing families, this means providing an attentive parenting environment for children and providing information and support to children when their sense of wellbeing becomes threatened. When a member of the family has cancer, these core functions become threatened. Spouses often do not know what to do to support the survivor, and they struggle with how to help. In the end, family functions become fragmented and family members develop an uncertainty about their roles.

Implications for nursing

The National Cancer Survivorship Initiative in the UK sets out a framework for responding to the unique needs of cancer survivors. The framework sets out the following key strategies:

- Providing information and support from the point of diagnosis, including the importance of specialist nurses in this area.
- Promoting recovery, including providing support relevant to the individual's particular needs, and which promotes healthy lifestyles and independence.
- Sustaining recovery, including offering tailored follow-up and stratifying for follow-up according to the individual's risk.
- Managing consequences of treatment, including assessment and monitoring for consequences of treatment during the active treatment phase, and for as long as necessary.
- Supporting people with active and advanced disease, acknowledging that the key principles of survivorship are equally important to individuals with advanced disease.

Four key areas of focus are proposed to improve outcomes for cancer survivors, including:

- ensuring all cancer patients have access to holistic needs assessment, treatment summary, cancer care review and a patient education and support event – the 'Recovery Package'
- developing and commissioning risk stratified pathways of post-treatment management
- promoting health and wellbeing, including physical activity
- understanding and commissioning for improved management of the consequences of treatment.

These focus areas have important implications for nursing. As a profession, nursing has to take a lead in helping survivors plan for optimal lifelong health. Much needs to be done in conducting nursing research to find appropriate interventions for the effects of cancer and its treatment. Nurses are in a strong position to take the lead in improving public health efforts to manage the long-term consequences of cancer. Improvement is also necessary in the education of nurses and survivors about the phenomenon of survivorship. As a nursing student, you too can make a difference. This section will address approaches to incorporate cancer survivorship into your nursing practice.

Survivor assessment

Knowing that there are many cancer survivors in the healthcare system, consider how to assess those clients who report a history of cancer. It is important to make assessment of cancer survivors' needs a standard part of your practice. The UK National Cancer Survivorship Initiative recommends assessment tools to ensure that care plans are based on a holistic assessment of a patient's needs (National Cancer Survival Initiative 2013). When you are collecting a nursing history (see Chapter 23), explore with your clients their history of cancer, including the diagnosis and type of treatment they are either undergoing or have received in the past. Be aware that some clients do not always report that they have had cancer. So, when a client tells you they have had surgery, ask if it was cancer-related. When a client reveals a history of chemotherapy, radiation, biotherapy or hormone therapy, you need to refer to resources to help you understand how those therapies typically affect clients in both the short term and the long term. Once you do so, extend your assessment to determine if these treatment effects exist for your client. Remember that you need to consider not only the effects of the cancer and its treatment, but also how it will affect any other medical condition. For example, if a client also

has heart disease, how will fatigue related to chemotherapy affect this individual?

Understanding the cancer experience comes from a client's own story. Asking a general question about the client being a cancer survivor will coach the client into revealing their story. For example, you might ask, 'Having cancer is a journey for many. How does the disease most affect you right now?' or 'What is the biggest problem that you are experiencing from cancer?' This type of question will help you focus on the area that is most important to the client. Communicate to clients your interest in their situation. Show a caring approach so that clients know their story will be accepted. You might further ask, 'What can I do to help you at this point?'

Symptom management is an ongoing problem for many cancer survivors. If cancer is their primary diagnosis, it will be natural for you to explore any presenting symptoms. Be sure to learn specifically how any symptoms are affecting the client. For example, is pain also causing fatigue, or is a neuropathy causing the client to walk with an abnormal gait? If cancer is secondary, you do not want important symptoms to go unrecognised. Ask the client, 'Since your diagnosis and treatment of cancer, what physical changes or symptoms have you had?' and 'Tell me how these changes affect you now'. Depending on the symptoms a client identifies, you will explore each one in order to gain a complete picture of the client's health status (Table 41-3). Remember that some clients are reluctant to report or discuss their symptoms. Be patient, and once you identify a symptom, explore the extent to which the symptom is currently affecting the client.

Because you know that cancer affects a client's quality of life in many ways, be sure to explore the client's psychological, social and spiritual needs and resources. Sometimes you will not be able to conduct a thorough assessment when you perform an initial nursing history. If this is the case, incorporate your assessment into your ongoing client care. Observe your client's interactions with family members and friends. When you are administering care to clients, talk about their daily lives and determine the extent to which cancer has changed their lifestyle.

One area that is often difficult for nurses to assess well is a client's sexuality. Sexuality is more than simply the physical ability to perform a sex act or conceive a child. It also includes a person's body image, sexual response (e.g. interest and satisfaction), and sexual roles and relationships (see Chapter 24). Surgery for many cancers is disfiguring, and chemotherapy and radiation often alter a client's sexual response. Cancer therapies have the potential to cause fatigue, apathy, nausea, vomiting, malaise and sleep disturbances, all of which may interfere with a client's libido. It is important to realise that cancer often does influence the client's sexuality. It helps to develop a comfort level in acknowledging with clients that sexual changes are common at any age level. Ask a client, 'Since your diagnosis and treatment of cancer, has your ability or interest in sexual activity changed? If so, how?' Clients will appreciate your sensitivity and interest in their wellbeing. When clients begin to discuss their sexual problems, know the expert resources in your institution (e.g. psychologist or social worker) available for client referral.

TABLE 41-3 Assessment questions for cancer survivors

Category	Examples of questions
Symptoms	Have you had any pain or discomfort in the area where you had surgery or radiation? discomfort, pain or unusual sensations in your hands or feet? weakness in your legs or arms? or problems moving around?
	Are you experiencing fatigue, sleeplessness, shortness of breath? If so, please describe.
	Sometimes people feel as if they are starting to have problems after chemotherapy such as paying attention, remembering things, finding words. Have you noticed any changes like these?
Psychosocial problems	How distressed are you feeling at this point on a scale of 0 to 10 with 10 being the worst distress that you could imagine?
	How do you think your family is coping with your cancer?
	What do you see in your family members' responses to your cancer that is a concern for you?
Sexuality problems	If you have had changes relating to sex, what strategies have you tried to make things better? Have these strategies worked?
	Would you be open to a healthcare provider who knows how to help you?
	Since your cancer, do you see yourself differently as a person?

• CRITICAL REFLECTION POINT

Do you have a friend or family member who has cancer and is willing to talk about it? If so, ask the individual to tell you what the experience has been like and what they would recommend to help you provide better care for survivors.

Client education

It is nursing's responsibility to educate survivors and their families about the consequences of cancer and cancer treatment. This means that when you care for

a cancer survivor you need to understand the nature of the client's particular disease and know the effects of each therapy a client receives and the short- and long-term consequences. You will play a key role in preparing a cancer survivor with the knowledge and resources needed for ongoing self-management. In the context of cancer, self-management programs have been defined as 'awareness and active participation by the person in their recovery, recuperation, and rehabilitation to minimise the consequences of treatment, promote survival, health and wellbeing' (National Cancer Survivorship Initiative 2015). In designing education that promotes self-management in caregiving, plan activities on the basis of the caregiver's and cancer survivor's perceived disease-related problems, and assist them with problem-solving and gaining the self-efficacy or confidence to deal with these problems. Client education will help survivors assume healthier lifestyle behaviours that will then give them control of some aspects of their health and improve outcomes from cancer and chronic illness. The concept of self-management programs is increasingly being incorporated into programs in Australia to optimise health and wellbeing for cancer survivors (Turner 2015).

When caring for clients with an initial diagnosis of cancer, reinforce their healthcare provider's explanations of the risks related to their cancer and treatment, what they need to self-monitor (e.g. appetite and weight, and effects of fatigue and sleeplessness) and what to discuss with healthcare providers in the future. If you teach clients about the potential for treatment effects such as pain, neuropathy or cognitive change, they are more likely to report their symptoms. Survivors need to learn how to manage problems related to persistent symptoms. For example, survivors with neuropathy need to learn how to protect the hands and feet, prevent falls and avoid accidental burns.

Because survivors have an increased risk for developing a second cancer and/or chronic illness, it is important to educate them about lifestyle behaviours that will improve the quality of their lives. Health promotion education is timely after an initial cancer diagnosis, when many survivors become motivated to change their behaviour. A recent Australian study identified that a range of factors needs to be considered when planning health promotion activities for cancer survivors, including pre-cancer diagnosis health behaviours, the disabilities resulting from cancer treatments, perceptions of risk, and the nature of participants' social support (McCarthy et al 2013). Many survivors become interested in learning more about dietary supplements and nutritional complementary therapies to manage disease symptoms (Hewitt et al 2006). Scientific evidence shows that there are several health promotion areas of interest to cancer survivors: smoking cessation, physical activity, diet and nutrition. You will teach clients useful strategies to promote their health. More than 70 intervention trials of physical activity for cancer survivors have been published, mostly focusing on breast cancer and colorectal cancer survivors. Overall, these studies suggest that physical activity interventions implemented during or following treatment may improve cardiorespiratory fitness; body composition (i.e. muscle mass and bone health); immune function; strength and flexibility; body image; self-esteem and mood; chemotherapy completion rates; and may allow for better adjustment to illness (Pollard et al 2009).

• CRITICAL REFLECTION POINT

Ms Ritter is a 32-year-old woman who has been receiving chemotherapy to treat breast cancer. She tells her nurse, 'This chemotherapy has made me feel so tired, and there are many nights I cannot sleep very well. I am looking forward to this going away.' What is an appropriate response the nurse might give Ms Ritter?

Providing resources

Numerous organisations and agencies provide resources to cancer survivors. The problem is that many survivors do not receive timely and appropriate referral to these resources. As a nurse, you will find that many people (e.g. friends, neighbours and family members) come to you for advice about health care before they actually become a client. It is important to know that cancer-related hospital and ambulatory care is not standardised. For example, when a client with cancer is hospitalised, the availability of ancillary services for long-term care will vary by care setting. Your role is to tell clients about the different resources available so that clients are able to make informed choices. There is a wealth of cancer-related community support services available to survivors through voluntary organisations (see Table 41-4). Most offer their services at no cost. Many supportive services offer call centres and web-based information and discussion boards in addition to direct service delivery. Healthcare professionals are not consistent in referring clients to these valuable services. In addition, although community-based services help most survivors, there are gaps in service provision for assistance with transportation, home care, childcare and financial assistance. Become knowledgeable about the services within your community. The Cancer Council in each state and territory of Australia and the Cancer Society in New Zealand provide comprehensive information and support services for people at all stages of their cancer journey, including cancer survivorship.

Components of survivorship care

Once a cancer client's primary treatment ends, healthcare professionals need to develop an organised plan for survivorship care. This does not always occur because of inadequacies in the healthcare system, including a lack of any one healthcare provider assuming responsibility for coordinating care, fragmentation of care between specialists and general practitioners, and a lack of guidance on how survivors can improve their health outcomes (Hewitt et al 2006). Cancer clients may neglect non-cancer care (e.g. care for diabetes or heart conditions) when their cancer diagnosis shifts attention away from care that is routine but necessary. There is also poor follow-up of cancer care even though recommended guidelines exist. For example, some women with a history of breast cancer do not get regular mammograms, and some clients with colorectal cancer do not have regular colorectal exams. The Institute of Medicine (Hewitt et al 2006) has made recommendations for four essential components of survivorship care:

1. Prevention and detection of new cancers and recurrent cancer.
2. Surveillance for cancer spread, recurrence or second cancers.
3. Intervention for consequences of cancer and its treatment (e.g. medical problems, symptoms and psychological distress).
4. Coordination between specialists and primary care providers.

BOX 41-3 Victorian cancer survivorship program

The Victorian Cancer Survivorship Plan (VCSP) aims to develop sustainable models of post-treatment survivorship care. The VCSP objectives are to:

- trial cancer survivorship post-treatment shared models of care across the acute and primary care sectors accessing existing services and funding streams (e.g. Medicare Benefits Scheme Chronic Disease Management items)
- evaluate cancer survivorship models and interventions in terms of their effectiveness, sustainability and transferability across settings
- develop resources (for both patients and service providers) and recommendations for future improvements in follow-up care
- improve understanding of the specific survivorship care needs of different groupings
- facilitate cancer survivor involvement and self-management.

Resources and tools developed by these projects are available via the Cancer Survivorship Collaborative Workspace at www.petermac.org/education/survivorship-education/implementing-survivorship-care

In Australia, many state cancer plans include consideration of improved post-treatment care (Jefford et al 2013). The Victorian Government implemented a Cancer Survivorship program in 2011 supporting a range of survivorship interventions (Box 41-3). In addition, the clinical practice guidelines for management of various cancer types, developed by groups such as the Cancer Council Australia and the National Health and Medical Research Council, provide specific evidence-based recommendations for surveillance and follow-up following completion of treatment for different cancers (see *Online resources*).

Survivorship care plan

If healthcare professionals succeed in improving cancer survivorship care, a strategy is needed for survivors' ongoing clinical care. The IOM (2006) in the United States made several recommendations for improving survivorship care. One recommendation was the pro-

vision of a 'survivorship care plan' written by the principal provider that coordinated the client's oncology treatment. Ideally, you would review a survivorship care plan with a client at the time they are formally discharged from a treatment program. The plan would become a guide for any future cancer or cancer-related care. Healthcare providers would use the plan as a guide for client education. Survivors would use the plan to raise questions with doctors to prompt appropriate care during follow-up visits. Box 41-4 highlights the components of a survivorship care plan.

• CRITICAL REFLECTION POINT

Ms Ritter visits the medical outpatient clinic for her final course of chemotherapy to treat the breast cancer. She is married and has one child, a daughter, who is 6 years old. She and her husband had hoped to have another child in the near future, but now wonder if that will be possible. Ms Ritter has shared with the nursing staff her concerns about the future and how cancer will affect her and her family. Her cancer nurse coordinator talks with her about a survivorship care plan before discharge from the clinic.

Identify two follow-up care plan components that would be important when considering Ms Ritter's role as a wife and a parent.

There are currently no clear guidelines in Australia or New Zealand regarding who should be responsible for providing survivorship care or what service model is the best to support it. Thus nurses and other healthcare providers need to become more vigilant in recognising cancer survivors and attempting to link them with the support and resources they require. Nurses can make a difference in considering the long-term issues cancer survivors face after their time of diagnosis and in contributing to solutions to manage or relieve cancer-associated health problems. A strong multidisciplinary approach is necessary, including nurses, oncology specialists, dietitians, social workers, pastoral care and rehabilitation professionals. Together, an interdisciplinary team will provide a plan of care that addresses treatment-related problems and future health risks and offers a wellness focus to give clients a sense of hope as they enter their survivor experience.

BOX 41-4 A survivorship care plan

Upon discharge from cancer treatment, every client and their primary healthcare provider should receive a record of all care received and a follow-up plan incorporating available evidence-based standards of care.

Care summary

- Diagnostic tests performed and results
- Tumour characteristics (e.g. site, stage, grade)
- Dates when treatment started and stopped
- Surgery, chemotherapy, radiotherapy, transplant, hormonal therapy or gene therapy provided, including the specific agents used
- Psychosocial, nutritional and other supportive services provided
- Full contact information for treating organisations and key providers
- Identification of a key point of contact and coordinator of care

Follow-up plan

- Likely course of recovery
- Description of recommended cancer screening and other periodic testing/examinations
- Information on possible late and long-term effects of treatment and symptoms of such effects
- Information on possible signs of recurrence and second tumours
- Information on the possible effects of cancer on marital/partner relationships, sexual functioning, work and parenting
- Information on the potential insurance, employment and financial consequences of cancer and, as necessary, referral to counselling, legal aid and financial assistance
- Specific recommendations for healthy behaviours
- Information on genetic counselling and testing as appropriate
- Information on known effective chemoprevention strategies for secondary prevention
- Referrals to specific follow-up care providers
- A listing of cancer-related resources and information

Modified from the President's Cancer Panel 2004 and Hewitt M, Greenfield S, Stovall E (eds) 2006 From cancer client to cancer survivor: lost in transition. Committee on Cancer Survivorship: improving care and quality of life. Institute of Medicine and National Research Council. National Academies Press, Washington DC.

Implications for people with active and advanced disease

This chapter began with an overview of the promising statistics about survival from cancer today. For some individuals, however, the cancer will recur and some may develop a second primary cancer. These individuals are considered to have secondary or advanced cancer, although many will continue to consider themselves to be cancer survivors. Individuals living with secondary or advanced cancer will continue to have many of the same health and support needs described earlier in this

chapter, although the person's experience will differ in some important ways. These differences reflect the fact that the progression of the disease can alter the symptom experience as the tumour spreads and affects a range of body systems. Additionally, the recurrence of cancer typically reflects a change in treatment goals from cure to control or palliation of disease. Nurses need to understand changing goals of care, and respond with appropriate information and support as recurrence of a cancer is often associated with significant uncertainty and distress. For some, referral to palliative care may also be considered where the individual's physical, psychological, social or spiritual needs require specialised intervention.

Summary

The number of people living with and beyond cancer continues to increase. The nature of cancer and its treatments means that these individuals have unique health and support needs that can create a significant burden for individuals, families and healthcare systems if not addressed. In recent years, a number of frameworks have been developed to guide the implementation of services for this population of cancer survivors. Nurses are central to implementing these frameworks, as the core elements of care focus on assessment, client education and supported self-management, and facilitating of linkages across the person's journey.

Key concepts

- The healthcare system has largely ignored or misunderstood cancer survivors' healthcare problems.
- The definition of cancer survivor also includes family members, friends and caregivers who are affected by survivorship.
- The majority of cancer survivors have serious health deficits that are related to their treatments.
- Evidence shows that cancer survivors have poorer health outcomes than similar individuals without cancer.
- Survivors are often reluctant to report symptoms because of a fear of being perceived as ungrateful for being disease-free or a fear of cancer recurrence.
- How well a survivor adapts to the cancer experience psychologically depends upon predisposing factors, the person's current psychological status, the extent of their disease and the presence of disruptive signs and symptoms.
- The developmental effects of cancer have a social impact that occurs across the life span.
- Relationships between cancer survivors and family members become difficult to maintain because family members often do not know, understand and report not having the skills or confidence to support the survivor's reactions to cancer.
- As a nursing student, incorporate cancer survivorship care into your nursing practice through client assessment, education and referral of clients to available resources.
- Because survivors are at an increased risk for developing a second cancer and/or chronic illness, it is important to educate them about lifestyle behaviours that will improve the quality of their lives.
- Once a cancer client's primary treatment ends, healthcare professionals should develop an organised plan for survivorship care.
- A client's principal healthcare provider should write a survivorship care plan that coordinates the client's oncology treatment.
- Ideally, you would review a survivorship care plan with a client at the time they are formally discharged from a treatment program, and it would become a guide for any future cancer or cancer-related care.
