This autosomal recessive syndrome is characterized by type II lissencephaly (absence of cortical gyri) (see Chapter 60), retinal dysplasia, cerebellar malformation, and congenital muscular dystrophy. Hydrocephalus is common, which is helpful for prenatal diagnosis by ultrasonography. Other variable features of the Walker–Warburg syndrome (WWS) include Dandy–Walker malformation and encephalocele. Neonatal death is common and survivors are severely developmentally delayed. The ocular features in this disorder are variable and include microphthalmia, Peters' anomaly, cataract, retinal coloboma, and retinal dysplasia.

There are two other rare autosomal recessive disorders characterized by the combination of congenital muscular dystrophy and brain malformations, including a neuronal migration defect: muscle–eye–brain (MEB) disease and Fukuyama congenital muscular dystrophy (FCMD) (see Chapter 60). Ocular abnormalities are a constant feature in MEB and WWS, but not in FCMD.[11] The distinction between MEB and WWS is difficult due to the overlap in their clinical characteristics.[11] Survival past 3 years of age is far more likely in MEB; death in infancy is more usual in WWS. Magnetic resonance imaging findings can also be helpful to differentiate between MEB and WWS: an absent corpus callosum suggests WWS.[11]

Genetic linkage studies have shown that WWS is not allelic to MEB.[11] The molecular genetics of these three disorders are likely to be helpful in distinguishing between them when the clinical diagnosis is unclear.

Molecular genetics and pathogenesis

The causative genes have been identified in MEB and FCMD; the encoded proteins are involved in protein glycosylation. Mutations in the gene *POMT1*, encoding *O*-mannosyltransferase 1, have been identified in WWS. Immunohistochemical analysis of muscle from patients with *POMT1* mutations corroborated the *O*-mannosylation defect, as judged by the absence of glycosylation of α-dystroglycan. The lack of this glycosylation is thought to explain the muscular dystrophy in WWS. The brain and eye phenotypes in WWS may involve defective glycosylation of other proteins. Further genetic heterogeneity in WWS is likely since only 20% of patients with WWS harbor *POMT1* mutations.

Autosomal recessive vitreoretinal dysplasia

Vitreoretinal dysplasia may occur as an isolated abnormality in a healthy child. The inheritance is presumed to be autosomal recessive. In male infants, mutations in the Norrie disease gene (*NDP*) must be excluded. Presentation is with bilateral poor vision in early infancy, a shallow anterior chamber, and white retrolental mass. Progressive shallowing of the anterior chamber can result in pupil-block glaucoma, which may require lensectomy.

Osteoporosis–pseudoglioma syndrome

Clinical findings

This autosomal recessive syndrome is characterized by osteoporosis, severe learning difficulties, and vitreoretinal dysplasia (Fig. 42.6). Multiple fractures, often after minor trauma, are commonplace. Affected children present in infancy

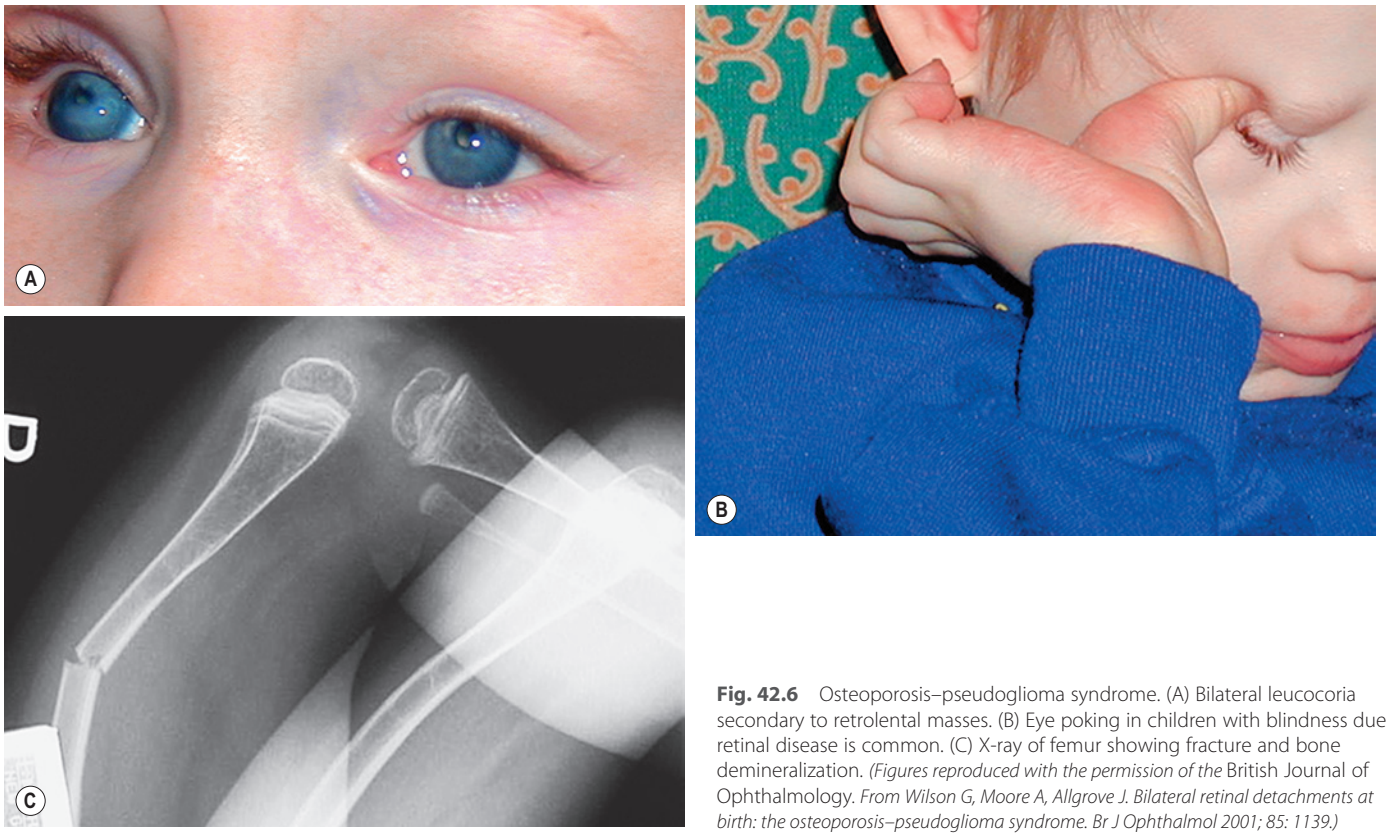

Fig. 42.6 Osteoporosis–pseudoglioma syndrome. (A) Bilateral leucocoria secondary to retrolental masses. (B) Eye poking in children with blindness due to retinal disease is common. (C) X-ray of femur showing fracture and bone demineralization. *(Figures reproduced with the permission of the* British Journal of Ophthalmology. *From Wilson G, Moore A, Allgrove J. Bilateral retinal detachments at birth: the osteoporosis–pseudoglioma syndrome. Br J Ophthalmol 2001; 85: 1139.)*

with bilateral nystagmus and severe visual impairment; the systemic features occur in later infancy and childhood. Ocular features include vitreoretinal dysplasia with retrolental masses, microphthalmia, anterior chamber anomalies, cataract, and phthisis bulbi. Most patients are blind from birth but a few patients have useful vision into their teenage years.

Molecular genetics and pathogenesis

Mutations have been identified in the gene encoding the low-density lipoprotein receptor-related protein 5 (LRP5). Mutations in *LRP5* have also been shown to be associated with both autosomal recessive and autosomal dominant familial exudative vitreoretinopathy (FEVR). These patients have also been shown to have reduced bone mineral density, suggesting that osteoporosis–pseudoglioma syndrome and *LRP5*-associated FEVR are part of a single phenotypic spectrum with both ocular and bone manifestations.[12]

Studies of LRP5 indicate that it affects bone accrual during growth by regulating osteoblastic proliferation. Furthermore, LRP5 is a component of the Wnt signaling pathway, regulating retinal development and angiogenesis. This accounts for the retinopathy resulting from LRP5 mutation.[4,13]

Oculopalatal–cerebral dwarfism

Three siblings of consanguineous parents were described with vitreoretinal dysplasia and systemic abnormalities including microcephaly, developmental delay, cleft palate, and short stature.[14] The ocular abnormalities, similar to those seen in PHPV, were bilateral in one child and unilateral in the others. It is probably autosomal recessive.

Unilateral retinal dysplasia

Lloyd et al. reported a family in which three affected members had unilateral retinal dysplasia without any systemic abnormalities.[15]

Genetic counseling in the vitreoretinal dysplasias

The vitreoretinal dysplasias are genetically heterogeneous disorders that result in a similar ocular abnormality; it is often not possible to subdivide them on the clinical or pathologic ocular findings alone, so the diagnosis depends on the systemic findings or molecular genetics, although the family history may suggest the mode of inheritance.

For the purposes of genetic counseling, families fall into two groups.

Group 1

The diagnosis and hence the mode of inheritance of the affected child is clear. When one child has been born with a trisomy, the risk of a similar affected child in a future pregnancy is 1%, but may be higher if one of the parents has a structural chromosome abnormality or mosaicism.[16] Such parents may be offered prenatal diagnosis.

In children with the systemic features of Walker–Warburg syndrome or the osteoporosis–pseudoglioma syndrome, the inheritance is autosomal recessive.

In Norrie disease there are no detectable clinical abnormalities in the carrier female to aid counseling. When there is another affected male relative, the mother can be assumed to be a carrier. In isolated boys, the status of the mother is uncertain,

but can usually be resolved by molecular genetic testing. If the mutation has been identified in the affected child, the mother and other at-risk female members can be screened for the mutation. Most mothers will be carriers. However, some mothers will not carry the identified Norrie gene mutation: their affected child may have a new mutation. Germline mosaicism is possible but rare. In this situation, the mother will need to be counseled that there is an increased, but low, risk of having a further child with Norrie disease.

Group 2

Counseling a family with an otherwise normal child with bilateral retinal dysplasia is more difficult. Isolated retinal dysplasia is rare so there are insufficient empirical data to aid counseling. If the affected child is female, retinal dysplasia may be autosomal recessive or non-genetic. Autosomal recessive dysplasia is rare; if there is no parental consanguinity, the recurrence risk is likely to be low. In an affected male child, retinal dysplasia may be autosomal recessive, X-linked, or non-genetic. Most affected males will have Norrie disease, which can be confirmed by molecular genetics. In the small minority without identifiable mutations in the *NDP* gene, if there is no parental consanguinity and other multisystem disorders have been excluded, the recurrence risk is probably low. Advances in molecular genetic testing using next-generation sequencing will greatly improve molecular diagnosis and genetic counseling.

Inherited vitreoretinal disorders

Wagner syndrome

Clinical findings

Wagner syndrome is an autosomal dominant vitreoretinal dystrophy with low myopia and vitreous and retinal abnormalities, without systemic abnormalities. The vitreous appears optically empty apart from scattered translucent membranes: there is usually a posterior vitreous detachment with a thickened posterior hyaloid. Peripheral vascular sheathing is common and normally associated with perivascular RPE atrophy and pigment deposition. The electroretinogram (ERG) is subnormal and parallels the chorioretinal pathology and poor night vision. Cataract develops after the second decade and is the usual cause of visual loss. Rhegmatogenous retinal detachment is infrequent, whereas peripheral tractional retinal detachment occurs in most of the elderly affected patients.

Wagner disease and erosive vitreoretinopathy share some clinical features; they both have subnormal ERGs, poor night vision, and field defects, which are not found in *COL2A1*-associated Stickler syndrome. The vitreoretinal phenotype is different, as neither of the recognized vitreous abnormalities in Stickler syndrome are present in Wagner syndrome (see below). In addition, retinal detachment is less common in Wagner syndrome, but occurs in the majority of patients with Stickler syndrome and erosive vitreoretinopathy.

Molecular genetics and pathogenesis

Wagner syndrome and erosive vitreoretinopathy are linked to 5q13–14 and are likely to be allelic disorders, distinct from Stickler syndrome. Heterozygous mutations in the gene encoding chondroitin sulfate proteoglycan-2 (CSPG2), a proteoglycan present in the vitreous body, have been identified in both Wagner syndrome and erosive vitreoretinopathy.

A phenotypically distinct vitreoretinopathy with early-onset retinal detachments and anterior segment developmental abnormalities, without systemic features, has been described, which also maps to 5q13–q14, to a 5-cM region already implicated in both Wagner syndrome and erosive vitreoretinopathy.

Erosive vitreoretinopathy

Clinical findings

Erosive vitreoretinopathy is characterized by autosomal dominant inheritance, night blindness, progressive field loss, vitreous abnormalities, progressive RPE atrophy, and combined tractional and rhegmatogenous retinal detachment.[17] ERG shows widespread rod and cone dysfunction. Peripheral RPE atrophy, field loss, and ERG abnormalities are evident in childhood. The vitreous is syneretic with areas of condensation but without the inflammatory signs seen in autosomal dominant neovascular inflammatory vitreoretinopathy. There are no systemic abnormalities.

Dragged retinal vessels and macular ectopia may occur, with tractional or rhegmatogenous retinal detachment in most affected adults. Twenty percent of affected eyes become blind from retinal detachment.[17]

Molecular genetics and pathogenesis

Heterozygous mutations in the gene encoding chondroitin sulfate proteoglycan-2 (CSPG2) have been identified.

Stickler syndrome (see also Chapter 52)

Clinical findings

In Stickler syndrome, abnormalities of vitreous gel architecture are a pathognomonic feature, usually associated with congenital and non-progressive high myopia. Other eye features include paravascular pigmented lattice degeneration, cataracts, and retinal detachment. Non-ocular features are very variable: deafness, a flat midface with depressed nasal bridge, short nose, anteverted nares, and micrognathia that can become less pronounced with age. Midline clefting, if present, ranges from a submucous cleft to Pierre–Robin sequence, whilst joint hypermobility declines with age. Osteoarthritis may develop after the third decade. Stature and intellect are normal.

Molecular genetics and pathogenesis

Most forms of Stickler syndrome are inherited as an autosomal dominant trait but rare recessive forms have been reported.

Autosomal dominant Stickler syndrome

The *COL2A1* gene encodes type II procollagen, a precursor of components of secondary vitreous and articular cartilage; several mutations occur in families with Stickler and Kniest syndrome. There is phenotypic variability with presence or absence of systemic features and locus heterogeneity with about two-thirds of families showing linkage to *COL2A1*.

Stickler syndrome can be divided into two types by slit-lamp biomicroscopy of the vitreous, facilitating prioritization of molecular screening:

1. type 1: with retrolental vitreous anomaly and is associated with mutations of the *COL2A1* gene;

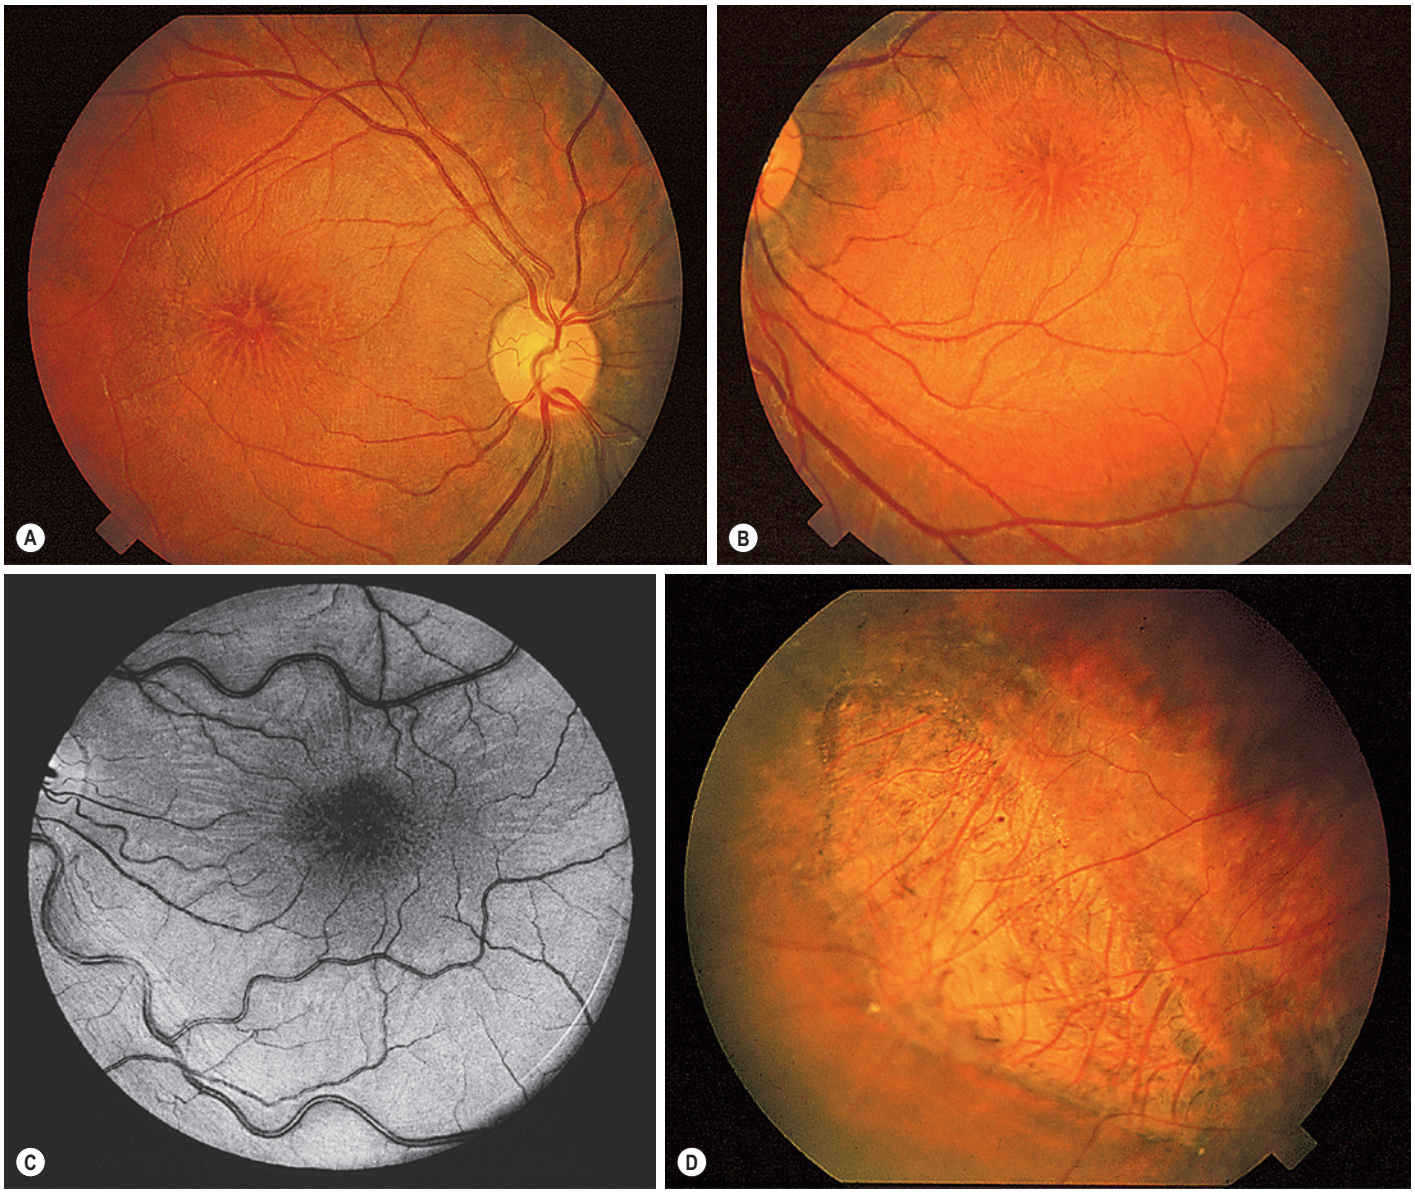

Fig. 42.7 Juvenile X-linked retinoschisis. (A,B) Bilateral foveal schisis. (C) The foveal schisis is best seen with ophthalmoscopy using a red free light. (D) Peripheral pigmentary changes in an area of schisis.

2. type 2: no retrolental vitreous anomaly and does not harbor *COL2A1* variants. Mutations in *COL11A1* (encoding α1 chain of type XI collagen) and *COL11A2* (encoding α2 chain of type XI collagen) have been identified in type 2 families.

Mutations in exon 2 of the *COL2A1* gene may produce a Stickler phenotype with predominantly ocular manifestations.

Autosomal recessive Stickler syndrome

Recessive forms of Stickler syndrome are rare and have been reported in association with mutations in *COL11A1*, *COL9A1*, *COL9A2*, and *COL9A3* genes.

Myelinated nerve fibres, vitreoretinopathy, and skeletal malformations

Severe vitreoretinal degeneration, high myopia, myelinated nerve fibers, and skeletal abnormalities were described in a mother and daughter that were distinct from those seen in Stickler syndrome. Both had severe visual impairment and roving eye movements, and electrophysiologic testing in the mother showed an abnormal scotopic and photopic ERG.

X-linked retinoschisis (see Chapter 51)

Clinical and histologic findings

This X-linked disorder is almost exclusive to males. The characteristic fundus abnormality is a cystic spokewheel-like maculopathy (foveal schisis), present in about two-thirds of males (Fig. 42.7A–C). Fifty percent of affected males show additional peripheral retinal changes (Fig. 42.7D). Foveal retinoschisis may occur in early infancy, but most children present between 5 and 10 years of age, either with reading difficulties or when they fail the school eye test. The visual acuity is 6/12–6/36 at presentation, and strabismus, hypermetropia, and astigmatism are common. If the macular changes are

Box 42.2

Classification of autosomal dominant familial exudative vitreoretinopathy

Stage I

Mild peripheral retinal changes with abnormal vitreous traction but no evidence of retinal vascular or exudative change.

Stage II

Dilated tortuous vessels between the equator and ora serrata with subretinal exudates and localized retinal detachment. Dragging of disc vessels and macular ectopia is often present.

Stage III

Advanced disease with total retinal detachment and extensive vitreoretinal traction. There may be secondary cataract and rubeosis iridis.

subtle, it may be misdiagnosed as strabismic or ametropic amblyopia or functional visual loss (see Chapter 63).

Familial exudative vitreoretinopathy

FEVR describes a group of inherited disorders with abnormal retinal vascularization often associated with exudation, neovascularization, and tractional retinal detachment.[18] In advanced disease there are some clinical similarities to cicatricial ROP. The clinical appearance varies considerably, even within families: severely affected patients are often registered as blind during infancy and mildly affected patients have few or no visual problems.

FEVR can be inherited as an autosomal recessive, autosomal dominant, and X-linked disorder. All the genes identified to date are components of the Wnt signaling pathway.[4,13] There appears to be no correlation between phenotype and mode of inheritance, particular mutations, or mutation types. *LRP5* mutation carriers (autosomal dominant and autosomal recessive FEVR) remain the only subset of FEVR patients that can be clinically distinguished by the presence of low bone-mass density.[4,12,13]

Autosomal dominant familial exudative vitreoretinopathy (AD-FEVR)

Clinical findings

The clinical expression is markedly variable (Box 42.2) with a widespread abnormality of the retinal vasculature, due to the arrest of normal vasculogenesis.[3,10] In the asymptomatic form, fundoscopy and fluorescein angiography reveals peripheral retinovascular abnormalities, particularly temporally, although fundus findings may be subtle (Fig. 42.8). These include vascular dilatation and tortuosity, arteriovenous shunting, capillary closure, and peripheral retinal neovascularization (Fig. 42.9). Optic disc neovascularization is less common. Vitreoretinal adhesions are frequently seen at the border between vascularized and non-vascularized retina, and other peripheral retinal changes include retinal pigmentation and intraretinal white deposits.

More advanced cases show vascular leakage, cicatrization with macular ectopia, tractional retinal detachment, and macular edema (Fig. 42.10). Vitreous hemorrhage and secondary rhegmatogenous retinal detachment are complications. The

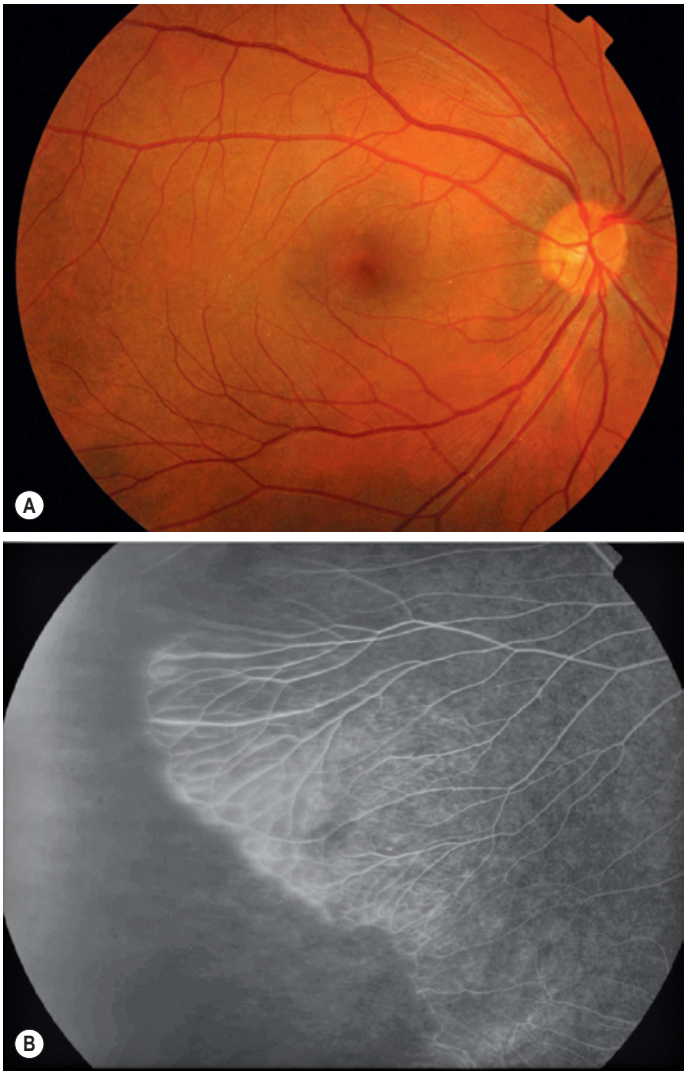

Fig. 42.8 Autosomal dominant familial exudative vitreoretinopathy. (A,B) An asymptomatic carrier with a normal examination of the posterior pole (A). The importance of fundus fluorescein angiography (FFA) can be seen in helping to determine status, with marked temporal retinal capillary closure observed on FFA.

Fig. 42.9 Autosomal dominant familial exudative vitreoretinopathy. Peripheral vascular dilatation, tortuosity, and shunting with some preretinal changes.

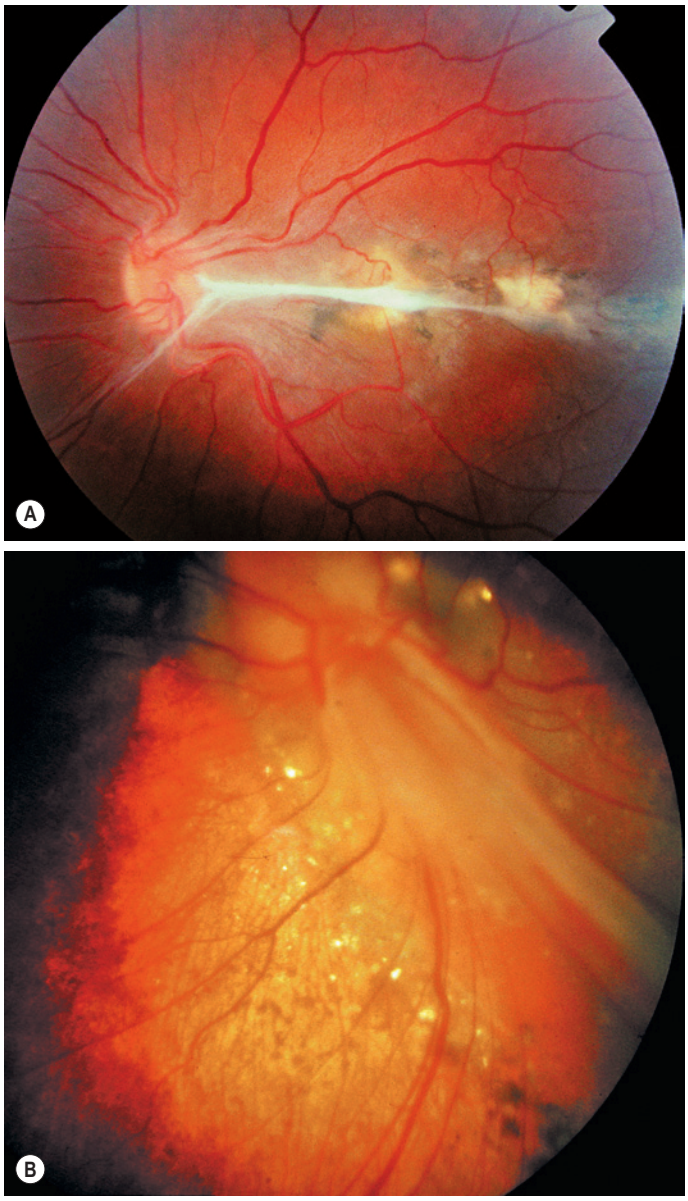

Fig. 42.10 Autosomal dominant familial exudative vitreoretinopathy (FEVR). (A) Cicatrization with macular ectopia. (B) Severe retinal fold secondary to FEVR.

retinal changes may progress throughout childhood, but rarely after the age of 20. In children who show progression from stage I disease (Box 42.2), laser ablation of peripheral ischemic retina may be indicated. In advanced cases, vitreoretinal surgery may be beneficial.

Many FEVR gene carriers are asymptomatic and have only minor retinovascular abnormalities. The gene is highly penetrant. It is important to perform a careful fundoscopic examination, preferably with fluorescein angiography, before excluding carrier status.

Molecular genetics and pathogenesis

Mutations in *FZD4* and *LRP5* have been detected in affected individuals.[4,13] *FZD4* and *LRP5* encode the receptors Frizzled-4 and low-density lipoprotein receptor-related protein-5, respectively, with these two proteins acting as co-receptors for Wnts and Norrin.[4,13] Mutations in *TSPAN12* have also been identified, which encodes a protein that facilitates the binding of Norrin to the aforementioned receptor. Other genes remain to be discovered, as not all cases are accounted for by current known genes. Recently, exome sequencing in Dutch families with FEVR with no known molecular cause has identified a missense variant in the *ZNF408* gene, which is a member of a family of zinc finger transcription factors.[19]

X-linked familial exudative vitreoretinopathy

Clinical findings

The phenotype may be similar to the severe form of dominant exudative vitreoretinopathy and may also resemble congenital falciform retinal folds. Affected males usually have severe early-onset visual impairment. Prominent retinal folds from the disc to the ora serrata are characteristic. Rarely, mildly affected males have been reported in families with X-linked FEVR.

Molecular genetics and pathogenesis

Point mutations in *NDP* have been identified. X-linked FEVR (XL-FEVR) and Norrie disease are thereby allelic disorders (different mutations of the same gene giving rise to a different but well-defined phenotype).

Autosomal recessive familial exudative vitreoretinopathy

Autosomal recessive FEVR (AR-FEVR) is less common than AD- and XL-FEVR. AR-FEVR is usually more severe than the dominant form of the disorder (Fig. 42.11). The management of the disorder follows the same principles as AD-FEVR.

Molecular genetics and pathogenesis

Biallelic mutations in *LRP5* and *TSPAN 12* have been detected in affected individuals.[4,13]

Autosomal dominant vitreoretinochoroidopathy (ADVIRC)

Clinical and histologic findings

This rare dystrophy has abnormal chorioretinal pigmentation in a 360° circumference between the vortex veins and the ora serrata, which is present in childhood and usually progresses. There are areas of hypo- and hyperpigmentation and scattered yellow dots may be seen in the peripheral retina and at the posterior pole. There are usually retinovascular changes with arteriolar narrowing, venous occlusion, and widespread leakage. A demarcation line is seen between the normal and abnormal retina. The vitreous is liquefied with peripheral condensation. Presenile cataract occurs frequently. Fluorescein angiography shows areas of capillary dilatation and diffuse vascular leakage; peripheral neovascularization may develop in a few cases.

Visual symptoms are rare in childhood but may occur in adults from cataract, macular edema, vitreous hemorrhage, and retinal detachment. Nyctalopia is not prominent and the ERG is normal, sometimes becoming abnormal with age. The electrooculogram (EOG) usually suggests a widespread RPE defect but can be normal. There are no consistent systemic abnormalities.

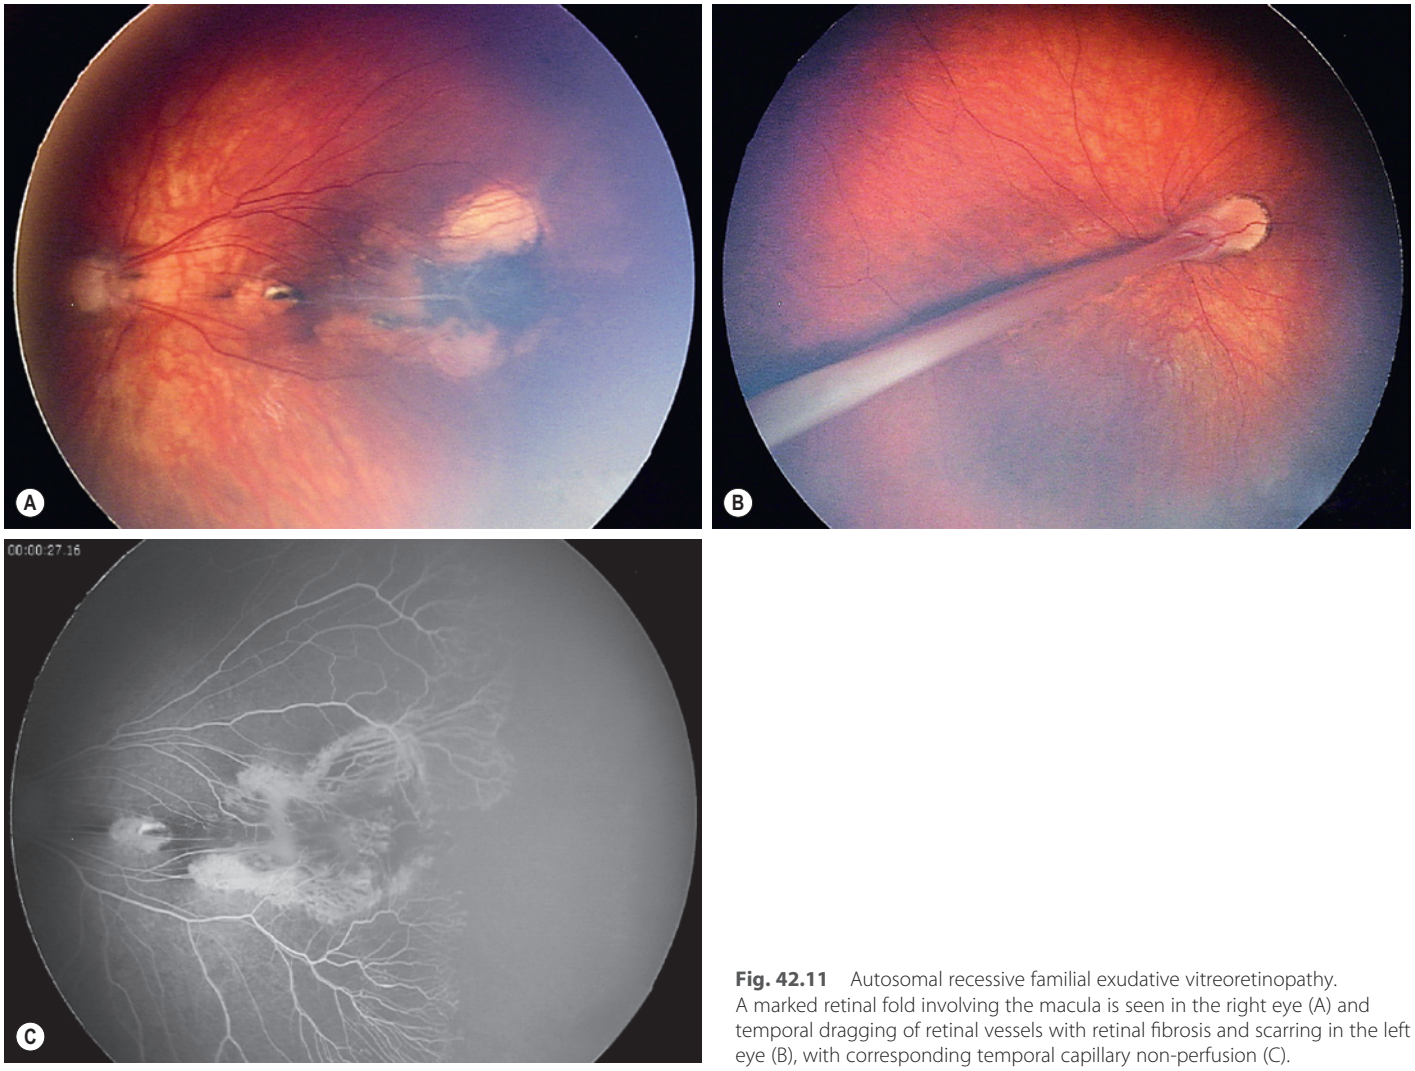

Fig. 42.11 Autosomal recessive familial exudative vitreoretinopathy. A marked retinal fold involving the macula is seen in the right eye (A) and temporal dragging of retinal vessels with retinal fibrosis and scarring in the left eye (B), with corresponding temporal capillary non-perfusion (C).

Light and electron microscopy showed similar findings in a young and an old patient suggesting that ADVIRC is an early-onset peripheral retinal dystrophy with minimal subsequent progression, characterized by a RPE response that includes marked intraretinal migration and extracellular matrix deposition.

Molecular genetics and pathogenesis

Mutations have been found in the bestrophin-1 gene (*BEST1*). Sequence variants have also been identified in *BEST1* in several other retinal phenotypes,[20] including Best disease (see Chapter 48), autosomal recessive bestrophinopathy, adult vitelliform macular dystrophy, MRCS (microcornea, rod–cone dystrophy, cataract, and posterior staphyloma), and retinitis pigmentosa (see Chapter 46).

Autosomal dominant neovascular inflammatory vitreoretinopathy

Clinical findings

This rare autosomal dominant disorder is characterized by panocular inflammation, peripheral retinal pigment deposition, retinal vascular occlusion and neovascularization, vitreous hemorrhage, and tractional retinal detachment. Presenile cataract is common. The single bright white flash ERG shows early selective loss of the b-wave ("negative-ERG"), which differentiates it from the other vitreoretinopathies with vascular closure. Night blindness is a late feature; the ERG may become totally extinguished in advanced disease. There are no reported systemic abnormalities.

The earliest signs are vitreous cells, mild peripheral retinal ischemia, and reduced b-wave amplitudes on ERG. It cannot be reliably detected in childhood.

Molecular genetics

It has been mapped to 11q, with heterozygous missense mutations identified in the gene *CAPN5*.

Autosomal dominant snowflake degeneration

This disorder is characterized by extensive "white-with-pressure" change in the peripheral retina, multiple minute "snowflake" retinal deposits, and sheathing of the peripheral retinal vessels. Later, there may be peripheral vascular occlusion and retinal pigmentation. The vitreous is degenerate and liquefied. Psychophysical studies show abnormal rod and cone function and although ERG may be normal initially, the b-wave amplitude is later reduced. There is an increased risk of retinal tears and detachment. The retinal changes may be

seen in childhood, but more often in the teens or later. There are no systemic abnormalities.

Molecular genetics and pathogenesis

A missense mutation has been identified in *KCNJ13*, which encodes an inwardly rectifying potassium channel. Null mutations in this gene have been implicated in Leber congenital amaurosis (see Chapter 46).

Acquired disorders of the vitreous

Acquired disorders of the vitreous are uncommon in childhood and generally occur when there is vitreous opacification caused by hemorrhage or, less commonly, inflammation. Tumor or infection may involve the vitreous cavity.

Vitreous hemorrhage (Box 42.3)

The management of vitreous hemorrhage is relatively straightforward in children who have reached the age of visual maturity. A conservative approach is preferred, with surgery only indicated if the hemorrhage is persistent or if there is an associated retinal detachment. In infants and young children, vitreous hemorrhage may lead to amblyopia and affect emmetropization. If, after a short period of observation, there is no resolution and if there is no underlying retinal abnormality that may herald a poor prognosis, early lens-sparing vitrectomy may be considered. Occlusion needs to be started as soon as possible.

Inflammatory disease of the vitreous

See Chapter 40.

Vitreous opacity due to tumor

Vitreous seeding may complicate retinoblastoma; clumps of tumor cells float in the vitreous but rarely give rise to diagnostic problems as there is usually a typical retinoblastoma. When there are clumps of cells in the anterior vitreous in an inflamed eye with an opaque vitreous there may be doubt as to whether the underlying etiology is inflammatory or neoplastic. Ultrasound or CT scan usually demonstrates a retinoblastoma, but not in the rare diffuse infiltrating forms.

Tumor cells may be found in the vitreous in leukemia but there is almost always associated retinal infiltration (see Chapter 67). Other intraocular tumors are rare.

PROGNOSIS
LONG-TERM FOLLOW-UP
LIFELONG IMPLICATIONS OF RETINOBLASTOMA
FUTURE PERSPECTIVE
REFERENCES

Retinoblastoma is an uncommon malignant ocular tumor of childhood, occurring in 1:18,000 live births.[1] Late diagnosis globally results in up to 70% mortality; where optimal therapy is accessible, more than 95% of children are cured. An integrated team approach of clinical specialists (ophthalmologists, pediatric oncologists and radiotherapists, nurses, geneticists) with imaging specialists, child life (play) specialists, parents, and others is an effective way to manage retinoblastoma. National guidelines can bring the whole health team up to developed country standards and set the stage for audits, studies, and clinical trials to continuously evolve better care and outcomes.[2] Retinoblastoma arises from embryonic retinal cells so the majority of cases occur under the age of 4 years. Primary treatments options include enucleation, or systemic or intra-arterial chemotherapy with laser and cryotherapy, selected with very careful considerations of the wellbeing of the whole child and family in treatment choices. Patients with a constitutional mutation of the *RB1* tumor suppressor gene are at increased lifelong risk of developing other cancers, which is increased with exposure to radiation (Figs 43.1 and 43.2).[3] Therefore, radiation is no longer a primary therapy to save an eye, and screening for extraocular and trilateral retinoblastoma is performed with magnetic resonance imaging (MRI) and ultrasound, not computed tomography (CT) scan.

The study of retinoblastoma has been seminal in the understanding of cancer in general. Studies of retinoblastoma have revealed that hereditary and non-hereditary tumors are initiated by the loss of both alleles of the tumor suppressor gene, *RB1*.[4,5] The existence of specific genes that act to suppress cancer was predicted from clinical studies of retinoblastoma.[6,7] The *RB1* gene was the first tumor suppressor gene to be cloned,[4] and has been found to have a critical role in many types of cancer.

Pathogenesis of retinoblastoma

Heritable and non-heritable retinoblastoma

All children with retinoblastoma tumors in both eyes (bilateral) have an *RB1* gene mutation on one of their chromosome 13s that predisposes them to develop retinal tumors in infancy and other cancers throughout life (see Figs 43.1 and 43.2). All bilaterally affected persons have *heritable* disease, but 90% have no family history of retinoblastoma (*not inherited*). They are the first affected in their family with a *new* germline mutation,[8] and 50% of their offspring will *inherit* the mutant *RB1* gene with 95% risk of developing tumors. Most children without a family history with retinoblastoma in only one eye have normal constitutional *RB1* alleles, but the eye tumor(s) has lost both functional alleles, similar to hereditary retinoblastoma. Fifteen percent of persons who had unilateral retinoblastoma have constitutional *RB1* mutations that can be transmitted to their offspring. Molecular and clinical genetics is an integral part of the management of all families affected by retinoblastoma.

Loss of both *RB1* alleles induces retinoblastoma

The observation that the children with bilateral retinoblastoma tend to be diagnosed at a younger age than those with non-hereditary retinoblastoma led to Knudson's prediction that two mutational events are required to initiate retinoblastoma tumors.[6] His analysis suggested that in the presence of a predisposing constitutional mutation, a single second mutation in one developing retinal cell initiates tumor development (heritable retinoblastoma) (median age of diagnosis 12 months), but both alleles are mutated in the single developing retinal cell in non-heritable unilateral retinoblastoma (median age of diagnosis 24 months). The two events were hypothesized to be mutations of both alleles of a gene that would "suppress" tumor formation in the retina.[7] The chance of losing the second *RB1* allele from developing retinal cells with only one normal *RB1* allele is sufficiently high that multiple tumors are common in hereditary retinoblastoma (see Fig. 43.1). However, it is virtually impossible for children without a constitutional *RB1* mutation to lose both alleles from several retinal cells so they develop only one, unilateral tumor (Fig. 43.3), and tend to

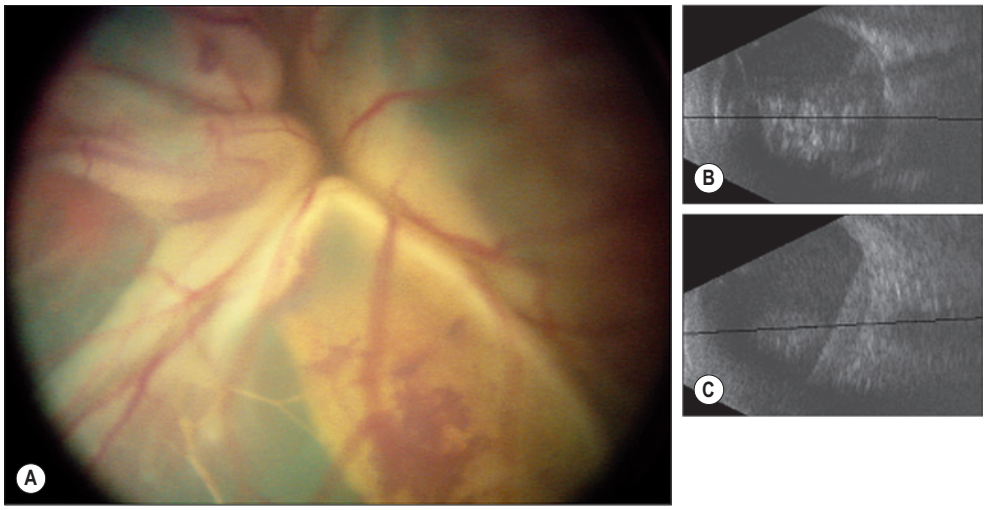

Fig. 43.3 (A) Exophytic retinoblastoma (IIRC[33] Group D) with retinal detachment in a unilaterally affected 3-year-old boy. Fig. 43.1 (A) Family tree: Mother was cured of bilateral retinoblastoma by enucleation of one eye and external beam radiation of the other eye. Both children were delivered at 36 weeks' gestation to facilitate early treatment of tumors and developed bilateral tumors. Mother and both children carry a germline *RB1* mutation (M1, deletion of ATTTC starting at bp 778, reading to a STOP, 9 codons away) that results in no product of the RB1 gene (pRB) when the normal *RB1* allele is lost (M2) from a developing retinal cell, initiating a tumor. (B) Wide-angle retinal images: Prior to treatment, right eye (IIRC[33] Group A, more than 1.5 mm from optic disc) of the boy at 3 months, showing two tumors; stable right eye of boy age 4 years after laser, two cycles of CEV (carboplatin, etoposide, and vincristine) with cyclosporin A chemotherapy, and more laser treatments. (C) Wide-angle retinal images: Prior to treatment, left eye (IIRC[33] Group B, tumor less than 3 mm from fovea) of the girl at 2 months; laser scar and new tumor above nerve at 4 months of age; recurrence in original scar extending toward fovea, with tumor vascularization showing on fluorescein angiography; after laser, two cycles of CEV chemotherapy with cyclosporin A to control recurrence threatening vision, flat scars at age 2.5 years. *(Images by Leslie MacKeen, Cynthia VandenHoven, and Carmelina Trimboli.)*

be diagnosed at an older age than children with hereditary retinoblastoma.

Function of the retinoblastoma protein

The product of the *RB1* gene (pRB) is a 110-kDa, phosphoprotein that interacts with many proteins in the regulation of the cell cycle, differentiation, and control of genomic stability.[9] DNA tumor viruses that induce cancer, such as human papilloma virus, do so in part by binding to the "pocket" region of pRB.

Germline mutation of *RB1* leads to a 40,000-fold relative risk (RR) for retinoblastoma, a 500-fold RR for sarcoma that is increased up to 2000-fold by therapeutic radiation, but no increase in the RR for leukemia.[10] Although pRB is key to all cycling cells, its function in development is highly tissue-specific. A subset of developing retinal cells may be uniquely dependent on pRB in order to differentiate terminally into adult, functioning retina. Loss of pRB promotes genomic changes and instability, leading to further mutations in oncogenes and other tumor suppressor genes that result in a retinal tumor.[11,12]

Spectrum of *RB1* mutations

The majority of *RB1* mutations are unique to each family, and are distributed throughout the *RB1* gene with no real hot spots.[8] Sensitive mutation identification requires determination of the copy number of each exon and the gene promoter to reveal large deletions and duplications, sequencing for point mutations, examination of the mRNA to confirm or detect intronic mutations altering exon splicing, and assay for the methylation status of the promoter in tumor samples (Fig. 43.4). Next generation sequencing technologies are rapidly developing with promise to efficiently identify *RB1* mutations,

but do not yet approach the overall sensitivity necessary for full clinical application. Application of multiple techniques, combined with a retinoblastoma-specific focused expertise in interpreting the data, can identify 97% of *RB1* mutations[8,13] (see Figs 43.1, 43.3, 43.4, 43.5).

Oncogene-initiated retinoblastoma

A rare subset (2%) of unilateral, non-heritable retinoblastoma tumors have normal *RB1* and the tumors are initiated instead by high level amplification of the MYCN oncogene.[14] These are aggressive cancers that arise in very young children (median age of diagnosis 4.5 months)

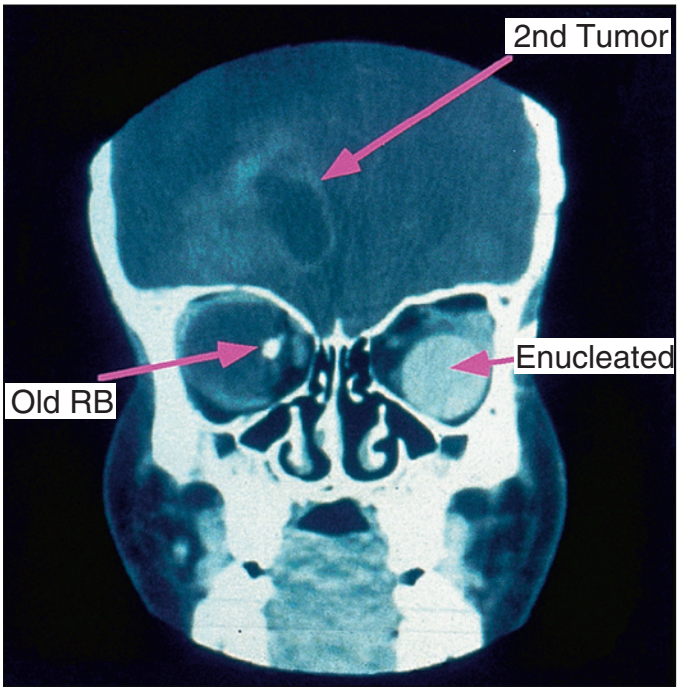

Fig. 43.2 Glioblastoma multiforme arising within the radiation field, 10 years after enucleation of the left eye and irradiation of the right eye for bilateral retinoblastoma (RB).

Other manifestations of *RB1* mutant alleles

Mutation of *RB1* also predisposes to benign retinal tumors, retinoma,[11,15] intracranial midline embryonic tumor (trilateral retinoblastoma),[16] and second non-ocular malignancies.[3]

Retinoma

A retinoma is a non-malignant manifestation of the *RB1* mutation.[15] Three features characterize these non-progressive lesions: an elevated grey retinal mass, calcification, and surrounding retinal pigment epithelium (RPE) proliferation and pigmentation (Fig. 43.5). These features are also seen after radiation treatment for retinoblastoma. If documented in childhood, which is very rare, retinoma is a quiescent tumor that has not progressed to malignancy. Occasionally a retinoma has been observed to later progress to active retinoblastoma. However, retinoma commonly underlies active retinoblastoma and can be discovered on pathologic examination of an enucleated eye with the distinctive features of fleurette formation and absence of proliferative markers.[11] Both *RB1* alleles are mutant in the retinoma and genomic instability is detectable, which progresses in degree and number of genes involved in the adjacent highly proliferative retinoblastoma. Discovery of retinoma on retinal examination of a relative of a patient with retinoblastoma indicates that they share an *RB1* mutant allele (see Fig. 43.5).

Intracranial midline embryonic tumor (trilateral)

Trilateral retinoblastoma is a midline intracranial tumor or a primary pineal tumor associated with heritable retinoblastoma that is not related to a metastasis.[16] The tumors are neuroblastic and resemble a poorly differentiated retinoblastoma. Pineal tumors arise in 5% of children with an *RB1* mutation but should not be confused with pineal cysts which occur in 2% of all children and require no treatment.[17] Affected children may present with raised intracranial pressure leading to diagnosis

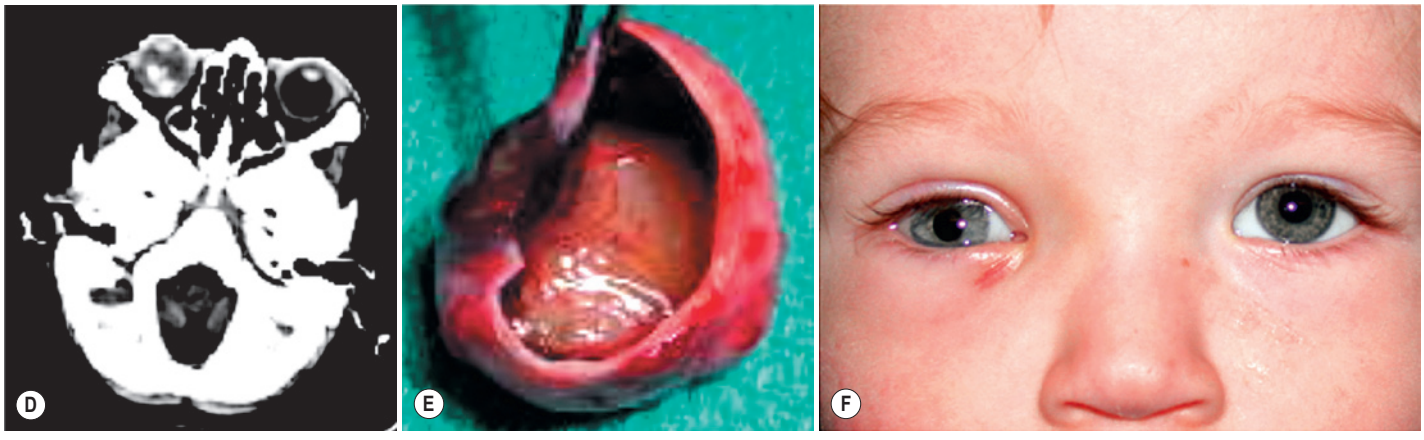

Fig. 43.3 (D) Computed tomography scan showing intraocular calcification, normal sized optic nerve. (E) The eye was opened immediately after enucleation, in order to obtain live tumor cells and the two *RB1* mutations (homozygous exon 16 deletion C-1450, insertion AT) defined. (F) The child 2 days after enucleation, wearing the temporary prosthetic conformer inserted at the time of surgery. The exon 16 *RB1* mutation of the tumor was not detected in blood, indicating high likelihood that the retinoblastoma is not heritable, eliminating risk for siblings. Due to the remaining possibility that the affected child is mosaic for the *RB1* mutation, his future offspring will be tested for this mutation. *(Images by Cynthia VandenHoven and Carmelina Trimboli.)*

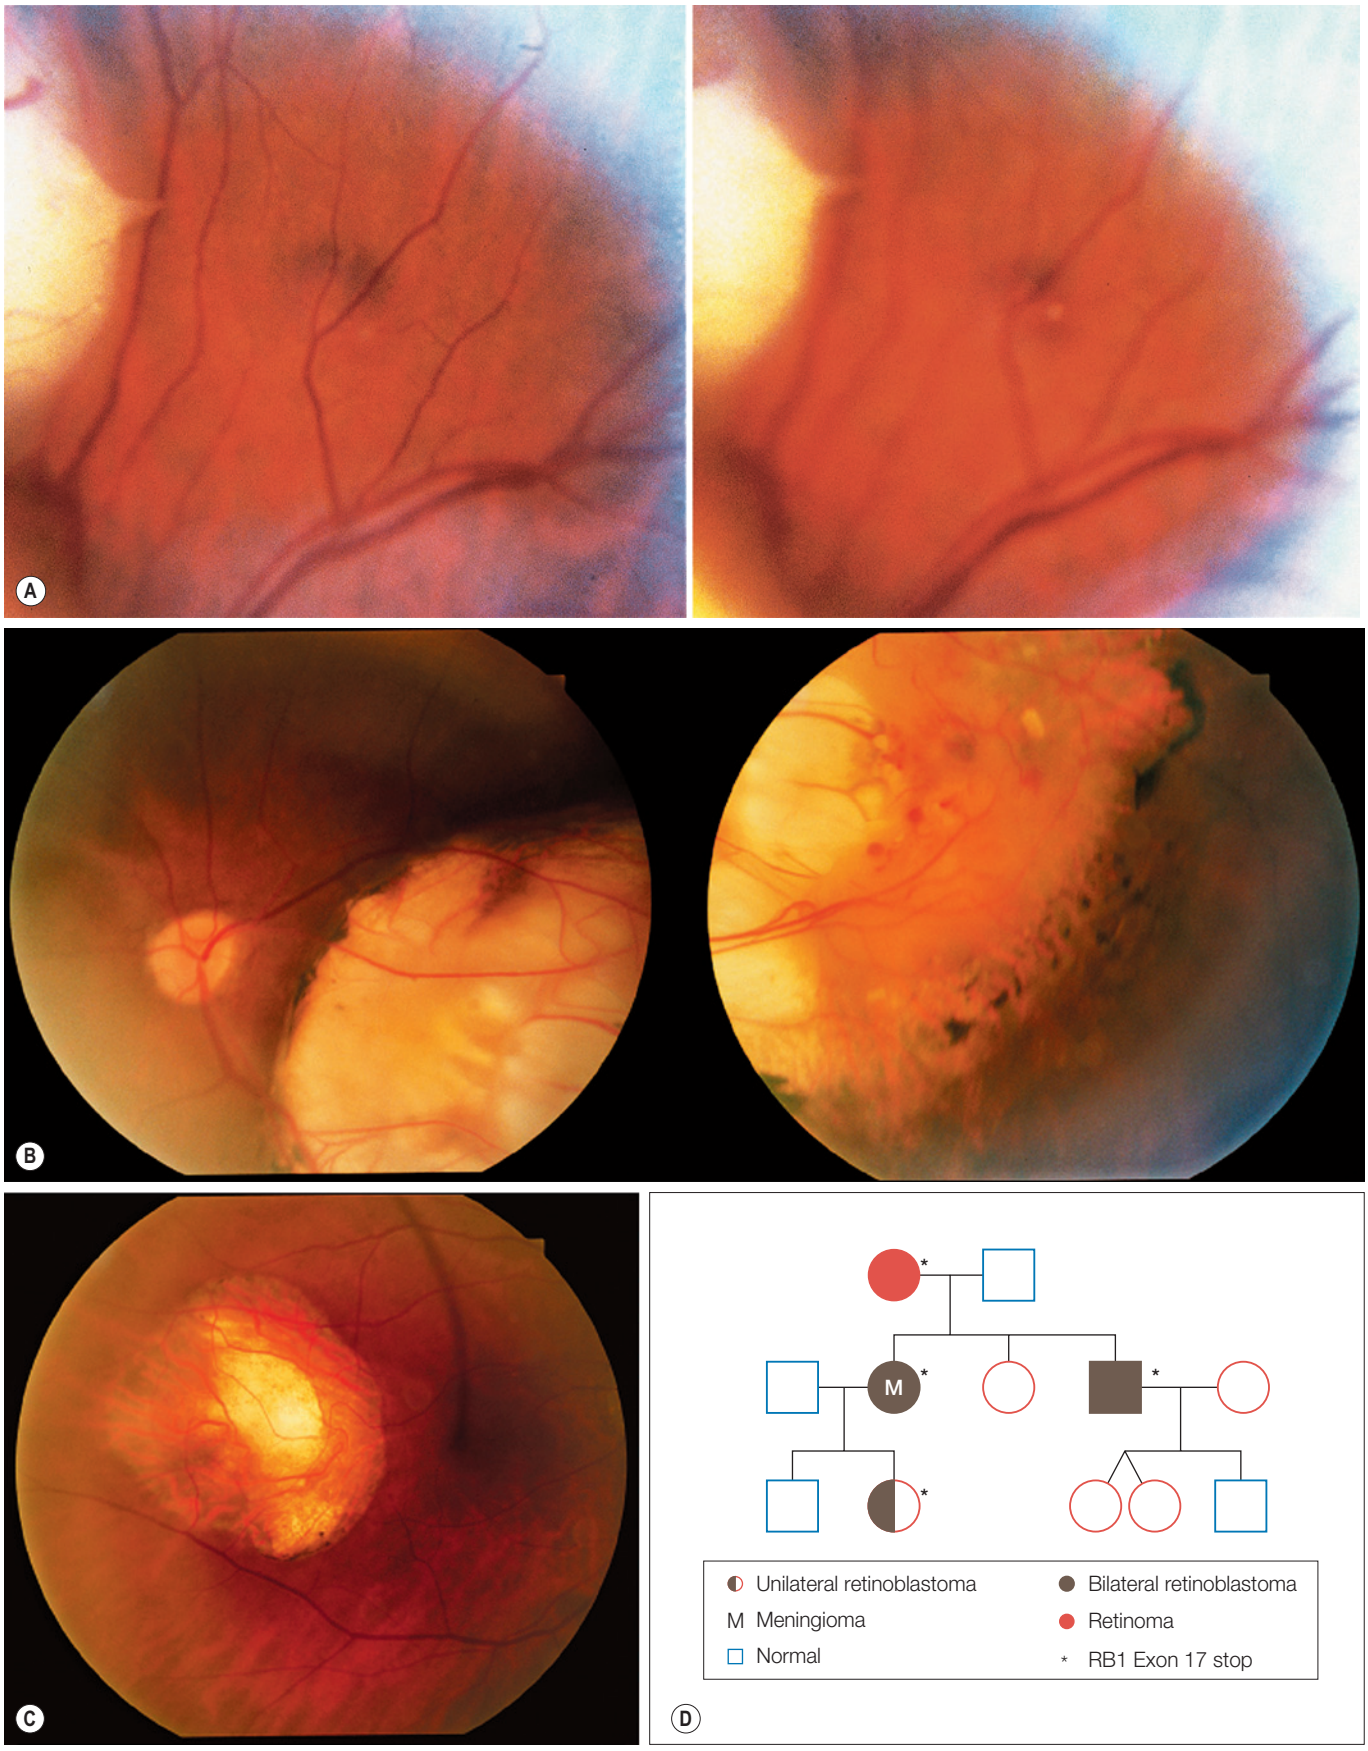

Fig. 43.5 (A) Retinoma with a vitreous seed (stereo images) discovered at age 18, followed for 30 years with no change; daughter had bilateral retinoblastoma. (B,C) Multifocal bilateral retinoma discovered in the grandfather when his granddaughter developed unilateral retinoblastoma. His daughter had bilateral retinoblastoma and meningioma at age 40. (D) All affected members carry a "null" germline *RB1* mutation (heterozygous point mutation in exon 17 resulting in a STOP codon).

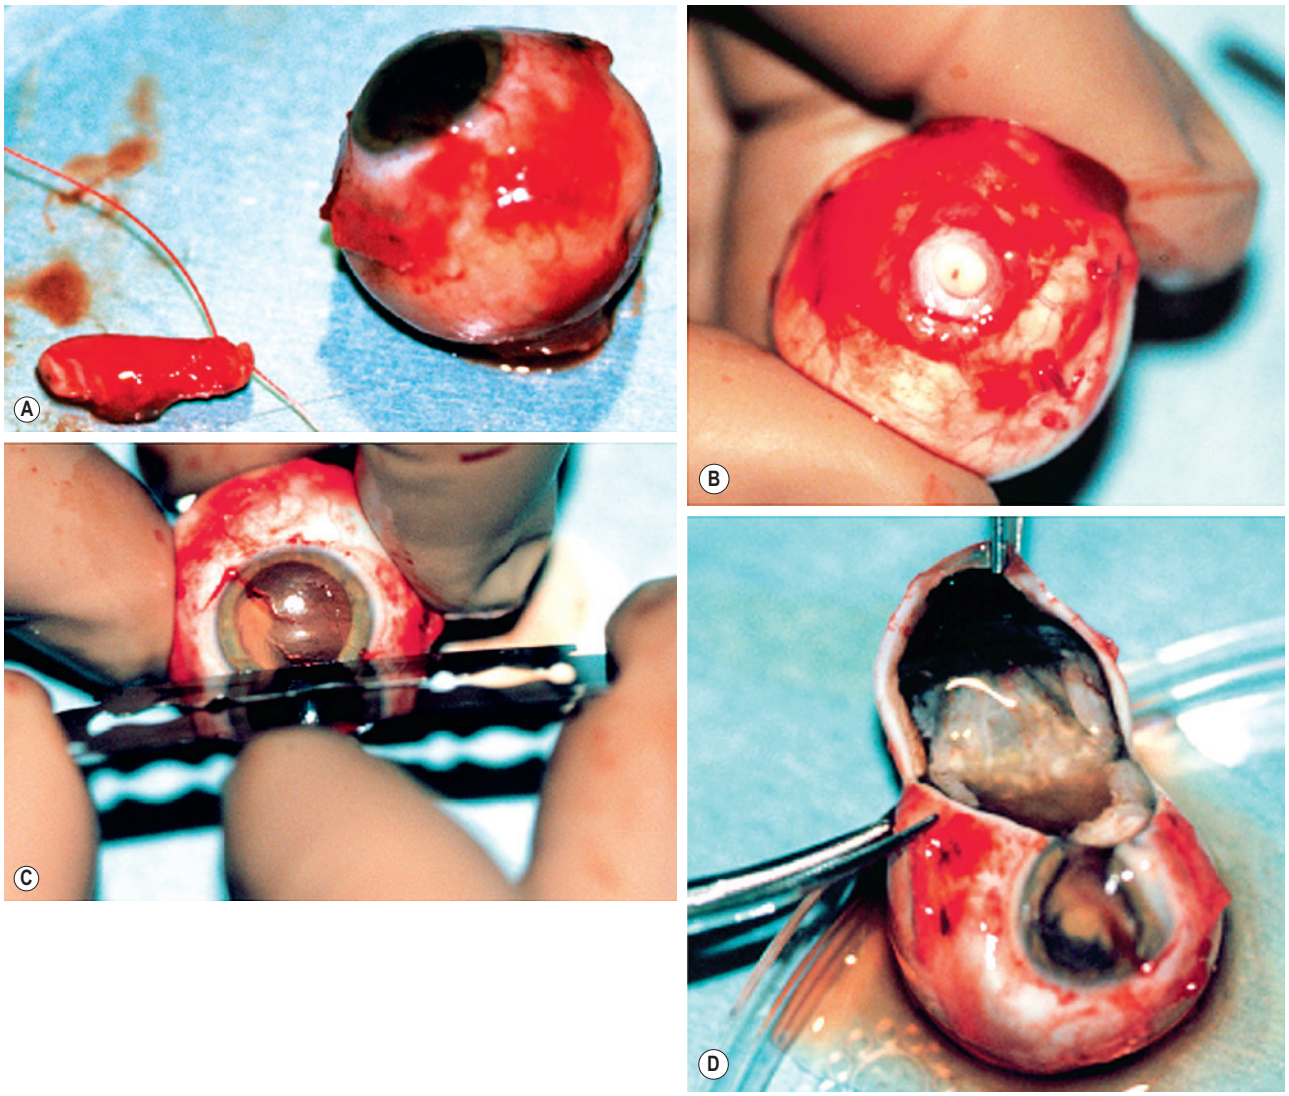

Fig. 43.4 Harvest of fresh tumor for determination of the *RB1* mutant alleles in unilateral tumor. (A) Optic nerve (8–12 mm) is excised from the globe and the distal end marked with a suture. The nerve is submitted as a separate specimen in a separate formalin container so that it is not contaminated by tumor from the opened eye. (B) Optic nerve just beyond the cribriform plate appears normal on gross inspection, to be confirmed microscopically. (C) Globe is opened with a razor incision in a pupillary–optic nerve plane, superior or inferior, at the limbus, in order to access intraocular live tumor. (D) Superior or inferior calotte allows harvest of large amount of intraocular tumor for adequate molecular studies. Optic nerve and choroid are not interfered with, since these are important for pathologic assessment for risk of extraocular spread. Tumor for molecular studies is sent to the lab in sterile tissue culture medium. The *RB1* mutations (M1 and M2) in this unilateral tumor were a heterozygous exon 14 CGA to TGA (R445X) and a heterozygous intron 16 G to A (cDNA 1498+5) causing a splice mutation. Neither M1 nor M2 were detected in blood of the child. *(Images by Cynthia VandenHoven.)*

of a pineal or parasellar mass on MRI.[18] Routine screening by MRI for intracranial tumors may detect pineal tumors at a stage when they can be cured, but formal evidence-based recommendations have not yet been produced.[16]

Multiple different malignancies

Persons with *RB1* gene mutant alleles are at increased risk of developing second non-ocular malignancies[3,19,20], which may occur within or outside the radiation field (see Fig. 43.2). Radiation, particularly of infants under 1 year of age, increases the risk of sarcomas and other cancers within the radiation field. Osteosarcoma is the commonest second primary tumor in persons with *RB1* mutations, but a wide variety of other neoplasms have been reported. Since these radiation-induced tumors are very difficult to treat, in the past more children with *RB1* mutations have died of their second tumor than have died of uncontrolled retinoblastoma. Radiation is now restricted to salvage of the remaining eye in children with retinoblastoma.[21]

Genetic counseling for retinoblastoma

The most accurate way to predict who in a family will develop retinoblastoma is to test them for the precise *RB1* mutant allele found in the proband. In the absence of precise knowledge of the *RB1* mutant alleles in tumor or blood, the empiric risk for the relatives of retinoblastoma patients to be affected can be estimated.[22] Offspring of patients with a family history of retinoblastoma or bilateral tumors have a 50% risk of inheriting the mutant allele and a 45% risk of developing retinoblastoma, due to incomplete penetrance related to "weak" *RB1* mutations. When two affected children are born to apparently normal parents, one parent must be carrying

but not expressing the mutant allele. Many such individuals are now shown to be mosaic for an *RB1* mutation.[13] Hence, there is also a 45% risk that any subsequent child born will develop retinoblastoma. The risk that other relatives have inherited the mutant allele depends on the number of intervening "apparently normal" individuals, each of whom have a 10% chance of carrying but not expressing the mutant allele. The risk falls by a factor of 0.1 for each intervening unaffected generation. Since 15% of patients with unilateral retinoblastoma have a germinal mutation, the offspring of individuals with unilateral retinoblastoma have a 7.5% risk of carrying the abnormal gene. The probability of other relatives developing retinoblastoma falls by a factor of 0.1 for each intervening unaffected generation.[22]

Infants born with a risk of developing retinoblastoma need to be examined immediately after birth and then at regular intervals to detect early tumors that can be treated to obtain the best visual result (see Fig. 43.1). Infants proven to carry the family's *RB1* mutant allele can be delivered at early-term gestational age, to optimize the chance of keeping good vision with minimally invasive therapy. Examination of the retina starts at birth, and continues at frequent intervals depending on the child's risk. Up to 3 months of age, examination may be done without general anesthetic, greatly facilitated by the wide-angle retinal camera on video mode. After 3 months, anesthetic is necessary to get an accurate view of the retina to detect tiny tumors up to the ora serrata. As soon as a tumor is documented, anesthetic is required to initiate treatment.

Timely and sensitive molecular diagnosis of *RB1* mutations has a strong positive effect on quality of outcomes: early treatment of retinoblastoma achieves lower risks and better health outcomes, allows families to make informed family-planning decisions, and costs less than conventional surveillance.[8,23] The savings when at-risk children avoid repeated examinations substantially exceeds the one-time cost of molecular testing. Moreover, health care savings continue to accrue as succeeding generations avoid the unnecessary examinations and often do not need molecular analysis or clinical surveillance, because their parents do not carry the family's mutant allele.

The *RB1* mutations usually result in unstable or absent protein. Such mutations show high penetrance (>95% of offspring affected) and expressivity (average of seven tumors per child). More uncommon *RB1* mutations cause lower penetrance and expressivity[23]: "in frame" deletions or insertions that result in a stable but defective pRB[24]; promoter mutations that result in a reduced amount of otherwise normal protein[23]; and splice mutations that may be additionally altered by unlinked "modifier genes".[25]

When a somatic *RB1* mutation occurs after embryo development has begun, the *RB1* mutation is present in only some cell lines distributed throughout the body. If the germline cells are involved, the mutation can be inherited by the offspring.[13]

Presentation

The majority of children with retinoblastoma without a family history are first noticed because of leukocoria, often detected on a digital image of the child (Table 43.1).[26,27] Parents observe an odd appearance in their child's eye. Too often, primary health care personnel are unaware of the importance of what the parents are saying and diagnosis is delayed. Awareness of the dangers underlying the parent's words will encourage health care professionals to respond to a parent's description of a "cat's eye reflex" by referring the child for full investigation of the eyes (Figs 43.6–43.8).

Table 43.1 Presenting symptoms and signs of retinoblastoma[26]

Sign/symptom	Percentage
White reflex	56%
Strabismus	20%
Glaucoma	7%
Poor vision	5%
Routine examination	3%
Orbital cellulitis	3%
Unilateral mydriasis	2%
Heterochromia iris	1%
Hyphema	1%
Other	2%

From Ellsworth RM. The practical management of retinoblastoma. Trans Am Ophthalmol Soc 1969; 67: 462–534.

Retinoblastoma families and support groups have embarked upon awareness campaigns to educate the lay public on the importance of a "white pupil" (see Fig. 43.6). Digital images of the baby with retinoblastoma frequently show a white pupil, "photoleukocoria," in contrast to the red eye reflex of the flash picture of a normal eye.[27] Although retinoblastoma is the most important and dangerous condition to cause leukocoria, various conditions also show unusual appearance on flash images, such as congenital cataract, toxocariasis, persistent fetal vasculature (PFV), cicatricial retinopathy of prematurity, myelinated nerve fibers, optic nerve coloboma, high myopia, astigmatism, and normal optic nerves when the camera angle is directed at the optic nerve.[28]

The second most common presenting sign of retinoblastoma is strabismus (esotropia or exotropia).[26] The red reflex test should be applied to any child with strabismus or suspected strabismus, with prompt, urgent referral from the primary health level to an ophthalmologist if the red reflex test is abnormal.[2] Other presenting symptoms and signs (see Table 43.1) include a painful red eye (due to glaucoma) (Fig. 43.9), orbital cellulitis secondary to extensive necrosis of the intraocular tumor (Fig. 43.10),[29] unilateral mydriasis, heterochromia, hyphema, hypopyon, uveitis, and "searching" nystagmus (due to blindness from bilateral macular involvement).[26] In countries with limited medical services, many children present with extensive unilateral or bilateral proptosis with orbital extension and/or metastatic disease due to delayed access to care (Fig. 43.11).

Screening of the retina for tumors in babies and children who are relatives of patients with retinoblastoma, before any signs are noted will enable early treatment and better outcomes. Genetic testing for the family's precise mutant *RB1* allele (see Fig. 43.1) can identify those at risk, to initiate treatment early when the tumors are small and curable by laser therapy alone, or with short cycles of local or systemic chemotherapy in order to obtain the best visual outcome. Family members shown to

not carry the mutant allele are free of the expense of clinical surveillance.[8]

Diagnosis

The initial examination of the child presenting as possible retinoblastoma will provide a short-list of differential diagnoses, including Coats disease (Fig. 43.12), persistent fetal vasculature, toxocara (Fig. 43.13), medullo-epithelioma (Fig. 43.14), and others (Box 43.1).[26] Referral of a child with possible retinoblastoma is urgent, generally requiring examination within 1 week.[2]

Ultrasound is a readily available tool to confirm the diagnosis, with the demonstration of a calcified mass in the eye with leukocoria, and also to check a "normal" other eye for possible tumor. To rule out trilateral retinoblastoma and evaluate the optic nerve, MRI is now standard. The whole multidisciplinary team should be aware of the patient since each will play a role throughout the course of care.

Examination under anesthesia

Full assessment of the eye with retinoblastoma, including anterior segment examination and complete fundus examination, requires examination under anesthesia (EUA). The pupils must be widely dilated and scleral depression used to visualize the retina to the ora serrata. Retinoblastoma appears as a creamy white mass (Figs 43.15 and 43.16) projecting into the vitreous with large irregular blood vessels running on the surface and penetrating the tumor. Hemorrhage may be present on the tumor surface. Spheres of tumor cells in

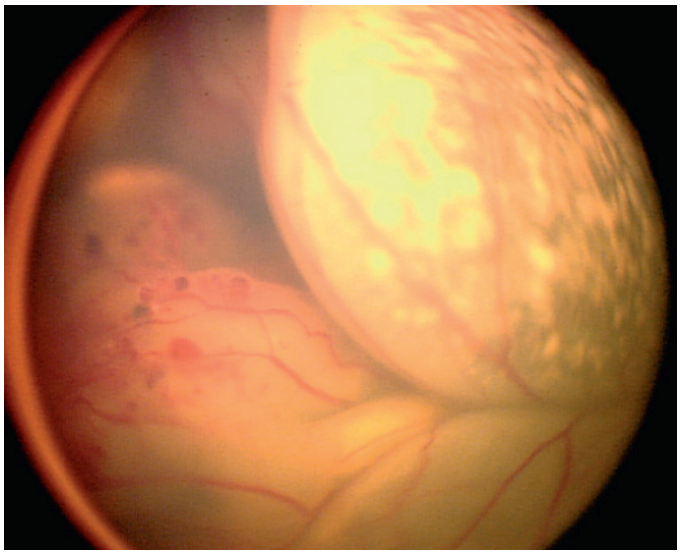

Fig. 43.12 Coats disease. Presenting with leukocoria, with a yellow appearance (xanthocoria), not white like retinoblastoma, total retinal detachment, and the characteristic aneurysmal vascular malformations in the peripheral retina.

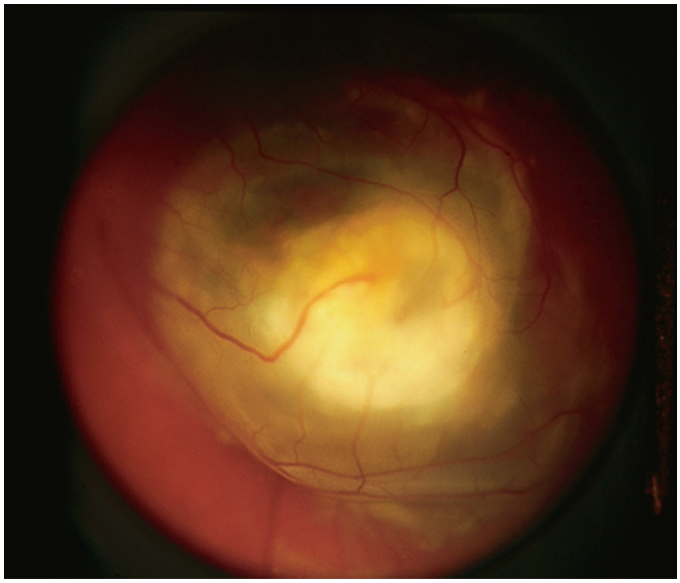

Fig. 43.13 Solitary toxocara granuloma in the macular, with a cilioretinal arteriole, masquerading as a retinoblastoma.

the vitreous ("seeding") are pathognomonic of retinoblastoma (see Figs 43.7 and 43.15). Seeds morphologically can be in the form of dust, spheres, or clouds, and may also lie in the subretinal space, and in advanced cases extend into the anterior chamber.[30] Tumors surrounded by a halo of proliferating retinal pigment epithelium may be slow growing and have a retinoma component.[15] Calcification within retinoblastoma is common and resembles "cottage cheese" (Fig. 43.17). Such tumors leave no doubt as to the diagnosis of retinoblastoma.

Less commonly, retinoblastoma presents as an avascular white mass in the periphery of the retina. The tumor may be obscured by vitreous opacity or extensive retinal detachment (see Fig. 43.3). Calcification of a mass shown on ultrasound, formerly by CT (see Figs 43.3 and 43.10) and MRI (see Figs 43.7 and 43.8), may be critical in establishing the diagnosis of retinoblastoma.

The presence of tumors in the second eye confirms the diagnosis of heritable, bilateral retinoblastoma. If no tumors are seen on clinical exam, the second eye cannot be assured to be normal until examined under anesthetic.

Unusual presentations such as heterochromia, hypopyon (see Fig. 43.11), uveitis, or orbital cellulitis may delay and

mask the diagnosis of retinoblastoma. It is important that retinoblastoma is considered an important differential diagnosis, which can be lethal with delay. Diffusely infiltrating retinoblastoma is uncommon, and can masquerade as uveitis. Since there is no solid, calcified tumor mass or retinal detachment, diagnosis is difficult.

When the inner limiting membrane of the retina breaks, "seeds" float in the vitreous cavity, where they are hypoxic, relatively resistant to therapy, and cannot be treated by laser or cryotherapy. When the seeds fall onto the retinal surface, they can attach and grow (see Fig. 43.15). If noticed early they can be successfully treated with laser and cryotherapy.

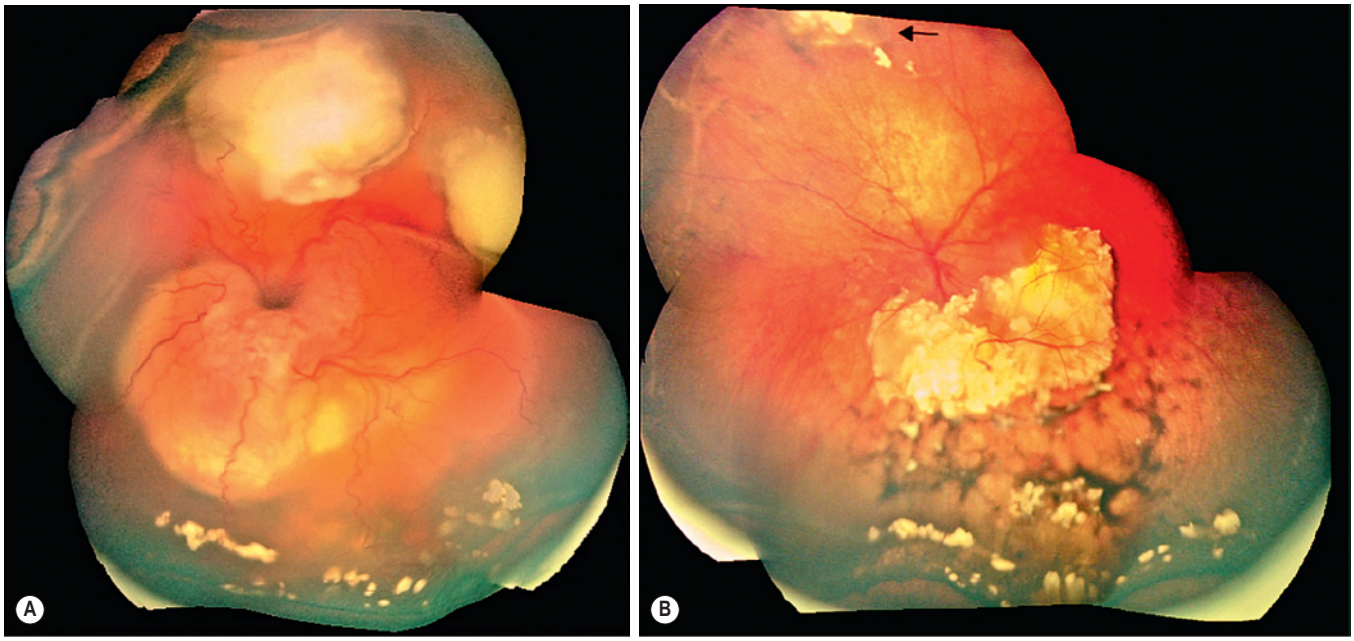

Fig. 43.17 Collage of wide-angle retinal images of the whole retina. The ora serrata is visualized for 360° by scleral depression. (A) Left eye at diagnosis of child with bilateral multifocal exophytic IIRC[33] Group D retinoblastoma, no family history, and a "null" *RB1* mutation (heterozygous deletion of exons 18–23) in blood. (B) Excellent regression after 3 of 7 cycles of CEV (carboplatin, etoposide, and vincristine) with cyclosporin A chemotherapy, with arrow indicating residual tumor treated by laser. Similar appearance of residual tumor and tented retina near the macula was not treated to optimize vision and has not changed over 1 year off treatment. This child had excellent response in both IIRC Group D eyes. *(RetCam images and collage by Cynthia VandenHoven.)*

Bone marrow aspiration and lumbar puncture to screen for metastatic disease are performed only when there is a suggestion of extraocular extension and can be performed later if high-risk pathologic features are discovered on the enucleated eye.

Images[31] for retinoblastoma management

The wide-angle retinal camera provides wide-field imaging of the retina and anterior segment, including the anterior chamber angle (Figs 43.1, 43.7, 43.9, 43.15, 43.17–43.20).[32] Some small retinoblastomas, obscuring the clarity of the choroidal vessels, and vitreous seeds, may be better noted by imaging than with indirect ophthalmoscopy (see Figs 43.1 and 43.20). Sequential images are useful to determine if the tumors are growing or regressing.

Digital fluorescein angiography can assess vascularity, residual tumor activity, and recurrences within laser scars (see Fig. 43.1). Islands of ischemic retina may complicate focal laser and cryotherapy leading to neovascularization that can be clearly distinguished from tumor by fluorescein angiography; prophylactic panretinal photocoagulation can block the stimulus for ischemic angiogenesis, whereas direct early treatment may control tumor recurrence.

Ultrasound biomicroscopy is the only way to detect disease anterior to the ora serrata in the ciliary body, behind iris, and touching lens (see Figs. 43.7 and 43.9). These parts of the eye cannot be viewed by indirect ophthalmoscopy, digital imaging, or conventional ultrasonography. It is critical to detect anterior disease (International Intraocular Retinoblastoma Classification [IIRC][33] Group E), which requires immediate enucleation, since it is not possible to deliver accurate focal therapy to the anterior part of the eye.

Optical coherence tomography (OCT) at the time of EUA may find invisible tumors, or confirm a suspicious retinal spot.[32,34] The smallest tumors appear to emerge in the inner nuclear layer on OCT, in the visually critical posterior pole of the eye in infants at risk (i.e. they carry a mutant *RB1* allele) (Fig. 43.21). OCT is also useful to monitor response to laser therapy, identify edge recurrences (Fig. 43.22), localize precisely sensitive structures such as the fovea for treatment planning, and identify secondary pathologies such as cystoid macular edema that may affect visual prognosis.

The survival of patients is normal if retinoblastoma remains intraocular (96% of cases), but cure of extraocular retinoblastoma is very difficult. Biopsy of retinoblastoma is contraindicated due to the risk for tumor spread outside the eye.

MRI of the brain (see Figs 43.7 and 43.8) and orbits[35] is essential in assessment of every child at presentation to ensure the diagnosis, assess potential optic nerve involvement and the possibility of scleral invasion,[35,36] the extent of suspected extraocular involvement, and to detect possible intracranial tumor (trilateral retinoblastoma).

Treatment

Optimal treatment of retinoblastoma depends on collaboration between all those involved in the care of the child, especially the parents. Specialized centers with inter-professional teams have developed expertise, resources, and equipment, and specific treatment protocols that are gradually gaining an evidence base. Global mapping of centers of excellence in retinoblastoma care now assists parent and caregivers to find expert care (http://www.1rbw.org) (Fig. 43.23). Retinoblastoma

is too uncommon for busy ophthalmologists and oncologists in non-specialized units to acquire the expertise necessary to optimize outcomes for the children and their families. Overall outcomes will improve over time when each affected child is treated systematically on carefully defined protocols, such that the knowledge gained can be used in the design of more effective future protocols.

Classification

Optimized care and outcome for intraocular retinoblastoma balances the morbidity of treatment with the likelihood to cure the cancer. Classification of cancer severity/extent is the standard way to categorize eyes/patients best suited to particular therapies most likely to succeed, based on current evidence.

The Reese–Ellsworth (R-E) classification was devised to predict prognosis when intraocular retinoblastoma was treated with external beam radiotherapy.[37] Since radiotherapy is no longer a primary treatment for retinoblastoma, due to the high risk of radiation-induced second cancers, the International Intraocular Retinoblastoma Classification (IIRC)[33] (Box 43.2) was developed to predict outcomes from current therapies (predominantly chemotherapy and focal therapy, with radiation as a salvage modality for refractory recurrence) (see Figs 43.1, 43.3, 43.4, 43.7, 43.10, 43.16, 43.17, 43.19, 43.24, and 43.25).[33] However, a second version of this classification[38] results in the safely treatable eyes being indistinguishable from eyes with imminent risk of, or actual, extraocular extension, resulting in un-interpretable data in the literature, and danger to children since the features of any eye appropriate for a specific treatment are not clear.[39] The TNM cancer staging system has been developed for all types of cancer, including retinoblastoma.[40] The two eyes are each scored for clinical intraocular disease (cTNM) (see Box 43.2) and pathology (pTNM). The stage of the worst eye, or extraocular disease, determines the whole patient cTNM stage. At diagnosis, it is valuable to record all three classifications: the R-E and IIRC[33] groups and the TNM stage. Major journals now request the TNM stage for publications.

The eCancerCare^{RETINOBLASTOMA} (eCC^{RB})[41,42] is a retinoblastoma-specific secure, online database in which point-of-care clinical data is recorded and used as a summary of the retinoblastoma-specific clinical care. Demographics, presenting symptoms and signs, medical history, treatments, retinal drawings, and photographic images of tumors are accessed through the Disease-specific ePatient Clinical Timeline (DePICT) (Fig. 43.26). The presenting clinical details are entered into eCC^{RB} at diagnosis, and the IIRC eye classification and TNM staging are automatically generated.

Enucleation

Enucleation is an excellent way to cure retinoblastoma confined to the eye. Immediate enucleation is indicated for all IIRC[33] Group E eyes (see Figs 43.15 and 43.19). A trial of chemotherapy (whether systemic or intra-arterial) prior to enucleation is very dangerous for IIRC[33] Group E since a good intraocular response creates a sense of false security and high-risk pathologic features endangering the child's

Box 43.2

International intraocular retinoblastoma classification[33]

Group A: Small intraretinal tumors away from foveola and disc

- Tumor ≤3 mm in diameter, located >3 mm from the fovea and >1.5 mm from the optic disc

Group B: All remaining discrete tumors confined to the retina

- Tumor >3 mm in diameter, located <3 mm from the fovea and or <1.5 mm from the optic disc with or without subretinal fluid less than 3 mm from the tumor with no subretinal seeding

Group C: Discrete local disease with minimal subretinal or vitreous seeding

- Tumor(s) with local fine vitreous or subretinal seeding, present or past, less than 3 mm (2 DD) from the tumor and or subretinal fluid, present or past, involving up to ¼ retina

Group D: Diffuse disease with significant vitreous or subretinal seeding

- Tumor(s) with diffuse vitreous or subretinal seeding, present or past, more than 3 mm (2 DD) from the tumor and or subretinal fluid, present or past, involving up to total retinal detachment
- Diffuse seeds may include "greasy" vitreous seeds, avascular vitreous tumor masses, subretinal plaques, or tumor nodules

Group E: Presence of any one or more of these poor prognosis features

- Tumor touching the lens
- Neovascular glaucoma
- Tumor anterior to anterior vitreous face involving ciliary body or anterior segment
- Diffuse infiltrating retinoblastoma
- Opaque media from hemorrhage
- Tumor necrosis with aseptic orbital cellulitis
- Phthisis bulbi

life are unrecognized and untreated.[43] When only one eye is involved, or when the other eye is Group A treatable with only focal therapy, a Group D eye may also be enucleated to avoid invasive therapies. On the other hand, unilateral Group C eyes with potential for useful vision may be suggested for curative therapy. A frank discussion with the family is essential as the treatment journey to save an eye with anticipated poor vision and a normal other eye carries significant socioeconomic and psychologic impacts for the families.[44] Enucleation is also indicated for recurrent tumor that has failed other treatment modalities; prolonged treatments risk metastasis and death, when up-front enucleation would have cured the unilaterally affected child.

Bilateral retinoblastoma commonly presents with one eye full of tumor, with smaller tumors in the fellow eye. Both eyes may be primarily treated with chemotherapy for Groups B, C, or D disease (see Figs 43.16 and 43.20).

If both eyes are Group E, bilateral enucleation may be indicated, since attempts to save severely involved Group E eyes puts the child's life in jeopardy from difficult-to-treat, poor-prognosis systemic metastasis.[43] Even if Group E eyes can be cured, vision is very poor in such severely damaged eyes. The short- and long-term morbidities of systemic or intra-arterial chemotherapy or radiation may not be in the best interest of a child with bilateral Group E eyes.

Enucleation should be performed with great care so as not to penetrate the eye and spill tumor. A long optic nerve (8–12 mm) is important to ensure that the surgical margin is tumor-free. For unilaterally affected children, the tumor is important for *RB1* mutation studies, since this is the best way to determine whether the child has heritable or non-heritable retinoblastoma (see Fig. 43.4).

Although expensive porous implants have been widely used to give good movement of the prosthesis, they frequently acquire a deep chronic infection that is challenging to treat. A randomized study showed significantly better movement of the prosthetic eye with less costly polymethyl methacrylate implants and the myoconjunctival technique compared to porous implants with muscle imbrication.[45] In the myoconjunctival technique, the four recti muscles are sutured to the conjunctival fornices rather than in front of the implant, where they act directly on the rims of the prosthesis. Immediately at the time of surgery, a "stock" prosthetic eye can be used as a conformer, so that when the patch is removed 24–48 hours later, the child looks quite normal, a psychological benefit to child and family[46] (see Fig. 43.4).

Histopathology

Retinoblastomas are poorly differentiated malignant neuroblastic tumors, composed of cells with large hyperchromatic nuclei and scanty cytoplasm. Mitotic figures are common. In some tumors, differentiated cells form typical Flexner–Wintersteiner rosettes[47,48] in which columnar cells are uniformly arranged in spheres around a lumen containing hyaluronic acid. Homer–Wright rosettes also occur, characteristic of many neuronal tumors, with centrally located neurofibrils. Benign, non-proliferative retinoma shows the fleurette pattern of partial differentiation,[49] although these premalignant retinomas have already lost both copies of the *RB1* gene.[11]

Retinoblastoma tumors often outgrow their blood supply leading to cell necrosis. True spontaneous regression of retinoblastoma is rare, but is probably due to extensive tumor necrosis and central retinal artery occlusion, resulting in phthisis bulbi.[15,29] Calcification is almost pathognomonic of retinoblastoma, but its etiology is not known.

The most important component of histopathology of eyes enucleated for retinoblastoma is accurate assessment of risk that the tumor has become extraocular and life threatening. The pTNM for retinoblastoma provides this evaluation (see Box 43.2).[40] The most common routes of dissemination are through the optic nerve to brain and hematogenous spread from invasion of choroid and/or sclera, usually to bone marrow. Post-enucleation adjuvant chemotherapy may still cure, if given when high risk is recognized, prior to clinical presentation of extraocular retinoblastoma.[50]

If retinoblastoma metastasizes, it generally becomes evident within 18 months of the last active tumor in the eye, and is rare beyond 3 years without evidence of ongoing tumor activity in the eye.[51] The most common and dangerous route of metastasis of retinoblastoma is direct extension into the optic nerve. The tumor can grow toward the optic chiasm and beyond, or into the subarachnoid space with leptomeningeal involvement (see Fig. 43.8). Direct extension via the choroidal vessels, or spread along the ciliary vessels and nerves into the orbit, may occur in advanced cases (see Fig. 43.11).[52,53] Systemic metastases may occur via the

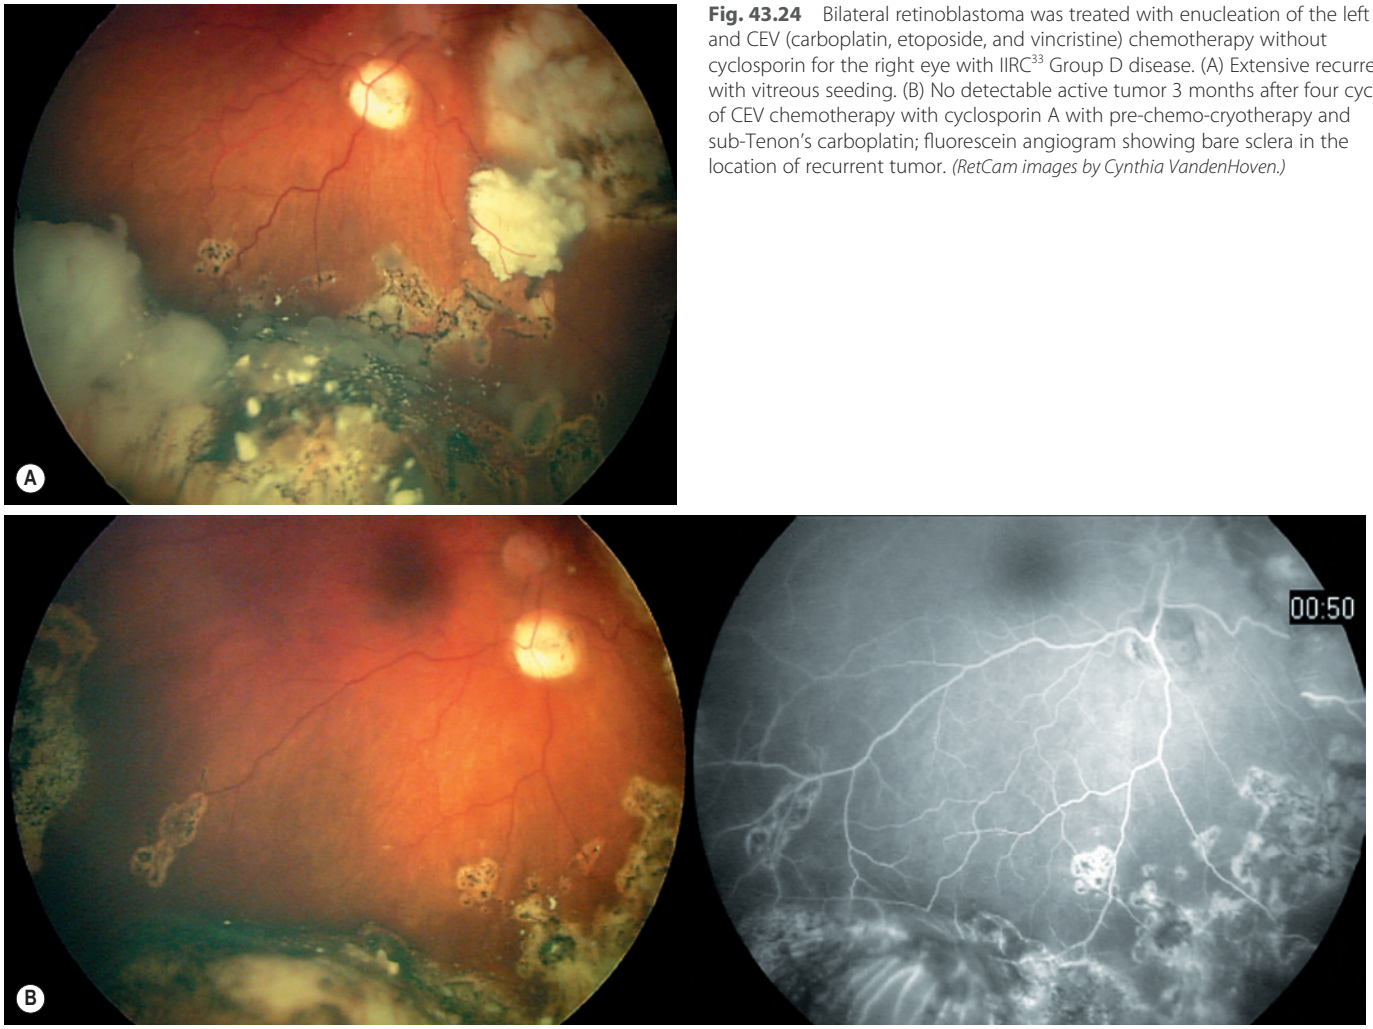

Fig. 43.24 Bilateral retinoblastoma was treated with enucleation of the left eye and CEV (carboplatin, etoposide, and vincristine) chemotherapy without cyclosporin for the right eye with IIRC[33] Group D disease. (A) Extensive recurrence with vitreous seeding. (B) No detectable active tumor 3 months after four cycles of CEV chemotherapy with cyclosporin A with pre-chemo-cryotherapy and sub-Tenon's carboplatin; fluorescein angiogram showing bare sclera in the location of recurrent tumor. *(RetCam images by Cynthia VandenHoven.)*

choroidal circulation or aqueous drainage, particularly if glaucoma is present. Bone marrow is the preferred site for retinoblastoma metastasis, and only terminally are bone, lymph node, and liver involved. Lung metastases are rare and occur late.

Chemotherapy

Systemic chemotherapy became the standard primary treatment for IIRC[33] Groups B, C, and D, after the lethal risk of second radiation-induced cancers became recognized.[19] Following an initial response to the first few cycles of chemotherapy, focal therapy with cryotherapy or laser therapy is initiated to destroy residual or recurrent tumor[54] (see Figs 43.1, 43.18, and 43.24). The most commonly used drugs are carboplatin, etoposide, and vincristine (CEV) given every 3 weeks through a central venous access line.[55]

The Toronto Multicenter Clinical Trial is studying the efficacy and toxicity of short 3-hour infusions of high-dose cyclosporin A (achieving high cyclosporin peak levels of >20,000 ng/ml for a very short time) to block P-glycoprotein that mediates multidrug resistance by acting as a plasma membrane drug-efflux pump, which is commonly overexpressed in retinoblastoma tumors.[56]

Increased intraocular concentrations of the chemotherapy drugs (e.g. carboplatin) was experimentally demonstrated by concurrent high-dose cyclosporin, possibly by inhibiting the P-glycoprotein expressed in the blood–eye barrier, and a single-freeze cryotherapy ("pre-chemo-cryotherapy") in peripheral retina to induce a small serous effusion.[57]

Following a good response to chemotherapy, consolidation is achieved by frequent (≈3–4 weeks) focal cryotherapy and laser therapy to destroy any surviving tumor cells (see Fig. 43.19). With high-dose CEV chemotherapy and focal therapy consolidation achieved 47% salvage of IIRC[33] Group D eyes without using radiation[58] (see Figs 43.3, 43.17, 43.24, and 43.25) and better results with less severely affected eyes. Note that the alternate definition of Group D/E eyes[38] inflates the success rate for treatment so studies cannot be compared.[39]

Unlike radiation, systemic chemotherapy is not associated with long-term cosmetic deformity of the orbit and upper face, radiation-induced cataracts, or ocular complications. Although chemotherapy is used in order to avoid the large risk of induction of a second primary tumor by radiation (estimated to be as high as 51% risk at 50-year follow-up),[59,60] etoposide also carries a small risk of induction of a specific type of acute myelogenous leukemia.[61] The cumulative dosage

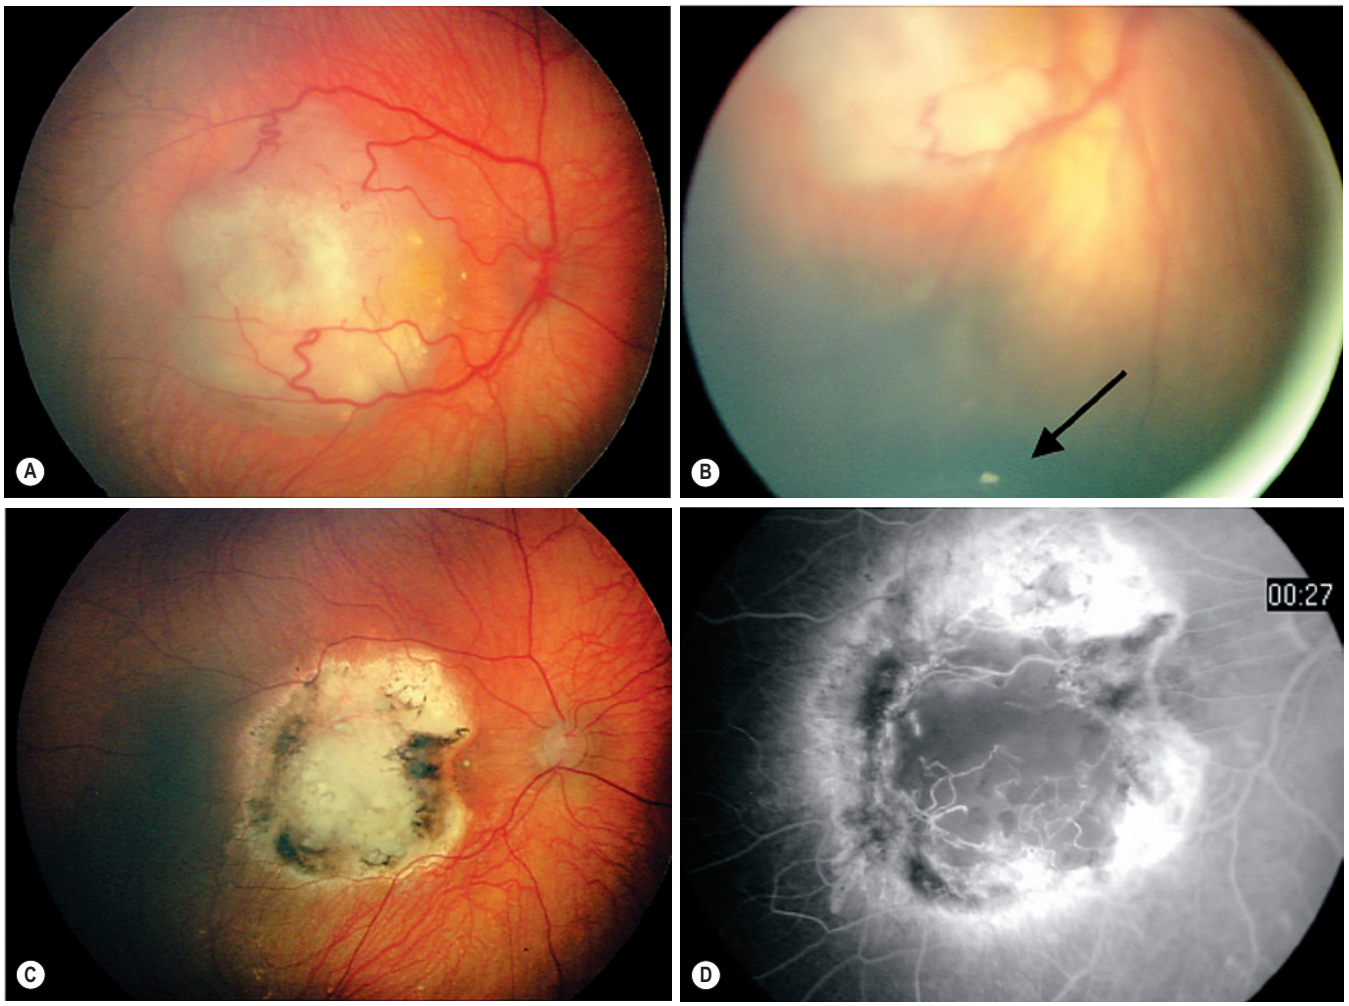

Fig. 43.25 (A) Unilateral retinoblastoma at diagnosis. (B) The subretinal seed (arrow) inferiorly at the 6 o'clock position places this eye in the IIRC[33] Group D (subretinal seeding more than 3 mm from the tumor). (C) Response to chemotherapy (four cycles of CEV [carboplatin, etoposide, and vincristine] with high-dose cyclosporin) and laser and cryotherapy. (D) Fluorescein angiography shows active tumor vessels in the scar, which were successfully ablated by 532-nm and 810-nm laser treatments. *(RetCam® images by Leslie MacKeen and Cynthia VandenHoven.)*

of etoposide used for treating retinoblastoma is less than the doses incurring a 2–3% risk of leukemia.[62]

Paraocular chemotherapy

To avoid systemic chemotherapy, carboplatin and topotecan have been given subconjunctivally to treat retinoblastoma. Instillation of carboplatin into Tenon's space has significant local orbital toxicity.[63] Topotecan given paraocularly in a fibrin clot at the usual systemic dose has no local orbital toxicity and no bone marrow toxicity, but is useful only as an adjunct to other therapies for small tumors.[64]

Cryotherapy

Cryotherapy is used for small anteriorly placed tumors (IIRC[33] Groups A and B eyes), or more posterior tumors when visual damage will not result.[65] Since the tumor cells are killed when they thaw, a triple freeze–thaw technique is used, with a full minute for thawing between the successive freezes (see Figs 43.18 and 43.20). Cryotherapy is repeated at several EUAs 4 weeks apart, until no residual active tumor remains. Cryotherapy may be used as a primary procedure for small tumors, or to treat residual or recurrent tumors. When moderately sized tumors are treated with cryotherapy, a laser barrier placed posterior to the tumor may protect the retina from detachment by the serous exudate of the acute freeze (see Fig. 43.18).

Laser

Laser coagulation is used for small tumors (IIRC[33] Groups A and B eyes) (see Fig. 43.1), for tumors that have been initially shrunk by chemotherapy, or for recurrences following chemotherapy. Small tumors (IIRC[33] Group A eyes) behind the equator are treated by encircling the tumor with a double row of contiguous laser burns. The small avascular tumor can be directly coagulated, starting with power/duration settings that barely blanch or opacify the tumor, and gradually increasing the power to make the tumor turn opaque white. Larger or visually threatening tumors (IIRC[33] Groups B and C eyes) treated first with chemotherapy and recurrent tumors after cessation of chemotherapy are treated with laser coagulation. For IIRC[33] Group D eyes, laser is used only after a good response has occurred with chemotherapy, to eliminate recurrence before the tumor has a chance to regrow (see Fig. 43.17).

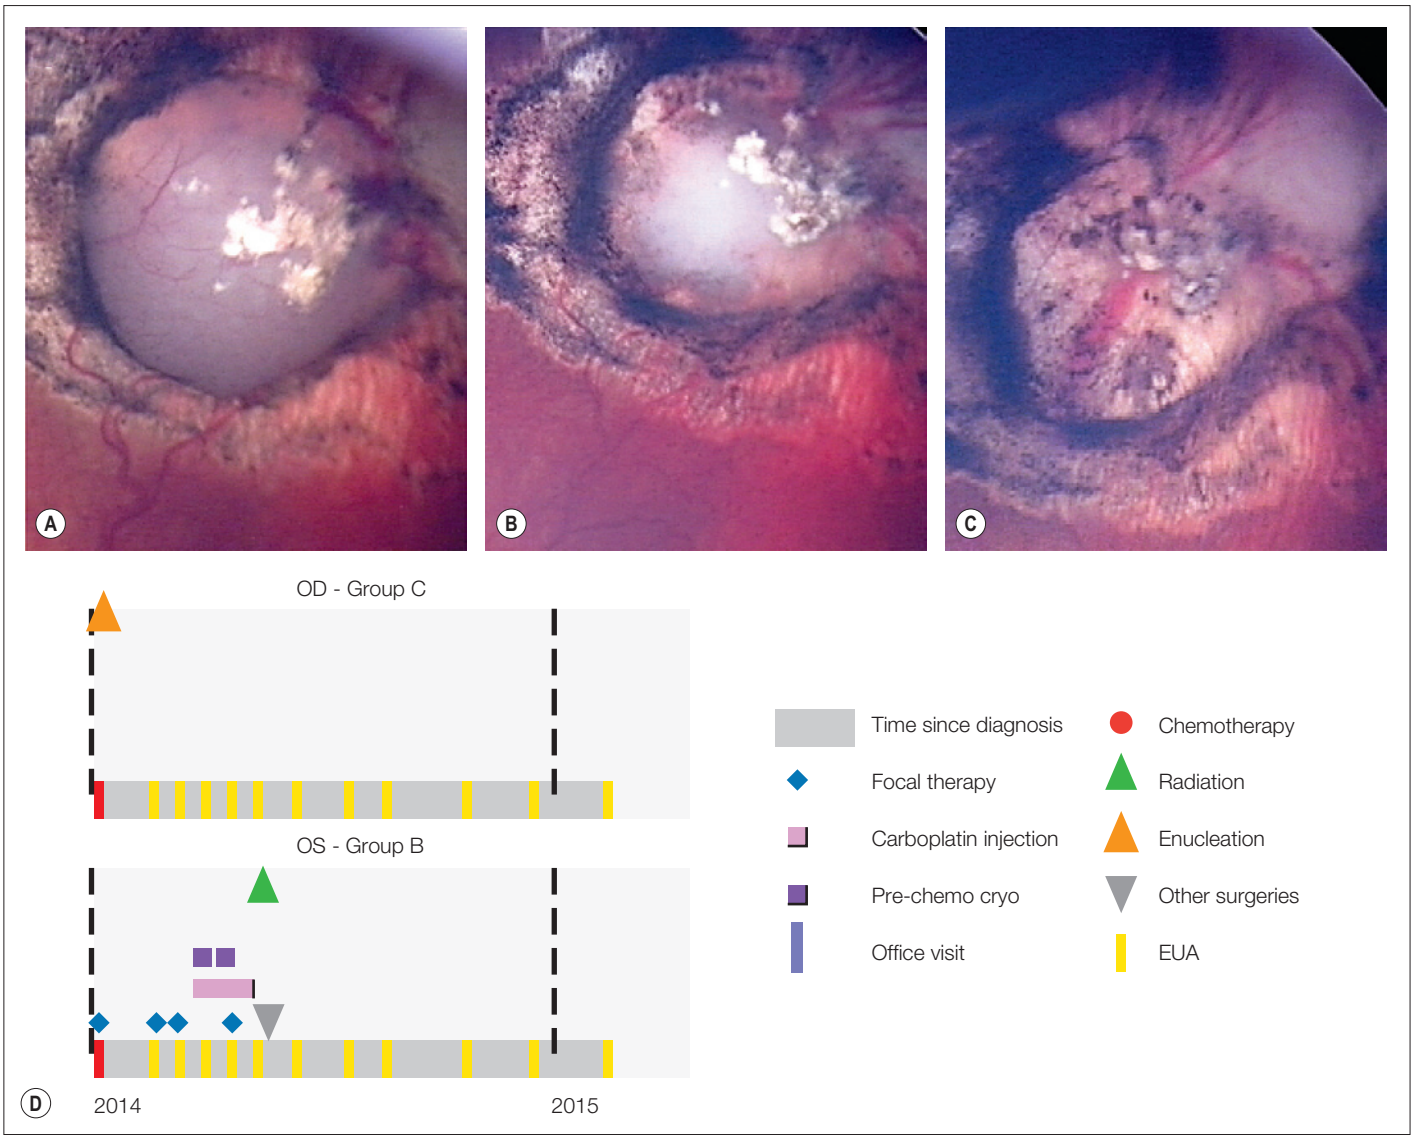

Fig. 43.26 Brachytherapy. (A) Tumor refractory to laser and cryotherapy was treated with a radioactive ^{125}I plaque applied on the sclera to deliver 40 Gy to the tumor apex over 7 days. (B) Tumor responded dramatically by the day of plaque removal. (C) A flat scar 1 month after removal of the plaque, which did not subsequently change. (D) eCancerCare$^{\text{RETINOBLASTOMA}}$ (eCC$^{\text{RB}}$) timeline describing the overall retinoblastoma care of this child. *(RetCam images by Leslie MacKeen and Cynthia VandenHoven.)*

The diode 810-nm laser is most widely available but causes more scarring and traction that may progress than the green frequency-doubled YAG at 532-nm. Thermotherapy has been promoted widely, using a 810-nm laser to gently heat tumors over a long period of time.[66,67] For IIRC[33] Group A small tumors, 532-nm is effective without drifting of the scars. Infrared lasers (diode 810-nm or 1064-nm-long duration YAG) can be applied after chemotherapy to larger, thicker tumors with good effect. With all lasers, it is important *not* to use too much power at any one treatment, and retreat at frequent intervals until only flat scars remain. Fluorescein angiography is useful for identifying early potential spots of recurrences in a laser scar (see Fig. 43.1).

Focal irradiation

Solitary tumors less than 15 mm in diameter that are not adjacent to the disc or macula may be treated with an episcleral radioactive plaque, iodine-125 (^{125}I), or ruthenium-106 (^{106}Ru)[68] (Fig. 43.26). Plaques are useful to treat single recurrences after chemotherapy or whole-eye radiation has failed. Under general anesthesia, the tumor is localized, and the plaque is sutured to the sclera apposed to the tumor and left *in situ* until the prescribed dose of radiation has been delivered to the apex of the tumor. A second course of radiation to the whole eye (external beam radiation) is prohibited because it will lead to severe radiation retinopathy and/or optic neuropathy, and potential increase in the already-high risk of late induced cancers.

External beam irradiation

Radiation was the first approach that cured intraocular retinoblastoma, saving many eyes with useful vision, but with severe consequences of inducing second cancers and severe cosmetic deformities. Most commonly, there is significant

calcification ("cottage cheese-like") or a combination of calcification and translucent residual tumor after radiation. The risk of second primary cancers within the radiation field in children with a germline *RB1* mutation is significant; most children die of these induced cancers[19,69] (see Fig. 43.2). The risk may be greatest when infants are irradiated under 1 year of age.[70] External beam radiotherapy has been used for treatment of recurrences after chemotherapy. However, intra-arterial chemotherapy for treatment of specific recurrent disease is now shown to be more effective with less toxicity than radiation.[71]

Intra-arterial chemotherapy (IAC)

Local treatment of retinoblastoma with chemotherapy is an attractive idea, sparing the child from the complications of systemic drugs. Injection of a chemotherapeutic agent (melphalan) into the carotid artery/ophthalmic artery has been performed for over 20 years in Japan, but the single outcome study is inconclusive about efficacy and safety.[72] Despite lack of clear outcome data, intra-arterial chemotherapy (IAC) has been widely adopted in the last few years because of the predictions that all eyes with retinoblastoma might be saved by this approach. Without formal rigorous follow-up of clinical trials, initial studies were very encouraging. A retrospective study suggests that IAC is most successful as primary therapy for less severely involved eyes.[73] Local side effects, such as third cranial nerve palsy, retinal pigment epithelial changes, and retinal detachment can occur, but external beam radiotherapy or enucleation can be avoided.[74]

However, the use of IA chemotherapy for IIRC[33] Group E retinoblastoma is very dangerous. The IAC results in a sometimes dramatic local shrinking of intraocular tumor, but tumor leaving the eye into the nerve, choroid, and blood remains unacknowledged. As a result, a child may be responding well until an extraocular relapse is identified and the child dies. Such a child might have been cured by enucleation of the IIRC[33] Group E eye with timely adjuvant therapy for high-risk pathologic features. Multiple cases of metastasis following IAC are reported[72,73,75,76] and more are evident on parent blogs that are not yet acknowledged in the medical literature.

Intravitreal chemotherapy

Delivery of the chemotherapy into the vitreous cavity theoretically provides the highest chemotherapeutic drug levels in the vitreous cavity, ideal for treatment of vitreous seeds. The fear of extraocular spread by injection into an eye with active seeds has been set aside by the careful technique for selected eyes with vitreous seeds after control of the source of seeds.[30,77–79] Responses are excellent, potentially solving the most difficult-to-treat problem in eye salvage, vitreous seeds.

Extraocular retinoblastoma

Extraocular retinoblastoma results in a precipitous drop in the prognosis for life (see Fig. 43.11). Until recently, metastatic retinoblastoma was considered fatal. Local orbital recurrence is generally treated with 40–50 Gy orbital radiation and systemic chemotherapy. Metastatic retinoblastoma to bone marrow or other sites may be treated with intensive chemotherapy, with cyclosporin to counter multidrug resistance, and, if remission is attained, supralethal chemotherapy and peripheral stem cell transplantation. Meningeal spread of retinoblastoma is treated additionally with intrathecal and intraventricular chemotherapy via an Ommaya reservoir, with rare cures.[80]

Prophylactic radiation is considered when histopathologic examination of the enucleated globe shows involvement of the cut end of the optic nerve with high risk of orbital recurrence. When marked choroidal invasion and involvement of the optic nerve past the cribriform plate are noted on histopathology (pT3), adjuvant therapy may be advised to treat potential tumor spread beyond the eye. However, tumor into or minimally past the lamina cribrosa may be managed by surveillance with regular MRI, bone marrow, and cerebrospinal fluid examinations, treating only when disease is documented. Otherwise, many children may be treated unnecessarily. Evidence to support these treatment recommendations is pending a multicenter trial of prophylactic treatment for adverse histology.

Children presenting with extensive orbital disease, with proptosis and likely intracranial extension, are now treated first with systemic chemotherapy.[81] After several cycles of chemotherapy, there is often a marked shrinkage of the orbital tumor, and enucleation can be performed. This is generally followed with more chemotherapy and orbit radiation. There is no role today for exenteration in the treatment of retinoblastoma.

Prognosis

With modern methods of diagnosis and treatment, the prognosis for retinoblastoma is excellent. The 3-year survival for both unilateral and bilateral retinoblastoma approaches 96%.[51] More patients with germline *RB1* mutations die of their second primary cancer than from uncontrolled retinoblastoma.[19]

The prognosis for vision is excellent in unilateral retinoblastoma (for the normal eye), but depends on the size and location of the tumors in bilateral cases. Awareness and prompt diagnosis, with good results with chemotherapy and focal therapy, means that bilateral enucleation is now rare. Extra-foveal tumors have a good visual prognosis but, when the macular region is directly involved, the visual results may be poor, despite tumor control. The most important impact on further improving visual outcome for retinoblastoma children lies in the earlier recognition of the presenting signs by the primary caregivers.

Long-term follow-up

Following the initial management and resolution of active tumor, assessment of the response to treatment will require frequent EUAs, especially in the first year following diagnosis with completion of chemotherapy, when recurrence or new tumors are most likely to occur. Regular EUAs will be necessary until the child is old enough to cooperate for a full-dilated eye examination in the clinic, variably at about 3 years of age. Follow-up can then be continued on an outpatient basis. However, children with IIRC[33] Groups C and D eyes may need a much longer follow-up with EUA in order to assess peripheral tumors for recurrence.

Lifelong implications of retinoblastoma

Retinoblastoma patients who carry a mutant *RB1* allele are at risk of other cancers throughout their lives, many years after their initial treatment for retinoblastoma. Anecdotal reports demonstrate that some adults who were treated as children (often by enucleation or radiation) are not aware that they had cancer and have been lost to follow-up. They may, however, present to their local ophthalmologists with ocular and/or orbital problems. It is important that ophthalmologists are aware of the long-term systemic problems associated with retinoblastoma as they may be the only secondary care physician seen by the patient.

Everybody in the Western world has a lifetime risk of approximately 1 in 3 of developing cancer. Patients with an abnormal *RB1* gene reach this risk by the age of about 50 years of age. The non-ocular cancers that have increased incidence include bone and soft tissue sarcomas during adolescence and early adulthood, malignant melanoma, epithelial cancers, bladder, esophagus, and probably breast cancer. These risks are increased significantly by radiation exposure.

All patients with a past history of retinoblastoma should be offered molecular *RB1* gene analysis for counseling with regard to the risk of retinoblastoma in their offspring, and their own increased risk of developing a non-ocular cancer. This is particularly important for the patients with unilateral disease who may carry a mutation of the *RB1* gene and are unaware of this fact. Emphasizing the dangers of known carcinogenic factors such as smoking, radiation, obesity, and excess ultraviolet light is particularly important. As radiation is associated with an increased risk of cancers, routine X-rays and CT scans are not advised.

Likewise, patients who have been treated with chemotherapy and/or radiation will require oncologic follow-up for early detection and appropriate management of possible long-term complications. It is important for retinoblastoma patients to retain contact with their oncologist because of the risk of secondary malignancies, whether sporadic or induced by radiation or chemotherapy. It is also important to ensure that accurate genetic counseling is available to the parents, and to the child when he or she reaches maturity.

Future perspective

Global collaboration and the ability of parents, health care teams, and scientist to communicate through the Internet now sets the stage to optimize care for all children and families who are affected by retinoblastoma. We look to projects such the 1RBW map (http://www.1rbw.org) (see Fig. 43.23) and retinoblastoma registries such as eCancerCare$^{\text{RETINOBLASTOMA}}$ (eCC$^{\text{RB}}$)[41,42] to ultimately perform as a "learning health system" to achieve equity in retinoblastoma management for all children, targeting zero deaths from retinoblastoma by year 2025.

Retinopathy of prematurity (ROP) was first reported by Theodore L. Terry in 1942. This condition, then known as retrolental fibroplasia, is a disorder of the immature retinal vasculature. It was extremely rare before the 1940s. The retinopathy developed after a normal fundus examination at birth. Clinical and experimental evidence supported a toxic effect of oxygen on the immature retinal vasculature, which led to the restriction of oxygen use in preterm neonates.[1] This resulted in a dramatic fall in the incidence of ROP, but even though oxygen plays a central role, many other factors contribute to the pathogenesis. However, despite major advances in our understanding, its identification, and treatment, ROP remains an important disorder as a cause of visual disability, and a consumer of health service resources.

Retinal vascular development

The choroid, which is vascularized by 6 weeks' gestational age (GA) meets the metabolic needs of the retina in early fetal life, but as the retina becomes increasingly complex and metabolically active, this single circulation is insufficient, resulting in a state of physiological retinal hypoxia so generating the stimulation of vascular endothelial growth factor (VEGF) and the development of a retinal circulation. This commences at about 13–14 weeks GA with the centrifugal migration from the optic disc of vascular endothelial cells, microglia, pericytes, and astrocytes. These proliferate, and become aligned into vascular cords that develop lumina and differentiate into capillaries, a process known as vasculogenesis. This is succeeded by angiogenesis in which vessels grow out from existing vessels, remodel, and form a mature retinal vascular network with capillary-free areas. The developing retina responds to excessive or insufficient oxygen by trimming or inducing growth in the microvasculature to match the retina's metabolic requirements.[2]

While oxygen-dependent VEGF plays a critical part in all stages of vascular development, other factors are also involved such as oxygen-independent insulin-like growth factor 1 (IGF-1) and erythropoietin.[3]

Pathogenesis

There are two phases in ROP development and both occur postnatally.

Phase I: decreased retinal vessel growth

Premature birth removes the fetus from a milieu uniquely suited to growth, so not only does it deprive the fetus of maternal nutrition, but also exposes the baby to a harsh environment requiring considerable physiological adaptation and also many potential pathological processes.

The cardiopulmonary adaptations associated with birth and transfer from the fetal environment to room air include PaO_2 rising from <25 mmHg (kPa <3.5) to 80–95 mmHg (kPa 10.5–12.5) within 6 hours. While this has no effect on the fully vascularized retina of the term infant, for the premature infant this so-called physiological hyperoxia causes a VEGF-mediated cessation of retinal vascular development, but may also cause retraction and loss of retinal vessels. Evidence of the former is the location of the ROP lesion. Vasobliteration was observed in the experimental animal over 60 years ago, but not confirmed in the human until very recently; eyes that initially were vascularized into zones II and III exhibited obliteration of formed vessels and regression into zone I following exposure to unblended oxygen.[4]

While the major factor in phase 1 of ROP is oxygen-induced VEGF downregulation and also suppression of hypoxia-induced erythropoietin, also important are deficiencies of several maternal nutrients, which can no longer reach the fetus, now baby.[3] These include growth hormone and IGF-1. IGF-1

controls VEGF activation of the Akt endothelial cell survival pathway and low levels result in reduced survival and growth of vascular endothelial cells – reduced suppression angiogenesis. Another nutrient normally transferred from mother to fetus and consequently deficient following premature birth is ω-3 long chain polyunsaturated fatty acids, which have a role in vascular and neuronal survival and have been shown to prevent ROP in the experimental animal.[3,5]

Phase II: vasoproliferation

In phase I, the retina is rendered hypoxic by hyperoxia-induced VEGF downregulation. The resultant cessation of vessel growth and vessel retraction is replaced in phase II by hypoxia-induced VEGF stimulation for which clinical features are described later.

The postnatal timing of the two ROP phases has attracted some attention and, as discussed below, in general, the timing of the phases is largely determined by postmenstrual age (PMA). However, the abnormal vascularization of phases of ROP occurs within a relatively short timeframe and must be complete for full retinal vascularization within certain confines, as ROP is a postnatal condition and must commence before full vascularization.

Risk or associated factors

The major ROP risk factor is the degree of immaturity as measured by either birth weight or gestational age. ROP may develop in preterm infants who never received oxygen. However, studies have confirmed the relationship between oxygen administration (and transcutaneous levels >80 mmHg) in the first few postnatal weeks and ROP, particularly within the first few weeks after birth.[6,7] A relationship between neonatal hypoxia and ROP has also been suggested.[8] That both hyperoxia and hypoxia may be associated with ROP is not contradictory as both are invoked in its pathogenesis, so explaining the association of recurrent apnea with ROP.

There has been a recent trend to keep babies at lower oxygenation levels. However, recent international randomized controlled trials reported significantly higher mortality and necrotizing enterocolitis in infants targeted to 85–89% SpO_2 compared to those targeted to 91–95% SpO_2, but with more ROP in the latter.[9] This confirms what was understood in the 1970s – that lower oxygen levels reduce the incidence of ROP blindness, but at the expense of reduced survival and higher morbidity. While a safe oxygen level still cannot be precisely given, SpO_2 targets of 85–89% are unsafe in extremely preterm infants. In contrast to oxygen management in the early neonatal period as described above, a meta-analysis concluded that "late" (≥32 weeks PMA) high oxygen was associated with reduced incidence of severe ROP.[10]

Acidosis is a risk factor for ROP, whereas hypercarbia is not; however, the combination of high PCO_2, PaO_2, and low pH in the first 3 days after birth is associated with severe ROP.[11]

It has been reported that mutations in the Wnt signaling pathway,[12] which also encompasses the Norrie's gene and familial exudative vitreoretinopathy, are associated with increased incidence of ROP. However, a recent study does not support this, noting instead an association of severe ROP with low levels of brain-derived neurotrophic factor.[13]

Many factors have been suggested as possible contributors to ROP. Some have been confirmed: male gender, assisted reproductive technology, and White compared to Black race are predictive factors for severe ROP.[14] The following are not independent ROP risk factors: multiple birth, early exposure to light, and hypercarbia. The roles of many other possible factors have not been confirmed or clarified such as: hyperglycemia,[15] inflammation, vitamin E, surfactant, and acidosis. The suggested association between ROP and blood transfusion has not been confirmed.[16]

Recombinant erythropoietin, a cytokine angiogenic factor that regulates fetal erythropoiesis, can be used to treat neonatal anemia, a use that has been reported to increase the risk of ROP; however, this is not borne out by systematic analyses.[17]

Many factors are active simultaneously and differently according to the standard of neonatal care. Thus, the characteristics of babies developing ROP in some countries are different from those in others: larger and more mature infants are at risk in less developed countries, where the unrestricted use of oxygen and sepsis are factors.[18]

Classification

A revision of the 1984 international classification of acute ROP[19] and 1987 expansion to include retinal detachment and sequelae[20] was published in 2005.[21] It maintained four basic parameters to describe ROP morphology including severity, location, extent of disease, and plus disease (Table 44.1), while expanding two concepts: pre-plus disease and aggressive posterior ROP (AP-ROP).

The normal fundus of the extremely premature baby can be difficult to visualize in detail (Figs 44.1 and 44.2). The retinal blood vessels are thin and straight. Later, they increase in caliber and tortuosity, but abnormally so with active ROP.

Severity of disease

The peripheral changes at the leading edge of the developing retinal vessels have been divided into five stages.

Stage 1

A flat gray-white demarcation line separates the vascularized from non-vascularized retina. Often faint, it can be difficult to identify. Retinal vessels run up to the line but do not cross it (Figs 44.3 and 44.4).

Stage 2

The demarcation line has increased in volume and extends out of the plane of the retina (Figs 44.4–44.6). The color of the ridge may be white or pink, and small neovascular tufts may be seen posterior to the ridge. Differentiating stage 1 and early stage 2 is difficult, but usually not prognostically important.

Stage 3

Stage 3 has the features of stage 2, but is characterized by extraretinal neovascularization (Figs 44.6 and 44.7). The new vessels may be continuous with, or disconnected from, the posterior border of the ridge, or extend into the vitreous. The extraretinal neovascularization may extend from the region of the ridge into the vitreous or, typically in more

Table 44.1 International classification of retinopathy of prematurity – revisited (2005)

Severity	
Stage of ROP	Stage 1: demarcation line Stage 2: ridge Stage 3: ridge with extraretinal vascular proliferation Stage 4: subtotal retinal detachment 4A: extrafoveal detachment 4B: foveal detachment Stage 5: total retinal detachment
Aggressive posterior ROP (AP-ROP)	Severe dilation and tortuosity of posterior pole vasculature Innocuous appearance of ROP at junction between vascularized and avascular retina Located in zone I or posterior zone II
Anterior-posterior location	Zone I: retina within a circle centered on the disc with a radius of twice the disc–foveal distance Zone II: a doughnut-shaped area that extends from the edge of zone I to a circle which has a radius of the distance from the disc to the nasal ora serrata Zone III: crescent-shaped retinal area peripheral to zone II
Extent of disease (in clock hours)	30° sectors of ROP along circumference of the vascularized retina
Plus disease	Abnormally dilated and tortuous vessels of the posterior pole (at least two-quadrant involvement required)
Pre-plus disease	Abnormal vascular dilation and tortuosity insufficient for diagnosis of plus disease (at least two-quadrant involvement required)

Adapted from An International Committee for the Classification of Retinopathy of Prematurity. The International Classification of Retinopathy of Prematurity revisited. Arch Ophthalmol 2005. 123: 991–9.

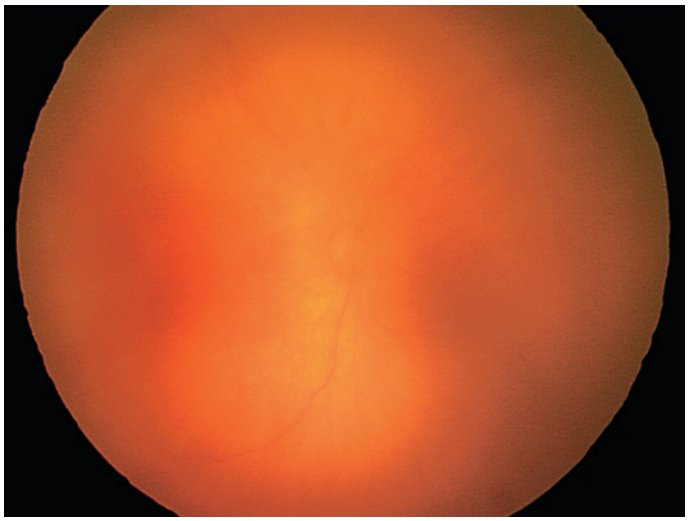

Fig. 44.1 Immature retinal vessels in an extremely immature baby. The view is hazy. Note how thin and straight are the retinal vessels.

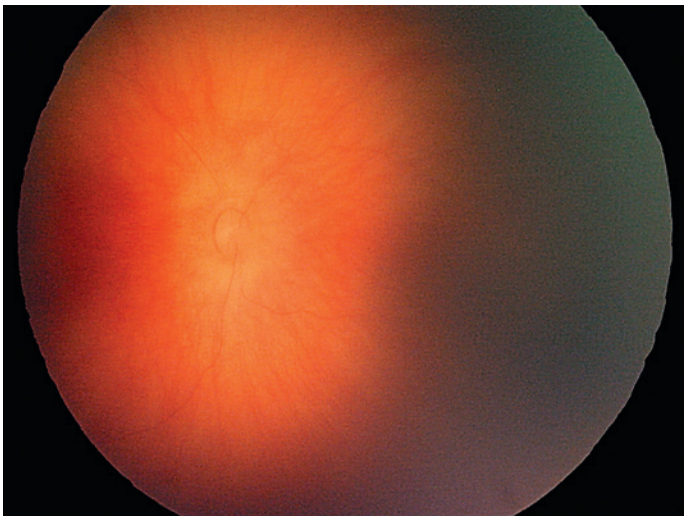

Fig. 44.2 Immature retinal vessels 1 week after image in Fig. 44.1. No retinopathy of prematurity.

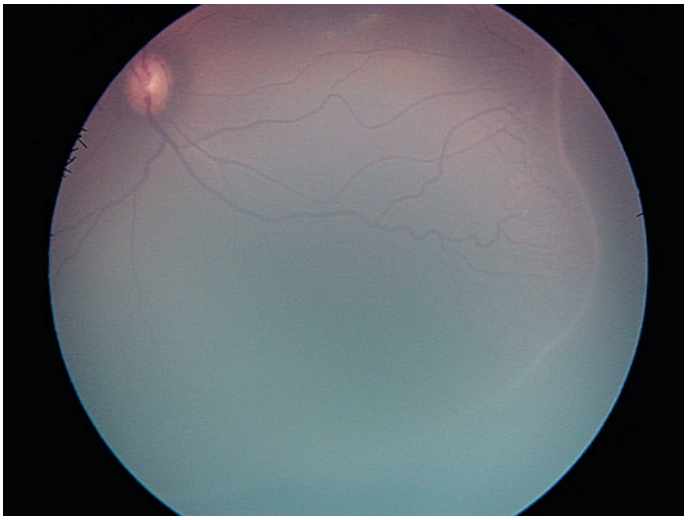

Fig. 44.3 Stage 1 retinopathy of prematurity. Thin line separates vascularized from avascular retinal regions. The bluish tint is due to dark fundus.

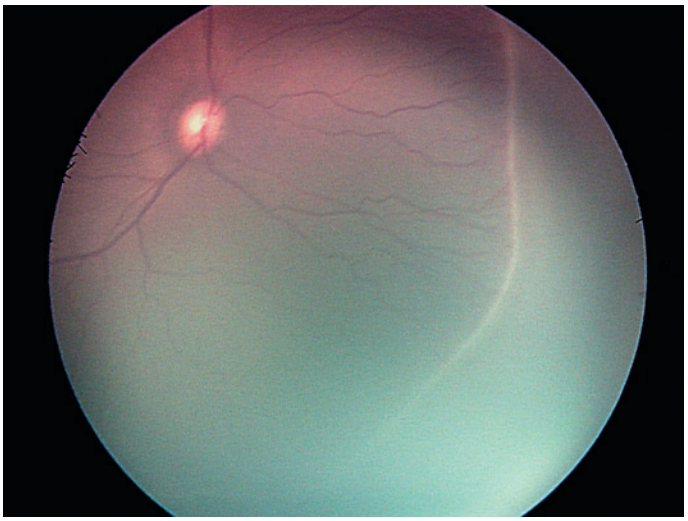

Fig. 44.4 Retinopathy of prematurity stages 1 and 2. Stage 1 in its lower part, but the line becomes thicker (ridge) toward the top of the image. Differentiating stages 1 and 2 is not always easy – or necessarily important.

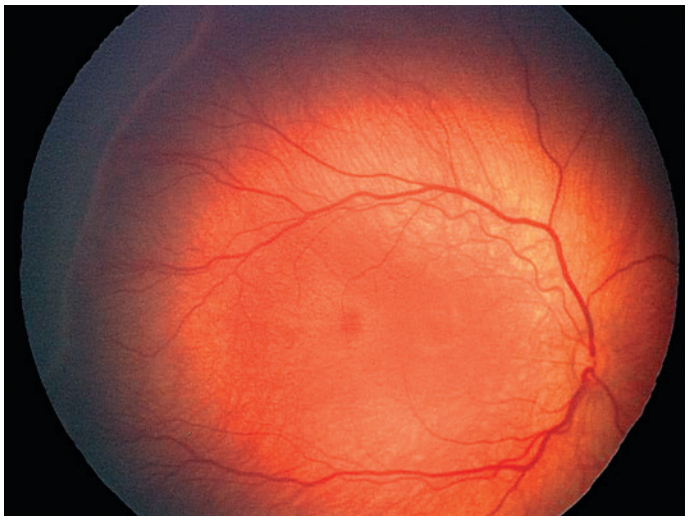

Fig. 44.5 Stage 2 retinopathy of prematurity.

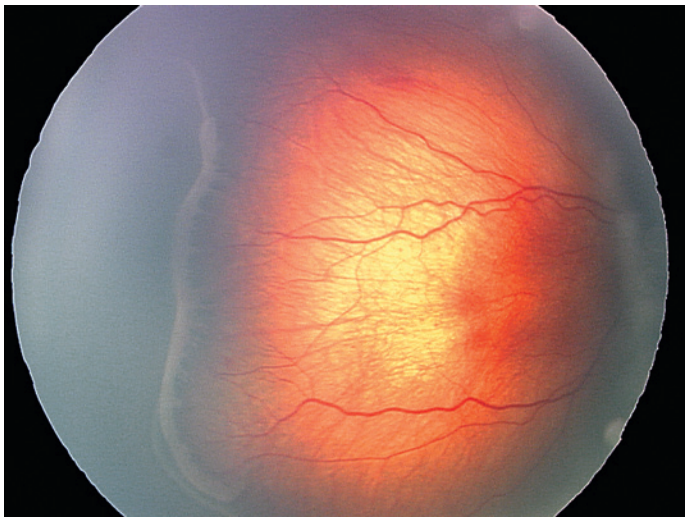

Fig. 44.6 Stage 2 and stage 3 retinopathy of prematurity. Stage 2 at top and bottom of the image with about 1 clock hour of mild stage 3 disease that curls away from the ridge at its lower edge.

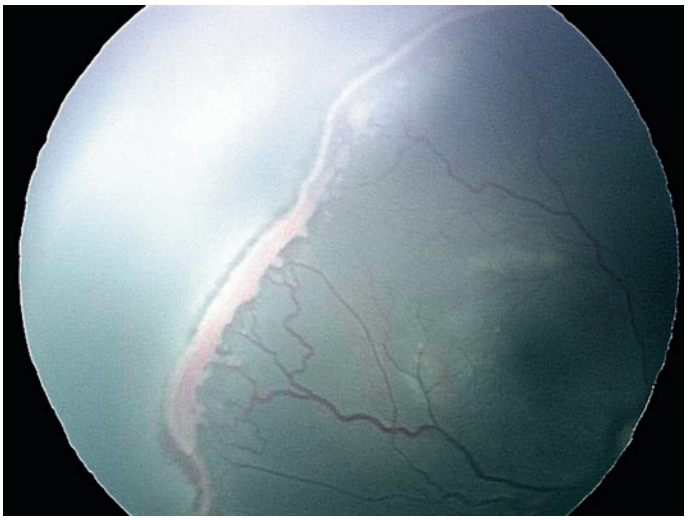

Fig. 44.7 Stage 3 retinopathy of prematurity (ROP) that has developed in the eye with stage 2 disease shown in Fig. 44.5. Note the peripheral tortuosity and dilation as the vessels become close to the ROP lesion (compare with Fig. 44.5). The shadow, just behind the lesion, indicates that the lesion is off the retinal surface.

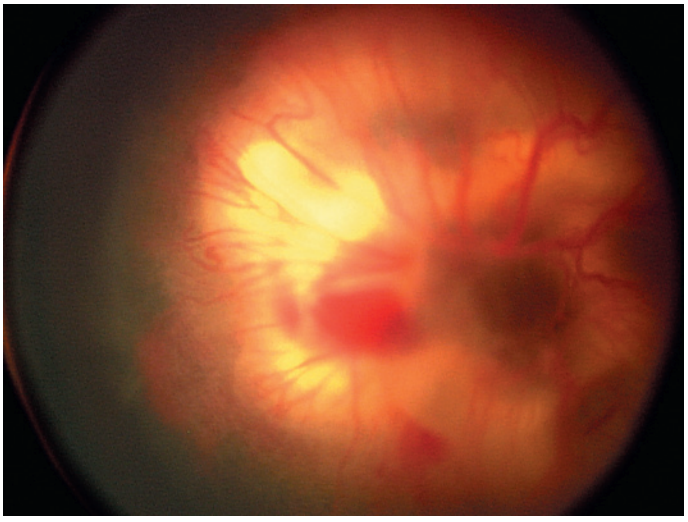

Fig. 44.8 Acute stage 5 funnel retinal detachment.

posterior disease, lies back across the surface of the vascularized retina.

Stage 4

This is characterized by subtotal exudative or tractional retinal detachment, that is extrafoveal (stage 4B), or involves the foveal region (stage 4A).

Stage 5

There is a funnel-shaped total retinal detachment (Fig. 44.8). This stage is further defined according to the anterior and posterior characteristics of the funnel.

Aggressive posterior ROP (AP-ROP)

This severe form of ROP[21] is characterized by a posterior location (zone I or posterior zone II) and a prominence of plus disease out of proportion with the rather innocuous appearance of the vascular abnormality at the vascular/avascular junction. The severity often makes it difficult to distinguish arterioles from venules (Fig. 44.9). Critically, AP-ROP does not show progression from stage 1 to stage 2 and stage 3; the flat network of new vessels can easily be missed.

Plus disease

The cardinal signs of plus disease (Fig. 44.10) are marked increased tortuosity of retinal arterioles and engorgement of venules near the optic disc. Engorgement of the iris vessels and poor pupillary dilatation and vitreous haze are late signs and generally indicate advanced disease. Signs of plus disease may appear at any ROP stage. This clinical diagnosis is made by comparing with a reference photograph in the classification.[21] At least two quadrants must be involved and the peripheral changes of ROP must be present. Plus disease does not refer to vascular changes in the retinal periphery. Plus disease is the current major ROP morphological sign indicating treatment,

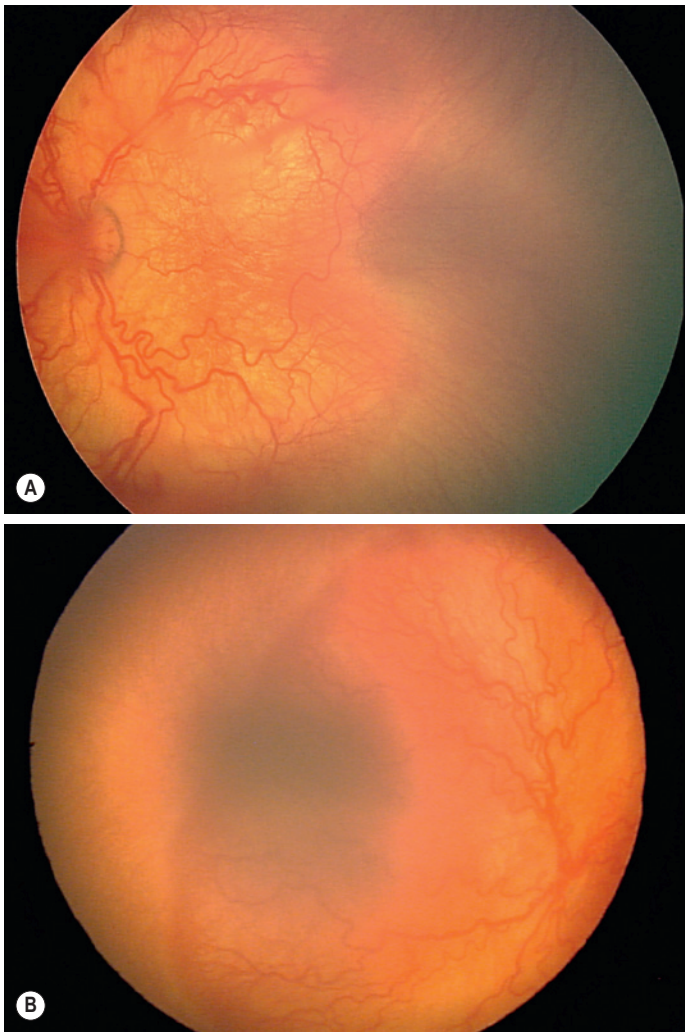

Fig. 44.9 Examples of aggressive posterior retinopathy of prematurity (AP-ROP). (A) View of AP-ROP – note the posterior locations, prominence of plus disease, and the modest appearance of the peripheral retinopathy. (B) AP-ROP image showing plus disease with a brush-like neovascular proliferation at junction between vascular and avascular retina. *(Reproduced with permission from An International Committee for the Classification of Retinopathy of Prematurity. The International Classification of Retinopathy of Prematurity revisited. Arch Ophthalmol 2005. 123: 991–9.)*

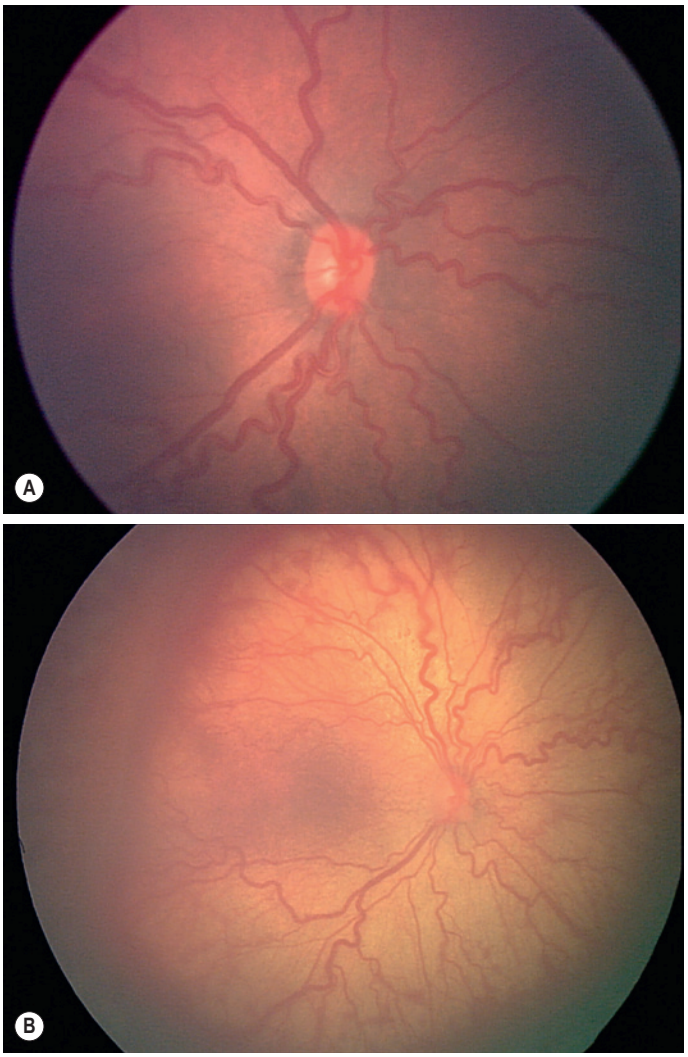

Fig. 44.10 Two examples of plus disease. Note the different appearance with different magnification and field of view between (A) and (B). *(Reproduced with permission from An International Committee for the Classification of Retinopathy of Prematurity. The International Classification of Retinopathy of Prematurity revisited. Arch Ophthalmol 2005. 123: 991–9.)*

and is associated with an increased likelihood of poor outcome.[22,23]

Pre-plus disease

The term "pre-plus" disease[21] indicates posterior vascular changes that are as yet insufficient to be termed plus disease (Fig. 44.11). It alerts to the likelihood of peripheral retinopathy.

Location

The retina is divided into three concentric zones centered on the optic disc, with zone I defined as a circle of approximately 30° with a radius twice the disc–foveal distance. Zone II is doughnut shaped, and extends from the edge of zone I with a radius reaching the nasal ora serrata. Zone III includes all retina anterior to zone II. With no anatomic landmarks identifying zone III, only when the direct nasal retina is fully vascularized can it be stated that zone III has been entered.

Extent

The extent of disease along the junction between the vascularized and avascular retina is described in clock hours or by 30° sectors.

Regression and resolution

Resolution of acute phase retinopathy has been less well studied. The first signs of regressing ROP are failure to progress and lessening of posterior pole vascular abnormalities. The ridge thins and breaks up, and retinal vessels grow through the ridge into the peripheral avascular retina. Involution is characterized by vascular remodeling with gradual movement of vessels toward the periphery, although in some eyes, vascularization does not proceed to the ora serrata. Vasoproliferative lesions become fibrotic. In general, stages 1 and 2 ROP completely resolve, while stage 3 may lead to peripheral fibrosis and retinal dragging (Fig. 44.12) or detachment. Residua of acute phase ROP were defined in the 1987 International

Classification of Retinopathy of Prematurity (ICROP) paper in terms of retinal and vascular changes in the peripheral retina such as incomplete vascularization, pigmentary changes, vitreoretinal interface changes, up to and including retinal detachment and posterior changes.[20] Posterior abnormalities resulting from acute phase ROP included vascular tortuosity, straightened temporal vessels, macular heterotopia, retinal fold (Fig. 44.13), and detachment.

The mean time of onset of signs of involution in children with birth weights of less than 1251 g was 38.6 weeks; 74% of all ROP had begun to involute by 40 weeks of PMA, 90% by 44 weeks.[24] Advanced scarring or "cicatricial" changes may shallow the anterior segment, leading to glaucoma and corneal decompensation.

Incidence and prevalence

The incidence of acute phase ROP and ROP blindness that may result from severe disease in an individual region varies with the level of health care provision and socioeconomic development in high-, middle-, or low-income countries.[18,25] There may, however, be diverse health–socioeconomic communities within a single country. In high-income countries, where economics and technology permit generally high-quality health care and neonatal intensive care, ROP-induced disability accounts for 3–8% of childhood vision impairment.[26,27] In middle-income communities, technology permits increased survival of preterm babies, but limited health resources may limit the standard of care.[25] Consequently, babies with higher birth weights and gestational ages are at risk of severe ROP; ROP-induced blindness contributes up to 39% of childhood vision impairment due to increased survival and associated limited resources with suboptimal quality neonatal care.[18,28] In low-income countries, very few preterm babies survive to develop ROP.[18,25]

As shown in Table 44.2, there have been three ROP epidemics.[18,29] The first in the 1940s was due to unrestricted, unmonitored oxygen, and was brought to an end by oxygen restriction. The survival of neonates of <1000 g birth weight was 5–8%, and most of the babies blinded during this period had heavier birth weights. ROP blindness was greatly decreased by advances in neonatal care.[30] In the late 1960s, in countries with well-developed neonatal intensive care services, the increased survival of the very immature neonate who had not previously survived (now around 50–60% <1000 g birth weight) resulted

Table 44.2 Risk factors for retinopathy of prematurity: a historical perspective

		First epidemic (1940–1950s)	Second epidemic (1970–1980s)	Current: Regions with well developed neonatal care systems	Current: Regions with developing neonatal care systems (third epidemic)
Risk factors	Prematurity	+	++	++++	+ to ++++
	Low birth weight	+	++	++++	+ to ++++
	Excessive oxygen supplementation	++++	+++	+	++++

in a second epidemic. In retrospect, the first epidemic could be considered largely preventable, whereas the second is not preventable at our current level of neonatal care.[18]

The term "third epidemic" describes the prevalence of ROP-induced visual disability that began to emerge worldwide in the early 1990s, with ROP blindness being an increasing cause for visual impairment in Latin America, South and Southeast Asia, China, Eastern Europe, and Central Asia. Blencowe et al.,[25] based on 2010 data, estimated that there were approximately 15 million premature infants born each year, with about 2.6 million <32 weeks' gestation. Estimated incidence of acute phase ROP in <32 week-gestation infants varied from 21.8% in countries with neonatal mortality rates (NMR) of <5, to 36.5% in countries with NMR ≥5. Overall, an estimated 20,000 (uncertainty range 15,500–27,200) of all premature survivors had severe visual impairment or blindness in 2010, with an additional more than 12,000 infants having mild or moderate visual impairment. As shown in Fig. 44.14,[25] the majority of visually impaired survivors were born in middle-income regions of Latin America, East and South Asia, and Eastern Europe and Central Asia. Since optimal neonatal care and effective ROP detection and treatment programs are still being developed in these regions, there are opportunities for preventive interventions from both neonatal care and ophthalmological perspectives.[18]

Not all premature infants who develop ROP will become visually impaired. In the US-based Multicenter Trial of Cryotherapy for Retinopathy of Prematurity (CRYO-ROP),[31] more than 4000 children with birth weights of less than 1251 g had serial eye examinations in 1986–87.[32] ROP was observed in one or both eyes of 65.8% of these infants, with ROP observed in 90% of children with birth weights of less than 750 g, in 78% of those with birth weights of 751–1000 g, and in 47% of those with birth weights of 1001–1250 g. These acute phase ROP data have been consistent in later studies[33,34] in the US, despite the increasing number of the smallest, least mature infants.

Natural history

Age at onset and rate of progression

ROP develops over a relatively narrow PMA range in the premature baby and its onset is linked more to the stage of development of the infant than neonatal events such as oxygen therapy or illnesses.[23] Further, the rate of progression to more severe disease is also governed predominantly by the stage of development rather than by postnatal age or neonatal events. As shown in Table 44.3 based on two large US trials conducted about 15 years apart,[32,33] there is a remarkable consistency in onset of various ROP stages and the behavior of ROP, with mean onset of stage 1 occurring at 34.3 weeks PMA in the CRYO-ROP trial and 34.1 weeks PMA in the Early Treatment for Retinopathy of Prematurity Randomized Trial (ETROP). Prethreshold ROP occurred at a mean of 36.1 weeks PMA for both studies, although there are wide 5% and 95% confidence intervals for all events in ROP progression. However, in countries with developing standards of neonatal care systems, sight-threatening disease frequently affects more mature and larger babies at similar rates of progression.[18,35,36]

Zone and site of involvement

The likelihood of developing severe ROP is closely related to the state of retinal vascularization.[32] More than half of the eyes

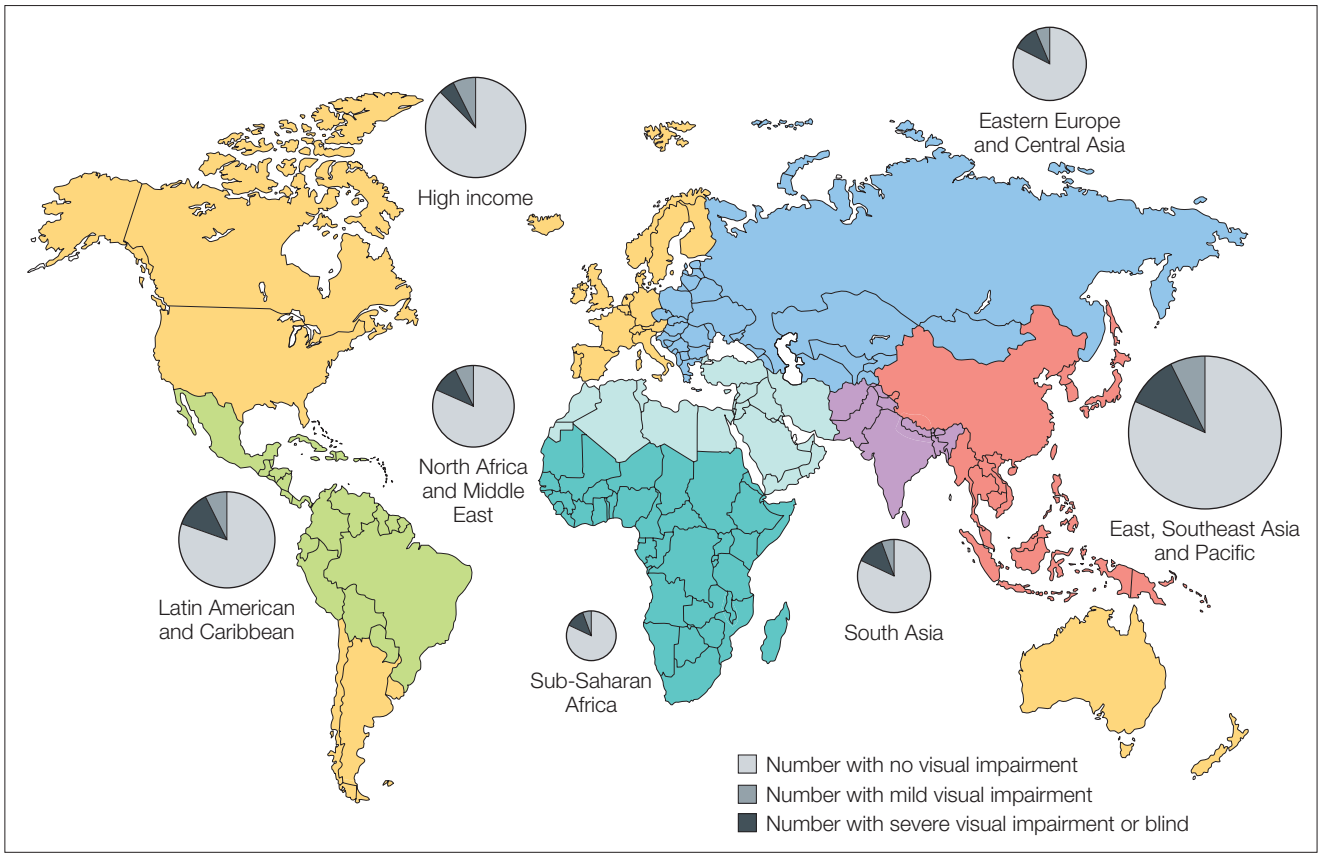

Fig. 44.14 Regional burden of visual impairment from retinopathy of prematurity among preterm babies born in 2010 and surviving the neonatal period. *(From Blencowe H, Lawn JE, Vazquez T, et al. Preterm-associated visual impairment and estimates of retinopathy of prematurity at regional and global levels for 2010. Pediatr Res 2013; 74 Suppl 1: 35–49.)*

Table 44.3 Onset of different ROP events by postmenstrual age in weeks. Median (5%, 95%)

ROP stage	CRYO-ROP (N=4099)	ETROP (N=6998)
Stage 1 ROP	34.3 (–, 39.1)	34.1 (–, 38.9)
Stage 2 ROP	35.4 (32.0, 40.7)	35.1 (32.4, 40.1)
Stage 3 ROP	36.6 (32.9, 42.4)	36.6 (33.4, 41.6)
Plus disease	36.3 (32.6, 42.9)	36.0 (33.0, 41.4)
Prethreshold ROP	36.1 (32.4, 41.5)	36.1 (32.1, 42.1)

CRYO-ROP; Cryotherapy for Retinopathy of Prematurity trial; ETROP, Early Treatment for Retinopathy of Prematurity study; ROP, retinopathy of prematurity. Pediatrics 2005; 116: 15–23.

with incomplete vascularization in zone I observed at the first ROP examination will require treatment. The risk falls to less than 10% when vascularization has proceeded to zone II, and to near zero when vessels reach zone III.

In the very immature baby, ROP commences preferentially in the nasal retina and later extends to other regions. In the 2005 ICROP revision,[21] the zones of vascular development were recognized as having an elliptical shape, with nasal ROP frequently closer to the optic disc than ROP in the temporal retina. The more premature the neonate, the more likely ROP is to be in a posterior zone and to have a greater potential for progression to severe disease.

Plus disease

Plus disease is a critical, but qualitative, sign of ROP severity and is now the main driver for treatment.[22] Plus disease may be observed at any stage of ROP and is a sign of disease severity.[36] It is relatively easy to distinguish between plus disease and "normal" posterior pole vessels, but since the vascular abnormalities in ROP are along a continuous spectrum, making the call for "plus" when "mild" is the least robust and worrying diagnostic aspect of ROP.

Retinopathy of prematurity detection programs

Severe ROP can usually be successfully treated. Thus the ophthalmologist needs to identify severe, potentially treatable ROP – at present that is type 1 ROP.[22] Also babies with stage 3 ROP have a high risk of developing strabismus, myopia, and various vision deficits and thus merit continued surveillance.

There is no one-size-fits-all guideline for determining which babies should be checked, since birth weight (BW) and GA characteristics of at-risk babies differ between countries and even between neonatal intensive care units within one city.

Nevertheless, there are fundamental principles that apply to all populations and can be applied broadly:

ROP has a clearly described natural history: The timing of its onset and progression are largely determined by PMA and are generally consistent across ethnic groups and settings, with more mature infants having an earlier age at onset and a shorter interval to resolution or progression than more immature babies.

Re-evaluation of inclusion criteria is essential from time to time, with local audit an essential component; the results of this can be used to broaden criteria; making them narrower, especially with a relatively small evidence base, should be undertaken with caution.

High-income countries

There are two approaches for developing guidelines in high-income countries that have a relatively uniform high level of neonatal care. The first, using GA and BW alone, is simple, but requires relatively wide criteria so that all at-risk babies are included. This scheme is used in the UK: all babies <31 weeks GA or <1251 g BW must be screened and a lower level of recommendation, "should" be screened, was made for babies between 31 and 32 weeks GA and 1251–1501 g BW. A second approach is combining sickness criteria with GA and BW. This approach permits screening of fewer babies and is used in many countries including the United States (<31 weeks GA or <1500 g BW), Sweden (<31 weeks GA), and Canada (<31 weeks GA and <1251 g BW). However, outliers can occur, so these countries suggest also the screening of larger, more mature babies if the clinical course is complex and unstable.[37]

Low- and middle-income countries

Compared to high-income countries, in low- and middle-income countries, variations in the standard of neonatal care render larger and more mature babies at risk of developing severe ROP – sometimes >2000 g BW and 34 weeks GA. Inclusion criteria on GA and BW alone would be inappropriate, as many babies would be unnecessarily included and the demand on ophthalmic services would be inordinate. In addition, sometimes the GA is unknown. For those middle-income countries with guidelines, inclusion criteria range from ≤30 weeks GA and <1500 g BW to ≤34 weeks GA and <1750 g BW, with, in most countries, additional sickness criteria to identify the larger and more mature babies falling outside the guideline.[37]

Timing of examinations

Examination timing is based on the principle that the onset and progression of ROP are predominantly determined by PMA. Timing is critical as there is only a narrow window of opportunity for treatment (Table 44.4).[38] Reynolds et al.[38] developed an algorithm, which is now widely accepted, and in Table 44.4 has been adapted to include more mature babies.

After the initial ROP examination, weekly or fortnightly examinations are indicated, but as ROP progresses, more frequent examinations will be required. A weekly visit to the neonatal intensive care unit (NICU) allows examination of those babies likely to be discharged home soon and decreases the need for babies to be recalled, so decreasing the likelihood of missed examinations and potentially disastrous consequences.

ROP, Retinopathy of prematurity.
Adapted from reference Reynolds JD, Dobson V, Quinn GE, et al. Evidence-based screening criteria for retinopathy of prematurity: natural history data from the CRYO-ROP and LIGHT-ROP studies. Arch Ophthalmol 2002; 120: 1470–6.

For the baby transferred to another hospital while still at risk, arrangements must be made for the continuation of ROP examinations.

One of the critical decisions in the screening program is when to stop screening examinations. For the baby who never developed ROP, once retinal vascularization has reached zone III, the risk of a serious adverse outcome is minimal, although accurate identification of the zone is often difficult and the PMA, GA, and BW of the infant must be considered. Whether screening needs to be continued for longer in the larger baby is not known.

The eye with ROP signs of regression should be seen on at least two examinations with regression.

Methods of examination

Eye examinations are stressful for the preterm baby,[39] but this can be reduced by supportive neonatal care. Babies should be handled gently with a trained nurse to help and to monitor the infant's wellbeing. After instilling dilating drops well prior to the examination, indirect ophthalmoscopy should be performed using a 28- or 20-diopter lens and an infant lid speculum as needed with a scleral depressor (for ocular rotation rather than indentation) after anesthetic eye drops. Observing the nasal retina allows the ophthalmologist to determine whether vascularization extends into zone III.

While indirect ophthalmoscopy currently remains the "gold standard," wide-field digital imaging is being increasingly used for routine ROP screening and is particularly useful when ROP is present.[40] However, visualizing zone III is difficult with imaging at present.

Clinical findings

Examination of the anterior segment should include checking for the tunica vasculosa lentis as persistence beyond 34 weeks suggests highly active ROP.[41]

Start the fundus examination with the posterior pole vessels for signs of pre-plus or plus disease. Both of these are powerful indicators that type 1 ROP is present or imminent.

The retinal periphery is white-gray in its non-vascularized regions; the extent of this depends on the degree of immaturity (see Fig. 44.1). The optic disc frequently has a grayish appearance and the macular and foveolar reflexes do not appear until 36 and 42 weeks PMA, respectively.

Retinopathy of prematurity screening in the future

Predicting severe ROP through postnatal weight gain

Both VEGF and IGF-1 are critical for normal retinal vascular development. IGF-1 is a somatic growth factor that is correlated with birth weight and postnatal growth. IGF-1 levels rise during the last trimester of pregnancy, so promoting, through VEGF activation, normal retinovascular development.[42–44] Following preterm birth, IGF-1 levels fall, inhibit retinovascular development, and set the scene for subsequent development of ROP. When IGF-1 increases some time after birth, VEGF is maximally stimulated and ROP results.

Since IGF-1 is a somatic growth factor, birth weight and postnatal growth can to be used as surrogates for retinal vascular development and assessing the potential for ROP. The decrease in IGF-1 levels after preterm birth is manifested by a corresponding decrease in postnatal weight gain and its magnitude indicates the severity of retinal hypoxia. Detection of decreased postnatal weight gain precedes the detection of acute phase ROP by several weeks and might be useful in identifying infants at higher risk early in the postnatal period. WINROP, a computer-based algorithm for ROP screening,[45] compared an individual infant's rate of weight gain to a series of premature infants who did not develop proliferative acute phase ROP (stage 3 or worse). It has been used to trigger an "alarm" to indicate the probable development of severe ROP, usually many weeks before ROP develops. Depending on the setting of the NICU in terms of case mix and country, the sensitivity of WINROP varies from very good (all 28 infants with severe ROP detected)[46] to detecting only 90.5% of infants with proliferative retinopathy.[47]

Other prediction models have been developed based on early weight gain.[48–50] The non-computer-based CHOP-ROP model uses birth weight, gestational age, and daily weight gain to determine if type 1 ROP is likely to develop. In a cohort of 524 at-risk infants in a level III NICU, this model accurately predicted, well in advance, all infants who developed type 1 ROP and, if it had been implemented clinically, would have reduced the number of examinations required by almost 50%.[50] The easy-to-use system is based on a simple logistic regression using a nomogram.

The use of postnatal weight gain algorithms for prediction of severe ROP could reduce the number of infants needing examinations significantly, but larger validation studies need to be conducted in various clinical settings to determine the utility of this approach.[51] Further, how these algorithms will perform in centers with developing NICU systems and larger more mature infants developing ROP remains to be seen.

Telemedicine and ROP

Several features of the epidemiology of ROP make ROP telemedicine an attractive option. For example, the infants who need treatment are usually still in the hospital, the natural history of ROP is well known, and there are guidelines for determining the timing of the evaluations needed. As digital imaging became feasible in the NICU in the 1990s, this technology has been increasingly used in clinical research and routine screening. In 2012, a report from the American Academies of Ophthalmology and Pediatrics and the American Association of Certified Orthoptists noted eight level 1 studies with from 43 to 1257 infants using digital retinal images to detect moderate to severe ROP.[40] Various definitions of moderate to severe ROP were used and sensitivity ranged from 57% to 100%.

In 2014, the largest of these studies, the "Telemedicine approaches for evaluating acute-phase ROP (e-ROP)" study was reported.[52] A multicenter observational study conducted in 13 clinical centers in North America enrolled infants with birth weights <1251 g and was designed to detect in digital retinal images eyes with "referral warranted" (or RW-ROP), which indicated the need for an ophthalmoscopic examination by an ophthalmologist to evaluate for possible treatment. RW-ROP was defined by Ells et al. in 2003 as any stage of ROP in zone I, any stage 3 or worse ROP, or the presence of plus disease.[53]

In the e-ROP study, infants underwent both diagnostic ROP examinations by e-ROP-certified ophthalmologists and imaging sessions undertaken by trained non-physicians using a wide-field camera in the neonatal intensive care nursery. For each eye, an image set, consisting of five retinal images – posterior, superior, inferior, nasal, and temporal and an external eye image, was graded by two trained non-physician readers for the presence of the retinal morphology findings consistent with RW-ROP. The result of the diagnostic examination was compared to the result of image grading and the sensitivity for detecting the RW-ROP in either eye of an infant was 90.0% (95% CI: 85.4–93.5%) with a specificity of 87% (95% CI: 84.0–89.5%) and a negative predictive value of 97.3%. The e-ROP study results provide strong support for the validity of a telemedicine system to detect the presence of potentially serious ROP.[52]

In other regions of the world with developing NICU systems and a limited number of ophthalmologists available, providing a telemedicine system can increase the likelihood of detection and treatment of potentially serious disease. An excellent example of such a system in place is in India under the guidance of A. Vinekar.[54] Technicians are trained to obtain images from at-risk infants and to recognize key signs of serious disease. If detected, those images are sent to the ophthalmologist and treatment given if needed. Such an approach is particularly important in countries with widely dispersed or large populations of at-risk premature babies and a very limited number of ophthalmologists.

Remoteness is relative. The infant with sight-threatening ROP who is only a mile or so from a too-busy ophthalmologist

is as equally remote from care as one many miles away. To have a real and sustainable effect, telemedicine needs not only to work afar, but must also contribute to routine medical care enabling local teams to work better than they do currently.

Large randomized trials of peripheral retinal ablation from 1986 to 2002

Cryotherapy and xenon arc photocoagulation were first used for treatment of acute ROP with argon laser later. However, it was not until 1988 that retinal ablative therapy was proven in large randomized clinical trials to have a beneficial effect on severe retinopathy.[31] The CRYO-ROP set out to determine prospectively whether cryotherapy is effective in the treatment of severe acute ROP and to study its natural history.[31,32] In 1986–87, 291 infants from among the 9751 enrolled at 23 US centers participated in a randomized trial comparing outcome of eyes treated with cryotherapy with those eyes assigned to observation. Treatment "threshold" was defined as five continuous or eight cumulative clock hours of stage 3 in zone I or II with plus disease, as previous studies had shown that without treatment, such eyes had a 50% risk of blindness. Cryotherapy produced a significant reduction in the unfavorable structural outcome of threshold ROP of 49.3% at 3 months[31] and 45.8% at 12 months,[31] as judged by fundus photographs and clinical examination. Visual function assessments were added beginning at the 1-year outcome visit with significantly better grating acuity in the treated eyes. The beneficial effect persisted with a 42.2% reduction in unfavorable structural outcomes and 43.4% reduction in visual acuity outcomes of 20/200 or worse at the final 15-year follow-up study examinations.[55]

The CRYO-ROP study showed that cryotherapy for threshold ROP produced a significant benefit for structural status of the eye and for vision. However, at 15 years, 23% of treated and control eyes had visual acuity of 20/40 or better, showing that retinal ablation did not necessarily result in normal structure or visual acuity.[55]

A second retinal ablation trial examined whether some eyes with ROP of less than threshold severity would benefit from treatment. Using a risk model (RM-ROP2, based on data from the CRYO-ROP study)[56] including patient demographic characteristics, pace of disease, and severity of retinopathy, ETROP[22] was conducted in 26 USA clinical sites to determine whether "high risk" prethreshold eyes (15% or greater likelihood of progression to unfavorable structural outcome) would benefit from earlier treatment. Prethreshold ROP was defined as: zone I ROP less than threshold; zone II, stage 2 with plus disease and stage 3 without plus disease; or stage 3 with plus disease but less than threshold. By this time in 2000, laser photocoagulation was widely available and eyes of 401 infants were randomized to treatment at "high risk" or conventional management consisted of observation with treatment only if threshold ROP developed.

The initial reports showed that early treatment of high-risk prethreshold eyes significantly reduced grating acuity and structural unfavorable outcomes.[22] To simplify the clinical applications of the ETROP findings, a clinical algorithm based on the ROP status of an eye was developed to determine if an eye required treatment (Table 44.5). Two types of prethreshold disease were defined with the recommendation that "type 1" be considered for earlier treatment and "type 2" be followed conservatively and treated if progression to type 1 developed. At the final ETROP 6-year examinations,[57] there continued to be a benefit to ocular structure in early-treated eyes compared to conventionally managed eyes (8.9% vs. 15.2%, $p<0.001$), but there was no statistically significant visual benefit from earlier treatment of high-risk prethreshold eyes. However, when the results at 6 years were classified using the type 1 or type 2 algorithm, visual acuity was significantly better in the group of eyes with type 1 compared to the eyes with type 2 ROP (25.1% vs. 32.8%, $p=0.02$). Furthermore, there was a significant benefit to the extent of visual field, measured using white-sphere double arc perimetry, for the group of eyes with type 1 ROP that received early treatment compared to the group of type 2 eyes.[58]

Table 44.5 Treatment algorithm based on results of the ETROP study

	Zone	Stage of ROP	Plus disease
Type 1 ROP: treatment indicated	Zone I	Any stage ROP	+
	Zone I	Stage 3 ROP	–
	Zone II	Stage 2 or 3	+
Type 2 ROP: observe closely for progression	Zone I	Stage 1 or 2	–
	Zone II	Stage 1	+
	Zone II	Stage 1, 2, or 3	–
Other ROP: observe for progression	Zone III	Any ROP	+/–

ETROP, Early Treatment for Retinopathy of Prematurity study; ROP, retinopathy of prematurity.

Involving parents

The parents of a very preterm infant have much to cope with and they have a right to know what ocular problems may befall their baby; providing sensitive, balanced information is important.

Information should be available at three levels for:

1. The parents of all babies who are to undergo ROP examination: Written information providing a general description of ROP is required, noting that, although ROP is a frequent occurrence, over 90% of cases of acute retinopathy spontaneously resolve. Generally, the ophthalmologist does not personally need to counsel the parents of all babies who have ROP examinations, but should be available to provide information if required.
2. The parents of babies with ROP that is or might become severe: Written information should be provided that emphasizes that treatment is available and may need to be considered. At this juncture, the ophthalmologist should discuss the situation face-to-face with parents.
3. The parents of the baby with end-stage disease: Not all eyes well treated respond satisfactorily to treatment and

blindness still occurs. Ophthalmologists should not lose contact with the family. Most parents accept that treatment sometimes fails, but they cannot accept lack of interest. The ophthalmologist must ensure that the child gains early access to the services for the visually impaired and with certification as blind or partially sighted as appropriate

Outcomes

Premature birth can affect the developing visual system by refractive changes (see Chapter 8), strabismus, neurologic damage (see Chapters 60 and 90), and ROP. Most infants with ROP undergo complete resolution without adverse effects, and mild ROP (stages 1 and 2) has no additional adverse effect on vision.[59,60] Severe ROP may impact acuity[59] and contrast sensitivity.[61] It was the less-than-ideal response following cryotherapy that generated the Early Treatment Study. Color vision does not seem to be affected by preterm birth alone, although the CRYO-ROP study noted an increased prevalence of blue–yellow deficits not related to ROP severity.[62,63] Visual field area measured at 10 or 11 years in children who had significant acute phase ROP was reduced regardless of whether the eyes underwent cryotherapy.[64,65] Both visual acuity and visual field benefited from treatment of type 1 but not type 2.[57,58]

The prevalence of strabismus is increased by preterm birth and by ROP stage (even mild ROP). The incidence of strabismus is raised from around 6% to over 60%, and this increases as acute phase ROP increases.[66–68]

The direct consequences of ROP are more frequent in severe and posterior disease, but occasionally occur in mild acute ROP. Retinal detachment can occur at any time of life, including after peripheral retinal ablation for severe ROP, although this is infrequent. Large punched-out macular lesions are infrequent sequelae of severe ROP. When they develop is unknown, but they have been observed during infancy. Originally thought to be the consequence of cryotherapy, they may occur in eyes that have not been treated. Anterior segment sequelae of severe ROP have been described.[69]

Microcornea/microphthalmos may be the consequence of reduced growth during the acute phase or later shrinkage due to advanced cicatrization. Other changes are due to changes in the anterior vitreous causing anterior displacement of the iris–lens diaphragm, causing shallowing of the anterior chamber[70] and, if severe, corneal opacity and cataract.

Children who were preterm have an increased prevalence of all refractive errors, especially myopia.[62,71,72] Myopia is a consequence of low birth weight even in the absence of ROP. The myopia is low and has the following characteristics: steep corneal curvature, shallow anterior chamber, thick lens, and an axial length shorter than expected for the degree of myopia.[62,72] Myopia is a well-known complication of severe ROP.[71] In contrast to myopia of prematurity, which has its onset in school years, myopia associated with severe ROP has its onset in infancy with progression during the first year after birth but with relative stability thereafter, unlike most forms of myopia not associated with ROP.[72,73] There is no significant difference in myopia between eyes with severe ROP that were treated compared to those that were not.[74]

Rationale for treatment

The neovascular manifestations of acute retinopathy of prematurity (ROP) are managed by reducing the stimulus for vessel growth. Traditionally this has been accomplished by ablating the peripheral avascular retina either with cryotherapy[1] or, more commonly in recent years, laser treatment.[2] Ablation of the peripheral avascular retina has its therapeutic effect by decreasing the production of pathologic vascular endothelial growth factor (VEGF), the dominant stimulus for neovascularization in ROP. In the last few years, anti-VEGF medications have been utilized to pharmacologically achieve this goal.[3] The most severe manifestations of ROP, stage 4 and 5 traction retinal detachments (TRDs), are managed with vitrectomy.[4–7]

Peripheral retinal ablation

The indications for ablative treatment of the avascular retina for acute ROP were initially established by the results of the Multicenter Trial of Cryotherapy for ROP Study (CRYO-ROP) published in 1988.[1] The Early Treatment for ROP Trial (ETROP) updated the indications for treatment in 2003.[2] The ETROP compared outcomes of early treatment to outcomes of treatment performed according to older guidelines established by CRYO-ROP. Results from ETROP demonstrated significant reduction in unfavorable structural outcomes at 9 months from 15.6% in eyes managed according to CRYO-ROP guidelines to 9.1% for eyes managed with early treatment ($p < 0.001$). The study recommended treatment for type 1 ROP and defined type 1 ROP as having any of the following three features:

1. zone I, any stage of ROP with plus disease;
2. zone I, stage 3 ROP with or without plus disease;
3. zone II, stage 2 or 3 ROP with plus disease.

Treatment should be performed within 48 hours of identifying type 1 ROP, and more severe cases should be treated sooner.

As can be seen in the recommended indications for treatment according to ETROP, the presence of plus disease is the main driver in the decision to treat. Controversy exists over the variability in detecting plus disease between observers.[8,9] Efforts have been made to more precisely quantify plus with digital image analysis. This topic was considered in more detail in the previous chapter.

Laser is the preferred method of achieving ablation of the avascular retina and portable laser indirect ophthalmoscopes (LIO) are generally used to deliver the treatment.[10] The pattern of treatment is semi-confluent to confluent and laser spots cover the entire avascular retina from the ridge to the ora serrata for 360° (Fig. 45.1).[11,12] Skip areas in laser treatment are to be avoided as even small skip areas can lead to treatment failure and progression to retinal detachment. Fundus photography after laser may aid in identifying and treating skip areas.[13] Treatment posterior to the ridge has been advocated and there is data from fluorescein angiography analysis showing capillary dropout, and presumably ischemic retina, posterior to the ridge.[14–17] There is no level 1 evidence, however, supporting treatment posterior to the ridge and this modification of standard technique is not recommended by the authors for most cases.

Refinements of the laser procedure to minimize stress on the infant and the ophthalmologist have been reported. Recent work has shown that sedation without endotracheal intubation works well in many cases and may reduce ventilator dependence along with associated ventilator complications and expense.[18–20] The authors' experience has been that laser can be performed without intubation in many cases. LIO can also cause stress on the ophthalmologist's cervical spine. The field of ophthalmology is known to have a high rate of spine-related pain that can be career threatening.[21] We have described an ergonomically superior method of indirect ophthalmoscopy that can be useful in treating ROP with LIO.[22]

Choice of laser wavelength for ROP treatment is important. Cataract can occur after laser and may result from uptake

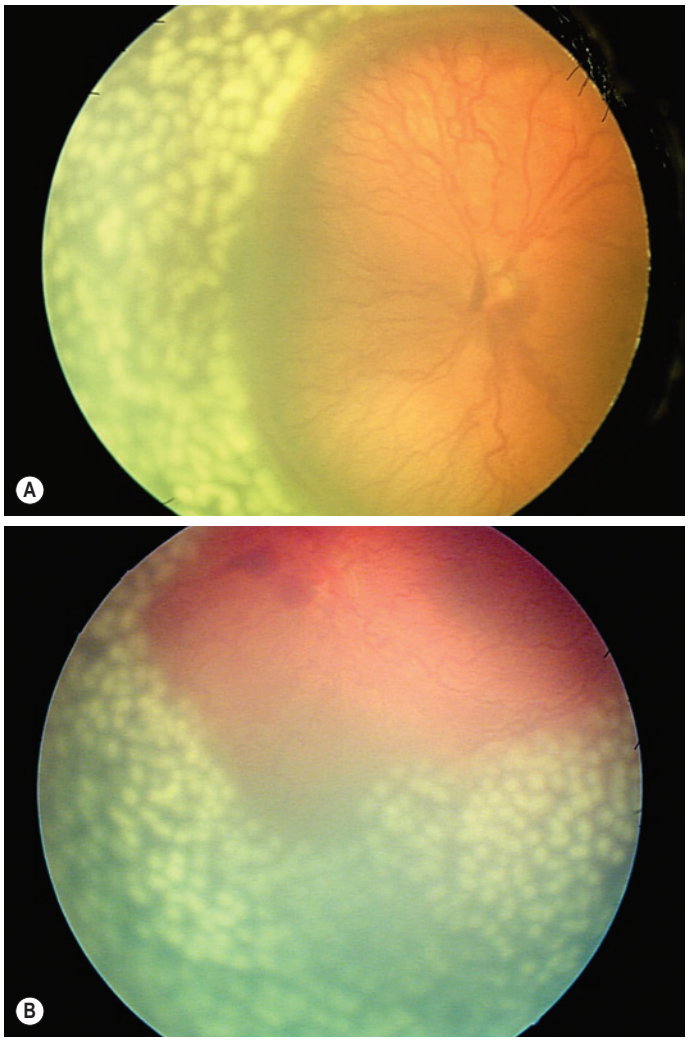

Fig. 45.1 (A) This infant was referred for laser treatment before anti-vascular endothelial growth factor (anti-VEGF) was available. Note the extensive stage 3 in the setting of severe plus disease. Despite the near-confluent laser pattern, this eye later developed stage 4 traction retinal detachment. (B) This infant with aggressive posterior retinopathy of prematurity was also referred for laser before anti-VEGF was available. After laser the retinopathy of prematurity regressed without traction. With 10 years of follow-up, the retina is attached but the child has severe high myopia.

of laser energy by the tunica vasculosa lentis with secondary heating of lens protein. Uptake of energy by the iris may also result in heating of the lens. Studies of cataract formation after laser have shown that 810 nm wavelength laser is less likely to cause cataract compared to argon green wavelengths (510–532 nm).[23] Uptake of energy by vascular structures occurs most efficiently with wavelengths in the yellow range (577 nm) and yellow laser should be avoided due to the presence of perfused tunica vessels around the lens in many cases of ROP. Other complications from laser include corneal edema, hyphema, iris atrophy, angle closure glaucoma, anterior segment ischemia, vitreous hemorrhage, retinal hemorrhage, and exudative retinal detachment.[24–33] In the ETROP study, early treatment was associated with more apnea and bradycardia, and a higher rate of reintubation for mechanical ventilation compared with standard treatment. There was no difference, however, between the groups for ocular complications, mortality, or known permanent morbidity.[2]

Cryotherapy can also be used to ablate the peripheral retina. This was the original modality of treatment in the 1980s and early 1990s.[1] Cryotherapy, however, causes more inflammation and more discomfort for the neonate. In addition, cryo application is less precise than laser and outcomes with laser are at least as good if not better than cryo.[34] With the wide availability of portable 810-nm lasers, cryotherapy is rarely used today.

Anti-vascular endothelial growth factor for retinopathy of prematurity

Pharmacologic modification of intraocular VEGF levels represents a promising approach in the management of acute ROP and this topic has been the subject of excellent recent reviews.[35,36] The BEAT-ROP (Bevacizumab Eliminates the Angiogenic Threat of Retinopathy of Prematurity) study was the first multicenter randomized trial of anti-VEGF for ROP and it compared the efficacy of intravitreal bevacizumab for stage 3 ROP to standard of care peripheral retinal laser ablation.[3,37] Recurrence of active ROP was the primary outcome and BEAT-ROP demonstrated reduction in recurrence with bevacizumab as compared to laser for zone I disease, but no difference was found for zone II disease. For zone I, the recurrence rate for the bevacizumab cohort was 6% versus 42% for the conventionally treated laser group ($p = 0.003$). Several limitations of BEAT-ROP have been highlighted in commentary.[38–40] One is the relatively short follow-up in the study with infants followed until 54 weeks postmenstrual age (PMA). Other reports on bevacizumab note that late recurrences of ROP may occur beyond 54 weeks PMA.[41] In addition, the reported laser failure rate of 42% is well above previously published reports for zone I disease (which are generally 18–22%).[42–44] Despite these limitations, BEAT-ROP established two important points about intravitreal bevacizumab: it is effective at stopping progression of neovascular ROP; and, unlike with laser ablation, avascular retina is not destroyed and may become at least partially vascularized with time. Long-term follow-up is lacking for anti-VEGF treatment of ROP, but emerging data suggest that visual results after bevacizumab are not significantly impaired compared to laser and that treatment with anti-VEGF results in less myopia.[45–48] The relatively low cost of bevacizumab and the ease of intravitreal injection technique compared to indirect laser have resulted in extensive worldwide use of bevacizumab for ROP; over 50 reports on its use for ROP have been published since 2007.

Systemic safety of intravitreal anti-VEGF remains a major concern for infants with ROP. VEGF is a key growth factor in the development and maintenance of nearly every human organ system.[49] Bevacizumab has been shown to reduce serum VEGF concentrations in human infants with ROP for at least 2 months following a single intravitreal injection.[50–52] It would logically follow that systemic suppression of this physiologic growth factor may have potential for harm when administered to developing preterm neonates, but the long-term clinical impact remains to be elucidated. The dose of bevacizumab used in BEAT-ROP and other studies was half the adult dose, or 0.625 mg. Lower doses may be as effective with reduced potential for systemic effects. Lower dosing of bevacizumab is currently under study (NCT02390531). The pharmacokinetics of ranibizumab seem more favorable than

bevacizumab for infants with ROP. Ranibizumab has a shorter half-life and is cleared from the systemic circulation faster than bevacizumab. A prospective multicenter trial of ranibizumab for ROP is underway in Germany (CARE-ROP NCT02134457) and planned for the US (RAINBOW NCT02375971). In assessing available information regarding systemic safety of bevacizumab, one finds limited data from case series emerging over the last few years.[46,53–58] No major systemic safety issues have become apparent. However, there have been no trials to date that have been powered to study systemic safety over a long course of follow-up. Such safety data is imperative before anti-VEGF can become standard therapy for ROP. The authors reserve intravitreal anti-VEGF for cases with the following features: posterior zone I disease, media opacity, poor pupillary dilation, or persistent vascular activity after laser ablation.

The technique for intravitreal injection is relatively straightforward for ophthalmologists. Anesthesia is achieved with topical proparacaine or tetracaine, and may be supplemented with light sedation. A neonatal eyelid speculum in inserted and topical povidone–iodine is applied to the ocular surface and lid margins. The injection should be administered 0.5–1 mm posterior to the corneoscleral limbus through the pars plicata. Injection sites located more posteriorly run the risk of penetrating avascular retina. The needle trajectory should parallel the visual axis to avoid injuring the disproportionately large infantile lens.

Post-laser and post-injection management

After treating acute phase ROP with laser ablation, initial postoperative management consists of treating inflammation with topical steroids. For anti-VEGF treatment, topical antibiotics may be used for a few days after the intravitreal injection but antibiotics are likely unnecessary. The role of topical antibiotics after intravitreal injection has been the subject of much attention in the adult literature and consensus has emerged that topical antibiotics are not necessary after routine intravitreal anti-VEGF injections.[59] At the authors' center topical antibiotics are no longer used after intravitreal injections in adults or neonates.

Improvements in plus disease and neovascularization occur more quickly after anti-VEGF injection than after laser ablation (Fig. 45.2). After laser, there can be initial worsening of vascular engorgement and exudation, presumably due to the inflammatory effects of the ablative procedure.[30,33] Generally,

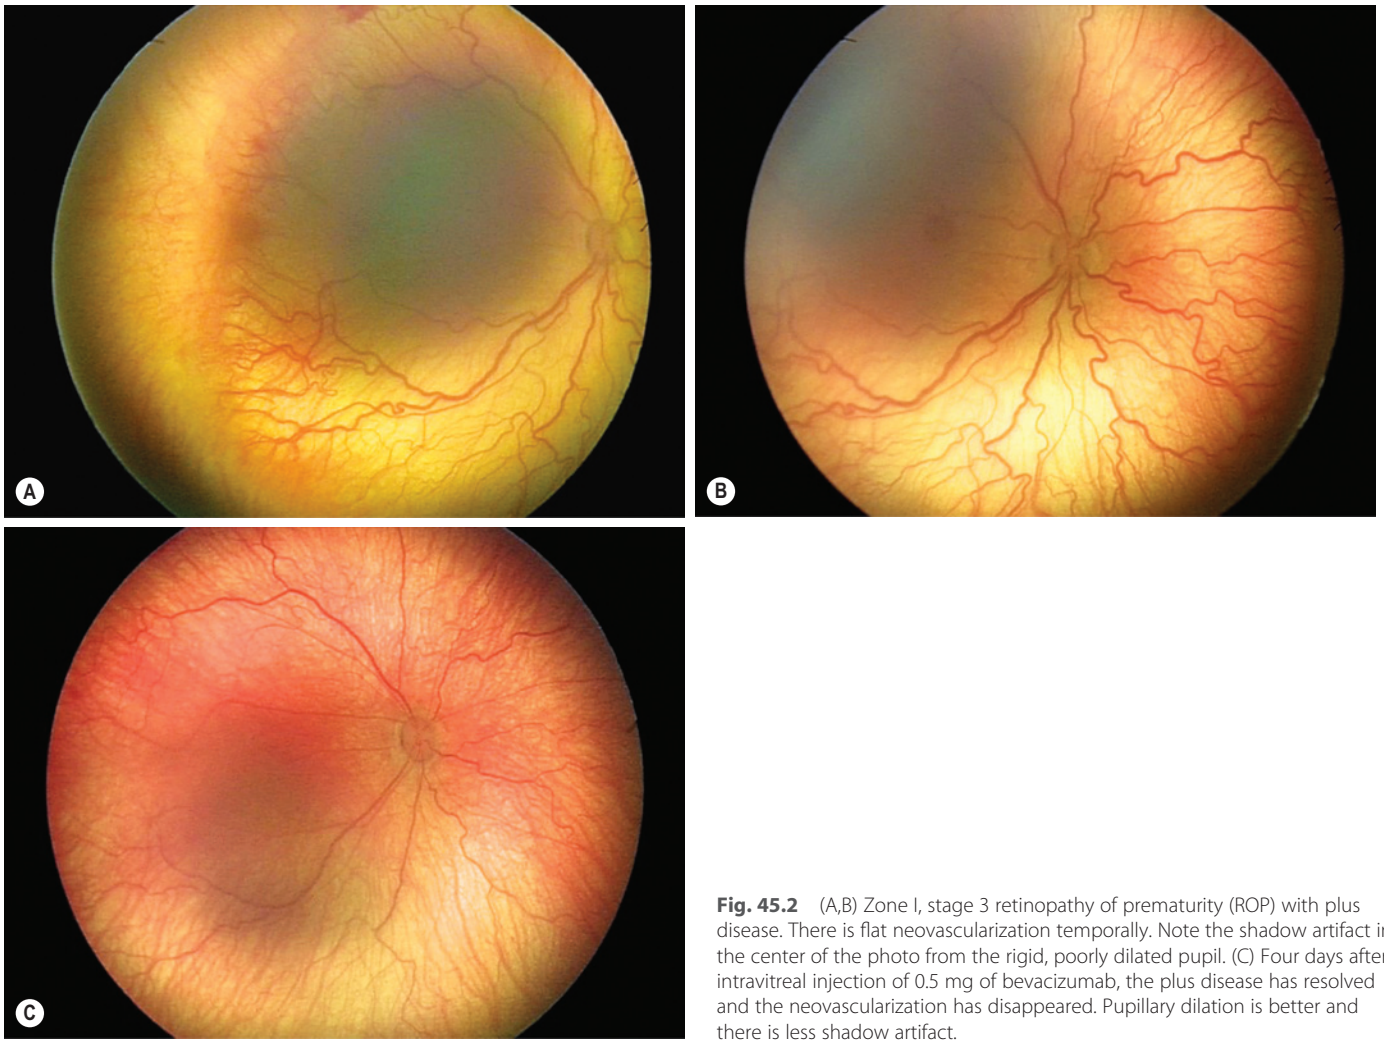

Fig. 45.2 (A,B) Zone I, stage 3 retinopathy of prematurity (ROP) with plus disease. There is flat neovascularization temporally. Note the shadow artifact in the center of the photo from the rigid, poorly dilated pupil. (C) Four days after intravitreal injection of 0.5 mg of bevacizumab, the plus disease has resolved and the neovascularization has disappeared. Pupillary dilation is better and there is less shadow artifact.

the vascular engorgement and exudation begin to improve 7–10 days after treatment. By 2 weeks, plus is nearly or completely resolved and neovascular tissue has become involuted and often almost completely disappears. The improved appearance is similar, but occurs more quickly, after anti-VEGF therapy.

While laser ablation is technically more difficult and time consuming to perform compared to anti-VEGF injection, the postoperative management is generally easier with laser. Once plus disease and neovascularization resolve, recurrence is unusual.[2] If there is no fibrosis, traction, or blood at 3–4 weeks after laser, then the authors generally follow monthly for two more visits and then discharge from acute ROP care, with follow-up in 6 months by a pediatric ophthalmologist.

Treatment failure after laser ablation for ROP does occur even with timely and thorough treatment. The clinical features of failing treatment have been well described.[60–62] Vitreous blood, along with organization of sheets and strands of condensed vitreous, are hallmarks of treatment failure. The persistence of plus or engorgement of vessel on or around the ridge with thickening of the ridge also may precede progressive traction and retinal detachment.[32] If these clinical features begin to appear, the treated avascular retina should be carefully inspected to look for skip areas or places where more laser can be applied. The authors generally examine patients 7–10 days after laser. Earlier exams reveal the exudative response to treatment-related inflammation. After 10 days, persistence of vascular engorgement is significant and may indicate that more treatment is needed. Proliferation and vascular engorgement may continue in any meridian where there is inadequate laser (Fig. 45.3). If the laser pattern is complete, and neovascular activity with plus disease are still present, intravitreal anti-VEGF can be considered. Contraction of membranes after anti-VEGF with worsening traction retinal detachment has been described.[63]

Primary treatment of ROP with anti-VEGF is easier initially but much more demanding in terms of follow-up.[64] Recurrence of ROP may be seen after the effects of the anti-VEGF injection have worn off.[41,65,66] Many cases continue to have substantial areas of persistent avascular peripheral retina for an indefinite amount of time after treatment and some will likely have permanent, large avascular zones. The clinical implications of this persistent avascular retina are not well understood but there are reports of recurrent neovascularization and plus with progressive traction and retinal detachment up to 35 weeks (69 weeks PMA) after intravitreal bevacizumab.[41] There are no established guidelines for follow-up after intravitreal anti-VEGF for ROP, but a sensible approach is to follow every 1–2 weeks until retinal vessels grow into zone III or until 60 weeks PMA. If avascular retina persists in zone I or zone II at 60 weeks PMA, consideration can be given to scatter laser treatment of residual avascular retina. The importance of follow-up must be stressed for parents and caregivers, as any loss of follow-up may have severe consequences in the event of late recurrence.

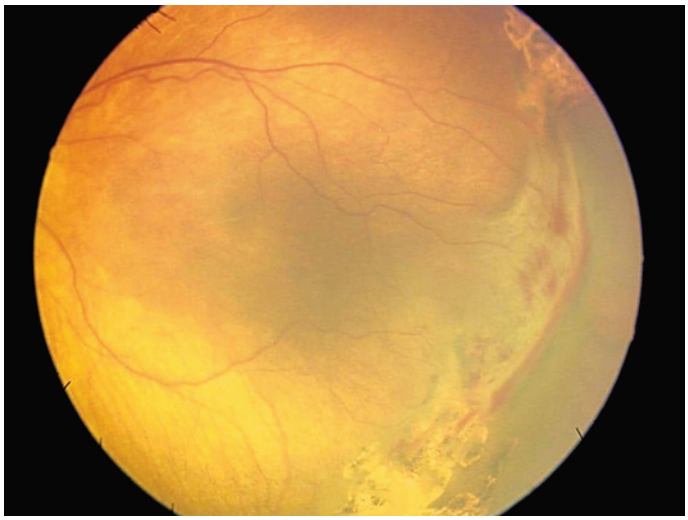

Fig. 45.3 This patient underwent laser treatment at an outside facility and was referred with persistent vascular activity after laser. Note the large skip area temporally with active stage 3 in the same meridians as the skip area.

Treatment of retinal detachment

Retinal detachment will occur in some cases of ROP even when the neovascular phase of the disease is managed with the best available treatment. For example, despite timely and thorough laser as performed in the ETROP study, almost one in 10 infants developed unfavorable structural outcomes.[2] Some eyes with retinal detachment in ETROP were treated with vitreoretinal surgery, but outcomes of this intervention were generally poor with attached macula present at 6 years in only 31% of stage 4A (5 of 16), 60% of stage 4B (6 of 10), and 0% of stage 5 (0 of 10) eyes.[67] These results contrast with results of other published studies of vitrectomy for stage 4 ROP in which re-attachment rates have been in the range of 80–90%.[4–7,68]

One key to successful outcome is to operate after the neovascular activity and plus disease have completely or almost completely resolved (Fig. 45.4).[69] Performing vitrectomy before resolution of this vascular activity may result in bleeding, increased exudation, or continued proliferation and contraction after vitrectomy. In some instances, however, detachment may progress rapidly after laser ablation before the plus disease and neovascular activity have a chance to resolve. This is more likely to be the case for more posterior ROP. For cases of aggressive posterior retinopathy of prematurity (APROP), early vitrectomy has been advocated before complete resolution of vascular activity and before onset of TRD.[70–72] Intravitreal anti-VEGF injection can facilitate vitrectomy before complete resolution of vascular activity and may result in better anatomic outcomes.[73,74] In general, eyes that fail despite early laser treatment are those that are inherently more severe and more likely to progress to total, stage 5, retinal detachment before the neovascular activity and plus resolve.

Successful repair of stage 5 ROP is very difficult because vitrectomy performed after laser-induced resolution of plus and neovascular activity usually is taking place in an eye that has massive proliferation. Success rate in this setting is in the range of 0–50%.[67,75–78] With the addition of triamcinolone or anti-VEGF agents, results may be better.[79,80] Visual function for successfully re-attached stage 5 eyes is generally poor, but any visual function can nevertheless be highly valuable for patients relative to complete blindness.[81–85]

The operative technique most commonly utilized for stage 4 ROP is lens-sparing, 2- or 3-port vitrectomy. Small, 23- and 25-gauge, instruments are now used commonly and are advantageous in small infant eyes.[86,87] Sclerotomies are created 0.5–1 mm posterior to the limbus and the blade or

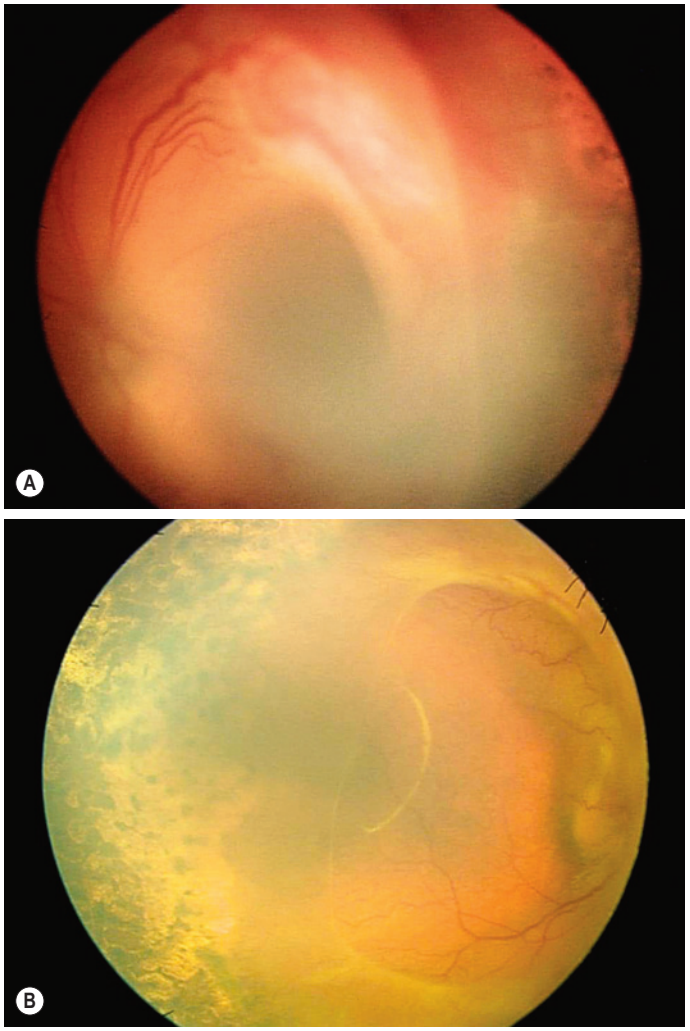

Fig. 45.4 (A) This eye has combined tractional and exudative stage 4B retinopathy of prematurity (ROP). Note the vitreous haze, vascular engorgement, and extensive proliferation. (B) This eye has tractional stage 4A ROP in the setting of almost completely regressed vascular activity. If traction progresses and threatens the macula, vitrectomy in this setting has an excellent anatomic prognosis.

trocar is oriented parallel to the visual axis during insertion to avoid the lens. Scleral buckling (SB) has been used in the past but vitrectomy is generally considered superior to SB. Vitrectomy combined with SB does not seem to be better than vitrectomy alone.[88] For stage 5 ROP, lensectomy in addition to vitrectomy is often required due to the presence of proliferative tissue in contact with the lens.

Long-term outcomes

Over the last 30 years, tremendous strides have been made in the management of ROP. Rigorous screening and treatment of ROP substantially reduces the societal burden of blindness and associated costs.[89–91] Despite the advances, however, long-term outcomes from the perspective of parents can seem rather modest, and counseling is important so that parents know what to expect. Data from ETROP and CRYO-ROP show that a large proportion of patients do not achieve reading vision and many are legally blind.[92,93] In addition, high myopia is common and peripheral vision is reduced after treatment with laser or cryotherapy.[94] It is important for parents to understand that reduction of peripheral vision is a function of the disease and not necessarily the treatment. Pathologic myopia is also a function of severe ROP but it may be exacerbated by treatment with peripheral ablation. Eyes treated successfully with peripheral ablation continue to have lifelong increased risk for strabismus, amblyopia, cataract, glaucoma, vitreous hemorrhage, and retinal detachment.[92,95] Whether treatment of ROP with anti-VEGF agents will result in better long-term outcomes is unknown, as no long-term data for ROP treatment with anti-VEGF exist. Limited data are available regarding long-term outcomes after repair of retinal detachment in ROP.[76,77,85,96,97] When treated with lens-sparing vitrectomy, eyes tend to retain a clear lens.[98] After successful repair of TRD, eyes continue to be at risk for recurrent detachment and other problems indefinitely. Patients and families should be educated about the ongoing lifetime risks of ocular complications after treatment of ROP, and the importance of lifetime surveillance should be emphasized.

INTRODUCTION
STATIONARY RETINAL DYSFUNCTION SYNDROMES
PROGRESSIVE RETINAL DYSTROPHIES
MANAGEMENT
CONCLUSIONS
REFERENCES

Introduction

The inherited retinal disorders are a clinically and genetically heterogeneous group of conditions. Many become symptomatic in childhood. They are usually an isolated abnormality in an otherwise healthy child but, in syndromic form, they may be associated with systemic abnormalities (see Chapter 47). Many of the genes causing childhood-onset retinal disorders have been identified. There is considerable genetic heterogeneity for individual clinical disorders, and mutations in a single gene may give rise to several different phenotypes. Despite this, these disorders can be usefully divided clinically according to whether they:

1. are stationary or progressive;
2. have generalized retinal or localized macular dysfunction; and
3. if the former, exhibit predominantly rod or cone involvement.

Stationary disorders usually present at birth or in the early months of life and are best referred to as dysfunction syndromes, as most do not show significant progression. Progressive conditions, which typically present later, are termed dystrophies.

Stationary retinal dysfunction syndromes

These include the forms of stationary night blindness and the cone dysfunction syndromes.

Stationary night blindness

There are three main forms of stationary night blindness: (i) congenital stationary night blindness (CSNB) in which the fundus is normal or shows myopic changes; (ii) fundus albipunctatus; and (iii) Oguchi disease. Both (ii) and (iii) have a distinctive fundus appearance.

Congenital stationary night blindness

Clinical findings

CSNB is characterized by night blindness, variable visual loss, and a largely normal fundus. It may be inherited as an autosomal dominant (AD), autosomal recessive (AR), or X-linked (XL) disorder.

The visual acuity is usually normal or mildly reduced in the AD form, whereas mild-to-moderate central visual loss is common in the AR and XL subtypes. Other features of XL and AR CSNB include moderate-to-high myopia, nystagmus, strabismus, and paradoxical pupil responses. Fundus examination is usually normal but some patients have myopic fundi and pale or tilted optic discs (Fig. 46.1). Patients with AD CSNB usually present with symptomatic night blindness, but patients with XL or AR CSNB may present in infancy with nystagmus, strabismus, and reduced vision. Nystagmus is not invariable and some patients are not diagnosed until late childhood or adulthood. The diagnosis is easily missed without electroretinography (ERG). XL and AR CSNB may be further subdivided into *complete* and *incomplete* forms. This differentiation, originally proposed in XL disease using electrophysiological and psychophysical criteria, was subsequently shown to reflect genetically distinct disorders.

Electrophysiology

International Society for Clinical Electrophysiology of Vision (ISCEV) standard ERGs should be performed, but this may not be possible in infants, for whom a simplified protocol is more appropriate (see Chapter 9). Four main responses are defined by the adaptive state of the eye (DA: dark adapted; LA: light adapted) and the flash strength in cd.s.m^2: a rod-specific ERG (DA 0.01) and a bright flash response (DA 10.0) performed under scotopic conditions, and two measures of cone function, a 30 Hz flicker ERG (LA 30 Hz) and a single flash photopic ERG (LA 3.0). Both complete and incomplete CSNB show a "negative ERG": the largely photoreceptor-derived a-wave in the bright flash response is normal, but there is selective reduction in the inner nuclear-derived b-wave, so that it is smaller than the a-wave, indicating predominantly inner retinal dysfunction. There is no detectable DA 0.01 ERG in

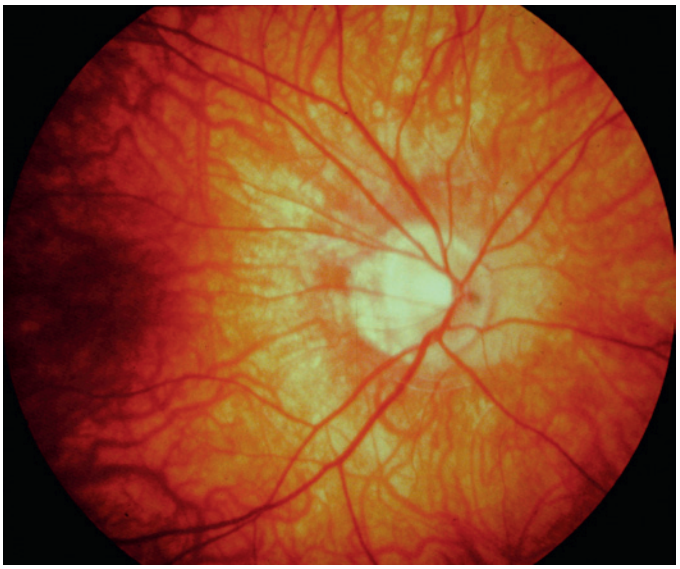

Fig. 46.1 X-linked congenital stationary night blindness. Tilted optic disc with myopic fundus.

complete CSNB and a profoundly negative DA 10.0 response. Cone ERGs show subtle abnormalities reflecting ON- bipolar cell dysfunction (Fig. 46.2). There is a detectable rod-specific ERG in incomplete CSNB, and a profoundly negative bright flash response. Cone ERGs are much more abnormal than in complete CSNB, reflecting involvement of both ON- and OFF- bipolar pathways. They show a characteristic triphasic appearance in the 30 Hz flicker response (see Fig. 46.2).

ERG evidence of inner retinal rod system dysfunction may also occur in AD CSNB but in association with normal ISCEV cone ERGs. In other cases of AD CSNB, ERG rod responses are attenuated with normal cone responses, but the standard bright flash response does not have a negative waveform.

Molecular genetics and pathogenesis

Autosomal dominant CSNB Mutations in the genes encoding three components of rod-specific phototransduction have been reported in AD CSNB: rhodopsin (*RHO*), the α-subunit of rod transducin (*GNAT1*), and the rod cyclic guanosine monophosphate (cGMP) phosphodiesterase β-subunit (*PDE6β*).

X-linked CSNB Two causative genes (*CACNA1F* and *NYX*) have been identified, accounting for most families with XL CSNB. *Incomplete* CSNB is associated with mutation in *CACNA1F*, which encodes the retina-specific α_{1F}-subunit of the voltage-gated L-type calcium channel. The expression of *CACNA1F* appears limited to photoreceptors and is prominent in the synaptic terminals. Most mutations are inactivating truncation sequence variants. The loss of functional channels impairs the calcium flux into rod and cone photoreceptors required to sustain tonic neurotransmitter release from presynaptic terminals. This results in the inability to maintain the normal transmembrane potential of bipolar cells, so the retina remains in a partially light-stimulated state, unable to respond to changes in light levels.

Complete CSNB is associated with mutation in *NYX*, the gene encoding the leucine-rich proteoglycan nyctalopin. Leucine-rich repeats are believed to be important for protein interactions, with many of the mutations identified within these repeats. Nyctalopin is expressed in photoreceptor inner segments, outer and inner nuclear layers, and ganglion cells. Nyctalopin may guide and promote the formation and function of the retinal ON- pathway.

Several genotype–phenotype studies have been performed in individuals with either *CACNA1F* or *NYX* mutations. There is considerable inter- and intra-familial phenotypic variability associated with *CACNA1F* mutations, even with an identical sequence variant,[1] suggesting that other genetic or environmental factors modify the phenotype. Although most patients with XL CSNB have non-progressive disease, Nakamura et al. reported two brothers with a *CACNA1F* mutation and progressive decline in vision, with eventually undetectable rod and cone ERGs.[2] We have also infrequently observed slow progression in patients with XL CSNB. Patients with complete XL CSNB (*NYX* mutations) are invariably myopic and have more pronounced night blindness.[3]

Autosomal recessive CSNB Mutations in *GRM6*, *TRPM1*, or *GPR179* lead to complete CSNB. *GRM6* encodes a metabotropic glutamate receptor (mGluR6) located on the dendrites of rod and cone ON- bipolar cells, mediating the sign inversion that occurs at the first synapse, such that glutamate release in the dark by photoreceptors causes hyperpolarization of the ON bipolar cell membrane. TRPM1, a transient receptor potential cation channel, subfamily M, member 1, is probably involved in effecting the membrane voltage change in ON- bipolar cells in response to glutamate. *GPR179* encodes a G protein-coupled receptor expressed in bipolar cells.

Mutations in *CABP4* have been associated with incomplete CSNB. CABP4, a member of the calcium-binding protein (CABP) family, is specifically located in photoreceptor synaptic terminals, where it is directly associated with the *C*-terminal domain of CACNA1F.

Sequence variants have been identified in *SLC24A1*, in patients with AR CSNB without a negative ERG; in the standard scotopic bright flash response, both the a- and b-waves are equally reduced.[4] SLC24A1 is a member of the solute carrier protein superfamily located in inner segments, outer and inner nuclear layers, and ganglion cells.

Åland Island eye disease

Åland Island eye disease (AIED) is an X-linked recessive disorder similar to incomplete CSNB, characterized by reduced visual acuity, nystagmus, nyctalopia, mild red–green dyschromatopsia, and myopia. Affected males may show iris translucency, foveal hypoplasia, and decreased fundus pigmentation. The clinical appearance may resemble X-linked ocular albinism (XLOA) but in XLOA color vision is usually normal and patients with AIED do not show the typical intracranial visual pathway misrouting associated with albinism.[5]

The symptoms of night blindness and the psychophysical and ERG changes seen in AIED are similar to those in the incomplete form of the XL CSNB. The disorders are allelic, with disease-causing variants now identified in *CACNA1F* in AIED.

Other related phenotypes

Patients with a contiguous gene syndrome (which includes glycerol kinase deficiency, congenital adrenal hypoplasia, Duchenne muscular dystrophy [DMD], and ocular abnormalities known as Oregon eye disease), with a deletion of Xp21, have

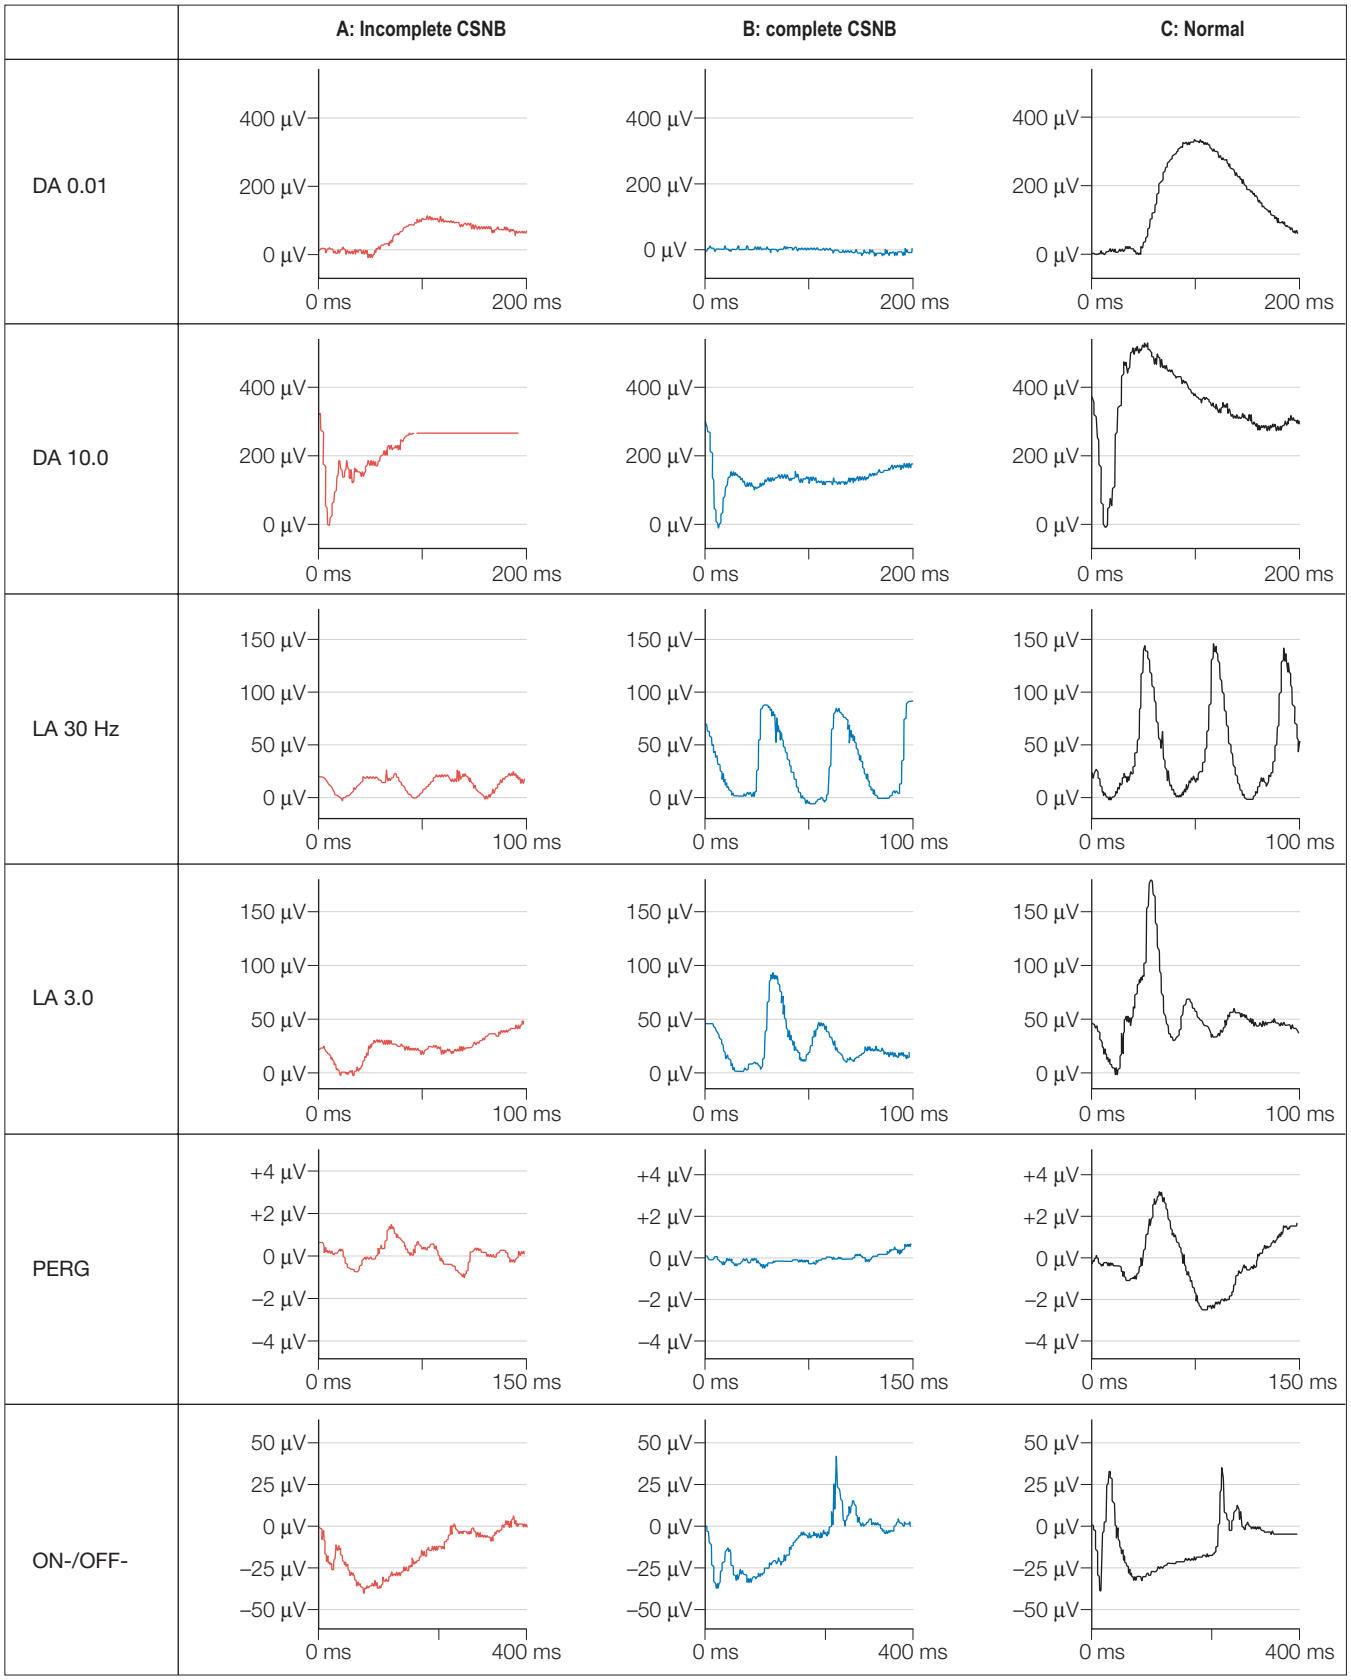

Fig. 46.2 Congenital stationary night blindness. The left-hand column traces (A) show data from a patient with "incomplete" CSNB (iCSNB); the center traces (B) are from a patient with "complete" CSNB (cCSNB); the right-hand column traces (C) are from a representative normal subject. In iCSNB the rod ERG (DA 0.01) is mildly subnormal. The bright flash response (DA 10.0) is electronegative, with a normal a-wave confirming normal photoreceptor function, but a profoundly reduced b-wave. The 30 Hz flicker ERG (LA 30 Hz) is markedly subnormal and clearly shows the delayed double peak characteristically seen in iCSNB. The photopic single flash ERG (LA 3.0) shows marked reduction in the b:a ratio with simplification of the waveform and loss of the photopic oscillatory potentials, shown on ON-/OFF-response recording (200 ms orange stimulus on a green background) to reflect involvement of both ON- (depolarizing) and OFF- (hyperpolarizing) cone bipolar cell pathways. The pattern electroretinogram (PERG) is mildly subnormal in keeping with mild macular dysfunction. In cCSNB there is no detectable DA 0.01 response and the profoundly electronegative DA 10.0 ERG confirms the site of the dysfunction to be post-phototransduction. The LA 3.0 response shows a distinctive broadened a-wave and a sharply rising b-wave with a reduced b:a ratio and lack of photopic oscillatory potentials. This appearance indicates marked dysfunction of cone ON-bipolar cell pathways but preservation of the OFF- pathways. The profoundly negative ON- response, with preservation of the ON- a-wave and loss of the ON-b-wave, accompanied by a normal OFF- response is confirmatory. The broadened trough of the 30 Hz flicker ERG with a sharply rising peak is a manifestation of the same phenomenon. The PERG is almost undetectable. Overall, the findings in cCSNB are those of loss of ON- pathway function in both rod and cone systems.

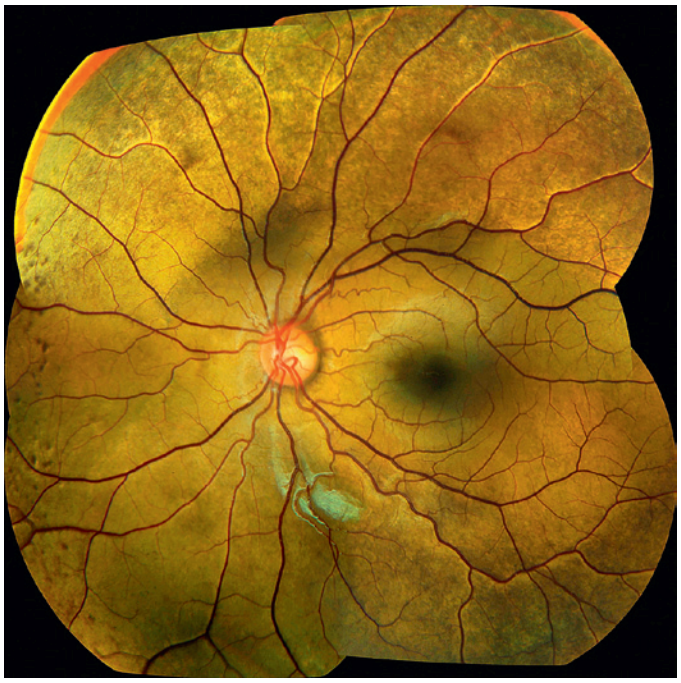

Fig. 46.3 Oguchi disease. Greyish or green-yellow discoloration of the fundus, which reverts to normal on prolonged dark adaptation (Mizuo phenomenon).

ocular features in common with affected males with AIED and have similar predominantly inner retinal ERG abnormalities. Furthermore, some males with isolated DMD (mutations of the dystrophin gene at Xp21) have ERG abnormalities similar to those of CSNB; the ERG phenotype is determined by the site of the mutation within the dystrophin gene. These multisystem disorders have a non-progressive form of predominantly rod system dysfunction.

Oguchi disease

Clinical findings

Oguchi disease is a rare autosomal recessive stationary night blindness with a greyish or green-yellow discoloration of the fundus at the posterior pole or extending beyond the arcades, which reverts to normal on prolonged dark adaptation (Mizuo phenomenon) (Fig. 46.3). Exposure to light then usually leads to the gradual reappearance of the abnormal discoloration in 10–20 minutes.

Most patients present with poor night vision. Visual acuity is normal or mildly reduced and photopic visual fields and color vision are normal. Most cases are from Japan, but it can occur in other races.

Electrophysiology and psychophysics

There are two types of Oguchi disease depending on the dark adaptation findings:

Type 1: rod adaptation is markedly slowed; full recovery of sensitivity takes several hours and the absolute threshold is normal or only minimally elevated.

Type 2: there is no recognizable rod adaptation; the abnormal retinal appearance is less marked and the Mizuo phenomenon may be absent.

Most patients with Oguchi disease have a "negative" bright flash ERG, confirming the site of dysfunction to be post-phototransduction, as in AR and XL CSNB. In contrast to fundus albipunctatus (see below), the ERG remains abnormal even after prolonged dark adaptation.

Molecular genetics and pathogenesis

Oguchi disease in some patients is a consequence of a truncating deletion in *SAG*, encoding arrestin. Reduced activity of arrestin is likely to result in prolonged activation of transducin and rod phosphodiesterase following light exposure. cGMP levels would thereby be maintained at a low level in even dim light exposure and the outer segment cation channels would remain closed resulting in prolonged rod hyperpolarization. The rods would behave as if they were light adapted and would be unresponsive to light at low levels of illumination, explaining the psychophysical abnormalities.

Null mutations in *GRK1*, encoding a second component of the rod phototransduction pathway, rhodopsin kinase (RK), have also been identified in Oguchi disease. The key function, of both RK and arrestin, in the normal deactivation and recovery of the photoreceptor after exposure to light, explains the delayed recovery in Oguchi disease. The consequences of these reported RK mutations have been assessed by expression studies in COS7 cells of wild-type and human mutant RK. The markedly reduced mutant RK activity supports their pathogenicity.[6]

Evidence from knockout mice models suggests that patients with *SAG* or *GRK1* mutations may be more susceptible to light-induced retinal damage; it may therefore be advisable for affected patients to wear tinted spectacles.[7,8]

Fundus albipunctatus

Clinical findings

This autosomal recessive form of stationary night blindness, most commonly related to mutation in *RDH5*, usually has a characteristic fundus appearance with multiple white dots throughout the retina; however, a normal fundus appearance has also been reported with molecular confirmation and the typical functional changes. Patients either present with night blindness or an abnormal retinal appearance on routine fundoscopy. The visual acuity is usually normal and the condition non-progressive.

The deposits are discrete dull-white lesions at the level of the retinal pigment epithelium (RPE). They are most numerous in the mid-periphery and are usually absent at the macula; the optic discs and retinal vessels are normal. Fluorescein angiography shows multiple areas of hyperfluorescence, which may not directly correlate to the deposits seen clinically. In some patients there is good correlation between the white dots and increased autofluorescence on fundus autofluorescence imaging, but not in others. The differential diagnosis is from other causes of flecked retina (see Chapter 50).

Electrophysiology and psychophysics

Dark adaptation is severely delayed in fundus albipunctatus (FA), reflecting abnormal regeneration of rhodopsin. The rod–cone break is delayed and full rod adaptation may take many hours. Rod ERGs are markedly abnormal, with the rod-specific ERG (DA 0.01) usually being undetectable under standard conditions, but normalizing following prolonged dark adaptation (Fig. 46.4). The dark-adapted bright flash ERG (DA 10.0), which after a standard period of dark adaptation arises in dark-adapted cones, can have a low b:a ratio; a red

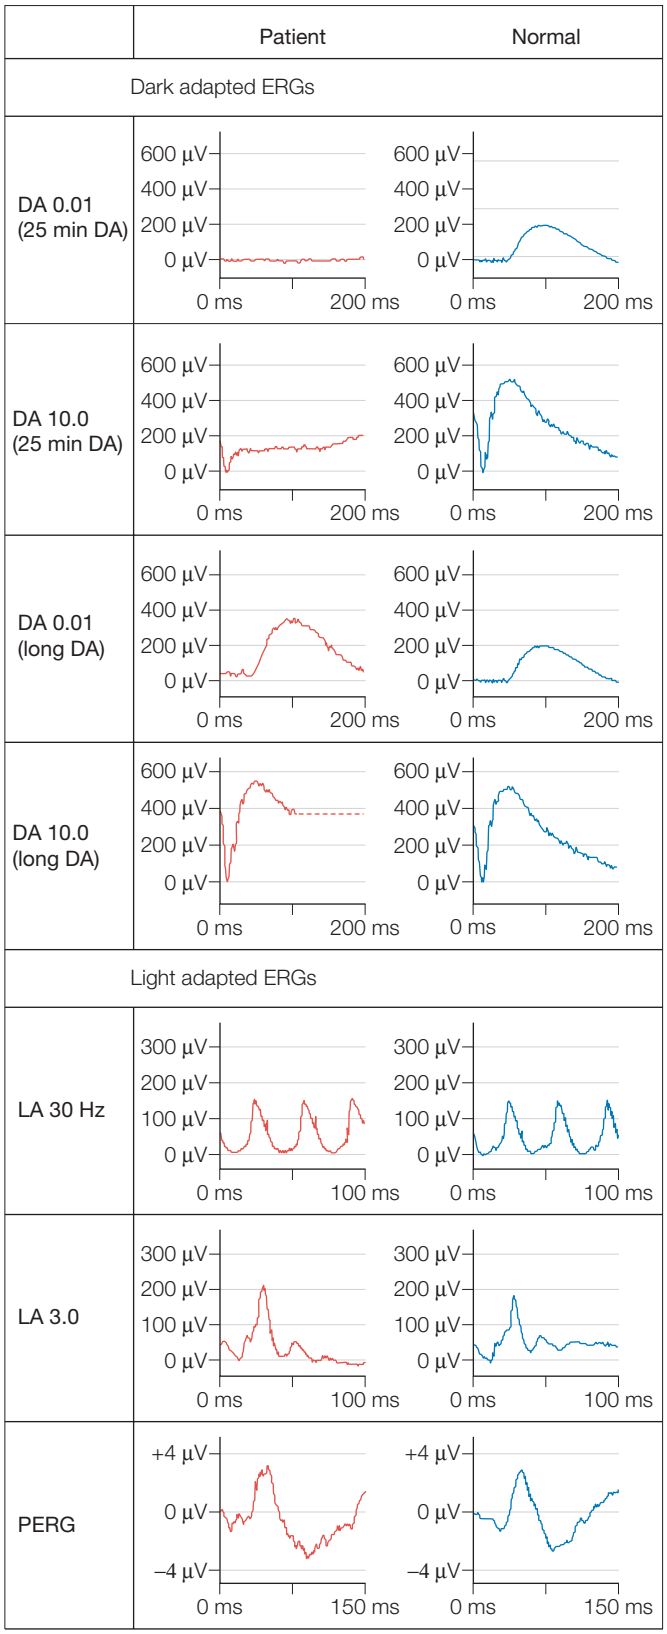

Fig. 46.4 Fundus albipunctatus. The DA 0.01 electroretinogram (ERG) is undetectable following a standard period of dark adaptation and the DA 10.0 response is reduced with additional reduction in the b:a ratio, in keeping with an origin in dark-adapted cones. Following an extended period of dark adaptation, both DA 0.01 and DA 10.0 responses are completely normal in keeping with delayed restoration of normal levels of rhodopsin.

flash stimulus under dark adaptation shows a normal cone component but an undetectable rod component and prevents confusion with CSNB associated with a negative ERG. It is necessary to considerably exceed the ISCEV ERG standard recommendations for dark adaptation to confirm the diagnosis of FA. Most but not all patients with *RDH5* mutations show full recovery of rod function with extended dark adaptation. This contrasts with the findings in retinitis punctata albescens (see below), related to mutation in *RLBP1*, and usually helps to distinguish between the two disorders.

There are two forms of FA, one in which cone ERGs are normal, and a rarer form described as fundus albipunctatus with cone dystrophy and negative ERG.[9–11]

Molecular genetics and pathogenesis

Mutations in three genes (*RDH5*, *RLBP1*, and *RPE65*), encoding components of the visual cycle, have been identified to date. The gene *RDH5* encodes 11-*cis*-retinol dehydrogenase. Recombinant mutant 11-*cis*-retinol dehydrogenases have reduced activity compared with recombinant enzyme with wild-type sequence.[10] The function of the protein product of *RDH5* is consistent with the delay in the regeneration of photopigments characteristic of the disorder.

Mutations have also been reported in *RLBP1*, encoding the cytosolic cellular retinaldehyde binding protein (CRALBP). *RLBP1* mutations usually cause retinitis punctata albescens (see below). CRALBP has been localized to the RPE, Müller cells, and ciliary epithelium. It can select 11-*cis*-retinaldehyde from a mixture of retinoids and protect it from photoisomerization, suggesting a possible role in the generation of 11-*cis*-retinoids in the visual cycle and in keeping with the phenotypic features of FA.

Sequence variants in *RPE65* have also been identified in patients with a retinal appearance similar to FA.[12] Reduced fundus autofluorescence has been observed in patients with *RPE65* and *RDH5* mutations,[11,12] supporting the concept that disruption of retinoid recycling in the RPE is essential for the development of FA.

Stationary cone disorders (cone dysfunction syndromes)

The cone dysfunction syndromes include congenital color vision disorders where there is normal visual acuity but defective color vision, and the various forms of cone dysfunction associated with reduced central vision and often nystagmus and photophobia (Table 46.1).[13]

Disorders of color vision with normal visual acuity

Color vision in humans is trichromatic; there are three classes of cone photoreceptor that contain visual pigments maximally sensitive at 560 nm (L-cones [red]), 535 nm (M-cones [green]), and 440 nm (S-cones [blue]). The genes for the protein component (opsin) of the L- and M-cone pigments are on the long arm of the X chromosome, and the S-cone opsin gene on chromosome 7. About 8% of men and 0.5% of women have a red–green color vision defect, which is associated with abnormalities of the red and green cone opsin genes. Tritanopia is an uncommon autosomal dominant disorder in which there is a specific deficiency of S-cone sensitivity associated with mutations of the S-cone opsin gene.

Table 46.1 Summary of the cone dysfunction syndromes

Cone dysfunction syndrome	Alternative names	Mode of inheritance	Visual acuity	Refractive error	Nystagmus	Color vision	Fundi	Mutated gene(s) or chromosome locus
Complete achromatopsia	Rod monochromatism Typical achromatopsia	Autosomal recessive	6/36–6/60	Often hypermetropia	Present	Absent	Usually normal	*CNGA3* *CNGB3* *GNAT2* *PDE6C* *PDE6H* *ATF6*
Incomplete achromatopsia	Atypical achromatopsia	Autosomal recessive	6/24–6/60	Often hypermetropia	Present	Residual	Usually normal	*CNGA3* *PDE6C*
Oligocone trichromacy	Oligocone syndrome	Autosomal recessive	6/12–6/24	Equal incidence of myopia and hypermetropia	Often absent	Normal	Normal	–
RGS9/R9AP retinopathy	Bradyopsia	Autosomal recessive	6/12–6/24	Equal incidence of myopia and hypermetropia	Often absent	Normal	Normal	*RGS9* *R9AP*
Cone monochromatism	–	Uncertain	6/6	–	Absent	Absent or markedly reduced	Normal	–
Blue cone monochromatism	X-linked atypical achromatopsia X-linked incomplete achromatopsia	X-linked	6/24–6/60	Often myopia	Present	Residual tritan discrimination	Usually normal or myopic	(i) Deletion of the locus control region (ii) Single inactivated L/M hybrid gene
Bornholm eye disease	–	X-linked	6/9–6/18	Moderate-to-high myopia with astigmatism	Absent	Deuteranopia Protanopia	Myopic	L/M opsin array

This group of disorders, their clinical characteristics, and the molecular pathology are reviewed elsewhere.[14]

Achromatopsia

Achromatopsia is genetically heterogeneous and characterized by an absence of functioning cones in the retina.[13] It may occur in complete (typical) and incomplete (atypical) forms.

Complete achromatopsia (rod monochromatism)

Clinical and histopathologic findings

The usual presentation is with reduced vision, nystagmus, and marked photophobia at birth or early infancy. The incidence is approximately 1 in 30,000. Parents often comment that vision is much better in dim illumination. Pupil reactions are sluggish or may show paradoxical constriction in the dark. High hyperopic refractive errors may be present and the fundi are normal. The nystagmus and photophobia, marked in infancy, may improve with age. The visual acuity is usually 6/60 and there is complete color blindness. Peripheral visual fields are normal but a central scotoma can often be detected. Achromatopsia is generally a stationary disorder but slow deterioration and macular atrophy may occur.[15,16]

Histopathologic studies have demonstrated cone-like structures in the retina,[17,18] which have also been observed *in vivo* using adaptive optics imaging, albeit to a variable degree.[16] Thus, cone function could potentially be rescued with gene replacement therapy.

Electrophysiology and psychophysics

The dark adaptation curve is monophasic with no evidence of a cone contribution. Spectral sensitivity studies show that rods mediate threshold under both photopic and scotopic conditions; there is no evidence of a Purkinje shift. Electroretinography (Fig. 46.5) shows normal rod-derived ERGs but no detectable cone-derived responses.

Molecular genetics and pathogenesis

Achromatopsia is recessively inherited and genetically heterogeneous. Five genes have been identified, *CNGA3*, *CNGB3*, *GNAT2*, *PDE6C*, and PDE6H, all encoding components of cone phototransduction.

CNGA3 and *CNGB3* code for the α- and β-subunits of the cGMP-gated (CNG) cation channel in cone cells, respectively. In the dark, cGMP levels are high in cone photoreceptors, enabling cGMP to bind to the α- and β-subunits of CNG channels. This results in them adopting an open conformation and permitting influx of cations, with consequent cone depolarization. When light is applied, activated photopigment interacts with transducin, a three-subunit guanine nucleotide binding protein, stimulating the exchange of bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP). The

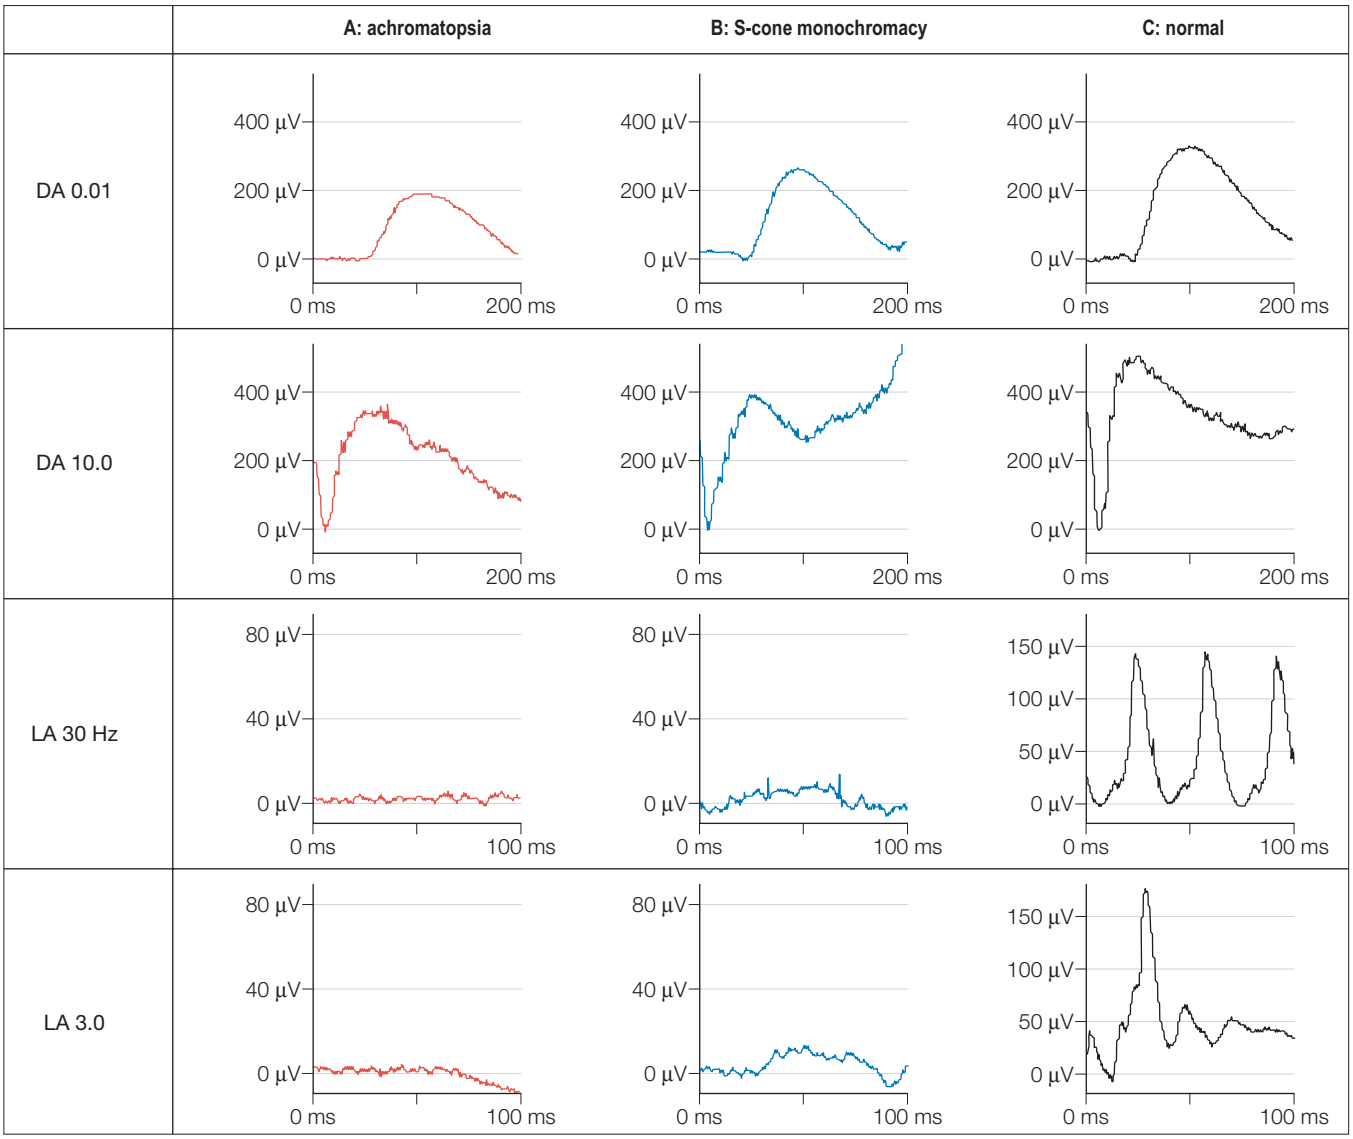

Fig. 46.5 Electroretinograms (ERGs) from a patient with achromatopsia (A), a patient with S-cone monochromacy (B), and a representative normal (C). The rod-specific (DA 0.01) and bright flash ERGs (DA 10.0) show no definite abnormality in either of these cone dysfunction syndromes. The 30 Hz flicker ERG (LA 30 Hz) is undetectable in both, but the single flash photopic ERG (LA 3.0) is small and late, typical of S-cone origins. Note that the scale for the photopic ERGs in the two patients differs from that in the normal subject better to illustrate the low amplitude LA 3.0 response in the S-cone monochromat.

cone α-transducin subunit (encoded by *GNAT2*), which is bound to GTP, is then released from its β- and γ-subunits and activates cGMP-phosphodiesterase by removing the inhibitory γ-subunits (encoded by *PDE6H*) from the active site of this enzyme, which is formed by two α-subunits (encoded by *PDE6C*). cGMP-phosphodiesterase lowers the concentration of cGMP in the photoreceptor, which results in closure of cGMP-gated cation channels.

More than 80 disease-causing mutations in *CNGA3* have been identified in patients with achromatopsia. Four mutations (Arg277Cys, Arg283Trp, Arg436Trp, and Phe547Leu) account for approximately 40% of all mutant *CNGA3* alleles.[19] Far fewer mutations have been identified in *CNGB3*. The 1 base pair frameshift deletion, 1148delC (Thr383fs), accounts for up to 80% of *CNGB3* mutant disease chromosomes.[20,21] The majority of *CNGA3* mutations identified to date are missense mutations, indicating that there is little tolerance for substitutions with respect to functional and structural integrity of the channel polypeptide. In contrast, the majority of *CNGB3* alterations are nonsense mutations.

About 70–80% of achromatopsia results from mutations of *CNGA3* and *CNGB3*, with *GNAT2*, *PDE6C*, *PDE6H*, and *ATF6* each accounting for less than 1–2%[19–21]; further causative genes remain to be discovered.

Incomplete achromatopsia

Clinical findings

The presentation and clinical findings in infancy are similar to the complete form of achromatopsia; however, visual acuity is slightly better (6/24–6/36) with some residual color perception. This form is also inherited as an autosomal recessive trait.

Molecular genetics and pathogenesis

As in the complete form, mutations in *CNGA3* have been identified in individuals with incomplete achromatopsia.[19] The identified mutations are all missense, located throughout

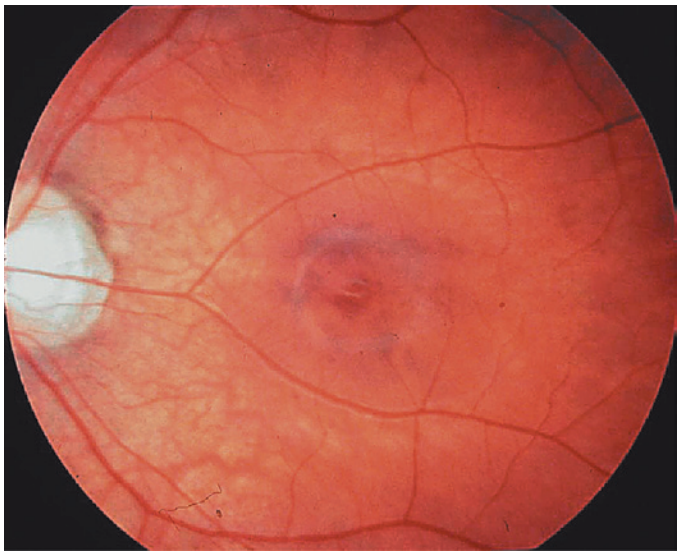

Fig. 46.6 Blue cone monochromatism. Pale tilted optic disc with myopic fundus.

the channel polypeptide including the transmembrane domains, ion pore, and cGMP-binding region. Only three of these, Arg427Cys, Arg563His, and Thr565Met, are exclusively found in patients with incomplete achromatopsia.[19] Therefore, in the majority of cases of incomplete achromatopsia, other factors may influence the phenotype such as modifier genes or environmental factors. The missense variants identified in incomplete achromatopsia must be compatible with residual channel function since the phenotype is milder than in complete achromatopsia. Mutations in *PDE6C*,[22] *GNAT2*, and *CNGB3* have also been identified in incomplete achromatopsia.

S-cone monochromatism (blue cone monochromatism)

Clinical findings

Blue cone monochromatism (BCM; also known as S-cone monochromacy) is an X-linked recessive disorder, affecting approximately 1 in 100,000 individuals, in which affected males have normal rod and S-cone function but lack L- and M-cone function. The clinical features are similar to complete achromatopsia but less severe. Affected infants have photophobia and nystagmus from early infancy. They are usually myopic, in contrast to achromatopsia (Fig. 46.6). The nystagmus often reduces with time.

BCM is generally accepted to be a stationary disorder but deterioration with macular atrophy may occur over time.[23–26]

Electrophysiology and psychophysics

Achromatopsia and BCM may be differentiated by the mode of inheritance, findings on psychophysical testing, and electrophysiology. There is some preservation of the single flash photopic ERG (LA 3.0) in BCM (see Fig. 46.5), and specialized spectral ERG techniques to measure S-cone ERGs can also be used (see Fig. 46.5). Female carriers of X-linked BCM may have abnormal cone ERGs and mild anomalies of color vision.

Color vision tests that probe the tritan color axis, such as the Hardy, Rand, and Rittler (HRR) plates, are necessary in order to distinguish between achromatopsia and BCM, with relative preservation of tritan discrimination in BCM. Blue cone monochromats display fewer errors along the vertical axis in the Farnsworth 100-hue test (fewer tritan errors), and may display protan-like patterns on the Farnsworth D-15.

Molecular genetics and pathogenesis

Mutation analyses have established the molecular basis for BCM.[24] The mutations in the L- and M-opsin gene array causing BCM fall into two main classes:

1. A normal L- (*OPN1LW*) and M- (*OPN1MW*) pigment gene array is inactivated by a deletion in the locus control region (LCR), located upstream of the L-pigment gene. A deletion here abolishes transcription of all genes in the pigment gene array and therefore inactivates both L- and M-cones.
2. The LCR is preserved but changes within the L- and M-pigment gene array lead to loss of functional pigment production. The most common genotype in this class consists of a single inactivated L/M hybrid gene. The first step in this second mechanism is unequal crossing over reducing the number of genes in the array to one, followed in the second step by a mutation that inactivates the remaining gene. The most frequent inactivating mutation that has been described is a thymine-to-cytosine transition at nucleotide 648, which results in a cysteine-to-arginine substitution at codon 203 (Cys203Arg), a mutation known to disrupt the folding of cone opsin molecules.

The data suggest that 40% of BCM results from the one-step mutational pathway (deletions in the LCR). The remaining 60% of BCM is predominantly secondary to the aforementioned two-step pathway. Other less common mutational mechanisms include the deletion of an entire exon in a single opsin array gene or gene conversion transferring a mutation between *OPN1LW* and *OPN1MW*.

Oligocone trichromacy

Oligocone trichromacy is characterized by reduced visual acuity (6/12 to 6/24), mild photophobia, normal fundi, reduced cone ERGs with normal rod responses, and normal color vision.[13] Patients have been described both with and without nystagmus. These patients have a reduced number of normal functioning cones (oligocone) with preservation of the three cone types in the normal proportions, thereby permitting trichromacy, supported by high-resolution quantitative retinal imaging.[27]

Color vision testing either reveals normal or slightly elevated color discrimination thresholds. Slightly elevated discrimination thresholds are compatible with a reduction in cone numbers.

Oligocone trichromacy is inherited as an autosomal recessive trait; the condition is likely to be genetically heterogeneous and some patients have been reported with variants in *CNGB3* and *CNGA3*. Patients with either *RGS9*/*R9AP* mutations ("bradyopsia", see below) or oligocone trichromacy have similar clinical phenotypes, characterized by stationary cone dysfunction with normal color vision[28] but the electrophysiologic features associated with *RGS9* and *R9AP* are distinctive.

RGS9/R9AP retinopathy ("Bradyopsia")

Clinical findings

Bradyopsia is a stationary cone dysfunction syndrome with onset in early childhood; it is characterized by mild photophobia, delayed dark and light adaptation, moderately reduced visual acuity, normal color vision, and normal fundi. Some patients report difficulty seeing moving objects. It is not possible clinically to distinguish bradyopsia from oligocone trichromacy; however, there are pathognomonic findings on extended electrophysiologic assessment.[28]

Electrophysiology

The rod-specific ERG (DA 0.01), the red flash ERG under dark adaptation (which has both a cone and rod component), and the single bright white flash (DA 10.0) with inter-stimulus interval (ISI) of 2 minutes are normal. The usual DA 10.0 ERGs, with an ISCEV standard ISI of 20 seconds show amplitude reduction and waveform change, which becomes progressively less severe with increasing ISI, consistent with delayed recovery following the flash. The pattern electroretinogram (PERG) and standard 30 Hz flicker ERG (LA 30 Hz) are usually undetectable. A residual low amplitude standard photopic single flash ERG (LA 3.0) is usually recorded.

The ISCEV ERG standard protocol in *RGS9/R9AP* mutation shows normal dark-adapted responses, an undetectable 30 Hz flicker ERG, and a severely reduced LA 3.0 ERG, suggesting incomplete achromatopsia. However, ERGs to a red flash under dark adaptation, which in a normal subject gives an early cone system-derived response and a later rod system-derived response, show that dark-adapted cones retain good function and rule out achromatopsia.

Molecular genetics and pathogenesis

Mutations in both *RGS9* and *R9AP* have been associated with bradyopsia, with no sequence variants in either of these genes identified in subjects with oligocone trichromacy.[28]

Each of the activated phototransduction molecules has to be deactivated to turn off the visual response; α-transducin and cGMP-phosphodiesterase are simultaneously deactivated by the hydrolysis of the α-transducin-bound GTP to GDP. This GTPase activity is substantially accelerated by RGS9, a GTPase-activating protein that binds to the Gβ5 subunit, and to R9AP, a membrane anchor protein. RGS9 and R9AP have a critical role in the recovery phase of visual transduction. RGS9 is anchored to photoreceptor outer segment disc membranes by R9AP; R9AP is required for the correct targeting and localization of RGS9 in photoreceptors and enhances RGS9 activity up to 70-fold.

Bornholm eye disease

Clinical findings

Bornholm eye disease (BED) is an X-linked disorder with myopia and astigmatism, impaired visual acuity, moderate optic nerve hypoplasia, thinning of the RPE in the posterior pole with visible choroidal vasculature, and abnormal cone ERGs.[29] Affected members in this single family were all deuteranopes, with a stationary natural history; a similar phenotype has however also been published in association with protanopia.[30,31] This disorder is therefore best described as an X-linked cone dysfunction syndrome with myopia and dichromacy.

Molecular genetics and pathogenesis

The condition was mapped by linkage analysis in the original Danish family to Xq28, in the same chromosomal region as the L/M opsin gene array. Subsequent genetic interrogation has shown that rare haplotypes ("L/M interchange haplotypes") at polymorphic positions in exon 3 of the opsin genes, which result from intermixing between L and M opsin genes, are the principal underlying genetic basis of BED. Some of these interchange haplotypes have been shown to result in aberrant splicing of the opsin genes and a variable degree of exon 3 skipping.

Progressive retinal dystrophies

Rod–cone dystrophies

The rod–cone dystrophies (retinitis pigmentosa [RP]) are a clinically and genetically heterogeneous group of disorders with progressive loss of rod and later cone photoreceptor function leading to severe visual impairment. RP usually occurs as an isolated retinal abnormality, but it may also be syndromic with other systemic abnormalities (see Chapter 47).

Leber congenital amaurosis

Clinical findings

Leber congenital amaurosis (LCA) is a severe congenital or early infant-onset non-syndromic retinal blindness first described by Theodore Leber in 1869. He characterized the disorder by a searching nystagmus, abnormal pupil responses, minimal, if any, vision beyond infancy, and an initially normal fundus appearance followed by the development of pigmentary changes. He later described a milder form of the same disease, which has had several names, including early-onset severe retinal dystrophy (EOSRD), severe early childhood-onset retinal dystrophy (SECORD), and early-onset retinitis pigmentosa. Whereas LCA is congenital or presents within the first few months of life, EOSRD is defined as a severe retinal dystrophy presenting before the age of 5 years. LCA/EOSRD is the most common inherited cause of severe visual impairment in children, accounting for 10–18% of children in institutions for the blind.

LCA is associated with severe visual impairment from birth or the first few months of life accompanied by roving eye movements or nystagmus and poor pupillary light responses. Eye-poking, the "oculodigital" sign, is common (Fig. 46.7). Fundus examination may be normal but a variety of abnormal fundus appearances may be present such as disc pallor, vessel attenuation, or mild peripheral pigmentary retinopathy. There may also be disc drusen, optic disc edema or pseudopapilledema (Fig. 46.8), a flecked retina, maculopathy, or nummular pigmentation. Affected infants often have high hyperopia or, less commonly, high myopia, suggesting impaired emmetropization.

Although most patients have normal fundi in infancy, signs of a pigmentary retinopathy appear in later childhood with optic disc pallor and retinal arteriolar narrowing. Other late signs, which may be related to eye-poking, include enophthalmos, keratoconus, and cataract. Eventual vision is in the region of 3/60 to perception of light. Some cases show no evidence of progression over time.

Fig. 46.7 Leber congenital amaurosis. Eye-poking, the "oculodigital sign," is very common but of unknown cause; it results in atrophy of orbital fat and enophthalmos.

Fig. 46.8 Leber congenital amaurosis. High hypermetropia and pseudopapilledema.

Fig. 46.9 Leber congenital amaurosis. *RDH12*-associated disease characterized by bone spicule pigmentation and maculopathy.

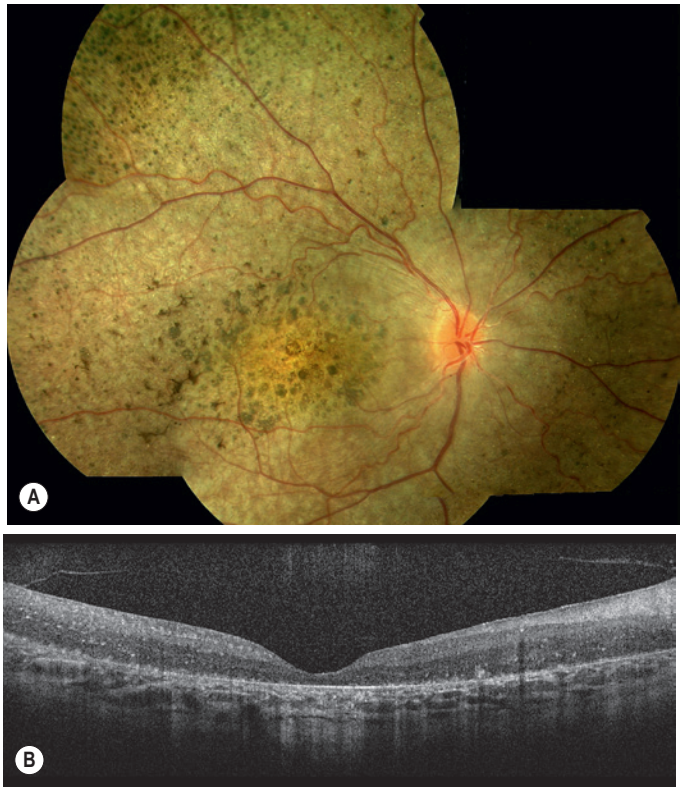

Fig. 46.10 Leber congenital amaurosis. *CRB1*-associated disease which is characterized by (A) nummular pigmentation, maculopathy, relative preservation of para-arteriolar retinal pigment epithelium (RPE), with (B) retinal thickening and loss of lamination observed on optical coherence tomography.

Following the discovery of many disease-causing genes (see below) it has sometimes been possible to identify characteristic associated phenotypes (Figs 46.9–46.12): *RDH12*-associated disease is characterized by bone spicule pigmentation and maculopathy (see Fig. 46.9) and *CRB1*-associated disease has nummular pigmentation, maculopathy, relative preservation of para-arteriolar RPE, with retinal thickening, and loss of lamination on optical coherence tomography (see Figs 46.10 and 46.11). *TULP1*, *AIPL1*, and *NMNAT1*-associated LCA are also characterized by maculopathy.

Electrophysiology

The ERG is undetectable or severely abnormal in infants with LCA. It is important to distinguish LCA from CSNB and achromatopsia, which may also present in infancy with nystagmus and poor vision. The visual evoked potential (VEP) is often undetectable, but VEP preservation, despite an undetectable ERG, is associated with a better visual prognosis.

Fig. 46.11 Leber congenital amaurosis. *CRB1*-associated disease can be complicated by a Coats-like exudative retinopathy.

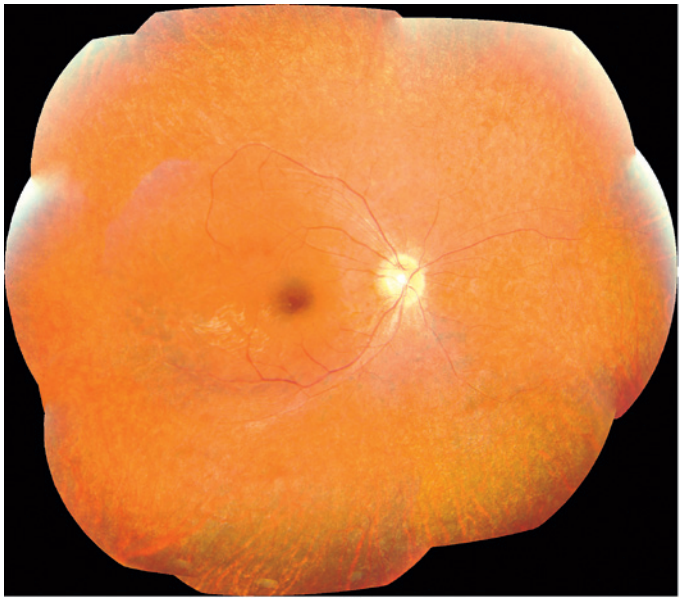

Fig. 46.12 Leber congenital amaurosis. *RPE65*-associated disease often characterized by mild peripheral retinal pigment epithelium (RPE) mottling and white dots at the level of the RPE, usually with relatively normal vessel caliber and optic disc.

Non-ocular features

Most cases of LCA occur in otherwise normal infants and any non-ocular symptoms or signs should be investigated for syndromic retinal dystrophies or neurometabolic disease, usually in conjunction with a pediatrician (see Chapters 47 and 65).

Molecular genetics and pathogenesis

LCA and EOSRD are extremely genetically heterogeneous, being caused by more than 18 genes (including *AIPL1*, *CEP290*, *CRX*, *CRB1*, *GUCY2D*, *IMPDH1*, *LCA5*, *LRAT*, *MERTK*, *RD3*, *RDH12*, *RPGRIP1*, *RPE65*, *SPATA7*, *KCNJ13*, *ICQB1*, *NMNAT1*, and *TULP1*).[32] All exhibit autosomal recessive inheritance except *CRX*, where certain *de novo* mutations result in an autosomal dominant trait.[32] These genes are usually expressed preferentially in the retina or the RPE. Their putative functions are quite diverse and include retinal photoreceptor development (*CRX*), photoreceptor cell structure (*CRB1*), phototransduction (*GUCY2D*), protein trafficking (*AIPL1*, *RPGRIP1*), and visual cycle function (*RPE65*, *LRAT*).

Molecular genetic testing can now refine the diagnosis in approximately 60–70% of patients, facilitating prognostic counseling. For example, patients with *RPE65* mutations have a better visual outcome than those with *GUCY2D* mutations.[32] Identification of disease-causing mutations in LCA patients allows improved genetic counseling, the potential for prenatal diagnosis, and selection of patients for gene-specific therapies.

Therapeutic intervention

Animal models of retinal blindness from deficiency of *RPE65* have either been engineered via targeted disruption of the gene in the mouse, or are available due to a natural mutation in the Briard dog. Pharmacologic bypass of the metabolic block, using synthetic retinoids, has resulted in rapid restoration of visual pigment and function in the mouse. Gene replacement, using a normal copy of the gene in an adeno-associated virus (AAV) vector administered subretinally, has successfully restored ERGs and retinal function in both the murine and the canine models, resulting in substantial, durable recovery of vision as determined by ERGs, pupillary responses, and behavioral measures. This success has led to human clinical trials in the USA and UK involving a subretinal injection of AAV-vector delivering a wild-type copy of *RPE65*. These have all reported good safety with varying degrees of efficacy, which waned over time.[33–35]

Further forms of LCA/EOSRD are now subject to ongoing gene replacement clinical trials, with more anticipated (www.clinicaltrials.gov).

Retinitis pigmentosa

Retinitis pigmentosa (RP) is a term used for a genetically heterogeneous group of disorders characterized initially by night blindness and visual field loss. ERGs may be undetectable or, more frequently, show the rod system to be more severely affected than the cone system, at the level of the photoreceptor. Dysfunction confined to the rod system is unusual but can occur early in the course of the disorder. Onset is often in childhood and inheritance can be autosomal recessive, autosomal dominant and X-linked. The disease may be confined to the eye or it may be part of a more widespread systemic disorder (see Chapter 47).

Clinical findings

Children with RP most commonly present with night blindness, but can also present with symptoms associated with peripheral field loss or central retinal involvement. The age of onset is extremely variable. In some, there may be no symptomatic night blindness and the child is referred after routine fundoscopy. When a close relative has RP, children may be referred early for investigation to exclude the disease.

In most cases, the visual acuity is initially normal; later, visual loss may occur from posterior subcapsular cataract, macular edema, or macular involvement. Early visual field changes are small scotomata in the mid-periphery, commonly in the upper visual field. These gradually coalesce to give

the classical peripheral ring scotoma. Visual fields become concentrically constricted over time, often leaving an island of preserved field in the far temporal periphery until late in the disease. In sector RP, which commonly involves the lower nasal quadrant, bilateral upper temporal field loss may lead to unnecessary investigation to exclude a chiasmal lesion – it should be noted that the temporal field defect in RP does not respect the midline.

The appearance of the fundus in the early stages of RP is variable and, in young children, subtle. The earliest change may be mild pigment epithelial disturbance in the mid-periphery, often with small white dots at the level of the RPE (Fig. 46.13). Later, pigment deposition is seen and there may be arteriolar narrowing and optic disc pallor. Abnormal pigment may be lacking in some children and, less commonly, there may be multiple white deposits throughout the retina (similar to retinitis punctata albescens). The classical fundus appearance of optic disc pallor, retinal arteriolar attenuation, and peripheral pigment epithelial atrophy and intra-retinal "bone corpuscle" pigmentation is present in late disease (Fig. 46.14). Other findings may include vitreous cells, posterior subcapsular cataract, optic disc drusen, and macular edema. Occasionally, retinovascular changes similar to Coats disease are seen.

The retinal phenotype is similar in most forms of RP although there may be marked variation in severity between affected individuals. There are, however, some gene-specific phenotypes. AD sector RP is usually associated with mutations in the rhodopsin gene, and the uncommon AR form of RP (RP12) with preserved para-arteriolar RPE, is associated with *CRB1* mutations. Two early-onset forms of AR RP caused by mutations in the *RLBP1* gene are associated with multiple white deposits at the level of the RPE (Newfoundland rod–cone dystrophy and Bothnia dystrophy).[36,37]

Electrophysiology and psychophysics

The ERG in RP shows a rod–cone pattern of dysfunction; the rod-derived responses are more affected than the cone-derived responses. There is marked variation in severity, partly related to the nature of the mutation, the inheritance pattern, and the subject's age. The ERG may be undetectable in the late stages of RP, or small residual cone responses may be found. There is reduction in the amplitude of the rod a- and b-waves in mild disease or early RP and the rod-mediated b-wave peak-time may be prolonged. The 30 Hz cone flicker ERG is usually both delayed and reduced, in keeping with generalized cone system dysfunction.

The macula may be spared and central retinal function tests, such as the PERG or multifocal ERG, may show minimal involvement despite almost complete loss of the full-field ERG. PERG may also be helpful in demonstrating central retinal involvement prior to the development of visible abnormalities. The electro-oculogram (EOG) provides little relevant information in RP and can be difficult to perform in young children.

Sector retinitis pigmentosa

The term "sector RP" should be reserved for those forms of RP (usually AD) where functional testing suggests restricted loss of function; pigmentary abnormalities are usually confined to the inferior retina (Fig. 46.15). A similar sectorial involvement may occasionally be seen in the female carriers of X-linked RP or as an early stage in generalized RP. The ERG in true sector RP usually shows amplitude reduction but no peak-time changes; the presence of marked peak-time shift suggests generalized dysfunction even though the pigmentary changes may be restricted. It is important in isolated cases to examine other family members, as the disorder is often asymptomatic. Dominant sector RP is often associated with mutations of the rhodopsin gene. Children with sector RP are usually asymptomatic and are referred when an abnormal fundus appearance is noted on routine fundoscopy or they are ascertained during family surveys.

Field loss on Goldmann perimetry is confined to the sector corresponding to the clinically involved retina. However, dark-adapted perimetry may show mild rod and cone threshold elevation in the apparently uninvolved retina indicating dysfunction outside the clinically evident region. Rod dark

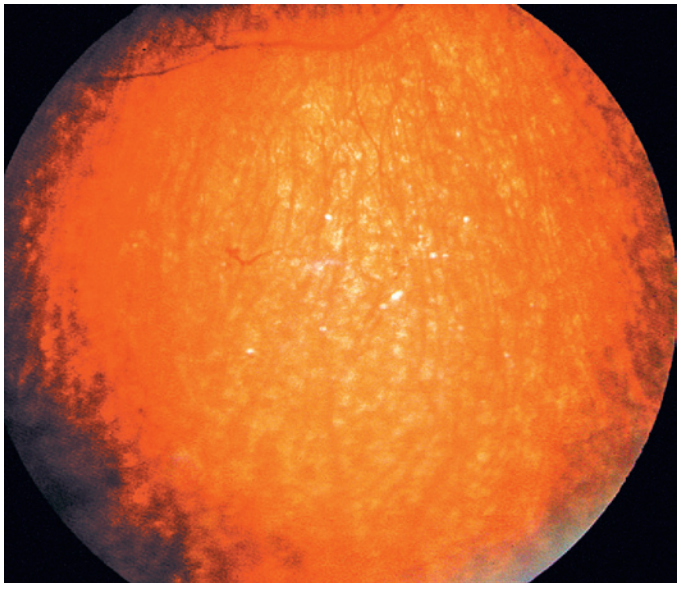

Fig. 46.13 Retinitis pigmentosa. Pigment epithelial atrophy in the mid-periphery with small white dots at the level of the retinal pigment epithelium.

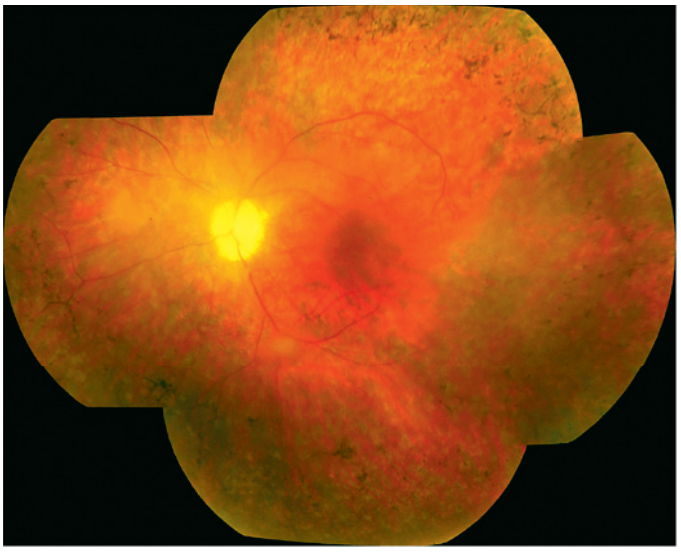

Fig. 46.14 Retinitis pigmentosa. "Bone spicule" formation, arteriolar narrowing, and optic nerve pallor.

Fig. 46.15 Sector retinitis pigmentosa. Retinal pigmentary changes confined to the lower quadrants.

adaptation may be extremely delayed. The ERG is usually relatively well preserved with mild or moderate reductions in both rod and cone amplitudes. Disease progression is slow and usually confined to the clinically involved sector. The visual prognosis is good.

Autosomal dominant retinitis pigmentosa with incomplete penetrance

Variability of expression is common in autosomal dominant RP, but true non-penetrance is unusual. However, incomplete penetrance is notable and common in many families. There is genetic heterogeneity in autosomal dominant RP with incomplete penetrance; mutations have been identified in several genes including *RP9*, *RP1*, *PRPF8*, and *PRPF31*.

Genetic counseling in families showing incomplete penetrance may be problematic because of the high incidence of asymptomatic gene carriers, but molecular genetic diagnosis is now possible in many families.

X-linked retinitis pigmentosa

X-linked RP is severe with onset of night blindness usually by 10 years and progression to blindness by the third to fourth decade. Those affected are often myopic and show fundus abnormalities and ERG changes early (Fig. 46.16). If there is a family history of other affected males, the diagnosis is usually straightforward. Examination of close female relatives is helpful in the absence of a family history, as the recognition of the XL carrier state confirms the diagnosis.

The carrier state for XL RP can be diagnosed with certainty in females who have affected sons or fathers and are therefore obligate gene carriers, or where they can be shown by molecular genetic testing to carry the causative mutation. In other female family members, carrier detection depends upon recognition of the heterozygote's abnormal fundus appearance or on the results of autofluorescence imaging, and electrophysiologic or psychophysical testing.

Fundus abnormalities are common in XL heterozygotes: a prominent "tapetal" reflex may be seen at the posterior pole (Fig. 46.17) or a mild pigment epithelial thinning and pigmentation. The ERG is usually abnormal and asymmetric in heterozygotes (see Fig. 46.16). Delay in the 30 Hz flicker response is probably the most frequent abnormality, but reduced rod amplitude may also occur. XL carriers can be identified in most cases using a combination of fundoscopy, autofluorescence imaging, and electrophysiology. Molecular genetic diagnosis is possible in many families and is increasingly the method of choice for identification of heterozygotes.

The retinal dysfunction in some XL carriers can be progressive, as older carriers may report symptoms of night blindness, have detectable field loss, and more extensive retinal pigmentation. Some carrier females may be severely affected at a relatively young age; however, there is considerable intra- and interfamilial variability. Skewed X inactivation, with the X chromosome having the mutant allele active in most cells, may account for severely affected females.

Unilateral "retinitis pigmentosa"

Fundus changes of unilateral pigmentary retinopathy have been described but only one genetically confirmed case from an extended family with RP. The patient with unilateral RP in that family[38] harbored a common nonsense mutation in *RP1*, a common cause of AD RP. Thus, a somatic mutation might have occurred in a progenitor cell during the development of the unaffected retinal tissue that ameliorates the effect of the *RP1* mutation.[38]

Most other cases are probably not genetically determined and may be post-inflammatory, post-traumatic, or follow retinal ischemia. A minority of individuals with RP have an asymmetric fundus appearance at presentation so that one eye appears clinically unaffected, but psychophysical testing and ERG demonstrate abnormal function bilaterally.

Differential diagnosis of retinitis pigmentosa

Other disorders may be confused with RP either because there is symptomatic night blindness or because of a similar fundus appearance (Table 46.2 and Fig. 46.18). Other inherited retinal dystrophies can usually be differentiated from RP by the clinical findings and electrophysiology. Although history and examination may exclude many of the acquired causes of pigmentary retinopathy, it is likely that some cases of apparently sporadic RP are due to acquired retinal or pigment epithelial disease.

Genetics of retinitis pigmentosa

RP may be inherited as an autosomal dominant, autosomal recessive, or X-linked recessive disorder. There is genetic heterogeneity within these subtypes. The relative frequency of the different modes of inheritance differs widely in different series, but 50% of patients have no family history of RP or parental consanguinity. It is unlikely that all such cases have AR disease. Some males may have XL disease transmitted via asymptomatic female carriers; other cases may represent new AD mutations or AD disease in a family with reduced penetrance. Some sporadic patients may not have genetic disease. Similar retinal dystrophies may be seen in association with mutations of mitochondrial DNA but there are usually other systemic abnormalities (see Chapters 47 and 65).

XL and AR RP tend to have an earlier onset and are more severe than dominant disease. The clinical findings should be taken into account, particularly when counseling those patients with apparently sporadic disease. A severely affected female is more likely to have AR disease, whereas a severely affected male may have XL or AR disease. A significant number of patients with sporadic RP, however, have mild disease and

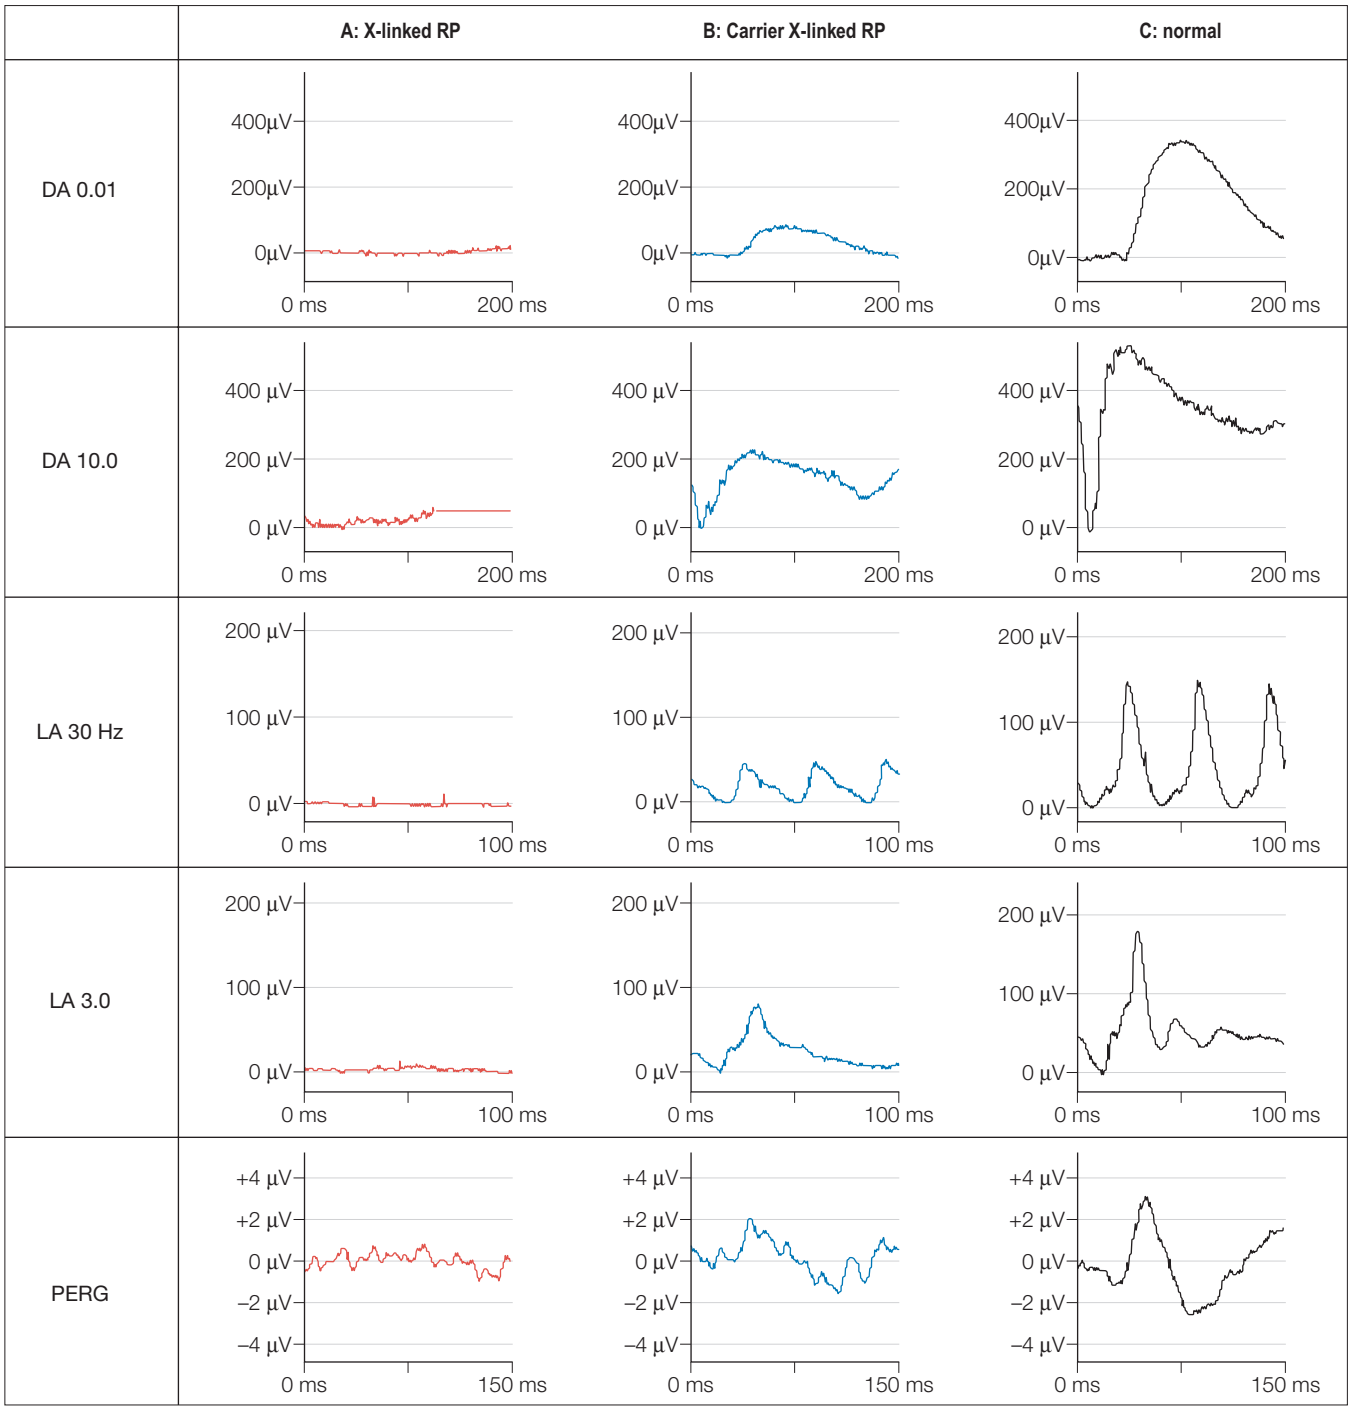

Fig. 46.16 X-linked retinitis pigmentosa (RP). Electroretinograms (ERGs) from a young affected patient (A), his heterozygote mother (B), and a representative normal subject (C). There is only residual ERG activity detectable in the patient. The ERGs in his mother are mildly subnormal under all stimulus conditions, the subnormal a-wave of the bright flash response (DA 10.0) confirming the abnormality to be at the level of the photoreceptor. ERG abnormalities are usually present in heterozygotes, and can vary from mild to severe.

some of these probably have new AD mutations. Prior to counseling, it is important to examine other family members, especially the mothers of severely affected males who may show the fundus/imaging or electrophysiologic abnormalities of an X-linked heterozygote.

Accurate genetic counseling depends upon identification of the causative mutation. Much progress has been made in identifying the causative genes, and molecular genetic diagnosis is now possible in many forms of RP. More than 60 genes have been identified in non-syndromic RP, encoding proteins of the phototransduction cascade, proteins involved in vitamin A metabolism and cell–cell interaction, photoreceptor structural proteins and transcription factors, intracellular transport proteins, and splicing factors.[39–41] The advent of exome and whole-genome sequencing, and their use in clinical practice, will greatly improve the efficiency of molecular diagnosis and will allow the causative mutation to be identified in most patients with RP.

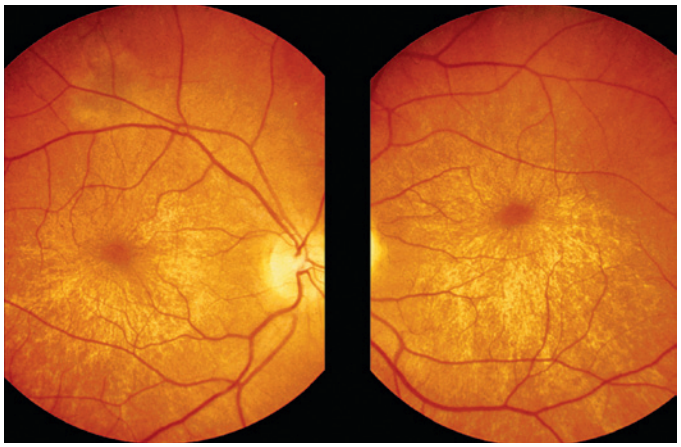

Fig. 46.17 X-linked retinitis pigmentosa carrier female showing the "tapetal reflex."

Fig. 46.18 Rubella retinopathy showing retinal pigment mottling. Retinal function is usually good and the electroretinogram (ERG) normal, whereas most retinal dystrophies with deafness have severely abnormal ERGs.

Table 46.2 Differential diagnoses of retinitis pigmentosa

Pigmentary retinopathy	Night blindness
Blunt trauma	**Genetic disorders**
Retained intraocular foreign body	Congenital stationary night blindness
Congenital infection	Oguchi disease
Rubella	Fundus albipunctatus
Varicella	Choroideraemia
Herpes simplex	Gyrate atrophy
Syphilis	Progressive cone–rod dystrophy
Acquired infection	Enhanced S-cone syndrome
Measles	**Acquired**
Onchocerciasis	Vitamin A deficiency
Metabolic	Desferrioxamine toxicity
Cystinosis	
Oxalosis	
Drugs	
Phenothiazines	
Chloroquine	
Desferrioxamine	
Resolved retinal detachment	
Ophthalmic artery occlusion	
Other retinal dystrophies	
Cone–rod dystrophy	
Inherited vitreoretinal dystrophies	
Enhanced S-cone syndrome	
Unknown etiology	
Pigmented paravenous chorioretinal atrophy	

Molecular genetics

Autosomal dominant retinitis pigmentosa There is considerable genetic heterogeneity within AD RP. Mutations in more than 25 genes have been identified, accounting for approximately 60–70% of patients with AD RP; mutations in the rhodopsin gene (*RHO*) are the most common. Sequence variants in *RP1* and *PRPF31* are the next most common causes of AD RP.

Mutations of the rhodopsin gene account for about 25% of patients with AD RP; more than 100 different mutations have been identified. There is considerable variation in the ocular phenotype seen with the different mutations, which has also been reported in dominant forms of CSNB and AR RP. The phenotypic variability is even more marked with mutations of the gene *PRPH2* (formerly *RDS/peripherin*), where the clinical picture may resemble RP, cone–rod dystrophy, cone dystrophy, a fleck retina syndrome, or macular dystrophy (see Chapters 48 and 50). *PRPH2* mutations account for about 5–10% of cases of AD RP.[39–41]

In an unusual form of RP showing digenic inheritance, mutations of both the *PRPH2* and *ROM1* (rod outer segment protein 1) genes are present within the same family. Individuals with a mutation of one gene but not the other are clinically unaffected. Affected individuals are double heterozygotes with mutations of both *ROM1* and *PRPH2*. Peripherin is located in rod and cone outer segment discs, whereas ROM1 is only found in rods. Interaction of the two proteins is important for the maintenance of structure in the rod outer segment; some mutations in the *PRPH2* gene may be insufficient to cause significant photoreceptor disease unless accompanied by a defective ROM1 protein.

Splice factors have increasingly been identified as being associated with AD RP, including mutations in *PRPF31*, *PRPF3*, *PRPF6*, and *PRPF8*.[39,40] An insufficiency in splicing function may be disease-causing only under conditions of elevated splicing demand. With the need to replenish disc proteins daily, such conditions exist in rod photoreceptors, which may explain the paradox of isolated retinal disease caused by ubiquitously expressed splice-factor genes.

See references 39, 40, and 41 for AD RP phenotype–genotype correlations.

Autosomal recessive retinitis pigmentosa Mutations in more than 35 genes have been identified to date in AR RP, accounting for approximately 50% of patients with AR RP, the most common being *USH2A* (10–15% of AR RP), with more severe

mutations causing Usher syndrome type 2 (see Chapters 47 and 99).[39–41]

Mutations in genes encoding many components of the rod phototransduction cascade have been identified[39–41] including:

1. the rhodopsin gene;
2. the genes coding for the α-subunit and the β-subunit of the rod cGMP-phosphodiesterase;
3. the genes for the α- and β-subunits of rod cGMP-gated cation channels;
4. S-antigen gene (arrestin);
5. genes coding for components of the visual cycle involved in recycling vitamin A which have been implicated in AR RP, including *RPE65*, *ABCA4*, *LRAT*, and *RLBP1*.

X-linked retinitis pigmentosa Mutations in three genes have been identified in X-linked RP, *RPGR* (RP3), *RP2* (RP2), and *OFD1* (RP23). Sequence variants in *RPGR* cause approximately 75% of all XL RP.[39–41] Two other loci have been reported: Xp21.3–p21.2 (RP6) and Xq26–27 (RP24).

RPGR mutations are usually associated with typical rod–cone degeneration, but in a few patients, retinal dystrophy, deafness, and abnormalities in respiratory cilia have been noted.[42] The majority of mutations may result in premature termination of translation. Exon ORF15 is a "hot spot" for mutations, responsible for 80% of cases of XL RP.[43] RPGR may act as a regulator of a specific type of membrane transport or trafficking that is particularly active in the retina or RPE.

Mutations in *RP2* account for up to 15% of XL RP.[39–41] RP2 is a protein of uncertain function, which is targeted to the plasma membrane by dual *N*-terminal acyl-modification. Dual-acylated proteins are targeted to lipid rafts, suggesting a potential role for the protein in signal transduction.

Management of retinitis pigmentosa

Most forms of RP are not amenable to specific treatment, but the deterioration may be slowed by dietary modification in some rare disorders where the biochemical basis of the disorder is better elucidated (see Chapters 47 and 65).

There was a small effect on the rate of decline of the cone flicker ERG in one randomized controlled trial of vitamin A supplementation in RP; the effect was, however, marginal and no beneficial effect was found on visual acuity or visual field loss.[44] This form of treatment has not gained widespread acceptance.

Despite the lack of effective treatment for RP, the ophthalmologist has an important role to play in the management of both the child and the family. Once the diagnosis is established, it is important that the parents and the child (if old enough) are given a full and sympathetic explanation; they can be reassured that most children complete their education at a normal school as central vision is preserved until later.

Parents are often concerned that other children may be at risk of developing the disease; they should be offered genetic counseling and it may be appropriate to examine other family members. It is also helpful to have available the contact details of patient self-help groups such as their national RP association.

Practical help can also be given when there are visual difficulties. Many patients with RP have poor vision in bright sunlight and have problems in adapting from bright to dim illumination; tinted lenses may be helpful. Significant refractive errors should be corrected. A trial of oral acetazolamide, topical dorzolamide, orbital floor or intravitreal steroids, or intravitreal anti-VEGF agents should be considered if there is macular edema. Low vision aids may be helpful in established edema or macular atrophy. Visual loss may also develop secondary to posterior subcapsular cataract and, although cataract surgery is often successfully performed in adults with RP, it is rarely necessary in childhood.

Research is being conducted to investigate multiple treatment avenues for retinal dystrophies including gene therapy, stem cell therapy, neuroprotective agents, and artificial vision – with clinical trials ongoing or planned in all of these areas. Some of the research is aimed at treating specific genetic mutations, whereas other research efforts are studying potential therapies that can be used in a broader range or potentially all RP types. It is possible that these novel therapies may be more valuable in combination, for example, by combining gene therapy or stem cell therapy with neuroprotective growth factors. These interventions may be applied sequentially, for example, pharmacological approaches may be beneficial early in the disease and stem cell therapies at later stages. Further detailed information on these research avenues can be obtained from the websites of Retinitis Pigmentosa Fighting Blindness (http://www.rpfightingblindness.org.uk/index.php?tln=research) or the Foundation Fighting Blindness (http://www.blindness.org/news-and-research).

Prognosis

The prognosis in RP varies according to the type of disease and the causative mutation. Ideally, prognosis should be inferred by the identification of the specific genetic mutation. Advice on prognosis can also be aided by deep phenotyping and a full family history to establish the mode of inheritance. However intrafamilial variability of disease expression commonly occurs: the visual outcome of older affected family members is not necessarily a good guide to the likely prognosis in younger children.

Affected males with XL RP are night blind in early childhood, usually show extensive field loss by their teens, and central visual loss in their twenties. By the fourth decade, most have visual acuity reduced to less than count fingers. AR RP is such a heterogeneous condition that accurate prognosis is difficult. The disease is often of early onset and severe. Most patients have a severely constricted visual field by their teens and may have marked central visual loss by their late twenties. Some with recessive disease follow a more benign course.

The prognosis is better in AD RP. Although night blindness and field loss may develop in childhood, central vision may remain normal throughout life. Many patients maintain reasonable visual acuity until the fifth or sixth decade, although they may have extremely constricted visual fields. There is, however, wide variation even in RP caused by mutations at the same locus.[39–41] Severe, early onset forms are unusual.

True sector RP has the best prognosis of any form of the disease. Although there may be marked altitudinal upper visual field loss, severe involvement of the macula is uncommon.

Pigmented paravenous chorioretinal atrophy (PPCRA)

This is a rare chorioretinal atrophy in which there is paravenous RPE atrophy and pigment clumping (Fig. 46.19). It is more common in males, most cases are sporadic, and it is usually diagnosed on routine examination in asymptomatic

Fig. 46.19 Pigmented paravenous atrophy. The veins are surrounded by a band of retinal pigment atrophy and clumping.

patients. The ERG shows a spectrum of abnormalities and, in contrast to most retinal dystrophies, often shows marked interocular asymmetry. This asymmetry is also often seen on fundoscopy, autofluorescence imaging, and visual field testing. Retinal function may be relatively stable, or may show slow deterioration.

It is uncertain whether this disorder may have a genetic basis, with only one report of a heterozygous *CRB1* mutation of uncertain significance identified in a family with dominantly inherited PPCRA with variable expressivity.[45] In one report, the monozygotic twin of an affected adult was unaffected, suggesting that at least some cases are non-genetic.[46]

Acquired rod–cone dysfunction

Vitamin A deficiency

Worldwide, vitamin A deficiency remains an important cause of blindness in childhood. In developing countries it is usually caused by a combination of malnutrition and malabsorption associated with frequent gastrointestinal infection. In developed countries, vitamin A deficiency is rare and usually seen in association with liver disease or malabsorption; rarely an unusual diet may be the cause.

Vitamin A is an essential component of rhodopsin and cone opsins; night blindness is an early symptom of deficiency. In early deficiency, there is slowing of rod dark adaptation and, later, rod and cone thresholds are elevated. Peripheral fields may be constricted and in some patients white dots at the level of the RPE are seen throughout the periphery. Rod ERGs are undetectable with cone responses usually being well preserved. Bright flash dark-adapted ERGs (DA 10.0) may show a pseudo-negative ERG, with the b-wave amplitude lower than that of the a-wave, reflecting origins in dark-adapted cones (as seen in the patient with fundus albipunctatus in Fig. 46.4).

The ocular abnormalities are reversible with vitamin A supplementation if this is started before the disease is too advanced.[47] The recovery of retinal function is extremely rapid and accurate early diagnosis is important, since vitamin A deficiency is a treatable cause of night blindness.

Vitamin A and vitamin E supplementation may be curative in abetalipoproteinemia (Bassen–Kornzweig disease), a malabsorption diarrhea syndrome of infancy (see Chapter 65).

Desferrioxamine toxicity

Desferrioxamine is a chelating agent used in the treatment of iron storage disorders such as transfusion siderosis. Ocular side effects include cataract, optic neuropathy, and retinal degeneration.[48] Patients with retinal toxicity develop night blindness, peripheral field loss, and a peripheral pigmentary retinopathy; dark adaptation is abnormal and both rod and cone ERGs can show abnormalities.[48] Some improvement occurs on stopping the drug. Histologically, the RPE is predominantly affected.

Isotretinoin toxicity

Isotretinoin (13-*cis*-retinoic acid) is a treatment for acne vulgaris, which has several potential severe adverse effects including liver toxicity and dysregulation of lipid metabolism, necessitating regular blood testing whilst on therapy. Ocular side effects include photophobia, meibomian gland dysfunction, blepharoconjunctivitis, corneal opacities, keratitis, and reversible decreased night vision.[49]

Inherited chorioretinal dystrophies

Choroideremia

Clinical and histopathologic findings

Choroideremia is an X-linked recessive disorder characterized by progressive atrophy of the RPE and choriocapillaris. Affected males usually present in early childhood with night blindness and progressive field loss, but central vision is usually preserved until late in the disease. A longitudinal study reported a slow rate of visual acuity loss and good retention of central vision until the seventh decade.[50] There is a wide variation in clinical expression.[51] Female carriers, usually asymptomatic, have a widespread fine peripheral RPE atrophy and granular pigment deposition (Figs 46.20 and 46.21). Cases with deafness, hypopituitarism, and developmental delay probably represent a contiguous gene defect.

Affected males usually present between the ages of 5 and 10 years with night blindness and mild myopia. The earliest fundus signs are fine pigment epithelial atrophy and pigmentation in the peripheral retina; the clinical appearance may then be confused with RP. Focal areas of atrophy of the RPE and choriocapillaris, well demonstrated on fluorescein angiography or autofluorescence imaging (Figs 46.22 and 46.23), develop as the disease progresses. These coalesce to give a widespread atrophic appearance throughout the equatorial retina, spreading to involve the peripheral and more posterior retina; the macula is spared until late in the disease.

Visual fields initially show small mid-peripheral scotomata corresponding to areas of atrophy. Marked constriction of the visual field develops with disease progression, often with a preserved island of field in the far periphery.

Histologic examination of eyes with early disease[52] showed marked degeneration of the outer retina with loss of RPE, Bruch's membrane, and choriocapillaris. Biochemical studies showed reduced levels of interphotoreceptor retinal binding protein (IRBP) and increased levels of cAMP in the RPE and choroid.

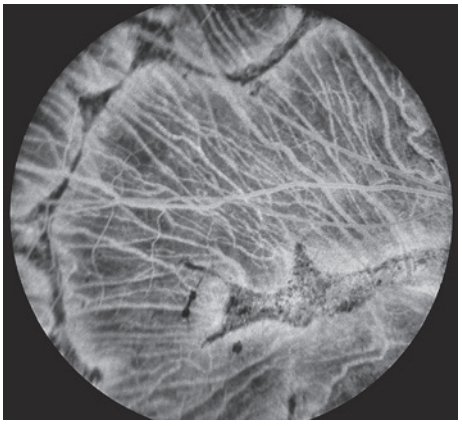

Fig. 46.23 Choroideremia. Fluorescein angiogram showing characteristic scalloped appearance given by the surviving retinal pigment epithelium and loss of the choriocapillaries.

Electrophysiology

The ERG is markedly abnormal at an early stage and may be undetectable. Rod and cone amplitudes are reduced in those with ERG preservation. Peak-time changes are less prominent, but may be present later in the disease process.

Female heterozygotes

Most female carriers are asymptomatic but the fundus appearance is characteristic (see Figs 46.20 and 46.21). The EOG and ERG are usually normal. Some elderly heterozygotes may develop nyctalopia and show more extensive RPE atrophy with an abnormal ERG and elevated rod thresholds on psychophysical testing. Molecular genetic diagnosis is now possible.

Molecular genetics and pathogenesis

The choroideremia gene (*CHM*) has been mapped to Xq21, with many mutations in *CHM* identified. An intronic mutation remote from the exon–intron junctions has been reported in *CHM*, creating a strong acceptor splice site and leading to the inclusion of a cryptic exon into the *CHM* mRNA. Intronic sequence is often not screened in inherited retinal dystrophy mutation investigations, which suggests that a significant proportion of disease-causing variants are being missed.

CHM is widely expressed and the product of this gene, Rab escort protein (REP)-1, is involved in the post-translational

lipid modification and subsequent membrane targeting of Rab proteins, small GTPases that play a key role in intracellular trafficking. It is thought that REP-2 compensates for the loss of REP-1 function elsewhere in the body but is insufficient to compensate in the retina.

Gene replacement therapy is a potential treatment for choroideremia and Edwards et al have recently reported encouraging results of gene replacement therapy, using an AAV vector in patients with choroideremia.[53] Longer term follow up in larger numbers of subjects will however be needed before the effectiveness of treatment can be confirmed.

Gyrate atrophy of the choroid and retina

Clinical and histopathologic findings

Gyrate atrophy of the choroid and retina is a rare autosomal recessive disorder with progressive chorioretinal loss, hyperornithinemia, and a deficiency of the mitochondrial enzyme ornithine aminotransferase (OAT). The level of OAT activity in obligate carriers of the gene is about 50% of normal.

Children may present with night blindness, progressive myopia, or field loss, but the diagnosis of gyrate atrophy may be made in early infancy when a raised level of plasma ornithine is found in a child with a family history. The earliest fundus changes are small discrete areas of choroidal and RPE atrophy in the mid- and far-peripheral fundus. The adjacent fundus may show diffuse depigmentation of the RPE and atrophic areas. The atrophic areas coalesce and enlarge toward the posterior pole with a characteristic scalloped leading edge.

Most patients have moderate-to-high myopia and posterior subcapsular cataracts develop in early-adult life. Some develop visual loss secondary to macular edema or atrophy. Most patients maintain a reasonable level of visual acuity until their forties or fifties, although with a constricted field. There are early small mid-peripheral scotomata, but progression leads to marked peripheral constriction.

Light and electron microscopy (EM) from a patient with a pyridoxine-sensitive form of gyrate atrophy showed focal areas of photoreceptor and RPE atrophy at the posterior pole; in the mid-periphery, there were areas of abrupt transition from near-normal to atrophic areas of retina.[54] EM showed abnormal mitochondria in the cornea, ciliary epithelium, ciliary muscle, and in the photoreceptors. Similar mitochondrial abnormalities in other tissues of patients with gyrate atrophy are likely to be a secondary effect of the biochemical disturbance.

Electrophysiology and psychophysics

The ERG relates to the severity of disease: early in the course of the disorder, rod and cone amplitudes are reduced; later, the ERG becomes undetectable. EOG reduction parallels the reduction in the rod ERG. Dark adaptation shows markedly elevated rod thresholds in areas of field corresponding to involved retina.

Non-ocular features

Although patients with gyrate atrophy show no muscle weakness, muscle biopsy shows atrophy of type 2 fibers with accumulation of tubular aggregates. Other reported abnormalities include structural abnormalities of the hair, electroencephalographic abnormalities, mild developmental delay, peripheral neuropathy, and mitochondrial abnormalities in a variety of tissues.

Molecular genetics and pathogenesis

A large number of mutations in the *OAT* gene have been identified in patients with gyrate atrophy including some in which the OAT is pyridoxine-responsive. Expression studies have demonstrated reduced mutant OAT activity.

Chronic reduction of ornithine may prevent the retinal degeneration of gyrate atrophy; using an arginine-restricted diet in a mouse model of OAT deficiency ($oat^{-/-}$),[55] plasma ornithine levels were substantially reduced and completely prevented retinal degeneration in $oat^{-/-}$, suggesting that ornithine accumulation is important in the pathophysiology of the retinal degeneration and that restoration of OAT activity in the retina may not be required for effective treatment.

Biochemical findings and treatment

Patients with gyrate atrophy have a deficiency of the pyridoxal phosphate-dependent mitochondrial enzyme OAT, which is responsible for the conversion of ornithine to glutamic acid. The major dietary source of ornithine is arginine, which may be converted to ornithine by the arginase reaction of the urea cycle or by the glycine transamidase reaction. Ornithine, an intermediary in the urea cycle, is necessary for the production of polyamines and in the synthesis of proline and glutamate.

It is not clear whether high levels of ornithine or the reduced levels of proline and glutamate that accompany OAT deficiency cause the retinal abnormalities. Not all patients with raised ornithine levels develop gyrate atrophy and one patient with gyrate atrophy has been reported who had normal ornithine levels and low plasma proline levels, suggesting that reduced availability of proline may be a contributory factor.[56]

Three different approaches to treatment have been used:

1. A few patients are responsive to pyridoxine (B_6) supplements and show reduced plasma ornithine levels and improvement in the ERG. Vitamin B_6 should be used initially in all patients and continued in those who show a positive response.
2. In non-responders, adhering to an arginine-restricted diet may reduce plasma ornithine levels.
3. Proline supplementation may slow the progress of retinal degeneration in some patients.[56,57]

Children with gyrate atrophy need to be managed in collaboration with a metabolic physician. Although present treatment regimens are promising, more long-term studies are needed to assess whether such treatments prevent retinal deterioration.

Cone and cone–rod dystrophies

The inherited cone dystrophies are a heterogeneous group of progressive disorders characterized by photophobia, reduced central vision, abnormal color vision, and abnormal cone ERGs.[58] Autosomal recessive, autosomal dominant, and X-linked recessive inheritance has been reported and there is heterogeneity even amongst these subtypes.[58]

The functional deficit is confined to the cone system in some forms of cone dystrophy, but in many there is later evidence of rod dysfunction (cone–rod dystrophy). The distinction between cone and cone–rod dystrophies may be difficult, particularly during childhood, and is dependent upon good electrophysiology. Most forms of cone and cone–rod dystrophy are seen in otherwise normal individuals; those associated with systemic abnormalities are discussed in Chapter 47.

Progressive cone dystrophy

Clinical findings

In contrast to the stationary cone disorders, which present in early infancy, the progressive cone dystrophies are not usually symptomatic until later childhood or early-adult life.[58] The age of onset of visual loss and the rate of progression show wide variability but eventually visual acuity usually deteriorates to the level of 6/60 or to count fingers only. Photophobia is a prominent early symptom, with progressive loss of visual acuity and color vision. Since all three classes of cone photoreceptor can be affected, the color vision defects are along all three color axes, often progressing to complete loss of color vision. Some cases have a predominant early involvement of L-cones leading to a protan color vision phenotype.[59,60] AD cone dystrophy pedigrees with early tritan color vision defects have also been reported.[61,62] Nystagmus may be present. A small central scotoma is frequently detected on visual field testing; peripheral fields may be normal in the early stages but constrict later.

Fundus examination may show a typical "bull's eye" maculopathy (Figs 46.24 and 46.25, and Box 46.1). In some cases, there may only be minor macular RPE atrophy. The optic discs show variable temporal pallor. The retinal periphery is usually normal although, rarely, white flecks may be seen. Fluorescein angiography shows typical "window" defects at the macula in the majority of cases and the so-called dark choroid sign (see Chapter 48) may be seen.

Electrophysiology and psychophysics

Electroretinography shows normal rod responses but substantially abnormal cone responses (Fig. 46.26). The 30 Hz flicker ERG is usually of increased peak-time but, rarely, such as in the cone dystrophy related to *GUCA1A* mutation,[58] the peak-time is normal and amplitude reduction is the only abnormality. A small subgroup of patients with cone dystrophy may show supernormal rod responses or rod responses within the normal range but with distinctive and specific abnormal characteristics[58] (see below).

Dark adaptation studies show either a monophasic curve with no recognizable cone component, or a biphasic curve with elevated cone thresholds; rod-mediated thresholds are normal. Spectral sensitivity studies show variable abnormalities of the photopic responses. In some families, there is generalized depression of sensitivity across all wavelengths tested, whereas others show more specific functional deficits in the early stages of the disease. A typical rod sensitivity curve may be seen under both scotopic and photopic conditions in advanced disease.

Obligate carriers of X-linked cone dystrophy may show evidence of cone dysfunction on electrophysiologic or psychophysical testing.

Cone dystrophy with supernormal rod ERG (KCNV2 retinopathy)

Clinical findings

An unusual AR disorder has been described with abnormal photopic responses associated with supernormal and delayed rod ERG b-waves.[58] Patients have generalized loss of cone vision, clinical evidence of progression, and often have nyctalopia.[63] The ERG findings are diagnostic. Cone ERGs are reduced and delayed, typical of a cone dystrophy. However, with a bright flash under dark adaptation the dark-adapted b-wave is of high amplitude (and may be supernormal), but at low stimulus strengths the rod b-wave is subnormal and profoundly delayed.[63] Some cases have supernormal rod ERGs without nyctalopia, suggestive of reasonable rod function despite an abnormal scotopic ERG.[64]

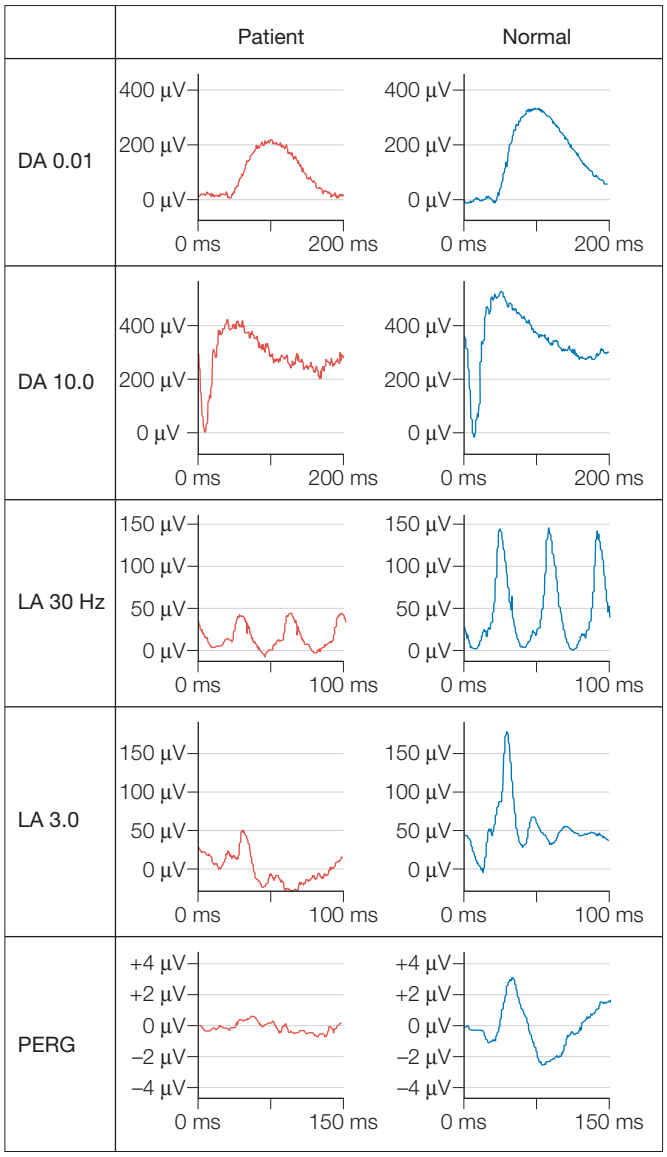

Fig. 46.26 The rod-specific (DA 0.01) and bright flash dark-adapted electroretinograms (ERGs) (DA 10.0) fall within the normal range. The 30 Hz flicker ERG (LA 30 Hz) is both delayed and reduced, typically present in most cone dystrophies. The photopic single flash ERG (LA 3.0) is markedly subnormal with particular reduction in the b-wave. The pattern ERG is profoundly subnormal in keeping with marked macular involvement.

Several clinical features may suggest the diagnosis.[58] Onset of symptoms of reduced central vision and photophobia is in the first and second decades of life. Patients are usually myopic and often have severely reduced red–green color discrimination with relative preservation of tritan color vision. Onset of nyctalopia and presence of nystagmus is variable.

There is often RPE disturbance at the macula with a normal retinal periphery. Autofluorescence (AF) imaging reveals a perifoveal ring of increased AF; in older subjects, an area of increased AF may be seen centrally. By the fifth decade, there is usually marked central atrophy.

Electrophysiology

The PERG is often absent, indicative of marked macular dysfunction. Rod ERG amplitudes are subnormal at the lowest flash energies, but a characteristic abnormality seen in all published cases is a profound and rapid increase in the amplitude of a delayed b-wave despite only a relatively small increase in stimulus intensity. At higher flash strengths under dark adaptation, the b-wave may exceed the upper limit of normal (supernormal). The initial phase of the bright flash dark-adapted ERG a-wave to a flash strength greater than the routine ISCEV standard flash is well formed, suggesting that the kinetics of phototransduction are within normal limits. The shape of the ERG is then characteristic. The normally commencing a-wave then plateaus, shows a small dip, and is then followed by a very sharply rising b-wave, which may be supernormal in some patients. Cone ERGs are reduced and delayed, typical of a cone dystrophy. Some cases have supernormal rod ERGs without nyctalopia, suggestive of reasonable rod function despite an abnormal scotopic ERG.

Molecular genetics and pathogenesis

Recessive mutations have been identified in *KCNV2*, encoding a voltage-gated potassium channel subunit.[65] *In situ* hybridization has demonstrated KCNV2 expression in human rod and cone photoreceptors.[65] *KCNV2* mutations might perturb or abrogate the potassium current within vertebrate photoreceptor inner segments shown previously to set their resting potential and voltage response.[65]

Progressive cone–rod dystrophy

Clinical findings

In this disorder, affected patients develop the typical findings of a cone dystrophy in early life but later develop rod involvement with night blindness. Most present in the first two decades of life, with the retinal dystrophy either being isolated or associated with systemic abnormalities. AD, AR, or XL inheritance has been reported.

Fundus examination shows macular atrophy in the early stages of the disease, with peripheral RPE atrophy, retinal pigmentation, arteriolar attenuation, and optic disc pallor in the late stages (Figs 46.27 and 46.28). A bull's eye maculopathy may also be seen.

Electrophysiology and psychophysics

Both rod and cone thresholds are elevated on psychophysical testing. Generalized abnormalities of rod and cone ERGs are present, with the cone ERGs being more abnormal than the rod ERGs. The 30 Hz cone flicker ERG peak-time is usually delayed. The bright flash dark-adapted ERG (DA 10.0) a-wave is subnormal, in keeping with rod photoreceptor involvement.

Molecular genetics of cone and cone–rod dystrophies

Most cases of progressive cone and cone–rod dystrophy are sporadic, with the majority of these probably representing AR inheritance, but some may represent new AD mutations, and, in severely affected males, X-linked disease.

Several loci and causative genes have been identified in the progressive cone dystrophies.[58] Mutations in *ABCA4*, *CNGA3*, *CNGB3*, and *PDE6C* have been identified in AR cone dystrophies, *GUCA1A* mutations have been reported in AD pedigrees, and *RPGR* and *OPN1LW*/*OPN1MW* sequence variants in XL disease.[22,58]

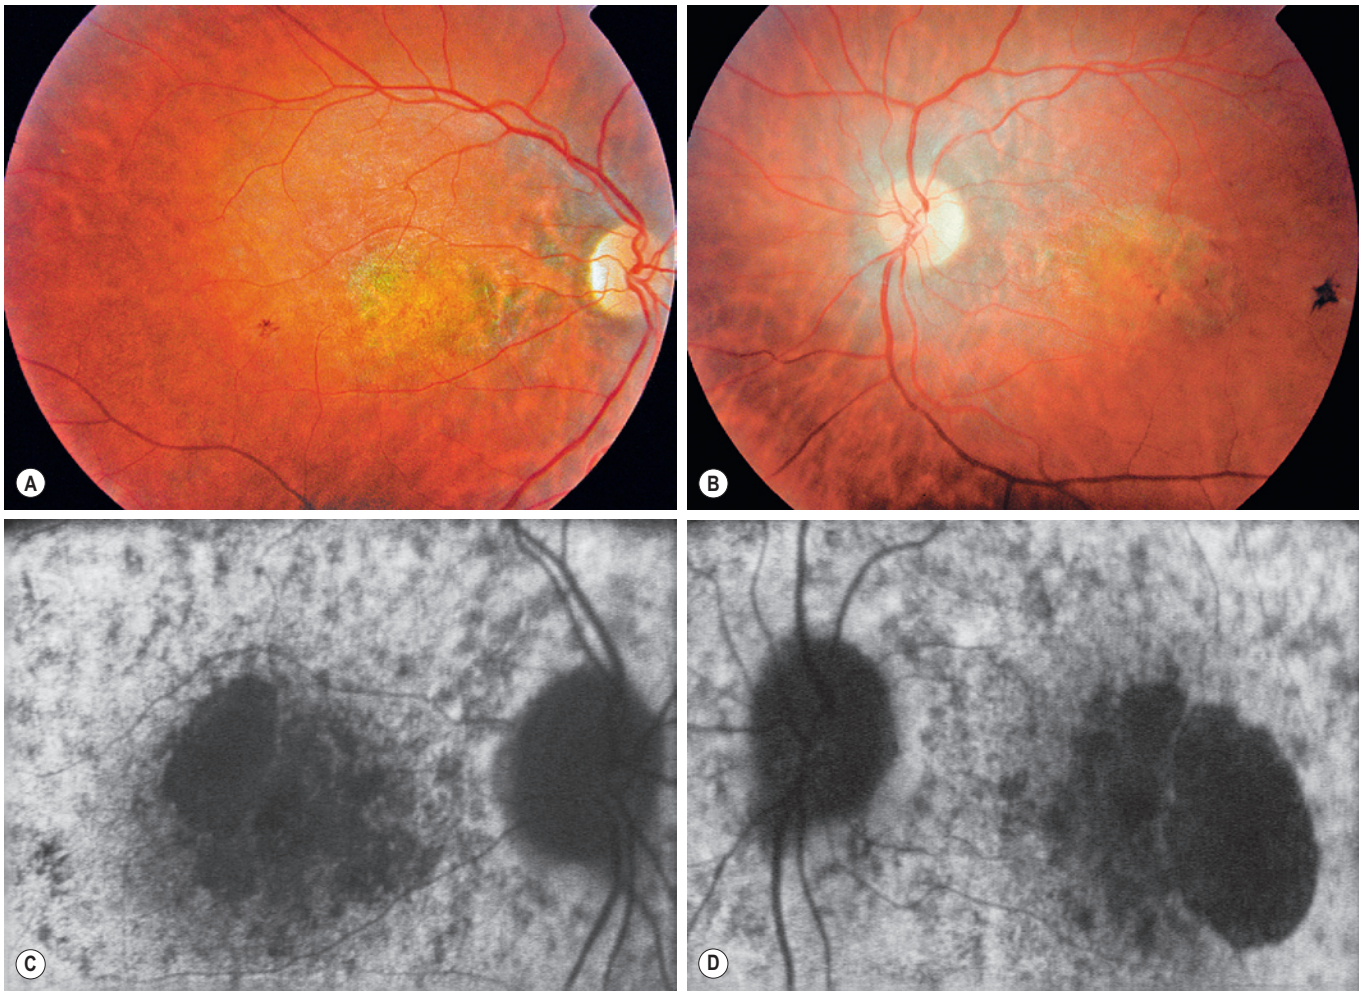

Fig. 46.27 Cone–rod dystrophy. (A,B) Bilateral macular atrophy. (C,D) Autofluorescence (AF) images showing decreased AF at the maculae corresponding to the atrophy seen ophthalmoscopically with an abnormal mottled appearance of the surrounding retina, with areas of relative increased and decreased AF.

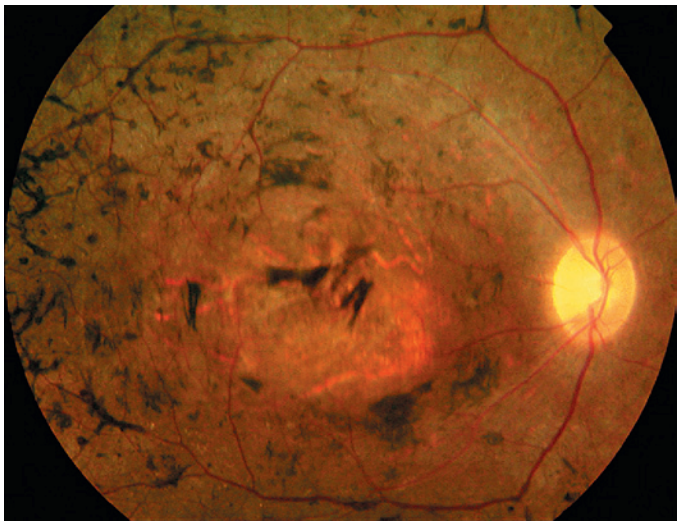

Fig. 46.28 Cone–rod dystrophy. End-stage disease with marked macular atrophy, retinal pigmentation, and arteriolar narrowing.

More than 10 genes have been associated with AD cone–rod dystrophy,[58] including *CRX*, *GUCY2D*, *RIMS1*, *PRPH2*, *GUCA1A*, *PROM1*, and *AIPL1*. Twelve genes have been associated with AR disease,[58] including *ABCA4*, *CNGA3*, *CNGB3*, *ADAM9*, *PCDH21*, and *RPGRIP1*. Mutations in *ABCA4* have been shown to be the commonest cause of AR cone–rod dystrophy.[58] Mutations in *RPGR*, the gene encoding the protein that interacts with RPGRIP1, have been associated with XL childhood-onset retinal dystrophy families.[58]

Goldmann–Favre syndrome and enhanced S-cone syndrome

Clinical findings and electrophysiology

Goldmann–Favre is a rare AR disorder characterized by gradual visual loss or night blindness with liquefaction of the vitreous, macular retinoschisis, and peripheral RPE atrophy and pigmentation. Peripheral retinoschisis and cataract may also occur. The retinal dystrophy is progressive, resulting in extensive visual field loss and variable central visual loss. Fluorescein angiography may show evidence of peripheral capillary closure and vascular leakage. ERG is markedly abnormal or undetectable. Studies of patients with the Goldmann–Favre

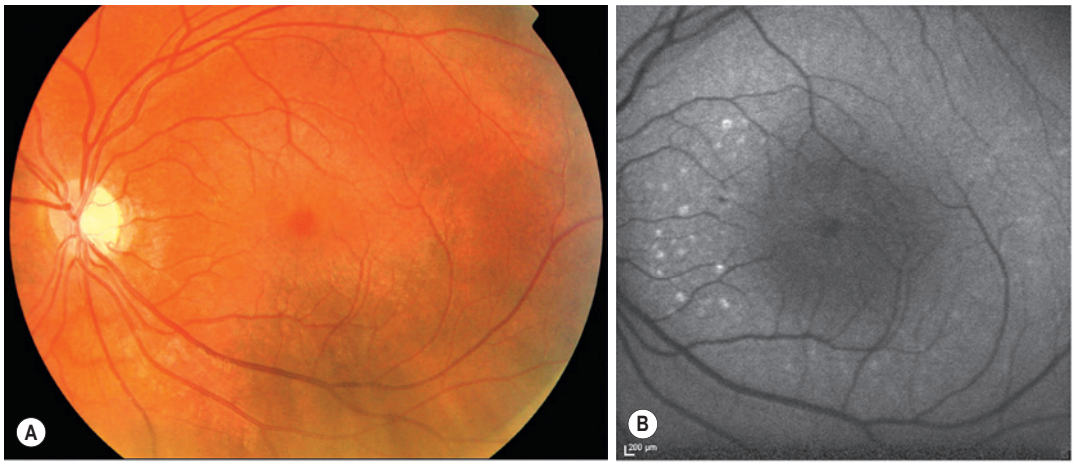

Fig. 46.29 Enhanced S-cone syndrome. (A) White dots are seen at the level of the retinal pigment epithelium in early disease, which are more readily seen on autofluorescence imaging (B).

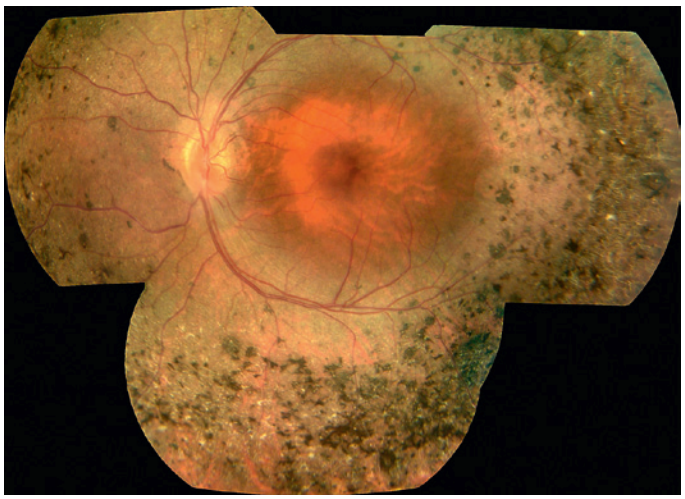

Fig. 46.30 Enhanced S-cone syndrome. Typical pigment clumps (including nummular pigmentation) seen at the posterior pole and macular atrophy (advanced disease).

syndrome using spectral ERG have demonstrated that S-cones are less affected than the mid-spectral cones.

There is overlap between Goldmann–Favre syndrome and enhanced S-cone syndrome (ESCS) where there are no rods but increased numbers of cones, mostly short wavelength sensitive. Patients usually present with nyctalopia and are found to have foveal schisis/cysts. Since mutations have been identified in *NR2E3* in both disorders, Goldmann–Favre syndrome may represent severe ESCS. Although the macular appearance may be similar, the vitreous changes, peripheral retinopathy, ERG abnormalities, and mode of inheritance help differentiate this condition from X-linked retinoschisis and inherited forms of isolated foveal schisis (see Chapter 51).

The characteristic pigmentary deposition in ESCS is at the level of the RPE rather than intraretinal, has a nummular appearance, and tends to be around the arcades (see Figs 46.29 and 46.30). Despite this typical appearance, patients are often diagnosed with RP due to the night blindness and pigmentary changes. The ERG in ESCS is diagnostic (Fig. 46.31). The rod-specific ERG to a dim flash under dark adaptation (DA 0.01) is undetectable. The responses to the same flash strength under photopic (LA 3.0) and scotopic conditions (DA 3.0) are of similar waveform, being simplified and very delayed. The flicker ERG is markedly delayed and, in addition, the amplitude of the 30 Hz flicker ERG, which in a normal subject falls between that of the LA 3.0 response a- and b-waves, is usually of lower amplitude than the photopic a-wave. PERGs, when detectable, can show profound delay.

Molecular genetics and pathogenesis

Mutations in *NR2E3* (encoding a transcription factor and thus believed to play a role in determining cone cell fate) have been identified both in ESCS and Goldmann–Favre syndrome.[66] There is evidence in ESCS of a greater than normal number of S-cones, with mutation in *NR2E3* thought to cause disordered cell differentiation, possibly by encouraging default to the S-cone pathway and thereby altering the relative ratio of cone subtypes. A small number of cones co-express L-/M- and S-opsins.[66] There are no rods.

Management

There is currently no specific treatment for the vast majority of these inherited retinal disorders. Nevertheless, it is important that the correct diagnosis is established early to enable accurate prognostic information and informed genetic counseling. A molecular diagnosis facilitates this process.

The provision of appropriate spectacle correction, low vision aids, and educational support is also important. Photophobia may be a prominent symptom, especially in the cone dysfunction syndromes, and tinted spectacles or contact lenses may be beneficial both to improved comfort and to vision. Macular edema or foveal schisis may be amenable to treatment with topical or oral carbonic anhydrase inhibitors.

Conclusions

Inherited retinal disorders are a common cause of childhood blindness and most are not currently amenable to specific forms of treatment. Advances in molecular biology have led to the identification of many causative genetic mutations and it is likely, given the advances in genetic analysis, that the

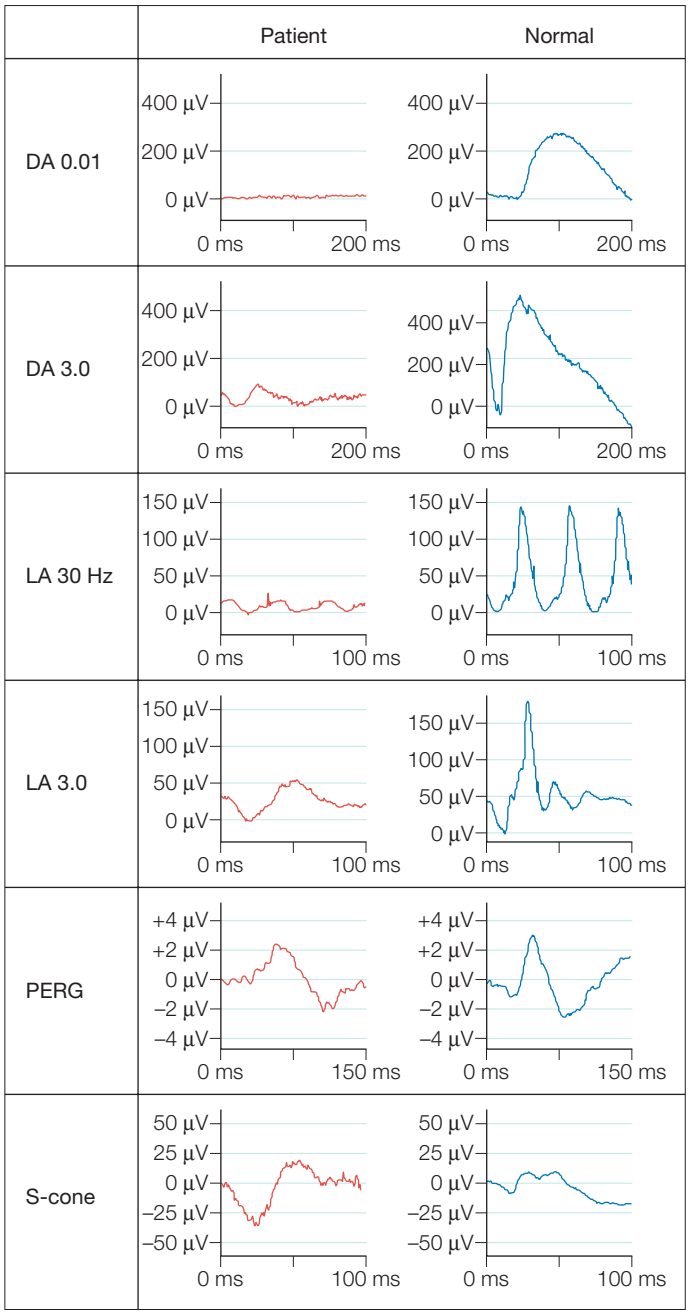

Fig. 46.31 Enhanced S-cone syndrome (ESCS). The rod-specific electroretinogram (ERG) (DA 0.01) is undetectable in keeping with the known absence of rods in this disorder. However, there are two main additional diagnostic features: firstly, there is a similar waveform between the photopic (LA 3.0) and scotopic (DA 3.0) ERGs to the same stimulus, both of which show a simplified, grossly delayed waveform. Secondly, the amplitude of the grossly delayed 30 Hz flicker ERG is lower than that of the photopic a-wave. In a normal subject, the 30 Hz flicker ERG amplitude always falls between that of the photopic a-wave and the photopic b-wave. Note the profoundly delayed pattern ERG (PERG), often present when the PERG is detectable in this disorder, and the increased sensitivity to short wavelength stimulation revealed by specific S-cone ERG recording (5 ms blue stimulus on a bright orange background). In a normal subject, the S-cone ERG consists of two components: a late S-cone specific component at ~50 ms and an L-/M-cone component at ~30 ms. The earlier component is not present in the patient, and the later component is enhanced.

molecular pathology of most disorders will be established in the near future. This is the first stage in understanding the pathophysiological mechanisms that lead to photoreceptor cell dysfunction and/or death.

Treatment strategies aimed at prolonging photoreceptor survival or improving function are currently being investigated in animal models and, increasingly, in human clinical trials (www.clinicaltrials.gov). They include the use of exogenous growth factors, pharmacologic intervention, gene therapy, and stem cell based therapies.[33–35,67–70] Another approach for more advanced disease is the development of retinal implants, which are also being investigated in clinical trials.[71]

There is cautious optimism that these multiple avenues of research will yield meaningful treatments for various forms of genetic retinal disease in the future.

Chapter contents

USHER SYNDROME: A DEAF CHILD WHO LOSES VISION
THE CILIOPATHIES: A NOVEL SYSTEMIC RETINAL DYSTROPHIES GROUP
OTHER RARE SYNDROMES WITH RETINAL DYSTROPHY
CONCLUSION
REFERENCES

Children affected by retinal degeneration associated with extraocular manifestations *define* the inherited systemic retinitis pigmentosa (RP) syndromes (retinal dystrophies related to inborn errors of metabolism are covered in Chapter 65) (Tables 47.1 and 47.2). The gene or the group of genes involved in the syndrome belong to a specific biologic network whose mutations lead to retinal degeneration associated with manifestations in other organs defined by the specific biologic role of the protein. Retinal degeneration occurs in these syndromes by virtue of the biologic complexity of the retina. The photoreceptor cell is remarkably sensitive to alterations in many biologic pathways but the clinical presentation is often indistinguishable between syndromes with the classical features of retinal degeneration: night blindness, visual field constriction, and reduced visual acuity. In the early phases of the retinal degeneration, the fundus may appear normal although the electroretinogram (ERG) is altered. Later, the fundus will acquire the usual aspects observed in retinal degeneration: pigment mottling, pigment migration with spicules, optic disc pallor, narrowed vessels, and macular changes that are prominent and early in the cone–rod dystrophies.

All the conditions are rare inherited diseases; the most frequent syndromes are Usher syndrome (USH) and Bardet–Biedl syndrome (BBS).

Over the last two decades, many of the genes responsible for these conditions have been identified. This field will continue to greatly benefit from new genome exploration especially high-throughput sequencing with next-generation sequencing (NGS) technologies (targeted, exome or genome sequencing).[1–5] Molecular diagnosis and genetic counseling are constantly improving, especially for the syndromes which are highly heterogeneous. The classical syndromes illustrating this group of diseases are described, but a growing number of overlapping phenotypes have become evident as molecular investigations improve. Moreover, different mutations in the same gene may lead to different syndromes on the same clinical spectrum (see section "The ciliopathies"). Major clinical variability in each syndrome has been described. For some genes, specific mutations may lead to isolated features such as isolated RP (e.g. Usher syndrome gene *USH2A* or Bardet–Biedl genes *BBS8* and *BBS3*).[6–8]

A child with RP should be systematically evaluated for extraocular associated features (unless he/she is proven to be affected by a non-syndromic mutation). These conditions require multidisciplinary follow-up and management.

Usher syndrome: a deaf child who loses vision

In Usher syndrome, sensorineural deafness is associated with progressive retinal degeneration. USH occurs in 1 of every 10 deaf children (5% of all cases of congenital deafness). It is the most frequently inherited syndrome with deafness and is the most common syndrome among the deaf–blind.[9–11] The syndrome is subdivided into three groups: Usher type 1 (USH1), type 2 (USH2), and type 3 (USH3). USH1 and 2 are usually diagnosed in early or late childhood, respectively, but may be diagnosed later in life as the visual impairment may be overlooked in a deaf child. Vestibular dysfunction is classically associated with USH1. Each type of Usher syndrome is autosomal recessive but genetically heterogeneous. For each type, a number of genes have been identified[12–16] (see Table 47.1). Molecular studies have shown clinical overlap between the classical types USH1 and USH2.[17] Some Usher genes can be involved in either isolated deafness or isolated RP (USH2A).[6,18]

Cochlear implantation is highly recommended for these children (especially in USH1).[19,20] No therapy is yet available for the retinal degeneration (Fig. 47.1A–C).

Usher syndrome type 1: the most severe form

The child with USH1 is affected with congenital severe to profound sensorineural hearing loss associated with delayed

Table 47.1 Main extraocular features found and the corresponding systemic retinitis pigmentosa (RP) syndrome

Extraocular clinical feature associated with RP in a child		Key feature found in systemic syndrome
Stature	Dwarfism	Cockayne syndrome (cachectic), spondylometaphyseal dysplasia or spondyloepiphyseal dysplasia associated with cone dystrophy
	Obesity	Bardet–Biedl syndrome (BBS), Alström syndrome, Cohen syndrome (truncal), MORM (mental retardation, truncal obesity, retinal dystrophy, and micropenis) syndrome
Skeletal abnormality	Polydactyly	BBS, Joubert syndrome, Jeune syndrome
	Short ribs with abnormal thorax	Jeune syndrome
	Various abnormal skeletal development	Spondylometaphyseal dysplasia or spondyloepiphyseal dysplasia
Deafness		Usher syndrome (variable severity according to types), Alström syndrome (progressive starting in childhood)
CNS malformations	Cerebellar vermis agenesis (molar tooth)	Joubert syndrome
Kidney dysfunction	Polyuria-polydypsia Kidney failure	BBS, Alström syndrome, Jeune syndrome, Senior–Loken syndrome, Joubert syndrome
Endocrine dysfunction	Type 2 juvenile diabetes	Alström syndrome
	Pituitary deficiency	Oliver–McFarlane syndrome
Cardiomyopathy		Alström syndrome
Cognitive impairment		Classical: Cohen syndrome, Joubert syndrome Occasional: BBS, Alström
Teeth	Amelogenesis imperfecta	Jalili syndrome
	Prominent incisors	Cohen syndrome
Skin/hair	Ultraviolet sensitivity	Cockayne syndrome
	Alopecia – early hair loss	Hypotrichosis with juvenile macular dystrophy; EEM (ectodermal dysplasia, ectrodactyly, macular dystrophy) syndrome
	Long eyelashes	Oliver–McFarlane syndrome

sitting and walking due to abnormal vestibular function. Retinal degeneration occurs early in childhood. As early as 2 or 3 years old, the ERG can confirm the diagnosis of retinal degeneration although the fundus appears to be normal.[21,22] Five causative genes are known and mutated in various proportions according to the studied population: *MYO7A* (recognized to be the main USH1 gene mutated in half of the cases and also responsible for non-syndromic deafness), *USH1C*, *CDH23*, *PCDH15*, *USH1G* and *CIB2*.[14,16,17] Although always severe, the course of disease may vary according to the type of mutation.[23]

Usher syndrome type 2: later onset retinal degeneration in a deaf child

Congenital mild to severe sensorineural stable hearing loss with major impairment in high frequencies and normal vestibular function are the main characteristics of USH2. The retinal degeneration occurs later than in USH1, usually during puberty or after. USH2 and USH3 are not usually symptomatic in the first decade and initially have a normal fundus appearance. Many patients retain good visual acuity in spite of constricted visual fields. The ERG may initially be normal; however, ERG changes may be detected in presymptomatic young children. During the second decade, night blindness and loss of peripheral vision become evident and inexorably progress (Fig. 47.1D). Four genes have been identified: *USH2A* (Usherin found also mutated in isolated RP), *GPR98*, *WHRN and PDZD7*.[14,16]

Usher syndrome type 3: the later onset, variable form

The onset of RP in USH3 is variable and is often recognized after the second decade of life, but can be confused with the two other types. Sensory hearing loss is postlingual, after the acquisition of speech (as opposed to the prelingual loss in USH1 and USH2), but it evolves progressively to profound deafness. Vestibular dysfunction of variable intensity occurs in half of the patients.

The USH3A gene (*CLRN1*) has been identified in particular in Askenazi Jews and Finns. USH3 has also been found mutated in patients with USH1 and USH2.[14,16]

Pathogenesis of Usher syndromes

Progress has been made in understanding the pathogenesis of this disease affecting the inner ear stereocilia and photoreceptor cells of the retina.[24] The USH1 gene products form a network, the Usher interactome, which plays a key role in the early hair bundle development.[25–26] They are also key components of the mechanoelectrical transduction machinery necessary for

Table 47.2 Main systemic retinitis pigmentosa syndromes

Name of the syndrome with retinal degeneration	Main diagnostic extraocular signs	Identified gene(s)	Pathogenesis
Usher syndrome type 1	Deafness: congenital and profound Vestibular dysfunction	MYO7A, cadherin-23 (*CDH23*), Harmonin, protocadherin-15 (*PCDH15*), *SANS*, *CIB2*	Stereocilia and photoreceptor development and function. Network of Usher proteins
Usher syndrome type 2	Deafness: congenital, moderate to severe No vestibular deficit	*GPR98*, *Ush2A*, *WHRN*, *PDZD7*	Stereocilia and photoreceptor development and function. Network of Usher proteins
Usher syndrome type 3	Late-onset rod–cone dystrophy Late-onset progressive deafness	*USH3A* (*CLRN1*),	Stereocilia and photoreceptor development and function. Network of Usher proteins
Bardet–Biedl syndrome	Polydactyly Obesity Intellectual disability Kidney dysfunction Urogenital malformation	*BBS1* to *BBS19*	Ciliopathy
Alström syndrome	Obesity Type 2 diabetes mellitus Deafness Cardiomyopathy Kidney dysfunction Liver dysfunction Growth and endocrine deficiency Occasional intellectual disability	*ALSM1*	Ciliopathy
MORM	Mental retardation Truncal obesity Micropenis	*INPP5E*	Ciliopathy
Senior–Loken syndrome	Nephronophthisis	*NPHP1* to *6*, *SDCCAG8*	Ciliopathy
Mainzer–Saldino syndrome	Renal dysplasia Cerebellar ataxia Skeletal dysplasia Cone-shaped epiphyses	*IFT140*	Ciliopathy

hearing. In the retina, the Usher interactome acts at the level of the ciliary/periciliary region of the connecting cilia of the photoreceptor cells. It is important in the transport of proteins between the outer and the inner segments.[27–30] Alteration of the USH proteins leads to early dysfunction of the inner ear and of the retina simultaneously (Fig. 47.1E).

The ciliopathies: a novel systemic retinal dystrophies group

A single non-motile cilium ("primary cilium") is present in almost every vertebrate cell; motile cilia are present only in specific organs such as in the respiratory or the reproductive systems (for review see Brown et al.[31]) (Fig. 47.2A). The primary cilium is the central "antenna" of the cell, allowing transduction of sensorial information from the extracellular environment to the cell. The photoreceptor cell has a connecting cilium and is, therefore, a ciliated cell.

Ciliopathies are rare genetic disorders characterized by primary cilium dysfunction, frequently affecting photoreceptors and causing retinal degeneration either as an isolated condition (e.g. Leber congenital amaurosis with *CEP290* mutations) or as a ciliopathy syndrome affecting more than one organ system.[32–34] Ciliopathies involve many target organs that have in common an important role of the primary cilia. Overlapping phenotypes have been reported, as well as high clinical variability on the number of affected organs among patients with the same syndrome. The most common ciliopathies are schematically represented in Figure 47.2B.

Molecular investigations have revealed major genetic heterogeneity for each syndrome and also allelic variability (different mutations in the same gene may lead to different syndromes). For instance, *CEP290-NPHP6* truncating mutations have been identified in Joubert syndrome and hypomorphic mutations in Leber congenital amaurosis (LCA). Moreover, CEP290-*NPHP6* is mutated in several distinct disorders (nephronophthisis, Senior–Loken syndrome, Joubert syndrome, BBS and the lethal Meckel syndrome).[35]

Supplementary genetic factors such as a third mutated allele in a BBS gene (known as oligogenism – a third mutation occurring in addition to the two main mutations found in recessive inheritance) or other genetic modifiers can influence the phenotype.[36,37]

A yearly multidisciplinary follow-up is recommended for these children with special attention given to kidney function and prevention of obesity.

Bardet–Biedl syndrome

The cardinal features of the BBS syndrome are early-onset retinal degeneration, obesity, polydactyly, renal failure, hypogonadism, and intellectual disability (Fig. 47.3A–D). Secondary features may include anosmia, diabetes, cardiac anomalies, hepatic fibrosis, brachydactyly, and Hirschprung disease.[38,39] The retinal dystrophy is early in onset, leading to severe visual handicap before adulthood. Profound ERG abnormalities can be detected as early as 3 years of age. Legal blindness usually results before the second decade of life.[40–46] Retinal dystrophies in BBS are mainly a rod–cone dystrophy or a cone–rod dystrophy,[46] usually classified as a global retinal degeneration because both rods and cones are affected[44] (Fig. 47.3E).

Obesity is the second major feature, present in 72–96% of BBS patients, usually beginning in early childhood and worsening with age. The origin of obesity is both central (hypothalamic eating control) and peripheral (adipose tissue).[47–49]

Limb anomalies are found in almost 95% of BBS patients, usually a postaxial polydactyly (69%). Other limb malformations such as brachydactyly or syndactyly are frequently reported for both hands and feet and have a diagnostic value. Abnormalities of the genitalia can occur: hypogonadism in males or vaginal atresia in females. Rarely, there is hydrometrocolpos, a neonatal vaginal malformation leading to a massive abdominal tumor.[50,51] Renal dysfunction can occur in late childhood and may lead to kidney failure.[52] Neuropsychiatric symptoms can include developmental delay, intellectual disability, learning difficulties, speech deficit, and

Continued

behavioral problems.[38] Intellectual function ranges from severe mental retardation (29%) through weak intelligence and average intelligence (29%). Slow ideation and hyperemotive status are common.

BBS is an autosomal recessive heterogeneous condition; more than 19 genes have been identified, accounting for about 85% of cases.[53] All the genes have been related to cilium biogenesis and/or function. *BBS1* and *BBS10* are the two most common, each accounting for about 20% of the cases. Implication of the other BBS genes ranges from a unique family to a few percent of mutated families. The classical autosomal recessive inheritance model has been challenged by molecular and functional investigations with the oligogenic model and the effect of additional genetic modulators on the phenotype.[37]

Alström syndrome

Alström syndrome (ALMS) manifestations include RP in early childhood, hearing impairment, and metabolic defects leading to hyperinsulinemia, type 2 diabetes mellitus and obesity in childhood. Polydactyly does not occur. Dilated cardiomyopathy can occur in infancy or later in life and renal dysfunction is reported in half of ALMS cases.[54] Developmental or motor delays occur, but most children have normal intelligence.

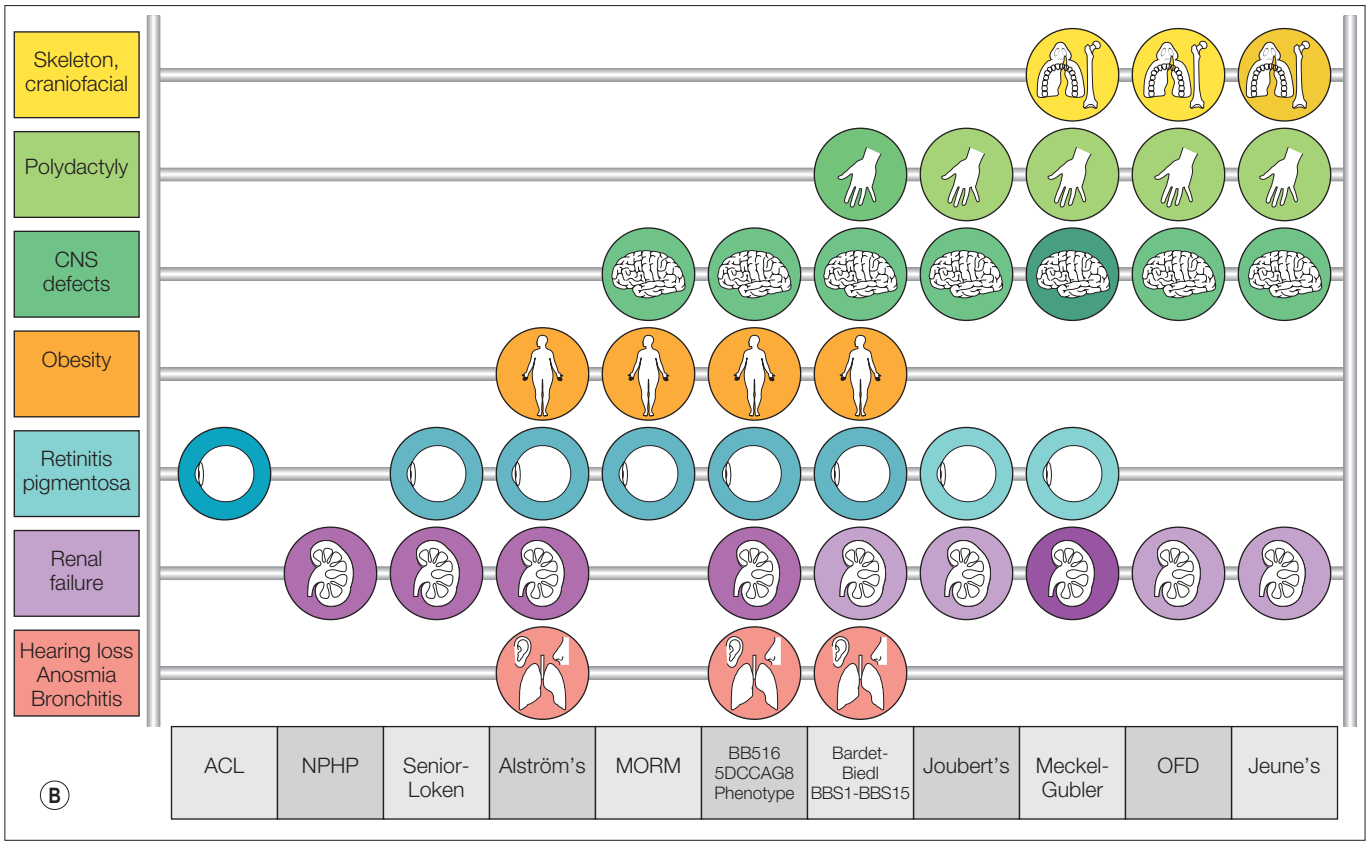

Fig. 47.2, cont'd (B) Schematic representation as an abacus (adding various target organs) of syndromes recognized as ciliopathies.

The first manifestation of ALMS is severe early-onset cone–rod retinal dystrophy, sometimes mimicking Leber congenital amaurosis with very early visual impairment, photophobia, and nystagmus (Fig. 47.4). Children usually become truncally obese during their first year. Sensorineural hearing loss presents in the first decade in up to 70%; it may progress to the moderately severe range (40–70 dB) by the end of the first to second decade. Insulin resistant type 2 diabetes mellitus often presents in the second decade and is accompanied by acanthosis nigricans (pigmentation mostly in body folds). Other endocrine and metabolic abnormalities include hypothyroidism, diabetes insipidus, growth hormone deficiency, hyperuricemia, hyperlipidemia, hypothyroidism, and hypogonadotrophic hypogonadism. Hepatic and renal dysfunction can be present in the second decade. This syndrome requires a multidisciplinary follow-up to detect complications once the diagnosis is confirmed.[54,55]

A single gene is involved in all the cases, *ALMS1*.[56,57] ALMS1 protein has been found to be located at the base of cilia.[58]

MORM syndrome

MORM syndrome (**m**ental retardation, truncal **o**besity, **r**etinal dystrophy, and **m**icropenis) is very rare.[59] A congenital non-progressive retinal dystrophy with poor night vision occurs within the first year of life with reduced visual acuity by 3 years of age that remains stable thereafter. The identified gene, *INPP5E* (inositol polyphosphate-5-phosphatase), classifies this syndrome as a ciliopathy. It is related to Joubert syndrome.[60]

Senior–Loken syndrome and Mainzer–Saldino syndrome

Senior–Loken syndrome (SLS) combines nephronophthisis (NPH) and retinal degeneration. NPH, the most common cause of inherited renal failure in childhood, is characterized by initial normal kidney size that will eventually shrink, tubulo-interstitial nephritis, and a loss of corticomedullary differentiation leading to cyst formation.[34,61–64] The first symptoms are polyuria and polydipsia caused by a urinary concentration defect. The end-stage of the renal failure is variable – infantile, juvenile, or adolescent. The occurrence of the retinal dystrophy is higher in the juvenile form of NPH. The early retinal dystrophy usually occurs years before the kidney involvement is detected. The retinal dystrophy may be very early, mimicking isolated LCA or may have a later onset. Thus, clinical diagnosis of LCA should lead to clinical and molecular testing for LCA-SLS associated genes and, according to the results, annual kidney follow-up may be indicated.

SLS is a ciliopathy and the kidney involvement is explained by the role of the *NPHP* proteins at the level of the tubular epithelial renal cells. Each of these has a primary cilium in contact with the urinary flow.

Nineteen (*NPHP1* to *NPHP19*) genes are known to be involved in NPH, and for many of them cases of SLS associated with RP have been reported.[34,65,66] Mutations in *NPHP5*[67] and *NPHP6*[68] are more often linked to severe and early RP. The Mainzer–Saldino syndrome is closely related. Kidney disease, retinal dystrophy, and skeletal features including the typical

(B) Polydactyly of the hand of a patient aged 6 months old with mutations in the *BBS1* gene. (C) Polydactyly of the foot of a patient aged 6 months old with mutations in the *BBS1* gene. (D) Bilateral scarring resulting from the surgical removal of the extra digits in the brother of the previous case. (E) Fundus photograph of a teenager patient carrying mutations in the *BBS16* gene showing widespread retinal degeneration.

cone-shaped epiphyses occur. It was recently shown to be associated to *IFT140* mutations [69,70]

Joubert syndrome

Joubert syndrome may be autosomal recessive or X-linked.[71,72] This syndrome is a combination of cognitive impairment, ataxia, tachypnea, eye movement abnormalities, with frequent retinal degeneration and kidney manifestations. Cerebellar vermis hypoplasia is a pathognomonic finding on magnetic resonance imaging (MRI) where it is evident as the "molar tooth" sign (Fig. 47.5).[73,74] Multiple other features can be associated with this midbrain–hindbrain malformation leading to the designation: Joubert syndrome and associated disorders

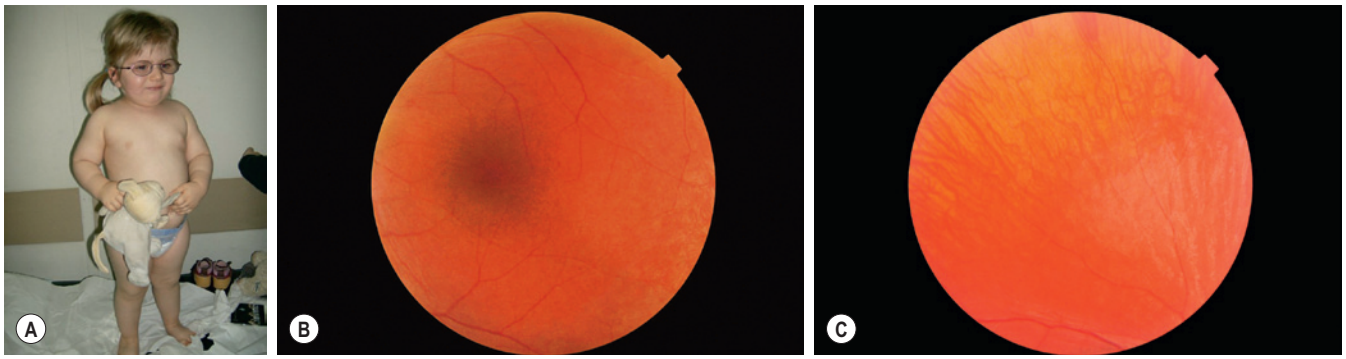

Fig. 47.4 Alström syndrome. (A) This 26-month-old girl was noted to be photophobic and overweight. She has mutations in the ALS gene. (B) Fundus photograph of the patient's macular region showing marked irregularity of the macula. Electroretinogram shows severe photopic reduction and a lesser degree of scotopic impairment. (C) Photograph of the peripheral retina; it is thinned with patchy pigmentation.

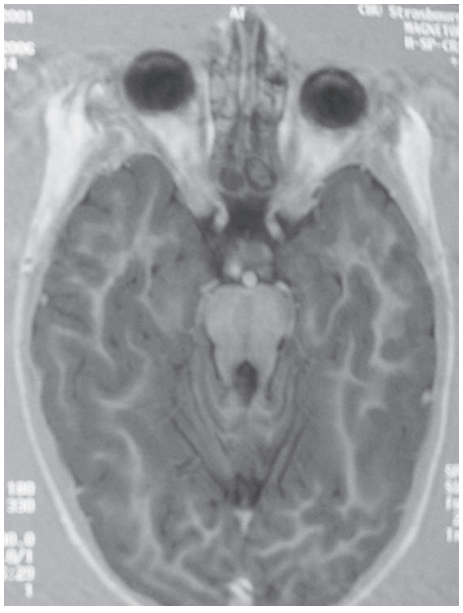

Fig. 47.5 Joubert syndrome. Molar tooth sign on the MRI of a child with Joubert syndrome carrying mutations in the *CEP290-NPHP6* gene.

(JSAD). In the kidneys, there may be a cystic dysplasia, caused by multiple cysts of different sizes, or NPH. More than 30% of patients with Joubert develop renal failure. Hepatic fibrosis occurs in 10% of patients. Skeletal findings are rarer and include polydactyly and cone-shaped epiphyses. The ocular phenotype is broad and may include abnormal motility, nystagmus, and ocular motor apraxia (saccade initiation failure; see Chapter 90). Coloboma has been reported rarely. RP occurs in a third of patients with either very early onset (mimicking LCA) or later-onset night blindness.[75] Twenty genes have been identified to be mutated in Joubert-related syndromes: *TMEM216*, *AHI1*, *NPHP1*, *NPHP6* (*CEP290*), *TMEM67*, *RPGRIP1L*, *ARL13B*, *CC2D2A*, *CXORF5* gene (X linked), *TTC21B*, *KIF7*, *TCTN1*, *TMEM237*, *TMEM138*, *C5ORF42*, *TCTN3*, *ZNF423*, *TMEM231*, *CSPP1*, and *PDE6D*.

The RP phenotype varies with the mutated gene and is not constant depending on the affected gene. Eighty percent of *AHI1*-mutated patients present with a retinal dystrophy and NPH-related renal disorder but no hepatic defects. RP has been observed in one family out of two mutated in *ARL13B*.[76] *CC2D2A* is found mutated in JSAD patients with or without RP.[77] The same mutation in *TMEM216* was identified in eight JSAD-related families presenting psychomotor retardation and frequent retinopathy.[78]

Jeune syndrome

Jeune asphyxiating dystrophy or Jeune syndrome is an autosomal recessive chondrodysplasia. The phenotype is highly variable and can lead to death in early infancy because of a severely constricted thoracic cage and respiratory insufficiency.[79,80] Patients present with a long narrow thorax due to short ribs (Fig. 47.6), shortened long bones, and sometimes polydactyly. Kidney cysts, hepatic fibrosis, and RP may occur as early as 5 years of age. Five genes are now reported for Jeune syndrome, but for each of them the risk of developing retinal degeneration remains unclear.[81–85]

Pathogenesis of the ciliopathies

The retinal degeneration in ciliopathies is related to dysfunction of the connecting cilium, a major site of transport and transit for proteins synthesized in the inner segment and necessary for phototransduction in the outer segment[86] (Fig. 47.7). The ciliary-specific transport machinery is known as the intraflagellar transport (IFT) machinery and is composed of molecular motors linked to IFT protein complexes that organize anterograde and retrograde transport. IFT gene mutations have been found in Jeune and Mainzer–Saldino syndromes. To regulate cargo delivery to the cilium, two main regulatory pathways occur: vesicular sorting from the Golgi to the ciliary base and selective transport along the cilium. BBS proteins (the BBSome complex) are involved in these regulatory processes.[86–87]

The extraocular manifestations are linked to specific roles of ciliary proteins involved in the development or function of many organs. As an example, the kidney epithelial cells' primary cilia are mechanosensors.[88] Primary cilia are implicated in major developmental processes and especially in planar cell polarity, body asymmetry, or limb development.[89]

The ciliopathies are a growing family of syndromes with overlapping features due to target organ manifestations that should be systematically sought when assessing any child with pigmentary retinopathy.

Retinal dystrophy in Bardet–Biedl syndrome and related syndromic ciliopathies. Prog Retin Eye Res 2011; 30: 258–74.)*

Other rare syndromes with retinal dystrophy

The following syndromes with retinal degeneration may result from a disorder of a well-defined biologic system (e.g. Cockayne syndrome and DNA repair); others are still under investigation (e.g. Cohen syndrome).

Cohen syndrome

Cohen syndrome is a rare worldwide autosomal recessive disorder, common in Finland where the phenotype is well defined, with clinical variability.[90–93] It is characterized by mental retardation, postnatal microcephaly, intermittent granulocytopenia, and facial dysmorphism with downslanting and wave-shaped palpebral fissures, short philtrum, heavy eyebrows, and a prominent nasal base (Fig. 47.8A,B). Long tapered fingers and joint laxity are common as well as prominent upper central incisors (Fig. 47.8C,D).[91,94] There may be a history of neonatal hypotonia with poor feeding and delay in motor milestones with speech delay, and stridor secondary to laryngomalacia. Truncal obesity is common, but not invariable, by 5 years of age. Early-onset retinal dystrophy with myopia is classical.[95] The onset of myopia is usually under 5 years of age and exceeds 7 diopters by the second decade. The macula may develop a "bull's eye" appearance (Fig. 47.8E) in the first decade evolving toward a cone–rod dystrophy. The first symptoms are of myopia and night blindness followed by reduced acuity, and reduced visual field, generalized pigmentary retinopathy with bone spicules or lacunar RPE atrophy in the mid-periphery by the second decade.

One gene (*COH1*) has been identified which encodes for VPS13B. This could have a role in vesicle-mediated sorting and transport of proteins within the cell.[96] Many mutations and intragenic deletions have been reported.[97,98]

Cockayne syndrome and DNA repair

Cockayne syndrome is a DNA repair disorder due to a dysfunction of the transcription-coupled DNA repair genes.[99,100] All the cells are hypersensitive to effects of ultraviolet (UV) light, which is used as the basis for the diagnostic cellular tests of cultured fibroblasts from a skin biopsy.

The main characteristics of the disease are UV skin sensitivity and severe physical and mental retardation (cachectic dwarfism) with progressive neurologic deterioration, sensorineural deafness, and retinal degeneration[101,102] (Fig. 47.9Ai–Aiii). The retinal dystrophy is characterized by a "salt and pepper" pigmentation with optic disc pallor and progressive deterioration in the rod and cone ERG.[103,104] The progression is usually rapid. Cataracts may be present from birth and are often associated with poorly developed iris dilator muscle (the children are difficult to dilate and examine). Corneal changes may occur associated with lagophthalmos as well as chronic blepharitis that can make aphakic contact lens wear difficult[105] (Fig. 47.9Aii). Cachexia may lead to massive orbital fat atrophy.

Early death can occur especially if early-onset cataracts are observed.[106] However, a spectrum of severity has been reported ranging from an early-onset severe form, the cerebro-ocular-facial syndrome (COFS),[107,108] to severe, moderate, and mild forms diagnosed in adulthood as UV sensitivity only[109] (Fig. 47.9Bi–Biv). Mutations in two genes have been identified: CSA (group 8 excision-repair cross-complementing protein; *ERCC8*) and CSB (group 6 excision-repair cross-complementing protein; *ERCC6*).[110–112] The latter is more frequently mutated (60–80%).[113]

Pediatric syndromes with retinal degeneration and features of the ectodermal spectrum (hair, skin, teeth)

Retinal degeneration observed in children with abnormalities related to the ectodermal dysplasia spectrum (affecting hair, skin, nails, or sweat glands or teeth) is rare.

Hypotrichosis with juvenile macular dystrophy

Congenital hypotrichosis associated with juvenile macular dystrophy (HJMD, OMIM 601553) is an autosomal recessive condition with early hair loss and juvenile macular degeneration in the first decade that can show phenotypic variability.[114–116] The retinal involvement becomes widespread and is a cone–rod dystrophy.[117] Mutations have been identified in a P-cadherin gene, *CDH3*, that encodes an integral membrane glycoprotein responsible for calcium-dependent cell–cell desmosomal adhesion.[118]

Ectodermal dysplasia, ectrodactyly, macular dystrophy syndrome

The ectodermal dysplasia, ectrodactyly, macular dystrophy (EEM) syndrome inherited as an autosomal recessive entity is a specific ectodermal entity because of the unusual associated retinal features.[119,120] The retinal involvement has a typical severe macular onset with geographic atrophy that has a peripheral progression. The patients are characterized by hypotrichosis with sparse and short hair, eyebrows and eyelashes, partial anodontia, and limb defects with syndactyly or "lobster-claw" hands.[120] The syndrome shares features with the HJMD syndrome and the *CHD3* gene is mutated, showing allelic variability.[121]

Interestingly, cadherins constitute a superfamily of genes found mutated in various genetic disorders including USH1. For the latter, there is a crucial role of transient fibrous links formed by cadherin 23 and protocadherin 15 in the cohesion of the developing hair bundle as well as the involvement of these cadherins in the formation of the tip link, a key component of the mechanoelectrical transduction machinery.[122] This illustrates that proteins of the same superfamily may have different roles in inherited systemic retinal degenerative syndromes.

Uncombable hair with retinal pigmentary dystrophy, brachydactyly, and dental anomalies

This is a very rare ectodermal dysplasia with RP and is reported to be autosomal dominant.[123,124]

Oliver–McFarlane syndrome, trichomegaly, and chorioretinopathy with pituitary dysfunction (Fig 47.10)

The Oliver–McFarlane syndrome is autosomal recessive, and most often reported as sporadic cases with long eyelashes, hair abnormalities such as early alopecia, and short stature due to pituitary deficiency. Developmental and neurologic

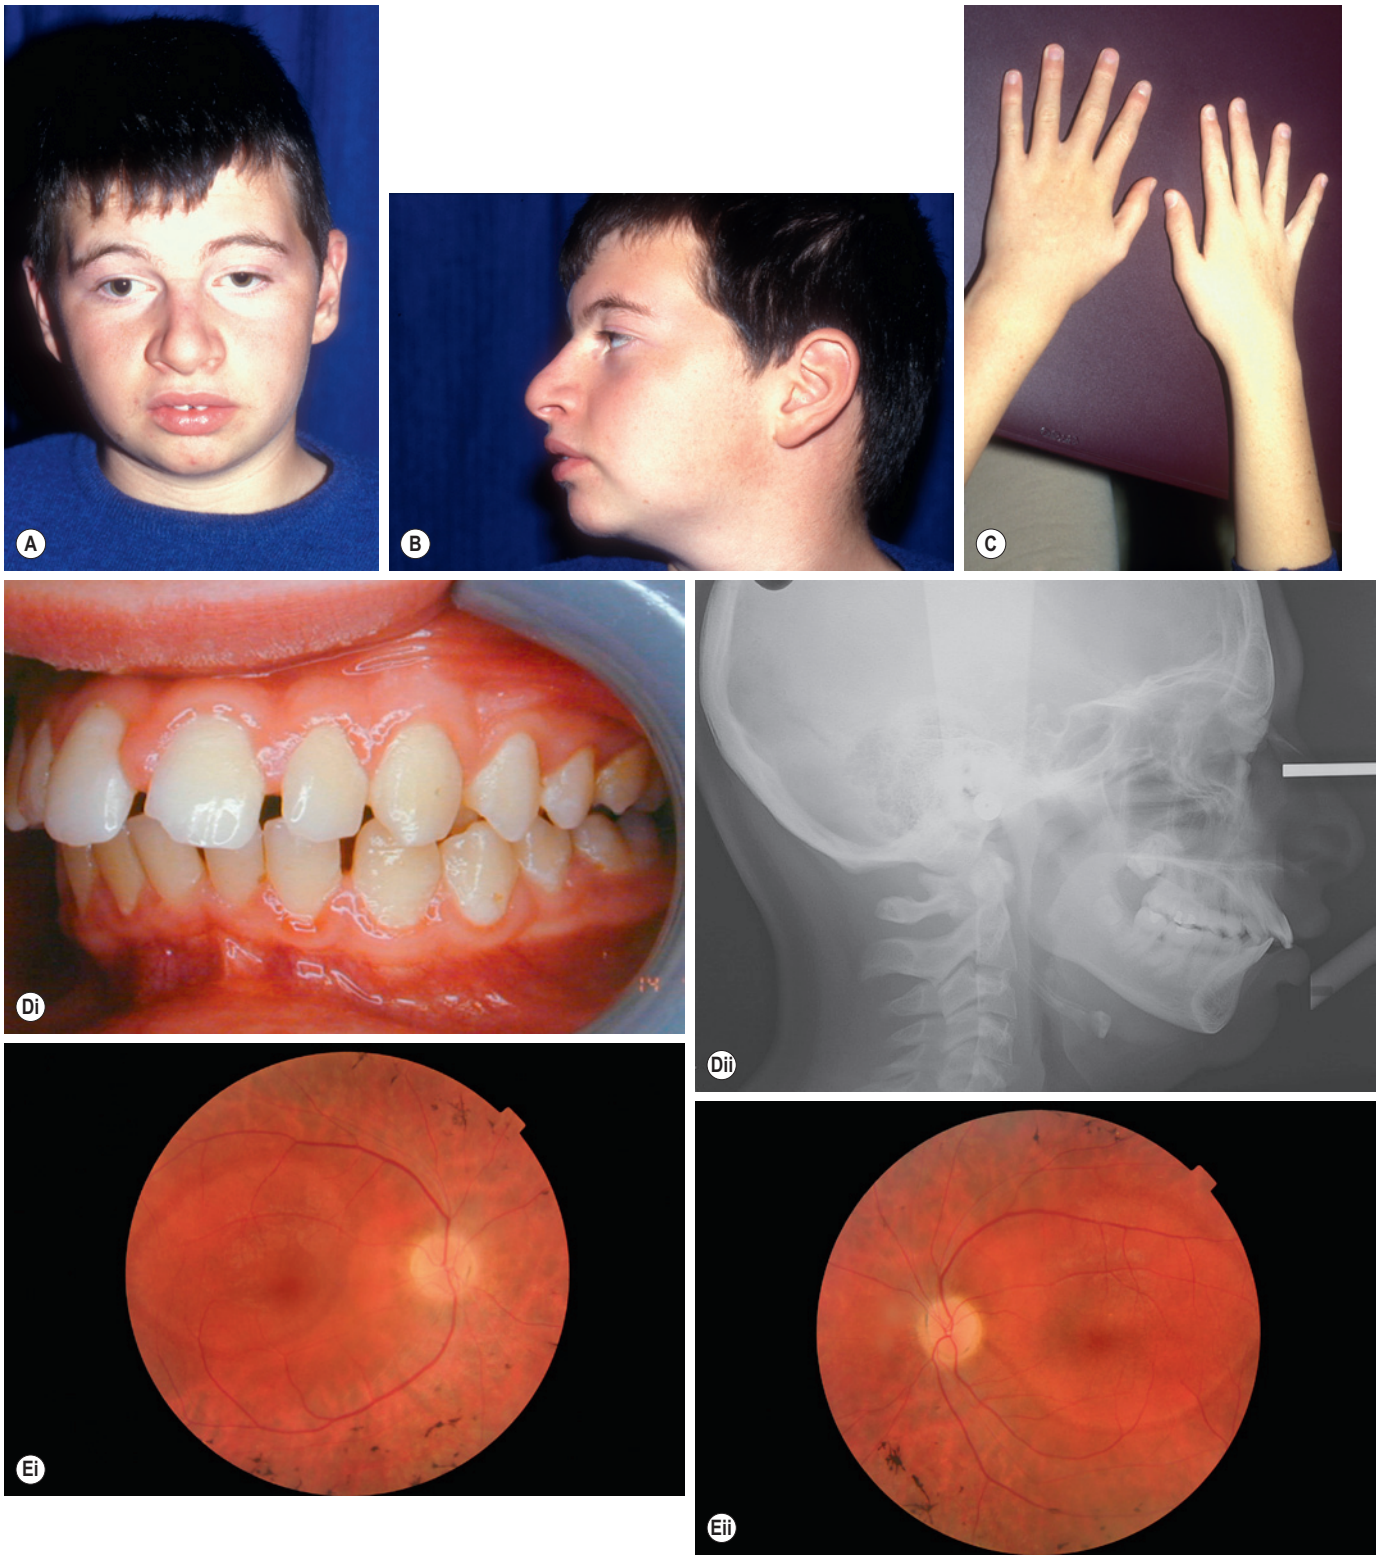

Fig. 47.8 Cohen syndrome. (A) Photograph of the face of a patient with Cohen syndrome carrying mutations in the *COCH* gene. (B) Profile photograph of the same patient. Fig. 47.9 Cockayne syndrome. (Ai) Patient with severe Cockayne syndrome with a *CSB* mutation showing cachetic dwarfism and ultraviolet sensitivity after a very short sun exposure coming into the clinic. (Aii) Close-up photograph of the same patient a couple of years later with atrophy of the periocular fat and sunken eye appearance. Both pupils are miotic; he has chronic blepharitis and corneal involvement. (Aiii) Profile picture of the sunken eye appearance. (Bi) Patient with moderate Cockayne syndrome with growth delay, carrying mutations in the *CSB* gene. (Bii) Facial close-up. The pupils are miotic. (Biii) Profile close-up showing sunken eye appearance. (Biv,Bv) Fundus photographs showing retinal dystrophy and optic atrophy.

impairment with cerebellar ataxia may occur.[125–127] The retinal degeneration occurs as early as 5 years of age with night blindness and rapid panretinal dysfunction. Vision is very reduced and there is extensive atrophy of the retinal pigment epithelium and choriocapillaris with an undetectable ERG.[128]

This syndrome has been found to be allelic with spastic paraplegia type 39, Boucher–Neuhauser syndrome, Laurence–Moon syndrome and Gordon Holmes syndromes as mutations in the *PNPLA6* gene have been discovered in these syndromes that share spastic paraplegia with various characteristic features trichomegaly/retinal degeneration/congenital hypopituitarism being specific for Oliver–Mcfarlane.[129,130]

Retinal dystrophy and dental abnormalities: Jalili syndrome

Jalili syndrome is a very rare autosomal recessive condition with early onset cone–rod dystrophy and *amelogenesis imperfecta* (abnormal tooth biomineralization). The *CNNM4* gene has been implicated. It encodes for a metal transport protein important for the retina and teeth[131] (Fig. 47.11).

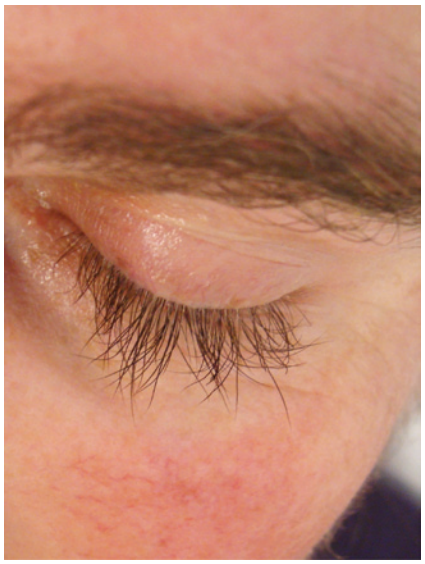

Fig 47.10 Oliver–McFarlane syndrome. Trichomegaly with long eyelashes. *(Courtesy of Dr Klaus Dieterich, Grenoble University Hospital, Grenoble, France.)*

RP syndrome with prominent skeletal involvement

Retinal degeneration may rarely be associated with inherited skeletal dysplasias. A child with spondylometaphyseal/epiphyseal dysplasia should undergo systematic ocular examinations. Genes and pathogenesis remain unknown although theories linking them to ciliopathies have been suggested.[132,133]

Spondylometaphyseal dysplasia short stature with cone dystrophy

This autosomal recessive condition has postnatal growth deficiency, profound short stature, platyspondyly (flattened vertebral bodies) and rhizomelic foreshortening of the limbs, and early bowing of the long bones of the legs with shortening of all the tubular bones.[133] The retinal degeneration occurs in early childhood. It initially involves the macula with a cone–rod evolution. Mutations in the *PCYT1A* gene inducing a deregulation of the phosphatidylcholine pathway has been reported.[134–135] A phenotypically less severe skeletal axial spondylometaphyseal dysplasia with features of retinal dystrophy has been reported.[136–137]

Spondyloepiphyseal dysplasia with cone–rod dystrophy

Another skeletal dysplasia with short stature characterized by spondyloepiphyseal dysplasia has been described with cone–rod dystrophy[138,139] and associated with growth hormone deficiency.[140–141]

Conclusion

Retinitis pigmentosa can be part of a syndrome, particularly when it presents in childhood. Extraocular manifestations may appear later or can already be present at the time of diagnosis. Follow-up of a child affected with syndromic RP is multidisciplinary. The molecular diagnosis of these conditions is continuously improving, facilitating diagnosis and genetic counseling. The understanding of the pathogenesis is important and opens avenues for specific treatment for the retinal degeneration, such as gene therapy or pharmacologic approaches.

Introduction

The inherited macular dystrophies are characterized by bilateral central visual loss and symmetrical macular abnormalities. Most present in the first two decades of life with a wide range of clinical, electrophysiological, psychophysical, and histological findings. The molecular basis of inherited macular disease is now well understood, providing insights into the pathogenesis (Table 48.1).

We review pediatric macular dystrophies and not those that present later, such as Sorsby fundus dystrophy, dominant drusen, and adult vitelliform macular dystrophy. Systemic disorders with macular dystrophy will be discussed in Chapters 47 and 65.

Autosomal recessive inheritance

Stargardt disease and fundus flavimaculatus

Clinical and histological findings

Stargardt macular dystrophy (Stargardt disease, STGD) is the most common inherited macular dystrophy with a prevalence of 1 in 10,000; it is inherited as an autosomal recessive (AR) trait. Most cases present with central visual loss in early teens. There is typically macular atrophy with yellow-white flecks at the level of the retinal pigment epithelium (RPE) at the posterior pole (Fig. 48.1). The flecks may be "fish-shaped" (pisciform), round, oval, or semilunar. The oval area of macular atrophy may, in the early stages, have a "beaten bronze" appearance (see Fig. 48.1). However, there may be no evidence of flecks at presentation, the only abnormality being macular atrophy, but in these patients, flecks usually develop over time. The term "fundus flavimaculatus" (FFM) is used to describe the phenotype of retinal flecks occurring without macular atrophy. STGD and FFM are caused by mutations in the same gene; both patterns may be seen in the same family. Most patients who present with FFM develop macular atrophy.

Table 48.1 Chromosomal loci and causative genes in inherited macular dystrophies

Macular dystrophy; OMIM number	Mode of inheritance	Chromosome locus	Mutated gene

Fig. 48.1 Stargardt disease. Yellow-white flecks at the level of the retinal pigment epithelium at the posterior pole. There is early macular atrophy.

In both STGD and FFM, fluorescein angiography classically reveals a dark or masked choroid (Fig. 48.2) in the early phase. This is due to excess lipofuscin accumulation in the RPE, which obscures fluorescence from choroidal capillaries. The retinal flecks appear hypofluorescent on fundus fluorescein angiography (FFA) early in their evolution, but later they appear hyperfluorescent due to RPE atrophy. Autofluorescence (AF) imaging, using the intrinsic fluorescence from lipofuscin in the RPE, has superseded FFA in confirming the diagnosis. The abnormal accumulation of lipofuscin, the presence of active and resorbed flecks, and RPE atrophy are characteristic on fundus AF imaging[1] (Fig. 48.3). In children with normal fundoscopy and visual loss from macular dysfunction, FFA may be helpful; a subtle window defect in the central macula or a dark choroid helps confirm the diagnosis. However, this has now been generally superseded by high-resolution optical coherence tomography (OCT), which shows abnormal foveal structure at very early stages of disease. In more established disease, OCT reveals loss, or marked disruption, of central outer retinal macular architecture with relative preservation of peripheral macular structure (Fig. 48.4).

Electrophysiology

Electrophysiological abnormalities in STGD are variable. An abnormal electro-oculogram (EOG), suggestive of generalized RPE dysfunction, is common. The pattern electroretinogram (PERG) and focal electroretinogram (ERG) are usually abolished or markedly reduced, suggesting macular dysfunction. The full-field ERG may be normal at diagnosis (group 1) or suggest widespread retinal dysfunction (group 2 or 3)[1]:

group 1: severe pattern ERG abnormality with normal full-field ERG;
group 2: additional generalized cone dysfunction;
group 3: generalized cone and rod dysfunction.

These groups are not explained by differences in age of onset or duration of disease and electrophysiological classification at onset of disease may be helpful in informing prognosis. Patients in group 1 have the best visual prognosis, with those in group 3 the worst.[1]

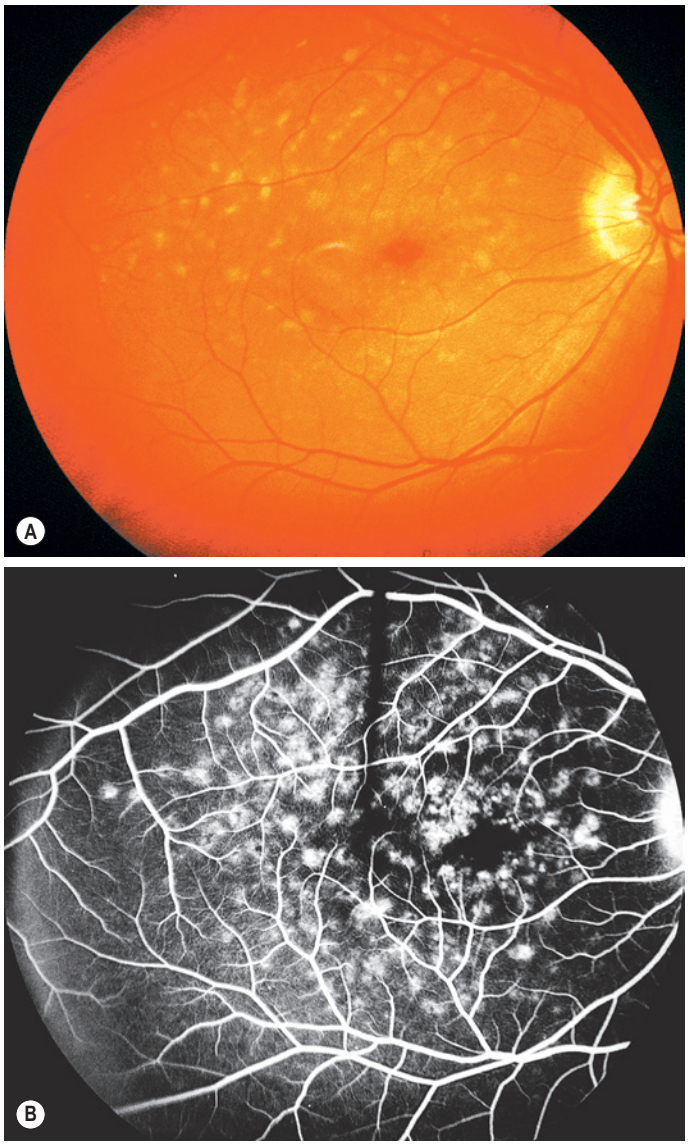

Fig. 48.2 Stargardt disease. Fluorescein angiogram (B) showing "dark choroid" and transmission defects with a color fundus photograph above (A) for comparison.

Molecular genetics and pathogenesis

Mutations in the gene *ABCA4* underlie STGD/FFM, and have also been implicated in retinitis pigmentosa (RP) and cone–rod dystrophy. *ABCA4* encodes a transmembrane rim protein in the outer segment discs of rod and cone photoreceptors involved in transport of retinoids from photoreceptor to RPE. Failure of this transport results in deposition of a lipofuscin fluorophore, A2E (*N*-retinylidene-*N*-retinylethanolamine), in the RPE,[2] which is deleterious to the RPE and leads to secondary photoreceptor degeneration.

More than 800 sequence variations in *ABCA4* have been reported, demonstrating the high allelic heterogeneity and highlighting the difficulties in assigning disease-causing status to sequence variants detected when screening such a large (50 exons) and polymorphic gene. Nonsense mutations with a major effect on the encoded protein can be confidently predicted to be disease causing. A major problem occurs with missense mutations since sequence variants are common in controls; therefore, establishing pathogenicity may be problematic. Direct evidence of pathogenicity can only be established by functional analysis of the encoded mutant protein.

Correlation between the type and combination of *ABCA4* mutations with the severity of the phenotype is often possible.[3] For example, biallelic null mutations usually lead to an early-onset cone–rod dystrophy phenotype rather than STGD. Variable retinal phenotypes within families may be explained by different combinations of *ABCA4* mutations segregating within a single family, but it is likely that other modifier genes or environmental factors may also influence intrafamilial variability.

Accumulation of lipofuscin-related products in the RPE, such as A2E, occurs in STGD and in *ABCA4* knockout mice (*abca4*$^{-/-}$), resulting in free radical generation, release of pro-apoptotic mitochondrial proteins, and lysosomal dysfunction.[2] This leads to RPE dysfunction and cell death and subsequent photoreceptor cell loss.

A2E synthesis can be reduced by raising *abca4*$^{-/-}$ mice in total darkness, and is increased by feeding the mice supplemental vitamin A. It seems reasonable to advise STGD patients to avoid vitamin A supplementation and to wear ultraviolet light-blocking sunglasses. We also recommend an antioxidant-rich diet, which slows photoreceptor cell death in animal models of retinal dystrophies. Affected children may be helped by low vision aids and educational support. Families should also be offered genetic counseling. STGD is inherited as an AR trait and thus younger siblings of an affected child have a 1 in 4 risk of developing the disorder. Older siblings are at a lower risk, as the age of onset is usually similar between affected siblings. The carrier frequency of STGD is 1 in 50; thus there is a 1 in 50 chance that an asymptomatic partner of an affected individual carries a disease-causing sequence change in *ABCA4*. Therefore, there is a 1% risk of an affected individual having an affected child (higher if the partner is a close relative).

Future therapies

New therapeutic interventions for STGD include drugs that target the adenosine triphosphate (ATP)-dependent transport mechanism, thereby augmenting ABCA4-related retinoid transport, or slow the visual cycle, reducing the production of A2E. Directly inhibiting the toxic effects of A2E may prove more effective. Pharmacological agents aimed at these three targets have been developed and are likely to progress to a human clinical trial in the near future.[2,4] Such agents may also be helpful in other macular degenerations associated with lipofuscin accumulation, such as Best disease.

Other interventions including gene-replacement therapy and stem cell-based transplantation are currently in clinical trial (http://www.clinicaltrials.gov).

Autosomal dominant inheritance

Autosomal dominant Stargardt-like macular dystrophy

Clinical and histological findings

Compared to the recessive disorder, individuals with autosomal dominant (AD) STGD-like dystrophy have a milder phenotype

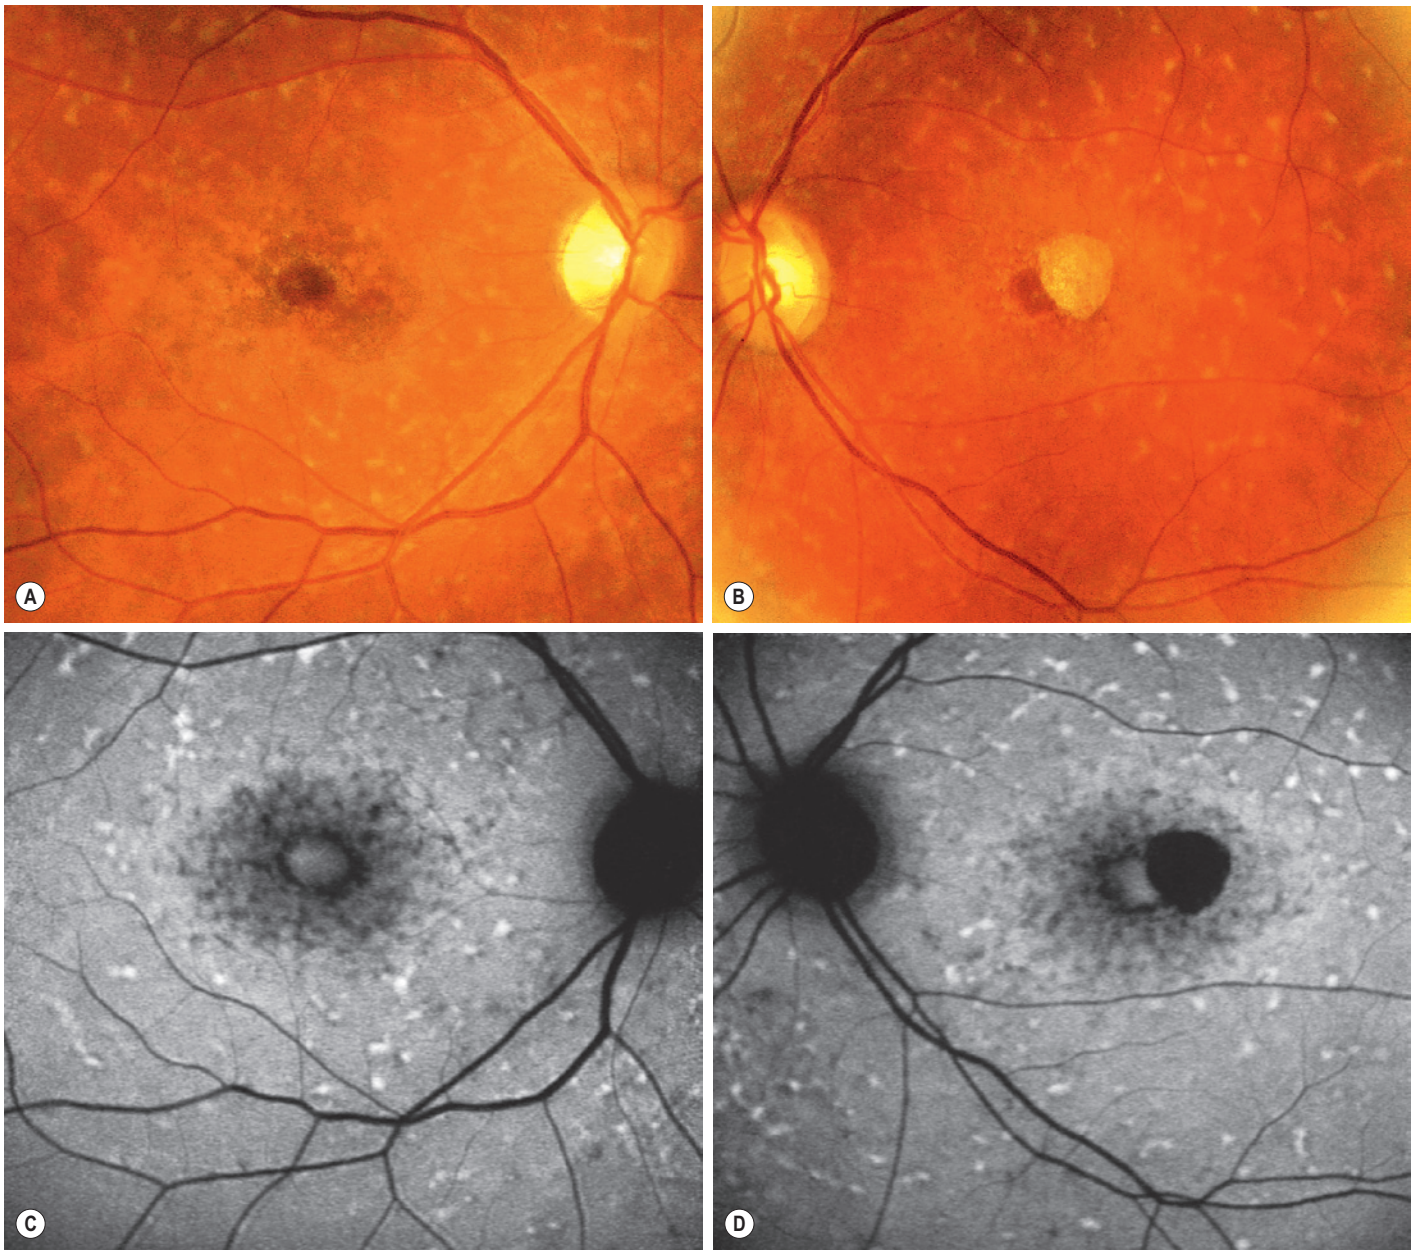

Fig. 48.3 Stargardt disease. Characteristic appearance on fundus autofluorescence imaging (C,D) showing abnormal accumulation of lipofuscin, the presence of active and resorbed flecks, and RPE atrophy. Color fundus photographs (A,B) are shown for comparison.

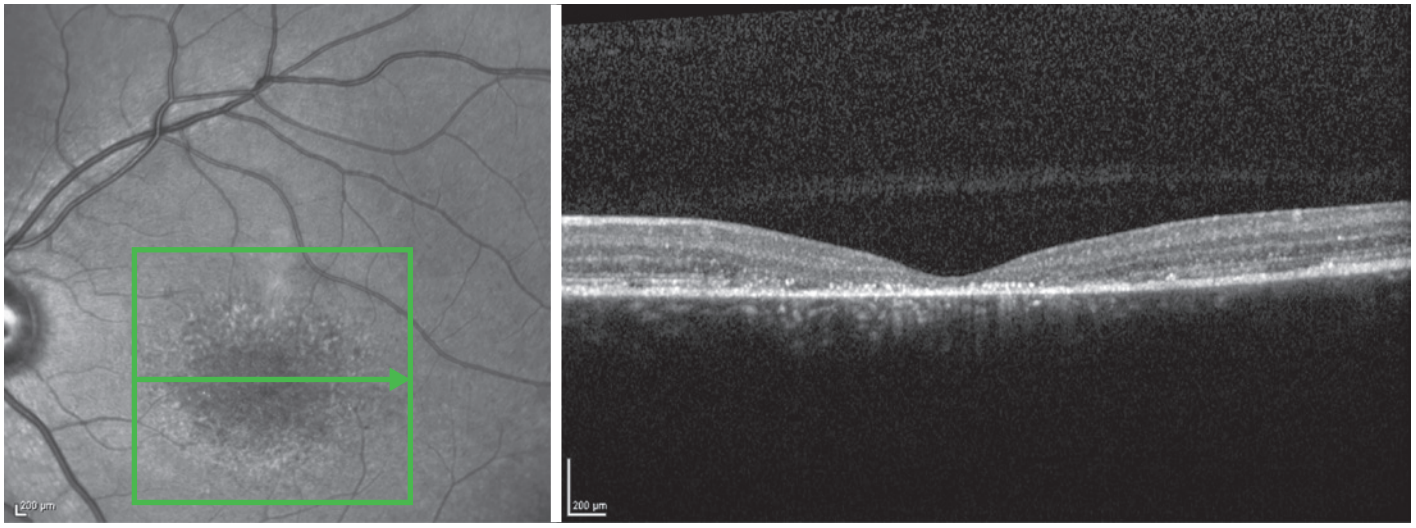

Fig. 48.4 Stargardt disease. Spectral domain optical coherence tomography (SD-OCT) showing loss of central outer retinal macular architecture with relative preservation of peripheral macular structure. Outer retinal debris can be seen at the fovea.

with good vision and minimal color vision defects. Individuals usually present in the first or second decades with visual loss, which may precede retinal changes. Temporal optic disc pallor may precede retinal findings. The "dark choroid" sign on fluorescein angiography is uncommon in the dominant form. Histopathological findings are similar to AR STGD, with widespread accumulation of lipofuscin throughout the RPE.

Electrophysiology

Individuals with AD STGD-like dystrophy often have no significant EOG or ERG abnormalities.

Molecular genetics and pathogenesis

Inheritance patterns may distinguish the two forms of STGD but pseudodominance is a confounding factor – the carrier frequency of AR STGD is sufficiently common (1 in 50) for an affected individual to have an asymptomatic partner carrying a disease-associated sequence change in *ABCA4*. Pseudodominance is also common in consanguineous families.

Two chromosomal loci have been identified: 6q14 (STGD3) and 4p (STGD4). Two mutations, a 5-base pair (bp) deletion and two 1-bp deletions separated by four nucleotides, in the gene *ELOVL4* have been associated with STGD3 and other macular dystrophies, including pattern dystrophy. *ELOVL4* is expressed in rod and cone photoreceptor inner segments and may be involved in retinal fatty acid metabolism.

A missense mutation, p.Arg373Cys, in *PROM1* co-segregates with disease in STGD4. *PROM1* encodes human prominin 1, which has a role in outer segment disc formation and maintenance. The same *PROM1* missense mutation, p.Arg373Cys, occurs in patients with an early-onset autosomal dominant "bull's eye" macular dystrophy (MCDR2).

Autosomal dominant "bull's eye" macular dystrophy (MCDR2)

Clinical and histological findings

Onset is from the end of the first to the sixth decade, with most presenting with reading difficulties.[5] RPE mottling in younger subjects progresses to a bull's eye maculopathy (BEM) and, later, macular atrophy. Some patients have typical features of RP (see Chapter 46). Patients have a mild to moderate reduction in visual acuity, except when associated with RP, where markedly reduced central vision is common.

Electrophysiology

Electrophysiological findings range from isolated macular dysfunction without generalized photoreceptor dysfunction, to a very severe rod–cone dysfunction.

Molecular genetics and pathogenesis

A distinct missense mutation, p.Arg373Cys, in *PROM1* has been identified.[5] Recessive nonsense mutations have also been reported in *PROM1* that cause a severe form of autosomal recessive RP, not associated with BEM.

Best disease (vitelliform macular dystrophy)

Clinical and histological findings

Best disease (BD) is an autosomal dominantly inherited macular dystrophy with a round or oval yellow subretinal macular deposit that is highly autofluorescent on AF imaging (Fig. 48.5). Although most gene carriers show a reduced light rise on EOG, the retinal phenotype is variable. Some gene carriers have a completely normal fundus. The phenotype is classified into five stages (Table 48.2):

stage 0: pre-vitelliform – a normal fundus in an asymptomatic gene carrier with an abnormal EOG;
stage I: minor RPE changes;
stage II: classical "egg yolk" macular lesion (Fig. 48.6A). FFA shows a corresponding area of blocked choroidal fluorescence (Fig. 48.6B). This appearance is usually seen during the first or second decades, often with near-normal visual acuity;
stage IIa: the "egg yolk" begins to break up secondary to resorption of the yellow material lying between the RPE and sensory retina, usually associated with noticeable visual impairment (Fig. 48.7);
stage III: pseudohypopyon – part of the lesion is resorbed leaving the appearance of a "fluid level" at the macula;
stage IVa: the yellow material is completely resorbed, leaving RPE atrophy;
stage IVb: subretinal fibrosis;
stage IVc: choroidal neovascularization (Fig. 48.6C,D).

Histopathology shows accumulation of lipofuscin throughout the RPE. Although the ophthalmoscopic abnormality is usually in the macular region, more widespread retinal involvement is present.

The visual prognosis is good; most patients retain reading vision beyond the fifth decade. Carriers who have minimal macular abnormality or a normal fundus appearance (but abnormal EOG) in early-adult life usually retain good visual acuity.

Electrophysiology

Full-field ERG is normal; the EOG shows a reduced or absent light rise, indicating widespread RPE dysfunction. Most individuals carrying mutations in the gene associated with BD, *BEST1*, have an abnormal EOG, but the macular appearance may be normal. True non-penetrance is rare.

Molecular genetics and pathogenesis

Best disease is caused by mutations in *BEST1*, encoding the protein bestrophin, localized to the basolateral plasma membrane of the RPE. It forms a calcium-activated chloride channel that maintains chloride conductance and regulates fluid transport across the RPE. OCT studies suggest that impaired fluid transport in the RPE secondary to abnormal chloride conductance leads to accumulation of fluid and/or debris between RPE and photoreceptors and between RPE and Bruch's membrane, leading to detachment and secondary photoreceptor degeneration.[6] The variable expression of BD remains unexplained: additional genes and/or environmental influences may play a role in the wide range of clinical expression.

Recessive mutations have been identified in *BEST1* in a condition associated with multiple vitelliform retinal deposits and maculopathy: autosomal recessive bestrophinopathy (ARB).[7] Hyperopia is common and there is an increased incidence of angle closure glaucoma. In childhood, the retinopathy is characterized by bilateral multifocal subretinal

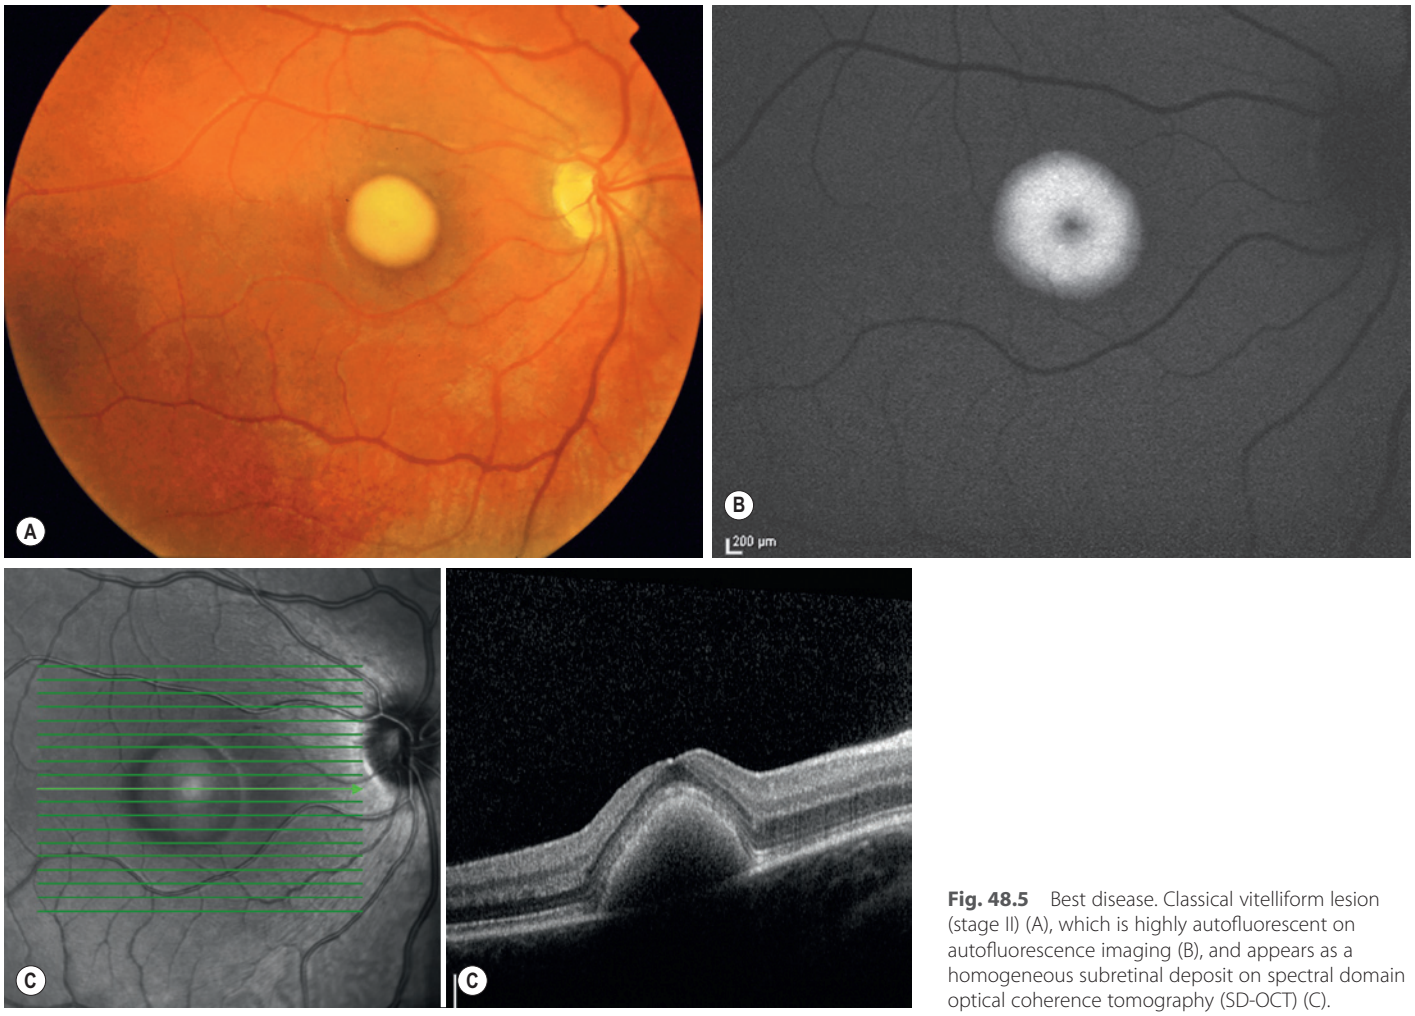

Fig. 48.5 Best disease. Classical vitelliform lesion (stage II) (A), which is highly autofluorescent on autofluorescence imaging (B), and appears as a homogeneous subretinal deposit on spectral domain optical coherence tomography (SD-OCT) (C).

Table 48.2 Classification of vitelliform dystrophy

Stage	Macular appearance
0	Normal fundus (abnormal EOG)
I	Minor retinal pigment epithelial changes
II	Typical vitelliform lesion
IIa	"Scrambled egg" appearance
III	Pseudohypopyon phase
IVa	Atrophic retinal pigment epithelium
IVb	Fibrous scar tissue
IVc	Choroidal neovascularization

EOG, electro-oculogram.
Modified from Mohler CW, Fine SL. Long-term evaluation of patients with Best's vitelliform dystrophy. Ophthalmology 1981; 88: 688–92.

yellow deposits seen most clearly on AF imaging. Retinal edema and subretinal fluid may be observed clinically and on OCT (Fig. 48.8). The EOG light rise is absent or severely reduced. In contrast to the dominant form, the parents of patients with ARB have a normal EOG. Adults with ARB have an abnormal EOG and reduced rod and cone responses on full-field ERG. In children with ARB, the ERG is usually normal. The prognosis for central vision is worse than in BD.

AD and AR mutations in *IMPG1* and *IMPG2* have been reported in families with AD and AR atypical vitelliform dystrophy.[8] The vitelliform lesions may be confined to the macula or be multifocal. This condition can be distinguished from BD by the later age of onset, drusen-like deposition, and by the fact that in patients with mutations in *IMPG1* and *IMPG2* the EOG light rise is normal or only mildly subnormal.

Future therapies

Future interventions may include gene-based therapies or therapeutic agents that either improve the function of the calcium-activated chloride channel and fluid exchange across the RPE, slow the visual cycle to reduce the accumulation of lipofuscin, or directly inhibit the toxic end-product, A2E, as has been described for STGD.[4]

Pattern dystrophies

Clinical and histological findings

Pattern dystrophies are usually dominantly inherited disorders of the RPE, with bilateral symmetrical yellow-orange deposits at the macula in various distributions, including butterfly or reticular patterns. There is increased AF (Fig. 48.9). On FFA,

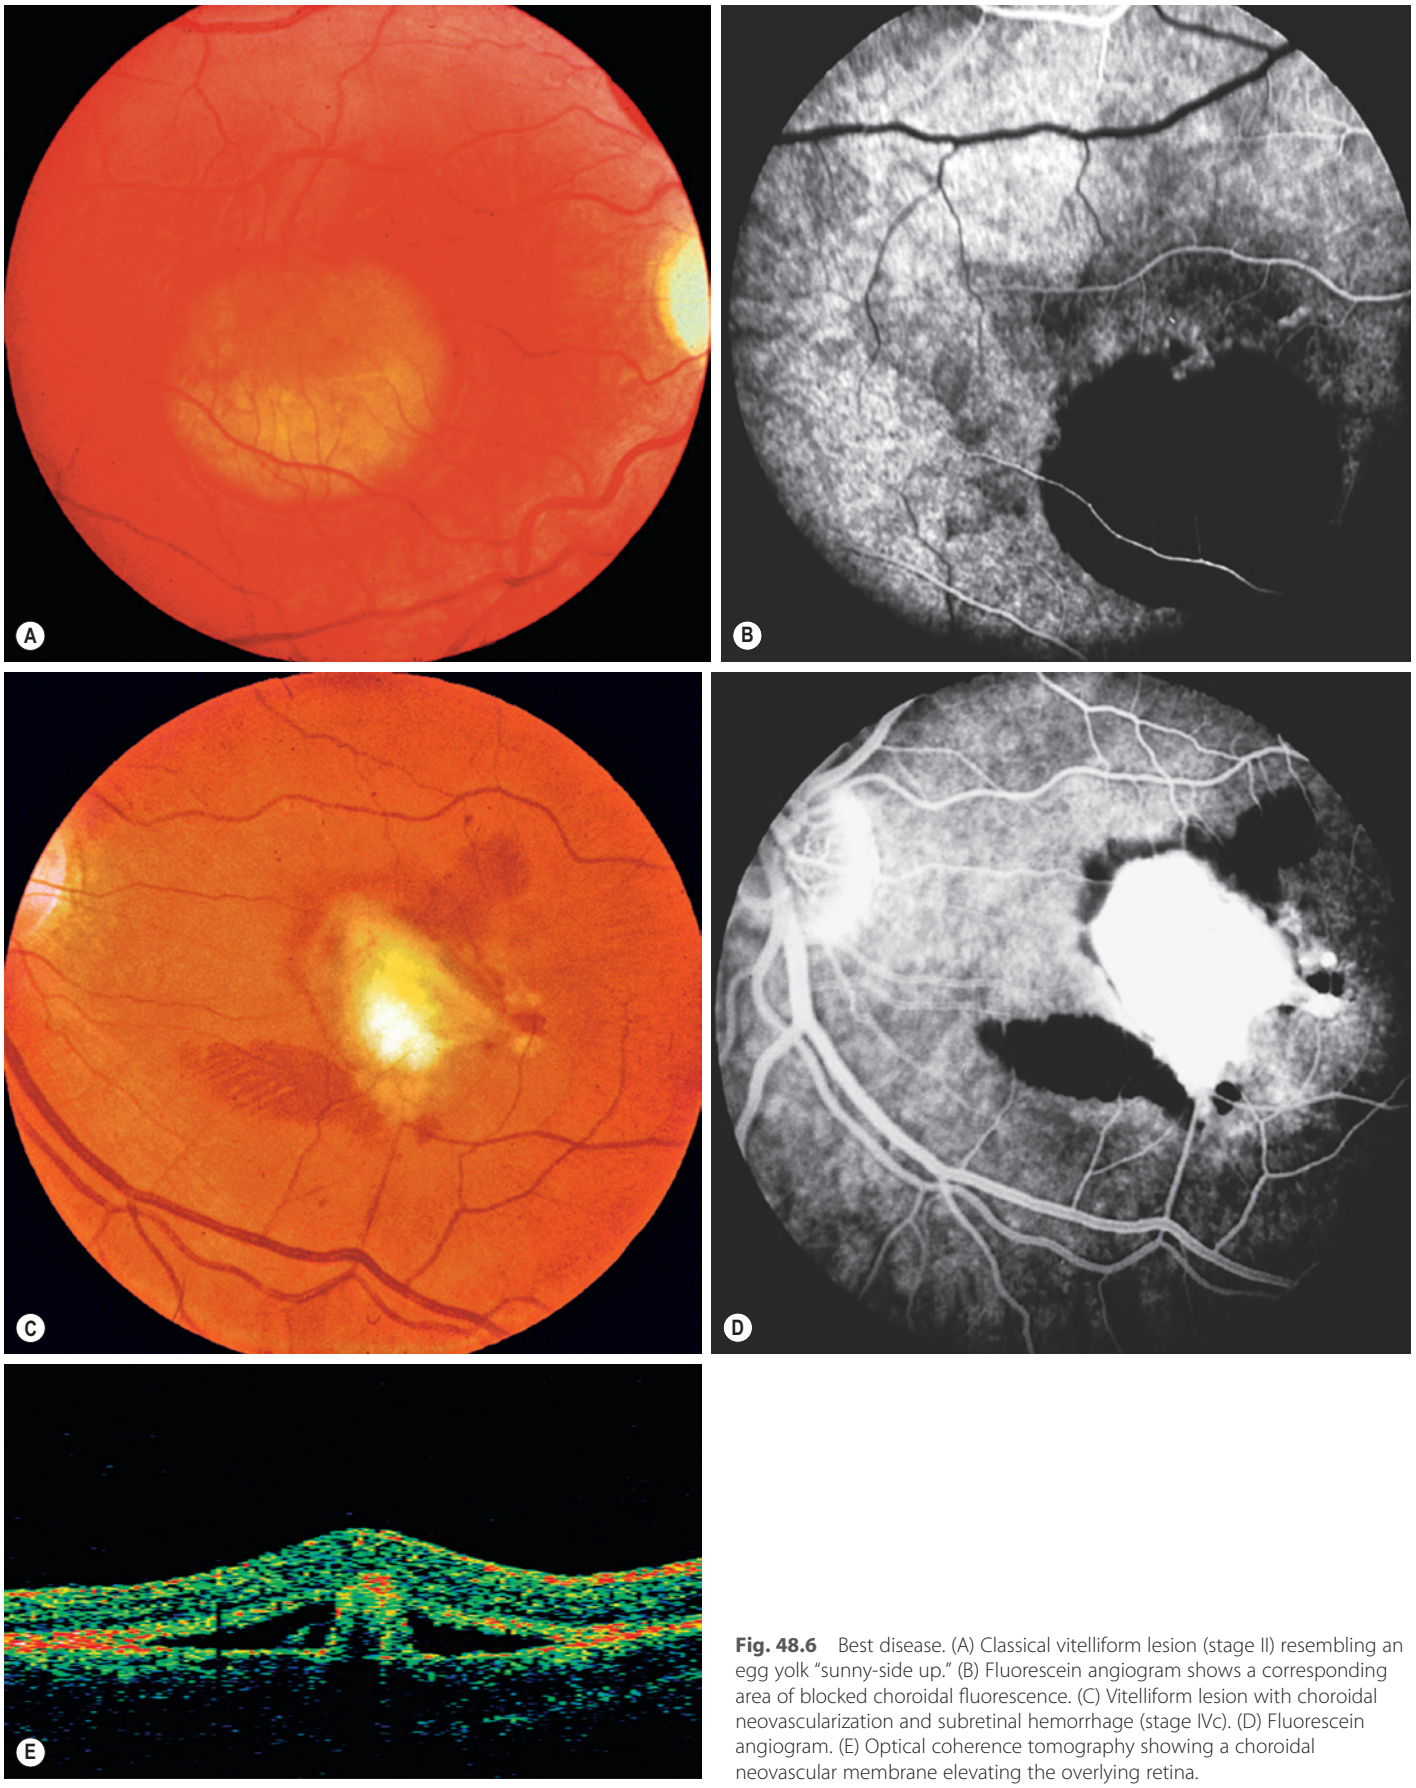

Fig. 48.6 Best disease. (A) Classical vitelliform lesion (stage II) resembling an egg yolk "sunny-side up." (B) Fluorescein angiogram shows a corresponding area of blocked choroidal fluorescence. (C) Vitelliform lesion with choroidal neovascularization and subretinal hemorrhage (stage IVc). (D) Fluorescein angiogram. (E) Optical coherence tomography showing a choroidal neovascular membrane elevating the overlying retina.

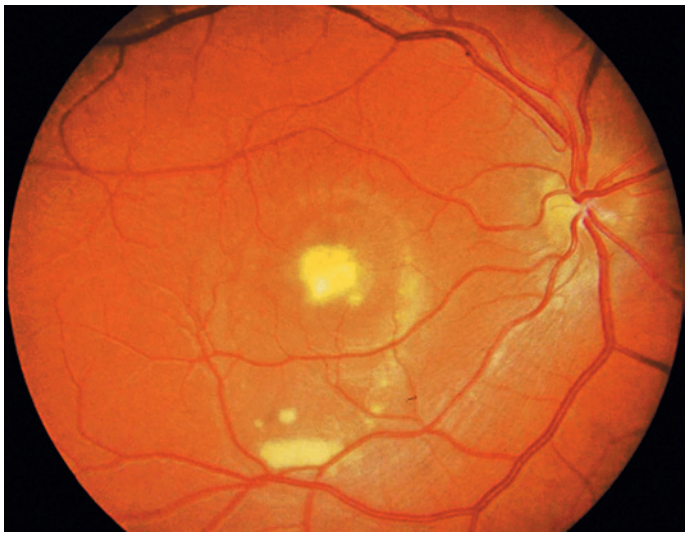

Fig. 48.7 Best disease. A partially resorbed yellow subretinal macular deposit (stage IIa).

the macular deposits appear hypofluorescent secondary to blockade of underlying choroidal fluorescence. The macular deposits represent the accumulation of lipofuscin in RPE cells and within the sub-RPE space, seen histopathologically. However, the RPE accumulation is not restricted to the macular region.

The macular changes are often associated with good vision, although a slowly progressive loss of central vision may occur with atrophic macular changes. The age at presentation is between the second to fifth decades: it is rarely symptomatic in childhood. Examination of at-risk young family members may show mild macular changes.

Three main pattern dystrophy phenotypes have been described: butterfly-shaped dystrophy, reticular dystrophy, and fundus pulverulentus:

Butterfly-shaped dystrophy is inherited as an autosomal dominant trait, first evident in late childhood, characterized by normal or mildly reduced visual acuity, and normal color vision, peripheral visual fields, and dark adaptation.

Reticular dystrophy is inherited as an autosomal dominant or recessive trait, first appearing in early childhood. First, there is an accumulation of pigment granules at the fovea; later a typical reticular pattern extends to the periphery. Visual acuity is usually normal.

Fundus pulverulentus is a rare non-progressive disorder characterized by normal visual acuity and a symmetrical granular mottled pigmentation at the posterior pole (Fig. 48.10).

Electrophysiology

Usually, the pattern ERG and the EOG are abnormal, with variable full-field ERG ranging from normal to generalized cone and rod system dysfunction, suggesting widespread RPE–photoreceptor dysfunction.

Molecular genetics and pathogenesis

Mutations in the gene *PRPH2* (previously *peripherin/RDS*) have been described. Further genes remain to be identified.

The *PRPH2* gene was identified in mice with a photoreceptor degeneration known as "retinal degeneration, slow" (rds). Subsequently, the orthologous human *PRPH2* gene was shown to cause autosomal dominant RP. Mutation in codon 172 of *PRPH2* has been implicated in autosomal dominant macular dystrophy. Weleber et al. described a 3-bp deletion in *PRPH2* that resulted in retinitis pigmentosa, pattern dystrophy, and FFM in different individuals.[9]

The PRPH2 protein is a membrane-associated glycoprotein restricted to photoreceptor outer segment discs in a complex with ROM1. It may function as an adhesion molecule involved in the stabilization and maintenance of a compact arrangement of outer segment discs. It interacts with the GARP domain (glutamic acid- and proline-rich region) of the beta-subunit of rod cyclic guanosine monophosphate (cGMP)-gated channels, in a complex including the Na^+/Ca^{2+}–K^+ exchanger. This interaction may anchor the channel–exchanger complex in the rod outer segment plasma membrane. The rds mouse (homozygous for a null mutation in *PRPH2*) fails to develop photoreceptor discs and outer segments with downregulation of rod opsin expression, resulting in apoptotic loss of photoreceptor cells. Subretinal injection of recombinant adeno-associated virus encoding a *PRPH2* transgene in these mice resulted in the generation of outer segment structures and formation of new stacks of discs containing both PRPH2 and rhodopsin with electrophysiological function preserved.[10] Ultrastructural improvement depended on the age at treatment, but a single injection may be longlasting. Thus, gene therapy in patients with photoreceptor defects may need early intervention and accurate control of transgene expression.

North Carolina macular dystrophy

Clinical and histological findings

North Carolina macular dystrophy (MCDR1) is a non-progressive autosomal dominant disorder with complete penetrance and a variable macular phenotype. Presentation is usually during the first or second decade. The disorder is a failure of normal macular development.[11] Bilaterally symmetrical fundus appearances in MCDR1 range from a few small (less than 50 μm) yellow drusen-like lesions in the central macula (grade 1) (Fig. 48.11) to larger confluent lesions (grade 2), and well-demarcated macular chorioretinal atrophy (grade 3) (Fig. 48.12). Peripheral retinal drusen-like deposits have been described. The severity of visual loss is grade dependent; vision is poorest with grade 3 lesions. Color vision is usually normal. Occasionally MCDR1 is complicated by choroidal neovascular membrane formation (CNVM).

Histopathology shows accumulation of lipofuscin in the RPE within the atrophic macular lesion.

Electrophysiology

EOG and ERG are normal.

Molecular genetics and pathogenesis

MCDR1 is linked to a locus on chromosome 6q16, but the causative gene has yet to identified.[11] The identification of the gene may improve our understanding of macular development in man.

A dominantly inherited macular dystrophy has been mapped to chromosome 6q14, adjacent to but probably distinct from

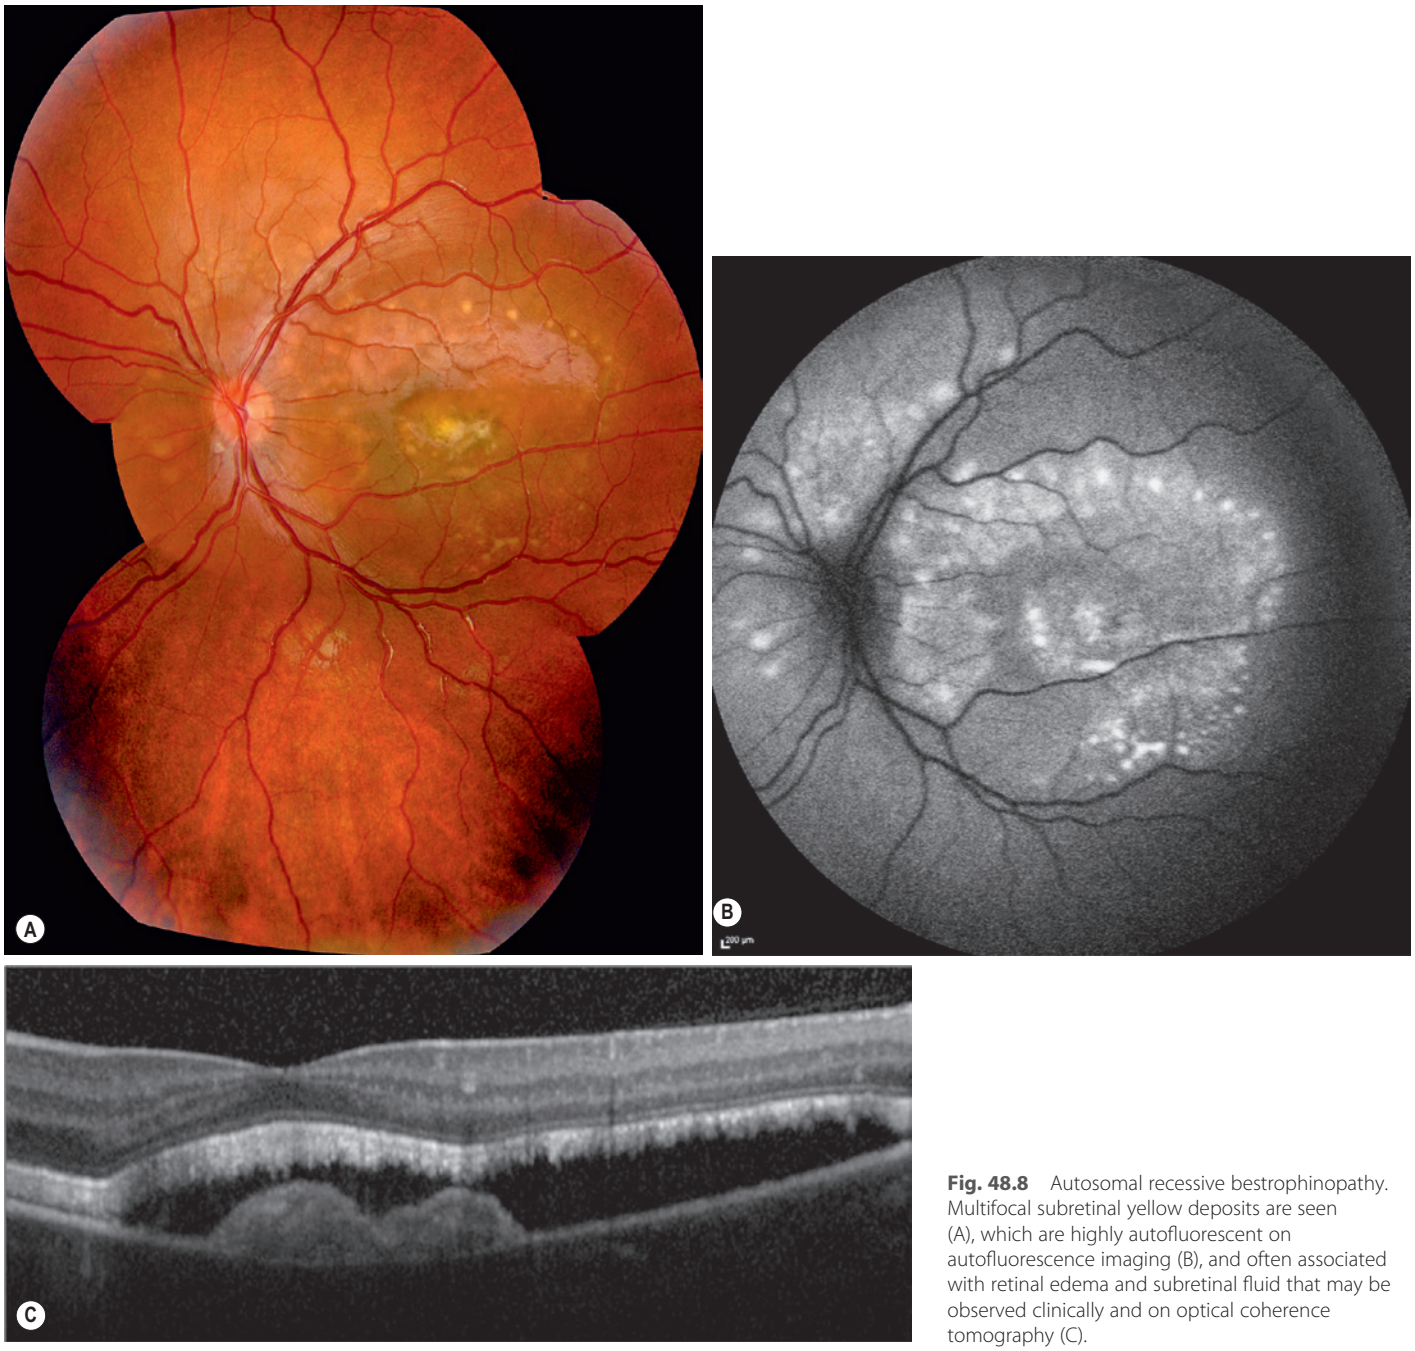

Fig. 48.8 Autosomal recessive bestrophinopathy. Multifocal subretinal yellow deposits are seen (A), which are highly autofluorescent on autofluorescence imaging (B), and often associated with retinal edema and subretinal fluid that may be observed clinically and on optical coherence tomography (C).

the MCDR1 locus.[12] It has a highly variable phenotype; an autosomal dominant drusen disorder with macular degeneration (DD). A study by Griesinger et al. showed that most young adults had fine macular drusen and good vision.[12] Patients who were symptomatic from infancy or early childhood had poorer vision with an atrophic maculopathy and drusen. There was also evidence of progression in late adulthood. The DD disease interval overlaps with that of STGD3 and an autosomal dominant atrophic macular degeneration (adMD),[13] suggesting an allelic disorder. However, the phenotype of DD differs from that of STGD3 and adMD. Macular drusen are a hallmark of DD, whilst RPE atrophy and subretinal flecks are prominent features of STGD3 and adMD.

North Carolina macular dystrophy-like phenotypes

Three North Carolina macular dystrophy-like phenotypes map to different genetic loci than MCDR1, suggesting further genetic heterogeneity in the MCDR1 phenotype.[11]

Autosomal dominant macular dystrophy (MCDR3) resembling North Carolina macular dystrophy

Clinical and electrophysiological findings

A pedigree has been described with an early-onset autosomal dominant macular dystrophy (MCDR3).[14] Visual acuity ranged from 6/5 to 6/60. The retinal changes, confined to

Fig. 48.9 Pattern dystrophy.

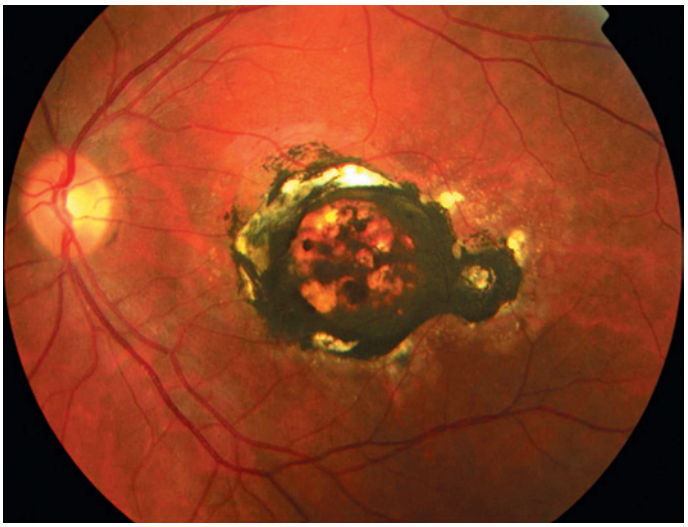

Fig. 48.12 North Carolina macular dystrophy (MCDR1). Macular atrophy and hyperpigmentation with surrounding drusen-like deposits (grade 3).

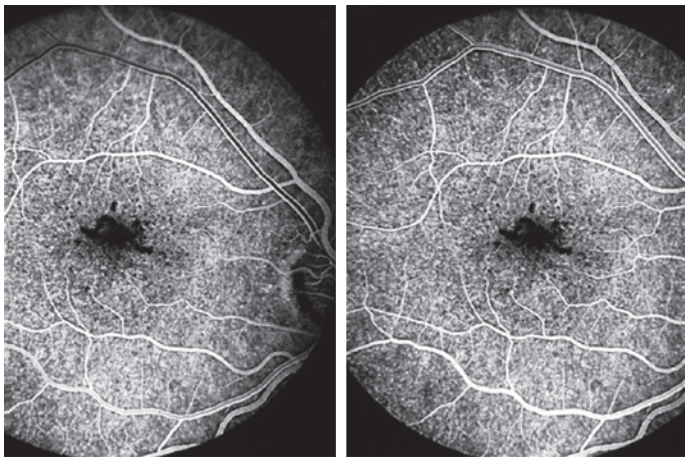

Fig. 48.10 Fundus pulverulentus. Fluorescein angiogram showing mottled and clumped pigment epithelium at the posterior pole. *(Courtesy of Professor A.C. Bird.)*

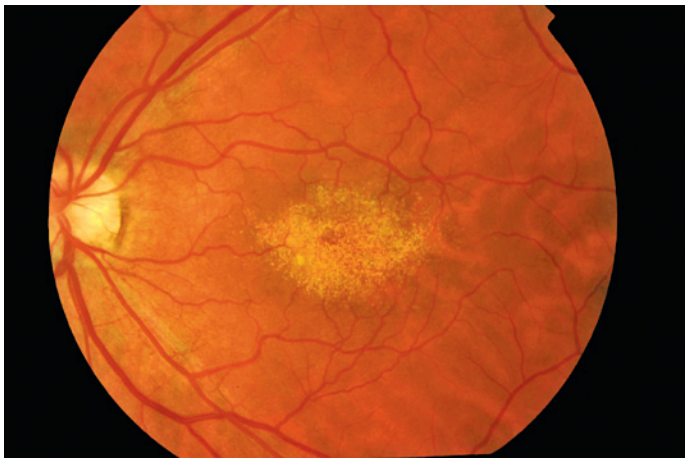

Fig. 48.11 North Carolina macular dystrophy (MCDR1). Small yellow drusen-like lesions at the central macula (grade 1).

the macular region, varied from mild RPE pigmentary change to atrophy. Drusen-like deposits were present to varying degrees and were characteristic of the phenotype (Fig. 48.13). Choroidal neovascular membrane formation is an uncommon complication. The only significant differences between this phenotype and MCDR1 is that in MCDR3 color vision is abnormal in the majority of affected individuals and there was evidence of disease progression in a single case.

A phenotype similar to MCDR3 mapping to the same locus has been reported.[15]

Molecular genetics

Linkage to chromosome 5p13.1–p15.33, but excluding the MCDR1 locus,[14,15] has been reported. The gene is unidentified.

North Carolina-like macular dystrophy and progressive sensorineural hearing loss

Clinical and electrophysiological findings

A non-progressive MCDR1-like macular dystrophy in association with progressive sensorineural hearing loss has been reported (MCDR4).[16] Visual acuity ranged from 6/9 to hand movements. The EOG and full-field ERG were normal. Progressive sensorineural deafness was present in all adult-affected individuals.

Molecular genetics

Genotyping excluded linkage to the MCDR1 locus and established linkage to chromosome 14q.

North Carolina-like macular dystrophy and digital anomalies (Sorsby syndrome)

Clinical findings

A dominantly inherited condition with bilateral macular dysplasia and apical dystrophy or brachydactyly has been reported (Fig. 48.14).[17,18] Visual acuity ranged from 6/12 to 4/60. The maculopathy was non-progressive and variable in severity, ranging from mild RPE pigmentary changes to excavated chorioretinal atrophic lesions. There was no generalized retinal dysfunction.

Molecular genetics

The MCDR1, MCDR3, and MCDR4 loci have all been excluded, providing evidence of further genetic heterogeneity associated with the North Carolina macular dystrophy-like phenotype.[11,19] This is in keeping with the established heterogeneity in the genetic mechanisms underlying split-hand and split-foot malformations (microdeletions being common) and the developmental macular dystrophies.

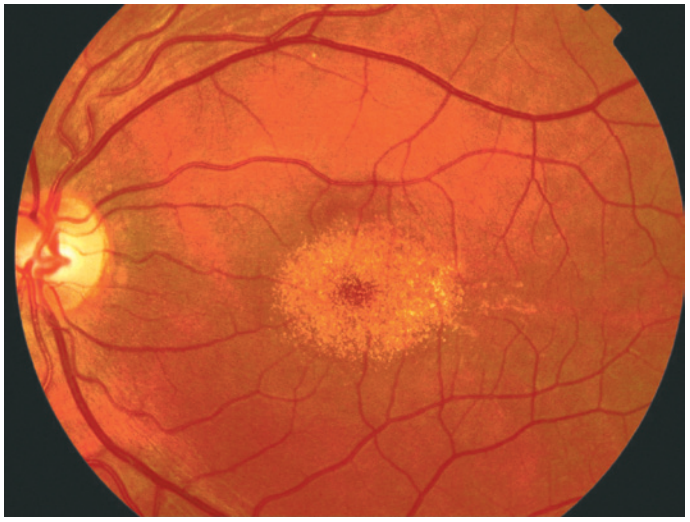

Fig. 48.13 Autosomal dominant macular dystrophy (MCDR3) resembling North Carolina macular dystrophy. Characteristic drusen-like deposits at the macula.

Progressive bifocal chorioretinal atrophy

Clinical findings

Progressive bifocal chorioretinal atrophy (PBCRA) is an early-onset autosomal dominant disorder characterized by infantile onset nystagmus, myopia, poor vision, and slow progression.[20] A large atrophic macular lesion and nasal subretinal deposits present soon after birth. An atrophic area nasal to the optic disc appears in the second decade and enlarges progressively (Fig. 48.15). Marked photopsia in early/middle age and retinal detachment extending from the posterior pole are complications. FFA and indocyanine green angiography (IGA) demonstrate a large circumscribed area of macular choroidal atrophy with staining of deposits in the peripheral retina.

Electrophysiology

Unlike MCDR1, both ERG and EOG are abnormal, reflecting widespread abnormality of photoreceptors and RPE.

Molecular genetics and pathogenesis

PBCRA has been linked to 6q14–q16.2; the disease locus overlaps with the established MCDR1 interval. These two

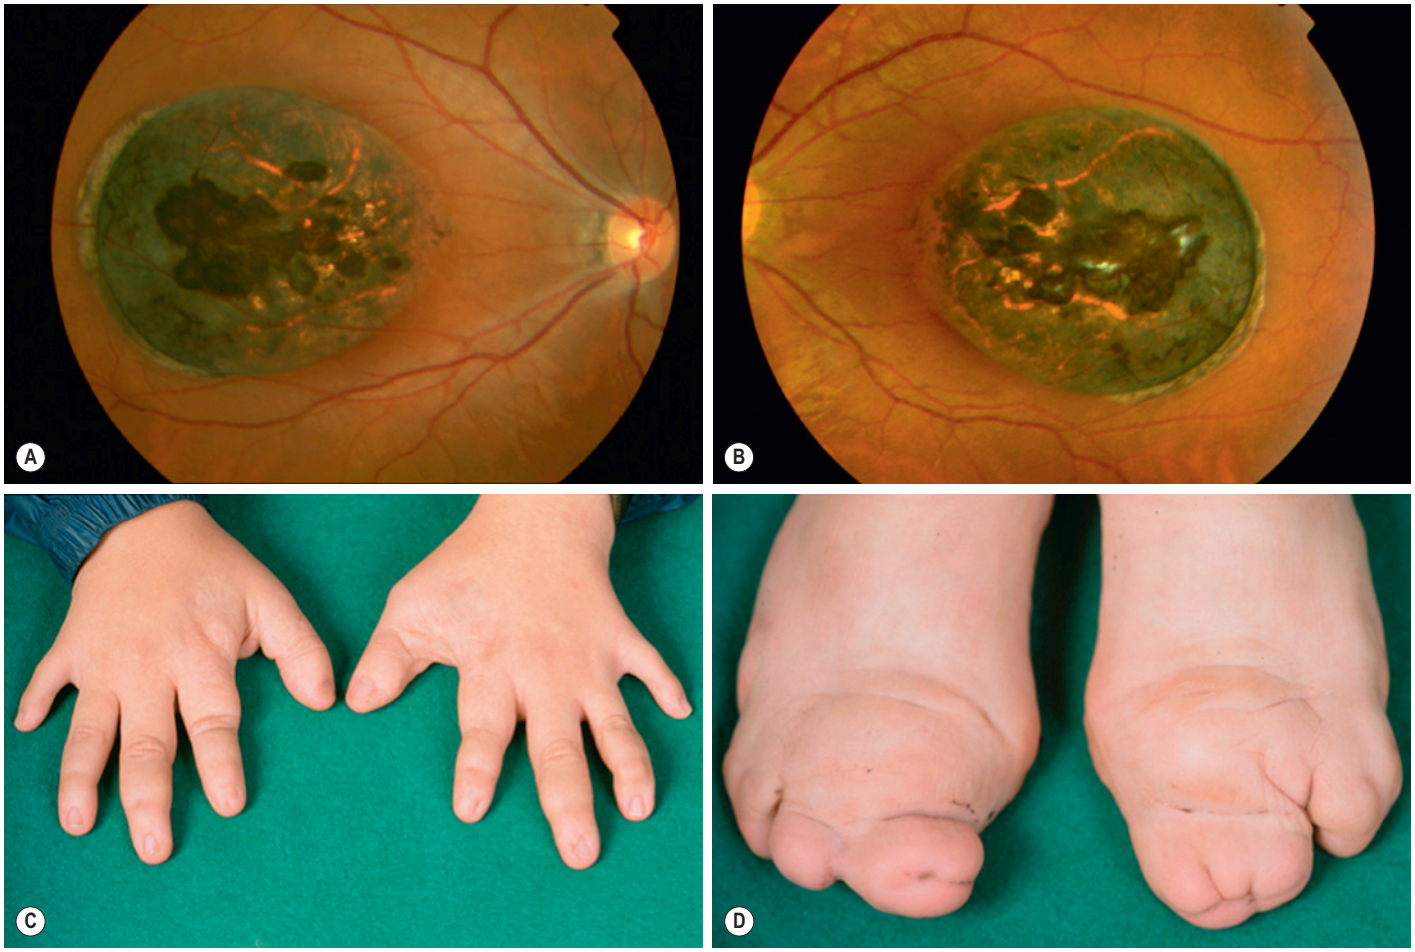

Fig. 48.14 North Carolina-like macular dystrophy and digital anomalies (Sorsby syndrome). (A,B) Color fundus photographs showing the typical bilateral macular dysplasia. (C,D) In this individual there is shortening and deformity of the fingers and toes due to aplasia and hypoplasia of middle and terminal phalanges. There is skin syndactyly in association with bifurcation of the terminal phalanx of the hallux causing severe deformity of the foot.

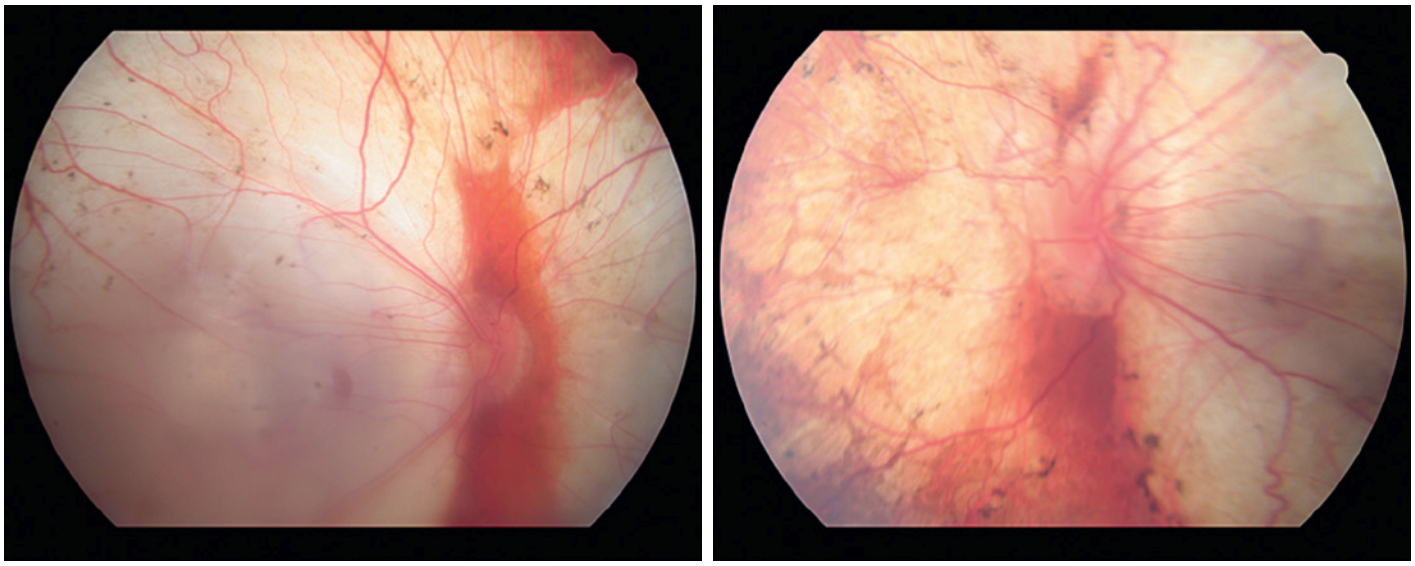

Fig. 48.15 Progressive bifocal chorioretinal atrophy. Color fundus photographs showing bilateral extensive macular atrophy and atrophy nasal to the optic nerve head.

autosomal dominant macular dystrophies have some phenotypic similarities; both result from a failure of normal macular development.[11] PBCRA differs significantly from MCDR1 in several important respects, including slow progression, abnormal color vision, extensive nasal as well as macular atrophy, and abnormal ERG and EOG. If allelic, it is likely that different mutations are involved in their etiology. An alternative explanation is that PBCRA and MCDR1 are caused by mutations in two different adjacent developmental genes.

Central areolar choroidal dystrophy

Clinical and histological findings

Central areolar choroidal dystrophy (CACD) is characterized by bilateral, symmetrical, subtle mottling of the RPE at the macula in the second decade, which progresses to atrophy of the RPE and choriocapillaris. The round or oval macular lesion is well demarcated. CACD has been divided into four stages[21]:

stage I: slight parafoveal changes of the RPE;

stage II: RPE mottling encircling the fovea;

stage III: additional atrophy of the choriocapillaris without central involvement;

stage IV: stage III plus central involvement.

Color vision is abnormal and central scotomata are present with normal peripheral visual fields. FFA and IGA reveal RPE atrophy and various degrees of choriocapillaris loss.

Electrophysiology

Full-field ERGs are normal in the early stages, but may become abnormal in advanced stages.

Molecular genetics and pathogenesis

A p.Arg142Trp mutation in *PRPH2* has been implicated as one cause of this rare autosomal dominant macular dystrophy. Sporadic cases of CACD have been described but no mutations have been found in *PRPH2* suggestive of further genetic heterogeneity. A locus at 17p13 has also been identified, with a novel mutation in *GUCY2D* reported.

X-linked inheritance

X-linked juvenile retinoschisis (XLRS)

See Chapter 51.

Foveal hypoplasia

Clinical findings

This presents in infancy with reduced vision, nystagmus, and a poorly developed fovea; there is no recognized foveal pit or luteal pigment, and blood vessels may cross the presumed foveal region. These changes can be demonstrated using OCT and AF imaging (Fig. 48.16). Foveal hypoplasia may be an isolated abnormality or associated with aniridia or albinism (see Chapter 41).

Molecular genetics

Isolated foveal hypoplasia is most commonly sporadic, but two dominant pedigrees have been reported, with a *PAX6* missense mutation identified in one of these families.[21,22] The mutation occurred in the C-terminal part of the paired domain.[21] However, *PAX6* has been screened in some reported isolated cases, with no mutations identified.[23] Autosomal recessive forms of foveal hypoplasia are also seen and recently mutations in a glutamine transporter gene *SLC38A8* have been reported in a rare recessive disorder with foveal hypoplasia associated with chiasmal misrouting.[24]

Bull's eye maculopathy

The term "Bull's eye" maculopathy (BEM) first described the characteristic appearance of chloroquine retinopathy. Bull's eye lesions have since been reported in cone dystrophy, cone–rod dystrophy, rod–cone dystrophy, *ABCA4*-retinopathy and in

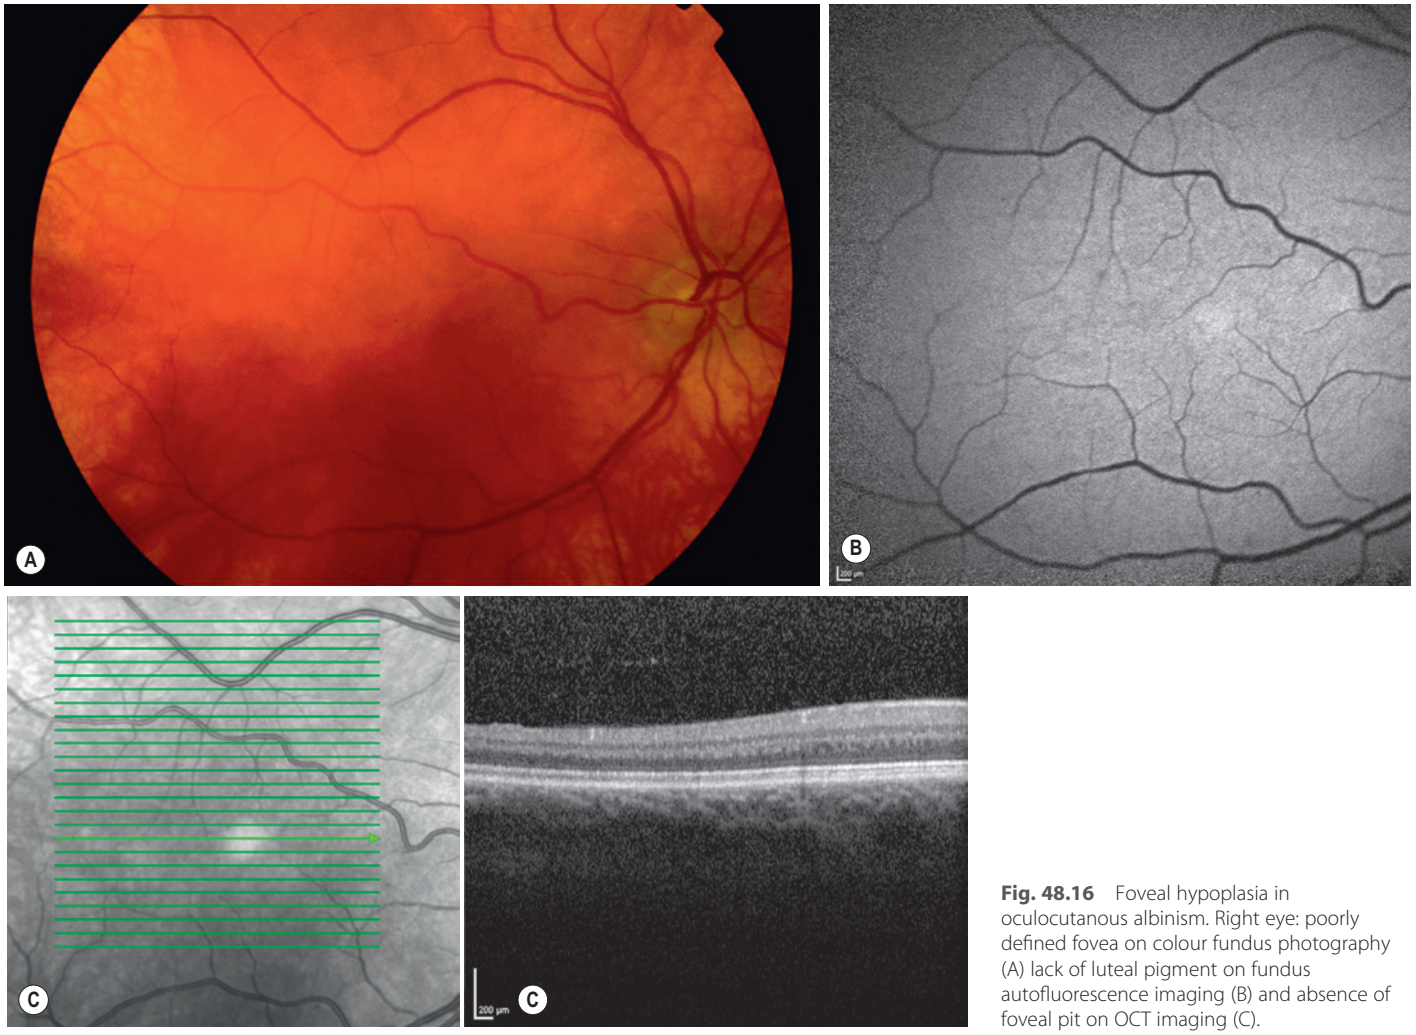

Fig. 48.16 Foveal hypoplasia in oculocutanous albinism. Right eye: poorly defined fovea on colour fundus photography (A) lack of luteal pigment on fundus autofluorescence imaging (B) and absence of foveal pit on OCT imaging (C).

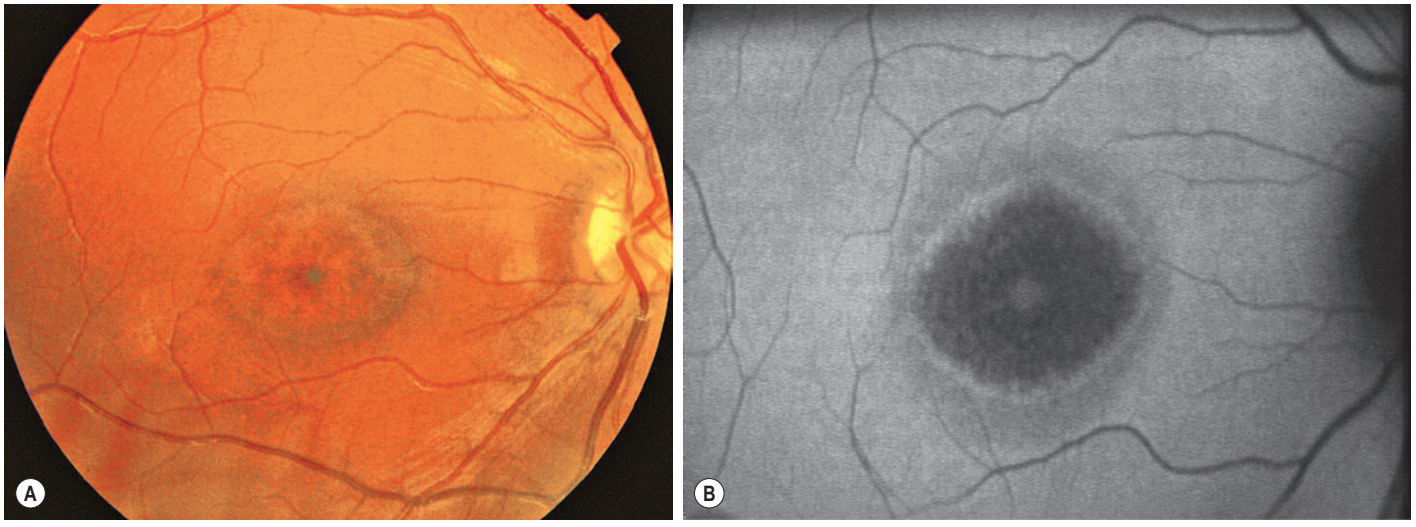

Fig. 48.17 Bull's eye maculopathy (BEM). (A) Characteristic ophthalmoscopic appearance in which there is annular retinal pigment epithelium atrophy and central sparing. (B) Typical autofluorescence image of BEM.

some dominantly inherited macular dystrophies, including benign concentric annular dystrophy, fenestrated sheen macular dystrophy and in association with the p.Arg373Cys *PROM1* variant.[5,25] BEM is a frequent finding in neurodegenerative disorders, especially Batten disease, Hallervorden–Spatz disease, and olivopontocerebellar atrophy (see Chapters 47 and 65).

The pathogenesis of BEM is poorly understood. The annular RPE atrophy and central sparing may correspond to the pattern of lipofuscin accumulation in the RPE, which in healthy individuals is highest at the posterior pole and shows a depression at the fovea (Fig. 48.17). The initially spared center usually becomes involved as the disease advances. BEM is not a discrete macular disorder but describes a retinal phenotype that may be seen in a wide variety of macular dystrophies at an early stage of their evolution.

Conclusions

The inherited macular dystrophies are clinically and genetically heterogeneous with well-characterized phenotypes; many causative genes have been identified. Although in some inherited macular dystrophies the disease is confined to the macula, in the majority there is electrophysiological, psychophysical or histological evidence of widespread retinal dysfunction.

There is no established treatment, but treatment trials have begun for STGD; others are anticipated over the next decade. Making the correct diagnosis is important in order to provide accurate information on prognosis and to offer informed genetic counseling. Prenatal and preimplantation diagnosis is possible when the mutation(s) causing disease in the family is known.

Although there is no specific treatment available for these disorders, research is resulting in clinical trials. We are cautiously optimistic that effective interventions will be available in the near future. The provision of best refractive correction, appropriate low vision aids and educational support is very important. Photophobia may be prominent and tinted spectacles or contact lenses and a sunhat may improve comfort and vision.

Congenital hypertrophy of the retinal pigment epithelium (CHRPE)

- Flat or slightly raised, round or oval, pigmented lesions of the retinal pigment epithelium (RPE).
- Located predominantly at the mid-periphery; less commonly at the posterior pole (Fig. 49.1).
- Pigmented and non-pigmented halo surround lesions.
- Multiple intralesional depigmented lacunae corresponding to areas of RPE loss.[1]
- Depigmented CHRPEs are less common.
- Intensely pigmented RPE cells that are 1.5–2 times the height of normal RPE cells.[2]

Investigations

- Optical coherence tomography (OCT): photoreceptors and outer retinal layers absent directly overlying the lesion.[2,3]
- Autofluorescence (AF): absence of autofluorescence within the lesion is consistent with a lack of lipofuscin with punctuated areas of isoautofluorescence within the lesion.[4]
- Fluorescein angiography (FFA): demonstrates choroidal masking.[4]

Prevalence

CHRPE has a prevalence of between 1.2% and 4.4% in the general population.[5,6] Age at presentation ranges from infancy to 80 years.

Associations

- Vessel sheathing, attenuation, and microangiopathy.
- Crusen.
- Adjacent white-without-pressure and depigmented linear RPE streaks.

Eighty-three percent of lesions enlarged at a median rate of 2 µm per millimeter lesion base per month due to flattening and shifting of cells to accommodate normal attrition of the surrounding RPE.[2]

In adults, 1.5% of lesions may contain a nodular component associated with remote macular edema or malignant transformation within lesions.[7,8]

CHRPE associated with adenomatosis polyposis of the colon (APC)

Multiple (more than three) bilateral, mixed pigmented and depigmented CHRPE are a highly specific and sensitive marker of adenomatous polyposis of the colon (APC) or familial adenomatous polyposis (FAP) and are highly penetrant. APC-associated CHRPEs are:

- Ovoid, pisciform or irregular in shape, surrounded by a pale-gray halo or adjacent depigmented linear streaks (Fig. 49.2).
- Variable sizes and location, from dot-like lesions to multiple disc diameters[9].
- Present at birth and do not grow throughout life.

Diffuse abnormalities of the RPE are also present, including enlargement of RPE cells outside the lesional area containing

Fig. 49.1 Congenital hypertrophy of the retinal pigment epithelium (CHRPE). Slightly raised jet-black lesion in the mid-periphery with an associated small visual field defect. *(Professor A.C. Bird's patient.)*

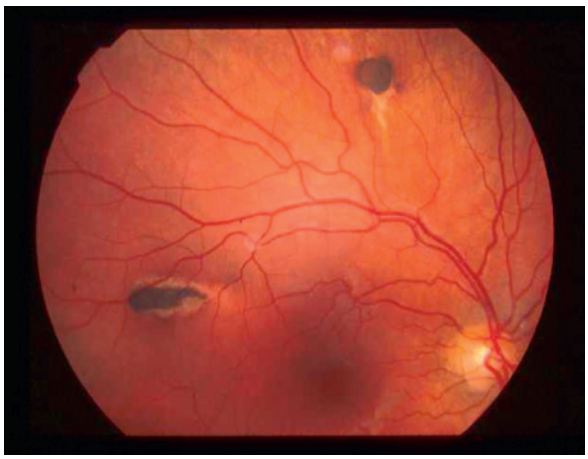

Fig. 49.2 CHRPE lesions in a patient with familial adenomatous polyposis.

enlarged, round melanin granules rather than the smaller, oval granules associated with normal RPE.[10]

Genetics of APC

- Autosomal dominant (AD) with an incidence of 1 in 8300.
- Accounts for ~1% of all colorectal cancers.[11]
- Associated with mutations of APC gene and cause:
  - Gardner syndrome – APC with extra-colonic manifestations such as osteoma and desmoid tumors (10%).
  - Turcot syndrome APC with primary brain medulloblastoma.
  - Also found in APC families without such extra-colonic manifestations.[11]
- APC gene:
  - A tumor suppressor gene on chromosome 5q21-22.[12] CHRPEs suggest the presence of a mutation between codons 148 and 2043.

Multiple adenomatous colorectal polyps (>100) appear between the second and fourth decades.[13] Malignant transformation is seen in over 90% by age 50 years. Colonoscopy is recommended from 12 years and may lead to elective colectomy. Polyps may exist in the upper gastrointestinal (GI) tract including stomach, small bowel, and duodenum, the latter being associated with a significant risk of malignant transformation. Mandibular osteomas and dental anomalies such as missing or supernumerary teeth are also common.

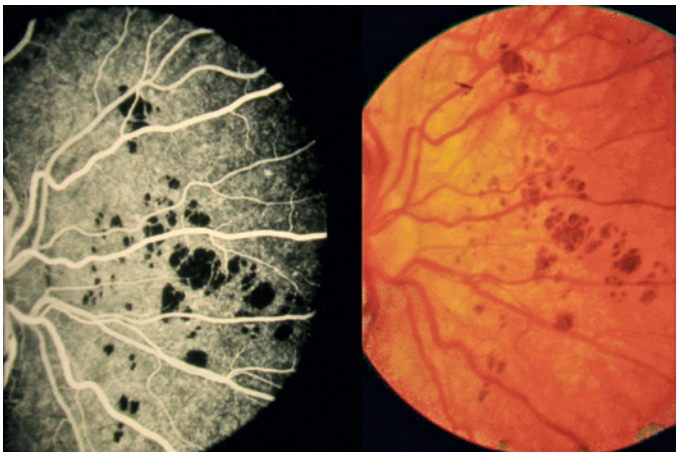

Fig. 49.3 Congenital grouped pigmentation ("bear track"). Unilateral, multiple brown patches in the retinal pigment epithelium of no functional significance. Fluorescein angiography shows masking of the underlying choroidal fluorescence. *(Professor A.C. Bird's patient.)*

Congenital grouped pigmentation of the RPE

- Small, darkly pigmented, flat, circumscribed lesions at the level of the RPE (also known as "bear tracks").
- Increasing in size as they approach the retinal periphery (Fig. 49.3).
- Unilateral and sectorial. Occasionally involving the entire fundus.[14]
- Normal visual function.
- Depigmented variant, "polar bear tracks."[15]
- Pigmented and depigmented lesions may co-exist within the same patient.[16]

Prevalence

The prevalence is 0.12% in the ophthalmic clinic population.[17]

Associations

Usually isolated but possible chance associations include:

- Retinoblastoma.
- Café-au-lait spots and hairy nevus.
- Persistent fetal vasculature.
- Microcephaly.
- Rieger anomaly.
- Macular coloboma.

Congenital simple hamartoma of the retina (CSHRPE)

- Rare, located within the macula region close to the fovea.
- Circumscribed, nodular, and heavily pigmented.

- Arise from RPE, project through the full thickness of the retina into vitreous.
- A feeder arteriole and venule are usually present.
- Subtle surrounding retinal traction may reduce visual acuity.

Investigations

- Ultrasound: nodular, echogenic mass with moderate-to-high internal reflectivity.
- Fluorescein angiography: demonstrates a non-fluorescent lesion with a variable surrounding ring of late hyperfluorescence.[18]
- Indocyanin green angiography: completely blocks choroidal fluorescence.
- OCT: elevation of the inner retina with enhanced reflectivity of its vitreal face and marked optical shadowing at the level of the outer retina and choroid, with normal retina immediately adjacent to lesion.[19,20]

The lesions are congenital, stable, and asymptomatic but can show adjacent intraretinal hemorrhage and exudation.[18]

Torpedo maculopathy

- An ovoid, sharply defined, non-pigmented lesion in the temporal region of the macula, centered on the horizontal raphé (see Fig. 49.3).
- Lesions are longer horizontally (2–3 mm) than vertically (1 mm) and point toward the fovea with either a frayed, pigmented tail or rounded margin located temporally (Fig. 49.4).
- Usually unilateral and unifocal, although satellite lesions have been described.
- The margins have a hyperpigmented border.

Investigations

- OCT: absence of RPE, overlying outer retinal disorganization and thinning, irregular, and degenerate photoreceptor outer segments, interruption of the ellipsoid layer, and clefting corresponding to a loss of the RPE and outer retinal layers.[21,22]
- Autofluorescence: variable hypoautofluorescence with most showing greatest absence in the temporal aspect of the lesion, confirming either non-functional or absent RPE.[23]

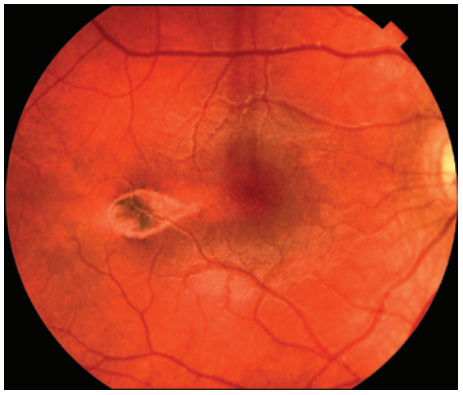

Fig. 49.4 "Torpedo" maculopathy. Sharply defined, non-pigmented lesion in the temporal region of the macula with a characteristic point aimed toward the fovea.

The fovea usually retains normal architecture preserving normal visual acuity but cases have been described with foveal involvement.[24]

Prevalence

A rare congenital abnormality and unknown prevalence.

Associations

Usually isolated but can co-exist with kidney disease, blepharophimosis, situs inversus, ipsilateral choroidal nevus, and ametropia.

Retinal astrocytic hamartoma (RAH)

- Benign glial tumors of the retinal nerve fiber layer.
- Present in 44% of patients with tuberous sclerosis (TSC).[25]
- Less frequently associated with neurofibromatosis.
- Flat or slightly elevated, semi-translucent or opaque lesions (type 1) with poorly defined borders within the nerve fiber layer, 0.5–5 mm in diameter.
- Occasionally nodular lesions (type 2), "mulberry tumors," containing calcospherites, which autofluoresce. Can be confused with retinoblastoma, although RAH is present in older children.[26] Rarely, lesions progress from a flat to a nodular appearance.

Investigations

- OCT: tumors originate from the nerve fiber layer as a thickened, hyperreflective mass with intact outer retinal layers and RPE.[27,28] Calcium-containing lesions have a "moth-eaten," cavitated appearance.

Acquired RAH are more aggressive, resulting in retinal exudation, vitreous hemorrhage, retinal detachment, retinochoroiditis, neovascular glaucoma, vitreous seeding,[29] and even globe perforation.[30] They are typically isolated and located at the posterior pole. Multiple RAH associated with systemic disease appear at both the posterior pole and peripheral retina.

Histopathology

Astrocytomas contain elongated fibrous astrocytes with interlacing cytoplasmic processes. Aggressive tumors are composed of larger, plump pleomorphic cells with abundant eosinophilic cytoplasm.[30]

Genetics

TSC is a disease associated with two tumor suppressor genes: hamartin (*TSC1*) and tuberin (*TSC2*), which control cell growth and survival via the mTOR signaling pathway.[31]

Management

TSC-associated RAH can be observed. Aggressive lesions associated with retinal neovascularization, vitreous hemorrhage, or macular edema have been treated with systemic or intravitreal bevacizumab, alone or in combination with vitrectomy or intravitreal triamcinolone.[32,33] More recently, inhibition of the

mTOR pathway using sirolimus to shrink retinal astrocytoma has been considered.[34]

Retinal capillary hemangioblastoma (RCH)

- Circumscribed, orange-red, round vascular tumors with a prominent feeding and draining vessel.
- Sporadic, usually unilateral and unifocal.
- RCH are frequently associated with von Hippel–Lindau syndrome (VHL), a multisystem, autosomal dominant, familial cancer-predisposition syndrome.
- VHL RCHs are more likely to be bilateral and multifocal.[35]

Investigations

- Fluorescein angiography: shows early hyperfluorescence with late leakage, identifies and distinguishes feeder vessels from draining venules, and highlights small peripheral RCHs.[36]
- Ultrasound: b-scan is used to measure basal dimension/vertical height as well as detecting subretinal fluid. Lesions have medium-to-high internal reflectivity.[37]
- OCT: used to monitor response to treatment.[38]

Most (85–90%) RCHs are located in the peripheral retina, anterior to the equator in the superior temporal quadrant followed, in order of frequency, by the superior-nasal, inferior-temporal then inferior-nasal quadrants.[39] They gradually increase in size with glial proliferation on their surface, with resulting tractional changes. Visual loss occurs through chronic leakage and exudation, leading to cystoid macular edema and exudative and tractional retinal detachment.[40] Neovascular glaucoma or cataract occurs less commonly.

Between 10% and 15% of lesions are found in the juxtapapillary region with sessile, endophytic (most common), or exophytic growth patterns.[41] They remain stable for prolonged periods. Many advocate observational management unless the macula becomes involved.[41]

Genetics

- VHL is autosomal dominant. Approximately 20% of VHL patients have no family history.
- Estimated prevalence of 1 in 39,000–53,000.
- The gene, located on the short arm of chromosome 3, encodes two proteins that regulate the degradation of α-subunits of hypoxia-inducible factors, HIF-1α and HIF-2α.[42]
- VHL is diagnosed in the presence of a positive family history or two typical tumors.
- Viscera affected include pancreas, kidney, liver, adrenal glands, inner ear, and epididymis.
- Typical lesions include central nervous sytem hemangioblastomas, multiple abdominal organ cysts, renal clear cell carcinoma, and phaeochromocytoma.

In VHL, hemangioblastomas occur in 45–60% of affected individuals, starting around the age of 4 years, and the probability increases with age. They begin to cause visual symptoms by the beginning of the second decade. Annual screening is recommended from 10 years. All RCHs will have appeared by the age of 30 years, so adults with normal retinal examination by this age are unlikely to develop RCH for the remainder of their life.[40,43]

Management

Severe visual loss may be seen in up to 25% of cases of RCH.[40] Prognosis may be worse with larger tumors or worse presenting visual acuity.[44] Treatment for RCH includes laser photocoagulation, photodynamic therapy (PDT), transpupillary thermotherapy (TTT), cryotherapy, plaque radiotherapy/brachytherapy, trans-scleral penetrating diathermy, vitreoretinal surgery, and systemic or intravitreal bevacizumab.

For small (<1.5 mm in diameter), posteriorly located lesions, laser photocoagulation applied directly to the RCH and to the feeder vessels has been shown to be highly effective.[45] Anterior lesions and those with subretinal fluid (SRF) may be best treated with cryotherapy.[45] PDT has been used in both peripheral and juxtapapillary RCHs.[46] PDT shows a relatively better outcome in juxtapapillary RCHs but may be associated with worsening of epiretinal membranes (ERMs).[46] Larger tumors are less responsive due to lack of penetration,[47] but TTT has deeper penetration.[44]

Anti-vascular endothelial growth factor (anti-VEGF) treatments given systemically or as intravitreal injection have mixed results, with some evidence of a transient reduction in retinal edema but no significant reduction in tumor size or new tumor development.[48,49] Combined anti-VEGF therapy, PDT, and/or vitreoretinal surgery has demonstrated some benefit, although not complication free.[50,51] Therapeutically targeting overexpression of HIF-2α may be a better alternative strategy.[52]

Retinal cavernous hemangioma

- A rare congenital vascular hamartoma of the retina.
- Usually sporadic, unilateral, and unifocal and are present within the inner retina.
- Occasional autosomal dominant inheritance with incomplete penetrance associated with intracranial and cutaneous cavernous hemangiomas.[53]
- Appear as a cluster of saccular aneurysms following the course of a retinal vein, frequently located in the mid-peripheral retina, but occasionally at the macula, optic disc, and peripapilllary area (Fig. 49.5).

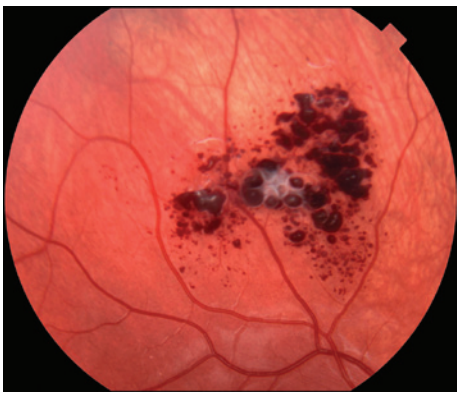

Fig. 49.5 Cavernous hemangioma of the retina showing the "grape-like" clusters of saccular aneurysms.

Visual loss occurs due to recurrent vitreous hemorrhage or macula involvement. Those located at the optic disc may cause nerve fiber compression.[54] Fluorescein angiography demonstrates delayed filling with hyperfluorescent capping of the saccules. Swept-source OCT demonstrates the intraretinal location of the saccular aneurysms.[55] No leakage or exudation occurs and vessel composition is identical to that of normal retinal vessels.[56]

Genetics

It is recommended to examine first-degree relatives. The co-existence of retinal cavernous hemangioma with cerebral cavernous malformations (CCM) may be associated with mutations of the *KRIT1* (CCM1), *MGC4607* (CCM2), and *PDCD10* (CCM3) involved in the regulation of endothelial cell morphogenesis, and blood vessel stability.[57]

Management

Mostly observational; neuroimaging is recommended where there is a positive family history of cavernous hemangiomas, associated cutaneous cavernous hemangiomas or multiple or bilateral retinal cavernous hemangioma or choroidal cavernous hemangiomas.[58] Lesions are non-progressive and frequently have an overlying pre-retinal glial membrane. Pre-retinal membrane traction may cause spontaneous vitreous hemorrhage[59] that may require vitrectomy. Occasionally, photocoagulation and cryotherapy have been used to treat these lesions and, recently, regression with intravenous infliximab has been reported.[60]

Combined hamartoma of the retina and retinal pigment epithelium (CHRRPE)

- Rare, benign, solitary lesions.
- Usually unilateral, but bilateral cases are described.
- Located at the posterior pole in the peripapillary or macular region or in the peripheral retina.[61]
- Likely to be congenital; cases described in infants as young as 2 weeks of age.[62]
- Mostly non-progressive.
- A small proportion of affected individuals may be asymptomatic; the majority present with reduced vision, metamorphopsia, or strabismus, particularly if there is macular involvement.[62]

Lesions are elevated with variable pigmentation (Fig. 49.6). Retinal vascular tortuosity and an overlying epiretinal membrane are typical. Lesions have been classified as melanocytic, vascular, or glial. Glial subtypes, associated with epiretinal membrane (ERM), are associated with progressive retinal traction resulting in visual loss. These may be most amenable to surgery.[63]

Investigations

- Fluorescein angiography: hypofluorescence of background choroid during arterial phase, underlying retinal vascular tortuosity, capillary dilation within the lesion, and intralesional vascular leakage.

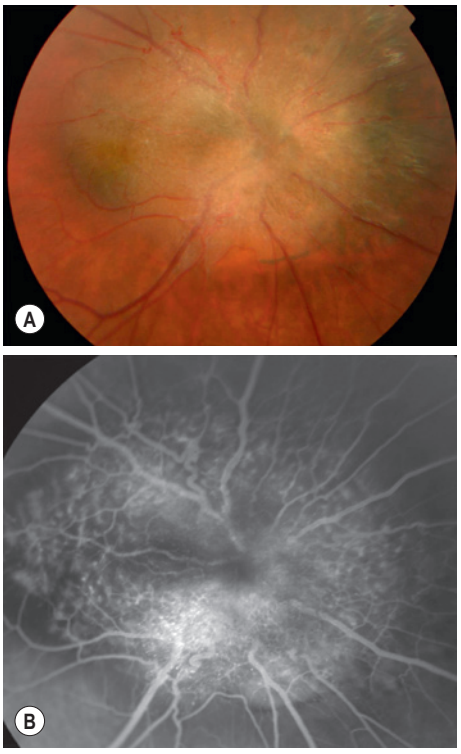

Fig. 49.6 Combined hamartoma of the retina and retinal pigment epithelium (CHRRPE). (A) Elevated, very slowly progressive right optic disc lesion presenting in a 6-year-old child with visual loss to 0.7 LogMAR at 11 years of age. Note the pigmentation, aneurysmal vessels, and pale "glial" tissue. (B) Fluorescein angiogram showing widespread telangiectatic vessels.

- OCT: hyperreflective epiretinal membrane with variable underlying retinal folds involving inner retina. In severe cases, folds extend to outer retina with retinal thickening and disorganization and underlying choroid thinning.[64,65]

Histopathology

- Thickened, disorganized retina and, if involved, optic nerve.
- Abundant hyperplastic and dysplastic glial cells.
- Reduplicated sheets and cords of proliferating RPE infiltrating the overlying tissue.
- Capillary hyperplasia and fibrous tissue proliferation overlying the lesion folding the anterior lesion surface.[66]

Associations

Notable associations include:

- Neurofibromatosis 1 and 2.
- Gorlin syndrome.
- Tuberous sclerosis.

A range of rare associations has been described:

- Poland anomaly.
- Branchio-oculofacial syndrome.
- Branchio-oto-renal syndrome.
- Juvenile nasopharyngeal angiofibroma.
- Incontinentia pigmenti.
- Juvenile retinoschisis.
- Optic disc coloboma and optic nerve head drusen.

Management

Progressive ERM traction may require intervention where loss of vision can be demonstrated due to extension of ERM

onto macula.[67,68] Complications include retinal and vitreous hemorrhages, retinal and choroidal neovascularization, retinoschisis, retinal detachment (usually exudative), and macular edema.[62]

Coats disease

An idiopathic retinal telangiectasia with intraretinal and/or subretinal exudation without appreciable retinal or vitreous traction.[69]

- Vascular telangiectasia (Fig. 49.7).
- Aneurysmal dilation of the retinal vessels ("light-bulbs"; Fig. 49.8).
- Retinal capillary microaneurysms.
- Subretinal and intraretinal, yellow-white patchy exudation located at the posterior pole and beneath the retinal vessels.
- Sheathing of retinal vessels with cholesterol deposits.

The equatorial and peripheral retina is usually affected with a predilection for the temporal side. The disorder generally progresses to retinal detachment (Fig. 49.9), glaucoma, cataract, and phthisis bulbi. Preschool-age children usually present with strabismus or leukocoria; older children, with subjective visual loss or on routine vision screening.[70] Cholesterolosis bulbi has been described rarely. Poor vision is present in over 50% as a result of exudative retinal detachment or macular involvement.[70,71] Macular pathologies include telangiectasia, exudation, edema, macular fibrosis, or full-thickness hole.[72]

The staging of Coats disease is listed in Table 49.1.[73] Most eyes present at stage 2 or 3, rarely at stage 1 or 5, with younger patients tending to present at stage 3.

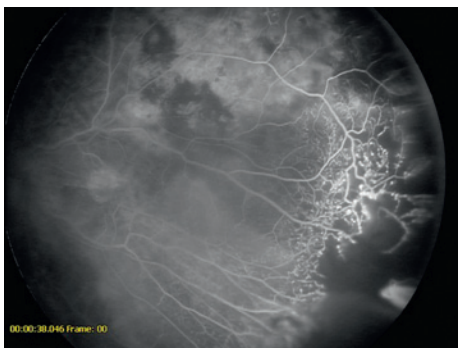

Fig. 49.7 Coats disease. The "hallmark" is vascular telangiectasia, shown in this peripheral fluorescein angiogram, and aneurysmal dilation of the retinal vessels.

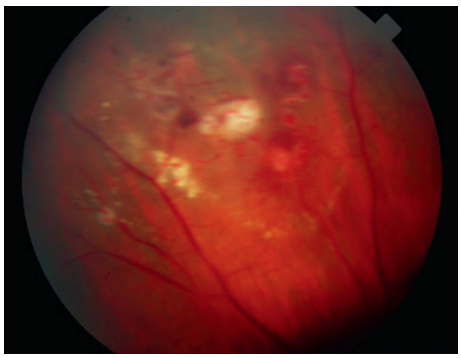

Fig. 49.8 Coats disease. Aneurysmal dilation of retinal vessels, exudates – few in this case – and microaneurysms.

Incidence

- Commoner in males (ratio of 17:3).
- Estimated population incidence of 0.09 per 100,000.
- Median age at presentation is 8 years, with the majority of patients presenting in the first 15 years of life, peaking between 5 and 10 years.

The earliest described presentation was in a 3-week-old baby.[74] Earlier-onset disease tends to have a more rapid progression.[70] Although classically described as unilateral, some bilateral cases have been documented.[71] Wide-field FFA demonstrates peripheral avascular retina in 61% of fellow eyes with classic, unilateral Coats disease.[75]

Histopathology

- Thickening and hyalinization of blood vessels.
- Thinning and loss of endothelial elements and plasma leakage into vessel walls.
- Vessel wall necrosis, formation of vessel dilation, and telangiectasias.
- Subretinal exudates, hemorrhage, cysts, edema, lymphocytic infiltration, and deposition of fibrin.
- The neural retina undergoes secondary degeneration.

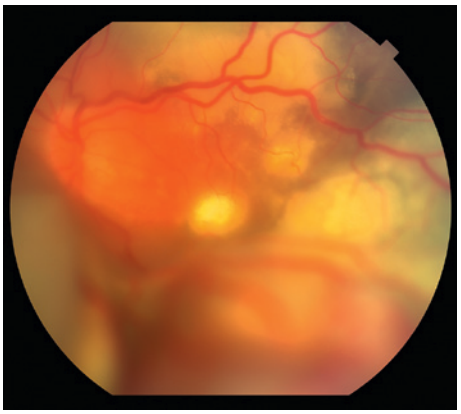

Fig. 49.9 Coats disease. Serous retinal detachment with massive subretinal cholesterol accumulation.

Table 49.1 The staging of Coats disease

Stage	Description
0	Regressed; no telangiectasia/exudation
1	Retinal telangiectasia only
2	Telangiectasia and exudation
2A	Extrafoveal exudation
2B	Foveal exudation
3	Exudative retinal detachment
3A1	Extrafoveal detachment only
3A2	Foveal detachment
3B	Total retinal detachment
4	Total retinal detachment with glaucoma
5	End-stage disease (phthisis bulbi)

- RPE cells phagocytose lipid, transforming them into lipid-laden "ghost cells."[76,77]

Genetics

Most cases of Coats disease appear to be sporadic although somatic mutations in the *NDP* gene (associated with Norrie disease) within a segment of the retina at an early stage of development has been described.[78]

Coats-like changes are seen in:

- Retinal dystrophies associated with *CRB1* and *CEP290* genes[79,80].
- Coats-plus disease (intracerebral calcification, cerebral microangiopathy, sparse hair, dystrophic nails, intrauterine growth retardation, bone marrow involvement, and postnatal growth failure); it is caused by mutations in the *CTC1* gene[81,82].
- Facioscapulohumeral muscular dystrophy.
- Plasminogen deficiency type 1.
- Cornelia de Lange syndrome.
- Hallerman–Streiff syndrome.
- Senior–Loken syndrome.
- Multiple glomus tumors.[83–88]

Management

An important differential diagnosis is retinoblastoma, in particular rare diffuse infiltrating tumors that are flat and ill defined, and present at an older mean age (around 4 years). Eyes with Coats disease are occasionally enucleated because of the inability to exclude retinoblastoma.[89] Other differential diagnoses include persistent fetal vasculature, vitreoretinal dysplasia, retinopathy of prematurity, pars planitis, idiopathic retinal vasculitis and neuroretinitis (IRVAN), X-linked retinoschisis, toxocariasis, and von Hippel–Lindau disease.

Slow progression to retinal detachment is seen in 64% of patients over a 5-year period. Progression appears more likely in patients 4 years or younger. Poor prognostic features include: postequatorial involvement, diffuse and superior retinal location, retinal macrocysts, failed resolution of fluid after treatment, and retinal detachment at presentation.[71,89] Enucleation is rare and performed due to concerns that retinoblastoma might be present in an otherwise blind, glaucomatous eye.[89,90] Most cases will stabilize or improve with treatment (98% in a British Ophthalmological Surveillance Unit [BOSU] study).[91] In milder cases, the goal is to preserve vision. In more advanced cases, the goal is preservation of ocular comfort and cosmesis.

Ablation of peripheral telangiectasia and aneurysms is more effective for stage 2 disease. Treatment includes cryotherapy, argon green or diode laser (532 nm).[92] Treatment complications include cataract, retinal detachment, and proliferative vitreoretinopathy.

In cases of retinal detachment, surgical correction by drainage of subretinal fluid and/or vitrectomy combined with laser or cryotherapy has been described,[93] although in many cases the visual outcome is limited due to the presence of a macular fibrotic scar, which may represent a retinal angiomatous proliferation associated with a chorioretinal anastamosis and pigment epithelium detachment.[94]

Adjunctive treatment with intravitreal anti-VEGF antibody has been used for stage 3a and b disease. However, tractional retinal detachment has been documented and there is lack of long-term safety and efficacy data.[95] Intravitreal steroid injections with triamcinolone or slow-release implants risk development of cataract and glaucoma.

Familial retinal arteriolar tortuosity (fRAT)

- Rare; autosomal dominant.
- Progressive tortuosity of second- and third-order retinal arterioles associated with retinal hemorrhages most obvious around the macular region.[96]
- The venules and major arterioles and capillaries are normal with no aneurysms or abnormal anastomoses.
- Fluorescein angiography shows no leakage from vessels.

Also seen are:

- Telangiectasia of the bulbar conjunctival vessels.
- Malformations of the Kieselbach nasal septum.
- Spinal cord vascular mass.
- Internal carotid artery aneurysm.

Retinal hemorrhages cause transient visual disturbance or loss when involving the central macular area and can arise following exertion or Valsalva maneuvre.[96]

Genetics

fRAT is caused by mutations in *COL4a1*,[97] also associated with hereditary angiopathy with nephropathy, aneurysm, and cramps (HANAC syndrome),[98] autosomal dominant infantile hemiparesis and porencephaly associated with leukoencephalopathy,[99] and diffuse small vessel disease of the brain accompanied by Axenfeld–Rieger anomaly.[100]

Inherited retinal venous beading

- A rare, autosomal dominant disorder of unknown etiology.
- Prominent sausage-like retinal venous beading of the retina.
- Retinal arterioles may show narrow caliber.
- Saccular, aneurysmal changes of the conjunctival vessels.
- Episodes of acute vascular decompensation characterized by neovascularization and vitreous hemorrhage.
- Intraretinal lipid
- Fluorescein angiography shows areas of capillary nonperfusion, leakage of fluorescein, and intraretinal microvascular changes including microaneurysms and telangiectasias.
- Families have been described with nephritis, neutropenia, and deafness.[101]

Congenital retinal macrovessel

- A large vessel crossing over the central macula with large tributaries extending on both sides of the horizontal raphé.
- Visual acuity is not normally affected.[102,103]
- Occasionally the macrovessel is an artery or combined artery and vein.[104]

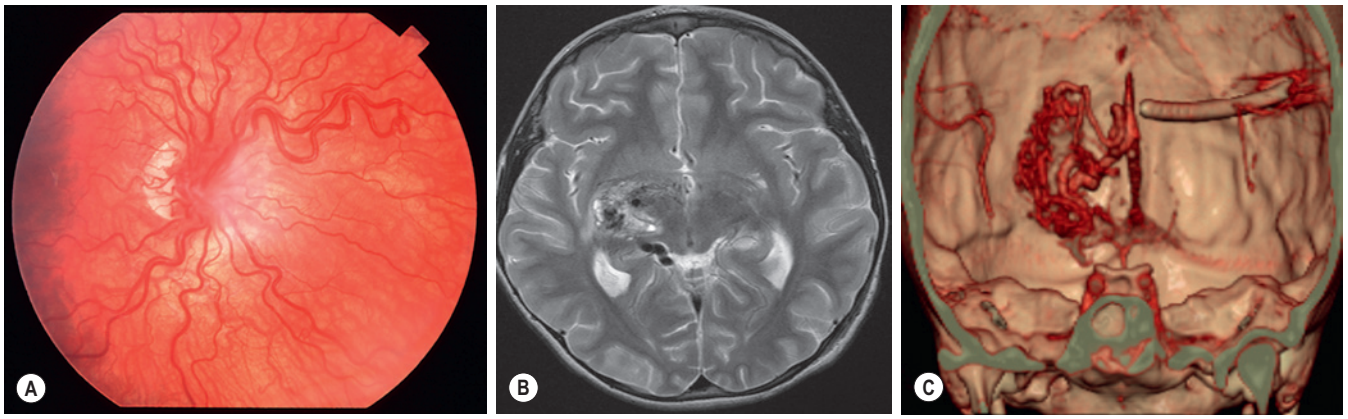

Fig. 49.10 (A) Racemose hemangioma. Large loop vein in upper nasal quadrant of the right eye. Normal visual acuity. (B) Magnetic resonance (MR) imaging showing right-sided vascular malformation from which a sudden hemorrhage occurred at 10 years of age causing obtundation (from which the child recovered) and a left homonymous hemianopia (which did not recover). (C) MR angiogram reconstruction showing anteroposterior view with a right-sided vascular malformation and a shunt on the left.

- Prevalence: rare; in a series of 3506 eyes, seven eyes of six patients had branches coming off the inferotemporal artery, with none having a branch of the superotemporal artery or vein.[105]
- Arteriovenous communications are frequently observed.

Investigations

- Fluorescein angiography: early filling of venous component, areas of capillary non-perfusion in the perifoveal or perivenular region, and disturbance of the foveal capillary microangioarchitecture with poorly defined, enlarged avascular zones and microaneurysms. During the late phase angiogram, the retinal macrovessel remains preferentially hyperfluorescent compared to other retinal vessels.
- Communication between a cilioretinal artery and macrovessel has been described and retinal macrovessels are classed as a mild arteriovenous anastamosis.[106,107]
- OCT imaging of the retina demonstrates macular thickening.[108]
- Complications include serous retinal detachment that may spontaneously resolve[109]; serous exudation, Valsalva retinopathy,[106] and intraretinal cyst.[103]

Racemose retinal hemangioma

These rare, unilateral congenital vascular malformations can be associated with brain vascular malformations that can cause strokes (Fig. 49.10). Usually discovered at routine examination or when the patient has presented with a neurological episode, they require no treatment.

Familial retinal arterial macroaneurysms (FRAM)

- Autosomal recessive disorder.
- Multiple, bilateral retinal arterial macroaneurysms and beading affecting first-order arterioles and progressing to second- and peripheral third-order vessels.[110]
- Retinal changes occur as early as 3 months.
- Macroaneurysms arise from areas of retinal arterial beading.
- Intraretinal and subretinal exudation gives a Coats-like appearance.
- Reactive changes at the level of the RPE leaves subretinal scarring, atrophy, and vascular sheathing.[110]
- Complications include recurrent sub-ILM hemorrhages, leakage from the macroaneurysms, and areas of exudative retinal detachment.
- Treatment: argon green laser photocoagulation.[110]

Genetics

FRAM is associated with mutations in the insulin-like growth factor binding protein 7 (IGFBP7).[111]

Associations

Cardiac abnormalities, including supravalvular pulmonary stenosis and congestive hepatopathy.[111]

YELLOW-WHITE RETINAL LESIONS IN PRIMARY OCULAR DISEASE
YELLOW-WHITE RETINAL LESIONS IN ACQUIRED DISEASE
YELLOW-WHITE RETINAL LESIONS IN SYSTEMIC DISEASE
REFERENCES

Introduction

A number of conditions, inherited or acquired, can present with multiple yellow-white retinal lesions. These lesions may look like flecks, dots/drusen, or crystals and can be associated with a variable degree of retinal dysfunction.[1–3] This chapter reviews the differential diagnosis of yellow-white spots in the pediatric retina; some disorders predominantly seen in adults are also included.

Clinical evaluation

It is important to inquire about visual symptoms such as blurred vision, night blindness, or light hypersensitivity and to obtain a family history. Examination of relatives can be helpful, as other affected family members may remain asymptomatic. Current or previous systemic drug administration and dietary habits should be inquired after. Careful note should be taken of any other medical disorders particularly those associated with malabsorption (e.g. cystic fibrosis[4]).

When examining the child, the distribution of retinal deposits, their depth in the retina, and whether they are crystalline in nature should be noted. Investigations that may assist in the differential diagnosis include optical coherent tomography (OCT), fundus autofluorescence (FAF) imaging and, in some cases, psychophysical and electrophysiologic (electroretinogram [ERG] and electro-oculogram [EOG]) testing. Molecular diagnostic testing can often prove useful to confirm the diagnosis.

Yellow-white retinal lesions in primary ocular disease

Stargardt disease and fundus flavimaculatus (see also Chapter 48)

Stargardt disease is a common retinal dystrophy, typically associated with autosomal recessive mutations in the *ABCA4* gene.[5] Pseudodominant inheritance can be observed, particularly in consanguineous families.[6] In such cases, it is important for counseling to distinguish *ABCA4*-related disease from phenotypically similar autosomal dominant disorders due to mutations in *ELOVL4*[7] or *PRPH2/RDS*.[8]

Stargardt disease is characterized by the presence of yellow-white flecks that are located in the deep retinal layers and are scattered throughout the posterior pole (Fig. 50.1). These classical flecks are not always present at diagnosis, but can appear later in the course of disease.[9,10] Macular atrophy is common, and affected individuals typically present with reduced visual acuity in the second decade of life; night blindness and light hypersensitivity may also be present.[11] Some patients have good central vision with minimal or no macular involvement at presentation, and may be diagnosed with fundus flavimaculatus (i.e. retinal flecks without macular atrophy).[12] Stargardt disease and fundus flavimaculatus are parts of the phenotypic spectrum of the same genetic disorder.

FAF imaging is a useful monitoring tool and allows detection of the abnormal phenotype even when it is not otherwise evident (including children with unexplained visual loss).[10] Abnormalities in the form of a speckled hyper- and hypoautofluorescence pattern and/or focal areas of increased signal spatially correlating with the retinal flecks may be observed.[13,14] Quantitative FAF imaging, a modality measuring FAF intensities in a standardized way, can provide further insights including distinguishing *ABCA4* mutation-positive from *ABCA4* mutation-negative individuals.[15] OCT, in particular the degree of preservation of the hyper-reflective line corresponding to the inner segment ellipsoid zone, allows accurate assessment of disease severity.[16] A "dark choroid" has been classically described on fluorescein angiography, although this is now not a commonly used diagnostic tool for Stargardt disease.[17]

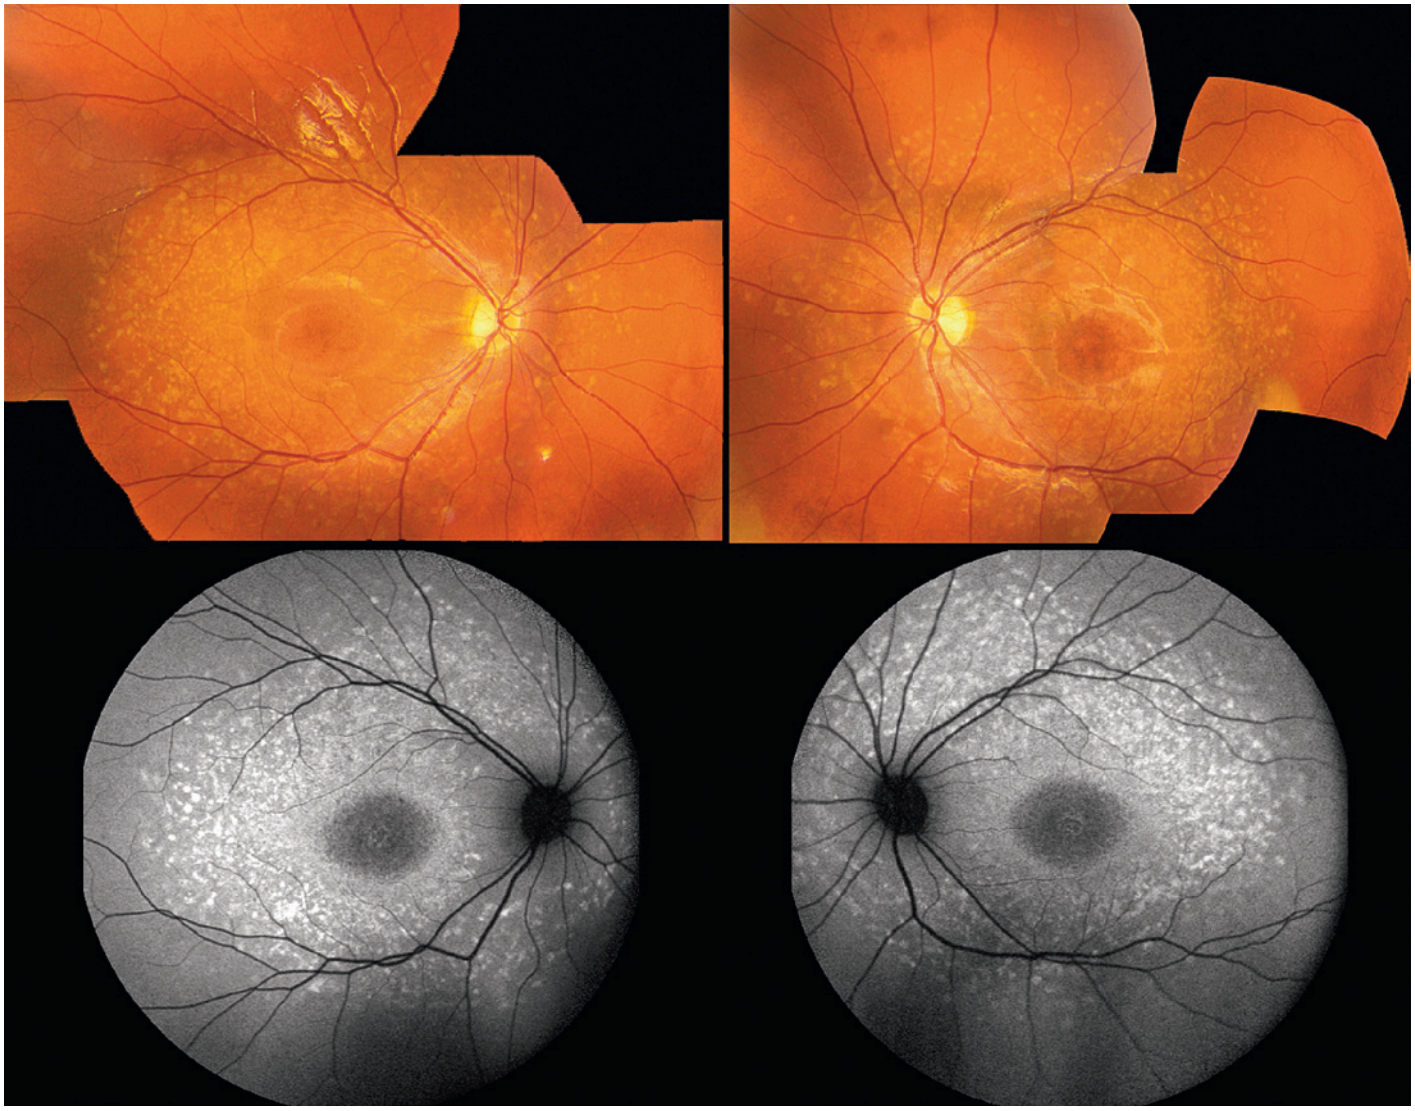

Fig. 50.1 Stargardt disease. Fundus photograph of the left and right eyes of a 9-year-old individual with Stargardt disease (top row). Fundus autofluoresence imaging (bottom row) revealed hyperautofluorescent lesions corresponding to the flecks and abnormal autofluorescence at the foveal region.

Electrophysiologic testing reveals attenuated central macular responses on the multifocal ERG and an abnormal pattern ERG. Full-field ERGs can be variable but may be prognostically useful, since individuals with early evidence of generalized rod and/or cone system dysfunction are likely to develop rapidly progressive disease.[18,19] Notably, generalized retinal dysfunction is more common in childhood-onset than in adult-onset disease, in keeping with a more severe phenotype.[9]

Benign fleck retina

Benign fleck retina is an autosomal recessive condition associated with a distinctive retinal appearance and no apparent visual or electrophysiological deficits.[20] Affected individuals are asymptomatic, but fundus examination reveals a striking pattern of diffuse, yellow-white flecks extending to the far periphery but sparing the foveal region (Fig. 50.2).[21–24] The flecks are located in the deep retinal layers and can be present in early infancy.

FAF imaging reveals multiple hyperautofluorescent lesions corresponding in location with the flecks. On OCT, there is discrete deposit accumulation located posterior to the inner segment ellipsoid zone.[24] Normal full-field and pattern ERGs confirm the diagnosis[22]; multifocal ERG may be slightly subnormal in some isopters.[23]

Recessive mutations in the gene encoding group V phospholipase A_2 (*PLA2G5*) and mildly elevated serum cholesterol levels have been described in some individuals with benign fleck retina.[24,25]

Benign fleck retina should not be confused with a condition described by Kandori in 1972.[26] This disorder, named "fleck retina of Kandori", has been associated with large white lesions, possibly atrophic changes, and night blindness.[26] It is not clear if "fleck retina of Kandori" is a genetic condition or even an independent clinical entity.

Fundus albipunctatus

Fundus albipunctatus is an autosomal recessive disorder associated with night blindness and multiple widespread yellow-white punctate lesions (Fig. 50.3); the spots spare the foveal region, are located at the deep retinal layers, and are

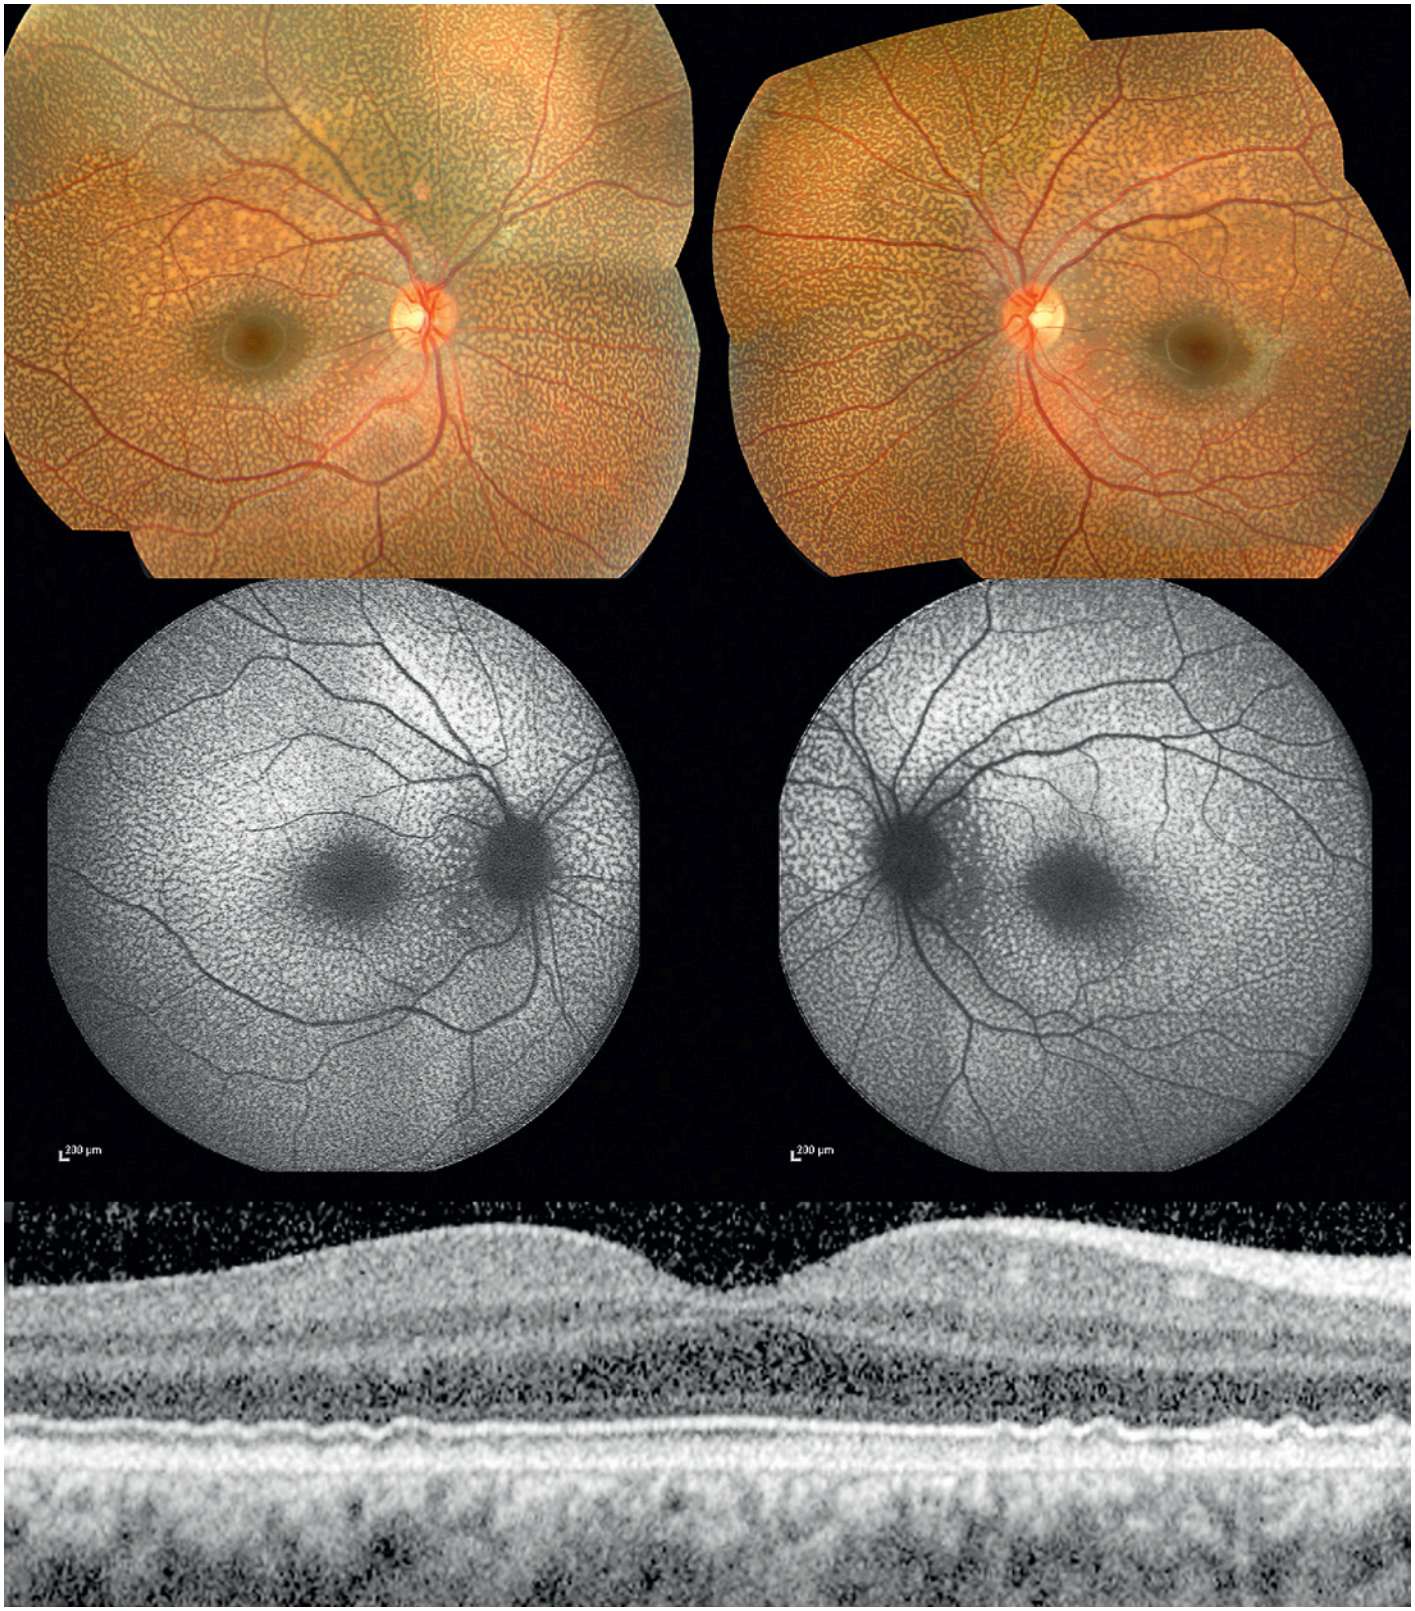

Fig. 50.2 Benign fleck retina. Fundus photograph of the left and right eyes of a 10-year-old individual with benign fleck retina (top row). Fundus autofluorescence (middle row) and optical coherence tomography (horizontal, centered on the fovea, linear scan of the right eye; bottom row) revealed endogenously fluorescent lesions at the level of the retinal pigment epithelium. These do not disrupt the inner segment ellipsoid zone.

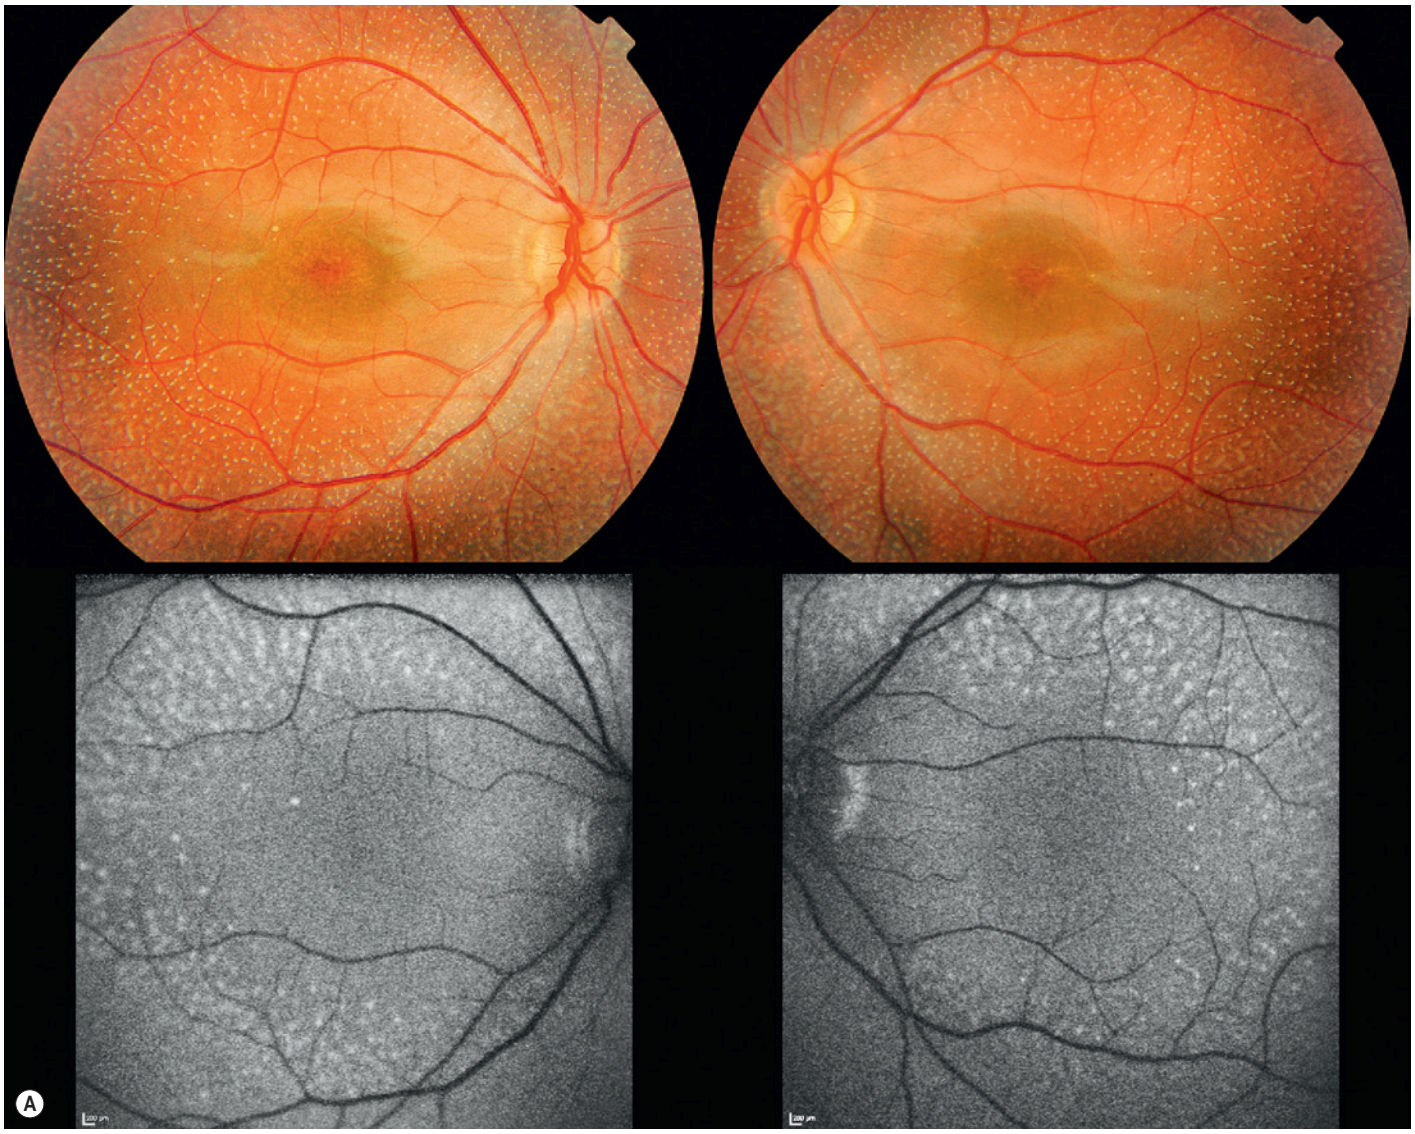

Fig. 50.3 Fundus albipunctatus. (A) Fundus photograph of the left and right eyes of an 18-year-old *RDH5* mutation-positive individual (top row). Fundus autofluorescence imaging (bottom row) revealed hyperautofluorescent lesions; these are unlikely to represent lipofuscin accumulation.

typically present in the first decades of life.[27,28] Patients are either noted to have an abnormal retinal appearance on a routine eye test or present with problems in dim illumination. On direct questioning, affected individuals often describe night blindness from birth and delay in dark adaptation after exposure to bright light.[27] Visual acuities and visual fields are usually normal.

FAF imaging reveals a low autofluorescent signal; digital enhancement artefacts such as autofluorescence from the optic disc and large vessels may be observed.[29,30] In young subjects, high-density foci partially associating with the yellow-white dots on fundoscopy can be seen (see Fig. 50.3A).[27,30] Hyper-reflective lesions extending from the retinal pigment epithelium (RPE) to the outer nuclear layer are detected on OCT (see Fig. 50.3B).[28,31,32]

Characteristic abnormalities on electrophysiology and dark adaptometry facilitate the diagnosis (see Chapter 46). Notably, scotopic ERG responses are subnormal following conventional dark adaptation, but partially recover or normalize following extended dark adaptation.[27,33] Photopic ERGs and pattern ERGs can be normal or abnormal[27,34,35] and adaptive optics imaging reveals an irregular macular cone mosaic.[30,31]

Molecular testing can be useful: fundus albipunctatus is commonly associated with recessive mutations in *RDH5*, a gene encoding an enzyme with 11-*cis*-retinol-dehydrogenase activity.[36] This enzyme catalyzes the oxidizing of 11-*cis*-retinol to 11-*cis*-retinaldehyde, the universal vertebrate chromophore of visual pigments in human RPE.[37,38] Mutations in *RPE65*[39] and *RLBP1*[40,41] have also been described in patients with some features of fundus albipunctatus.

Retinitis punctata albescens, Bothnia, and Newfoundland retinal dystrophies

Retinitits punctata albescens is a variant of recessive retinitis pigmentosa characterized by multiple retinal yellow-white dots rather than pigment deposition.[42] Affected individuals present with night blindness and/or peripheral vision problems; early

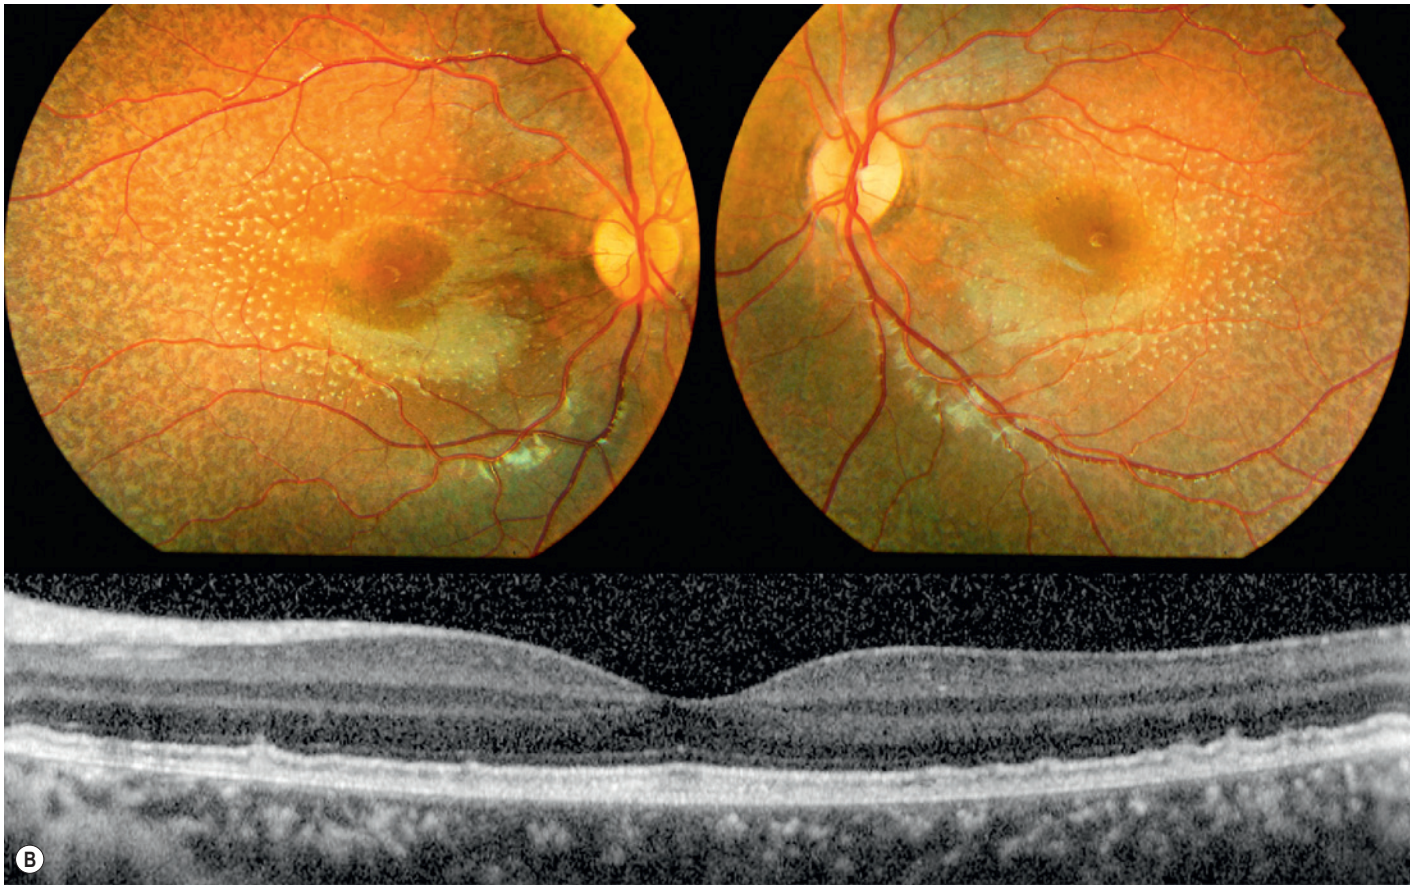

Fig. 50.3, cont'd (B) Fundus photographs of the left and right eyes of a 10-year-old, *RDH5* mutation-positive individual (top row). Optical coherence tomography (horizontal, centered on the fovea, linear scan of the left eye; bottom row) revealed hyper-reflective lesions extending from the retinal pigment epithelium to the outer nuclear layer.

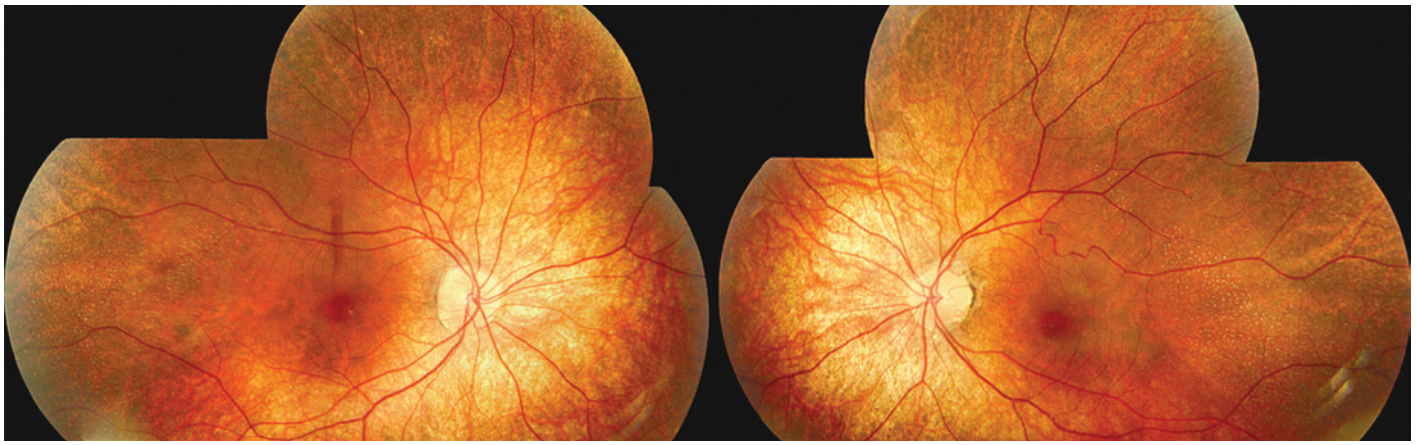

Fig. 50.4 Retinitis punctata albescens. Fundus photograph of the left and right eyes of a 15-year-old *RLBP1* mutation-positive individual.

macular involvement resulting in visual acuity loss may also be a feature of the disorder.[43,44] On fundoscopy, yellow-white spots similar to the ones seen in fundus albipunctatus are observed (Fig. 50.4). These spots spare the fovea and may evolve to give rise to a more classical pigmentary retinopathy.[45] It is important to differentiate early retinitis punctata albescens from fundus albipunctatus: the prognosis for daytime vision is considerably better in the latter and the former features more severe and progressive retinal degeneration. Vascular attenuation, visual field loss, retinal thinning on OCT and a more severe electrophysiological phenotype are key distinguishing features (see Chapter 46).[41,46]

Retinitis punctata albescens is primarily associated with recessive mutations in *RLBP1*[47]; this gene encodes a key component of the retinal visual cycle with a role in maintaining normal cone-driven vision and in accelerating cone dark adaptation.[48] Recessive mutations in *LRAT*[49] and dominant mutations in *PRPH2/RDS*[50] and rhodopsin[51] have also been described in a small number of retinitis punctata albescens cases.

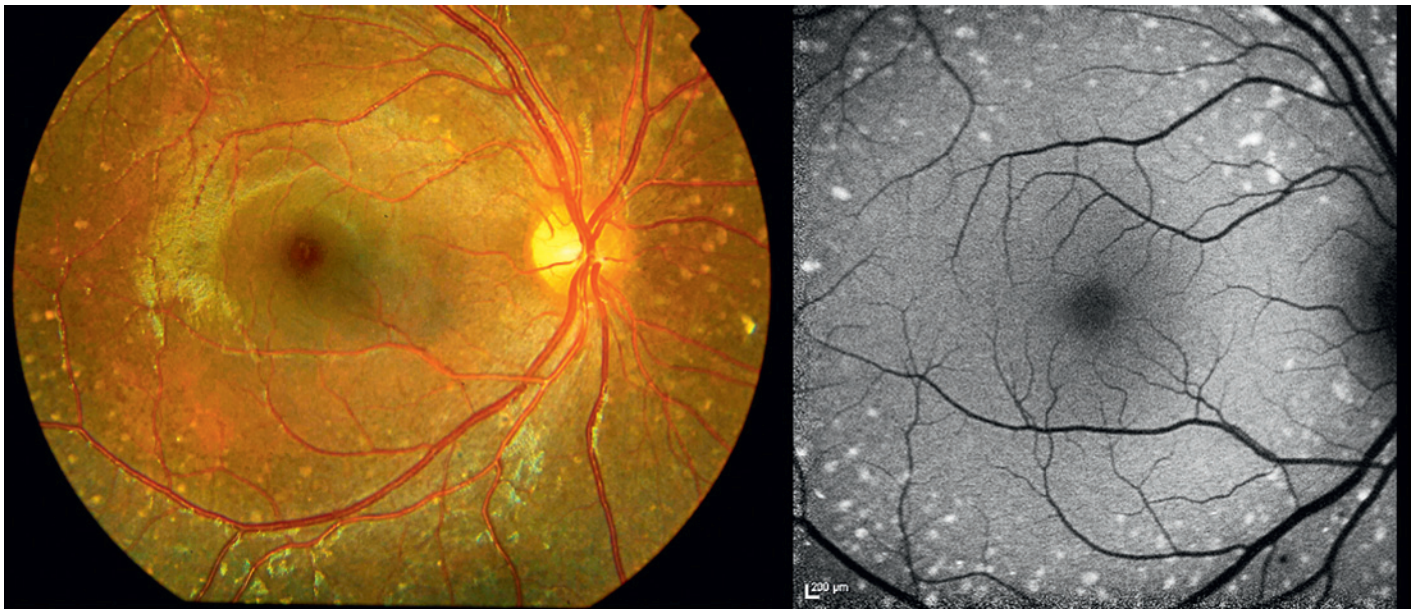

Fig. 50.5 Enhanced S-cone syndrome. Fundus photograph and fundus autofluorescence imaging of the left eye of a 13-year-old affected individual.

Newfoundland rod–cone dystrophy[52] and Bothnia dystrophy[45] are two early-onset forms of retinal disease that have high prevalence in the genetically isolated populations of northeastern Canada and northern Sweden, respectively. Both share genetic etiology (*RLBP1* mutations) and key phenotypic features with recessive retinitis punctata albescens and should be considered parts of the phenotypic spectrum of the same disorder.[41]

Enhanced S-cone syndrome and Goldmann–Favre syndrome

Yellow-white flecks at the deep retinal layers can be an early feature of "enhanced S-cone syndrome" (ESCS), an autosomal recessive progressive retinopathy.[53,54] Patients typically present with night blindness and/or visual acuity loss in the first or second decade of life; a hypermetropic refraction is often noted.[55] Various fundoscopic features have been described; a sequence of change from a normal fundus appearance, followed by RPE mottling along the vascular arcades, and then the development of yellow-white spots (primarily along the arcades; Fig. 50.5), followed by deep nummular pigmentary deposition has been suggested. Macular retinoschisis can also be a feature of the disorder[54,56] and visual field loss can occur in later adulthood.[57,58]

FAF imaging is a useful monitoring tool that typically reveals abnormal signal, in particular beyond the vascular arcades; midperipheral hyperautofluorescent spots only partially corresponding to the flecks are often observed in young subjects.[54,58] A hyperautofluorescent ring may also be present.[55,59] Intraretinal cysts that may involve the fovea (resulting in reduced vision), outer retinal rosette-like structures and, in some cases, a disorganized retinal architecture, can be observed on OCT.[54,58,60,61]

ESCS is unique among retinal dystrophies as there is both retinal degeneration resulting in visual loss and increased function in a subset of photoreceptors, the S-cones.[62–64] Consequently, a distinctive electophysiological phenotype is observed[65,66] (see Chapter 46). ESCS is associated with recessive mutations in *NR2E3*, a gene encoding a transcription factor with a role in activating rod development and repressing cone development.[64,67,68]

Goldmann–Favre syndrome was initially described as an autosomal recessive vitreoretinopathy characterized by night blindness, pigmentary degeneration, macular and peripheral retinoschisis, cataract, and degenerative vitreous changes.[69,70] Many of these features are shared with ESCS and appropriate electrophysiological and genetic testing revealed that they are not distinct entities but simply two identifiable phenotypes in a wide spectrum of clinical expression of the same retinal degeneration.[57,70,71]

Miscellaneous reports of retinal flecks associated with inherited retinal disease

Small yellow-white lesions have been also reported in association with a number of other retinal disorders, including juvenile retinoschisis[72,73] and early-onset retinal dystrophy due to *RPE65*, *LRAT*, *LCA5*, or *CEP290* mutations.[74–76] In these subtypes of early-onset retinal dystrophy, the flecks/dots tend to be more fine and peripheral; in juvenile retinoschisis, they are usually within the posterior pole. Additionally, autosomal recessive bestrophinopathy, a condition associated with biallelic *BEST1* mutations, may present in childhood with yellow-white hyperautofluorescent subretinal deposits in the fovea and around the vascular arcades (see Chapter 48).[77,78]

Drusen-like deposits in inherited retinal disease, including North Carolina macular dystrophy

Drusen deposition at the macula is the hallmark of age-related maculopathy. Similar lesions may also be seen in young adults affected with Sorsby fundus dystrophy (mutation in

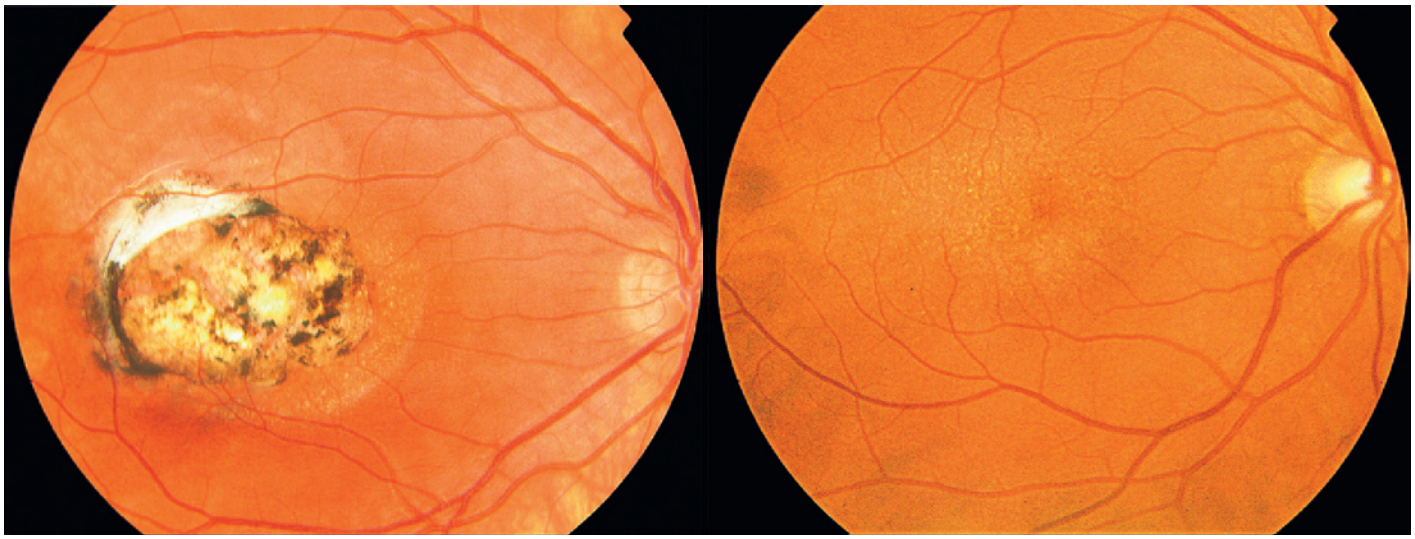

Fig. 50.6 North Carolina macular dystrophy. Fundus photograph of the right eyes of a 12-year-old boy (left panel) and his 40-year-old father (right panel). Both are affected with North Carolina macular dystrophy.

the *TIMP3* gene[79–81]) or autosomal dominant drusen (also known as Doyne honeycomb retinal dystrophy[82] or malattia leventinese[83]; mutation in the *EFEMP1* gene[84]), two dominantly inherited maculopathies. Rarely, dots or drusen-like lesions are seen in asymptomatic children as an incidental finding.[1,85]

Drusen-like deposits in pediatric patients can be observed in children with North Carolina macular dystrophy. This autosomal dominant condition is characterized by macular drusen that are present from birth.[86,87] Fundoscopic findings are highly variable (Fig. 50.6) and tend to be more dramatic than one would predict from visual acuity measurements. Affected individuals may have only a few drusen in the fovea (grade I), confluent drusen with or without RPE changes (grade II), or central macular chorioretinal atrophy with hypertrophic fibrous tissue (grade III)[86,88] (see Chapter 48). Importantly, the condition rarely progresses and the grading does not reflect successive stages of progression.[88–90] Visual acuity is stable and generally well preserved, except in those with central atrophic lesions. Development of choroidal neovascularization is uncommon, but can result in late visual loss.[86,90]

Mutations in the long arm of chromosome 6 causing dysregulation of PRDM13, a retinal transcription factor, have been described in 12 affected families. [91,92] Notably, a number of macular dystrophies that do not map to chromosome 6 but share features with North Carolina macular dystrophy (including macular drusen) have also been described[93–95] (see Chapter 48).

Bietti crystalline corneoretinal dystrophy

Bietti crystalline dystrophy is an autosomal recessive progressive chorioretinal degeneration characterized by night blindness, reduced visual acuity, visual field constriction and multiple yellow-white crystalline deposits at the retina, in circulating lymphocytes and, occasionally, in the anterior stroma of the peripheral cornea.[96–98] Retinal crystals are observed predominantly at the posterior pole (Fig. 50.7); they are often associated with multiple, sharply demarcated areas of RPE atrophy and tend to disappear as the disease advances.[98,99] Affected individuals typically become symptomatic after the second decade of life.[98–100] However, some pediatric cases have been described.[101,102]

On FAF imaging, lesions partially corresponding to the crystals may or may not be evident.[103,104] OCT reveals hyperreflective lesions in all retinal layers; many of these lesions do not spatially associate with the retinal crystals.[105–108] Intraretinal rosette-like structures and reduced subfoveal choroidal thickness are other common OCT features.[103,108–109] Full-field ERGs range from normal to undetectable, with most affected individuals having generalized cone and rod system involvement, even in the early stages of disease.[98,101,110,111]

Bietti corneoretinal dystrophy is associated with defects in *CYP4V2*,[97] a gene encoding an enzyme with a role in fatty acid metabolism.[112,113] A high heterozygous carrier frequency for *CYP4V2* mutations and, therefore, relatively high prevalence of the condition have been reported in East Asia, especially in Chinese and Japanese populations.[100]

Yellow-white retinal lesions in acquired disease

Vitamin A deficiency

Deficiency of the fat-soluble vitamin A limits growth, weakens innate and acquired host defenses, and increases the risks of infectious morbidity.[114–116] Ocular manifestations of hypovitaminosis A are an important health problem worldwide and a common cause of pediatric blindness, typically as a result of corneal scarring (xerophthalmia; see Chapter 34).[117,118] Vitamin A deficiency can be due to malnutrition, malabsorption, or impaired metabolism of vitamin A associated with liver disease, Crohn disease, or cystic fibrosis.[119]

Chronic vitamin A deficiency may lead to visual symptoms as a result of reduced photoreceptor visual pigment formation.[120] Night blindness is a common complication and an early symptom of the disorder; visual field loss, abnormal color vision, and visual acuity loss may occur in advanced

Fig. 50.7 Bietti crystalline corneoretinal dystrophy. Fundus photograph of the left and right eyes of a 16-year-old *CYP4V2* mutation-positive individual showing crystalline deposits.

disease. Fundus examination often reveals multiple gray-white punctate spots scattered in the peripheral retina.[121,122] OCT changes associated with these lesions are observed in the deep retinal layers; these are remarkably similar to the ones seen in *RDH5* or *RLBP1* retinopathy (see Fig. 50.3B).[28,44,122] Atrophic and pigmentary changes may occur with disease progression. Dark adaptometry demonstrates elevated rod and cone thresholds, with rods more severely affected.[123] Electrophysiology reveals reduced or undetectable scotopic ERGs and reduced amplitude cone-flicker ERGs of normal implicit time.[121,123] The flecked retinopathy, visual field, psychophysical and electrophysiological abnormalities usually resolve upon prompt vitamin A supplementation (see Chapter 46).[124,125]

Inflammatory chorioretinopathies

A heterogeneous group of rare inflammatory chorioretinopathies can be associated with multiple yellow-white macular lesions of various sizes. These conditions are more commonly seen in adults and are broadly termed "white dot syndromes."[126–128]

Drug-induced crystalline retinopathies

Acquired yellow-white retinal lesions that are crystalline in nature[3] may be due to medication side effects or associated with West African crystalline maculopathy.[129] Drug-related causes include methoxyflurane anesthesia, tamoxifen therapy, canthaxantine therapy, and talc retinopathy.[130–132] These are generally seen in adults rather than children.

Inherited causes of crystalline retinopathy in children include Bietti crystalline dystrophy (described above), primary hyperoxaluria type I and Sjogren–Larsson syndrome (discussed later in this chapter).

Yellow-white retinal lesions in systemic disease

Abetalipoproteinemia

Abetalipoproteinemia is a rare metabolic disorder that affects absorption of cholesterol, dietary fats and fat-soluble vitamins from the small intestine.[133–136] It is associated with recessive mutations in the *MTTP* (microsomal triglyceride transfer protein) gene and typically presents with failure to thrive and diarrhea in infancy.[134,135,137] A number of multisystem manifestations including abnormally shaped red blood cells (acanthocytosis) and ataxic neuropathy have also been described (see Chapter 65).[138]

Ophthalmic involvement in abetalipoproteinemia is variable and a wide range of signs has been reported. These include ophthalmoplegia, ptosis, nystagmus, anisocoria, cataract, angioid streaks, and a progressive retinal dystrophy characterized by pigmentary changes and yellow-white mid-peripheral dots located at the deep retinal layers.[139–141] Treatment with vitamins A and E has been reported to slow the course of disease or prevent the development of retinal degeneration.[142,143]

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum (PXE) is a connective tissue disorder causing abnormal mineralization and fragmentation of elastin fibers.[144,145] Characteristic skin findings include lax, redundant, and relatively inelastic skin in flexural areas. Cardiovascular abnormalities (occlusive peripheral vascular disease) and retinal complications are also observed.[146,147] Recessive mutations in *ABCC6* are identified in the majority of affected individuals.[148–150] Pseudodominance is relatively common due

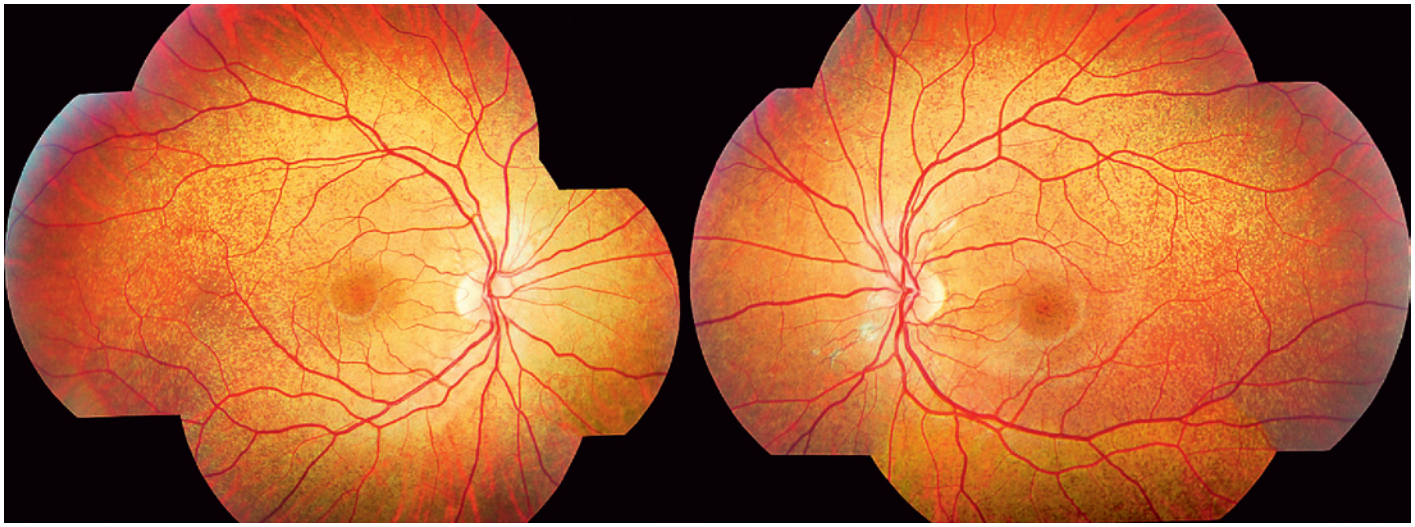

Fig. 50.8 Pseudoxanthoma elasticum. Fundus photograph of the left and right eyes of a 16-year-old individual affected with pseudoxanthoma elasticum.

to an unexpectedly high prevalence of heterozygous carriers in the population.[151]

The most frequent retinal abnormalities in PXE are a characteristic fundal sheen, primarily in the temporal macula (peau d'orange), and jagged cracks radiating around and away from the optic disc (angioid streaks).[152] The former is associated with subconfluent calcification of Bruch's membrane.[153] The latter develop in more heavily calcified portions of Bruch's membrane and are present in almost all PXE patients; they often lead to choroidal neovascularization, fibrovascular scarring of the posterior pole, and visual loss.[153–155] The peau d'orange appearance seems to precede angioid streaks and can be observed in younger patients as fine, yellow-white lesions in the temporal posterior or midperipheral fundus (Fig. 50.8).[152,156] FAF imaging is useful in assessing individuals with PXE, as it reveals the extent of RPE alterations.[157,158] OCT reveals increased reflectivity from the outer border of the RPE/Bruch's membrane complex.[153,158,159] Early recognition of the PXE phenotype is important, alerting the ophthalmologist and prompting a referral to a dermatologist and cardiologist.

Alport syndrome

Alport syndrome is a rare, genetically heterogeneous disorder caused by mutations in collagen biosynthesis genes (*COL4A3*, *COL4A4*, and *COL4A5*); these result in defective production or assembly of the type IV collagen network.[160–163] X-linked semidominant (~85% of cases; *COL4A5* gene), autosomal recessive (~15% of cases; *COL4A3* and *COL4A4* genes), autosomal dominant (rare; *COL4A3* gene), and digenic inheritance have been described.[164–166]

This disorder of the basement membrane results in progressive renal failure, high-tone sensorineural hearing loss, and variable ocular abnormalities including cataract, anterior lenticonus, corneal posterior polymorphous dystrophy, macular hole, and a dot-and-fleck retinopathy.[167–170] Retinal changes in the latter, typically occurring in adulthood, comprise numerous yellow-white perimacular flecks and/or dots (Fig. 50.9). These spare the fovea, and may extend to or solely affect the retinal periphery; an associated dull macular reflex has been described in some cases.[170] FAF imaging may show irregular signal in the retinal periphery and OCT often reveals temporal perifoveal thinning.[171–175] In a small number of cases, larger, central, vitelliform-like lesions have been described.[172] Though there are exceptions, visual function and electrophysiological testing are generally normal.[171]

Dense deposit disease

Dense deposit disease (a C3 glomerulopathy previously known as membranoproliferative glomerulonephritis type II) is a rare renal disorder manifesting in childhood or young adulthood. It is characterized by the presence of complement deposits within the glomerular capillary basement membrane; deposits of similar composition and structure are also found along the Bruch's membrane/RPE interface of affected individuals.[176–178] These drusen-like lesions ("cuticular drusen"[179]) are bilateral, symmetrical, and typically detectable in the second decade of life. They are most easily visualized on fluorescein angiography where they can exhibit a "stars-in-the-sky" pattern (marked hyperfluorescence in early arteriovenous phase).[179] In terms of distribution, they can be only peripheral or only macular at early stages, but they tend to increase in number and eventually affect the entire fundus.[180–183] Although initially they have little impact on vision, they can sometimes lead to vision loss due to choroidal neovascularization or RPE atrophy.[178,184–188] Therefore, ophthalmic screening in individuals with dense deposit disease is recommended. Notably, the extent of ocular involvement does not appear to be related to the severity of renal involvement.[180]

Primary hyperoxaluria

Primary hyperoxaluria is a rare inborn error of oxalate metabolism resulting in increased serum and urinary levels of oxalate.[189,190] As serum levels rise, calcium precipitates with oxalate to form insoluble crystals that are then deposited in various organ systems (mainly bone, blood vessel wall, and

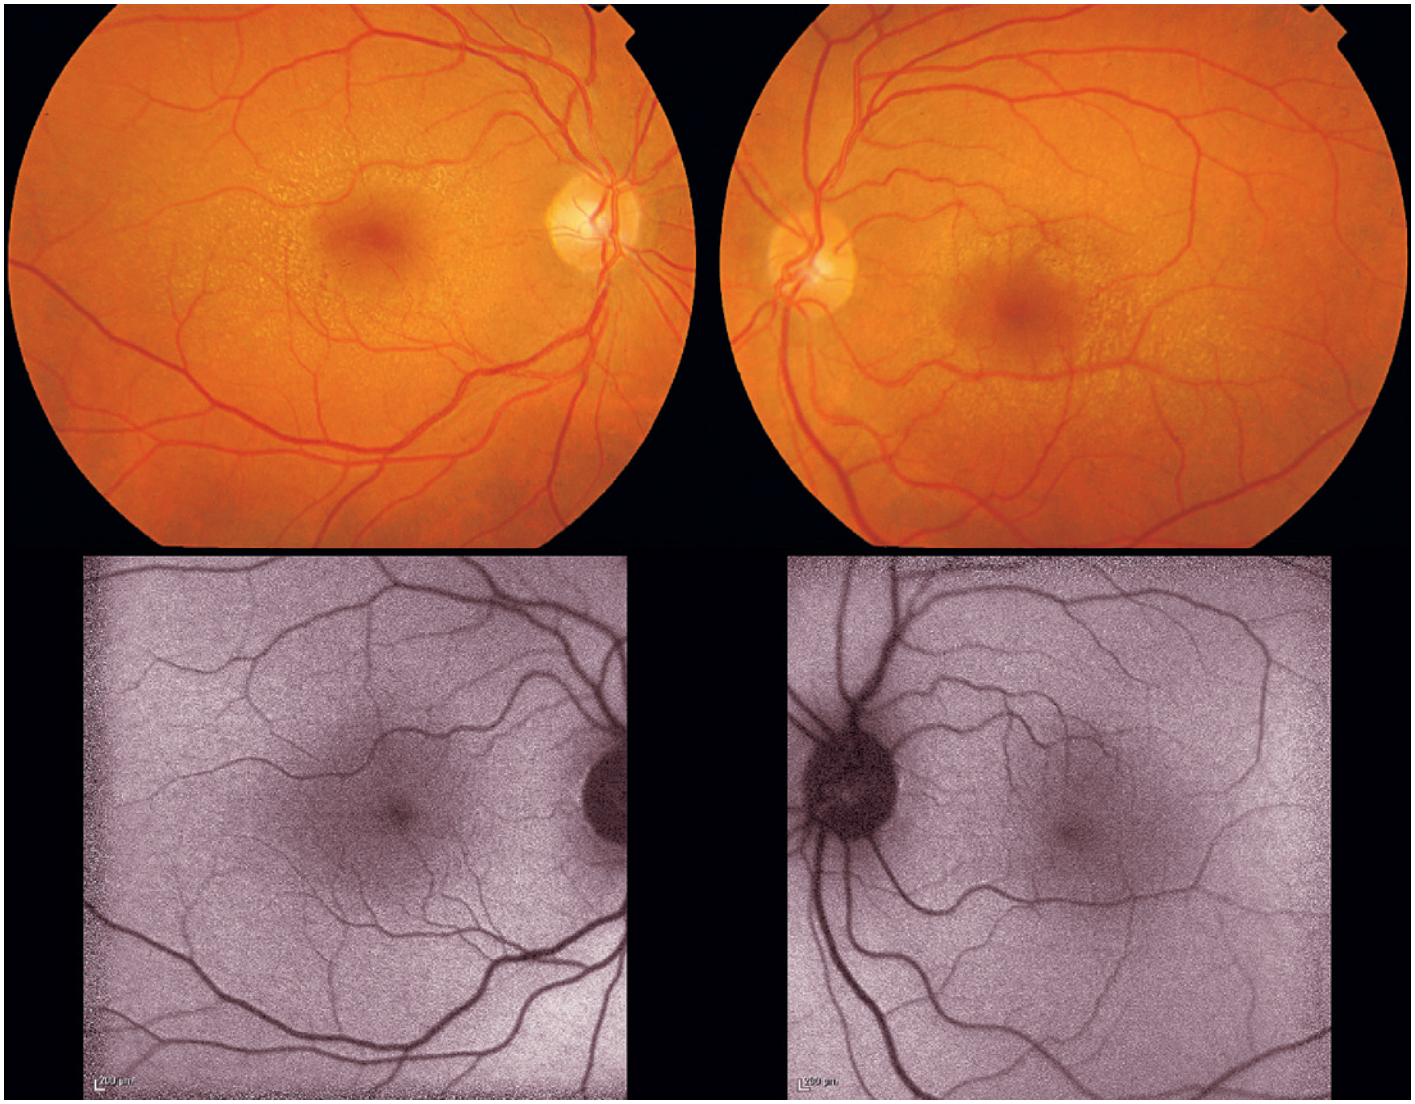

Fig. 50.9 Alport syndrome. Fundus photograph of the left and right eyes of a 28-year-old individual with Alport syndrome (top panel); fundus autofluorescence imaging (bottom panel) was normal. *(Courtesy of Professor Andrew R. Webster.)*

kidney).[191] Primary hyperoxaluria usually presents in early childhood but can occur at almost any age; it often leads to end-stage renal disease and is associated with significant morbidity and mortality.[192] A high index of suspicion and timely diagnosis are key, especially because renal transplantation alone cannot correct the abnormality (the primary metabolic defect is in the liver).[190,193]

Three different types have been described.[191] Type I hyperoxaluria, the most common and severe form, is caused by deficiency of the liver-specific peroxisomal enzyme alanine: glyoxylate aminotransferase (AGT) and has been associated with ocular abnormalities.[194,195] The main ophthalmic feature is the presence of multiple crystals deposited in the deep retinal layers. These are more numerous at the posterior pole and along the vascular arcades (Fig. 50.10).[196–199] Abnormalities of the retinal vasculature and optic disc pallor have been described in a few cases.[200,201] Over time, atrophic macular lesions may develop and patches of pigment may be observed.[201,202] Choroidal neovascularization can also be a feature of the disorder.[203]

Sjogren–Larsson syndrome

Sjogren–Larsson syndrome is an autosomal recessive neurocutaneous disorder of childhood caused by deficiency of the microsomal enzyme fatty aldehyde dehydrogenase (FALDH).[204] Clinical features include congenital ichthyosis, spastic paresis (legs more than arms), and moderate cognitive impairment.[205,206] Most affected individuals are born preterm and exhibit a characteristic crystalline, childhood-onset maculopathy; this can be accompanied by photophobia and visual acuity loss. Yellow-white glistening macular deposits (Fig. 50.11) corresponding to intraretinal spots of increased reflectivity on OCT (mainly in the perimacular ganglion cell layer and inner plexiform layer) are observed.[207] Inner retinal microcystoid spaces ("pseudocysts") at the fovea and/or parafovea may also be seen.[207–211] On FAF imaging there is increased foveal autofluorescent signal surrounded by an irregular pattern of hypoautofluorescence; this appearance is associated with a characteristic widespread congenital loss

of macular pigment.[207,212] Generalized retinal function is preserved.[213–215]

Miscellaneous reports of retinal flecks associated with syndromic eye disease

A number of other systemic disorders can give rise to yellow-white retinal lesions. They include:

1. Kjellin syndrome (recessive mutations in *SPG11* or *SPG15*)[216–219];
2. sensorineural hearing loss, dental abnormalities, and flecked retina[220];
3. flecked retina syndrome and ring chromosome 17 (Fig. 50.12)[221–223];
4. peroxisomal bifunctional enzyme complex deficiency.[224–226]

Diabetic retinopathy

Diabetic retinopathy (Fig. 51.1) is uncommon in children and is strongly correlated with the duration of diabetes mellitus and the overall long-term metabolic control (mean glycosylated hemoglobin A1c). Therefore, children and young adults with diabetes should be cared for by a multidisciplinary team including a diabetologist, pediatrician, and ophthalmologist.[1]

At this time, no definite genetic associations with diabetic retinopathy have been consistently reported. However, a genetic susceptibility to proliferative diabetic retinopathy has been suggested.[1,2]

The 25-year cumulative rate of progression of diabetic retinopathy and incidence of proliferative diabetic retinopathy was reported to be 83% and 42%, respectively, in a major study.[3] In this study, however, a lower prevalence of proliferative diabetic retinopathy was observed in more recently diagnosed persons, reflecting improvement in diabetes care. The prevalence of diabetic retinopathy seems to be decreasing; in a recent study, diabetic retinopathy was found in approximately 50% of adolescents with type 1 diabetes mellitus after a median duration of 9 years in the early 1990s, compared with only 12% in recent years.[4] This is likely due to more intensive therapy for patients with type 1 diabetes, as a result of the findings of the American Diabetes Control and Complications Trial in 2000.[5]

Longitudinal studies demonstrate clinically significant macular edema after 7 years of systemic disease, with a linear yearly cumulative risk as high as 6.7% between 10 and 20 years of duration.[6] Older age at onset of type 1 diabetes is a risk factor for macular edema.[2] The onset of puberty does not affect this significantly.[7]

Until recently, pediatric diabetes was almost exclusively the type 1 insulin-dependent form. With increasing obesity in the pediatric population, particularly in higher income countries, type 2 diabetes and insulin resistance in children and adolescents is an emerging epidemic, comprising 8–45% of all juvenile diabetes.[8] Impaired glucose tolerance was noted in 21% of obese children aged 11–18 years and 25% of obese children aged 4–10 years.[9] As the prevalence of childhood-onset type 2 diabetes increases, the number of children with diabetic retinopathy will also increase.

The majority of guidelines recommend that the first fundus examination occurs after puberty in children and adolescents with type 1 diabetes.[10] The American Diabetes Association and the American Academy of Pediatrics guidelines recommend annual eye exams for children with type 1 diabetes who are older than 10 years, starting 3–5 years after diagnosis.[11] The feasibility of using a non-mydriatic fundus camera to screen children as young as 2 years for changes related to diabetic eye disease was recently demonstrated.[12]

Sickle cell retinopathy

Hemoglobinopathies are inherited disorders characterized by hemoglobin abnormalities and diagnosed by hemoglobin electrophoresis. Sickle cell retinopathy is the most important hemoglobinopathy in children. Sickle cell disease, leads to a variety of occlusive vascular changes, both proliferative and non-proliferative, in the anterior and posterior segments of the eye.[13] Proliferative sickle cell retinopathy is characterized by the development of peripheral retinal neovascularization, eventually giving rise to a "sea fan" proliferative retinopathy (Fig. 51.2). Vitreous hemorrhage and tractional or rhegmatogenous retinal detachments may also occur.[14] Natural history studies demonstrate a high rate of autoinfarction of neovascular

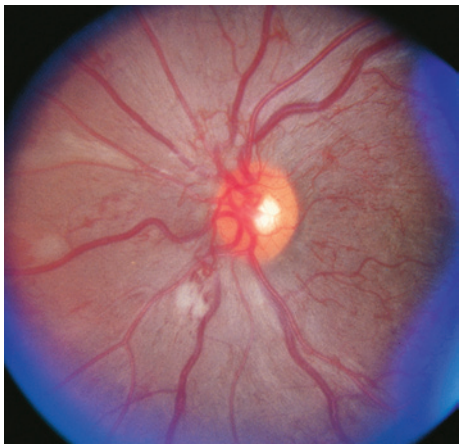

Fig. 51.1 Diabetic retinopathy. Proliferative diabetic retinopathy in a young adult. Neovascularization of the disc is present, in addition to multiple cotton-wool spots and intraretinal hemorrhages.

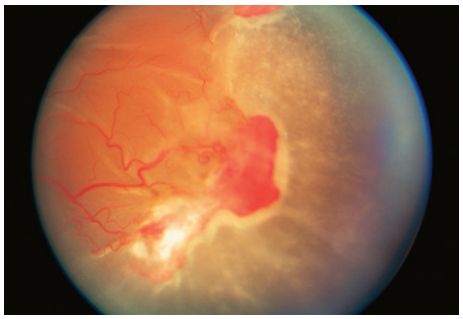

Fig. 51.2 Sickle cell retinopathy. Proliferative SC retinopathy in a young male with hemoglobin SC disease. The patient subsequently developed a tractional retinal detachment.

complexes in the absence of treatment, but selected cases require vitreoretinal surgical management to improve or stabilize vision.[15]

Suggested mechanisms for autoinfarction include feeder arteriolar occlusion, capillary occlusion, or hemodynamic alterations induced by vitreous traction.[16] Peripheral scatter photocoagulation may induce regression and reduce the risk of vitreous hemorrhage.[17]

Wide-field imaging detected peripheral vascular changes in sickle cell retinopathy that were missed on the seven-standard field photographs. Wide-field fluorescein angiography and color photography enhance the clinician's ability to visualize peripheral vascular remodeling in sickle cell disease, and to identify high-risk characteristics for proliferative sickle cell retinopathy.[18]

SC hemoglobinopathies in children with traumatic hyphema increase the risk of complications, including raised intraocular pressure as a result of aqueous outflow obstruction by sickled erythrocytes.[19] Additionally, there is an increased risk of re-bleeding in pediatric SC patients after the initial hyphema.[20]

Central retinal artery occlusion is a rare and potentially devastating complication of sickle cell disease.[21,22]

Radiation retinopathy

Radiation retinopathy in children is a delayed-onset complication of radiation exposure secondary to focal plaque (brachytherapy) or external beam treatment for retinoblastoma, orbital tumors, and, rarely, uveal melanoma.[23] Radiation retinopathy most commonly develops between 6 months and 3 years following treatment; however, retinal changes have been observed as early as 1 month following both plaque and external beam.[24] It may be progressive. Radiation induces a cascade of changes in the retinal vascular architecture, predominantly in the macula, which lead to vascular non-perfusion, leakage, and proliferation. Histologic studies demonstrate a preferential loss of vascular endothelial cells with relative sparing of the pericytes (which is a distinct contrast to the early loss of pericytes in diabetic retinopathy).[24] Besides retinopathy, radiation may lead to maculopathy, cataract, neovascular glaucoma, optic neuropathy, persistent exudative retinal detachment, and scleral necrosis.

Various host and radiation parameters determine the risk of developing radiation retinopathy. The major modifiable risk factor is the total dose of radiation.[23] More severe and extensive radiation retinopathy is associated with diabetes mellitus and the administration of chemotherapeutic agents.[25]

Focal laser photocoagulation and photodynamic therapy have been the primary treatment options; more recently anti-vascular endothelial growth factor agents and periocular or intravitreal steroids (during radiotherapy and/or postoperatively) have been shown to have some efficacy.[23,26]

Fig. 51.3 Bone marrow transplant retinopathy. Multiple cotton-wool spots and a small perifoveal hemorrhage occurring 3 months after bone marrow transplant.

Bone marrow transplant retinopathy

An ischemic retinopathy, similar to that observed with radiotherapy, is seen following bone marrow transplantation (BMT) for hematologic malignancies and aplastic anemia. The retinopathy is decreasing in prevalence as better chemotherapy makes BMT less necessary and stem cell transplants reduce immunologic complications. Retinal manifestations include capillary non-perfusion, cotton-wool spots, and intraretinal hemorrhages (Fig. 51.3).[27] The vasculopathy generally develops within 6 months of BMT, with histologic changes resembling those of early radiation retinopathy.[28] While the most common ocular complications associated with BMT are cataract and dry eye, the incidence of ischemic retinopathy and disc swelling ranges from 6.9% to 13.5%.[29,30] In a study of children undergoing bone marrow transplantation, 95.7% of eyes retained visual acuity of 20/40 or better, with poor visual outcomes associated with cytomegalovirus retinitis, a presumed sub-

macular *Nocardia* abscess, corneal ulcers secondary to dry eye syndrome, and cataracts.[30]

The pathogenesis of the retinopathy in BMT patients remains unclear, confounded by the conditioning regimens administered prior to transplantation, which typically involve total body radiation and chemotherapy, as well as agents following transplantation designed to suppress graft-versus-host disease. The chemotherapeutic agents may be directly toxic to the retinal vasculature, potentially increasing the susceptibility to retinopathy, since retinopathy develops with relatively low doses of total radiation as well as in its absence.[30,31] Atypical cases of bone marrow transplant retinopathy were recently reported.[32,33]

Retinal vasculitis

Retinal vasculitis (Fig. 51.4) in children is very rare and usually occurs in the setting of intermediate uveitis, posterior uveitis, or panuveitis.[34] The causes are: (1) infectious (e.g. toxoplasmosis, viral [human immunodeficiency virus – HIV, human T-cell lymphotropic virus type-1,[35] H1N1-influenza[36]], Candida); (2) non-infectious (e.g. collagen vascular disorders, Behçet disease,[37] multiple sclerosis,[38] idiopathic retinal vasculitis, aneurysms and neuroretinitis [IRVAN],[39] systemic lupus erythematosus, Susac syndrome[40]); and (3) isolated idiopathic (Eales disease). The diagnosis of Eales disease is made by exclusion. Although usually seen in adult males, Eales disease may occur in children.[41] It is sometimes difficult to differentiate between vasculitis and vascular occlusion. Fluorescein angiography is very helpful to show vascular leakage, cystoid macular edema, or optic disc leakage as possible signs of inflammation. However, fluorescein angiography may be difficult to perform in children. An alternative is to perform an oral angiogram, by having a child swallow pure fluorescein dye with some sweetener and taking fundus photographs 20 minutes later. The time needed for the dye to appear in the fundus after passing the gastrointestinal system is variable.

The treatment will depend on the cause and the extent of the condition; often, laser photocoagulation will be necessary to prevent bleeding from proliferative retinopathy.

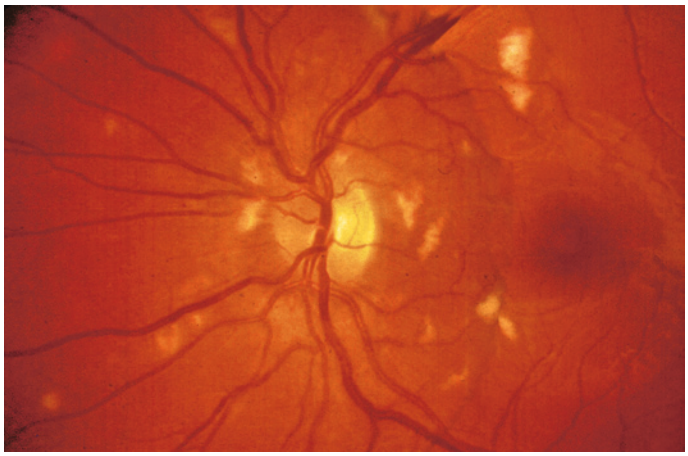

Fig. 51.4 Retinal vasculitis in a child with systemic lupus erythematosus. Shows multiple cotton-wool spots.

Frosted branch angiitis

Frosted branch angiitis is not a true diagnosis but a term that describes a form of panuveitis or posterior uveitis with retinal vasculitis and extensive perivascular exudates, causing vessels to appear white. Fluorescein angiography shows leakage from the affected vessels without occlusive vasculopathy. Venous involvement is more common than arteritis. It may be associated with a variety of causes, but in spite of an extensive work-up many cases remain "idiopathic." These idiopathic cases are often seen in healthy children or adults, especially in Japan.[42] The preceding flu-like illness may suggest a viral cause.

It may also be associated with a variety of conditions,[42] including cytomegalovirus, herpes simplex, Epstein–Barr virus, syphilis, HIV, Behçet disease,[43] immune reconstitution syndrome with Langerhans' cell histiocytosis,[44] and even after blunt trauma.[45]

In spite of the often-dramatic fundus picture (Fig. 51.5), the prognosis is said to be usually favorable with a good response to systemic steroid therapy. Intravitreal triamcinolone has been reported to successfully treat persistent macular edema after idiopathic frosted branch angiitis in an 11-month-old boy.[46]

Angioid streaks

Angioid streaks are dark or light broad lines radiating from the optic disc that have the appearance of retinal vessels, hence the name "angioid streaks." They represent cracks in a fragile and calcified Bruchs' membrane and are typically associated with pseudoxanthoma elasticum[47] (PXE; also see Chapter 50). Angioid streaks usually appear in the third decade of life and are rarely seen in teenagers (Figs 51.6 and 51.7; also see Fig. 50.8). However, angioid streaks have been reported in a 5-year-old girl with generalized arterial calcification of infancy (GACI).[48] This rare condition is caused by biallelic mutations in the *ENPP1* gene, leading to arterial stenosis from calcification of the internal elastic lamina and fibrotic myointimal proliferation of muscular arteries. The prognosis used to be poor because of severe congestive heart failure and ischemia during the neonatal period, but the outcome has improved as a result of treatment with bisphosphonates.

Other systemic conditions associated with angioid streaks in children are sickle cell disease and thalassemia. A family with optic disc drusen, mottled fundus appearance, and angioid streaks not associated with PXE has also been described.[49]

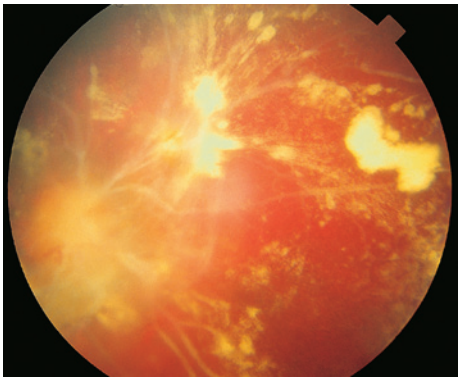

Fig. 51.5 Frosted branch angiitis. Unilateral frosted branch angiitis in a 10-year-old girl, of no known cause. Sheathed retinal vessels and subretinal exudates.

Angioid streaks are visible using fundoscopy (see Fig. 51.6), but stand out more clearly with near-infrared reflectance, fundus autofluorescence, fluorescein angiography, and the late phase of indocyanine green angiography (ICG). The streaks may be either hypo- or hyperfluorescent in the late phase of ICG. They radiate from the optic disc, sometimes with circumferential connections, and tend to increase with age. The pattern is believed to result from traction forces exerted by the extraocular muscles.

The importance of recognizing angioid streaks lies in discovering a systemic illness like PXE, but also in ophthalmological care: early detection and treatment of choroidal neovascularization (CNV) and counseling about wearing protective eyewear during contact sports (polycarbonate safety glasses). Their presence infers an increased risk of serious retinal hemorrhage from minor (blunt) trauma.[50]

The streaks, like lacquer cracks in myopia, traumatic choroidal ruptures, and peripapillary atrophy in presumed ocular histoplasmosis syndrome are believed to be a "low resistance pathway" (locus minoris resistentiae) for ingrowth of new vessels in the subretinal space. Sooner or later CNVs will occur, but fortunately the results of treatment have improved.

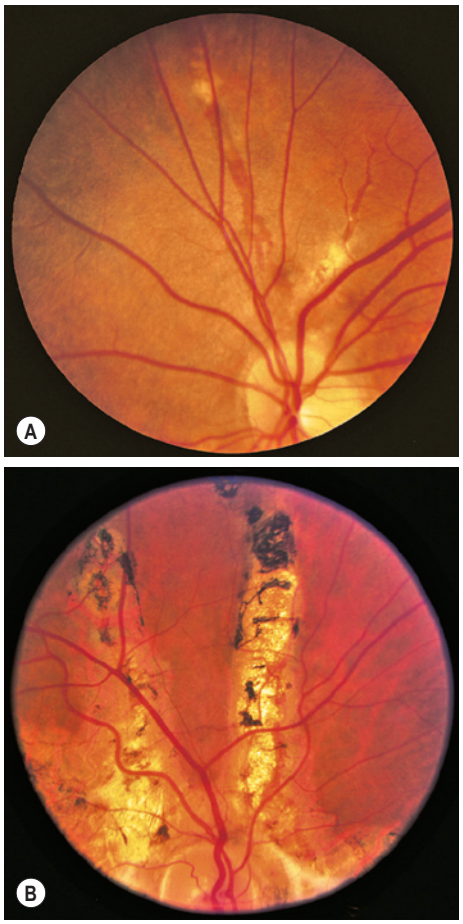

Fig. 51.6 Angioid streaks. (A) Angioid streak above the left optic disc in a 10-year-old girl with abetalipoproteinemia. (B) Marked angioid streaks in an adult with pseudoxanthoma elasticum. They taper away from the optic disc where they have formed a confluent ring around the disc. Neovascularization and hemorrhage occur at the margins of the streaks.

Idiopathic epiretinal membrane

Unlike in adults, idiopathic epiretinal membranes (Fig. 51.8) are rare in children and adolescents.[51] Epiretinal membrane formation (macular pucker, premacular gliosis, premacular fibrosis, cellophane maculopathy) diagnosed in young adults is often associated with an underlying etiology such as retinopathy of prematurity,[52] ocular trauma,[53] posterior segment inflammation,[54] combined hamartoma of the retinal pigment epithelium (RPE) and retina,[55] Coats disease,[56] and neurofibromatosis type 2.[57]

In children, an idiopathic epiretinal membrane may be secondary to vitreous hemorrhage or retinal hemorrhages.[58,59] Histopathologic studies demonstrate that epiretinal membranes consist of glial and RPE cells, with a greater proportion of myofibroblasts and collagen formation observed in the epiretinal membranes of adolescents than in the elderly.[60]

The etiology of idiopathic epiretinal formation in children and young adults remains unknown, with cases of epiretinal membranes occuring both with and without a posterior vitreous detachment.[60,61] The congenital persistence of primary vitreous has been proposed, supported by reports of epiretinal membranes in young patients with both a Mittendorf dot and a Bergmeister papilla.[62] In contrast, epiretinal membrane formation in young adults may be an acquired abnormality, with reported cases of epiretinal membrane in eyes with previous normal funduscopic examinations.[63] Optical coherence tomography (OCT) is helpful in evaluating idiopathic epiretinal membrane in children.[52,64]

Many young adults with epiretinal membranes can be followed conservatively without surgical intervention.[63,65,66] Epiretinal

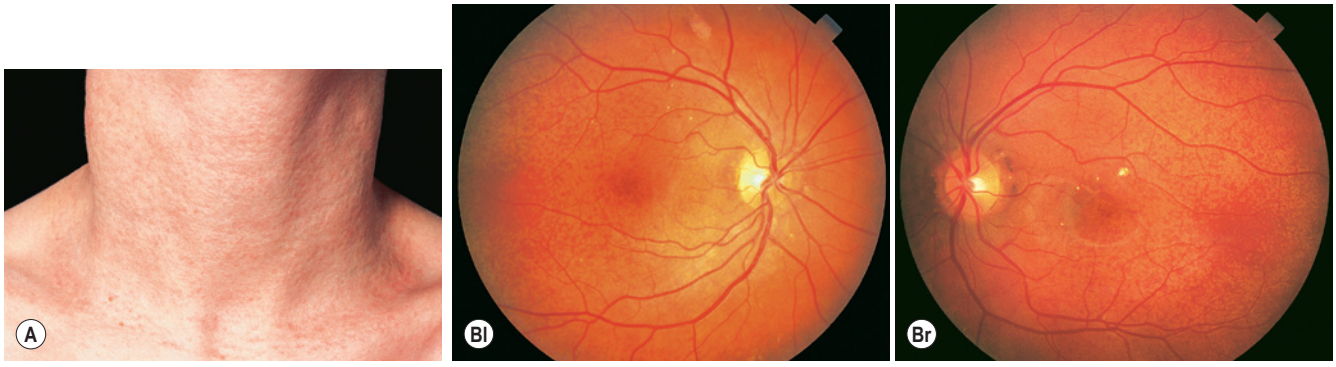

Fig. 51.7 Pseudoxanthoma elasticum (PXE). (A) The skin lesions of PXE consist of small, yellowish bumps in rows or a lacy pattern, which may join to make large patches. The skin is soft, lax, and slightly wrinkled or pebbly in appearance, which has been described as cobblestoned. The neck is often affected. (B) A 14-year-old child with PXE. "Peau d'orange" pigment speckling in the retinal pigment epithelium (RPE) at the posterior pole, yellow deposits in the RPE in both eyes, and angioid streaks at 12 and 6 o'clock in the right eye (Br) and 3 o'clock in the left (Bl).

Surgical management of epiretinal membrane in young patients. Am J Ophthalmol 2002; 133: 358–64.)*

membranes in young adults tend to be thicker, whiter, more adherent, and associated with a higher recurrence rate than in adults, particularly when overlying retinal blood vessels.[67] Spontaneous separation of idiopathic epiretinal membrane in young patients, even in the absence of a posterior vitreous detachment, has been reported.[58,68,69] When the contracting forces of the immature idiopathic epiretinal membrane are stronger than its adhesions to the retina, the membrane may separate spontaneously. Banach et al.[70] reported that patients with a visual acuity of 20/50 or better have favorable outcomes with observation alone, while patients with 20/60 or worse vision had significant improvement following vitrectomy and membrane peeling. In cases in which spontaneous peeling occurs, long-term follow-up is warranted until posterior vitreous detachment is complete, as delayed cases of macular hole have been reported.[71]

Lipemia retinalis

Lipemia retinalis – white retinal vessels filled with a creamy content (Fig. 51.9) – is an impressive but extremely rare ocular manifestation of hypertriglyceridemia. It is quite unusual in children, but may occur even in neonates[72] as a result of primary hypertriglyceridemia (not hypercholesterolemia!) in patients with lipoprotein lipase (LPL) deficiency. A transient LPL deficiency has been described in a premature male infant with extremely low birth weight.[73] Secondary hyperlipidemia has

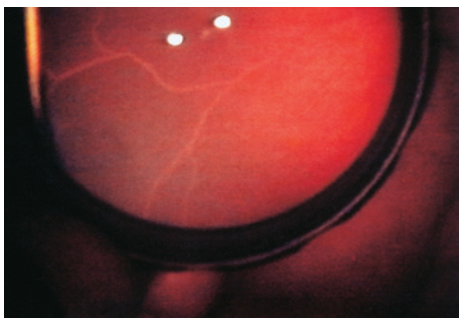

Fig. 51.9 Lipemia retinalis. Indirect ophthalmoscopic view of the retinal vessels, which stand out pale against the background, in a child with hyperchylomicronemia.

been associated with diabetes mellitus,[74,75] biliary obstruction, nephrotic syndrome, pancreatitis, hypothyroidism, alcoholism, medications (estrogens, beta-blockers, protease inhibitors), and in a patient with acquired immunodeficiency syndrome treated with protease inhibitors.[76]

With serum triglyceride levels above 2500 mg/dl (normal <200 mg/dl), the peripheral retinal vessels appear creamy and thin, and above 5000 mg/dl the fundus becomes salmon colored with creamy arteries and veins in the posterior pole.

The visual acuity usually remains unaffected, but electrophysiological abnormalities (reduced scotopic and photopic amplitudes, reduced Arden ratio with electro-oculography)

have been observed in an 11-year-old girl with diabetes.[75] Treatment of the underlying condition is mandatory, of course, and results in normalization of the fundus picture and the electroretinogram (ERG).

Cystoid macular edema

Macular cystoid structures may be seen in 39% of neonates undergoing screening for retinopathy of prematurity (ROP).[77] Cystoid macular edema (CME) has been reported to be common in premature infants independent of ROP. It may serve as an indicator of neurodevelopmental health for very preterm infants.[78,79] CME may occur in children with chronic ocular inflammation, retinitis pigmentosa, diabetes, radiation, Coats disease, X-linked retinoschisis, and autosomal dominantly inherited cystoid macular edema. In X-linked juvenile retinoschisis and enhanced S-cone syndrome it is not true CME, but rather foveal schisis without leakage on fluorescein angiography. CME is a common complication in children with uveitis and can be present even with good visual acuity.[80]

Serial spectral-domain OCT before and up to 12 months after cataract surgery demonstrated no cystoid macular edema in a pediatric patients cohort of 3 years and older.[81] Explanations for the lower incidence of postoperative CME in children than adults include a healthier vitreous body and vasculature, a lack of systemic disease, and possible differences in prostaglandin physiology.[82]

Choroidal neovascularization

CNV (Fig. 51.10) is quite rare in children and adolescents. It may be associated with a range of conditions as outlined in Box 51.1, including (1) scars of intraocular inflammation and infection[83]; (2) dystrophies (like Best disease or, very rarely, hyperoxaluria); or (3) weak anatomic spots between the retina and choroid (the so-called locus minoris resistentiae [see above], e.g. choroidal ruptures, dysplastic optic discs and optic disc drusen, angioid streaks, choroidal osteoma and choroidal coloboma). Often, no cause is found and the CNV is said to be idiopathic.[83,84] Later on, signs of presumed ocular histoplasmosis syndrome (POHS) may subsequently develop.

Fig. 51.10 Choroidal neovascularization. This 7-year-old with congenital rubella had a congenital cataract in the left eye and noted a reduction in the vision in the right eye. Background pigment mottling is present as well as serous detachment and a disciform lesion. The acuity fell to 6/60 but recovered to 6/12 over 4 months.

Children may complain of metamorphopsia and blurred vision, but often they do not inform their caretakers of any trouble. Fundus findings may include a dark gray membrane, subretinal or intraretinal hemorrhage, hard exudates, and pigmentary changes, most commonly in the macula or peripapillary region.

CNV in children has a more favorable prognosis than in adults with age-related macular degeneration. Goshorn et al.[83] reported spontaneous involution of CNV in 11 of 19 (58%) untreated eyes in children; nine patients achieved visual acuity better than or equal to 20/50. Laser photocoagulation, photodynamic therapy with verteporfin,[85] and submacular surgery[86] have been employed successfully. However, anti-vascular endothelial growth factor (anti-VEGF) agents[87,88] intravitreal injections, with or without corticosteroids, are the preferred treatment option, although the long-term effects of suppressing VEGF in children is uncertain.[89]

Chronic granulomatous disease

Chronic granulomatous disease (CGD) is a hereditary immunodeficiency disorder caused by a defect in the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex that causes dysfunction of phagocytes, making these patients more prone to severe infections including sepsis. Uncontrolled inflammation may also occur in various organs including the gastrointestinal tract, the bladder, the skin, and the eye.[90] The condition is very rare, with an incidence between 1 : 200,000 and 1 : 250,000 and occurs as an X-linked form (mutation in *CYBB* gene) in about two-thirds of cases and several autosomal recessive forms in the remainder. Several therapeutic strategies are under investigation including: anti-tumor necrosis alpha (anti-TNF-α) agents, hematopoietic stem cell transplants, and gene therapy. Eye involvement may consist of blepharitis, conjunctivitis, and chorioretinitis in

about one-third of patients.[91,92] Severe atrophic scarring may ensue as can be seen in Figure 51.11. Bad outcome may occur secondary to complications like retinal ischemia, neovascular membranes, subretinal fibrosis, and macular edema.[91,92]

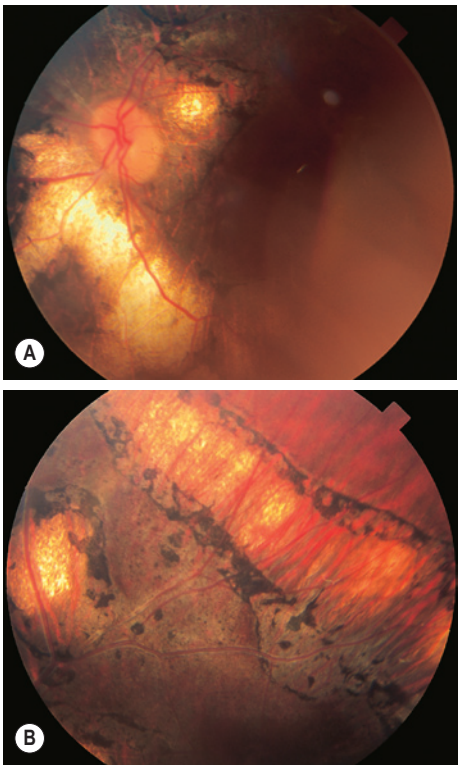

Fig. 51.11 Chronic granulomatous disease. (A) Chorioretinal atrophy and pigment clumping in the retinal arcades. (B) Linear peripheral chorioretinal atrophy and pigment clumping.

Juvenile X-linked retinoschisis

Juvenile retinoschisis (XLRS) is an X-linked condition without any symptoms in female carriers. The presentation can be quite characteristic, almost pathognomonic, with low vision in a young male due to foveal schisis (Fig. 51.12), with additionally peripheral retinoschisis (present in about half of the cases), golden reflexes seen with fundoscopy in the periphery, an electronegative ERG, often associated with a visually handicapped maternal uncle or grandfather. The diagnosis is confirmed with DNA investigation and the finding of a causative mutation in the *RS1* gene on the short arm of the X-chromosome. The gene product, retinoschisin, is implicated in cell adhesion and the development of the inner retina, but the function is still not precisely understood.[93] About 200 different mutations have been described with no clear genotype–phenotype correlation.[94] The condition is almost as frequent as Stargardt disease with a prevalence of 1 : 15,000 males.[95] However, misdiagnoses often occur, as the presentation may be quite variable (Fig. 51.13), with falciform folds, toxoplasmosis-like scars, ectopic maculae, gliotic maculopathy in adult or elderly males, a

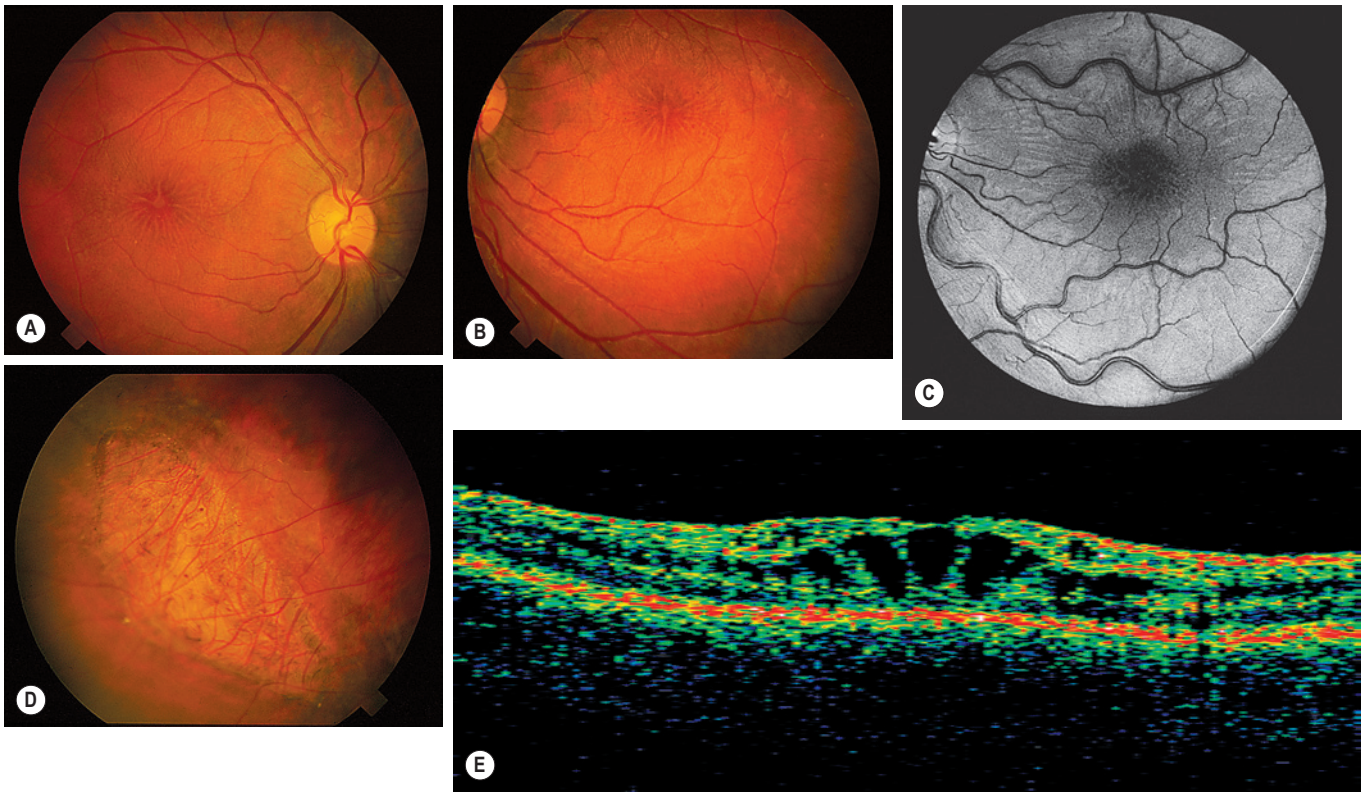

Fig. 51.12 Juvenile X-linked retinoschisis. (A,B) Bilateral foveal schisis. (C) The foveal schisis is best seen with ophthalmoscopy using a red free light. Fig. 51.13 Juvenile X-linked retinoschisis. Fundus appearance after a bullous retinoschisis cyst involving the macula has resolved, leaving a flat retina with a pigment demarcation line.

fundus albipunctatus-like appearance, widespread pigmentations similar to retinitis pigmentosa, exudative Coats-like abnormalities, and even atypical glaucoma or buphthalmus. Hyperopia, strabismus, nystagmus and (additional) amblyopia are often present.

Vitreous hemorrhage often occurs, especially when peripheral schisis is present and the retinal vessels lack support. This may lead to deprivation amblyopia in young children in whom surgical intervention may result in cataract formation. Retinal detachment, although feared, is relatively uncommon. Nonetheless, it is important to warn the parents about the vulnerability of these eyes and advise protective eyewear during sports and outside activities.

With the new imaging techniques, especially OCT, the cystic maculopathy is less easily missed. However, OCT has also shown that the typical maculopathy may be absent even in DNA-proven cases[96]!

Treatment with dorzolamide drops may reduce foveal cysts in some patients but the effect on visual acuity seems to be modest.[97] Proof of principle of gene therapy in a mouse model of XRS has been established,[93] and gene therapy in humans is now being performed at two sites in the USA (see NCT02416622 and NCT02317887 at www.ClinicalTrials.gov).

Laser pointer maculopathy

In the late 1990s, concerns about retinal damage from laser pointers were raised in the media but there was no convincing evidence of retinal damage.[98,99] Case reports of visual disturbances, without maculopathy, were reported due to afterimage or psychogenic effects. Although the American laser classification differs from that in Europe, laser pointers emitting visible radiation with an upper power limit of 5 mW are designated as class 1 or 2 and are regarded as safe if used properly as a pointing device.

However, the introduction of more powerful laser pointers and the easy availability of these on the Internet has led to renewed concerns about possible retinal damage. A recent PubMed literature search of proven laser pointer maculopathy (Fig. 51.14) revealed 15 cases.[100] These were more commonly caused by green rather than red laser pointers and mainly affected teenagers who used the laser pointer inappropriately as a toy.[100,101] In one case, the output of the involved laser pointer could be measured and was reported to be unsafe due to a high output (150 mW).[101] Laser pointers are not designed to be children's toys, popping balloons as a party trick. Neither should they be used to annoy people in a crowd as hooligans did during the 2015 Union of European Football Associations

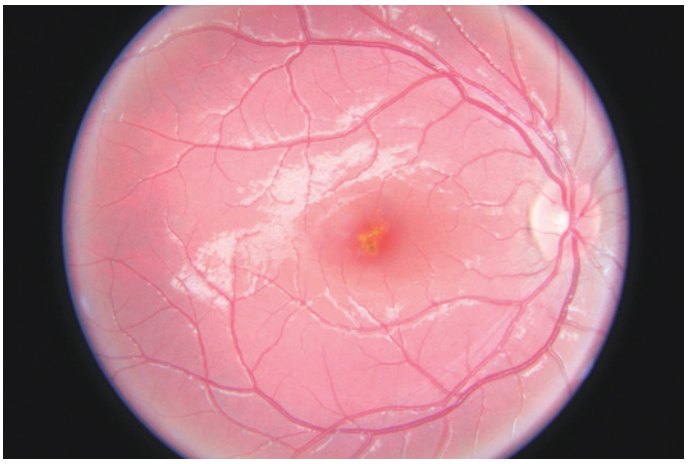

Fig. 51.14 Laser pointer maculopathy. Fundus of the right eye with a scar in the center of the macula.

(UEFA) Champions League. A drastic increase in instances of laser pointers aimed at aircrafts was reported in 2011 by the Federal Aviation Administration's Civil Aerospace Medical Institute, distracting pilots during their flight.[102] Unfortunately, the regulation and control of laser pointer sales do not fully apply in many countries. Green laser pointers of up to 1200 mW, which are very likely to be harmful to the retina if misused, can be easily ordered through on the Internet. Only very attentive custom declaration officers might stop the illegal import of such dangerous devices. The widespread availability of unsafe laser pointers, and consequently increased laser pointer-induced visual loss and increased risk for aviation incidents, raises an important social issue for health authorities and government officials.

Retinal detachment in childhood

Martin P Snead

Chapter contents

RHEGMATOGENOUS RETINAL DETACHMENT ASSOCIATED WITH TRAUMA
RHEGMATOGENOUS RETINAL DETACHMENT ASSOCIATED WITH DEVELOPMENTAL ABNORMALITY
RHEGMATOGENOUS RETINAL DETACHMENT ASSOCIATED WITH INHERITED VITREORETINOPATHIES
SURGICAL CONSIDERATIONS IN PEDIATRIC RHEGMATOGENOUS RETINAL DETACHMENT
REFERENCES

Rhegmatogenous retinal detachment (RRD) is uncommon in childhood but the prognosis is often poor due to aggressive proliferative vitreoretinopathy (PVR) and late presentation with or without second eye involvement at the time of diagnosis. The majority of cases of RRD in childhood are associated with inherited vitreoretinopathies and developmental abnormalities, with trauma making up the remainder.

Rhegmatogenous retinal detachment associated with trauma

Traumatic retinal detachment is seen mostly in older children, usually caused by blunt trauma where retinal tears may be found in 2–5%.[1] Penetrating injuries and retained intraocular foreign bodies are less common causes[2,3] but are frequently associated with severe PVR.

Blunt ocular trauma

Retinal dialysis

Retinal detachment due to blunt trauma is usually caused by a disinsertion at the ora serrata in older children. Sudden anteroposterior compression of the globe with a violent coronal expansion leads to retinal avulsion (Fig. 52.1A) characterized by a festoon of non-pigmented pars planar epithelium in the vitreous cavity. This is the hallmark of traumatic retinal dialysis. There may be signs of related orbital injury (Fig. 52.2) or, more frequently, subtle signs of collateral trauma to the iris, lens, or drainage angle. Superior quadrant involvement (Fig. 52.3) is more frequent than the lower temporal quadrant involvement seen in non-traumatic dialysis (Fig. 52.1B). Although the disinsertion may exceed 90° and resemble a giant retinal tear, the vitreous characteristically remains attached to the posterior flap so that independent mobility is not a feature. Dialyses, therefore, respond very well to conventional scleral buckling techniques. Further distinguishing features are the absence of radial extensions, which frequently occur at the apices of "true" giant retinal tears (GRTs) (Fig. 52.4) and the normal compact healthy vitreous architecture. Subretinal fluid recruitment in dialyses is typically slow, so that unless the ora serrata is routinely inspected after blunt trauma, the diagnosis may be delayed by weeks or months until macular involvement.[3]

Ragged impact necrosis breaks account for about one-fifth of the retinal breaks in blunt trauma.[3] Retinal vessel and retinal pigment epithelial (RPE) disruption may be confirmed on fundus fluorescein angiography, and retinal detachment usually presents within 6 weeks.[3] These breaks are often large, post-equatorial, and irregular, making closure by external buckling problematic. An internal approach is frequently required.

Giant retinal tears

True GRTs account for a minority of retinal breaks due to blunt trauma.[4] They are best managed with vitrectomy and internal tamponade (see below), although the visual prognosis may be limited by associated collateral ocular trauma.[5]

Penetrating ocular trauma

Penetrating injury is an uncommon cause of retinal detachment in childhood and may rarely follow inadvertent perforation of the globe at strabismus surgery. Intraocular foreign bodies are rarely seen in very young children, although penetrating injuries from air-gun pellets may be seen in older children and adolescents, usually with a poor prognosis because of the associated damage and aggressive PVR. Retinal perforation or incarceration from penetrating trauma rarely causes acute rhegmatogenous retinal detachment. The corneoscleral wound provides access for extrinsic fibroblasts, often leading to late tractional and rhegmatogenous retinal detachment.[5]

Non-traumatic retinal dialysis

Non-traumatic retinal dialysis accounts for approximately 10% of all juvenile retinal detachments[2,4] and in 97% affects the inferotemporal quadrant (Table 52.1 and see Fig. 52.1B). Examination of the entire retinal periphery may reveal two or

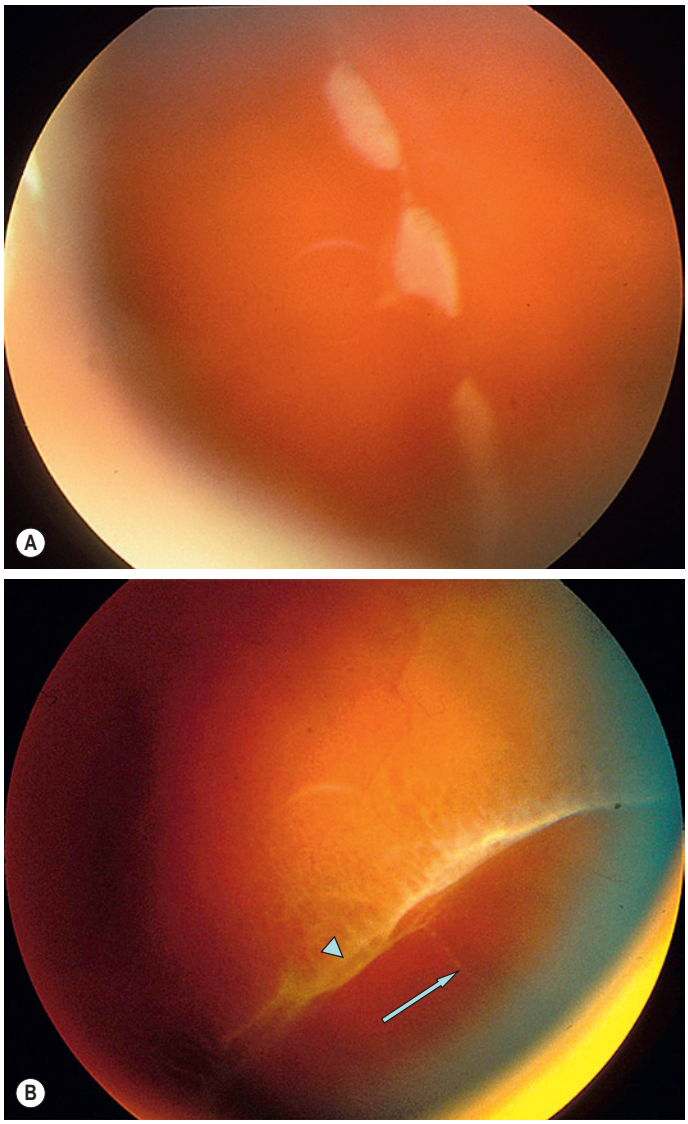

Fig. 52.1 Retinal dialysis. (A) Traumatic 180° "bucket handle" avulsion non-pigmented pars planar epithelium from patient in Fig. 52.2. (B) Non-traumatic retinal dialysis. Note characteristic associated cystic oral frill (arrowhead) and trans-dialysis tissue bridges (arrow).

Table 52.1 Cambridge guide to characteristic retinal break types in rhegmatogenous retinal detachment

The more common pediatric subgroups are highlighted in yellow.

Break type	Sex	PHM	Refractive error	Fellow eye pathology
Horseshoe tear	M=F	OFF	Myopic	15%
Round hole	F>M	ON	Myopic	50%
Dialysis	M>F	ON	Hypermetropic	15%
Giant retinal tear	M=F	OFF	Myopic	Up to 80%
Macular hole	M=F	OFF	Highly myopic	Rare
XLRS	M	ON	Hyperopic	100%

PHM, Posterior hyaloid membrane; XLRS, X-linked retinoschisis.

more separate dialyses in the same eye. There is a 2:3 male preponderance. The majority of patients are hypermetropic or emmetropic.[6,7] Detachments associated with dialyses progress slowly and often present either as an incidental finding or when the macula becomes detached. They are routinely managed with conventional buckling. Although the anatomic success rate of surgery is high, visual acuity may remain poor if there has been chronic macular involvement. Familial dialyses are rare, but consideration should be given to sibling examination because: (1) the patients are asymptomatic and (2) visual recovery once macular involvement has occurred may be poor. Examination of the fellow eye under anesthesia is important as retinal dialysis may be bilateral and abnormalities of the ora serrata, in the form of a "frill" or flat dialysis, are found in the fellow eye in up to 15% (see Table 52.1). In such cases, prophylactic retinopexy can be applied to the fellow eye to avert detachment with potential macular involvement requiring formal repair.

Rhegmatogenous retinal detachment associated with developmental abnormality

Ocular coloboma

Eyes with colobomas are at increased risk of detachment and account for approximately 0.5% of pediatric retinal detachments,[8,9] forming part of the spectrum of wider systemic developmental abnormality (Fig. 52.5). GRTs are seen with lens colobomas.[10] Rhegmatogenous detachment may develop in eyes with choroidal coloboma, when small retinal breaks develop in the hypoplastic retina overlying the coloboma. Assessment of vision can be difficult and the diagnosis of detachment can be further impaired by restricted pupil dilation, nystagmus, microphthalmos, and cataract (Fig. 52.6). The intercalary membrane stretched across the coloboma cavity can simulate a retinal detachment on ultrasound examination. The clinician should be alert to this and assess the retinal mobility on dynamic examination before surgery. The intercalary membrane consists of hypoplastic inner retina with reversal and duplication of outer neuroblastic layers at the coloboma margin.[11] Since both retinal pigment epithelium and Müller cells are vestigial or absent within the coloboma, effective retinopexy may be impossible unless applied outside the margin.

When retinal breaks occur away from the coloboma, they may be managed by conventional buckling provided the sclera is of sufficient quality and the break can be adequately closed. More usually, the retinal break lies within the coloboma (Fig. 52.7) so that identification and closure with retinopexy may be impossible without an internal approach. Retinal breaks over a coloboma are often small, multiple, and difficult to localize against the pale scleral background, but may be confirmed intraoperatively by the visualization of proteinaceous "schlieren" during internal drainage. Laser may be applied around the border of the colobomatous area. If this includes the papillomacular bundle it may be applied prior to retinal re-attachment to minimize the risk of thermal damage to the nerve fiber layer. Maintenance of tamponade whilst the retinopexy matures to full strength can be compromised by the abnormal configuration of the colobomatous globe and recurrent detachment occurs in up to 30%,[12] which may then require permanent internal tamponade.

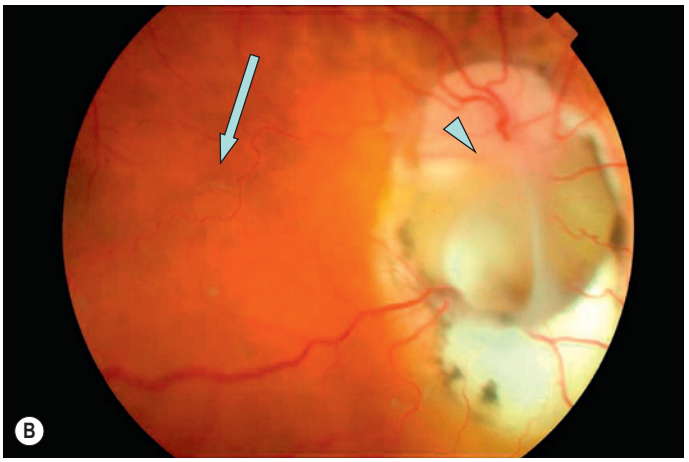

Fig. 52.5 Optic disc coloboma (arrowhead) associated with macula-off retinal detachment (arrow) in CHARGE syndrome. *(© Addenbrooke's Hospital.)*

Optic disc pits and macular detachment

The association of serous macular detachment and optic disc pits and coloboma is well recognized, and similar findings with the morning glory disc abnormality suggest that these conditions are variations of the same abnormality (Fig. 52.8A–D). The vitreous is characteristically attached. It has been suggested that up to 45% of optic disc pits may be complicated by serous retinal detachment.[13–15]

Although natural history studies have shown eventual spontaneous re-attachment in 25% of cases,[14] the combination of vitrectomy, laser photocoagulation, and gas tamponade may offer a greater chance of visual improvement, albeit with a risk of operative morbidity.[13,15]

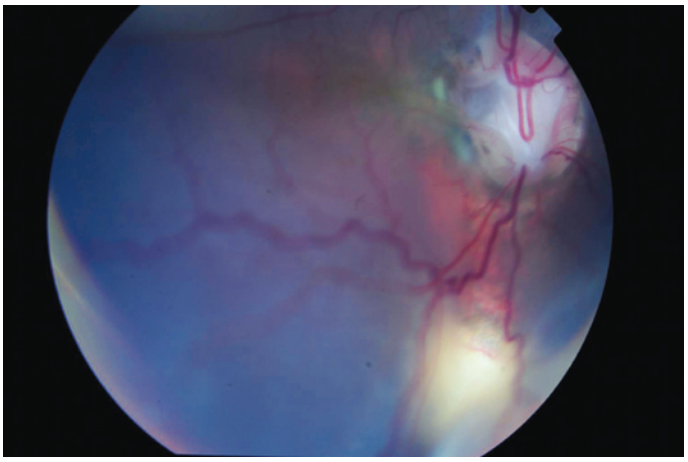

Fig. 52.7 Rhegmatogenous retinal detachment complicating coloboma in a 9-year-old boy. Retinal breaks may be difficult to identify preoperatively, but visualization of schlieren during vitrectomy can assist localization.

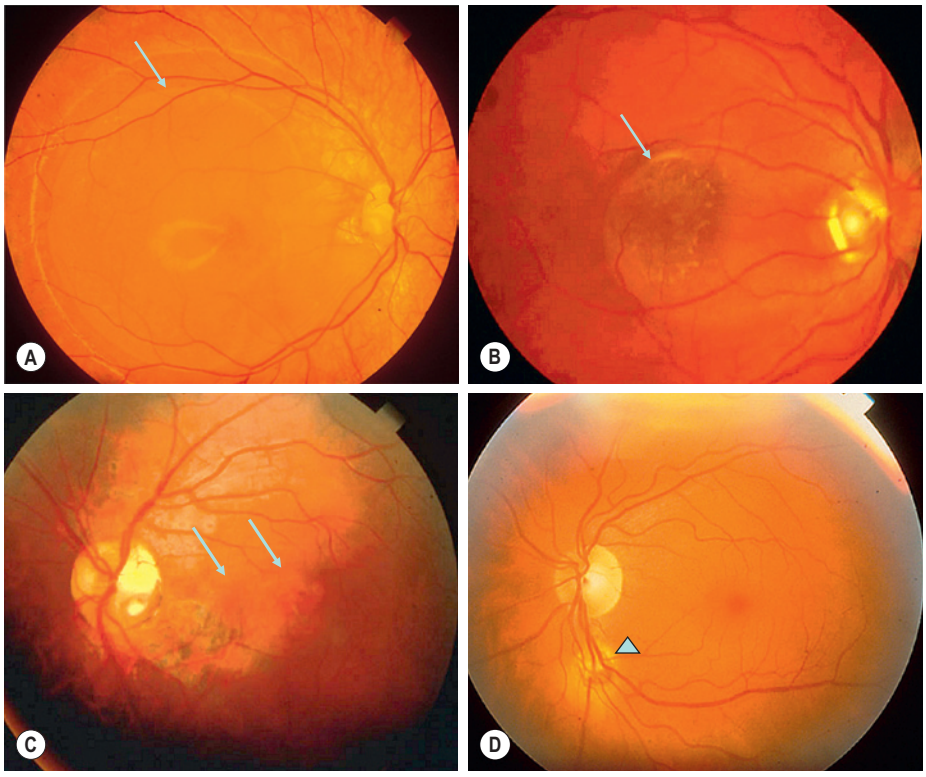

Fig. 52.8 (A,B) Two examples of optic disc colobomas associated with macular detachment (arrows). (C,D) child [optic disc pit with serous macular detachment (arrows)] and parent [choroidal coloboma (arrowhead)], respectively, illustrating inherited etiology in some cases.

Rhegmatogenous retinal detachment associated with inherited vitreoretinopathies

Inherited vitreoretinopathies are the basis for the majority of rhegmatogenous retinal detachments in childhood and may be classified as follows[16]:

1. vitreoretinopathies with skeletal abnormalities;
2. vitreoretinopathies with progressive retinal dysfunction;
3. vitreoretinopathies with abnormal retinal vasculature;
4. vitreoretinopathy with corneal changes.

The detachments are often complex and frequently associated with GRTs.

Vitreoretinopathies with skeletal abnormalities

Vitreoretinopathies associated with skeletal abnormalities are the largest subgroup (Table 52.2). The various forms of the Stickler syndromes account for the majority of these.

Table 52.2 Vitreoretinopathies associated with skeletal abnormalities

Syndrome	Gene	Distinguishing features	MIM #
STICKLER SYNDROME			
Type 1	*COL2A1*	Membranous congenital vitreous anomaly, congenital megalophthalmos, deafness, arthropathy, cleft palate	108300
Ocular only	*COL2A1*	Membranous congenital vitreous anomaly (usually), congenital megalophthalmos. No systemic features	609508
Type 2	*COL11A1*	Beaded congenital vitreous anomaly, congenital megalophthalmos, deafness, arthropathy, cleft palate	604841
Type 2 recessive	*COL11A1*	Autosomal recessive; beaded congenital vitreous anomaly, congenital megalophthalmos, cleft palate, profound severe congenital deafness	TBC
Type 3	*COL11A2*	Normal vitreous and ocular phenotype, deafness, arthropathy, cleft palate	184840
Type 4	*COL9A1*	Recessive inheritance; sensorineural deafness, myopia, vitreoretinopathy, epiphyseal dysplasia	614134
Type 5	*COL9A2*	Recessive inheritance; sensorineural deafness, myopia, vitreoretinopathy, epiphyseal dysplasia	614284
Type 6	*COL9A3*	Recessive inheritance; sensorineural deafness, myopia, vitreoretinopathy, epiphyseal dysplasia	TBC
Other	Unknown	Hypoplastic vitreous, deafness, arthropathy, cleft palate	Not assigned
KNEIST DYSPLASIA			
	COL2A1	Congenital vitreous anomaly, severe arthropathy, short stature, phalangeal dysplasia	156550

SEDC, Spondyloepiphyseal dysplasia congenita; V-PED, vitreoretinopathy with phalangeal epiphyseal dysplasia.

The Stickler syndromes

The Stickler syndromes form part of the spectrum of type II/IX/XI collagenopathies, which include Kniest dysplasia (MIM #156550) and spondyloepiphyseal dysplasia congenita (SEDC, MIM #183900). So far, at least eight clinically different subgroups have been identified (see Table 52.2) and further genetic heterogeneity remains to be resolved.

The majority of cases are type 1 Stickler syndrome, inherited in an autosomal dominant fashion. However, a significant minority results from *de novo* mutations with no family history. Furthermore, there are "ocular-only" variants, which have few, if any, systemic features to suggest the possible diagnosis.[17] The clinician should be alert to this possibility and the need to consider and/or exclude the diagnosis in all cases of pediatric giant retinal tear detachment.

Diagnosis

Before routine molecular genetic analysis, diagnosis was wholly reliant on the combination of major and minor clinical criteria.[18] The assignment of clinical phenotype still assists substantially in directing molecular genetic analysis (Fig. 52.9).[17,19–26]

Clinical features

Ocular features The fundamental feature of Stickler syndrome is a congenital abnormality in vitreous development, which manifests as an abnormal architecture visible on slit-lamp examination (see Fig. 52.9). This pathognomonic feature is especially important for the clinical diagnosis of the ocular-only subgroups, which have no systemic features to suggest the diagnosis.[17] The majority of patients presenting to an ophthalmologist will have either type 1 or type 2 Stickler syndrome and are frequently myopic.[16] Autosomal recessive Stickler syndrome due to mutations in type IX collagen is rare (see Table 52.2).

There is usually high myopia, which is congenital and often associated with significant astigmatism (Fig. 52.10). However, in some series, almost a quarter of patients have no significant refractive error. The association with congenital cataract is well recognized, and some patients exhibit a characteristic quadrantic lamellar cortical lens opacity, which can be a very useful diagnostic sign (Fig. 52.11). It does not, however, differentiate between subgroups, being present in both type 1 and type 2 Stickler syndrome.

In the UK and USA, over 50% of patients with a clinical diagnosis of one of the Stickler syndromes will develop retinal

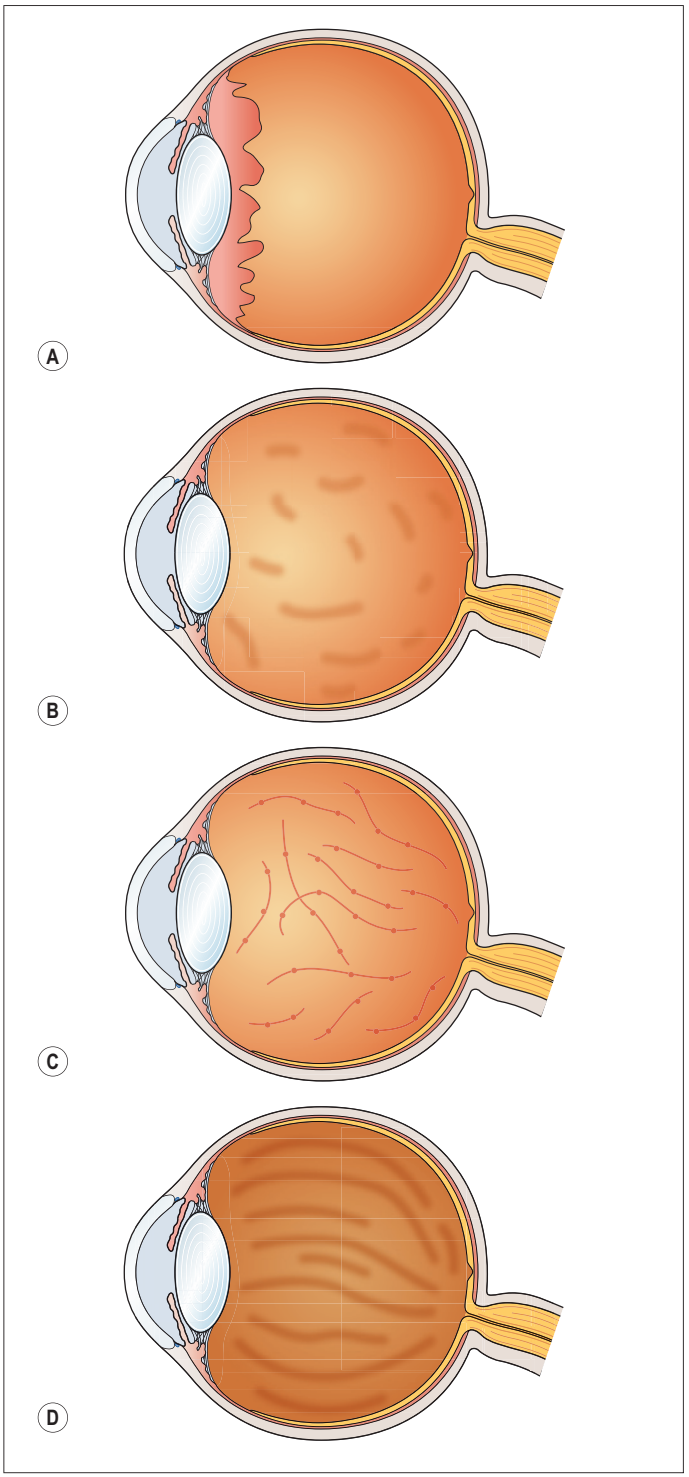

Fig. 52.9 Schematic illustration of vitreous phenotypes in Stickler syndrome. (A) Membranous congenital vitreous anomaly (haploinsufficiency mutations of *COL2A1*). (B) Hypoplastic congenital vitreous anomaly (*COL2A1* splicing mutations). (C) Beaded congenital vitreous anomaly (*COL11A1*-dominant negative mutations). (D) Normal vitreous architecture: compact lamellar array (*COL11A2* mutations).

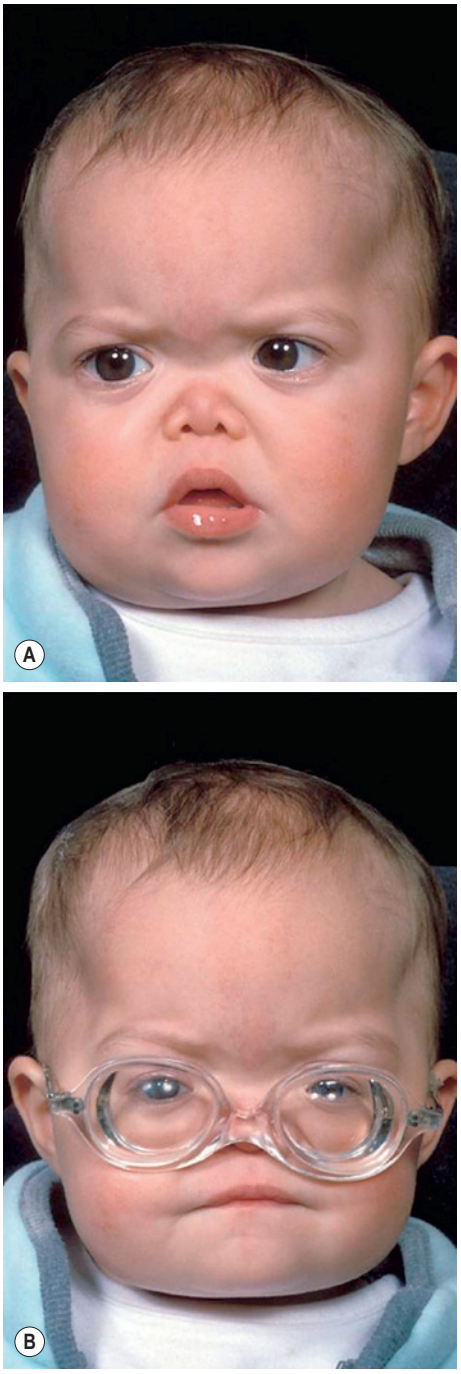

Fig. 52.10 Stickler syndrome. Marked nasal hypoplasia (A) and congenital high myopia (B) revealed under cycloplegic refraction.

detachment.[27] However, in the genetically confirmed high-risk subgroup, this figure rises to over 70%.[28,29] In a recent study, the median interval between retinal detachment in the first eye and retinal detachment in the second eye was 4 years[29] and, although rare before 1½ years of age, the youngest child with bilateral retinal detachment was 6 weeks of age, with a further case of bilateral total retinal detachment before 1 year of age. The risk of retinal detachment in type 2 Stickler syndrome appears to be slightly lower but remains to be quantified; surveys suggest that between 40% to 50% of patients had suffered retinal detachment. In the non-ocular subgroup (type 3), the risk appears to be no greater than the average population.

Systemic features All subgroups of Stickler syndrome may exhibit abnormalities of the hard or soft palate that are frequently associated with eustachian tube dysfunction and

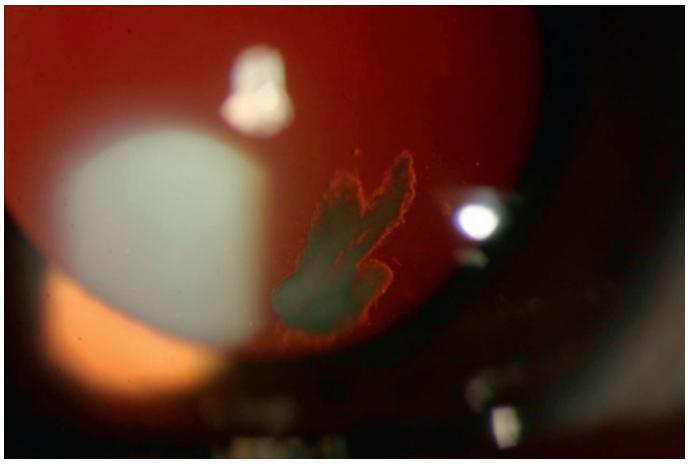

Fig. 52.11 Classic quadrantic lamellar cataract found in both type 1 and type 2 subgroups of Stickler syndrome.

middle ear impairment. In those patients without a history of palate repair, direct examination and palpation will help identify those with subclinical clefts – an easily overlooked diagnostic sign. In addition to conductive hearing impairment, many patients also exhibit a subtle, subclinical high-tone sensorineural hearing defect due to cochlear abnormalities.

Over 80% of children with Stickler syndrome report musculoskeletal symptoms, and joint hypermobility is common (Fig. 52.12). Patients are occasionally given an erroneous diagnosis of Perthe's disease, as the appearances can be similar radiologically. It is also common for adolescent Stickler syndrome patients to receive a diagnosis of Osgood–Schlatter disease, but since this is a clinical rather than a radiologic diagnosis, the true nature of this association remains to be clarified.

Kniest dysplasia (MIM #156550)

Kniest dysplasia is an autosomal dominant disorder that shares many similarities with Stickler syndrome and the same genetic locus. Mutations are found in the same gene as for type 1 Stickler syndrome (*COL2A1*), but result in dominant-negative effects rather than haploinsufficiency, resulting in more severe arthropathy.[30] It typically presents at birth with shortened trunk and limbs, congenital megalophthalmos, and flattened nasal bridge (Fig. 52.13A,B). The joints are often large at birth and the fingers long and knobbly. Motor milestones can be delayed by joint deformities, and disuse muscle atrophy may result. Both conductive and sensorineural hearing loss may be present, as with the Stickler syndromes. The intellect is normal. Myopia, retinal detachment, and GRT are the major ophthalmic complications.

Spondyloepiphyseal dysplasia congenita (MIM #183900)

Spondyloepiphyseal dysplasia congenita (SEDC) presents at birth with shortening of the trunk and, to a lesser extent, the extremities (rhizomelic limb shortening) (Fig. 52.14). It is an autosomal dominant disorder and characteristically results from dominant-negative mutations in the gene for type II collagen (*COL2A1*). In common with other type II collagenopathies, patients exhibit congenital abnormalities of vitreous development, retinal detachment, hearing loss, and cleft palate. Odontoid hypoplasia may be present, predisposing to cervicomedullary instability. Imaging of the cervical spine should therefore be considered prior to general anesthesia.

Knobloch syndrome (MIM #267750)

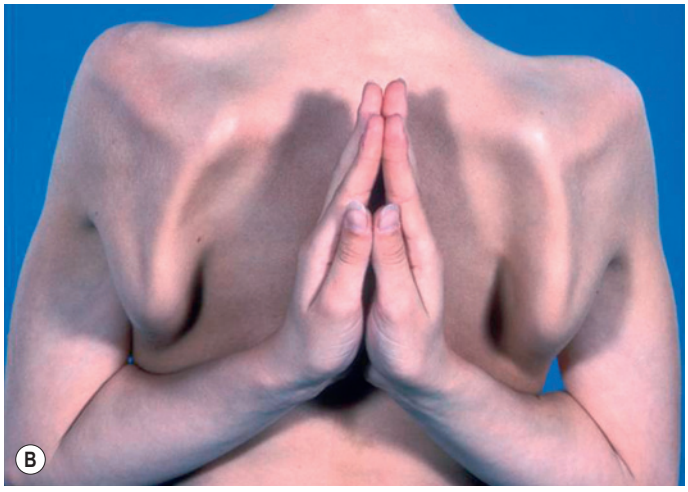
Knobloch syndrome is an automosomal recessive vitreoretinopathy. There is high myopia, nystagmus, featureless iris, cataract, ectopia lentis, retinal detachment, severe RPE atrophy resulting in prominent choroidal vasculature, congenital occipital encephalocele, unusual palmar creases, nail hypoplasia, and dental caries (Fig. 52.15). In instances where the occipital encephalocele is subclinical, computed tomography or magnetic resonance imaging may be required to support the clinical diagnosis. Molecular genetic analysis most commonly implicates homozygous splice site changes in the gene encoding the α1 chain of type XVIII collagen (*COL18A1*), although compound heterozygotes have also been identified.

Marfan syndrome (MIM #154700)

Marfan syndrome is an autosomal dominant connective tissue disorder associated with an abnormal vitreous architecture, myopic astigmatism, and characteristic skeletal features, including increased height with disproportionately long limbs and digits, scoliosis, lumbar lordosis, joint laxity, a crowded, high-arched (but not cleft) palate, and anterior chest deformity. It is a disorder of fibrillin, a high molecular weight extracellular glycoprotein. Mutations in the fibrillin gene on chromosome 15 (*FBN1*) cause both Marfan syndrome and dominant ectopia lentis. Other ocular features include retinal detachment, myopia, megalophthalmos, cornea plana, hypoplastic iris, glaucoma, and early nuclear sclerotic cataract.

An association with rhegmatogenous retinal detachment has been reported in 8–50% of cases; approximately 75% of these occur before 20 years of age. The myopia is characteristically developmental: in one large series, no case of myopia was found under 3 years of age. This contrasts with the congenital non-progressive myopia found in type 1 Stickler syndrome. In Marfan syndrome, the pupils dilate poorly because of a structural iris abnormality. This, combined with lens subluxation and weak scleral architecture, can make retinal detachment repair a formidable surgical challenge. Pars plana lensectomy and internal tamponade are often required.

Cardiovascular associations include mitral valve prolapse, mitral regurgitation, dilation of the aortic root, and aortic regurgitation. Aortic aneurysm and dissection are the most significant life-threatening complications.



Vitreoretinopathies associated with progressive retinal dysfunction

Wagner vitreoretinopathy (MIM #143200) (see also Chapter 42)

Wagner syndrome features autosomal dominant inheritance, low myopia (−3.00 diopters or less), fluid vitreous, cortical cataract, inconstant and variably affected dark adaptation, and retinal detachment. The cardinal features are absence of the normal vitreous architecture and thickening and incomplete separation of the posterior hyaloid membrane, which tends to occur in a circular band. A large range of chorioretinal abnormalities has been described, including the typical chorioretinal atrophy with pigment migration into

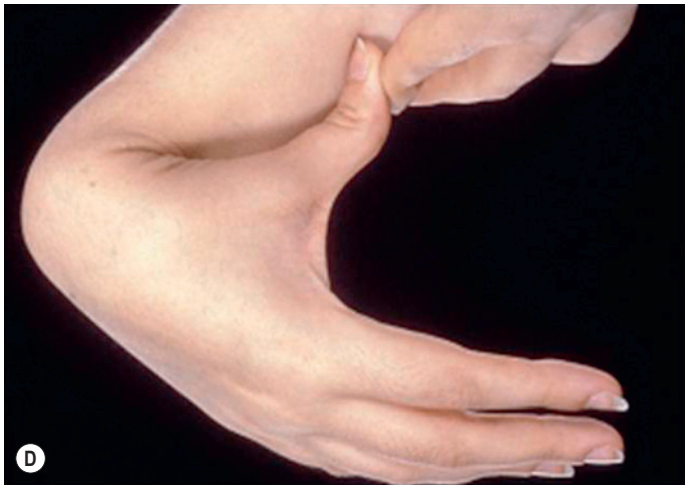


Fig. 52.12 Stickler syndrome. (A–D) Joint hypermobility can be assessed in a variety of ways.

Fig. 52.14 Spondyloepiphyseal dysplasia congenita. Note short stature, barrel chest, and rhizomelic (proximal) limb shortening. Patients typically exhibit the membranous congenital vitreous anomaly. *(Reproduced with permission from Snead MP, Richards AJ. Hereditary vitreoretinopathies. In: Sebag J, editor. The Vitreous in Health and Disease. New York, NY: Springer, 2014: 21–40.)*

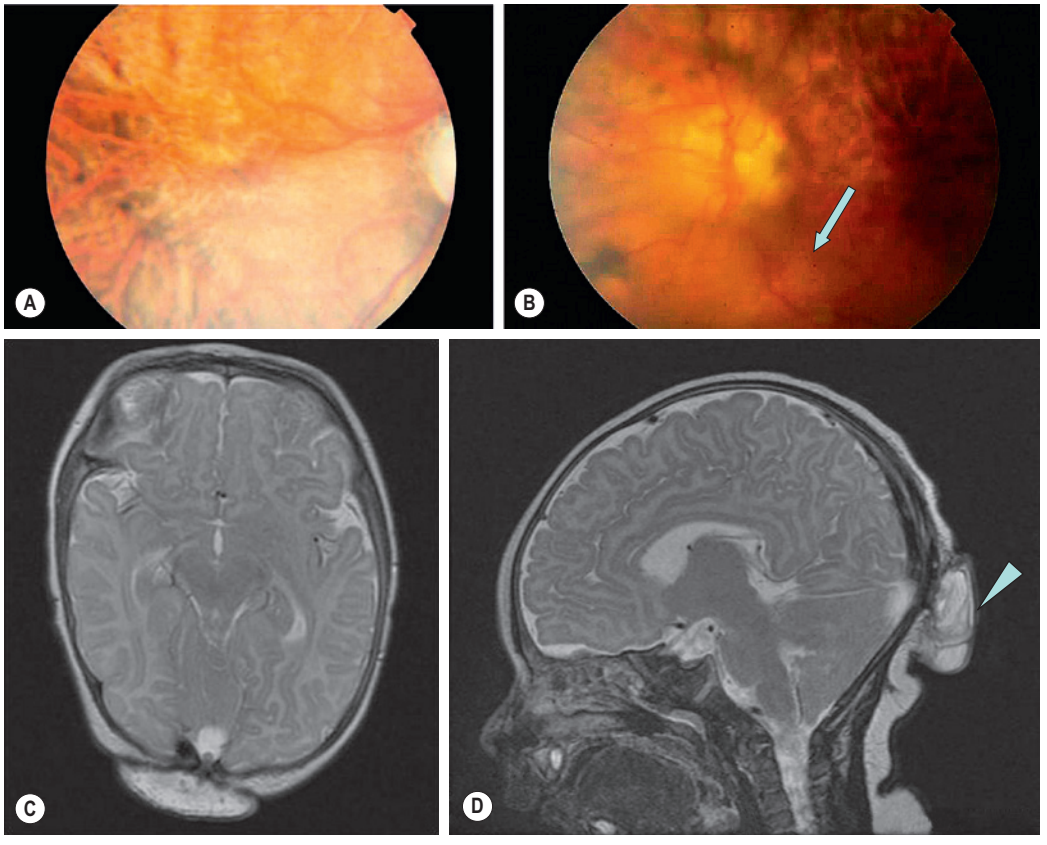

Fig. 52.15 Knobloch syndrome. Macula-off detachment left eye (arrow) associated with high myopia and occipital encephalocele (arrowhead).

the retina (Fig. 52.16). There is gradual progressive visual loss even without retinal detachment. Electroretinographic responses are progressively reduced, and visual-field testing demonstrates ring scotomas with eventual loss of central visual acuity. The phenotype at the end-stage is referred to as erosive vitreoretinopathy. The lenses typically develop anterior and posterior cortical opacities in puberty, with rapid progression during the fourth decade. The anterior lens capsule is tough and elastic, which can make capsulorrhexis difficult. Rhegmatogenous retinal detachment and glaucoma

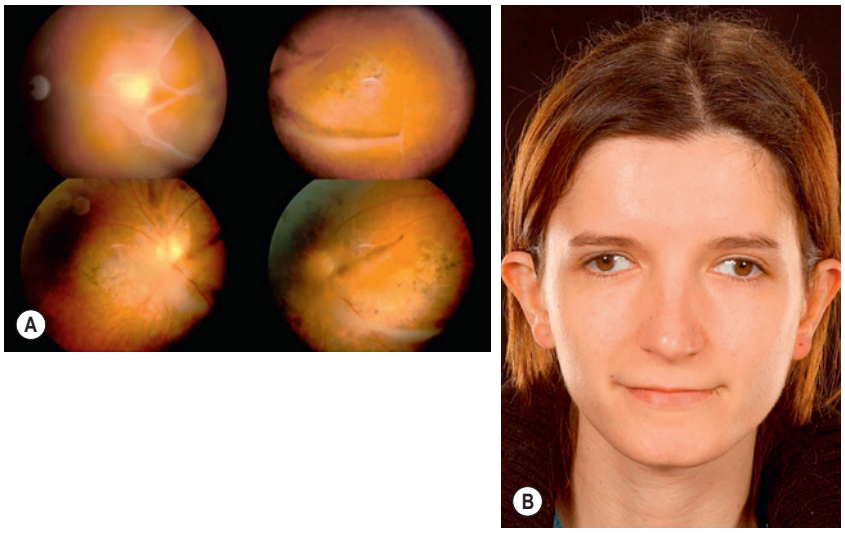

Fig. 52.16 Wagner vitreoretinopathy. Note thickening and incomplete separation of the posterior hyaloid membrane (A) and marked pseudo-exotropia (B). *(Reproduced from Meredith SP, Richards AJ, Flanagan DW, et al. Clinical characterisation and molecular analysis of Wagner syndrome. Br J Ophthalmol 2007; 91: 655–9.)*

were not reported by Wagner, but are now recognized. Wagner syndrome is also associated with large angle kappas indicative of an ectopic fovea (Fig. 52.16). The prognosis is poor, with progressive visual loss. The risk of rhegmatogenous retinal detachment, although higher than normal, is not as high as in the Stickler syndromes. The term "Jansen syndrome" has been used to describe a hereditary vitreoretinopathy with clinical features consistent with Wagner syndrome. It shows linkage to the same genetic locus.

Goldmann–Favre syndrome/enhanced S-cone dystrophy (MIM #268100)

Patients with Goldmann–Favre syndrome have liquefaction and fibrillar changes of the vitreous, night blindness, equatorial chorioretinal atrophy, and pigment clumping. There is also peripheral and macular schisis, cortical lens opacities, rod–cone dysfunction, and diffuse vascular leakage on fluorescein angiography. Goldmann–Favre syndrome is inherited as an autosomal recessive disorder, and is caused by a mutation in the same gene (the *NR2E3* gene) that causes enhanced S-cone syndrome (ESCS). ESCS is the only inherited retinal disease that exhibits a gain in photoreceptor function. Patients show enhanced sensitivity to blue (short-wavelength) light, night blindness, and loss of sensitivity to long and medium wavelengths. The electroretinogram (ERG) findings in this group demonstrate undetectable rod-isolated responses and reduced combined rod–cone responses.

Vitreoretinopathies associated with abnormal retinal vasculature

Familial exudative vitreoretinopathy (MIM #133780, #601813, #305390) (see also Chapter 42)

Familial exudative vitreoretinopathy is believed to be a premature arrest of retinal angiogenesis and vascular differentiation resulting in incomplete vascularization of the peripheral retina. The failure to fully vascularize the retina may be asymptomatic, but secondary changes can include neovascularization, retinal exudate, peripheral snowflake vitreous changes, and tractional or combined tractional and rhegmatogenous retinal detachment. Epiretinal membranes can cause severe retinal distortion and macular ectopia, which may be the presenting feature of poor vision in children (Fig. 52.17). The prognosis is highly variable, with some individuals blind by 10 years of age and others asymptomatic throughout adult life. Vascular abnormalities in individuals with milder phenotypes may only be evident on fluorescein angiography. It is an autosomal dominant condition.

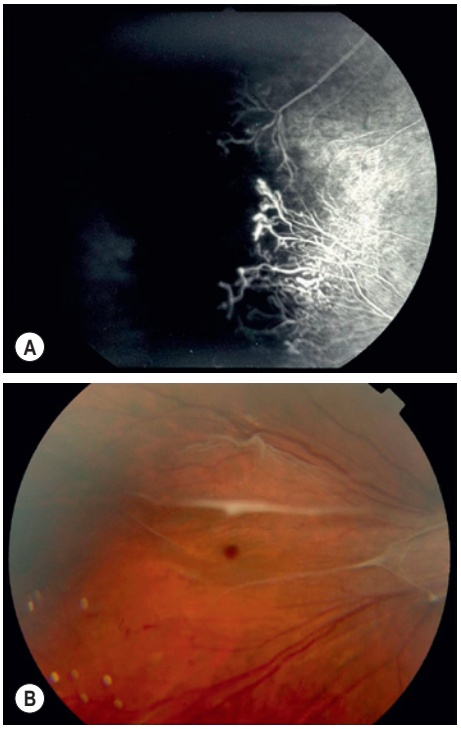

Fig. 52.17 Familial exudative vitreoretinopathy (A). Epiretinal surface membrane can cause severe retinal distortion and macular ectopia (B).

Autosomal dominant vitreochoroidopathy (MIM #193220)

Autosomal dominant vitreochoroidopathy is characterized by vitreous syneresis with or without peripheral vitreous changes.

Peripheral pigmentary changes typically occur at the equatorial region with a discrete posterior boundary (Fig. 52.18) associated with diffuse retinal vascular leakage, cystoid macular edema, and early-onset cataract. The peripheral pigmented band extends from the ora serrata to the equator through 360° of the retina. Other features are rhegmatogenous retinal detachment, punctate retinal opacities, choroidal atrophy, and early nuclear sclerosis. The ERG responses are normal, although the electro-oculogram is abnormal.

Vitreoretinopathy associated with corneal changes

Snowflake vitreoretinal degeneration (MIM #193230) (see also Chapter 42)

The pathognomonic feature of snowflake vitreoretinal degeneration is the association with corneal guttata, and disc pallor, which is not a feature of any of the other hereditary vitreoretinopathies. The vitreous has a fibrillar appearance, and small snowflake-like opacities in the retina may not be immediately obvious. Minor vascular abnormalities of small retinal vessels have been reported.

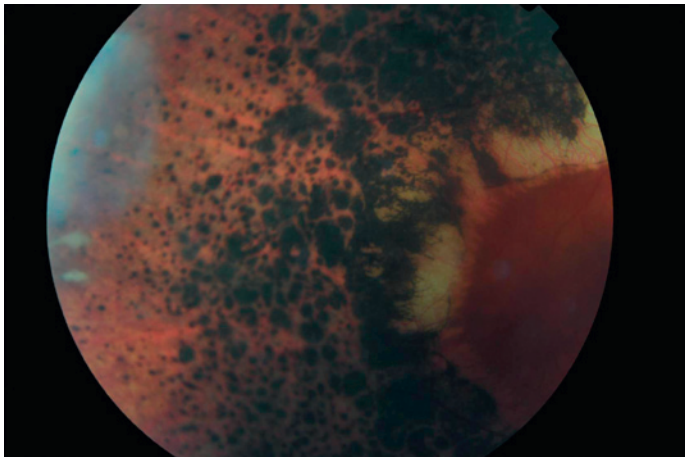

Fig. 52.18 Autosomal dominant vitreochoroidopathy. Peripheral pigmentary changes typically occur at the pre-equatorial region with a characteristically sharp posterior boundary.

X-linked retinoschisis (MIM #312700) (see also Chapter 42)

X-linked retinoschisis is an uncommon cause of retinal detachment in childhood, accounting for 2.5–5% of all pediatric retinal detachments. The incidence of retinal detachment varies in the different series, but it may occur in up to 16% of affected patients. Vitreous hemorrhage is another cause of visual loss (Fig. 52.19). Peripheral retinoschisis is found in approximately 50% of cases, and can be complicated by retinal detachment by various mechanisms. A full-thickness retinal break occurring *de novo*, or a communication between outer and inner leaf defects in the schisis wall, may lead to rhegmatogenous retinal detachment. Full-thickness breaks may be managed by scleral buckling procedures, provided complete break closure can be achieved. Where communication exists between inner and outer leaf breaks, an internal approach may be required.

Occasionally, X-linked retinoschisis can be complicated by cyst formation, hemorrhage into the cavity, or even be so bullous as to obscure the visual axis. Spontaneous resolution can occur, but prolonged delay may compromise the visual prognosis, so some advocate surgical drainage and internal de-roofing of the cyst.

Surgical considerations in pediatric rhegmatogenous retinal detachment

Prophylaxis

For the most common cause of RRD in childhood (Stickler syndrome), the risk of retinal detachment in childhood and blindness can be substantially reduced by accurate genotyping and prophylaxis. Patients with type 1 Stickler syndrome are the subgroup at highest risk of developing retinal detachment, typically as a result of a GRT – that is to say a circumferential break at the pars plana junction caused by a separation of the posterior hyaloid membrane much more anteriorly than would normally be the case (Fig. 52.20A–E). Prophylactic retinopexy, deployed and specifically positioned to prevent GRT progression, has been shown to substantially reduce the risk of retinal detachment and blindness from this type of break in type 1 Stickler syndrome (Fig. 52.21A). In a cohort analysis of 487 patients with type 1 Stickler syndrome, those

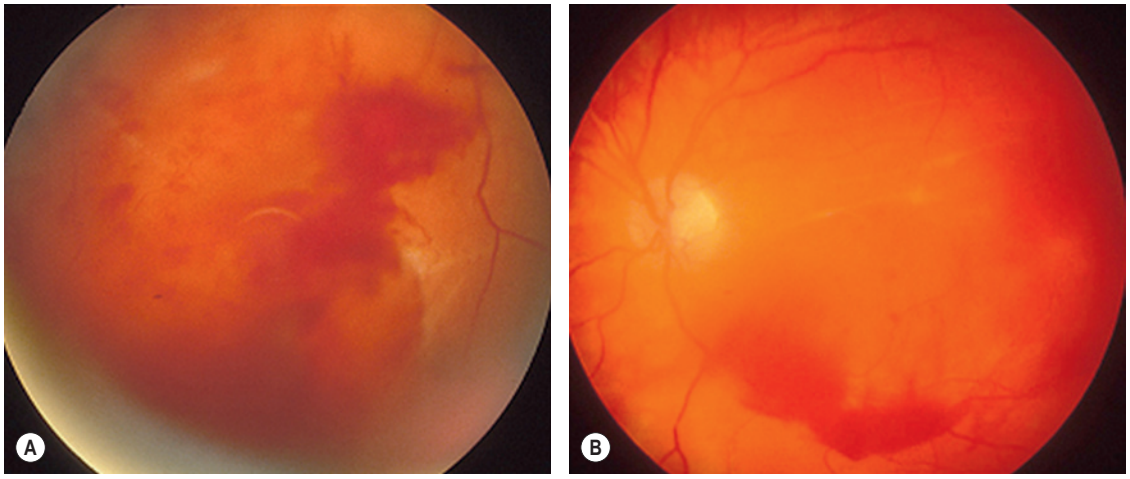

Fig. 52.19 Non-accidental injury was initially queried in this 10-year-old boy with X-linked retinoschisis with bilateral vitreous hemorrhage (A) Right eye; (B) left eye.

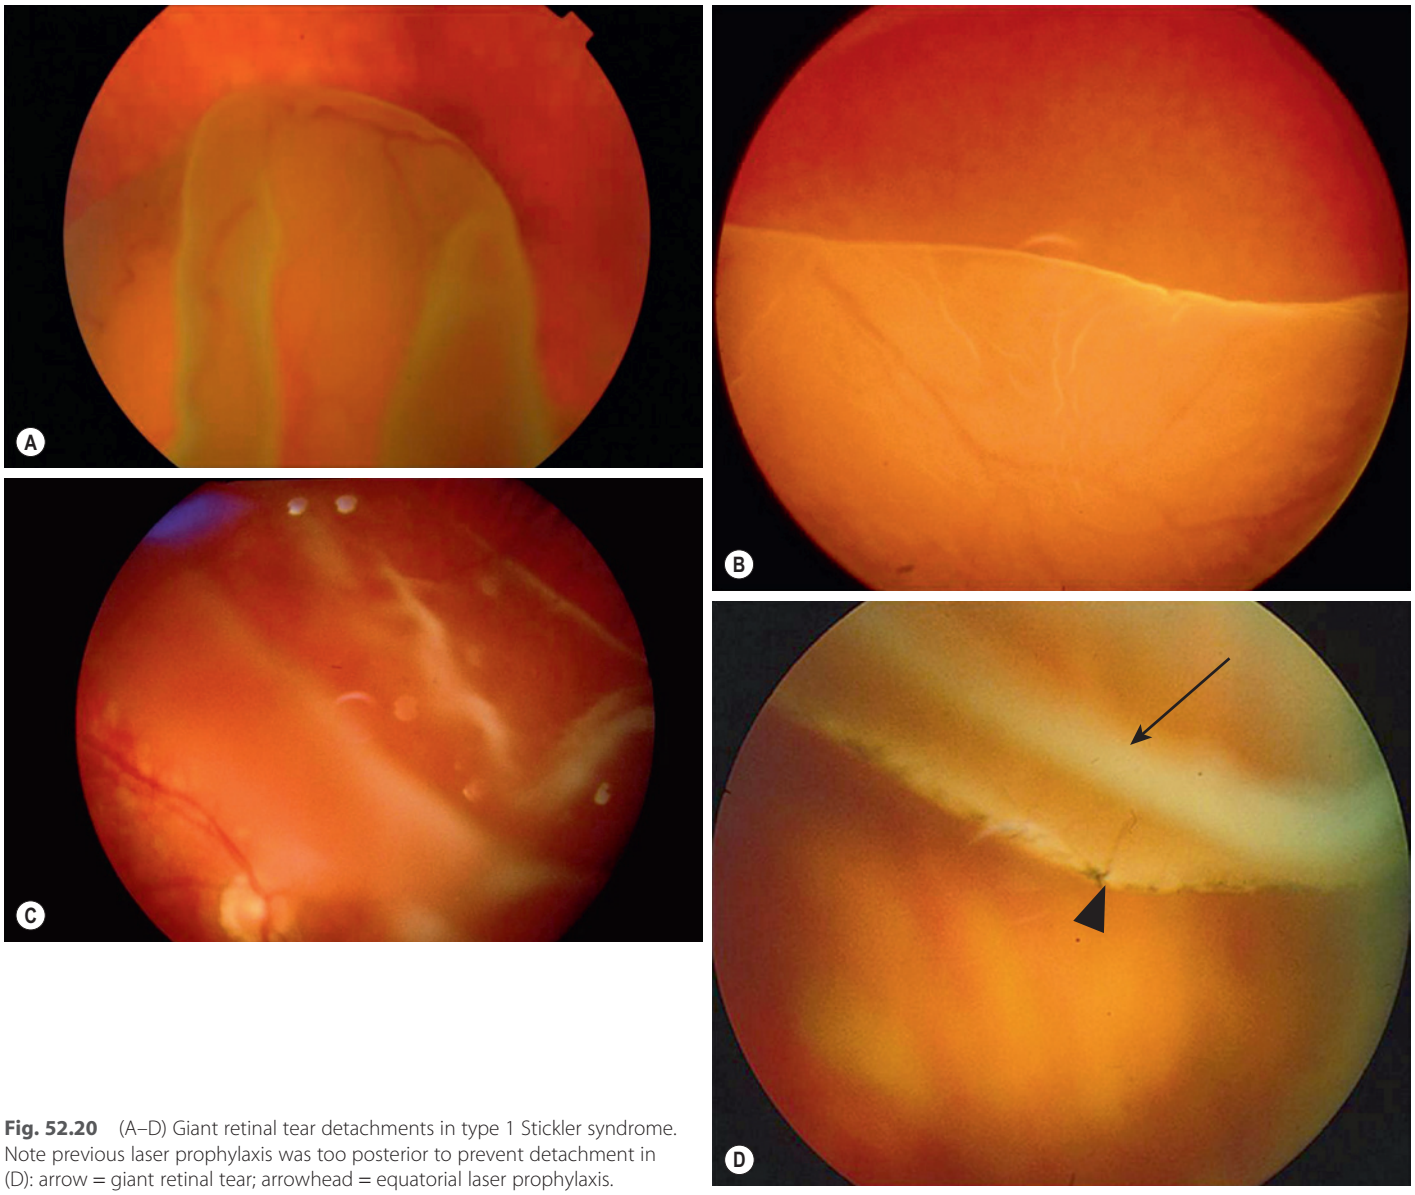

Fig. 52.20 (A–D) Giant retinal tear detachments in type 1 Stickler syndrome. Note previous laser prophylaxis was too posterior to prevent detachment in (D): arrow = giant retinal tear; arrowhead = equatorial laser prophylaxis.

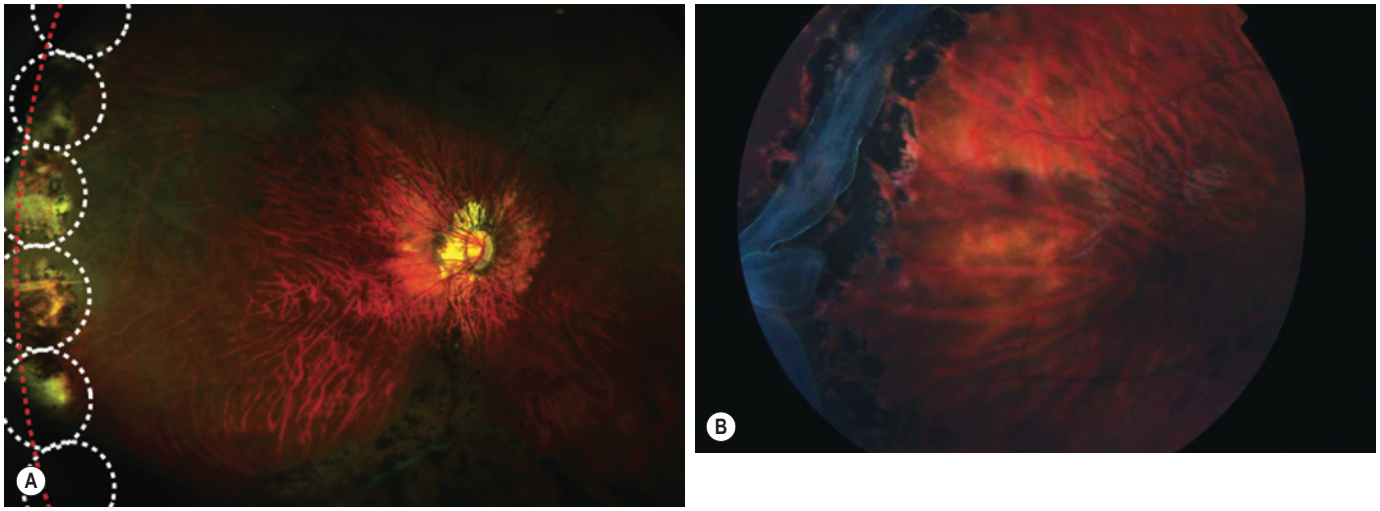

Fig. 52.21 (A) Prophylactic 360° cryoretinopexy in type 1 Stickler syndrome according to Cambridge Prophylactic Cryotherapy Protocol.[29] (B) Laser retinopexy to arrest progression of a giant retinal tear in type 1 Stickler syndrome (no prophylaxis).

patients who were untreated had a greater than seven-fold increased risk of detachment compared to those who received prophylaxis.[29] Detachment due to retinal breaks at other more posterior locations can occur, but are impossible to predict in terms of position, making effective prophylaxis in all cases impractical.

Surgical approaches and considerations in pediatric rhegmatogenous retinal detachment repair

General considerations and principles of repair

The prime goal in all cases should be to achieve successful and permanent re-attachment of the retina, with the minimum number of procedures (ideally one), and with the minimum risk of collateral or secondary damage. Some complex situations may need to be approached in two stages (with a second procedure to remove cataract and/or internal tamponade). Primary repair is now successful with a single operation in well over 90% of cases. Children (much more than their adult counterparts) develop particularly rapid and aggressive PVR with failed surgery. Even if re-attachment is achieved after surgery for recurrent retinal detachment, macular and binocular function may still be severely compromised.

Examination under anesthesia (EUA)

Children with retinal detachment may be difficult to assess in clinic; indirect ophthalmoscopy with scleral depression is frequently impossible. Examination under anesthesia allows the assessment of the type, number, and extent of retinal breaks, together with a risk assessment/prophylaxis to the fellow eye (see Prophylaxis above, Table 52.1 and Vitrectomy and internal approaches below).

Scleral buckling: when, why, and how?

Although there has been a pronounced shift in recent years towards vitrectomy and internal approaches for all types of RRD repair, scleral buckling remains a valuable procedure. In correctly selected cases, it is a quick, extraocular, and highly effective technique for RRD repair. Indeed, in two common varieties of pediatric RRD where the vitreous remains attached (see Table 52.1), the primary success for buckling far exceeds anything achieved by internal approaches, where the risk of PVR with failed surgery is high, and firm vitreous attachment may impair internal drainage.[31] External buckling also reduces the need for simultaneous or subsequent removal of the crystalline lens, an important amblyogenic factor, especially in unilateral retinal detachment. Scleral buckling may also be required in combination with vitrectomy for complex cases and those associated with advanced PVR. The main indications favoring an external approach are cases where the vitreous remains attached (round hole and dialyses), or in cases of PVD where breaks are single or small, and anterior, with shallow, non-bullous detachment. Key steps in a safe, successful procedure include the absence of any associated scleromalacia (Fig. 52.22), accurate identification and application of retinopexy to all retinal breaks, and precise selection and localization of scleral buckle. Accurate break and buckle localization also allows smaller explants to be used, with consequently reduced risks of extrusion, drainage requirements, hemorrhage, incarceration, and extraocular motility problems (Fig. 52.23). In

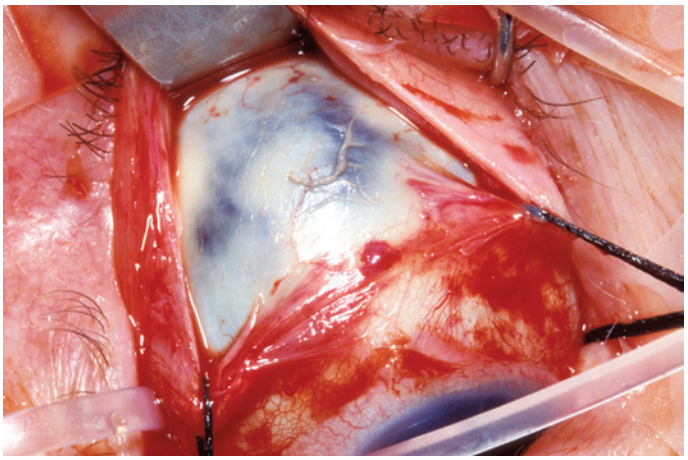

Fig. 52.22 Severe scleromalacia in a patient with type 2 Stickler syndrome. Scleral buckling attempts in such cases are hazardous and an internal approach will be required.

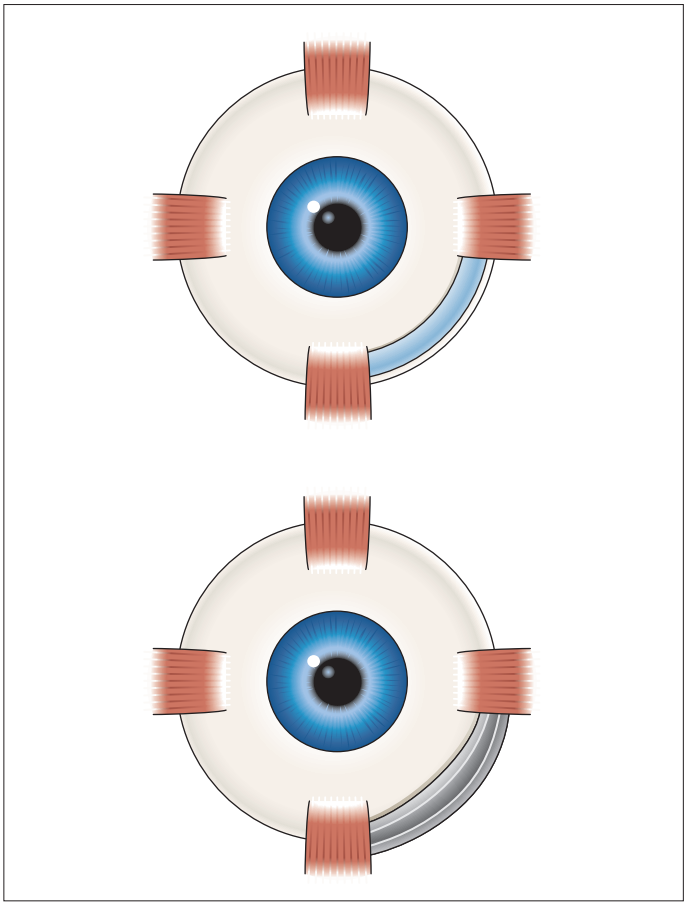

Fig. 52.23 Scleral buckling for repair of retinal dialysis. Accurate localization and break closure with a narrow gauge sponge (top) substantially reduces problems with drainage, intraocular pressure, ocular motility, and extrusion, all of which may occur after wide solid explants (below). The latter are virtually never required.

situations where a radial explant is required to close a break that is equatorial or posterior, it is often safer to use two backhand sutures (both in an anteroposterior direction), which circumvents the need to attempt one with a posterior-to-anterior path and its attendant high risk of inadvertent

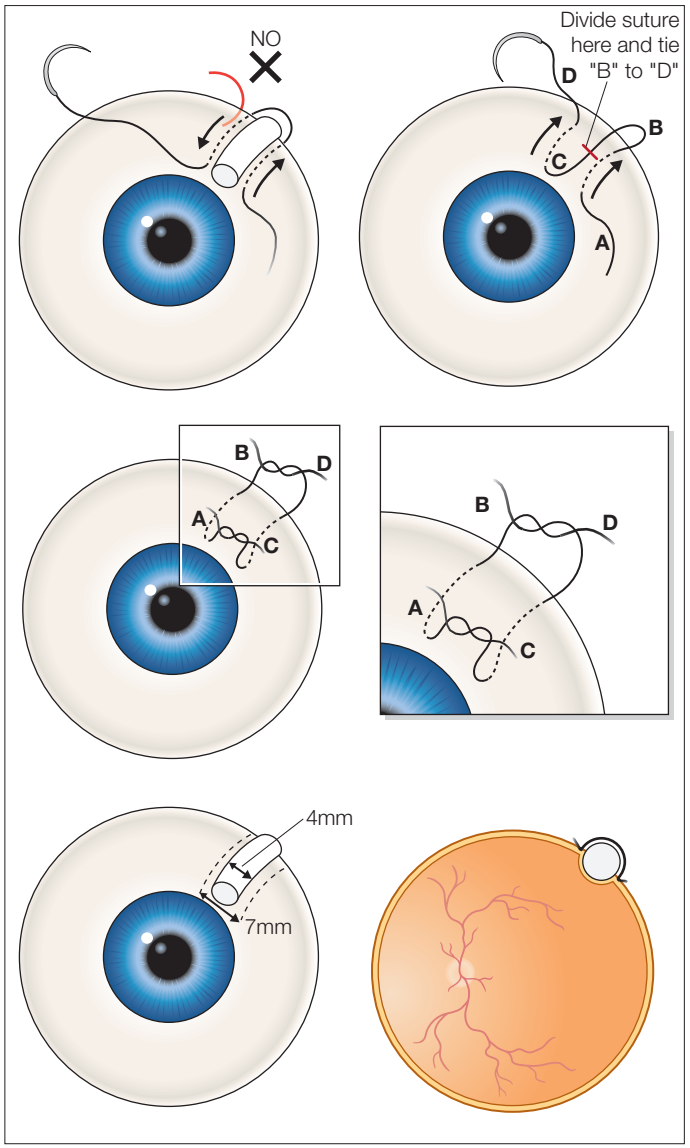

Fig. 52.24 Technique for applying radial buckle. A single modified radial mattress suture is produced by deploying two backhand sutures (both in an anterior-to-posterior direction, bottom left and right), which circumvents the need to attempt one with a posterior-to-anterior path (top left) and its attendant high risk of inadvertent perforation and incarceration on the forward passage from deep behind the globe.

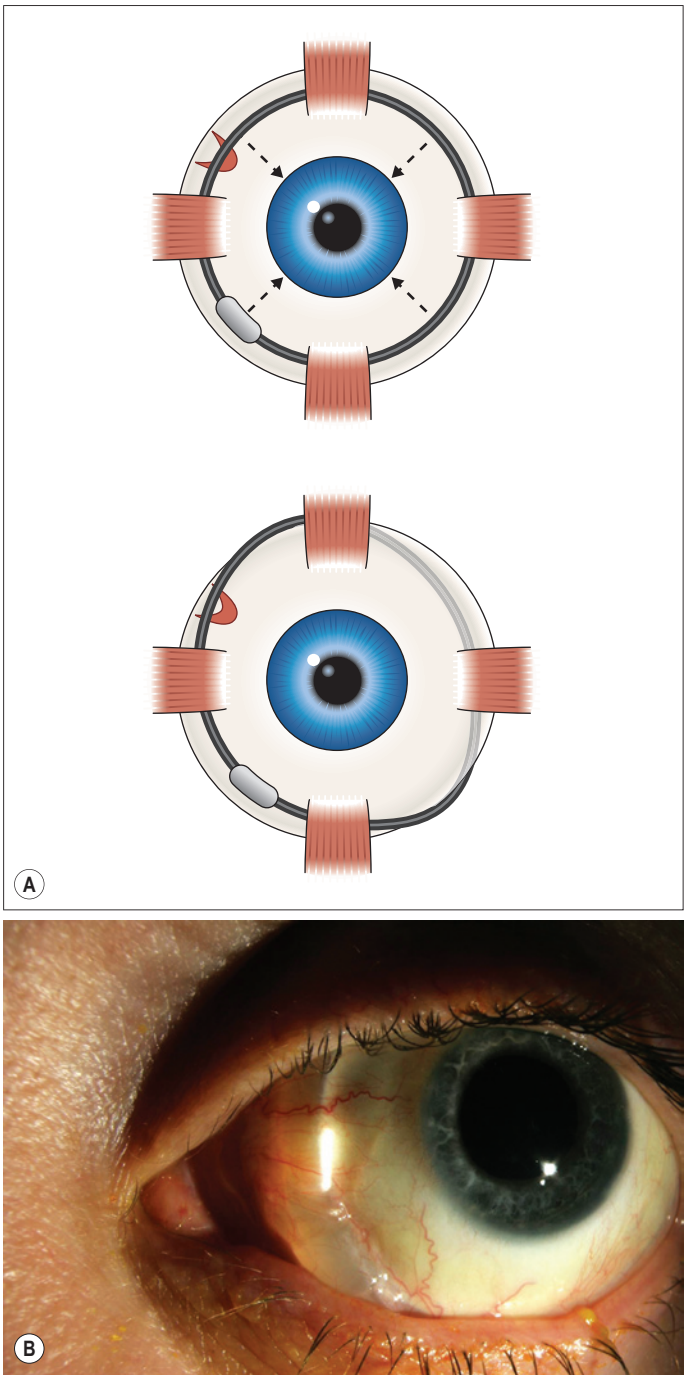

Fig. 52.25 Encircling buckle. After accurate break localization and closure, care should be taken to ensure the remainder of the buckle continues on a "great circle" of the globe (A, bottom) thereby avoiding the risk of secondary anterior migration (A, top) – an inevitable but unwanted sequel to encircling elements sutured anterior to the equator in their entirety (B).

perforation and incarceration on the forward passage from deep behind the globe (Fig. 52.24).

In some cases with multiple breaks (particularly with round atrophic holes), an encircling buckle is often very effective,[31] but if the breaks being buckled are anterior to the equator, care should be taken to localize the reciprocal extent of the buckle an equal distance posterior to the equator, so that the entire extent of explant remains on a "great circle" of the globe (Fig. 52.25). This will avoid the risk of subsequent slippage of the buckle anteriorly (Fig. 52.26) – an inevitable but unwanted sequel to encircling elements mistakenly sutured anteriorly to the equator in their entirety.

Vitrectomy and internal approaches

Cases complicated by large and/or multiple breaks, GRTs, media opacity, PVR, penetrating trauma, and developmental anomalies will usually require an internal approach. This is distinct from "giant" dialyses, which may also extend circumferentially over 90°. As discussed above, these latter cases are most safely and easily managed with an external approach, even when chronic and associated with subretinal fibrosis (see Fig. 52.3).

Cases of PVR and penetrating trauma will have additional tractional components that can only be divided by vitrectomy; cases in which shortening is very severe may need to be stabilized

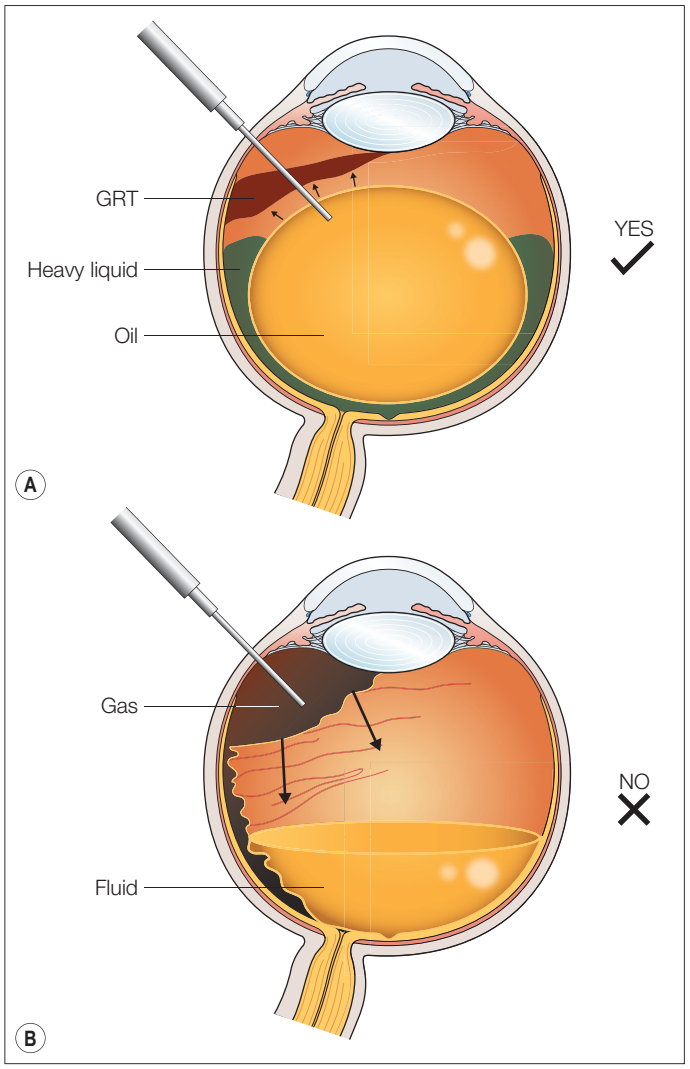

Fig. 52.26 Perfluorocarbon liquids (PFCLs) and a giant retinal tear repair. Slippage of the posterior flap can be avoided by direct PFCL/oil exchange (A), avoiding the intermediary gas exchange phase (B) when the risk of slippage is exacerbated.

by a tailored combination of buckling with vitrectomy and retinectomy.

Fellow eye considerations

General anesthetic surgical repair of retinal detachment allows assessment of the fellow eye for prophylaxis (see above) or treatment of undiagnosed tears. The incidence of bilateral pathology varies between break types and is summarized in Table 52.1.

Giant retinal tear approaches

Giant retinal tears are the most common cause of retinal detachment in Stickler syndrome, and present their own individual surgical challenges. Extensive separation of the posterior hyaloid membrane anteriorly to the pars plana, in combination with the rapid and massive circumferential extension of the retinal break, leads to an independent mobility and collapse of the retina under gravity to the posterior pole (see Fig. 52.20A). Perfluorocarbon liquids (PFCLs) have greatly simplified the perioperative repositioning of the retina, but have a high rate of emulsification and uveitis if left *in situ*. Slippage of the posterior flap may occur during the PFCL exchange, which can be avoided by direct PFCL/oil exchange (avoiding the intermediary gas exchange phase when the risk of slippage is exacerbated) (Fig. 52.26). GRTs of less than 360° are frequently associated with small, non-contiguous satellite tears, and it is vital that these are also identified and treated to avoid risk of recurrent detachment at stage II surgery (silicone oil removal).

Introduction

Overview

1. Children with bilateral optic disc anomalies present in infancy with poor vision and nystagmus; unilateral cases present during preschool years with sensory esotropia, occasionally nystagmus.
2. Any structural ocular abnormality that reduces visual acuity in infancy may also lead to amblyopia.[1]
3. Malformed optic discs are often associated with central nervous system (CNS) malformations.
4. Small discs are associated with malformations involving the cerebral hemispheres, pituitary infundibulum, and midline structures. Large anomalous discs may be associated with a trans-sphenoidal encephalocele.
5. Many optic discs that are congenitally anomalous do not fit into any category. Rather than put them conveniently into a diagnostic category, it is preferable to label them as an optic disc dysplasia (Fig. 53.1).

Epidemiology (see Chapter 2)

Four or more of every 10,000 children born in the UK will be diagnosed as severely visually impaired or blind (SVI/BL) by their first birthday, increasing to nearly 6 per 10,000 by the age of 16 years.[2]

Congenital optic nerve defects now account for a significant number of cases of visual impairment (VI),[3] about 15% of SVI/BL patients in the UK. Optic nerve hypoplasia alone accounts for over 10%,[2] and the incidence may be increasing.[4,5] In the early literature, developmental abnormalities such as optic nerve hypoplasia were unusual.[6] The early ophthalmoscopists were able to see retinal minutiae, some, which are rarely recognized by today's practitioners with technologically advanced kit, so it seems likely that it was overlooked as a diagnosis much more than it is today because it was not commonly known. After all, "you see what you know." Thus, optic nerve hypoplasia is now probably more common, but, more significantly, it is better recognized than a few decades ago.

As developmental abnormalities of the anterior visual pathways are often associated with brain, endocrine, and other systemic problems and syndromes, they may have far greater significance than to vision alone and some may be hereditary.

Normal and abnormal retinal ganglion cell (RGC) development

RGCs are the first retinal cells to appear, at about 4 weeks' gestation from progenitor (stem) cells, from posterior to anterior. Guided by a complex series of time-linked guidance molecules and molecular gradients, axonal growth cones guide them almost unerringly towards the optic disc, through it, and on across the chiasm. There, they make binary decisions as to whether they decussate and project to the contralateral lateral geniculate body (LGB), or whether they remain ipsilateral. They grow to the LGB, guided by attractant, repellent, and fasciculant molecules. Their number increases to over 3.5 million in each eye, only to decrease by apoptosis to about 1.2 million at around term birth. This fascinating programmed cell birth and death probably ensures a complete connection of retinal elements to the LGB to achieve a retinotopic projection.

Optic nerve hypoplasia (ONH) may result from primary failure of retinal ganglion cells at 4–6 weeks of gestation, or failure secondary to other disease processes at any site from the eye to the visual cortex, and maybe from other brain areas in young preterm infants. ONH may also occur from failure of a proper concert of guidance molecules anywhere along the path. In prenatal and very early postnatal life, retrograde trans-synaptic degeneration may result in some forms of ONH.

Retinal ganglion cell developmental disorders

Optic nerve aplasia

Imagine the wonderment of Dr W. Newman in 1864, using the newly invented ophthalmoscope, when he looked into the

recently visible depths of the eye to find no optic nerve and no retinal vessels[7]!

Optic nerve aplasia is rare enough to contribute nothing to the epidemiology of childhood blindness. Diagnosed in a blind eye, there is no optic disc nor retinal vessels visible, but the occurrence of partial cases, with a few retinal blood vessels or an area in the fundus that corresponds to an optic disc, makes it difficult to be dogmatic about inclusion.[8]

From the cases of the author[8] and from the literature there may be three groups:

1. A grossly normal choroid but absent retinal vessels and no ophthalmoscopically visible optic disc. The electroretinogram (ERG) may be present, but abnormal.
2. A severely abnormal hyper/hypopigmented fundus (Fig. 53.2), abnormal choroid, absent retinal blood vessels and absent optic disc. The ERG is absent. Choroidal neovascularization is an occasional finding.
3. Cases that have signs of fetal fissure closure defects (colobomas) but with no visible disc (Fig. 53.3) or an extremely abnormal disc. Retinal vessels may be present but arise and are distributed abnormally. An ERG is present (Table 53.1).

There are no unifying hypotheses on etiology and pathogenesis, as one might expect for such a diverse condition. It may be due to ganglion cell development problems, although some cases (group 3) seem to be related to abnormalities of the

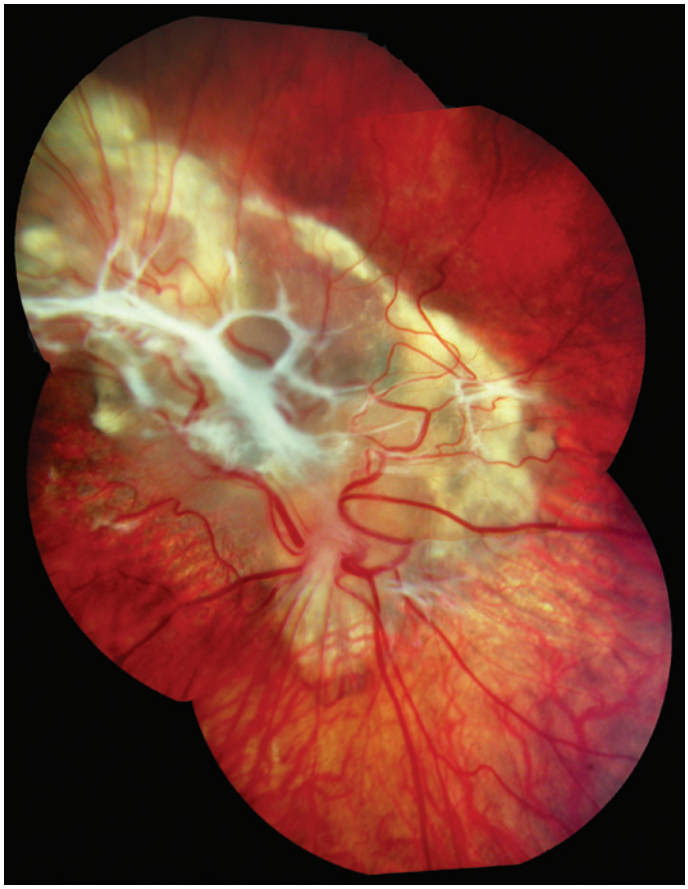

Fig. 53.1 Collage of the optic disc of a healthy infant with bilateral optic disc anomalies. It does not fit in any category and is best designated "optic disc dysplasia (category unknown)."

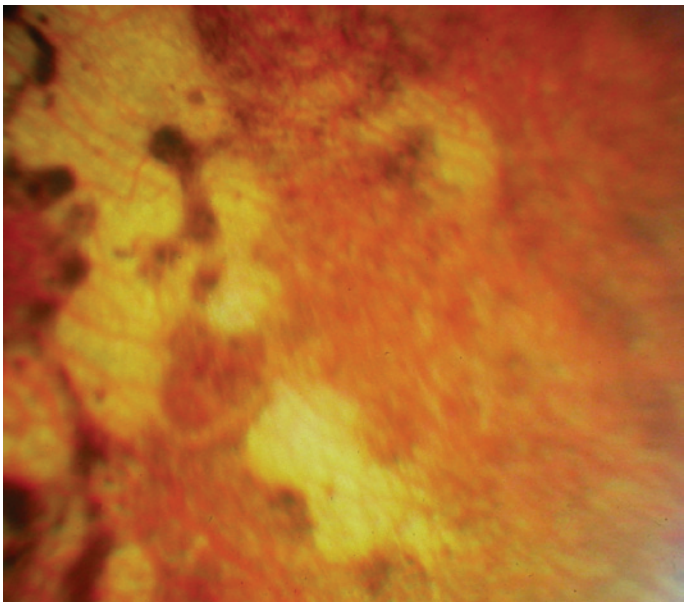

Fig. 53.2 Bilateral optic nerve aplasia, group 2. This child shows gross retinal and choroidal pigment disturbance and absence of retinal vessels.

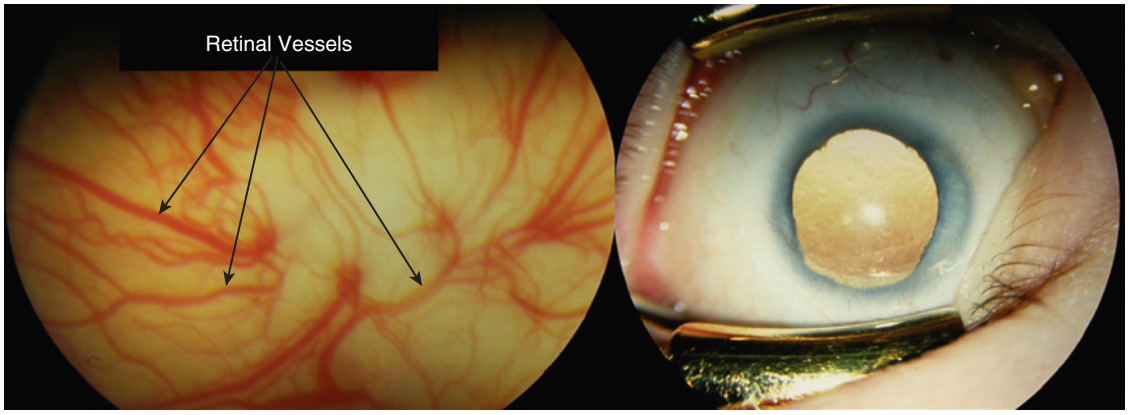

Fig. 53.3 This male child with a left iris coloboma (right) has no visible optic disc but retinal vessels emerging through the sclera. There was a rudimentary electroretinogram and no visually evoked potential responses from the affected eye.

Table 53.1 Optic nerve aplasia

	Optic disc	Retinal vessels	Choroid	ERG	VEP	Coloboma
Group 1	Not visible	Absent	Grossly normal	Present, abnormal	Absent	No
Group 2	Not visible	Absent	**Severely abnormal**	Absent	Absent	No
Group 3	Not or barely visible	Some present	Grossly normal	Present +/– normal	Severely abnormal	**Present in one or both eyes**

ERG, Electroretinogram; VEP, visually evoked potential.

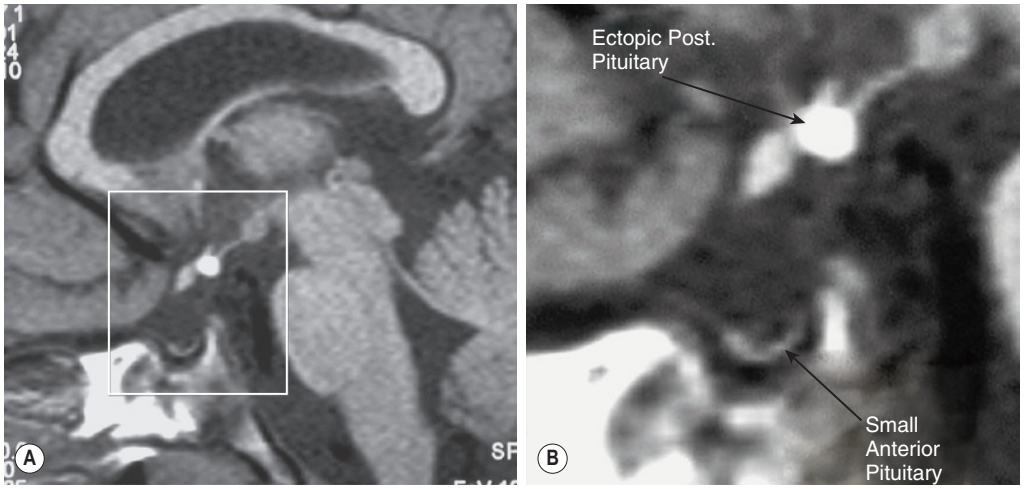

Fig. 53.4 Septo-optic dysplasia. Infant with bilateral optic nerve hypoplasia without clinically apparent growth or endocrine disturbances. The corpus callosum is hypoplastic and the anterior pituitary is small and there is no posterior pituitary bright spot in the pituitary fossa – it is sited ectopically, a high T1 signal nodule posterior to the tuber cinereum.

development of the fetal fissure or mesenchyme around the optic stalk.

A general rule of developmental disorders is that if there is one developmental anomaly, there may well be another. While unilateral cases are usually otherwise normal, bilateral cases may have associated brain, cardiac, and other abnormalities. There are 10 associated syndromes in the "GENEEYE" database (www.lmdatabases.com). For cases without a family history or a history of consanguinity, the recurrence risk seems low. Since this is based on little data, expert advice is necessary.

Optic nerve hypoplasia

ONH is an abnormality of the optic disc that occurs before the full development of the optic nerve. There is a reduced population of retinal ganglion cell axons. It is the cause of over 10% of SVI in childhood.[2] The genetic and molecular events leading to the successful development of the hypothalamic–pituitary axis and related structures during embryogenesis are complex.[9] It is not surprising that ONH is related to midline developmental abnormalities (Fig. 53.4). A significant proportion of patients with ONH have associated brain abnormalities, mostly involving midline structures – usually the septum pellucidum, and accompanying hypothalamic–pituitary abnormalities (Fig. 53.5). This constellation is graced with the term septo-optic dysplasia (SOD), but the presence or absence of the septum does not alter their management.

Presentation

Bilateral, severe, ONH presents as blindness in early infancy with roving eye movements and sluggish or absent pupil reactions to light. Lesser degrees of bilateral ONH may cause lesser visual defects, strabismus, or nystagmus. Unilateral or highly asymmetrical cases may present with nystagmus,

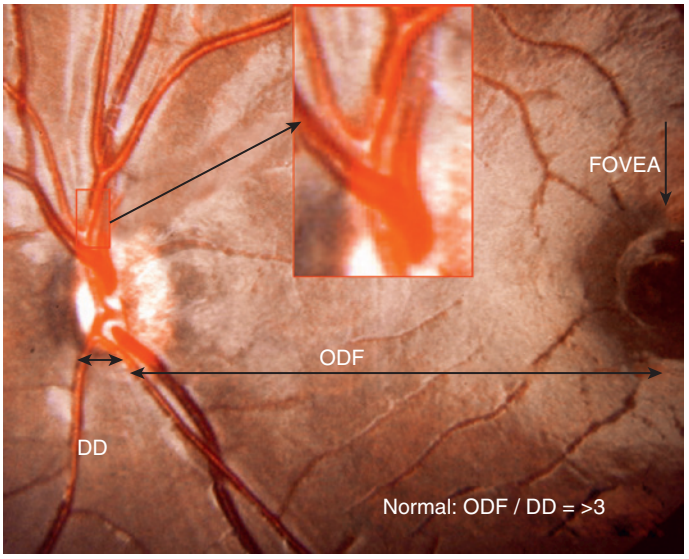

Fig. 53.5 Optic nerve hypoplasia. If the ratio of the distance of the optic disc edge to the fovea (ODF) to the average (vertical + horizontal divided by 2) disc diameter (DD) is greater than 3, optic nerve hypoplasia is a possibility. The inset shows how a main branch retinal vessel diameter can also be used to estimate the size of the optic disc. Optical coherence tomography studies are also very helpful (see Chapter 10).

sometimes "manifest latent nystagmus" (MLN, see Chapters 89 and 90), and strabismus. ONH may also be found at a routine test. Amblyopia may contribute to the poor vision and the vision may improve with patching.[1] Astigmatism may be more frequent than in the population as a whole, and all children with ONH, regardless of severity, should be refracted. Affected patients may also present because of a variety of endocrine disorders or brain defects, neonatal jaundice, or hypoglycemia.

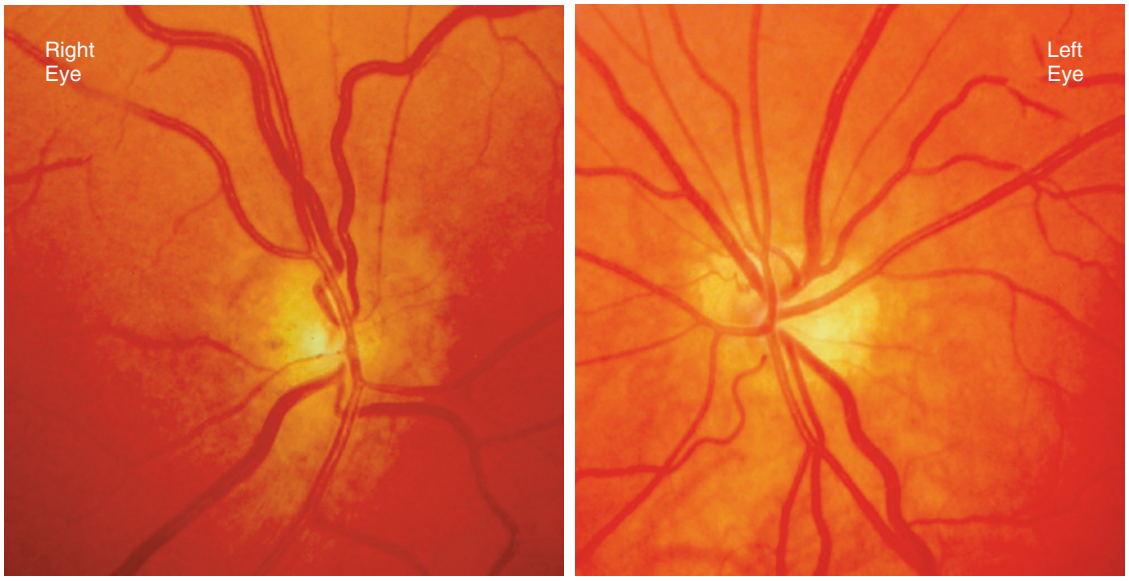

Fig. 53.6 Bilateral optic nerve hypoplasia. The right eye has "counting fingers" vision. The left eye has 0.0 LogMAR acuity (6.6, 20/20, 1.0) but the visual field is restricted enough to preclude driving.

Demographics

Hypoplastic nerves occur more frequently in males than females, and probably without racial predilection. The parents of children with ONH tend to be young and may be from certain ethnic groups,[10] but this is likely to result from overlapping with adverse socioeconomic environments and unemployment.[11]

Clinical assessment

The diagnosis of optic nerve hypoplasia is not made on size of the optic nerve alone: it is made on a combination of size, shape, an estimate of the number of axons, a small or absent cup, an increase in the tortuosity of the retinal vessels – with fewer than normal branching points – and the presence of peripapillary abnormalities. Some objectivity can be introduced by comparing ratios of vessel size and optic disc size or the disc–macula to disc diameter ratio (see Fig. 53.5). This ratio does not change with time.[12] Using volumetric, heavily T2-weighted magnetic resonance imaging (MRI) orbital sequences[13] of ONH patients compared with controls, it has been possible to provide a useful formula to more objectively determine the significance of the size of the optic nerve. Optical coherence tomography can usefully define the nerve fiber pattern around the optic disc[14] and improve objective disc measurement. Ultrasound and photogrammetry may also be helpful.

Ophthalmoscopy

There is a very wide variation in the appearance and effects of hypoplastic optic discs (Fig. 53.6), all of which are best seen with high magnification, using a direct ophthalmoscope. The baby can usually be kept quiet for a few moments by allowing feeding after the pupils have been dilated. The area of the optic disc (outer ring) is composed of bare sclera or cribriform plate; this is variably larger than the circular area (inner ring), which contains any retinal nerve fibers (the optic disc "substance"). The difference between the two gives rise to the "double ring" appearance (see Fig. 53.5). Histopathologically, retinal ganglion cell axons are reduced in number with normal mesodermal elements and glial supporting tissue. Between the inner and outer ring there is dysplastic retina and pigment epithelium. The double ring sign is, however, not pathognomonic of ONH, especially in milder degrees.

There is a spectrum between the normal, atrophic and hypoplastic disc that depends on how severe the causative event was and at which time or times it occurred. The optic disc substance may be a normal color if the fibers that survived the journey from RGCs to the LGB are healthy and relatively numerous; equally, it may be pale (see Fig. 53.6), suggesting atrophy of the remaining fibers after the event that caused the hypoplasia.[15]

Visual effects

The visual effects vary from good visual acuity (often with a field defect) to blindness. Visual acuity is determined largely by the size of the papillomacular bundle, not by the overall size of the disc (Fig. 53.7). The eventual visual acuity may be predicted from assessment of the optic disc size (and distribution of RGC axons), the initial acuity card assessment, and visually evoked potentials (VEPs).[16] Associated delayed visual maturation (see Chapter 5) is not uncommon, but it is best not to be too pessimistic after examinations in infants. Refraction, visual acuity, color vision, and visual fields are mandatory studies in older children, as are flash and pattern VEPs at all ages.

Timing and site of causative agents

The timing of any "insult" is likely to be after the retinal ganglion cell precursors appear and suggests that the defect, when severe, occurs early in prenatal development. The development of the optic disc continues after birth, albeit at a greatly reduced rate, and some cases occur from an insult in late in pregnancy and even postnatally. Very hypoplastic discs may be the result of an early insult, whereas subtle degrees of hypoplasia, where the optic disc size is overall roughly normal, are due to a later insult.

Specific patterns of optic nerve hypoplasia

These result from local defects throughout the central nervous system[17]; the site of the "insult" in optic nerve hypoplasia is reflected in the pattern of disc hypoplasia (Fig. 53.8). Optic

disc hypoplasia results from an early injury at any site in the developing visual system.

Homonymous hemi-optic hypoplasia

Retro-geniculate lesions in primates[18] may give rise to a pattern of ONH by trans-synaptic degeneration across the lateral geniculate body. In humans these were first described[19] in a case in which trans-synaptic degeneration from a cerebral lesion gave rise to a pattern of optic disc hypoplasia and retinal nerve fiber defects that reflected the field defect that the lesion caused. The ipsilateral optic tract may be shown to be hypoplastic on MRI scanning. It may be mixed with direct damage to the developing visual system occurring with trans-synaptic degeneration.

Optic tract hypoplasia

Isolated damage to the optic tract may occasionally occur (Fig. 53.9[20]) in patients with an incongruous hemianopia from a developmental lesion. Many more cases are associated with more widespread damage to other brain structures.

Chiasmal hypoplasia and achiasmia

When the optic nerves are hypoplastic, the chiasm is hypoplastic in most cases and the crossed and uncrossed fibers are reduced proportionally. If the chiasm is not just hypoplastic but crossing fibers are either absent or reduced, this is known as achiasmia. In achiasmia, some cases may have a hemianopia, often reflected in the optic disc morphology (Fig. 53.10), but in many the retinotopic projections have compensated in early development and there is no visual field defect, and the optic discs may also be normal

Segmental hypoplasia

The occurrence of specific patterns of hypoplasia (see Fig. 53.8) may result from localized defects throughout the central nervous system[17]; the site of the "insult" in ONH is reflected in the pattern of disc hypoplasia. For instance, the appearance of segmental optic disc hypoplasia related to a macular coloboma means that the site of the injury is in the eye, while optic disc

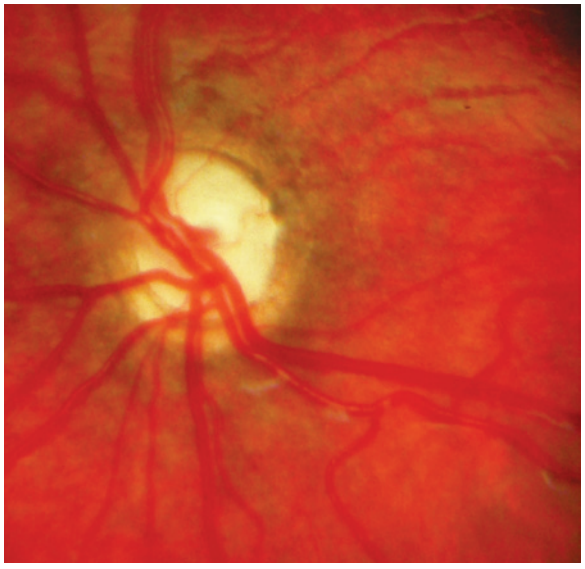

Fig. 53.7 The optic disc is small with a double ring sign, suggesting that the causative factor was early in gestation. The hypoplastic disc itself is atrophic and pale, suggesting continuing damage to retinal ganglion cells and axons.

Fig. 53.8 Unilateral temporal segmental hypoplasia of the left optic disc of unknown cause.

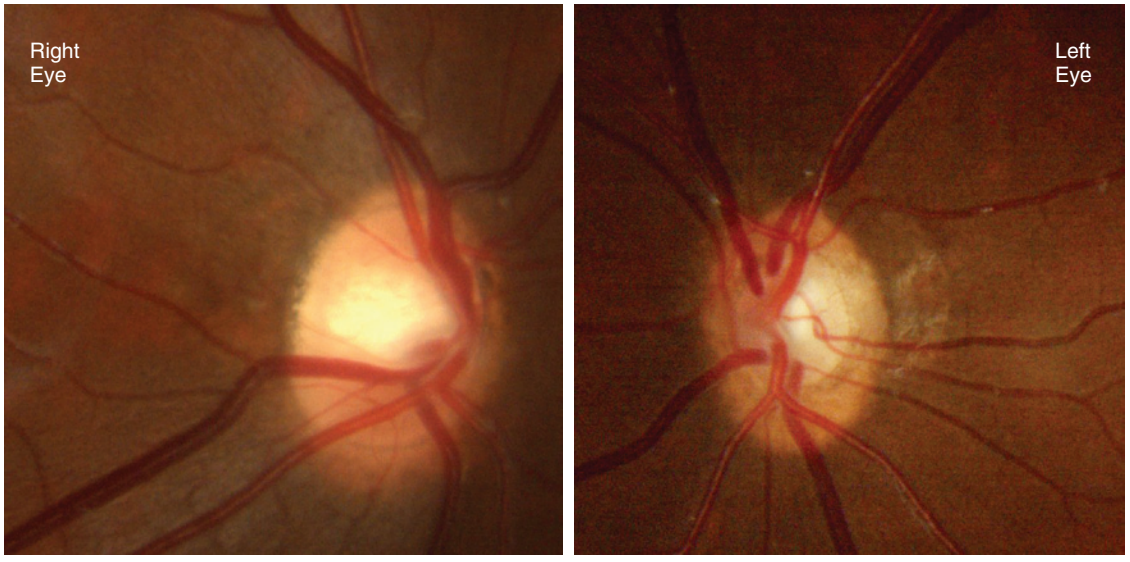

Fig. 53.9 This healthy 19-year-old male had a longstanding incongruous hemianopia secondary to right optic tract hypoplasia of unknown cause. The left optic disc is hypoplastic with LogMAR acuity of 0.4 (6/15, 20/50, 0.4). The right visual acuity was 1.0 LogMAR (6/6, 20/20, 1.0) and the optic disc shows hypoplasia of the central horizontal band. *(From Hatsukawa Y, Fujio T, Nishikawa M, et al. Congenital optic tract hypoplasia. J AAPOS 2015; 19: 383–5.)*

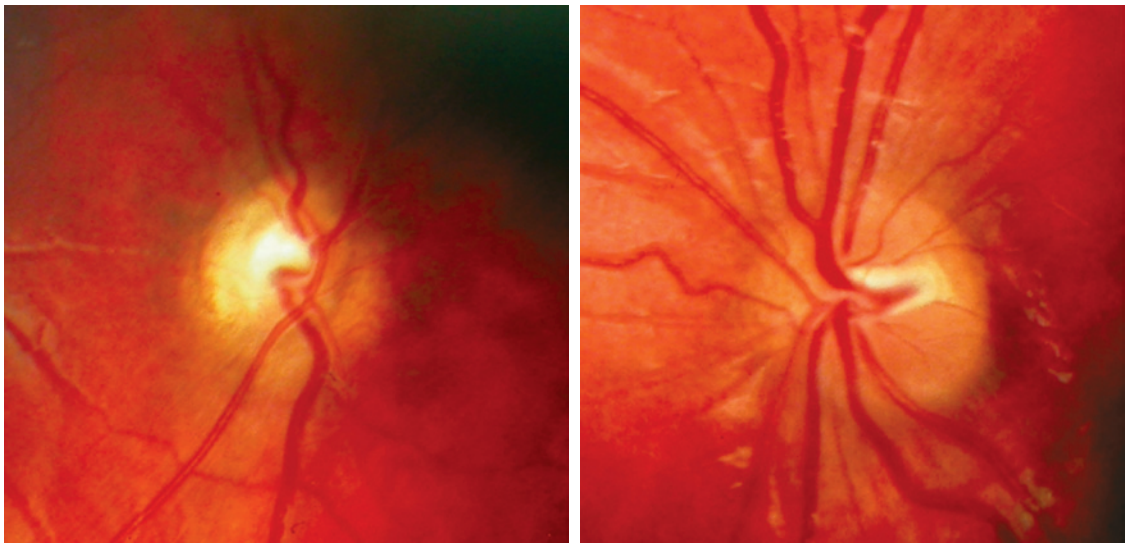

Fig. 53.10 This child, who has radiologically and electrophysiologically proven achiasmia, has a markedly hypoplastic right optic disc and horizontal band hypoplasia of the left disc.

Fig. 53.11 Right optic disc of a child with a congenital tumor, presumed optic glioma, of the optic chiasm.[24] The disc is hypoplastic and has a "figure of eight" shape, presumably due to the early prenatal shaping of the disc with early loss of the crossing retinal ganglion cell axons.

hypoplasia of a "figure of eight" shape (Fig. 53.11) in patients with a suprasellar tumor suggests a chiasmal site. Segmental optic disc hypoplasia therefore results from an early injury at any site in the developing visual system.

Superior segmental hypoplasia

Babies of diabetic mothers may have neurological anomalies, including optic disc hypoplasia. In these cases, the superior half of the disc may be most affected, the so-called superior segmental ONH[21] (SSONH), or "topless" optic discs (Fig. 53.12). The visual defect may be relatively mild and the signs subtle. About 10% of children of diabetic mothers are at risk for this condition. Female gender, short gestation time, low birth weight, and poor maternal diabetes control are additional risk factors. It is not pathognomonic: it may occur without maternal diabetes. SSONH has been described in identical twins, but there are no pathogenetic clues other than the fact that certain RGC axon guidance proteins (i.e. EphB) are found in the superior (dorsal) retina; their absence in mice lets the developing axons stray away from their normally tightly fasciculated paths to the optic disc.[22]

Causes and associations

Drugs and alcohol

Causative agents include quinine, anticonvulsants, serotonin re-uptake inhibitors, LSD and crack cocaine, and, particularly, maternal alcohol ingestion.

Family history and genetics

Familial cases are rare and not all necessarily genetic; in the absence of a recurrent environmental cause (such as drugs or alcohol) or a family history or consanguinity, a very low recurrence risk can be given. *HESX1* mutations, amongst others, have been recorded but seem quite unusual.

Optic nerve hypoplasia with early-onset tumors

Optic nerve hypoplasia or tilted discs may rarely be associated with a developmental tumor (see Fig. 53.11), particularly an optic glioma, in the region of the chiasm.[24]

Optic nerve hypoplasia in children with brain abnormalities

There is a causal association with a wide variety of brain malformations, probably of common origin. Premature babies with periventricular leukomalacia (PVL, see Chapter 60) may have optic discs that are of normal overall size but may fall within a broad definition of hypoplasia[23] by trans-synaptic degeneration causing cupping (Fig. 53.13). Acuity may be normal despite quite large cups, and field defects may cause concern about glaucoma. However, the history of prematurity, the non-glaucomatous fields (when field studies are possible), the round cup displaced temporally or superotemporally, and the normal intraocular pressure should be enough to distinguish PVL-associated cupping from glaucoma.

Septo-optic dysplasia

Although the term septo-optic dysplasia implies absence of the septum pellucidum and optic nerve hypoplasia only, the syndrome encompasses a wide variety of structural abnormalities of the cerebral hemispheres and commissures, hypothalamus, visual system, the pituitary body and stalk. Hemispheric abnormalities occur in nearly half of patients with optic nerve hypoplasia, including migration anomalies

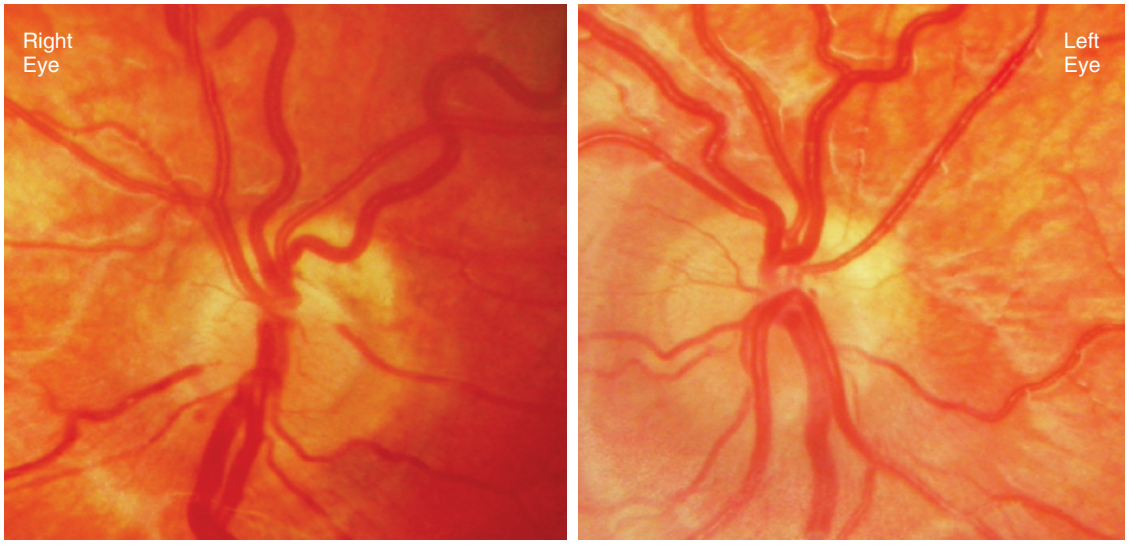

Fig. 53.12 Bilateral superior segmental hypoplasia in the child of a type 1 diabetic mother. The upper halves of the optic discs are virtually absent and the lower halves are small. There was an irregular inferior visual field defect but the visual acuity was LogMAR 0.40 (6/15, 20/50, 0.40) in each eye.

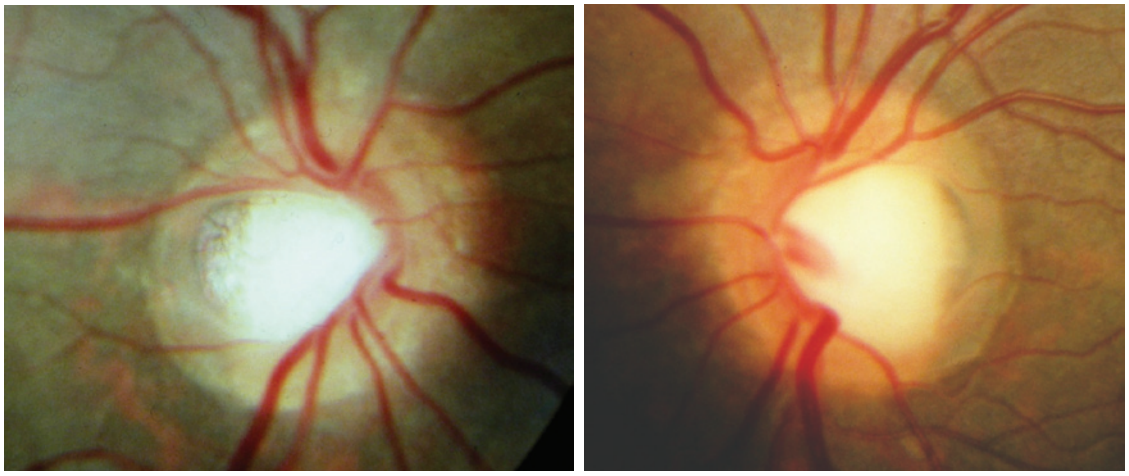

Fig. 53.13 The optic discs of a 6-year-old child who was born prematurely and developed periventricular leukomalacia (PVL).The discs have an irregular margin and are somewhat pale with large cups. There is an ill-defined inferior visual field defect. The intraocular pressures were normal.

(polymicrogyria, schizencephaly, and heterotopia), intrauterine or perinatal hemispheric injury (PVL, encephalomalacia). In holoprosencephaly, a variable midline facial defect is associated with a single cerebral ventricle, and absence of the corpus callosum and septum pellucidum.

Normally, the posterior pituitary gland appears bright on T1-weighted images, but in posterior pituitary ectopia, there is absence of the normal posterior pituitary and its infundibulum. Instead there is an ectopic posterior pituitary bright spot at the tuber cinereum (see Fig. 53.4). This suggests anterior pituitary hormone deficiency, whereas the cerebral hemispheric abnormalities and thinning or agenesis of the corpus callosum suggest neurodevelopmental deficits in both bilateral and unilateral cases: Absence of the septum pellucidum alone is not endocrinologically significant, and if the septum pellucidum and the hypothalamic–pituitary axis are both normal, it is unlikely that there will be any endocrine disturbance.

A variety of hormonal defects have been described ranging from isolated growth hormone, adrenocorticotrophic, or antidiuretic hormone deficiency to panhypopituitarism. Hypothyroidism may be the most common significant abnormality, but there is wide variation and the possibility of minimal abnormalities in multiple hormones should be remembered. Growth hormone defects may present later in childhood, as growth can be stimulated by prolactin. Whether or not MRI or endocrine abnormalities are found, weight and height must be monitored annually, usually under the care of an endocrinologist or pediatrician.

Children with septo-optic dysplasia are at risk of sudden death from the combination of reduced anterior and posterior pituitary hormones and hypothalamic defects when exposed to stress, especially in the form of hyperthermia or infection (Fig. 53.14). Parents must be warned to avoid exposure of an affected child to such stresses.

Management of children with optic nerve hypoplasia

All cases should, wherever possible at diagnosis, have a full clinical ophthalmology and endocrinology assessment and neuroimaging: MRI looking especially at the hypothalamus and pituitary. Patients with any abnormalities will need expert monitoring and possibly treatment for life. If they are found to be normal, their height, weight, and development should still be monitored at least yearly until fully grown. The management of the visual defect is discussed in Chapters 5 and 61.

Tilted optic discs

The tilted disc, in which the optic disc is D-shaped (Fig. 53.15), is accompanied by a defect in the retinal nerve fiber layer adjacent to the flat arm of the "D," usually inferiorly.[25] Peripapillary fundus ectasia or staphyloma are sometimes associated (Fig. 53.16). Although most are myopic and astigmatic, nearly half of the patients have non-refractive visual abnormalities associated with the defect, suggesting it may represent a form of segmental hypoplasia. The visual field defects are frequently superotemporal but, unlike chiasmal compression, do not follow the midline and should be repeated with refractive correction appropriate to the ectatic area. Tilted optic discs may also be mistaken for mild papilledema. Myopia and tilted optic discs commonly occur together in X-linked congenital stationary night blindness.

Situs inversus

Situs inversus is a more widespread defect in which the vessels emerging from the often-small optic disc are so distorted that, together with the appearance resulting from the tilt *per se*, the disc appears to be rotated through approximately 180° (Fig. 53.17). Although the anomaly was thought to be related to coloboma, in reality the cause is unknown. When these occur bilaterally, superior bitemporal relative visual field defects may occur, which also cross the midline. There may be an

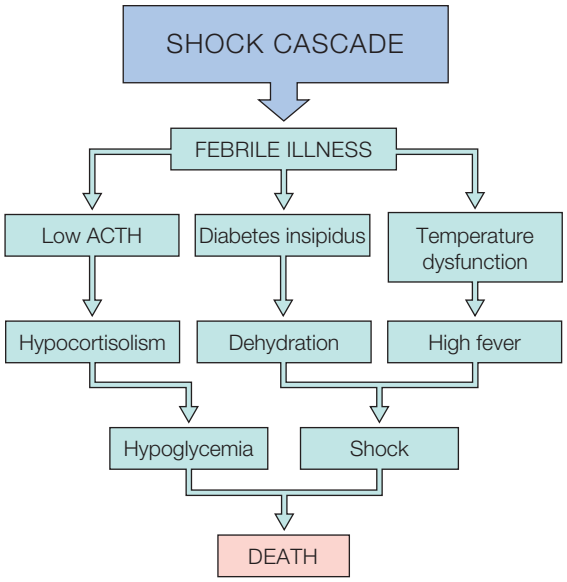

Fig. 53.14 Children with septo-optic dysplasia may die as a result of their brain defects or because they are more susceptible to death from various causes due to their brain and endocrine defects. A prominent and preventable cause of early death is a combination of low adrenocorticotropic hormone (ACTH), hypothalamic dysfunction, and diabetes insipidus (DI). When the child has a fever or is in an unaccustomed hot climate, a cascade occurs which may result in death.

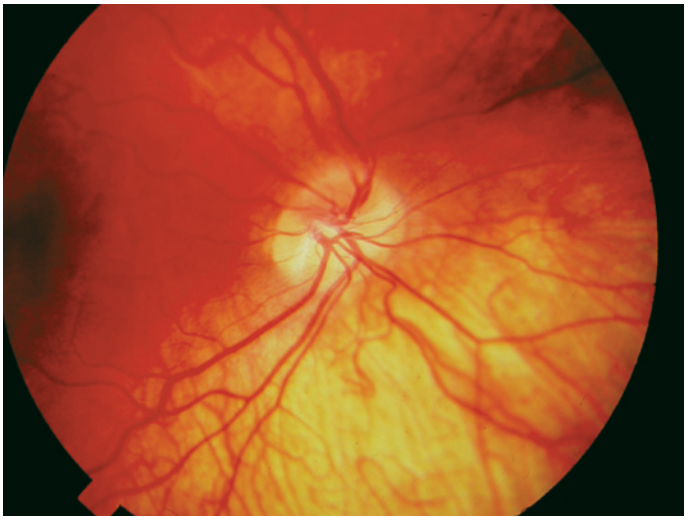

Fig. 53.16 Right eye with the macula visible. Inferonasal to the tilted optic disc is a pale area that represents a staphyloma. There is marked myopic astigmatism.

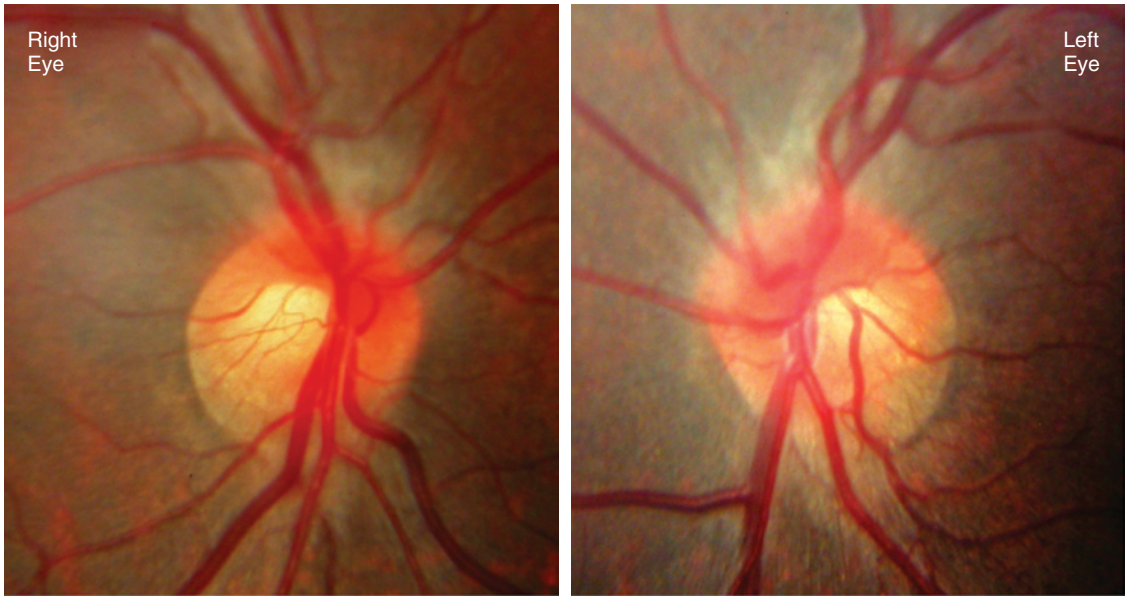

Fig. 53.15 Bilateral "tilted" optic discs in a myopic and astigmatic child.

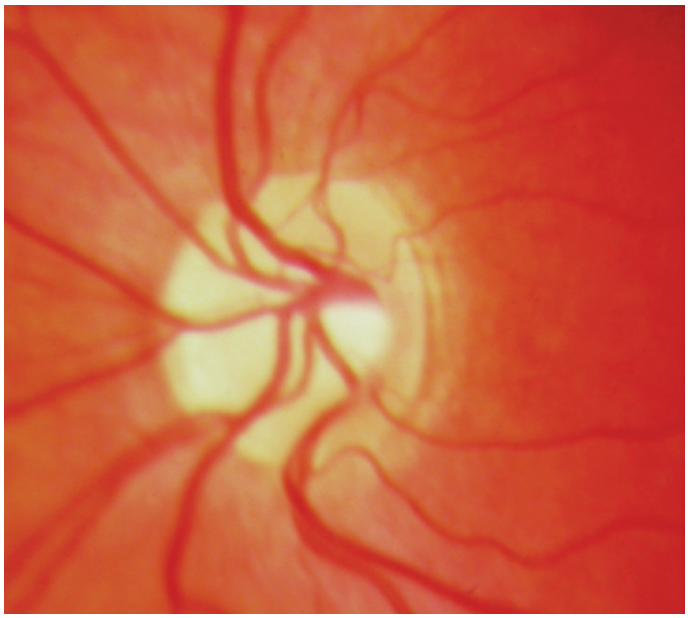

Fig. 53.17 Unilateral situs inversus in an astigmatic man. The corrected acuity was LogMAR 0.18 (20/30, 6/9, 0.67).

associated posterior staphyloma below the disc. In many cases, the apparent field defect disappears with appropriate optical correction of the myopia caused by the staphyloma.

Fetal fissure-related optic disc abnormalities

Coloboma

Developmental aspects

A coloboma is a defect that results from an abnormality of the closure of the fetal fissure in the inferonasal quadrant of the developing optic cup. Closure starts at the equator and extends anteriorly and posteriorly. Incomplete closure creates a defect of any size from the margin of the pupil to the optic disc. Some are quite subtle. Microphthalmos and clinical anophthalmos may represent extreme manifestations of the same disorder.

Presentation

Children with colobomas present either as a result of the appearance of microphthalmos, abnormally shaped pupil, or, if bilateral, because of poor vision. If unilateral with poor vision, they may present with a squint or manifest latent nystagmus. If a fundus coloboma is extensive, the parent may notice an abnormal red reflex on flash photography or a mother may notice it when feeding the baby with the light coming from behind her. Sometimes the systemic associations of colobomas are the presenting features, or the coloboma may only be discovered on routine examination.

Clinical features

Typically, optic disc colobomas are inferonasal and range from a subtle change in the retinal pigment epithelium (RPE) (Fig. 53.18) to a hugely excavated disc (Figs 53.19 and 53.20). Colobomas of the disc may be associated with subtle manifestations of choroioretinal colobomas, iris or, rarely, inferonasal lens defects. Very rarely, neoplasms may occur along the line of closure of the fetal fissure: these include glioneuromas and medulloepitheliomas.

Fig. 53.18 Right eye: there is an inferonasal retinal pigment epithelial defect extending from a cupped anomalous optic disc with normal intraocular pressure. Although this has no functional consequences, its diagnostic significance is as great as any other coloboma.

Colobomas of the choroid result in scotomas in proportion to their size. Optic nerve colobomas cause varying visual defects, depending on their size and the degree of macular involvement. Amblyopia is often a significant factor, related to associated myopic astigmatism.

Various intraocular abnormalities may occur in association with colobomas. These may include a preserved hyaloid vascular system, an anomalous Cloquet's canal, lens notches, vitreous striae, cataract, and glial tissue with dysplastic retina near the optic disc. Heterotopic intraocular tissues, including lacrimal, cartilage with or without ossification, adipose, and smooth muscle sometimes occur. Smooth muscle, when present, may be the basis for periodic contraction of some colobomatous defects. The scleral canal can be large and the central nerve head is occupied by loose vascular connective tissue and the peripapillary retina "bunched-up" and folded (Fig. 53.21).

Other eye malformations may be associated, in particular to glaucoma resulting from an anterior chamber anomaly, which may also cause disc excavation. Retinal detachment, subretinal neovascularization, and disciform degeneration may all occur as complications of colobomas of the choroid. Their prevalence is unknown but they are more frequent in severe colobomas.

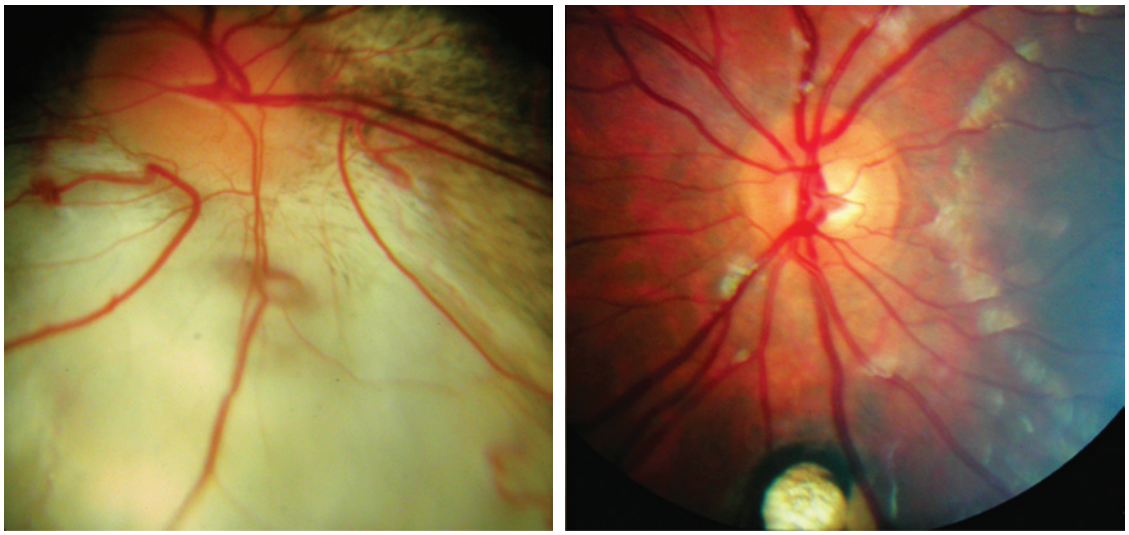

Fig. 53.19 This infant with the CHARGE syndrome (see text) presented with a white reflex from the right pupil when feeding. An iris coloboma extended back to the optic disc but the optic disc itself was quite healthy and there was a macula present. The baby was able to fix with this eye but required patching and astigmatic spectacles. The left eye had a normal optic disc and good vision, but a small, colobomatous defect inferiorly.

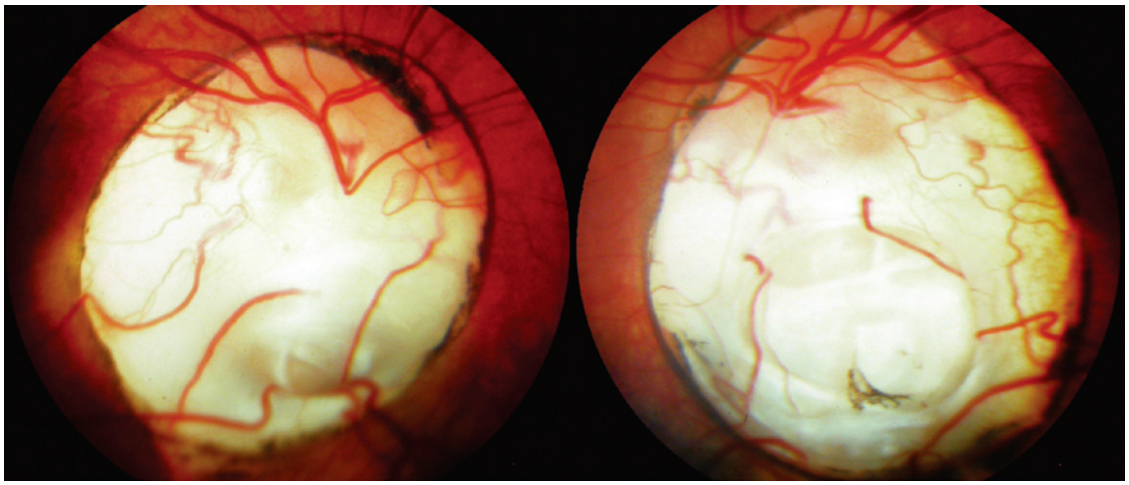

Fig. 53.20 Deeply excavated bilateral large colobomas in a child with the CHARGE syndrome.

The retinal detachments are usually reported by retina units; incidence studies are difficult to conduct.

Coloboma with cyst

Colobomas may be associated with developmental cysts that are related fetal fissure closure defects. Orbital cysts with colobomas or colobomatous microphthalmos are unusual. Affected infants usually present because of the ocular abnormality, and the cyst becomes evident as it subsequently enlarges. Occasionally, it can be large at birth (Fig. 53.22). The cysts appear as a bluish swelling in the lower lid, which enlarges on crying, or as a thin-walled cyst adjacent to the globe; it may cause a gradual proptosis and orbital enlargement. The cyst may communicate with the microphthalmic eye or even be fused with it. Surgical decompression of the cyst may cause decompression of the eye and, if functionless, the microphthalmic eye may need to be removed. The benefit of leaving the cyst, if possible, is that it allows better orbital growth. Needle aspiration of the cyst can cause a useful reduction in the size, which can be permanent.[26] These cysts contain cerebrospinal fluid and the wall may contain neuroglial tissue. The inheritance is similar to other colobomas.

Double optic discs

"Double" optic discs are usually a form of coloboma. The second optic disc usually lies below the "main" disc and has its own set of retinal vessels; it is often joined to the main disc by an arteriolar and venular connection and a bridge of the coloboma (Fig. 53.23).

Family history

Many cases of coloboma without systemic associations are sporadic or dominantly inherited with variable expressivity. The subtle phenotypic expressions have the same diagnostic and genetic implications as gross manifestations and it is very important to examine both parents and any siblings in detail (see Fig. 53.22). Autosomal recessive inheritance is less frequent.

Systemic associations of colobomas

Colobomas may occur either as part of a chromosomal syndrome or other systemic disease. One database (www.lmdatabases.com) lists 80 syndromes associated with optic

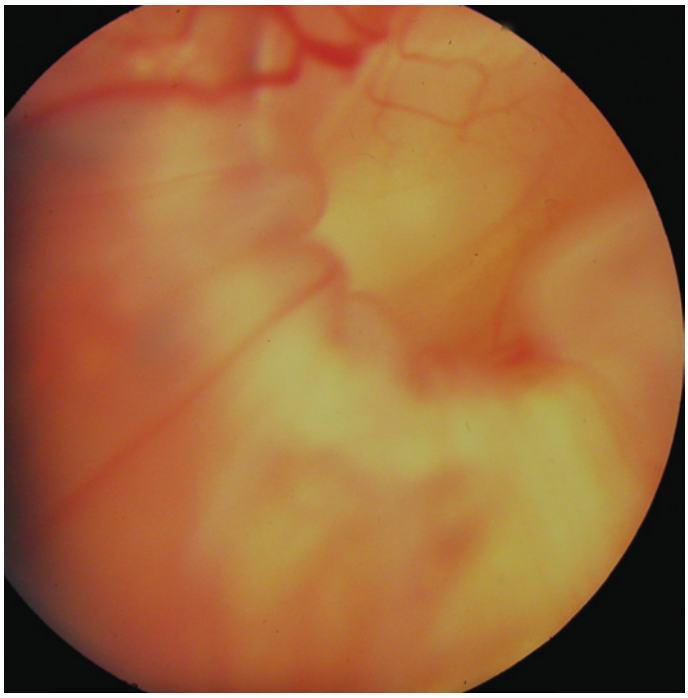

Fig. 53.21 Large colobomatous disc with overlay of the peripapillary retina.

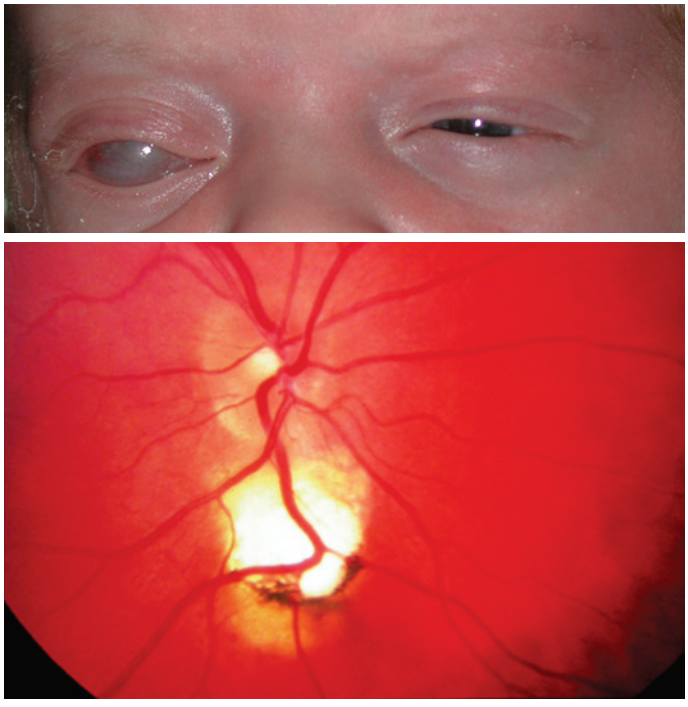

Fig. 53.22 The neonate in the top of the figure was born with a large cyst in the right orbit. The left eye was normal. The diagnosis was suggested by the finding of a coloboma in the mother's right eye (below). The cyst responded partially to repeated aspiration.[26]

disc coloboma and 104 with iris coloboma, many overlapping. Such databases are helpful for the systemic diagnosis and management of patients with colobomas, as the systemic associations are too diverse for all to be included in this chapter!

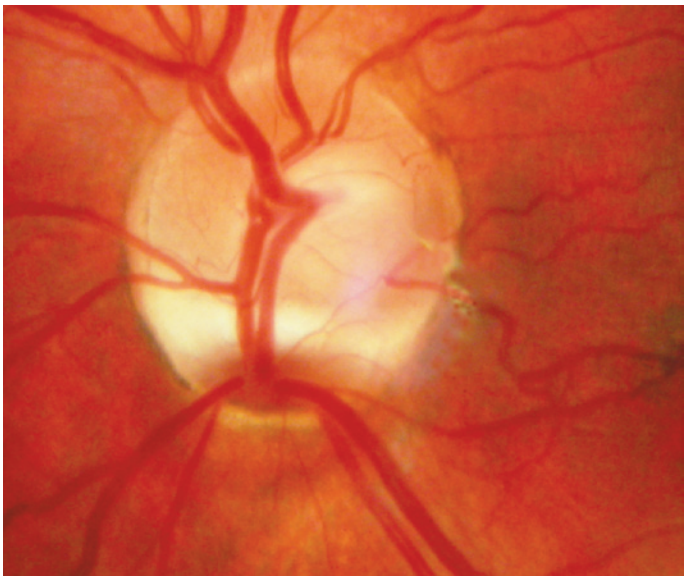

Fig. 53.23 A "double" optic disc. The inferior disc is joined to the superior one by a set of vessels.

Box 53.1

Chromosomal syndromes frequently associated with coloboma

Trisomy 13 (Patau syndrome)
Cat eye syndrome (tri- or tetrasomy 22pter)
4p- syndrome (Wolf–Hirschhorn syndrome)
Triploidy

Chromosomal syndromes uncommonly associated with coloboma

Trisomy 18 (Edwards syndrome)
Monosomy 9
11q- , 13q- trisomy 4p and trisomy 22

The occurrence of colobomas with a systemic defect thus warrants chromosome studies.

Coloboma with chromosomal syndromes (Box 53.1)

Coloboma as a part of a multisystem disorder

CHARGE syndrome CHARGE is an mnemonic for **c**oloboma, **h**eart defect, **a**tresia choanae, **r**etarded growth and development, **g**enital anomalies, and **e**ar anomalies and deafness. A patient needs four of these major findings to fit the diagnosis. Other anomalies may include facial palsy, micrognathia, cleft palate and pharyngeal incompetence, tracheo-oesophageal fistula, and renal anomalies. Many cases are associated with a CHD7 mutation. Colobomas, some atypical, occur in most cases of the CHARGE association: they range from subtle (Figs 53.19 and 53.20) to microphthalmos.

Lenz microphthalmia syndrome This is an X-linked condition with microphthalmos, microcephaly, vertebral, dental, renal, and urogenital anomalies, congenital heart disease, protruding simple ears, and finger defects. The colobomas or colobomatous microphthalmos are variable. Affected males rarely reproduce, reducing familial recurrences. *BCOR* and *NAA10* genes are sometimes implicated. If the mother is a carrier, the chance of

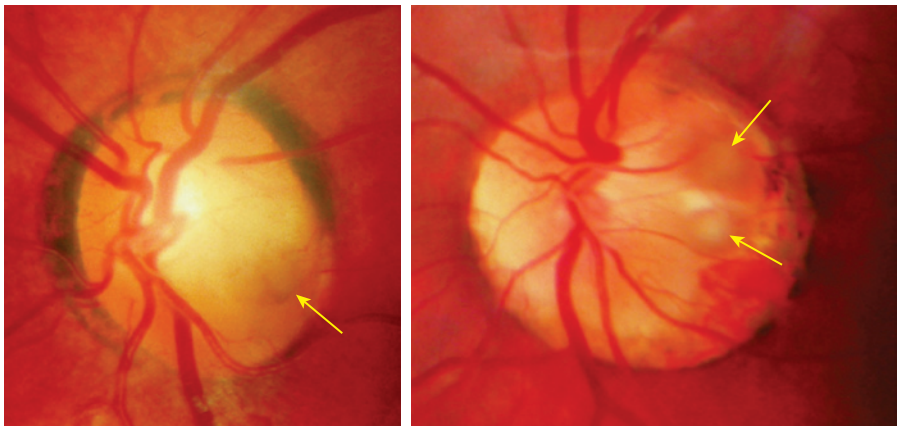

Fig. 53.24 Optic disc pits in the left eyes of two unrelated children. The yellow arrows point to the pits.

transmitting the pathogenic variant is 50% in each pregnancy: males affected, females carriers.

Focal dermal hypoplasia (Goltz syndrome) Affected children, mostly female, are born with focal dermal hypoplasia. Bony defects, "keratocystic" odontogenic tumors and mental retardation occur. Coloboma occurs with or without microphthalmos. The skin findings are striking, with pink atrophic macular areas, pinkish-brown nodules of fat herniation through the dermis, and "raspberry" papillomas at skin–mucous membrane junctions, including the lids. It is thought to be X-linked dominant, lethal in males.

Meckel–Gruber syndrome This is a severe disorder of presumed autosomal recessive inheritance. Affected infants usually have a very short lifespan. Findings include, in order of decreasing frequency, abnormal kidneys, occipital encephalocele, polydactyly, cleft palate and micrognathia, abnormal urinary tract, microphthalmia or coloboma, and congenital heart disease. It is a ciliopathy.

Joubert syndrome (see Chapter 47) These children often present in the first days of life with apnea or tachypnea, rhythmic tongue protrusions, and developmental delay. They have a retinal ciliopathy, a saccade initiation failure ("oculomotor apraxia") associated with hypoplasia of the cerebellar vermis. Up to a quarter have colobomas.

Branchio-oculo-facial syndrome The branchio-oculo-facial syndrome is an autosomal dominant syndrome with variable expression associated with mutations in the transcription factor TFAP2A. Patients have hypertrophy of the lateral pillars of the philtrum, vertical ridges between the lip and the nose, and aplastic or hemangiomatous cervical skin lesions, which may contain thymic tissue, with or without branchial sinuses. Malformed ears, cleft lip and palate, and colobomas with or without microphthalmos occur.

Basal cell nevus (Gorlin) syndrome These children present with macrocephaly, frontal and temporoparietal bossing, prominent supraorbital ridges, prognathism, and telecanthus or hypertelorism. Multiple odontogenic keratocysts of the jaw develop during the first decade of life. These and multiple nevoid basal cell carcinomas occur from late childhood, especially on the face and trunk. Colobomas may occur and myelinated retinal nerve fibers have been associated (see Figs 53.34 and 53.37). Inheritance is autosomal dominant with high penetrance and variable expression.

Linear nevus sebaceous syndrome Also known as the epidermal nevus, Jadassohn syndrome, Soloman syndrome, or Fuerstein–Mims syndrome; affected children have a non-dermatomal linear pigmented nevus, a variety of other skin defects, skeletal anomalies, and usually severe developmental delay. Eye abnormalities include ptosis, epibulbar dermoids, and lid colobomas. Fundus abnormalities have been described, including colobomas, anomalous discs, peripapillary staphyloma, Coats disease, pseudopapilledema, osseous choristoma of the choroid, and optic nerve hypoplasia.

Optic disc pits

These are grayish pits of variable size that usually occur temporally near the temporal margin of the disc, sometimes elsewhere (Fig. 53.24). They can be multiple and may be bilateral. They may be associated with visual field defects, a large blind spot with a paracentral arcuate scotoma.

Optic disc pits may be of a similar pathogenesis to colobomas, but they may occupy a site unlikely to result from an abnormal closure of the fetal fissure, although they occasionally occur with an optic disc coloboma either in the same eye or in the other eye. There are no regularly occurring systemic associations and they are rarely inherited.

Up to 60% of patients will develop central serous retinopathy with visual symptoms from the third decade of life, especially if the pit lies by the rim of the optic disc. The origin of subretinal fluid in humans with central serous retinopathy associated with a pit is still uncertain, but cerebrospinal fluid seems the most likely source. Although often following a benign course, subretinal neovascularization and other complications may occur, and some authors advocate aggressive treatment in selected cases such as pars plana vitrectomy with or without internal limiting membrane peeling, with or without endolaser photocoagulation and C3F8 gas tamponade.[27]

Other optic disc anomalies

Morning glory optic disc anomaly

This is an unusual defect that should be diagnosed specifically because of its significant associations. The disc may be large and

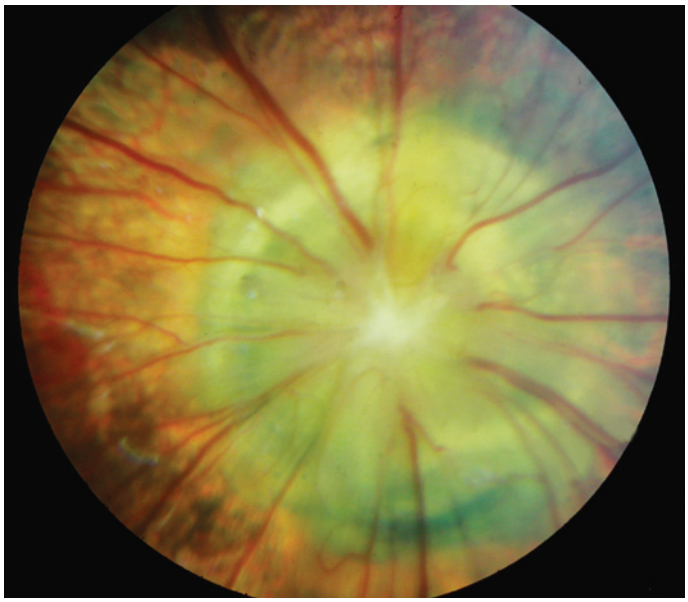

Fig. 53.25 Morning glory disc anomaly. This child presented with strabismus and poor vision at 5 years of age. Occlusion was abandoned, as the child was unable to navigate with the occlusive patch.

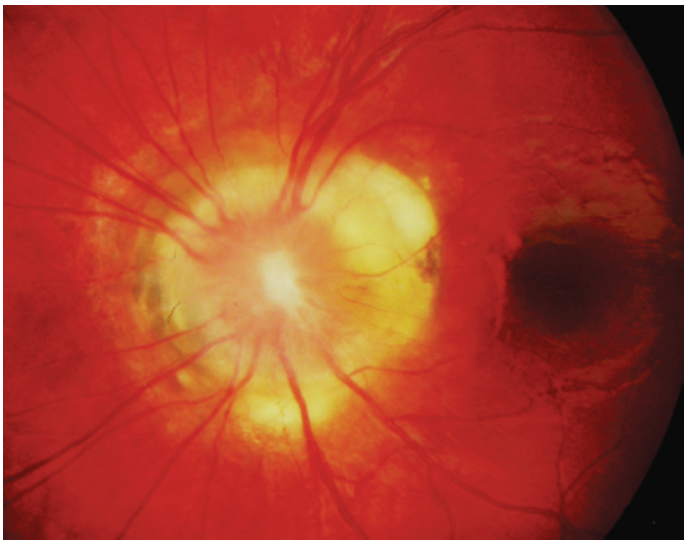

Fig. 53.26 Morning glory disc anomaly. The macula is present and the visual acuity is LogMAR 0.48 (20/60, 6/18, 0.33).

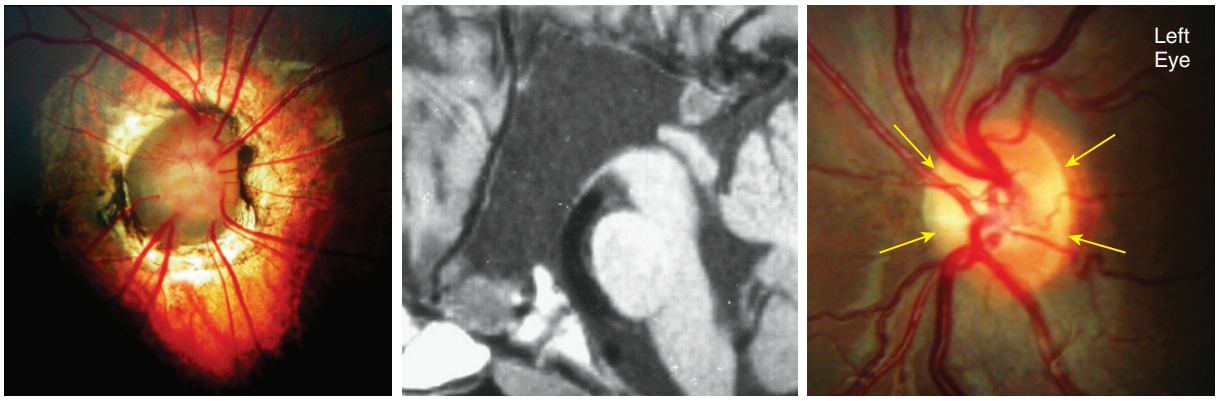

Fig. 53.27 The central part of this figure shows a coronal magnetic resonance imaging of an encephalocele. The patient's right eye has a morning glory disc anomaly with low vision and the left has horizontal band atrophy (arrows) and a temporal visual field defect. Electrophysiology showed crossed asymmetry (see Chapter 9).

the peripapillary area is variably elevated with an associated annulus of pigment, and there is a central glial tuft containing abnormal tissue on MRI studies, extending anteriorly to a variable extent. The vessels, which originate from near the disc edge, radiate outwards (Fig. 53.25); it is often difficult to determine whether they are arterioles or venules, sometimes with A–V communications adjacent to or distant from the disc.

The vision in the affected eye is usually, but not invariably (Fig. 53.26), poor and may be worsened by amblyopia from myopic astigmatism.

Similar to some colobomatous and other optic disc defects, they may show slow contractile movements.

There are three main systemic associations:

Basal encephaloceles Basal encephaloceles are associated with a variety of dysplastic discs, including typical morning glory anomaly (Fig. 53.27); mostly, they are dysplastic, sometimes with features of colobomas, notably an inferior V-shaped chorioretinal pigment anomaly. The encephalocele may present with difficulty feeding, mouth breathing, or snoring because of nasal obstruction, hypertelorism, or because of a midline notch in the upper lip or a cleft lip or palate.

Moyamoya disease The morning glory anomaly may be associated with (usually ipsilateral) cerebral vascular narrowing or closure; some may be associated with moyamoya disease. Affected patients may present with strokes, transient ischemic attacks (TIAs or mini-strokes), or epilepsy. Revascularization surgery may be successful in children. Spontaneous improvement may occur.[28]

PHACES syndrome A morning glory disc anomaly (MGDA) may, mostly in girls, be associated with **p**osterior fossa malformations, **h**emangiomas, **a**rterial anomalies, **c**ardiac defects, **e**ye abnormalities, **s**ternal cleft, and supra-umbilical raphe syndrome (PHACES syndrome; Fig. 53.28). The MGDA is usually ipsilateral to the hemangioma. The visual prognosis is usually, but not necessarily, poor for the affected eye, which may also be amblyopic.

Other associations include microtia (small pinna of the ear), Duane retraction syndrome, Brown syndrome, cleft lip and palate, hypertelorism, agenesis of the corpus callosum, endocrine and central nervous system anomalies, and a variety of ocular defects. Not infrequently there is a widespread non-rhegmatogenous or rhegmatogenous retinal detachment, often early in life, which may settle spontaneously or with treatment.

MGDA is usually unilateral and non-genetic: its nosology and relationship to typical coloboma are uncertain. The association with moyamoya disease and PHACES syndrome and the vascular features of the optic disc anomaly, both suggest an abnormality of vasculogenesis, but the presence of an inferior tongue of depigmentation suggests a fetal fissure-related pathogenesis (see Fig. 53.27).

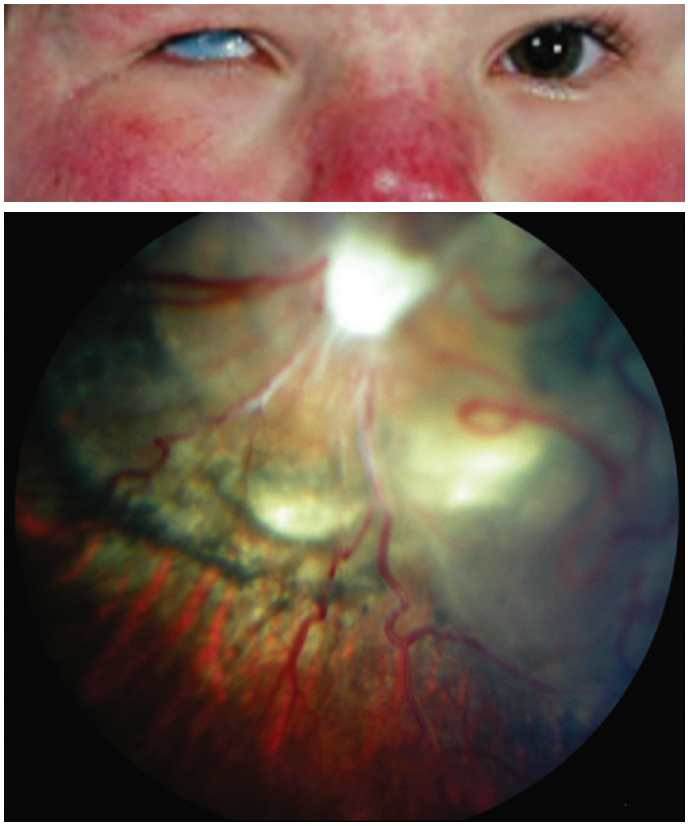

Fig. 53.28 This infant with the PHACES syndrome has an opaque right cornea and a morning glory disc-like anomaly in the left eye.

Renal-coloboma (papillorenal) syndrome

In this autosomal dominant syndrome, there may be some central optic disc excavation, with multiple cilioretinal vessels exiting the optic disc radially. Not all patients have renal disease and not all patients with the associated renal disease, or even with a family history, have the disc anomaly. Doppler ultrasound of the optic discs may show reduced central retinal artery flow. Because there are no normal central vessels, the disc may be excavated or "vacant" (Fig. 53.29), the central part having few vessels.

Patients with the syndrome may develop serous retinal detachments, perhaps associated with a pit, and they may have thin peripheral retinas.

Renal disease is variable and usually progressive, often necessitating renal transplantation for chronic renal failure in young adulthood. The diagnosis is usually made only when there is frank renal disease or a family history. The optic disc findings, although characteristic, are not pathognomonic but the appearance demands renal investigation. About a half of patients with the syndrome have a *PAX2* mutation.

Megalopapilla

Megalopapilla is a generic term used to describe large optic discs without other significant abnormalities. The optic disc may also be large in, for instance, morning glory syndrome and peripapillary staphyloma or congenital glaucoma, but in those instances the primary diagnosis is used. Many represent the extreme end of the normal range of optic disc size.

There seem to be two main phenotypes:

1. A usually bilateral form with a basically normal configuration but an overall diameter of over 2.1 mm, a large round or horizontally oval cup associated with a normal rim volume and area without notches, a normal visual field (but large blind spots), a normal intraocular pressure, and normal retinal nerve fiber layer thickness.[29] They may appear pale, as the axons are spread over a larger area of cribriform plate.
2. A large dysplastic disc (Fig. 53.30) not fitting into a clear diagnostic category, often with an excavation that is

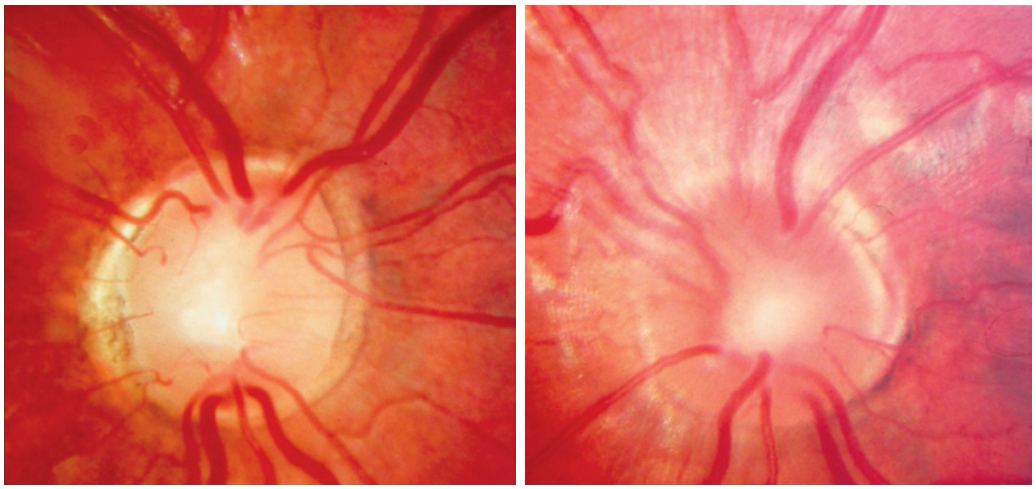

Fig. 53.29 The optic discs of a child with the renal-coloboma (papillorenal) syndrome. The vessels appear like cilioretinal vessels and radiate out from the periphery of the cupped optic discs.

non-colobomatous (does not occur in the inferonasal quadrant). Cilioretinal arteries are common. Associated midline facial abnormalities, midline clefts or pits, etc., require neuroimaging.

Peripapillary staphyloma and posterior staphyloma

Peripapillary staphyloma is a non-hereditary congenital optic disc anomaly in which a fundus excavation surrounds, locally, a relatively normal-appearing optic disc. It is generally unilateral and is also associated with poor vision, including amblyopia.

"Posterior staphyloma" is a term used to describe the very variable ectasia of the posterior pole (see Fig. 53.16), usually centered on the macula (Fig. 53.31), which is usually bilateral. It is not usually congenital and is very strongly associated with progressive myopia.

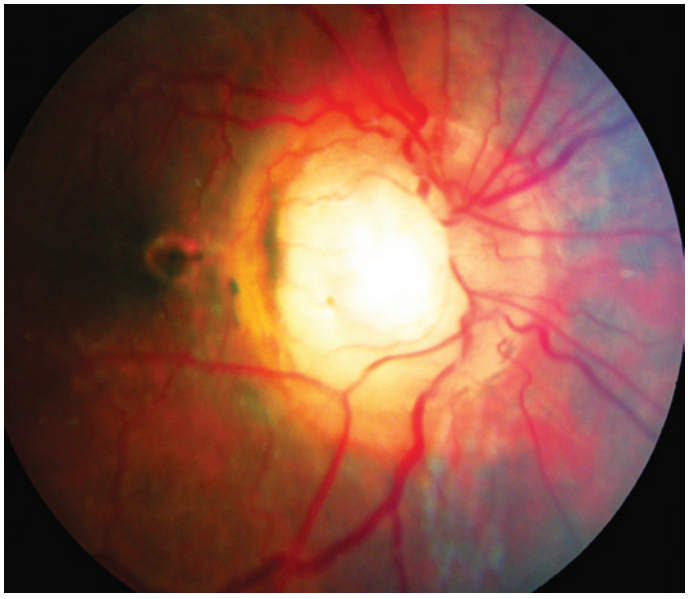

Fig. 53.30 Megalopapilla: a large dysplastic optic disc.

In peripapillary staphyloma, the area of the sclera around the optic disc is ectatic and thus relatively myopic (Fig. 53.32A). There is often a certain amount of glial tissue in the disc, and the vessels radiate out from the edge of the disc. Occasionally a serous detachment of the retina occurs around the disc. Retinal detachment, choroidal neovascular membranes and hemorrhages are not uncommon. Intermittent contraction suggests that some are associated with midline encephaloceles (see morning glory syndrome, above). Some cases are deeply excavated behind the staphyloma (Fig. 53.32B,C). The pathogenesis of these cases is unknown, but their relationship to fetal fissure closure problems is attested to by thinning of the choroid, usually inferior to the disc as in Figure 53.32A, and the often inferior site of the staphyloma. Not all cases are below the disc, however, suggesting multiple etiologies.

Congenital optic disc pigmentation and grayness

True congenital optic disc pigmentation is extremely rare, but it has been described in a child with an interstitial deletion of chromosome 17 and in Aicardi syndrome, in congenital varicella syndrome and, very rarely, in an otherwise normal eye. In itself, it is compatible with good visual acuity, but may be associated with co-existent optic disc anomalies that decrease vision. It is very frequently found as clumps of black pigment in colobomatous defects.

Gray optic discs are sometimes seen in premature, albino, or just young infants and were once thought to suggest that a slow myelination of the optic nerves might be an underlying mechanism for delayed visual maturation (DVM; see Chapter 5). Since they more commonly occur in otherwise-normal children who develop normal vision, their significance is not certain.

Aicardi syndrome

Aicardi syndrome[30] is a disorder of unknown cause that occurs in people with two X chromosomes (XX or XXY). The main features are agenesis of the corpus callosum, intractable seizures with a hypsarrhythmic electroencephalogram, profound

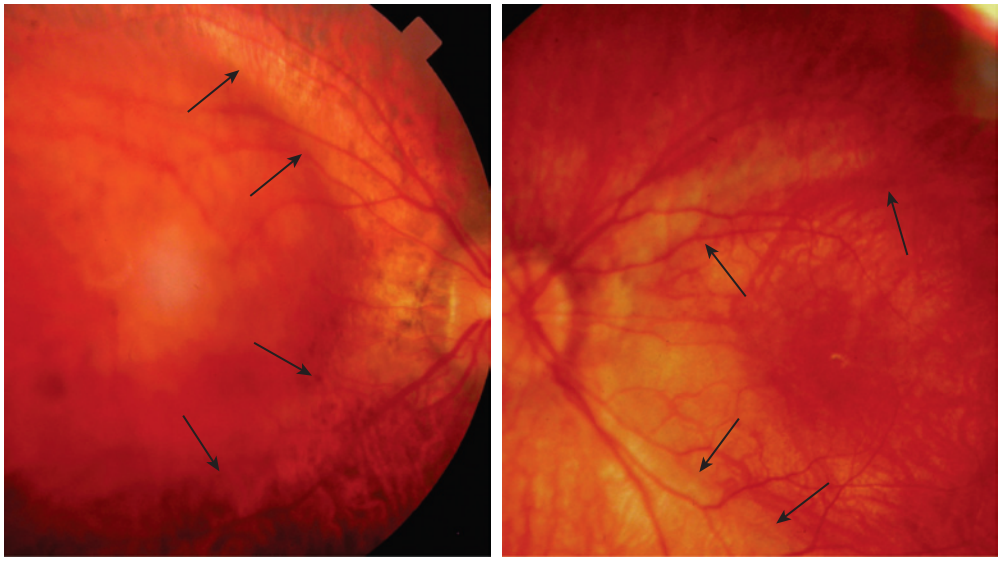

Fig. 53.31 Bilateral posterior staphylomas in a highly myopic teenager. The arrows delineate the margins of the staphyloma.

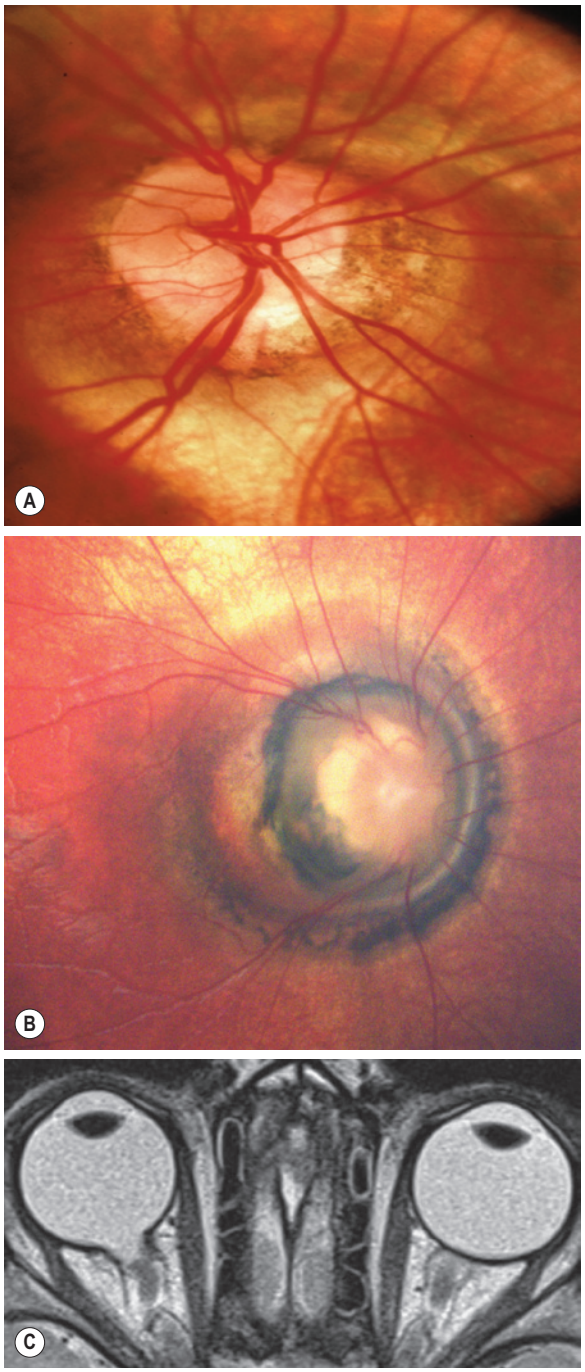

Fig. 53.32 Peripapillary staphyloma. (A) The optic disc is recessed on a circumpapillary ectatic area with inferior extension in this man with a congenital basal encephalocele. (B) There is an optic disc seen eccentrically inside an elevated partly pigmented ring, which surrounds the area; its apex shows as a sickle-shaped light gray line. The disc itself, inside the elevated ring, is surrounded by a black-pigmented circle. There are radial vessels except temporally and some "glial" tissue anterior to the center of the optic disc. There are some similarities to the morning glory disc anomaly, the significance of which is not clear. Such patients should be managed with both conditions in mind. (C) The cavitary defect in the anterior optic nerve on the right side (left of image) is well shown. *([A] Courtesy of Dr William F. Hoyt. [B,C] Courtesy of Ms Tamsin Sleep, FRCOphth.)*

developmental delay, and chorioretinal lacunae mostly distributed around the optic disc (Fig. 53.33). The chorioretinal lacunae are full-thickness defects of the RPE and choroid and abnormal retina. Even a small lacuna can be of diagnostic significance.

Other ocular abnormalities include optic disc and iris colobomas, optic nerve hypoplasia, optic disc pigmentation and dysplasia, microphthalmos, retrobulbar cyst, pseudoglioma, retinal detachment, macular scars, cataract, and pupillary membranes.

Fused vertebrae, scoliosis, spina bifida and rib malformations, muscular hypotonia, microcephaly, and auricular anomalies also occur. Severe mental retardation is almost invariable. CNS anomalies in Aicardi syndrome include agenesis of the corpus callosum, cortical migration anomalies (pachygyria, polymicrogyria, ectopic gray matter) and structural CNS malformations. The inheritance of Aicardi syndrome is probably X-linked dominant with lethality in the hemizygous male. All cases would, on this hypothesis, be new mutations.

Other optic disc dysplasias

It is easy for us to fall for the Procrustean crime of squeezing uncertain findings into a definite diagnosis. The term "dysplastic" might best be applied to any optic disc that is congenital anomalous but does not fall within one of the clearly defined anomalies (coloboma, hypoplasia, etc.). It is better, for instance, to call the anomalous optic disc of the papillo-renal syndrome "dysplastic" than "colobomatous," since the latter implies a fetal fissure-related anomaly, which is likely not the case. Many abnormalities are given the euphonic name "morning glory" discs when they do not fall strictly into that description.

Myelinated nerve fibers

Myelination of the optic nerve begins posteriorly from the lateral geniculate body at about 5 months of gestation, reaching the lamina cribrosa at around term. Myelinated (also termed medullated) retinal nerve fibers are found in up to 1% of humans. They appear as white striated "feathered" patches at the poles and at the optic discs (Fig. 53.34). They are not uniform and there may be areas of normal retina (Fig. 53.35). They may simulate papilledema (Fig. 53.36). They are frequently bilateral. The pathogenesis is unknown but may be due to anomalies of the cribriform plate allowing access for oligodendrocytes to the retina, allowing myelination of retinal ganglion cell axons.

Extensive unilateral (or, less commonly, bilateral) myelination of nerve fibers, often all around the optic disc, can be associated with high myopia and often profound amblyopia. The macula is usually unmyelinated, but may appear abnormal with a dull reflex and pigment dispersion.

Myelinated nerve fibers may be inherited as an autosomal dominant trait and occur in association with Gorlin basal cell nevus syndrome (see above and Figs 53.34 and 53.37), or in association with epiretinal membrane, vascular abnormalities,[31] and retinal and vitreous hemorrhages.

Rarely, areas of myelinated nerve fibers may be acquired after infancy and even in adulthood associated with trauma, surgery, or optic nerve glioma, and they may disappear as a result of demyelination, ischemia, inflammation, or glaucoma.

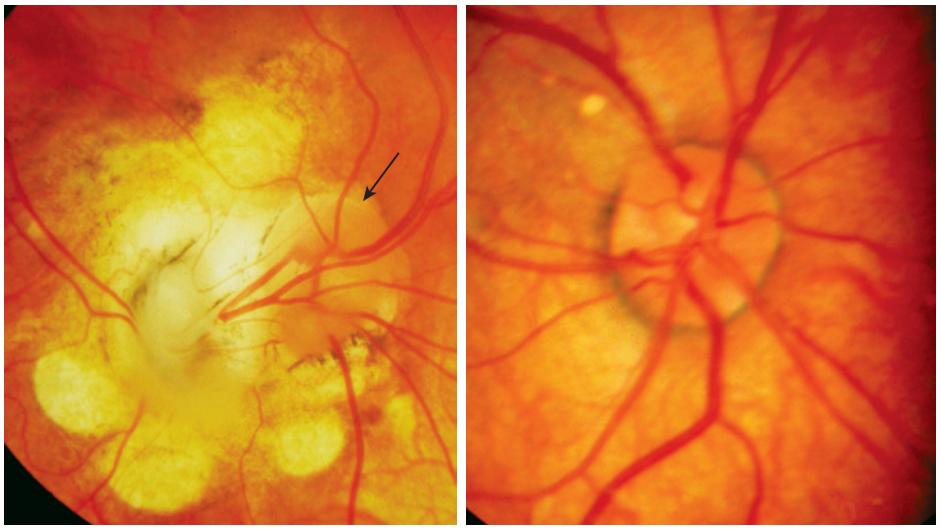

Fig. 53.33 Both these fundi are of girls with Aicardi syndrome. The very dysplastic right posterior fundus on the left of the figure shows multiple retinal pigment epithelium lacunae, a relatively normal optic disc (arrowed) and a vascular anomaly at the posterior pole. The fundus on the right belongs to a girl with severe Aicardi syndrome but the only ocular indication is the small lacunae: these, though small, have great diagnostic significance.

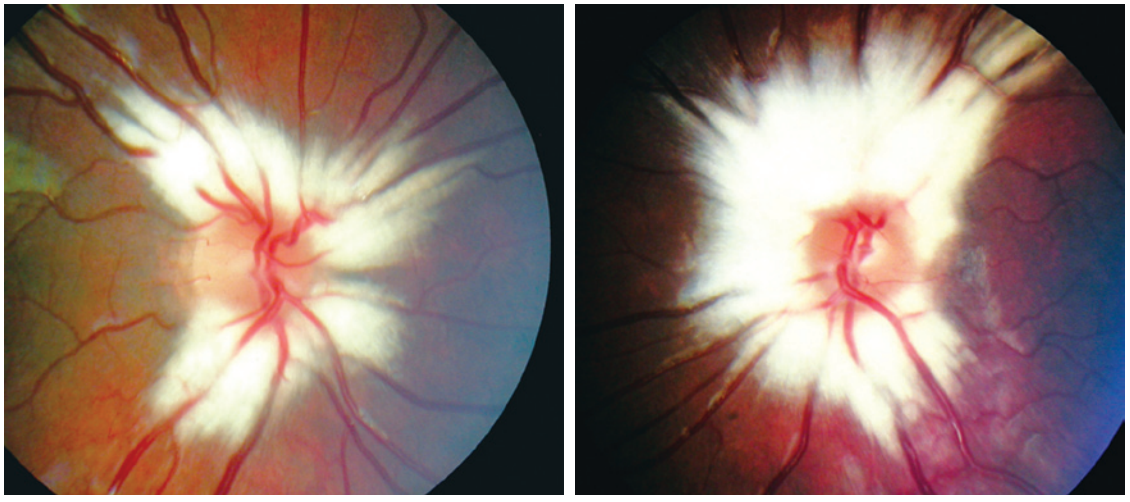

Fig. 53.34 Bilateral myelinated nerve fibers in a child with Gorlin syndrome.

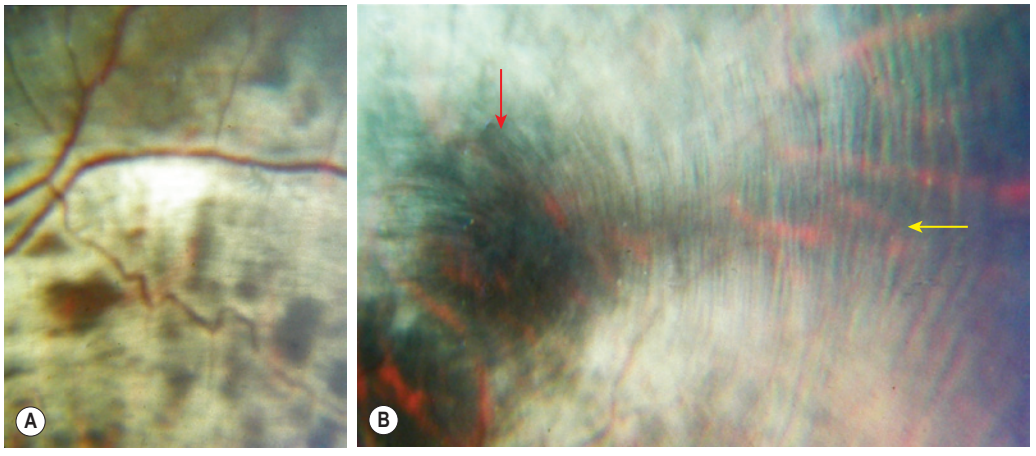

Fig. 53.35 Myelinated nerve fibers showing (A) areas without myelination and (B) the unmyelinated foveal area (red arrow) and interdigitation at the median raphe (yellow arrow).

The optic disc in albinism and aniridia

See Chapters 39 and 41.

Vascular anomalies and prepapillary looped vessels

A persistent hyaloid artery results from failure of regression and is seen as a small vascular or avascular thread coming from the optic disc anteriorly through Cloquet's canal in the vitreous towards the posterior lens capsule. It is commonly associated with persistent hyperplastic primary vitreous (PHPV or persistent fetal vasculature; Fig. 53.38), and is usually asymptomatic. It can bleed after trauma or posterior vitreous detachment.

A congenital retinal macrovessel may extend to the optic disc, and retinal arteriovenous malformations often extend to the optic disc (see Chapter 49). Optociliary shunt vessels (between the retinal and ciliary vessels) are almost exclusively seen with large optic nerve tumors, central vein obstruction, or other causes of raised ciliary venous pressure, but may rarely be mimicked as a congenital anomaly.

Looped or coiled peripapillary retinal vessels are rare congenital anomalies. They can be unilateral or occasionally bilateral.[32] Often asymptomatic (Fig. 53.39), they may present with floaters from preretinal or vitreous hemorrhage. Occasionally, usually in older children or adults, they may obstruct, resulting in infarction of the retinal zone supplied.

Fig. 53.36 Myelinated nerve fibers in a child with raised intracranial pressure. The patient was known to have myelinated nerve fibers before she had a shunt blockage. The myelinated nerve fibers are obvious but the thickened nerve fibers are visible near the black arrow.

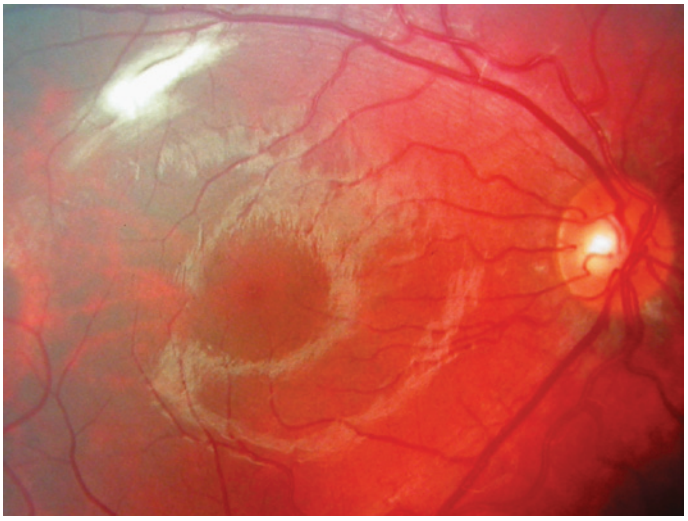

Fig. 53.37 A small patch of nerve fibers near the temporal arcade in a child with Gorlin nevoid basal cell carinoma syndrome.

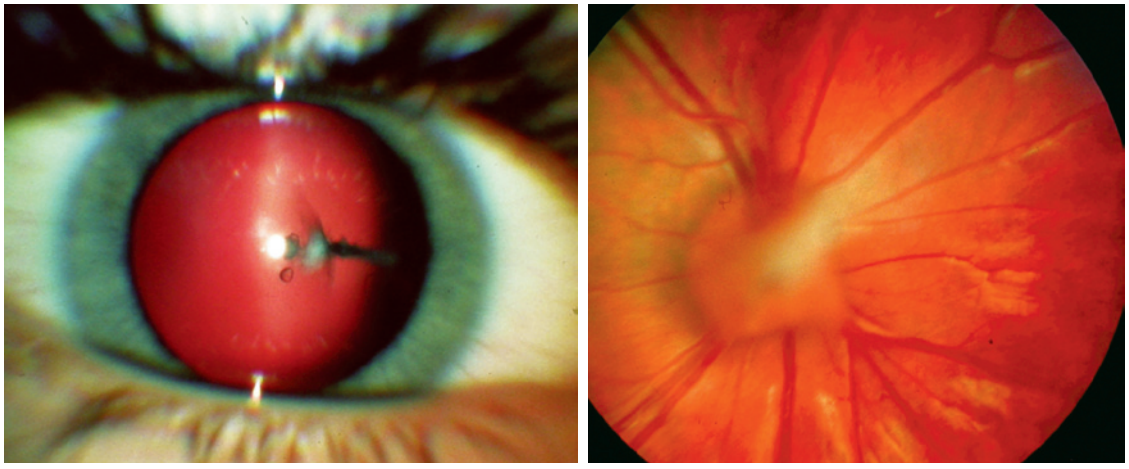

Fig. 53.38 A persistent fetal vasculature with a persistent hyaloid artery passing forward from the optic disc (right) to the back of the lens where there is a small cataract (left).

Fig. 53.39 Small looped vessel (arrow) at the optic disc.

HEREDITARY OPTIC ATROPHY WITH OTHER NEUROLOGIC OR SYSTEMIC SIGNS
OPTIC NEUROPATHY AS A MANIFESTATION OF HEREDITARY DEGENERATIVE OR DEVELOPMENTAL DISEASES
REFERENCES

The hereditary optic neuropathies comprise a group of disorders in which the cause of optic nerve dysfunction appears to be hereditary, based on familial expression or genetic analysis. Clinical variability, both within and among families with the same disease, often makes recognition and classification difficult.[1–3] Inherited optic neuropathies are often classified by pattern of transmission, most commonly autosomal dominant, autosomal recessive, and maternal (via mitochondrial DNA [mtDNA]). The same genetic defect may not be responsible for all pedigrees with optic neuropathy inherited in a similar fashion. Similarly, different genetic defects may cause identical or similar phenotypes – some inherited in the same manner, others not. Alternatively, the same genetic defect may result in different clinical expression, although the pattern of inheritance should be consistent. Single cases are often presumed or proven to be caused by inherited genetic defects, making the pattern of familial transmission unavailable as an aid to classification.

The inherited optic neuropathies typically manifest as symmetric, bilateral, painless, central visual loss. In many of these disorders, the papillomacular nerve fiber bundle is affected, with resultant central or cecocentral scotomas. The exact location of initial pathology along the ganglion cell and its axon, and the pathophysiologic mechanisms of optic nerve injury, remain unknown, but mitochondrial dysfunction plays a central role in the pathogenesis of most, if not all, of the inherited optic neuropathies.[2,3] Optic nerve damage is usually permanent and may be progressive. Once optic atrophy is observed, substantial nerve injury has already occurred.

In some of the hereditary optic neuropathies, optic nerve dysfunction is isolated. In others, various neurologic and systemic abnormalities are regularly observed and inherited diseases with primarily neurologic or systemic manifestations, such as the multisystem degenerations, can include optic atrophy. In this chapter, the hereditary optic neuropathies are classified into three major groups[1]:

1. Those that occur primarily without associated neurologic or systemic signs.
2. Those that frequently have associated neurologic or systemic signs.
3. Those in which optic neuropathy is usually recognized as secondary in the disease process.

As more specific genetic defects are discovered, our concept of the phenotypes of these disorders will likely change, as will our classification.

Monosymptomatic hereditary optic neuropathies

Leber hereditary optic neuropathy

Leber hereditary optic neuropathy (LHON) is one of the first diseases to be etiologically linked to specific mtDNA defects.[1–3] It has a minimum point prevalence of 1 in 31,000 in the northeast of England, 1 in 39,000 in the Netherlands, and 1 in 50,000 in Finland.[3] Age of onset is typically between 15 and 35 years, but may range from 1 to 87 years. LHON is expressed predominantly in males, a feature not expected from mtDNA inheritance. Between 25% and 50% of male and 5% and 10% of female LHON carriers will have vision loss during their lifetime. Visual loss is bilateral, painless, central, and usually abrupt in onset. In about 50% of cases, the vision loss is recognized as occurring sequentially, with one eye affected weeks to months before the second eye. Within 1 year, both eyes are invariably affected. Over weeks or months, vision worsens in each eye to acuities of 20/200 or worse. Color vision is affected early and severely, and visual fields typically show central or cecocentral defects. Funduscopic abnormalities may be seen in patients with LHON and in their asymptomatic maternal relatives. Especially during the acute phase of visual loss, there may be hyperemia of the optic nerve head (pseudo-edema), dilation and tortuosity of vessels, and circumpapillary telangiectatic microangiopathy (Fig. 54.1). Eventually, there is optic atrophy with nerve fiber layer dropout, especially in the papillomacular bundle, sometimes with non-glaucomatous cupping of the disc. In most LHON patients, visual loss is the only manifestation of the disease. Some pedigrees have family members with associated cardiac conduction abnormalities,

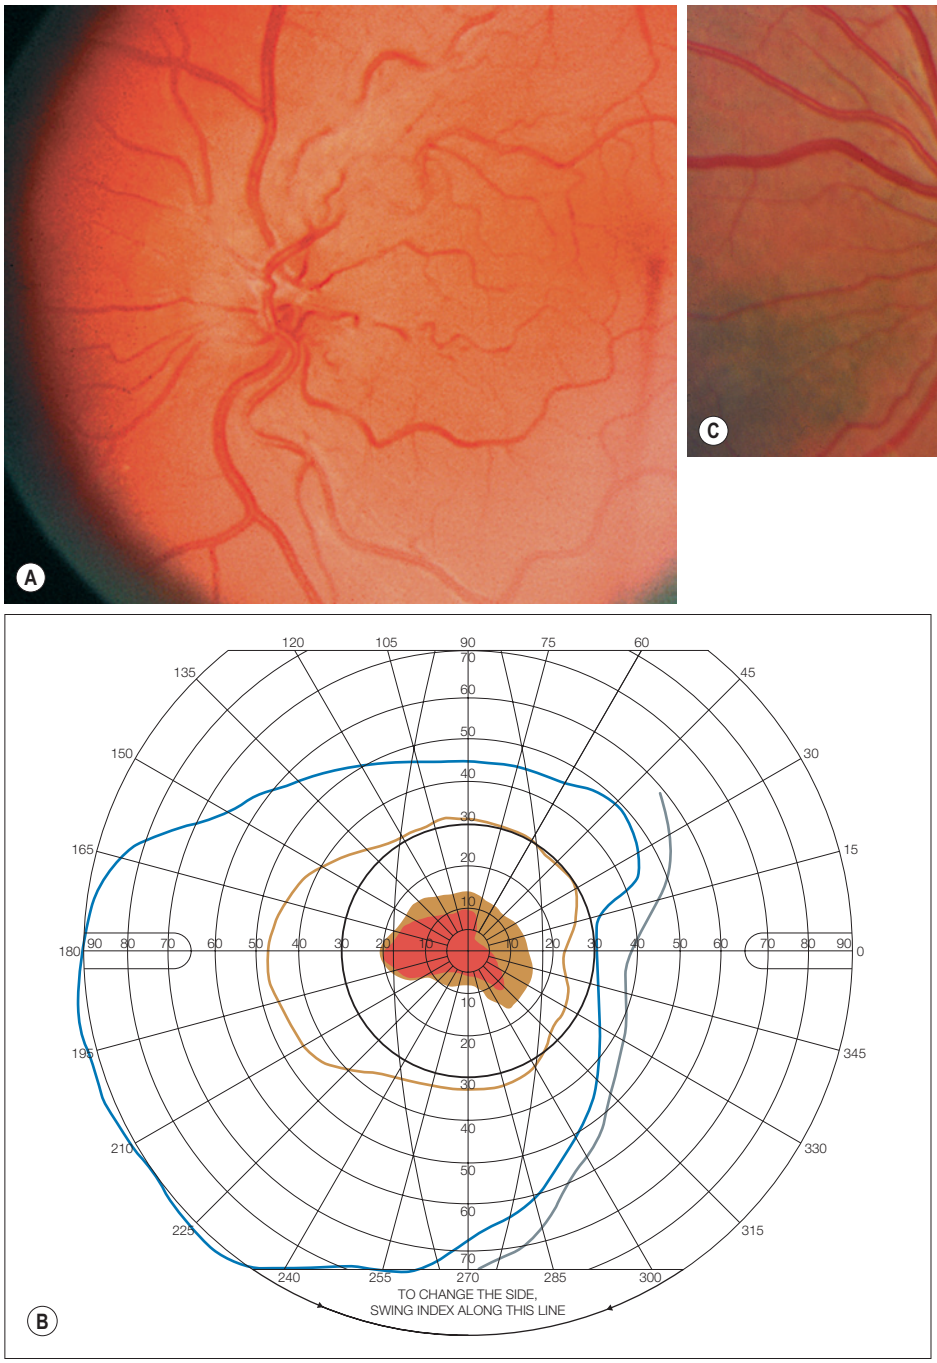

Fig. 54.1 Leber hereditary optic neuropathy. (A) Left fundus at the time of visual loss showing mild hyperemia of the optic disc with peripapillary telangiectasias. (B) Goldmann visual field demonstrating a central scotoma in the left eye. (C) Left optic disc pallor with cupping 5 months after visual loss in a patient with Leber hereditary optic neuropathy.

especially pre-excitation syndromes, minor neurologic and skeletal abnormalities, and even multiple sclerosis-like disease.

Ancillary tests in LHON are of limited clinical value. Fluorescein angiography may help distinguish the LHON optic disc from true disc edema. Electrocardiograms may show cardiac conduction abnormalities. Optical coherence tomography has demonstrated initial thickening of the peripapillary nerve fiber layer, followed by thinning as optic atrophy ensues. Visual evoked responses are predictably abnormal when there is visual loss. Standard flash electroretinograms, electroencephalograms, cerebrospinal fluid (CSF), and brain computed tomography (CT) and magnetic resonance imaging (MRI) are generally normal. Rarely, MRIs show anterior visual pathway enhancement acutely in affected LHON patients and bright T2 lesions in the late phases.

LHON pedigrees follow a maternal inheritance pattern, and the disease has been linked to point mutations in the mtDNA[1–4] (Fig. 54.2). Three point mutations in the mtDNA, known as the "primary LHON mutations," cause about 90% of cases of LHON worldwide. They are located at mtDNA nucleotide positions 11778 (69% of cases), 3460 (13% of cases), and 14484 (14% of cases) (see Fig. 54.2). Other point mutations have been found with a greater frequency in LHON patients than controls. Some of these mutations may

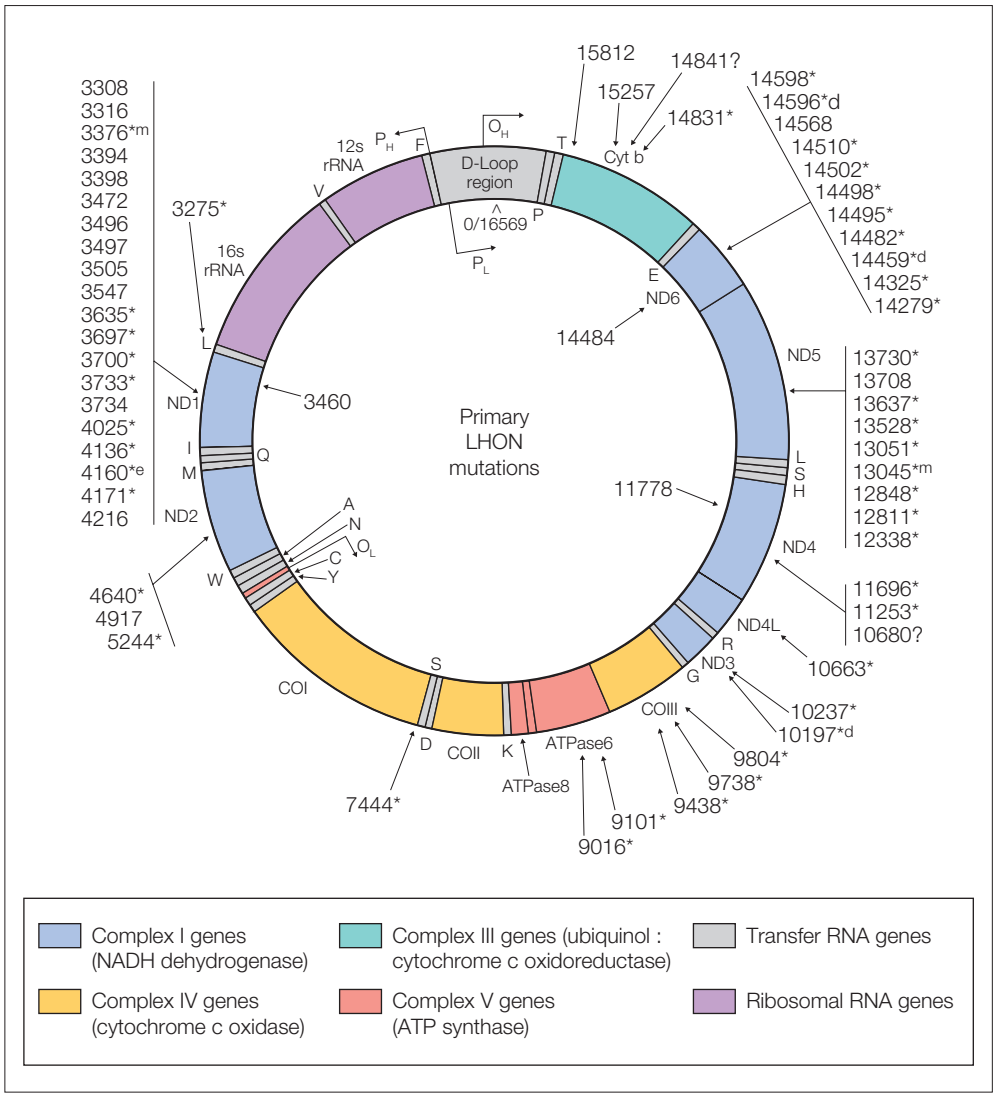

Fig. 54.2 Mitochondrial genome showing the point mutations associated with Leber hereditary optic neuropathy (LHON). Over 90% of all cases of LHON are associated with the three primary mutations located inside the genome (circle), and the other mutations are shown outside the genome. These other mutations vary markedly in their prevalence, degree of evolutionary conservation of the encoded amino acids altered, and frequency among controls. Mutations marked * may be primary, but they each account for only one or a few pedigrees worldwide. Mutations marked *d are primary mutations associated with LHON and dystonia. Mutations marked *m are primary mutations associated with MELAS. Mutations marked *e are primary mutations associated with LHON and encephalopathy. *(Adapted and updated from Newman NJ. Hereditary optic neuropathies. In: Miller NR, Newman NJ, Biousse V, et al. editors. Walsh and Hoyt's Clinical Neuro-Ophthalmology, Vol I, 6th ed. Baltimore, MD: Williams & Wilkins; 2005: 465–501.)*

be true primary mutations in a few pedigrees. Others are of unknown significance. Screening for LHON in a patient with visual loss should begin with the three primary mutations. In those primary mutation-negative patients in whom suspicion remains high, mitochondrial genome sequencing can be considered, but should be interpreted by someone familiar with the complexities of mitochondrial genetics.

Among the primary mutations, the LHON clinical phenotype is remarkably similar. The only consistent differentiating feature is the better prognosis for visual outcome in those patients with the 14484 mutation.[1] Up to 70% of patients with the 14484 mutation will have some degree of visual improvement compared to only 18% of patients with the 11778 mutation. Patients with the 3460 mutation may have a better chance of visual recovery than those with the 11778 mutation, but the numbers of patients are too small for meaningful analysis. Patients with an age of onset of visual loss of less than 20 years, especially less than 10 years, have a much better visual prognosis.[2,3]

The genetic defects, however, cannot fully explain the determinants of expression in this disease. The presence of a mtDNA mutation is necessary for phenotypic expression, but it is not sufficient.[1–3] The presence of heteroplasmy (the co-existence of both mutant and normal mtDNA) may be a factor in expression. Other mitochondrial or nuclear DNA factors may modify expression of the disease, including X-linkage as an explanation for the prominence of male expression. Various environmental triggers for the development of visual loss in LHON have been suggested. Systemic illnesses, nutritional deficiencies, and medications or toxins that stress the organism's mitochondrial energy production might be detrimental to those individuals already genetically at risk for

mitochondrial energy deficiency. Smoking, probably through its deleterious effect on mitochondrial function, has been associated with a higher expression of visual loss among carriers of the LHON primary mutation; only heavy alcohol intake has been similarly associated.[5]

The pathophysiology of LHON remains unknown.[2–4] It may involve abnormal oxidative phosphorylation and deficient generation of adenosine triphosphate (ATP), either directly or indirectly related to free radical production, resulting in irreversible damage to the ganglion cells and their axons. The reason these mechanisms result in selective damage to the optic nerve remains uncertain. Histochemical studies of the optic nerve in animals have shown a high degree of mitochondrial respiratory activity within the unmyelinated, prelaminar portion of the optic nerve, suggesting a particularly high requirement for mitochondrial function in this region. Of great interest is the recent identification of genetically induced rodent models of complex I deficiency that show histopathological features of optic nerve degeneration similar to those seen in LHON patients.[4]

Therapies tried in the treatment of LHON include coenzyme Q10, idebenone, L-carnitine, succinate, dichloroacetate, vitamin K_1, vitamin K_3, vitamin C, thiamine, vitamin B_2, and vitamin E.[1–4,6] A randomized, controlled study of idebenone in the treatment of LHON patients within 5 years of visual loss suggested that patients with a disparity in their visual function between the two eyes (i.e. those likely earlier in the course of their disease) may have a better visual outcome with treatment.[7] Treatment effect persisted following cessation of therapy at 30 month follow-up.[8] However, irreversible damage makes optic atrophy an unlikely candidate for a good response to any therapy. Avoiding agents that might stress mitochondrial energy production is a non-specific recommendation with no proven benefit. However, we suggest that LHON patients and maternal relatives at risk avoid tobacco, excessive alcohol, and environmental toxins. Symptomatic therapies include pacemakers in those patients with serious cardiac conduction defects and low-vision aids for the patient with severe visual loss. As the specific genetic and biochemical abnormalities become better defined, more directed therapies may be created to replace or bypass the genetic or metabolic deficiencies in patients with the disease and in their relatives at risk. Rodent models of induced LHON with the G11778A mutation have been phenotypically rescued by allotopically expressed wild-type ND4, paving the way for phase I clinical trials in humans.[9] This form of gene therapy known as allotypic expression may play a future role in the therapy of LHON and other mitochondrial diseases.[4,6] Genetic counseling regarding maternal inheritance among family members is essential.

Dominant optic atrophy

Autosomal dominant ("Kjer type") optic atrophy (DOA) is the most common of the autosomal hereditary optic neuropathies, with an estimated disease prevalence in the northeast of England of 1 in 35,000 individuals, and as high as 1 in 12,000 in Denmark.[1–3]

Although it is difficult for patients to identify a precise onset of reduced vision, the majority of affected patients date the onset of visual symptoms between 4 and 10 years of age, with 58–84% of patients reporting visual impairment by age 11 years. Rarely, severely affected individuals have visual difficulties and sensory nystagmus prior to schooling. Many patients are unaware of a visual problem and are discovered to have optic atrophy as a direct consequence of examination of other affected family members.[1,2] Visual acuity is usually reduced to the same mild extent in both eyes. Acuities range from 20/20 to 20/800. Only about 15% of patients have vision of 20/200 or worse. Hand motion or light perception vision is extremely rare. There is considerable interfamilial and intrafamilial variation in acuities. Although not as rapid and devastating as LHON, DOA results in visual impairment severe enough to preclude driving in about 50% of affected adults. Blue–yellow color defects are classic in patients with dominant optic atrophy, but a mixed color deficit is most common. Visual fields in patients with dominant optic atrophy characteristically show central, paracentral, or cecocentral scotomas. A bitemporal depression may mimic chiasmal compression. The optic atrophy in patients with dominantly inherited optic neuropathy may be subtle, temporal only, or involve the entire disc (Fig. 54.3). The most characteristic change is a striking triangular excavation of the temporal portion of the disc, sometimes leading to the erroneous diagnosis of glaucoma. Insidious progressive decline in visual function occurs in about 50–75% of patients.[10]

Dominant optic atrophy is believed to be a primary degeneration of the retinal ganglion cells. The majority of cases of DOA (50–60%) are the result of mutations in the *OPA1* gene, located on the long arm of chromosome 3 (3q28–q29).[1–3] This nuclear gene is widely expressed in mitochondria and encodes a dynamin-related protein anchored to the inner membrane of mitochondrial cristae, abundantly represented in the retina. More than 300 pathogenic mutations in the *OPA1* gene have been identified, including missense, nonsense, deletion/insertion, and splicing mutations. However, the monosymptomatic DOA phenotype is genetically heterogeneous, and other genetic loci have been implicated. In a single family of German descent with DOA, the causative *OPA4* locus was mapped to chromosome 18 (18q12.2–12.3), and in two unrelated French families the *OPA5* locus was mapped to chromosome 22 (22q12.1–13.1).[2,3] Interestingly, linkage analysis of patients with normal-tension glaucoma has shown an association with polymorphisms of the *OPA1* gene.[2]

Classically, DOA presents with monosymptomatic optic atrophy and no other neurologic or systemic manifestations. However, it has long been known that some pedigrees with individuals manifesting classic DOA, have also included affected family members with other clinical features such as sensorineural hearing loss and even chronic progressive external ophthalmoplegia, ataxia, myopathy, peripheral neuropathy, and, rarely, phenotypes suggestive of hereditary spastic paraplegia. Most of these families are not genetically distinct from pedigrees with monosymptomatic DOA, and, indeed, *OPA1* gene mutations have been confirmed as the causative genetic defects in many of these syndromic forms of DOA, so-called "DOA plus."[11] Some patients with monosymptomatic DOA have been found to have subclinical features of DOA plus.[12] In these patients, a severely dysfunctional OPA1 protein may result in aberrant replication of mtDNA and multiple large-scale deletions of the mtDNA, and hence a more dramatic phenotype suggestive of mitochondrial disease.[13,14] While these new observations emphasize the common final pathway of mitochondrial dysfunction in the hereditary optic neuropathies, they also blur the classic classification distinctions of

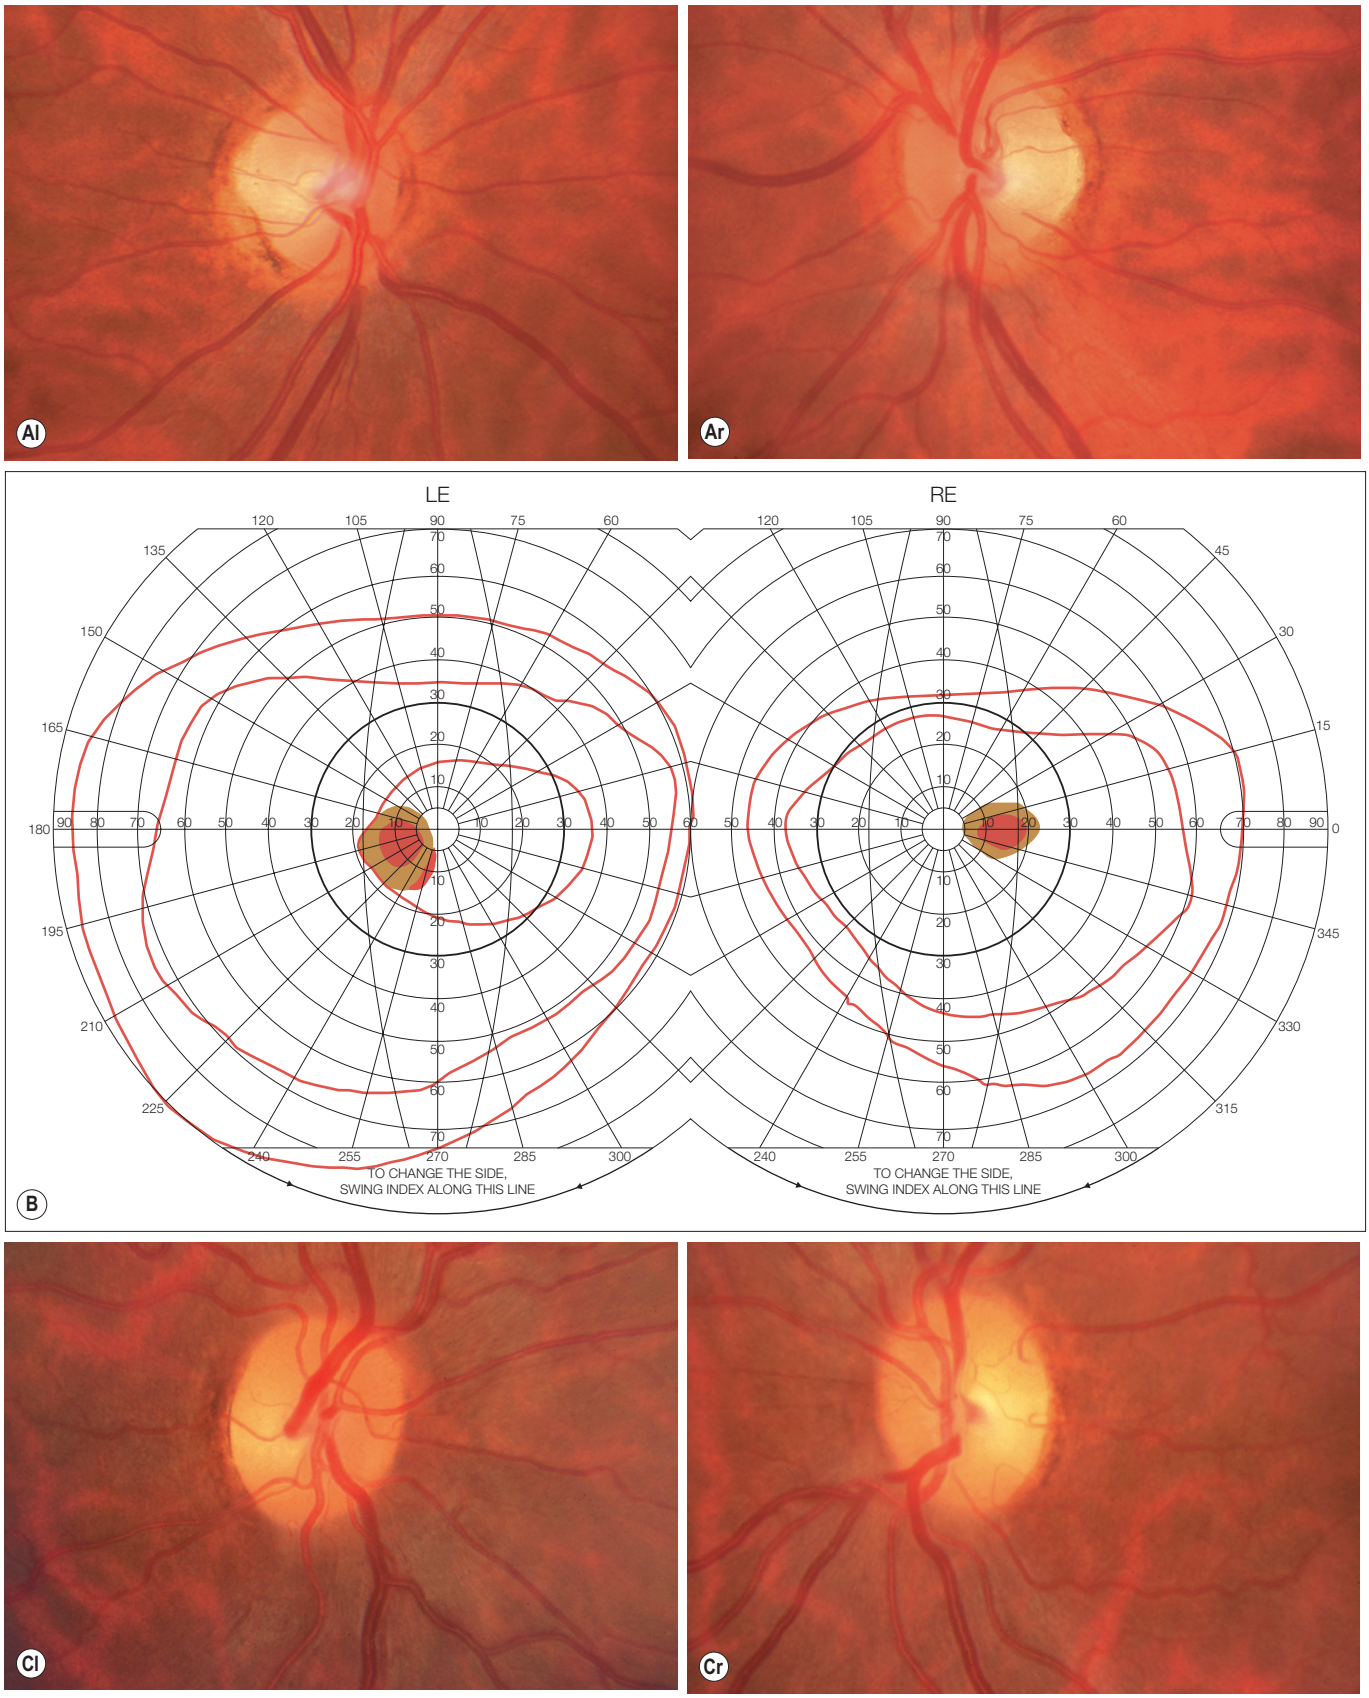

Fig. 54.3 Dominant optic atrophy. (A) Funduscopy showing bilateral temporal pallor with excavated appearance. (B) Goldmann visual field showing bilateral cecocentral scotomas (depression). (C) Funduscopy of the above patient's mother who is asymptomatic. Note the temporal pallor of both optic discs.

the non-syndromic from the syndromic forms of hereditary optic neuropathy.

Autosomal recessive optic atrophy

This form of optic atrophy is present at birth or develops at an early age and is usually discovered before the patient is 3 or 4 years old.[1] It is presumed to have autosomal recessive transmission and there is often consanguinity between parents. The visual acuity is so severely affected that the patient may be blind, with sensory nystagmus. The optic discs are completely atrophic and often deeply cupped. By funduscopy alone, it is difficult to differentiate this entity from infantile retinal degeneration, making electroretinography essential. In one consanguineous family of French origin, isolated autosomal recessive optic atrophy was linked to chromosome 8 (8q21–q22),[15] and the gene was designated *OPA6*. In a number of consanguineous North African families with autosomal recessive optic atrophy, both with and without mild (often asymptomatic) sensorineural hearing loss, defects were found in a gene designated *OPA7* on chromosome 11 (11q14.1–q21), which codes for a transmembrane mitochondrial protein.[16]

X-linked optic atrophy

Pedigrees with optic atrophy inherited in a documented sex-linked fashion are extremely rare, especially with the primary manifestation of only monosymptomatic optic atrophy. In two families, linkage to the X chromosome at the same locus (Xp11.4–Xp11.2) has been established and the gene designated *OPA2*.[17] Other families with presumed X-linked optic atrophy more consistently have other neurologic and systemic signs.

Hereditary optic atrophy with other neurologic or systemic signs

Autosomal dominant optic atrophy and sensorineural hearing loss

Several pedigrees with DOA and hearing loss have been described. In many of these pedigrees, there are no other systemic or neurologic abnormalities. Some, but not all, of these pedigrees have now been shown to harbor *OPA1* mutations that in other pedigrees cause only optic neuropathy.[1–3] In one Italian family, a new locus on chromosome 16 (16q21–q22) was designated *OPA8*, and preliminary studies suggest its pathogenesis may also be via mitochondrial dysfunction.[18]

In a Dutch pedigree with DOA and deafness, *OPA1* mutations were excluded, but a novel missense mutation was found in the *WFS1* gene on chromosome 4 (4p16.1), a common locus for mutations typically causing the autosomal recessive DIDMOAD or Wolfram syndrome (see below).[19] Similarly, in another DOA pedigree with hearing impairment and impaired glucose regulation, mutation analysis excluded mutations within the *OPA1*, *OPA3*, *OPA4*, and *OPA5* genes, but identified a novel missense mutation in the *WFS1* (Wolfram) gene.[20]

In other pedigrees with DOA and deafness, there may be associated ataxia, limb weakness, or polyneuropathy. The hearing loss in these pedigrees may be severe at birth with poor speech development, or may be only moderate and slowly progressive. The acronym CAPOS (cerebellar ataxia, areflexia, pes cavus, optic atrophy, and sensorineural deafness) has been suggested, but is as yet genetically undefined.[1] "DOA plus" with *OPA1* mutations may ultimately account for many of these more complicated syndromic pedigrees, but clearly the syndromic combination of DOA and hearing loss is genetically heterogeneous.

Autosomal dominant optic atrophy, deafness, ophthalmoplegia, and myopathy

The combination of autosomal dominant optic atrophy, deafness, ptosis, ophthalmoplegia, dystaxia, and myopathy should raise suspicion for "DOA plus" and prompt testing for mutations in the *OPA1* gene on chromosome 3.[11] Visual loss usually occurs in the first decade and progresses to the 20/30 to 20/400 range. Hearing loss is sensorineural and progressive, with onset in the first or second decade. Ophthalmoplegia and myopathy occur in midlife. This disorder likely represents mitochondrial disease secondary to nuclear genetic abnormalities (see above under DOA).

Autosomal dominant optic atrophy with premature cataracts

Two French families manifest optic atrophy and premature cataract in an autosomal dominant mode of inheritance. Mutations in the *OPA1* gene were excluded and pathogenic mutations were found in the *OPA3* gene on chromosome 19 (19q13.2–q13.3), a locus for mutations that typically cause Costeff syndrome (see below). Screening for *OPA3* mutations as a cause of monosymptomatic DOA cases in multiple other pedigrees has failed to identify any pathogenic OPA3 variants, suggesting that *OPA3* mutations as a cause of DOA are likely very rare.[21]

Autosomal recessive optic atrophy with progressive neurodegeneration and type III 3-methylglutaconic aciduria (Costeff syndrome)

In this autosomal recessive syndrome, most commonly seen in Iraqi Jewish pedigrees, severe optic atrophy is associated with extrapyramidal signs, cognitive impairment, increased urinary levels of 3-methylglutaconic acid, and elevated plasma levels of 3-methylglutaric acid. The causative gene is located on chromosome 19 (19q13.2–q13.3), and has been designated *OPA3*.[2,3]

Autosomal recessive optic atrophy with juvenile diabetes mellitus, diabetes insipidus, and hearing loss (Wolfram syndrome)

This syndrome consists of juvenile diabetes mellitus and progressive visual loss with optic atrophy, almost always associated with diabetes insipidus, neurosensory hearing loss, or both (hence, the acronym DIDMOAD for diabetes insipidus, diabetes mellitus, optic atrophy, and deafness).[3,22] Diabetes mellitus develops within the first or second decade of life and usually precedes the development of optic atrophy. In several cases, however, visual loss with optic atrophy is the first sign of the syndrome. In later stages, visual loss usually becomes severe. Visual fields have shown both generalized

Fig. 54.4 DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness). The optic disc is atrophic and there is retinal hemorrhage associated with the diabetes mellitus.

constriction and central scotomas. Optic atrophy is uniformly severe (Fig. 54.4), and there may be mild-to-moderate cupping of the disc. Both hearing loss and diabetes insipidus begin in the first or second decade of life and may be quite severe. Atonia of the efferent urinary tract is present in half of patients and is associated with recurrent urinary tract infections, neurogenic incontinence, and even fatal complications. Other systemic and neurologic abnormalities include ataxia, axial rigidity, seizures, startle myoclonus, tremor, gastrointestinal dysmotility, vestibular malfunction, central apnea, neurogenic upper airway collapse, ptosis, cataracts, pigmentary retinopathy, iritis, lacrimal hyposecretion, Adie's pupil, ophthalmoplegia, convergence insufficiency, vertical gaze palsy, nystagmus, mental retardation, psychiatric abnormalities, short stature, primary gonadal atrophy, other endocrine abnormalities, anosmia, megaloblastic and sideroblastic anemia, abnormal electroretinography, and elevated CSF protein. Neuroimaging and pathology in some patients reveal widespread atrophic changes and malformations of cortical development, and suggest a diffuse neurodegenerative disorder, with particular involvement of the midbrain and pons. When the syndrome is accompanied by anemia, treatment with thiamine may ameliorate the anemia and decrease the insulin requirement.

Linkage analysis in several families has shown localization of a Wolfram gene to chromosome 4 (4p16.1). The gene responsible at this locus has been designated *WFS1*, in which multiple point mutations and deletions have been identified. The gene product, wolframin, is an endoplasmic reticulum protein, which plays a role in the regulation of intracellular calcium. A second causative Wolfram gene on the other arm of chromosome 4 (4q22–24) has been identified and designated *CISD2*; it is associated with bleeding tendency and peptic ulcers. Knockout of the *CISD2* gene in mice results in a Wolfram-type syndrome associated with mitochondrially mediated premature aging. Indeed, many of the associated abnormalities reported in Wolfram syndrome are commonly encountered in patients with presumed mitochondrial diseases, especially those patients with the chronic progressive external ophthalmoplegia syndromes. This has led to speculation that the Wolfram phenotype may be non-specific, reflecting a variety of underlying nuclear or mitochondrial genetic defects with a final common pathway of mitochondrial dysfunction.[2,3] Indeed, most cases of Wolfram have been classified as sporadic or recessively inherited, the latter usually concluded from sibling expression (which is now known to also be consistent with maternal transmission).

Spastic paraplegia, optic atrophy, and neuropathy (SPOAN syndrome)

An autosomal recessive neurodegenerative disorder was clinically defined by: non-progressive congenital optic atrophy; infantile-onset spastic paraplegia; childhood-onset of progressive motor and sensory axonal neuropathy; dysarthria starting in the third decade of life; exaggerated acoustic startle response; and progressive joint contractures and spine deformities.[23] Linkage is to chromosome 11q13.[23]

Congenital cerebellar ataxia, mental retardation, optic atrophy, and skin abnormalities (CAMOS)

Non-progressive autosomal recessive congenital ataxia associated with optic atrophy, severe mental retardation, and structural skin abnormalities is caused by a mutation in *ZNF592*, which encodes for a zinc finger protein thought to be involved in a complex developmental pathway.[24]

Deafness, dystonia, and optic neuropathy (DDON, Mohr–Tranebjaerg syndrome)

In this X-linked disorder, sensorineural deafness, dystonia, and ataxia present in late childhood, followed by optic atrophy by the age of 20, and cognitive decline and psychiatric manifestations before the age of 50.[2] The visual prognosis is poor; most patients are blind by the age of 40. The disorder is caused by mutations in the *TIMM8A* gene on the X chromosome (Xq22), whose gene product localizes to the mitochondrial intermembrane space.

Complicated hereditary infantile optic atrophy (Behr syndrome)

The designation of Behr syndrome reflects optic atrophy beginning in early childhood, associated with variable pyramidal tract signs, ataxia, mental retardation, urinary incontinence, and pes cavus. Both sexes are affected, and the syndrome is usually inherited as an autosomal recessive trait. Visual loss usually manifests before age 10 years, is moderate to severe, and is frequently accompanied by nystagmus. In most cases, the abnormalities do not progress after childhood. Neuroimaging may demonstrate diffuse symmetric white matter abnormalities. Clinical findings in some patients with Behr syndrome may be similar to those in cases of the hereditary ataxias. Behr syndrome is likely heterogeneous, reflecting different etiologic and genetic factors.[1]

Progressive encephalopathy with edema, hypsarrhythmia, and optic atrophy (PEHO syndrome)

A progressive encephalopathy with onset in the first 6 months of life, followed by severe hypotonia, convulsions with hypsarrhythmia, profound mental deterioration, hyperreflexia,

transient or persistent facial and body edema, and optic atrophy has been described. Optic atrophy is usually noted by the first or second year of life, and nystagmus is common. A metabolic defect has yet to be determined and an autosomal recessive mode of inheritance is likely.[1] This could be considered a form of Behr syndrome, which likely represents a heterogeneous group of disorders (see above).

Optic neuropathy as a manifestation of hereditary degenerative or developmental diseases

Optic neuropathy may be associated with a variety of hereditary degenerative or developmental systemic disorders. Table 54.1 and Box 54.1 summarize the important findings in the more common such disorders.

Hereditary ataxias

The hereditary ataxias comprise a group of chronic progressive neurodegenerative conditions involving the cerebellum and its connections, and are sometimes associated with optic atrophy. A genomic classification by chromosomal location is available for many of these disorders, and the abnormal gene products involved are under investigation, many of them localized to the mitochondria.[1–3,25,26]

Friedreich ataxia is inherited in an autosomal recessive manner, and the gene defect has been localized to the proximal long arm of chromosome 9 (9q13–q21). The majority of cases are homozygous for a GAA trinucleotide expansion in a gene designated *FRDA/X25* that codes for a protein called frataxin, which regulates iron levels in the mitochondria.[1,26] The disease usually begins during the second decade of life and includes progressive ataxia, dysarthria, loss of joint position and vibratory sensation, absent lower extremity tendon reflexes, and extensor plantar responses. Scoliosis, foot deformity (pes cavus), diabetes mellitus, and cardiac disease are common. Other manifestations include distal wasting, deafness, nystagmus, eye movement abnormalities consistent with abnormal cerebellar function, and optic atrophy. The course is progressive, with most patients unable to walk within 15 years of onset, and death from infectious or cardiac causes usually in the fourth or fifth decade. Although optic atrophy is a common feature of Friedreich ataxia, most patients are visually asymptomatic, and severe visual loss occurs rarely,[27] sometimes resembling LHON.

The spinocerebellar ataxias (SCAs), previously called olivopontocerebellar atrophy or autosomal dominant cerebellar ataxia, include a group of dominantly inherited ataxic disorders in which the ataxia is related more to degeneration of the cerebellum rather than the spinal cord.[1,25,26] In 2015, there were at least 37 different genetic loci for the SCAs (SCA1 through SCA39). The combination of SCA1 (chromosome 6p), SCA2 (chromosome 12q), SCA3 (chromosome 14q), SCA6 (chromosome 19p), and SCA7 (chromosome 3p) comprises approximately 80% of the autosomal dominant ataxias. Most of the SCAs are caused by mutations involving the expansion of a CAG trinucleotide repeat in the protein-coding sequences of specific genes. As with other diseases with abnormal repeats, the expanded regions can become larger with each generation, resulting in a younger age of onset in each, so-called anticipation. Clinically, the SCAs have signs and symptoms of cerebellar degeneration, and sometimes other neurologic dysfunction secondary to neuronal loss. Loss of vision is usually mild but may be prominent, occurring with constricted visual fields and diffuse optic atrophy. However, it is not clear in some cases whether the primary process is retinal with secondary optic atrophy or primarily involving the optic nerve. SCA7 is specifically associated with retinal degeneration, whereas optic neuropathy is usually associated with SCA1 or SCA3.[25]

Hereditary polyneuropathies

Charcot–Marie–Tooth disease (CMT) encompasses a group of heredofamilial disorders characterized by progressive muscular weakness and atrophy that begins during the first two decades of life.[1–3] This group of hereditary polyneuropathies accounts for 90% of all hereditary neuropathies, with a prevalence of at least one in 2500 individuals. Most forms of CMT begin between the ages of 2 and 15 years, and the first signs may be pes cavus and other foot deformities, or scoliosis. There is slowly progressive weakness and wasting, first of the feet and legs, and then of the hands. Motor symptoms predominate over sensory abnormalities. At the time of writing, causative mutations for the hereditary peripheral neuropathies have been identified in more than 80 different genes.[28] Numerous patients with CMT and optic atrophy have been reported. Taking into account both electrophysiologic and clinical data, up to 75% of patients with CMT have some afferent

visual pathway dysfunction, demonstrating that subclinical optic neuropathy occurs in a high proportion of patients with CMT. A subtype of CMT, hereditary motor and sensory neuropathy type VI (HMSN VI), is defined by the combination of axonal peripheral neuropathy and optic atrophy, and has both autosomal dominant and autosomal recessive forms of inheritance.[1–3] The optic atrophy typically develops in late adolescence, a decade or more after the peripheral neuropathy, with a subacute visual decline, usually to below 20/400. As in LHON, a subset may recover vision years after the onset of optic neuropathy. The autosomal dominant form of HMSN VI is caused by a mutation in the nuclear mitofusin-2 gene, and constitutes a subclass of CMT2A, the most common autosomal dominant form of axonal CMT. The mitofusin-2 protein is a

GTPase localized to the mitochondrial outer membrane, and shares many structural and functional similarities with the OPA1 protein in DOA.[2,3]

Familial dysautonomia (Riley–Day syndrome) is an autosomal recessive disease that almost exclusively affects Ashkenazi Jews. Abnormalities of the peripheral nervous system cause the clinical manifestations of sensory and autonomic dysfunction. Optic atrophy is very common in patients with familial dysautonomia, with involvement of the papillomacular bundle similar to the other hereditary optic neuropathies, suggesting familial dysautonomia may affect mitochondrial function.[29] However, in most cases, early mortality from the disease probably precludes the later development of optic atrophy.[1] Other ophthalmic features of familial dysautonomia include dysmetric saccades, saccadic intrusions, abnormal smooth pursuit, and corneal opacities.

Hereditary spastic paraplegias

The hereditary spastic paraplegias (Strümpell–Lorrain disease) are inherited disorders characterized by progressive spasticity of the lower limbs with degeneration of the corticospinal system. The prevalence of these disorders is about 3–10 per 100,000. As of 2015, there were at least 72 mapped loci for the hereditary spastic paraplegias, and 55 identified genes.[30] Hereditary spastic paraplegia is classified as "pure" if spasticity is the only manifestation, or as "complicated" if other features, such as optic atrophy, are present. Complicated hereditary spastic paraplegia with optic atrophy may result from several different nuclear DNA mutations. The *SPG7* gene, found on chromosome 16 (16q24.3), encodes for a mitochondrial metalloproteinase, paraplegin. Mutations in the *SPG7* gene have been identified in an autosomal recessive form of hereditary spastic paraplegia in which some patients have bilateral optic atrophy as a prominent manifestation of their disorder.[2,3]

Hereditary muscular dystrophies

Myotonic dystrophy is a relatively common autosomal dominant disorder with a prevalence of 1 in 20,000, characterized by progressive myopathy, ptosis, cataracts, cardiomyopathy with conduction defects, frontal balding, bifacial weakness, and diabetes mellitus. Less common ophthalmic manifestations include external ophthalmoplegia, pigmentary retinopathy, and optic atrophy.[1,26] Most have an expansion of a CTG repeat in a protein kinase gene on chromosome 19q13.3.

Storage diseases and cerebral degenerations of childhood

Over 100 inherited metabolic and degenerative diseases with ocular manifestations have been described, some detailed in Chapter 65 (see also Table 54.1).

Mitochondrial disorders

The subacute necrotizing encephalomyelopathy of Leigh results from multiple different biochemical defects that impair cerebral oxidative metabolism.[1–3] This disorder may be inherited in an autosomal recessive, X-linked, or maternal pattern, depending on the genetic defect. The onset of symptoms is typically between the ages of 2 months and 6 years, and consists of progressive deterioration of brainstem functions, ataxia, seizures, peripheral neuropathy, intellectual deterioration, impaired hearing, and poor vision. Visual loss may be secondary to optic atrophy or retinal degeneration. Leigh syndrome is likely a non-specific phenotypic response to certain abnormalities of mitochondrial energy production.

Other presumed mitochondrial disorders of both nuclear and mitochondrial genomic origins may manifest optic atrophy as a secondary clinical feature, often a variable manifestation of the disease.[1–3] Examples include cases of MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes), DCMA (dilated cardiomyopathy with ataxia), MERRF (myoclonic epilepsy and ragged red fibers), MNGIE (mitochondrial neurogastrointestinal encephalomyopathy), and chronic progressive external ophthalmoplegia, both with and without the full Kearns–Sayre phenotype. The other, more constant, phenotypic characteristics of all of these mitochondrial disorders distinguishes them from diseases such as LHON in which visual loss from optic nerve dysfunction is the primary manifestation of the disorder.[1–3]

PSEUDOPAPILLEDEMA AND OPTIC DISC DRUSEN
TUMORS
ACQUIRED OPTIC ATROPHY IN CHILDHOOD
REFERENCES

Introduction

Acquired optic disc abnormalities in children can range from benign incidental findings to harbingers of serious systemic diseases. It is important for ophthalmologists to understand the various findings that one might detect when examining the optic disc of a child, and to recognize when a systemic evaluation is required. Acquired optic disc abnormalities discussed in this chapter include pseudopapilledema and optic disc drusen, intrinsic optic disc tumors, and optic disc atrophy secondary to nutritional, toxic, and hypoxic/ischemic etiologies. Other causes of acquired optic disc abnormalities will be covered in Chapters 23 and 57 (optic nerve and chiasmal tumors), 56 (inflammatory, infectious, and infiltrative optic neuropathies), and 59 (papilledema).

Pseudopapilledema and optic disc drusen

Optic disc elevation may be due to causes other than increased intracranial pressure or intrinsic optic neuropathies. The term "papilledema" refers strictly to disc swelling secondary to raised intracranial pressure. In cases where the disc appears edematous (either due to disc elevation or blurring of the disc margin) but the intracranial pressure is normal, the term "pseudopapilledema" can be applied. Optic disc drusen is the most common cause of pseudopapilledema; however, there are several other causes. For example, children with high hyperopia often have small, crowded and elevated discs, suggesting possible optic disc edema. Myelinated nerve fibers, papillary glial tissue, or persistent hyaloid vasculature may obscure the disc margin, causing the appearance of optic disc edema. In such cases, a high index of suspicion will lead the clinician to recognize pseudopapilledema and avoid further diagnostic testing.

Optic disc drusen

Unlike the etiologies described above, optic disc drusen may be buried deep in the optic disc, preventing easy recognition. Co-existent disc hemorrhages and visual field defects can also complicate the clinical picture and lead to unnecessary diagnostic studies to rule out increased intracranial pressure.[1] Optic disc drusen are present in approximately 2% of the population.[2] They may be inherited in an autosomal dominant fashion with incomplete penetrance.[3] They are less common in black patients, possibly due to larger cup-to-disc ratio or a lack of a genetic predisposition.[4] They are acellular hyaline concretions located in the prelaminar portion of the optic nerve head, and can be present on the surface of the optic disc ("surface drusen") or buried deeper in the disc and not readily visible ("buried drusen"). In contrast to adults, drusen in children are often buried and more difficult to see; however, as children grow older, the drusen often emerge to become visible on the surface of the disc.[5] Superficial drusen may be seen in less than 20% of children with drusen who are under 15 years of age.[6]

The pathogenesis of optic disc drusen is poorly understood; however, anatomical predisposition appears to play a role. Whether a small scleral canal or congenitally abnormal disc vasculature are the underlying etiologies is unclear, but it is hypothesized that one or more of these anatomical predisposing factors leads to axoplasmic stasis and degeneration, leading to extrusion of mitochondria and eventual calcification.[7]

Clinical findings

Surface drusen (Fig. 55.1) protrude from the disc and are most prominent at the nasal aspect, giving the margin of the disc a "lumpy-bumpy" appearance. They appear as globular yellow formations that may accumulate in conglomerations. Conversely, buried drusen (Fig. 55.2) often cause the appearance of elevation of the optic disc with associated blurring of the disc margins.[8] In cases of buried drusen, the elevated disc may be gray or yellow-white. Indirect illumination of the disc can often cause a diffraction of light from buried drusen. With time, the border of the disc becomes more scalloped due to early protrusion of the buried drusen. Optic disc drusen are often accompanied by anomalous retinal vessels, with increased looping, branching, and tortuosity.[8]

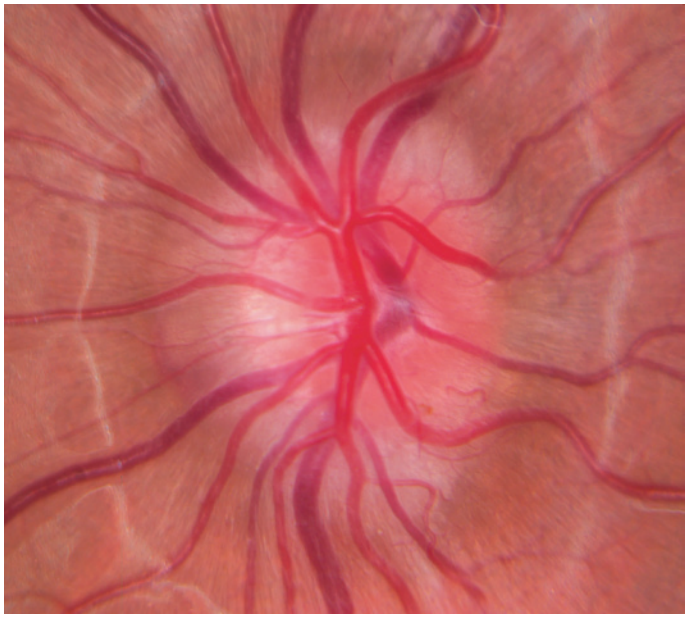

Fig. 55.2 Buried optic disc drusen cause optic nerve elevation and blurring of the optic disc margins.

While visual acuity loss is extremely rare in patients with optic disc drusen, visual field defects occur frequently. The prevalence of visual field defects in children with buried drusen ranges from 11% to 51%[6,9]; however, the prevalence of visual field defects seems to increase by adulthood to up to 87%.[3] Studies comparing the prevalence of visual field defects in patients with surface versus buried drusen have shown a much greater incidence of visual field defects with surface drusen (73%) compared to buried drusen (36%).[8] The most common visual field defects are nerve fiber bundle defects, followed by generalized constriction, and enlarged blind spot.[8] Visual field defects are typically asymptomatic and, when asymmetric, are often associated with an afferent pupillary defect.[6]

Differentiating optic disc drusen from optic disc edema: diagnostic testing (Table 55.1)

Fundus examination

Optic disc drusen can often be differentiated from true optic disc edema by a lack of other findings, including a lack of hyperemia, hemorrhages, and exudates (Table 55.2). Obscuration of the blood vessels as they exit the optic disc can be an indicator of true edema, as opposed to the blood vessels coursing over a disc harboring drusen, which are never obscured by nerve fiber layer edema. Also, spontaneous venous pulsations, when observed, can indicate a lack of true edema. Patients with drusen have also been shown to have larger arterial diameter and more secondary venous branching than patients with true papilledema.[10]

Autofluorescence

A variety of ancillary tests can be performed to help differentiate drusen from papilledema. Optic disc drusen are known to autofluoresce when photographed using angiography filters.[11] Autofluorescence has been found to be a somewhat sensitive test in adults with optic disc drusen, with sensitivity nearing 80%[11,12]; however, it is not clear whether autofluorescence is equally sensitive in children with buried drusen since adults with buried drusen have been found to have a much lower rate of autofluorescence.[13] One study found a sensitivity of 94% despite most of their children harboring buried drusen, but this study was small and has yet to be reproduced.[11]

Ultrasound

B-scan ultrasound has also been used as a diagnostic tool to detect calcified drusen.[14] Even in uncooperative children, deep calcified drusen can be seen as a highly reflective round structure with acoustic shadowing in the medium-gain scan. They can also be seen in low-gain scans due to their calcium content (Fig. 55.3).[7] In a study of adults, B-scan was approximately 50% sensitive in detecting optic disc drusen.[13] Given the higher likelihood of children harboring buried and non-calcified drusen, B-scan ultrasound is a useful test, but a negative result does not completely rule out the presence of optic disc drusen.

Fluorescein angiography

Fluorescein angiography has also proven to be a useful diagnostic tool in patients who are cooperative.[15] Although the youngest patients may not cooperate for angiography, children older than 5 years are often capable of doing so. In a large study of adults with optic disc drusen, fluorescein angiography correctly differentiated true optic nerve edema from pseudoedema based upon a lack of dye leakage from the disc. In addition, several angiographic characteristics have been defined to aid diagnosing optic disc drusen.[15] Surface drusen can often be seen due to their autofluorescence on pre-injection photos as described above. Additionally, they are usually associated with early and late nodular staining of the disc. Buried drusen can be differentiated from true disc edema based on a lack of dye leakage and the presence of late nodular or peripapillary circumferential staining (Fig. 55.4).

Table 55.1 Different imaging modalities to diagnosis optic disc drusen

Modality	Advantages	Disadvantages
Fundus examination	Simple, inexpensive; most useful in cases with surface drusen	Often insufficient for differentiating buried drusen from true edema
Autofluorescence	Does not require injection; most useful in cases with surface drusen; highly specific	Often does not detect deep buried drusen; lacks sensitivity
Fluorescein angiogram	Easily differentiates true edema from pseudoedema based on dye leakage	Requires high degree of cooperation from patient
Computed tomography (CT) scan	Detects calcified drusen	Radiation exposure, expense, and low sensitivity for non-calcified drusen
B-scan ultrasound	Simple, inexpensive and non-invasive; does not require high level of cooperation to detect calcified drusen	Often does not detect deep buried drusen; poor resolution; lacks sensitivity
Optical coherence tomography	May be useful in detecting both superficial and buried drusen. Patterns of reflectivity and internal contour may aid in differentiating true edema from drusen; able to produce retinal nerve fiber layer thickness	Sensitivity and specificity still under investigation; requires cooperation

Table 55.2 Fundus findings in pseudopapilledema from optic disc drusen and true optic disc edema

Feature	True optic disc edema	Optic disc drusen
Disc contour	Smooth, elevated	Lumpy, elevated
Disc color	Hyperemic	Normal or yellow-white
Disc vasculature	Normal configuration with venous congestion	Increased branching and number of major vessels
Disc vasculature obscuration by edematous nerve fiber layer	Common	Not seen
Nerve fiber layer	Grayish, thickening extends beyond disc	Normal color with thickening abruptly ending at disc margin
Hemorrhages	Splinter hemorrhages common	Splinter and deeper hemorrhages rare
Exudates	Common	Rare

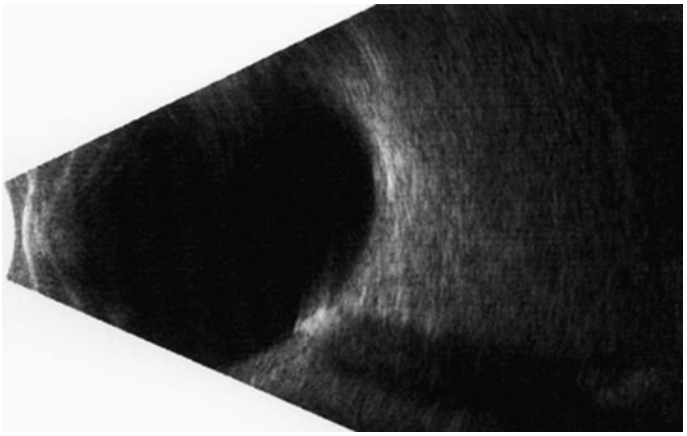

Fig. 55.3 B-scan ultrasound revealing a highly reflective round structure with acoustic shadowing at the medium-gain scan that persists on the low-gain scan due to its calcium content.

Optical coherence tomography (OCT)

The ability of OCT to determine *in vivo* measurements of retinal nerve fiber layer thickness, optic disc volume, and anatomical information may help clinicians to diagnose buried optic disc drusen. Early studies using spectral-domain OCT demonstrated a significant difference in nerve fiber layer thickness between patients with drusen and those with true chronic papilledema.[16] In a study comparing patients with true papilledema to patients with drusen, OCT characteristically revealed a "lumpy-bumpy internal contour" in the eyes with drusen, and a "smooth internal contour" in eyes with true edema (Fig. 55.5).[17] Spectral domain OCT has been shown to reveal a hyperreflective or hyporeflective mass within the optic nerve head in some drusen cases.[18,19] Additionally, as resolution improves with new techniques such as enhanced depth imaging OCT and swept source OCT, drusen can be directly imaged, appearing either as poor signal intensity regions surrounded by hyperreflective bands or as isolated hyperreflective bands without the associated poor signal area in the center.[20] Furthermore, these newer imaging techniques allow for delineation of the posterior extent and shape of each individual druse.[20] Unfortunately, studies of all diagnostic modalities, including OCT, are limited by the lack of a gold standard in diagnosing buried optic disc drusen.

Prognosis and treatment

There is no known treatment for optic disc drusen. Typically, they do not impact central visual acuity and the visual field defects are often not progressive. However, some physicians will recommend lowering the intraocular pressure in cases where the visual field defect is progressing. Superficial flame-shaped and deep peripapillary hemorrhages can also be seen, but these do not typically cause visual symptoms. Rarely, choroidal neovascular membranes can occur, and reported treatment modalities include laser photocoagulation, photodynamic therapy, and intravitreal anti-vascular endothelial growth factor agents.[21–23] Finally, ischemic events such as ischemic optic neuropathy and retinal vascular occlusions have all been reported in children with optic disc drusen.[24–26]

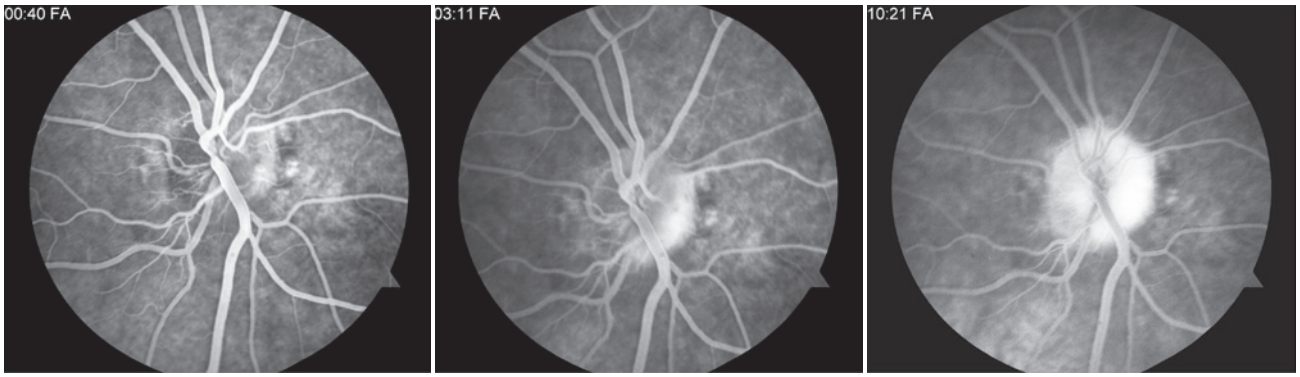

Fig. 55.4 Fluorescein angiography of optic disc drusen demonstrates early and late nodular staining of the disc without leakage of dye.

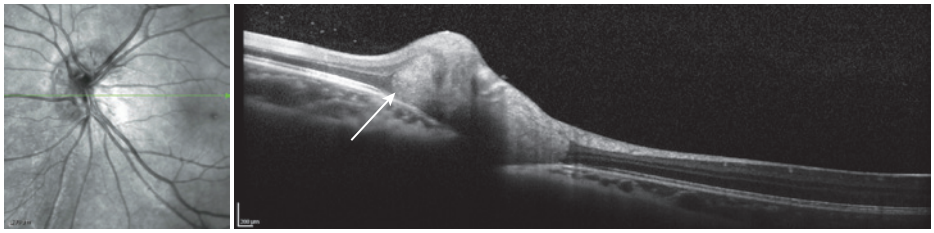

Fig. 55.5 Optical coherence tomography of optic disc drusen reveals a "lumpy-bumpy" internal contour (arrow) that is not seen in eyes with true optic disc edema.

Systemic associations

Optic disc drusen can be seen in association with several systemic diseases. The incidence of pseudoxanthoma elasticum in patients with drusen is much higher than that of the general population (1–3% vs. 1 in 160,000).[7] Additionally, optic disc drusen appear to be more common in children with retinitis pigmentosa.[27]

Tumors

Acquired tumors that directly affect the optic nerve and chiasm will be discussed in Chapters 23 and 57. However, the following section will briefly discuss the optic nerve appearance in cases of intrinsic optic disc tumors.

Intrinsic optic disc tumors

Intrinsic optic nerve tumors are rare and include optic disc gliomas, optic disc hemangiomas, simple optic disc hamartomas, and combined hamartomas of the retina and retinal pigment epithelium (CHRPE). Many of these tumors are often seen in association with a systemic condition. For example, optic disc hemangiomas are often seen in patients with von Hippel–Lindau disease. Astrocytic hamartomas of the optic disc are most commonly seen in patients with tuberous sclerosis, and appear as an elevated protrusion of the optic disc that is translucent in early childhood and progresses to be a yellow, opaque mulberry lesion over time. Both optic disc gliomas and CHRPEs are seen most commonly in neurofibromatosis type-2.[28,29]

Acquired optic atrophy in childhood

The differential diagnosis of acquired optic atrophy in childhood is wide and includes hereditary, nutritional, toxic, metabolic, hypoxic, compressive, traumatic, metabolic, and neurodegenerative conditions. This chapter will focus on nutritional, toxic, hypoxic, and traumatic etiologies of optic atrophy in children.

Nutritional optic neuropathies in children

Several vitamin deficiencies can cause clinical syndromes that include optic neuropathy. Reported etiologies of nutritional optic neuropathy in children include vitamin A deficiency,[30] vitamin B_{12} deficiency,[31] thiamine deficiency,[32] and folate deficiency.[33] Although vitamin deficiencies are rare in children residing in developed countries, several scenarios should raise a clinician's index of suspicion. For example, children with autism often assume highly stereotyped diets and refuse all foods except those of a certain color or texture. For this reason, they may present with a wide range of vitamin deficiencies, some of which have been reported to result in optic atrophy, including vitamin A and vitamin B_{12}.[30,31] In addition, children with gastrointestinal diseases such as celiac disease may also present with nutritional deficits. Children on severely limited diets due to anorexia nervosa, ketogenic diet for seizure control, or fad diets should also be evaluated for a nutritional etiology when presenting with vision loss. Increasingly, gastric bypass surgery is being performed for the treatment of childhood obesity. This procedure has often been linked to vitamin deficiency optic neuropathy secondary to malabsorption.[34] Finally, in developing countries, optic neuropathy secondary to malnutrition has been reported in children as young as 12 years.[33]

Nutritional optic neuropathies commonly present with a gradual, insidious vision loss related to central scotomata, and diminished color vision. Clinicians should ask about a diagnosis of autism, gastrointestinal disease or surgery, or strict dietary limitations. Clinical examination typically reveals diminished central visual acuity and color vision, with visual field defects including central scotoma, cecocentral scotoma, or

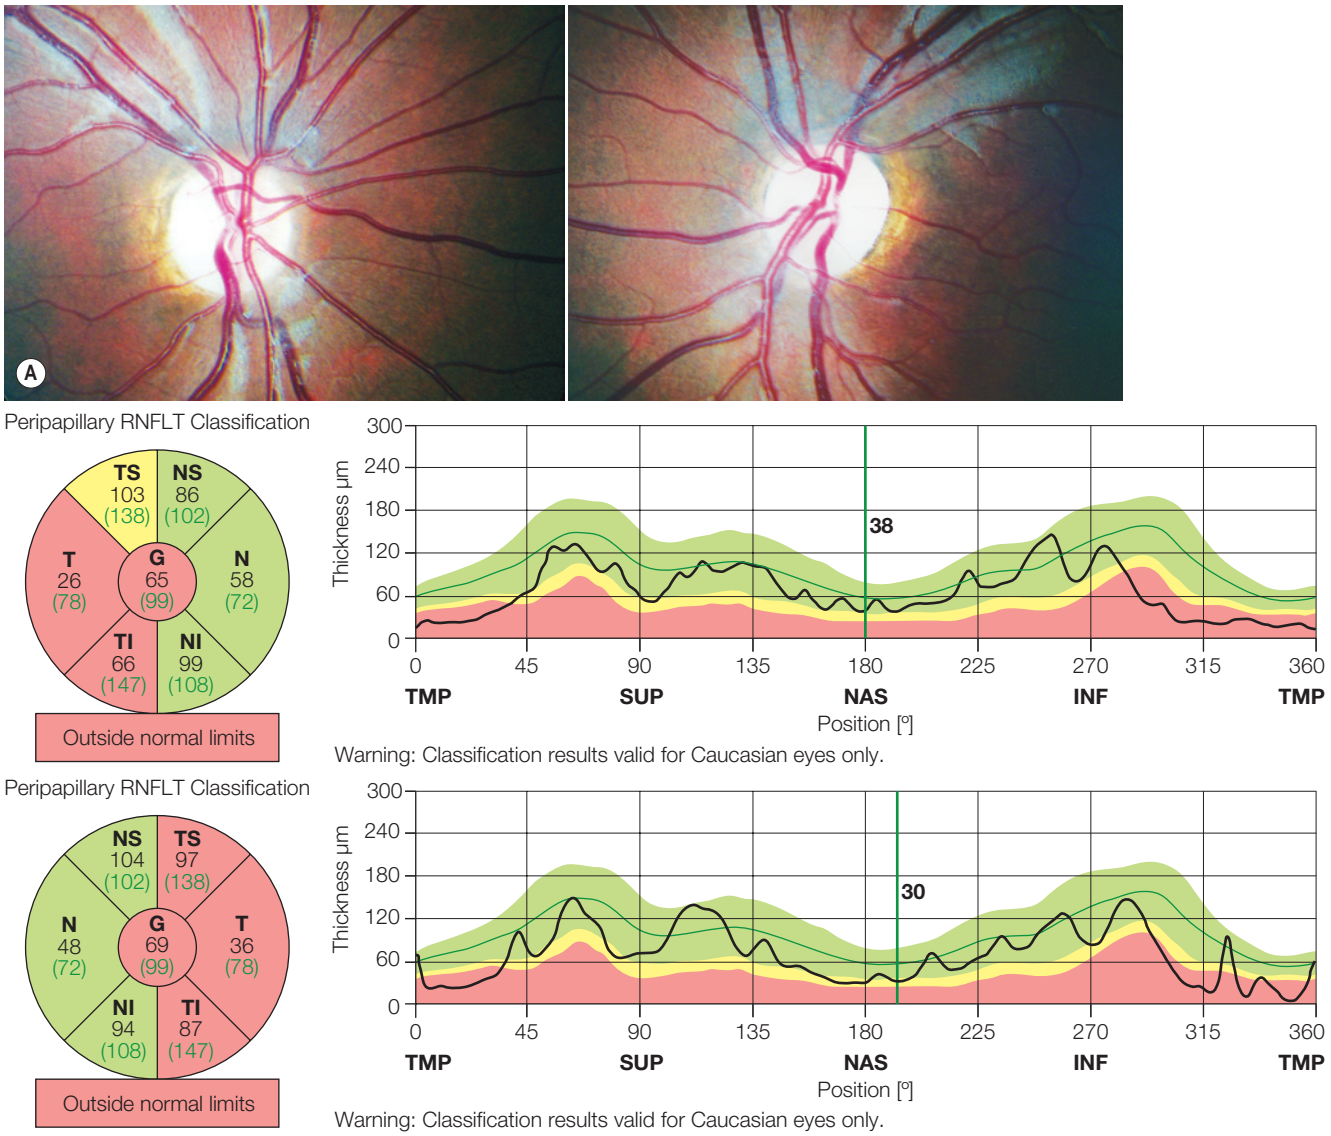

Fig. 55.6 Child with vitamin B_{12} deficiency optic neuropathy. (A) Fundus photograph reveals temporal optic nerve pallor. (B) Optical coherence tomography demonstrates temporal thinning of the retinal nerve fiber layer.

arcuate defects. The optic nerve in these cases typically reveals temporal pallor and nerve fiber layer dropout throughout the papillomacular bundle (Fig. 55.6). OCT has been shown to reveal significantly decreased retinal nerve fiber layer thickness in the superior and temporal peripapillary region (see Fig. 55.6).[35]

Toxic optic neuropathies in children

Anti-tuberculous agents

Streptomycin, isoniazid and, more frequently, ethambutol are implicated in optic nerve toxicity (Fig. 55.7). Age, duration of treatment, and dose are correlated with toxicity. In addition, ethambutol has been reported to trigger or accelerate visual loss in patients harboring mutations associated with Leber hereditary optic neuropathy and autosomal dominant optic atrophy.[36]

Antibiotics

Systemic administration of chloramphenicol is associated with an optic neuropathy.[37] This is characterized by mild disc swelling and central/cecocentral scotomas, with partial resolution on discontinuing treatment. Chloramphenicol results in depletion of mitochondrial DNA, implicating a mitochondrial toxic effect as a cause of the optic neuropathy. Linezolid is a synthetic antibiotic used in the treatment of serious gram-positive infections. Prolonged treatment is associated with a reversible optic neuropathy and usually with a peripheral neuropathy that has been linked to mitochondrial toxicity.[38]

Immunomodulatory agents

Infliximab is an anti-tumor necrosis factor alpha antagonist. Optic nerve toxicity has been reported following its use in the treatment of Crohn disease, ulcerative colitis, and psoriatic arthropathy.[39]

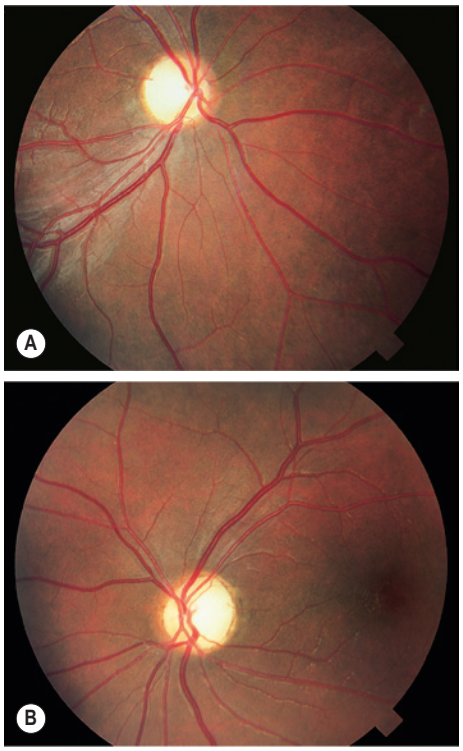

Fig. 55.7 A patient with tuberculous meningitis. Bilateral optic neuropathy was presumed secondary to ethambutol toxicity.

Anti-neoplastic agents

Vincristine disrupts neurofilament organization, resulting in a reversible optic neuropathy.[40]

Hypoxic/ischemic optic neuropathies in children

The typical adult presentation of anterior ischemic optic neuropathy on waking, presumably linked to nocturnal blood pressure reduction, is not seen in children. Anterior ischemic optic neuropathy in children is usually associated with more severe dips in blood pressure, for example with hemodialysis, peritoneal dialysis, or overly aggressive treatment of severe hypertension.[40] In these settings, uremia, hypotension, and diabetes may also be contributory.[41] Finally, ischemic optic neuropathy has also been reported in children with congenital heart disease or pulmonary hypertension taking sildenafil.[42]

Traumatic optic neuropathy in children

Traumatic optic neuropathy is classified according to the site of injury (optic nerve head, intraorbital, intracanalicular, and intracranial), or according to the mode of injury (direct and indirect). It is an uncommon cause of visual loss with a reported incidence of 0.7–2.5% following blunt or penetrating head trauma, and a prevalence of about 1 in 1,000,000 in the general population.[43] Bilateral optic nerve involvement is rare (5%). Although most patients are young adult males, 20% occur during childhood. In children, the most common causes of traumatic optic neuropathy are falls, road traffic crashes, and sporting injuries.[44]

A diagnosis of traumatic optic neuropathy is based on the clinical history and corroborative examination findings. The assessment can be difficult when the patient's mental status is impaired due to severe trauma. It is essential to exclude other reversible causes of visual loss, such as a retrobulbar hemorrhage. Traumatic optic neuropathy frequently results in profound loss of central vision, with 50–60% of patients presenting with visual acuities of light perception or worse. The optic disc usually looks normal in the acute phase, but with injuries anterior to the entry point of the central retinal vessels, edema of the optic nerve head and retinal hemorrhages can be observed. In cases of optic nerve avulsion, the optic disc is absent and there is a surrounding ring of hemorrhage. The visual outcome in traumatic optic neuropathy is largely dictated by the patient's initial visual acuities. Little or no visual recovery can be expected for patients with light perception or worse at baseline. Other poor prognostic factors include loss of consciousness, no improvement in vision after 48 hours, and the absence of visual evoked responses. Optic canal fractures have been associated with a worse visual prognosis in some case series.

The management of traumatic optic neuropathy remains controversial. Some clinicians favor observation alone, while others treat with systemic steroids (in various doses, duration, and mode of administration), surgical decompression of the optic canal, or both. An optic canal fracture with a bone fragment impinging on the optic nerve is an indication to some clinicians for prompt surgical intervention. The evidence base for these treatments is weak. Recent reviews have not supported the routine use of high-dose steroids or surgery in traumatic optic neuropathy.[45,46] There is a high rate of spontaneous visual recovery (40–60%) among patients managed conservatively, and the adverse effects of intervention need to be carefully considered. It is essential to be vigilant about the possibility of delayed visual loss in traumatic optic neuropathy. If this is secondary to the development of an optic nerve sheath hematoma, urgent decompression with sheath fenestration is indicated.

Pediatric optic neuritis

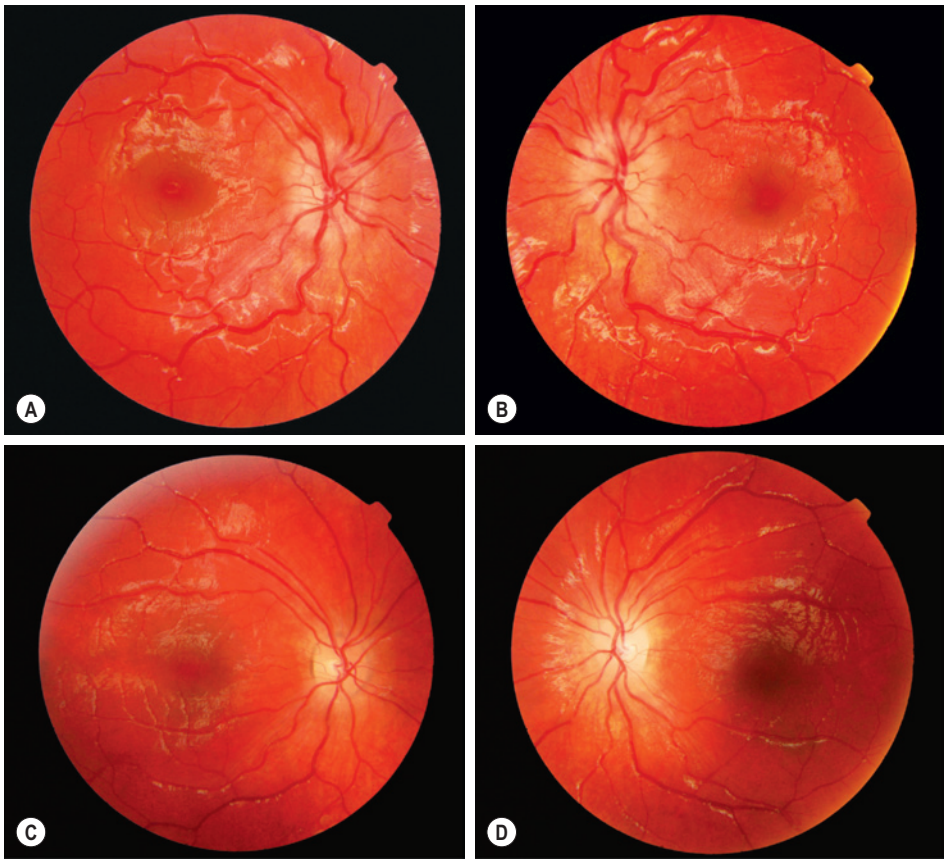
Optic neuritis is an inflammatory process involving the optic nerve. It presents with a painful, acute/subacute vision loss with corroborating evidence of an optic neuropathy on examination. This may include a relative afferent pupillary defect, visual field dysfunction, dyschromatopsia, and optic nerve edema. Optic neuritis may occur as a clinically isolated syndrome or in association with neurologic/systemic disease. This section examines pediatric optic neuritis in the context of demyelinating and inflammatory disease processes in children. When possible, a careful understanding of the underlying etiology of optic neuritis is critical in order to target the appropriate treatment to protect the child from irreversible vision loss, and to address neurologic or systemic disease. Therefore, a multidisciplinary approach involving both ophthalmology and neurology is essential to assess visual function and to manage systemic therapy when relevant.[1]

Optic neuritis associated with demyelinating disease

The prevalence of pediatric optic neuritis is unknown. In one retrospective study of all patients presenting with optic neuritis in Minnesota, USA, pediatric optic neuritis accounted for fewer than 5% of cases, with a higher prevalence in adolescents compared with children.[2] The clinical presentation differs from adult optic neuritis: nearly half the pediatric cases of optic neuritis were bilateral. Also, the anterior optic nerve was more commonly involved (Fig. 56.1).[3-6] In a meta-analysis of 223 published cases, bilateral optic nerve involvement was associated with younger age at presentation, with 72% of children <10 years experiencing bilateral disease and 70% of children ≥10 years with unilateral involvement.[4] Further, pain with eye movements is not a universal presenting symptom in pediatric optic neuritis.[3,5] Multiple retrospective studies have reported on the variable levels of vision loss at presentation, which range from minimal to severe, with excellent visual recovery of high-contrast acuity.[3,5] In one retrospective study of a large pediatric cohort with their first episode of optic neuritis, the primary risk factor for a poor high-contrast acuity at 1 year of <20/40 was lack of recovery to 20/20 vision at 3 months after the initial presentation.[3] Recent work has emphasized that low-contrast acuity highlights the persistent visual disability occurring after optic neuritis even when there is good recovery of high-contrast visual function.[7] Vision loss may be accompanied by visual field defects including, but not limited to, central or paracentral scotomata (Fig. 56.2). Optical coherence tomography (OCT) demonstrates damage to the retinal nerve fiber layer (rNFL) as well as the ganglion cell layer (GCL) after an episode of optic neuritis. These changes correlate well with visual function as measured by low-contrast acuity.[7,8] In the future, OCT changes may therefore become a useful metric in clinical studies of optic neuritis and demyelinating disease.

The diagnosis may be made in the context of the clinical symptoms and signs coupled with findings on magnetic resonance imaging (MRI). Contrast enhancement of the optic nerve is seen on T1-weighted MRI images, and hyperintensity of the optic nerve is evident on T2-weighted images (Fig. 56.3).

The treatment of pediatric optic neuritis is institution-dependent but typically involves intravenous (IV) methylprednisolone followed by an oral prednisone taper.[1,3,9] This strategy was derived from the corticosteroid regimen used in the landmark adult Optic Neuritis Treatment Trial, in which IV methylprednisolone followed by an oral prednisone taper was shown to hasten visual recovery.[10] This consideration is particularly helpful in pediatric patients when bilateral disease is present. Nevertheless, prospective data on the efficacy of corticosteroid treatment in pediatric optic neuritis are lacking. In patients with refractory vision loss, a multimodal approach including plasma exchange (PLEX) or administration of intravenous immune globulin (IVIg) is often used.[3] Since optic neuritis often occurs in the context of demyelinating disease, and indeed may be the initial presenting sign of a demyelinating condition, its management must involve both ophthalmology and neurology. Three primary considerations arise in children: multiple sclerosis (MS), acute disseminated encephalomyelitis (ADEM), and neuromyelitis optica (NMO; also known as Devic disease). The reported incidence of an acquired demyelinating condition of the central nervous system (CNS) (including transverse myelitis) in children is



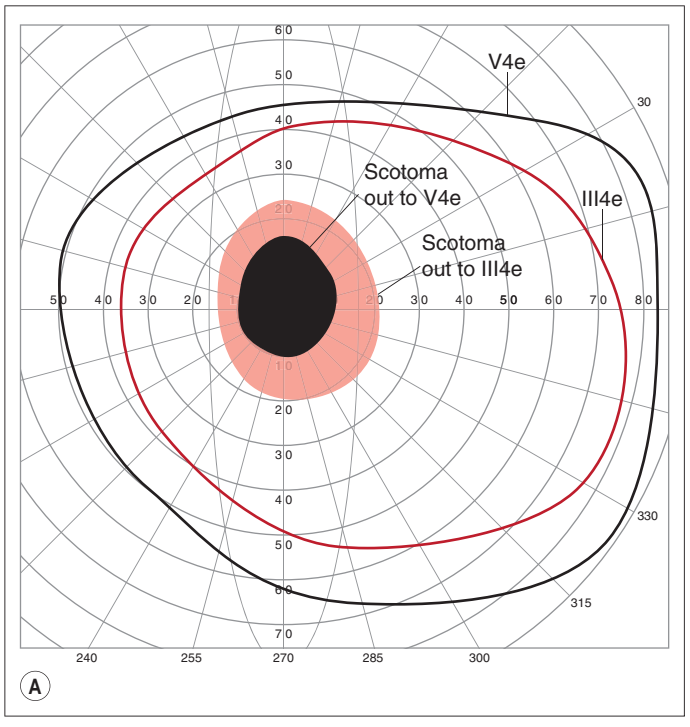


Fig. 56.1 Bilateral optic neuritis. Fundus photography revealing swollen right optic nerve (A) and left optic nerve (B) of a 7-year-old girl with bilateral optic neuritis. When she presented, she was legally blind with acuities of 20/400 right eye and light perception left eye. Three weeks following the initial presentation and after corticosteroid treatment, visual acuities recovered to 20/20 right eye and 20/25 left eye with resolution of optic nerve edema in both the right (C) and left (D) eyes.

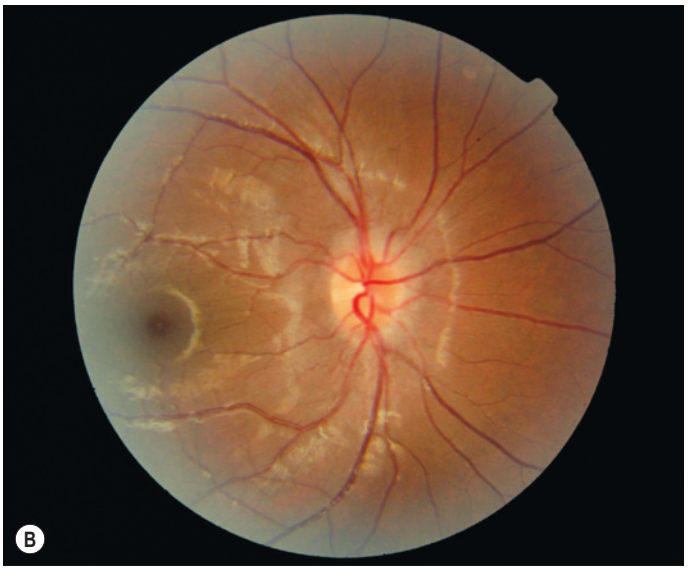

Fig. 56.2 Optic neuritis in a 16-year-old girl. Goldmann visual fields showing central scotoma right eye (A) and optic nerve edema right eye (B) in the setting of subacute vision loss to 20/80 right eye, dyschromatopsia, and a relative afferent pupillary defect right eye.

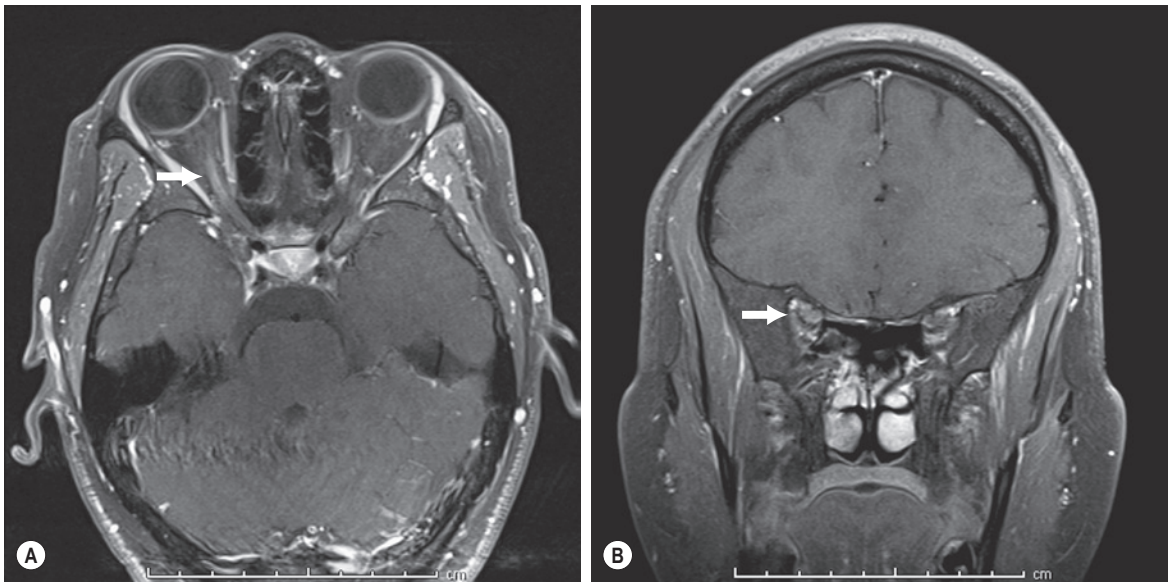

Fig. 56.3 Magnetic resonance imaging (MRI) findings in unilateral optic neuritis. T1-weighted post gadolinium MRI axial (A) and coronal (B) images revealing contrast enhancement of the right optic nerve (arrows) in the patient in Figure 56.2.

0.9 per 100,000 person-years in Canada and 1.66 per 100,000 person-years in a multi-ethnic California-based cohort.[11,12] Each condition is associated with a unique prognosis and treatment plan and therefore a careful evaluation for these conditions is essential in a child with optic neuritis.

The incidence of MS specifically in US children has been reported at 0.51 per 100,000 person-years with the relapsing-remitting form of MS. This form is far more common than the primary progressive form in pediatric patients.[12,13] In addition to optic neuritis, children presenting with MS may have accompanying ataxia, brainstem involvement, and encephalopathy, making it difficult to distinguish MS from other acquired demyelinating syndromes such as ADEM.[13] Many important studies have evaluated the risk of conversion to MS in children who present with first time optic neuritis. The conversion rate to MS in children has not been prospectively evaluated. However, as with adults, T2 lesions on MRI scan outside the visual system at presentation are associated with an increased risk of developing MS.[1,4,14,15] In addition, older age at presentation of optic neuritis has been found to be an independent risk factor for conversion to MS.[4]

Demyelination in ADEM is multifocal and may include optic neuritis, encephalopathy unrelated to fever, and irregular, large MRI lesions involving the white matter and potentially deep gray matter. ADEM is considered classically to be a monophasic condition, although multiphasic ADEM has been described.[16] Distinguishing ADEM from other demyelinating syndromes may be difficult at presentation. Recent studies have demonstrated a high proportion of children with ADEM to be positive for antibodies to myelin oligodendrocyte glycoprotein (MOG), which become undetectable at follow-up.[17] Presence of MOG-Ig antibodies may be associated with a better prognosis.[18]

NMO or Devic disease is a central nervous system inflammatory disorder affecting predominantly the optic nerves and spinal cord. The pathogenesis of NMO is distinct from MS, and in about 70% of cases it is associated with an NMO-IgG autoantibody, which targets aquaporin-4 water channels (AQP4) expressed in astrocytes.[19] The NMO-IgG antibody is not present in patients with MS.

Box 56.1

Diagnostic criteria for definite neuromyelitis optica[16]

Acute myelitis
Optic neuritis
Two of three additional supporting criteria:
- Aquaporin-4 immunoglobulin G seropositivity
- Non multiple sclerosis brain magnetic resonance imaging findings
- Longitudinally extensive transverse myelitis involving three or more vertebral segments

NMO appears to affect predominantly female patients and NMO-optic neuritis is associated with more profound, irreversible vision loss.[20] OCT reveals more severe rNFL thinning and evidence of microcystic macular edema in NMO-optic neuritis compared with MS-optic neuritis.[21] NMO should be considered in any case with severe bilateral optic neuropathy, particularly with evidence of transverse myelitis, although optic neuritis may precede the onset of transverse myelitis. The term "NMO spectrum disorder" is used for patients with some, but not all, of the disease-defining features. The diagnostic criteria for pediatric NMO are shown in Box 56.1.

On MRI, NMO-optic neuritis may involve longer segments of the optic nerve that extend more posteriorly towards the optic chiasm compared with MS-optic neuritis. Importantly, brain findings may be present in NMO, including large tumefactive lesions, but the periventricular white matter lesions seen in typical MS are generally not present.[22] Spinal cord involvement is classically characterized by longitudinally extensive transverse myelitis involving three or more vertebral segments (Fig. 56.4).[22]

Standard corticosteroid treatment may not be effective, and plasma exchange or IVIg may be required for an acute attack. Long-term immunosuppression to prevent relapse is the goal

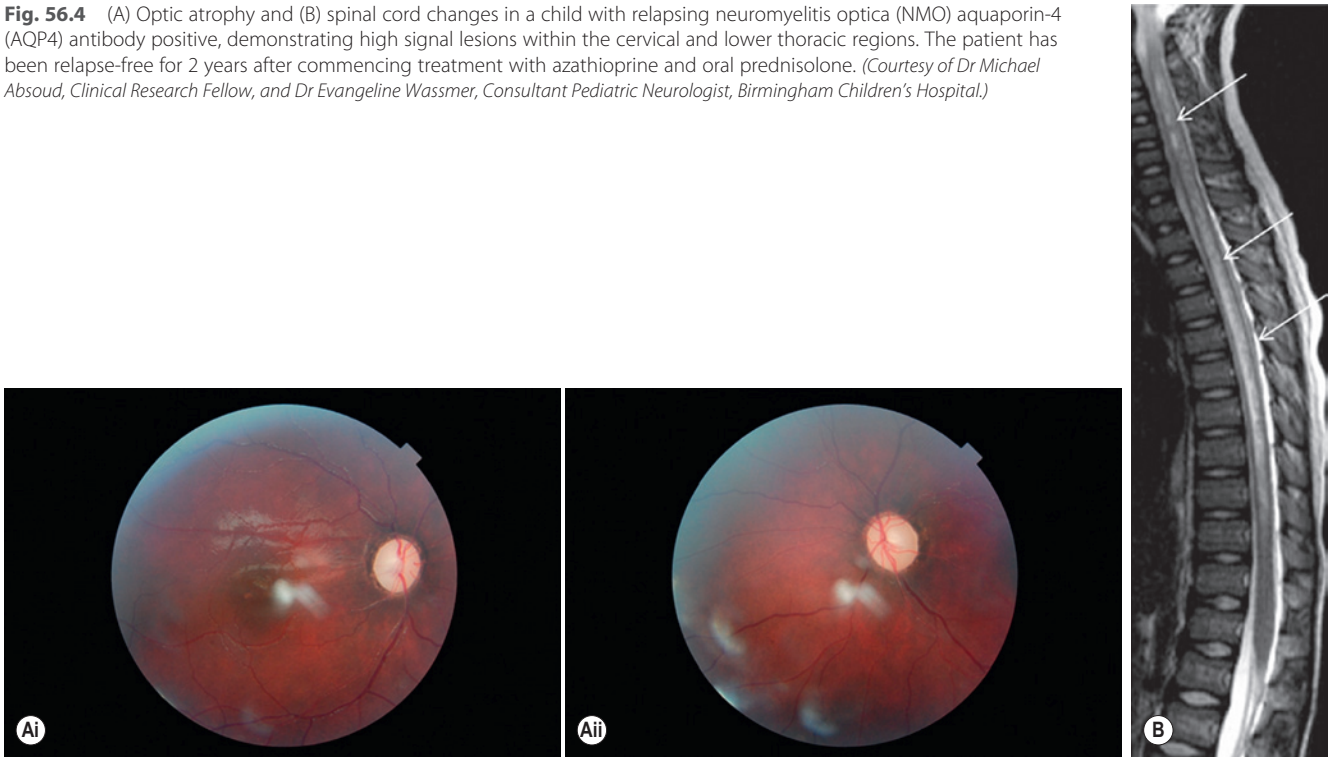

Fig. 56.4 (A) Optic atrophy and (B) spinal cord changes in a child with relapsing neuromyelitis optica (NMO) aquaporin-4 (AQP4) antibody positive, demonstrating high signal lesions within the cervical and lower thoracic regions. The patient has been relapse-free for 2 years after commencing treatment with azathioprine and oral prednisolone. *(Courtesy of Dr Michael Absoud, Clinical Research Fellow, and Dr Evangeline Wassmer, Consultant Pediatric Neurologist, Birmingham Children's Hospital.)*

of therapy using agents such as rituximab, mycophenolate mofetil, and azathioprine, and avoiding MS treatments thought to exacerbate NMO such as fingolimod.[23]

Para-infectious optic neuritis

Para-infectious optic neuritis following a febrile illness occurs in both children and in adults. In children, clinical symptoms of optic neuritis generally present 1–2 weeks after the febrile illness, with either unilateral or bilateral disease and optic nerve swelling.[24] Cases of para-infectious optic neuritis have been reported in association with *Mycoplasma pneumoniae*,[24] varicella,[25] rubeola,[25] mononucleosis,[25] and influenza B infection.[26] This form of optic neuritis is often responsive to corticosteroid treatment; an autoimmune process is thought to be implicated rather than primary infection of the optic nerves. Although the visual outcome is favorable, many children will have residual optic atrophy after an episode.[24,25]

Post-immunization optic neuritis

A link between optic neuritis and inoculation with a number of different vaccines including measles, rubella,[27,28] rabies,[29] meningococcus,[30] and influenza has been reported, based on vaccine administration a few days prior to the onset of optic neuritis. There is no conclusive evidence of an epidemiologic association between routine childhood immunization and optic neuritis.[31]

Chronic relapsing inflammatory optic neuropathy

Chronic relapsing inflammatory optic neuropathy (CRION) is a poorly understood inflammatory optic neuropathy characterized by recurrent optic neuritis that is highly sensitive to corticosteroid treatment. Kidd and colleagues first codified this entity and proposed the nomenclature of "CRION" in 2003 in their series of 15 patients with relapsing, isolated optic neuritis.[32] Since 2003, approximately 122 cases of CRION have been reported in the literature with an age range of 14–69 years.[33]

The characteristic features of CRION include pain with subacute vision loss, prompt response to corticosteroid treatment, and relapse upon cessation of corticosteroid treatment. The interval between episodes ranges from less than 1 year to years,[34] and the number of relapses has been reported to range from 2 up to 18 episodes of optic neuritis.[33] Involvement may be unilateral or bilateral, with simultaneous or sequential involvement of the optic nerves.[32,33] Commonly, vision loss is profound to the level of "counting fingers" or worse, with anterior optic nerve involvement.[32] Visual field changes are similar to those seen in demyelinating optic neuropathy, including central or paracentral scotomata or altitudinal visual field loss.[32] Visual outcome data are heterogeneous and limited. In one review of all published cases of CRION from 2003 to 2013, approximately 30% of affected patients had vision less than LogMAR 0.5 (Snellen 20/60) compared with 2% of adults with optic neuritis in the Optic Neuritis Treatment Trial.[33,35]

The diagnosis is one of exclusion and is established after careful assessment for underlying neurologic or systemic causes of optic neuritis that may include neuroimaging, lumbar puncture, and serologic testing. On MRI, contrast enhancement of the optic nerves should be seen in the acute phase. Otherwise, neuroimaging should essentially be negative, with the exception of non-diagnostic and non-specific T2 changes, which have been reported in patients with CRION.[32] In the acute phase of an episode of optic neuritis, IV methylprednisolone followed by an oral corticosteroid taper is used with or without adjunctive IVIg or plasma exchange.

With respect to chronic immunosuppression, a variety of agents have been tried including IVIg, mycophenolate mofetil, azathioprine, and methotrexate.[32,36] Importantly, in contrast to the demyelinating optic neuritis associated with MS, vision loss associated with CRION may be progressive without appropriate chronic immunosuppressive therapy.[33]

Infectious optic neuropathy

Neuroretinitis

Neuroretinitis is an inflammatory disorder characterized by optic nerve edema and the subsequent development of a macular star. Most commonly, unilateral involvement is seen, although bilateral cases have been reported (Fig. 56.5). The formation of the macular findings is thought to occur because of increased permeability of the optic disc vasculature with leakage of fluid into the peripapillary retina.[37] Fluorescein angiography shows an arteriolar vasculitis on the optic disc. The macular star has a characteristic perifoveal appearance.

An underlying infectious cause is common; the most frequent etiologies are *Bartonella henselae* (cat scratch disease) or *Borrelia burgdorferi* (Lyme disease). Neuroretinitis has been reported in association with syphilis, tuberculosis, leptospirosis, and toxoplasmosis.[38] Therefore, serologic testing should be performed to assess etiology. Although spontaneous recovery may ensue, many ophthalmologists will treat neuroretinitis before an underlying etiology can be confirmed. Specifically in the setting of cat scratch disease, doxycycline, azithromycin, and rifampin have all been used.[39]

Other infectious optic neuropathy

Many infectious agents have been associated with the development of an optic neuropathy. Spirochetes associated with optic neuropathy include *Borrelia burgdorferi*, causing Lyme disease, and *Treponema pallidum*. A fungal optic neuropathy may occur in immunosuppressed patients, most commonly due to *Cryptococcus neoformans*. Although cytomegalovirus optic neuropathy is usually associated with juxtapapillary retinitis, cases with optic neuropathy in the absence of retinitis have been described,[40] presumably due to direct invasion of the retrolaminar optic nerve. Optic neuropathy may occur primarily due to human immunodeficiency virus type 1 (HIV-1) infection rather than secondary to opportunistic infections.[25]

Infiltrative optic neuropathy

Leukemic infiltration (see Chapter 67)

Leukemic optic disc infiltration tends to be associated with central nervous system relapses, and it may be the presenting feature of relapses among patients in prolonged remission. The affected nerves appear swollen and may have surface hemorrhages. However, no disc appearance is diagnostic. Optic nerve involvement may be seen in association with leukemic retinopathy, which is characterized by tortuous vessels, dilated veins, retinal hemorrhages, and cotton-wool spots. MRI may show perioptic nerve infiltration.[41] About 90% of the cases of optic nerve involvement occur in the acute forms of leukemia.

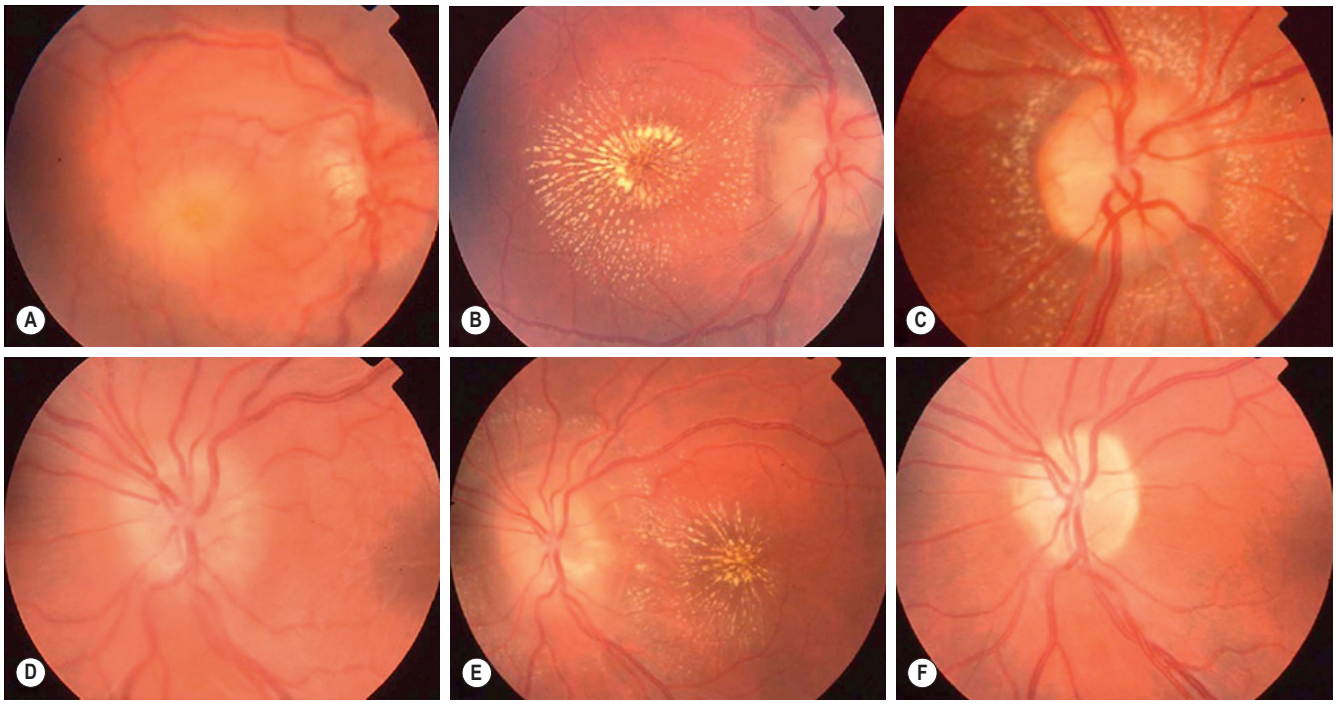

Fig. 56.5 Stages of evolution of fundus changes in neuroretinitis. (A) At presentation the optic disc is swollen and the macula has an opaque appearance. (B) Three weeks later, there is a well-formed macular star. (C) Further resolution leading later to optic atrophy. Optic nerve involvement in leukemia is an emergency. Without prompt diagnosis and treatment, permanent and catastrophic loss of vision may occur. The optic nerve and meninges are pharmacologic sanctuary sites where leukemic cells are resistant to systemic chemotherapy. Intrathecal chemotherapy doses of primary treatment may be inadequate to destroy leukemic cells in the optic nerve, hence the propensity for recurrence at this site. Urgent low-dose radiotherapy to the orbital apex may be sight-saving in this context.[42,43]

Sarcoid-related optic neuropathy

Sarcoidosis is a multisystem inflammatory condition characterized by the development of non-caseating granulomas with predilection for the lungs. Neurosarcoidosis is the term used to describe sarcoidosis that involves the CNS, and is a rare manifestation of the disease. Data are limited regarding neurosarcoidosis and include few large case series and many smaller case reports.[44-46] In neurosarcoidosis, cranial neuropathy, may occur with the development of optic nerve granulomas. In one study of 54 predominantly adult patients, optic neuropathy both unilateral and bilateral, was the most commonly observed presentation, affecting 35% of patients. Bilateral involvement was associated with a poorer visual recovery: 7/13 bilateral patients in this series had an acuity of <20/200 in one eye at follow-up.[45] Although the clinical presentation in children is thought to be similar to adults, increasingly studies have demonstrated that in addition to cranial neuropathy, many children may present with seizures.[44,46] Although uncommon in children, sarcoid granuloma of the optic nerve should be included in the differential diagnosis of an inflammatory optic neuropathy, particularly if there is indication of both optic neuritis and/or perineuritis on neuroimaging (Fig. 56.6). Corticosteroid treatment is the mainstay of initial therapy.

Introduction

The chiasm is so named because it is shaped like the Greek letter chi.[1] Over 2 million nerve fibers pass through it: most are visual, but some non-visual fibers project from the optic chiasm to hypothalamic nuclei, forming the retinohypothalamic tract subserving circadian rhythms.[2] The ratio of crossed to uncrossed fibers in the human chiasm is about 53:47.[3]

Evolutionary considerations

The chiasm provides the major route for the juxtaposition of corresponding parts of the visual field in each eye. It is important for binocular vision. To establish fusion, it is necessary to have overlapping visual fields, congruence of corresponding retinal elements, and for the extraocular muscles to maintain alignment of the visual axes.[4] In lateral-eyed animals, optic fibers from each eye decussate entirely to the contralateral hemisphere. The percentage of uncrossed fibers increases as the orbits rotate anteriorly and the frontal field of single binocular vision increases.[5] The reason that our visual system is crossed is controversial[5,6] (Fig. 57.1).

In humans, there is more retina nasal to the fovea than temporally, so the right eye covers more right visual field than left visual field. The primordial nasal retinas are concerned with a phylogenetically older "panoramic" function. The temporal retinas have entered into a phylogenetically younger "binocular" function.

Our foveas are placed where nasal (panoramic) and temporal (binocularity-providing) retinas intersect.[6] This allows vision to subserve its elemental functions, namely:

- Exploration (mobility)
- Detail (foveas)
- Stereopsis (binocularity).[6]

Exploration of the surround is a primordial panoramic function of the nasal retinas, while binocular vision, stereopsis, and convergence concern the temporal retinas.

Anatomy

The optic nerves, chiasm, and optic tracts extend posteriorly and upward 45° from the optic canals in adults and children.[7] The chiasm lies in the suprasellar cistern several millimeters above the diaphragma sellae. The anterior cerebral arteries and the anterior communicating arteries lie anteriorly and above the chiasm and optic nerves. The carotid arteries lie laterally, with the posterior communicating artery passing underneath the optic tracts. The chiasm lies in the floor of the anterior end of the third ventricle. Expansion of the third ventricle may cause chiasmal compression. Posteriorly lie the hypothalamus and the pituitary stalk, the tuber cinereum, and the mamillary bodies. The optic nerves emerge from the optic canals. The length of the intracranial optic nerve varies, so the position of the chiasm in relation to other structures also varies. When the optic nerves are short, the chiasm is "prefixed," when long it is "postfixed." Von Willebrand's knee is an artefact.[8]

Embryology

The chiasm appears in the first month of life,[9] arising from a thickening of the floor of the forebrain. Retinal ganglion cells (RGCs) grow down the optic stalks and enter the floor of the third ventricle where they decussate to form the optic chiasm.

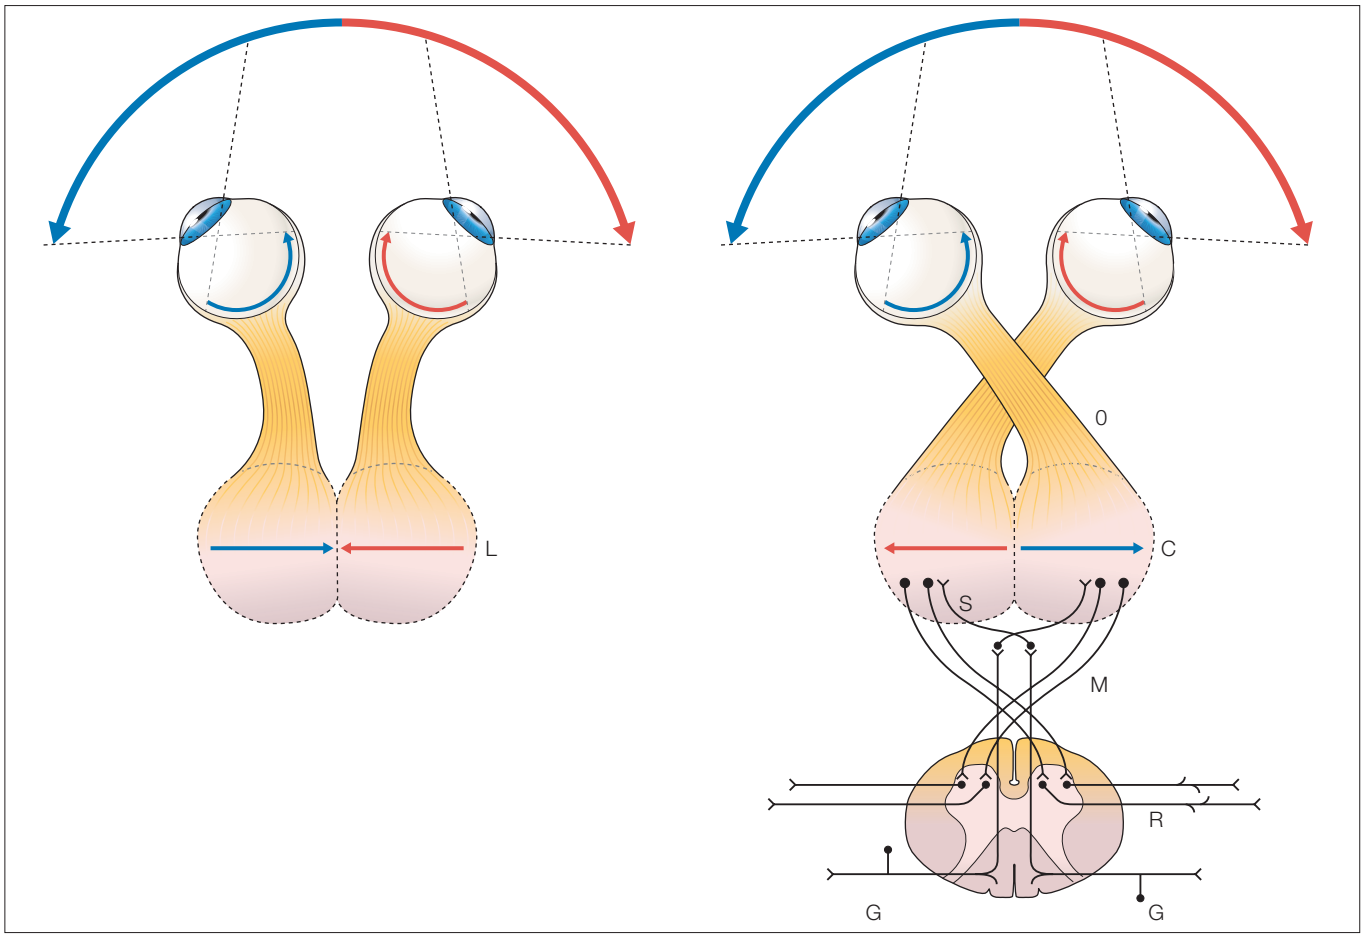

Fig. 57.1 Ramón y Cajal's original diagram of the hypothetical uncrossed chiasm (left). On the right is the completely crossed chiasm in lateral-eyed animals. *(With permission from Polyak S. In: Kluver H, editor. The Vertebrate Visual System. Chicago, IL: University of Chicago Press, 1957.)*

The pattern of axon crossing occurs in two phases.[10] The first retinal axons meet in the midline at the ventral diencephalon, forming an X-shaped chiasm; subsequent axons grow into either the ipsilateral or contralateral optic tract.[11]

A morphological specialization of the axon called a growth cone allows the axon to sense and respond to signals in the embryonic brain environment.[12] Neuronal and glial cells provide guidance information to ingrowing RGC axon. Histologic evidence suggests that uncrossed axons are confined within the lateral portion of the optic nerve and do not approach the chiasmal midline.[13] Neurons and radial glial cells in the ventral diencephalon serve a role in RGC axon guidance during chiasm formation. Growth-associated proteins in retinal growth cones enable RGC axons to progress and perform path-finding tasks. In the mouse, neurons at the site of the future chiasm are required for its formation by retinal ganglion cell axons. A growth-associated protein essential for chiasm formation has been identified.[14] There is substantial overproduction of neurons which later die back by apoptosis.[15] The chiasm reaches its definitive form by the fourth month of gestation.

Transcription factors that pattern the developing chiasm have been identified.[16–19] Foxd1 expressed in the developing temporal retina and its downstream effectors (tyrosine kinase membrane proteins) are involved in patterning of the optic chiasm in chicks and mammals.[17,18] Foxd1 imprints axons ipsilaterally. Foxd1 is expressed in progenitors of Zic2-positive retina ganglion cells and is the determinant of temporal retinal identity.[17,18] Neuropilin molecules, transmembrane proteins, serve as receptors for axonal guidance to regulate axon divergence at the chiasm in mammals.[19] Neuropilin 1 (NRP1) is expressed at the chiasm midline, and acts on contralateral retinal ganglion cells to provide growth-promoting and chemo-attractive signals for commissural axon crossing at the chiasm.[19] Ventral anterior homeobox 1 (Vax1) has also been found to possess retinal ganglion cell growth factor activity that is necessary for chiasmal development in the mammalian binocular visual system.[20]

Signs and symptoms

Developmental defects and suprasellar tumors are common in children (Box 57.1). Most chiasmal syndromes result from neoplastic disorders, developmental derangements, radiation injury, inflammation, infection, demyelination, infarction, transection, or hypoplasia.[21] Dominant optic atrophy may present with a bitemporal hemianopia simulating a chiasmal disorder.[21]

In young children, chiasmal disease often presents late because the child compensates and is not suspected of having poor vision until there is substantial bilateral visual loss.

Box 57.1

Signs and symptoms of chiasmal disease

Symptoms

Loss of stereopsis
Postfixational blindness
Loss of motor fusion
Hemifield slide
Bitemporal hemianopia
Bagolini striated lenses "mountain" pattern
Worth Four Dot (selective loss of temporal green dot as viewed through green lens)

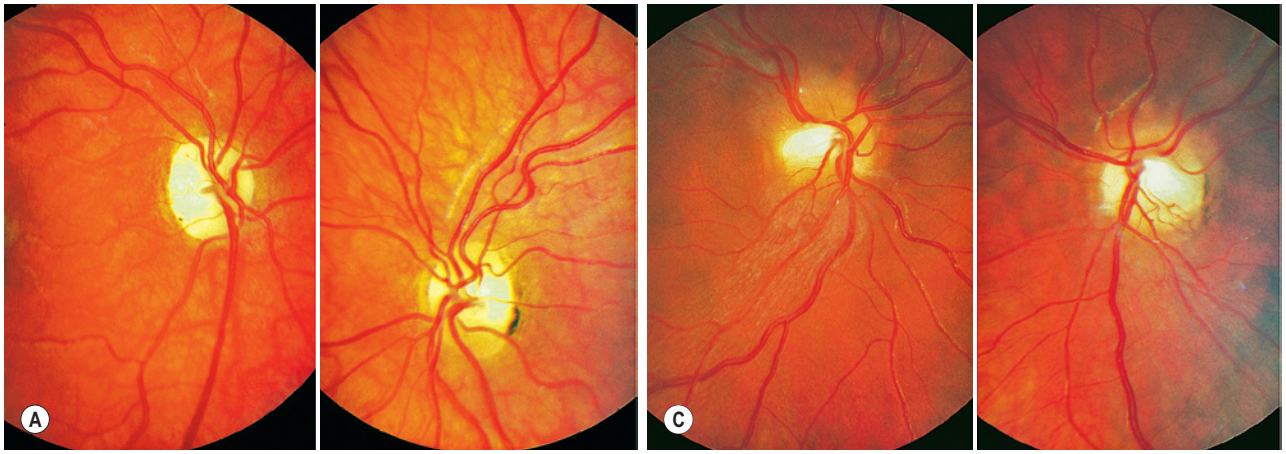
Signs

Large pupils/sluggish pupillary responses/light near dissociation
Small optic discs (for congenital tumors)
Bilateral band atrophy (for acquired lesions)
"Spasmus nutans" in infancy
See-saw nystagmus
Monocular temporonasal optokinetic asymmetry

The hallmark of chiasmal disease is a bitemporal hemianopia. Some form of visual field testing is essential. Inferior lesions have to grow large before signs of chiasmal compression appear. They compress the lower nasal fibers first and tend to give an upper bitemporal field defect. Lesions from above tend to cause an inferior defect. By the time a compressive lesion has caused defects, there is usually thinning of the chiasm and the pattern of the field defect is not always clear-cut.

There is often an acuity defect. Chiasm-splitting lesions, such as trauma, do not affect acuity greatly because the nasal field and the nasal half of the fovea is not affected, but involvement of the optic nerve or widespread involvement of both crossed and uncrossed fibers in the chiasm give rise to an acuity defect. Frequently, one eye has a very severe acuity defect and the other is relatively spared, except for a field defect. In chronic lesions, there is often preservation of a high level of acuity despite funduscopic evidence of a profound loss of neurons.

With optic nerve involvement, there is significant color vision defect. Some patients notice postfixational blindness (e.g. noticing that the road disappears when looking at the front windshield glass from the inside of the car). When there is chiasmal compression, the pupils may be large and sluggishly reactive to light, resulting in light-near dissociation. Stereoacuity tests and Bagolini striated lens are useful tests in patients with suspected chiasmal compression.[4] Decreased stereoacuity is common with chiasmal lesions, even when no visual field abnormalities are detectable.[4] However, stereopsis can be elicited with complete chiasmal transection by haploscopic stimulation of the intact temporal retinas.[22] This shows the sensory capacity for stereopsis is retained in chiasmal transection, but the absence of motor fusion precludes stereopsis.[23] A valuable and underutilized diagnostic test involves testing Titmus stereoacuity with the book held upright, then turning the Titmus book upside-down and repeating the test. Viewing the Titmus stereoacuity book upside-down normally causes the circles to appear retruded into the page, because the figures are monocularly displaced onto each nasal retina and defective temporal field. In chiasmal disease, this stereoscopic retrusion cannot be readily appreciated, because of the bitemporal hemianopia. Thus, the finding of an "inverse Titmus stereoacuity" that is lower than the upright Titmus stereoacuity should signal chiasmal disease. In chiasmal disease, the upside-down Titmus test furnishes figures that are monocularly displaced onto each nasal retina and defective temporal field, resulting in a more severe stereoacuity deficit relative to the upright Titmus test. Bagolini striated lens testing reveals a binocular "mountain" pattern in chiasmal lesions.[24] Children with early-onset chiasmal disease may present with nystagmus. The classic form is a spasmus nutans-like nystagmus with variable head titubation, but isolated see-saw nystagmus can also occur (see Chapter 89). Loss of chiasmal crossing fibers also causes loss of monocular nasalward horizontal optokinetic responses in each eye. In young children in whom reliable visual fields are not easily obtained, we have found this monocular temporonasal optokinetic asymmetry to be a useful clinical clue to the presence of chiasmal disease.[25]



Optic atrophy frequently occurs in chiasmal disease. There may be a generalized loss of neurons, or a pattern of band atrophy due to the loss of fibers subserving the temporal fields and the preservation of fibers subserving the intact nasal field (Fig. 57.2). In developmental chiasmal defects and tumors, there are often optic disc anomalies (Figs 57.3 and 57.4).[26,27] Congenital suprasellar tumors can produce horizontal "bow-tie" cupping with selective loss of the nasal and temporal nerve fiber layer.[28] Papilledema in these optic discs occurs predominantly in the superior and inferior poles (see Fig. 57.2C).

Because of the proximity of the hypothalamus and pituitary gland, endocrine and growth defects may occur. Infants with hypothalamus-involving tumors may develop Russell diencephalic syndrome: emaciation with loss of subcutaneous fat (Fig. 57.5), accelerated growth in length relative to weight (Fig. 57.6), and personality changes with euphoria and hyperactivity. One must examine and measure the infant's body habitus and inquire about weight gain.

In bitemporal hemianopia, the hemifield slide phenomenon may occur (Fig. 57.7). Since only the nasal portion of each visual field is functioning fully, corresponding retinal points between the two eyes no longer exist. Sensory fusion becomes impossible, and motor fusion cannot maintain alignment. A previous heterophoria becomes a manifest deviation. Esodeviations lead to letters or words appearing deleted. Exodeviations produce letters or words appearing duplicated. A vertical hemifield slide causes the child to lose track of which line of text they are reading. These children do not complain of diplopia but rather a duplication of the middle of words or objects. The hemifield slide phenomenon does not require a complete bitemporal hemianopia, and can occur as the initial symptom.[29] Signs and symptoms of chiasmal disease are summarized in Table 57.1. Rarely, chiasmal tumors can produce photophobia as their presenting symptom.[30]

Further investigations

Further investigations consist of endocrine studies, neurophysiological evaluation (see Chapter 9), and neuroimaging. Optical coherence tomography of the macular ganglion cell layer is highly sensitive to binasal retinal nerve fiber layer thinning resulting from congenital or acquired chiasmopathies. Neurophysiological studies may detect a crossover defect (particularly in a preverbal child) and quantitatively

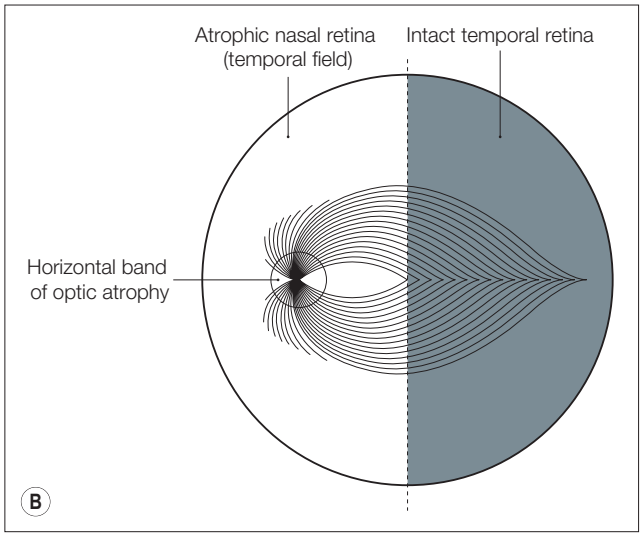


Fig. 57.2 Craniopharyngioma. (A) The right eye has bare perception of hand movements. The left eye has an absolute temporal hemianopia, normal color vision, and a visual acuity of –0.1 LogMAR (6/4.8, 20/16, 1.25). The left optic disc shows band atrophy: there is loss of the nerve fibers that subserve the temporal visual field but preservation of those that subserve the nasal field, which are inserted into the upper and lower segments of the disc. (B) The origin of the band of atrophy is due to the fact that the horizontal band or bow-tie area is the visible area of atrophy where temporal field fibers alone are inserted into the disc. (C) Craniopharyngioma showing "bi-lobed" papilledema during a period of raised intracranial pressure. Since papilledema occurs only when the retinal ganglion cell axons are swollen and only the superior and inferior (nasal field) axons survive in chiasmal compression, the papilledema occurs only in the upper and lower poles giving bi-lobed or "twin peaks" papilledema.

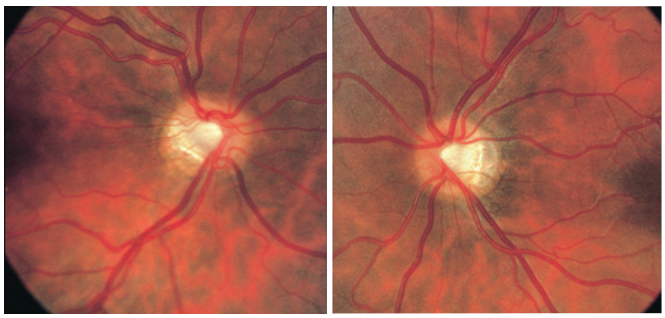

Fig. 57.3 Craniopharyngioma. Bilateral segmental hypoplasia or "tilted" optic disc. Bitemporal hemianopia with a visual acuity of –0.1 LogMAR (6/4.8, 20/16, 1.25) right eye (refraction: –4.0 D) and –0.22 (6/3.6. 20/12, 1.67) left eye (–4.50 D).

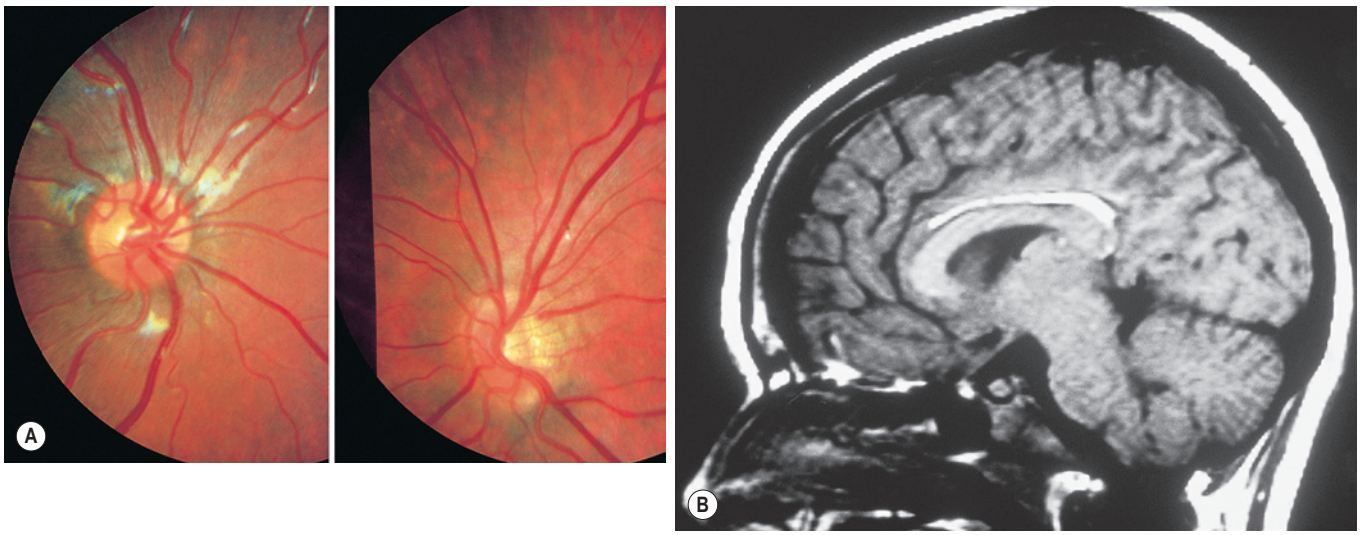

Fig. 57.4 Midline facial defect. (A) Dysplastic tilted left optic disc in a patient with a midline facial defect. (B) Magnetic resonance imaging of corpus callosum lipoma in a patient with a midline facial defect.

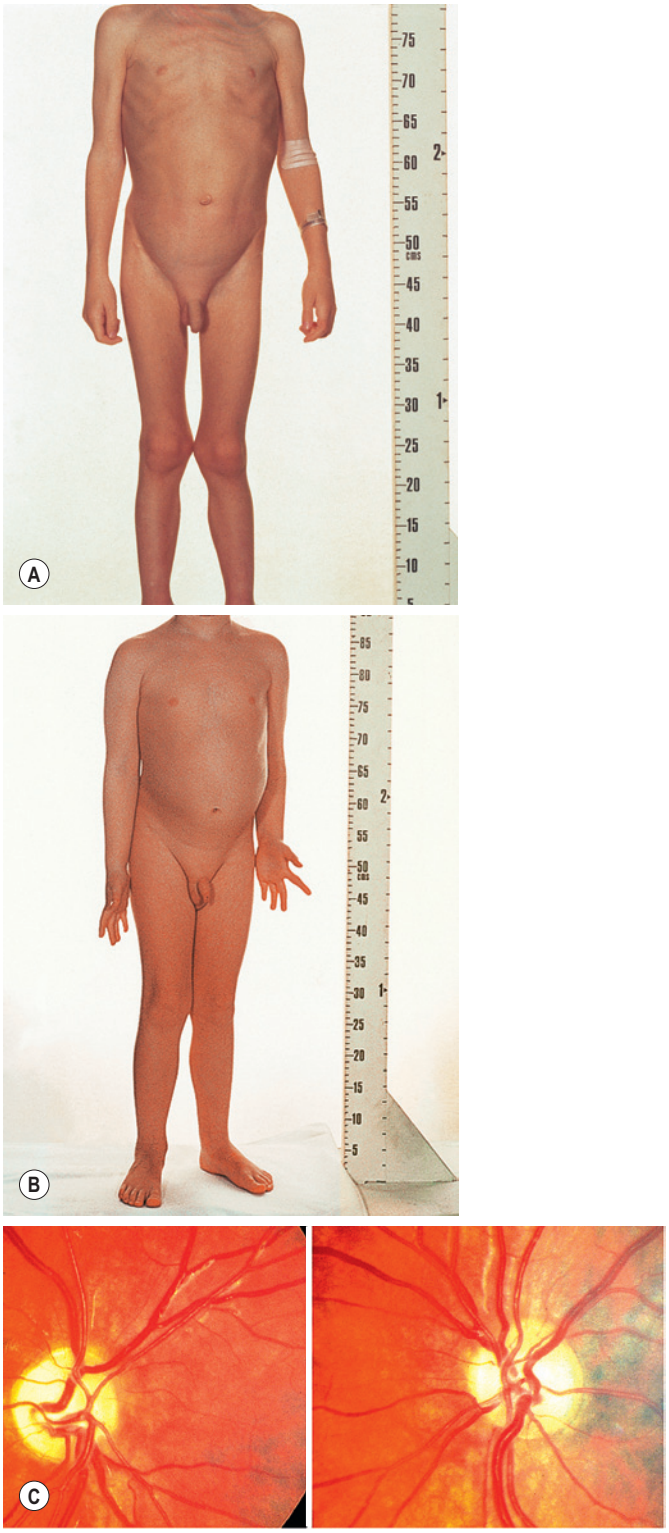

Fig. 57.5 Chiasmal glioma. (A) This boy presented with poor vision and recent weight loss – photograph on 12 February 1973. (B) Photograph on 31 January 1974 showing rapid growth in weight and height. Weight and growth rate fluctuation are common in chiasmal glioma. (C) Bilateral band atrophy (same patient).

and qualitatively assess the visual defect. Magnetic resonance imaging (MRI)[31,32] provides neuro-anatomical detail of the chiasm and surrounding structures. Computed tomography (CT) scanning may provide important information about bony changes involving the parasellar area.

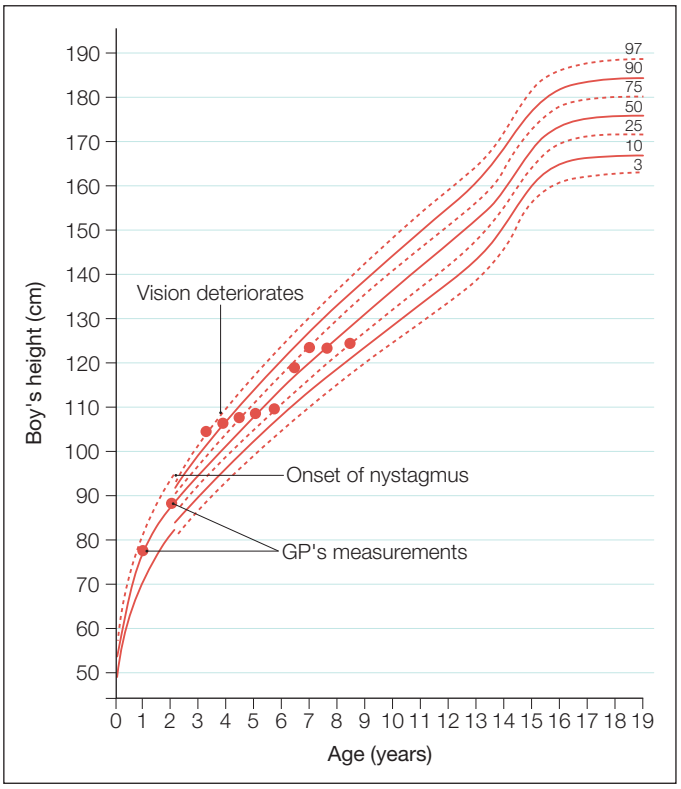

Fig. 57.6 Height growth record of a child with chiasmal glioma showing height growth rate fluctuation. Pediatric ophthalmology clinics need to have these charts available.

Developmental defects

Developmental derangements of the optic chiasm include:

- Albinism
- Achiasmia
- Aplasia
- Anophthalmia

Albinism (see Chapter 41)

Anomalous decussation of chiasmal projections occurs in persons with albinism.[24] Retinogeniculate axons arising from ganglion cells in the portion of the temporal retina within 20° of the vertical meridian decussate abnormally in the optic chiasm to synapse in the contralateral lateral geniculate nucleus.[33–35] The human optic chiasm has a predominance of crossed fibers. Albinism is associated with smaller optic nerves, chiasm, and tracts and a wider angle between the optic nerves and tracts.[36] The crossed predominance can be diagnosed electrophysiologically by finding asymmetrical hemispheric visual evoked potentials[37,38] (Fig. 57.8; see Chapters 9 and 41). Pigment around the optic disc plays an important role in axonal guidance, suggesting that loss of retinal epithelial pigment could be the source of chiasmal misrouting in albinism.[39] Recently, the role of the transcription factor Zic2 has been implicated in the chiasmal misrouting in albinism.[40]

Achiasmia

Belgian sheep dogs with achiasmia have congenital and see-saw nystagmus.[41,42] Two unrelated girls with achiasmia had normal

Table 57.1 Chiasmal diseases in children

Category	Disease/disorder
Developmental defects	Albinism Achiasmia Aplasia Anophthalmia
Tumors	Chiasmal glioma Craniopharyngioma Pituitary adenoma Dysgerminoma Retinoblastoma ("trilateral")
Trauma	Transection Hematoma Contusion Traction
Infiltration	Langerhans cell histiocytosis Sarcoidosis Juvenile xanthogranuloma
Chiasmal neuritis	Postviral Postimmunization Multiple sclerosis
Optochiasmatic arachnoiditis	Tuberculosis Neurosyphilis Fungal Cysticercosis
Vascular anomalies	Arteriovenous malformation Cavernous angioma
Radiation	Acute visual loss months to years after radiation
Empty sella	Third ventricular distension secondary to aqueductal stenosis Downward traction on chiasm secondary to surgical scarring on pituitary apoplexy

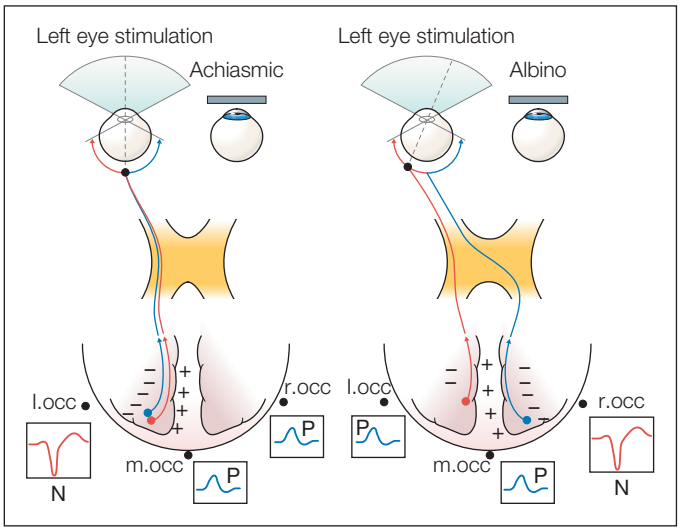

Fig. 57.8 Schematic comparing the visual pathway and visual evoked potential (VEP) distribution in albino and achiasmic patients for flash stimulation of the left eye. Stimulation of the right eye produces the mirror image distribution for either condition. In the achiasmic subject, all the visual fibers from the left eye project to the left occipital cortex, and at 80–100 ms a positivity is recorded over the right scalp and a negativity over the left. In contrast, most of the fibers from one eye cross at the chiasm in albinism, and the VEP distribution is the opposite, with a positivity recorded over the left scalp, and negativity over the right. *(Courtesy of Dr Dorothy Thompson.)*

Fig. 57.9 Achiasmia in a child who presented with a cleft lip and palate: see-saw nystagmus. (A) Coronal magnetic resonance imaging (MRI) and (B) sagittal MRI showing a large encephalocele completely dividing the chiasm. (C) The encephalocele protruding through the hard palate. *([A,B] Photographs courtesy of Dr Dorothy Thompson.)*

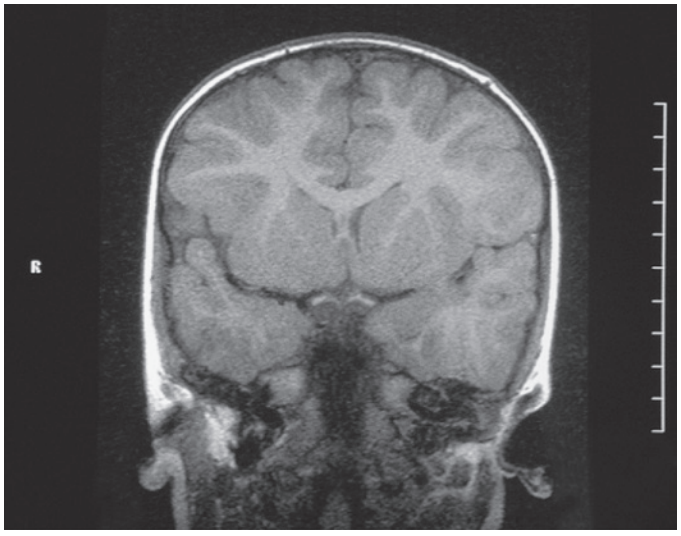

Fig. 57.10 Chiasmal hypoplasia. The chiasm is divided into two halves that are joined by a fragment of tissue. Electrophysiologically the patient was achiasmic. *(Photograph courtesy of Dr Dorothy Thompson.)*

visual fields and no stereoacuity.[43] Eye movement recordings showed congenital nystagmus in the horizontal plane and see-saw nystagmus in the vertical and torsional planes. MRI showed absence of the chiasm, with each optic nerve projecting entirely to the ipsilateral hemisphere. The polarity of the visual evoked potential (VEP) distribution across the occiput was the reverse of the crossed asymmetry that has been described in albinism (see Fig. 57.8).[44] Altered expression of transcription factors such as NRP1, which promotes contralateral axon projection in mammals, may be found to produce achiasmia.[18]

Achiasmia may be complete (Fig. 57.9) or partial (Fig. 57.10). Patients with bilateral optic nerve hypoplasia invariably have chiasmal hypoplasia; those with unilateral optic nerve hypoplasia have selective hypoplasia of the ipsilateral side of the chiasm.[45] Patients with isolated chiasmal hypoplasia may have segmental optic nerve hypoplasia confined to the nasal and temporal sectors of the optic discs.[46,47] Chiasmal anomalies have been described in patients with midline defects in the brain, midfacial defects, and basal encephaloceles.[48–50]

Aplasia and anophthalmia

Unilateral anophthalmos or optic nerve aplasia produces an asymmetrical chiasm.[51] Bilateral anophthalmia or optic nerve aplasia is usually associated with absence of optic nerves, chiasm, and lateral geniculate bodies,[52–54] although some show remnants of the optic nerves and chiasm.[55] In mice, prenatal removal of one eye produces a preponderance in crossed fibers from the other eye, whereas postnatal removal of one eye produces an increase in the surviving uncrossed component.[35] Patients with unilateral optic nerve aplasia may show crossed hemispheric VEP asymmetry.[51] Loss-of-function mutations in *ALDH1A3* can cause anophthalmia/microphthalmia with hypoplasia of the optic nerve and chiasm by reducing retinoic acid synthesis, which is critical for normal ocular morphogenesis and downstream signaling.[56]

Trauma

Following closed head trauma, a child may develop an absolute bitemporal hemianopia and poor acuity and color vision if there is also damage to the non-crossing fibers or optic nerve.[57] Damage to surrounding structures may lead to diabetes insipidus, anosmia, cerebrospinal fluid rhinorrhea, growth defects, and mood changes. Traumatic enucleations can produce tractional injury to the optic chiasm and a temporal hemianopic defect in the other eye.[58]

Tumors

The peculiar geometry of the optic chiasm may render its midportion more vulnerable to deformation stress exerted from below. Despite its anatomic vulnerability to compression by suprasellar tumors, the optic chiasm is surprisingly resistant to compression.[59] Frisén and Jensen found an elevation of 6 mm is necessary to produce visual field defect in 50% of patients, and an additional elevation of 5 mm to produce visual field defects in 90% of patients.[60]

Chiasmal glioma

Chiasmal, optic nerve, and hypothalamic gliomas are closely related; they may show common histopathological features and clinical behavior. All occur with increased frequency in neurofibromatosis (NF).[61] It may occur in Beckwith–Wiedemann syndrome – macrosomia, macroglossia, encephalocele, hemihypertrophy, hepatomegaly, and advanced bone age.[62]

Infants with large chiasmal–hypothalamic glioma can present with Russell diencephalic syndrome. The main features are emaciation despite a normal or only slightly diminished caloric intake, alert appearance, hyperkinesis or increased vigor, euphoria, skin pallor, irritability, and normal or accelerated linear growth (see Fig. 57.5). These infants usually have large chiasmal gliomas. Radiation therapy can induce dramatic tumor shrinkage and long-term regression of clinical abnormalities.[63,64]

Small children often present with a compound nystagmus, typically see-saw in nature (see Chapter 89). Any child with a compound nystagmus with rotary, vertical, and horizontal elements should be suspected of having a chiasmal lesion.[65] Visual loss is often profound before it is noticed, but in older children the visual defect may be noticed by the child or detected by school visual testing. Some large optic gliomas may have no gross visual defect.[66] Chiasmal gliomas may affect growth and development. An unusual presentation is the "bobble-headed doll syndrome." This is usually an indication of hydrocephalus.

The diagnosis can be suggested by visual field testing or multifocal visual evoked cortical potential testing. Plain X-rays are seldom used, but the classical finding is an expanded and pear-shaped sella turcica (Fig. 57.11) with chronic bone changes without calcification. One or both optic foramina may be enlarged, especially if there is an optic nerve component to the tumor. CT scanning shows three diagnostic patterns (Fig. 57.12)[67]:

1. A tube-like thickening of optic nerve and chiasm.
2. A suprasellar tumor with contiguous optic nerve expansion.
3. A suprasellar tumor with optic tract involvement.

Cystic or "globular" suprasellar tumors are not characteristic and may require histological confirmation.[54] MRI scanning better delineates the extent and nature of the tumor.[68] CT and MRI scanning will both diagnose hydrocephalus. Tumors may evolve in areas thought to be normal on initial CT and even MRI scans.[69]

Fig. 57.11 Expanded pituitary fossa shown on plain X-ray with some calcification due to a craniopharyngioma.

The histopathology of optic gliomas has long been the subject of discussion because it is relevant to treatment decisions. Optic gliomas are benign tumors that often behave similarly to hamartomas.[70] They undergo enlargement by an accumulation of mucosubstance, local invasion, induction of hyperplasia in adjacent glial cells, or growth of cell "rests" present in adjacent optic nerve or chiasm.[71] Malignant gliomas rarely occur and mainly in adults. Meningeal spread in children, however, is not unknown[72,73] and spread through a ventriculoperitoneal shunt has been recorded.[74]

The clinical course of 36 optic gliomas (29 chiasmal) were reviewed[70]: some were reviewed in 1971,[75] others in 1986.[61] The 1971 follow-up showed a very stable course, but the later follow-up showed that 57% of the 29 patients with chiasmal gliomas were dead, although only 18% from the direct effects of the glioma. The patients were more at risk from other tumors associated with neurofibromatosis type 1 (NF1). Twelve survivors had not had radiation therapy, whereas 11 of 16 patients who died had.[61]

Early studies reported that NF had no influence on the prognosis of optic pathway gliomas. It now appears that NF acts as a protective factor, both visually and neurologically.[76–78] In one study, the most common site of visual pathway involvement in NF was the orbital optic nerve (66%), followed by the chiasm (62%). This contrasted to patients without NF, in which the chiasm was the most common site of involvement (91%), and the orbital optic nerves were involved in only 32%. Extension beyond the optic pathway at diagnosis was uncommon in the NF group (2%), but frequent in the non-NF group (68%). In the NF group, the tumor was smaller and the original shape of the optic pathways was preserved (91% vs. 27% in the non-NF group). The presence of a cystic tumor was significantly more common in non-NF patients (66% vs. 9% in the NF group). The tumors in half the NF patients remained stable, in contrast to 5% of the non-NF group. Hydrocephalus as a presenting symptom was found only in the non-NF group.

In children with NF and optic pathway gliomas, the likelihood of visual loss is dependent on the extent and location of the tumor and is particularly associated with involvement of postchiasmal structures.[79] Complete spontaneous regression can occur in both NF- and non-NF-associated gliomas.[80] Spontaneous visual improvement can also take place in the absence of MRI changes.[81] Many authors have reported a reasonable long-term prognosis that does not seem to be improved by treatment.[61,82,83] Radiotherapy may decrease the size of tumors[54] and may improve vision,[84–88] but its use should be avoided, except in the Russell diencephalic syndrome, because of its serious side effects, especially in young children.[89–91] Chemotherapy[72,92,93] is as yet of uncertain benefit. Newer agents are promising, and may allow deferment of damaging radiotherapy in the young child.[93]

Surgery is not indicated except to treat obstructive hydrocephalus in large chiasmal/hypothalamic gliomas,[94] in rare cases of optochiasmatic apoplexy,[95] or if there is a cystic tumor with doubts about its pathology. A biopsy and cyst aspiration may be indicated.

Follow-up usually involves periodic review of the visual fields, acuity, color vision and optic discs, neurophysiological studies, where available, and CT or MRI scanning.

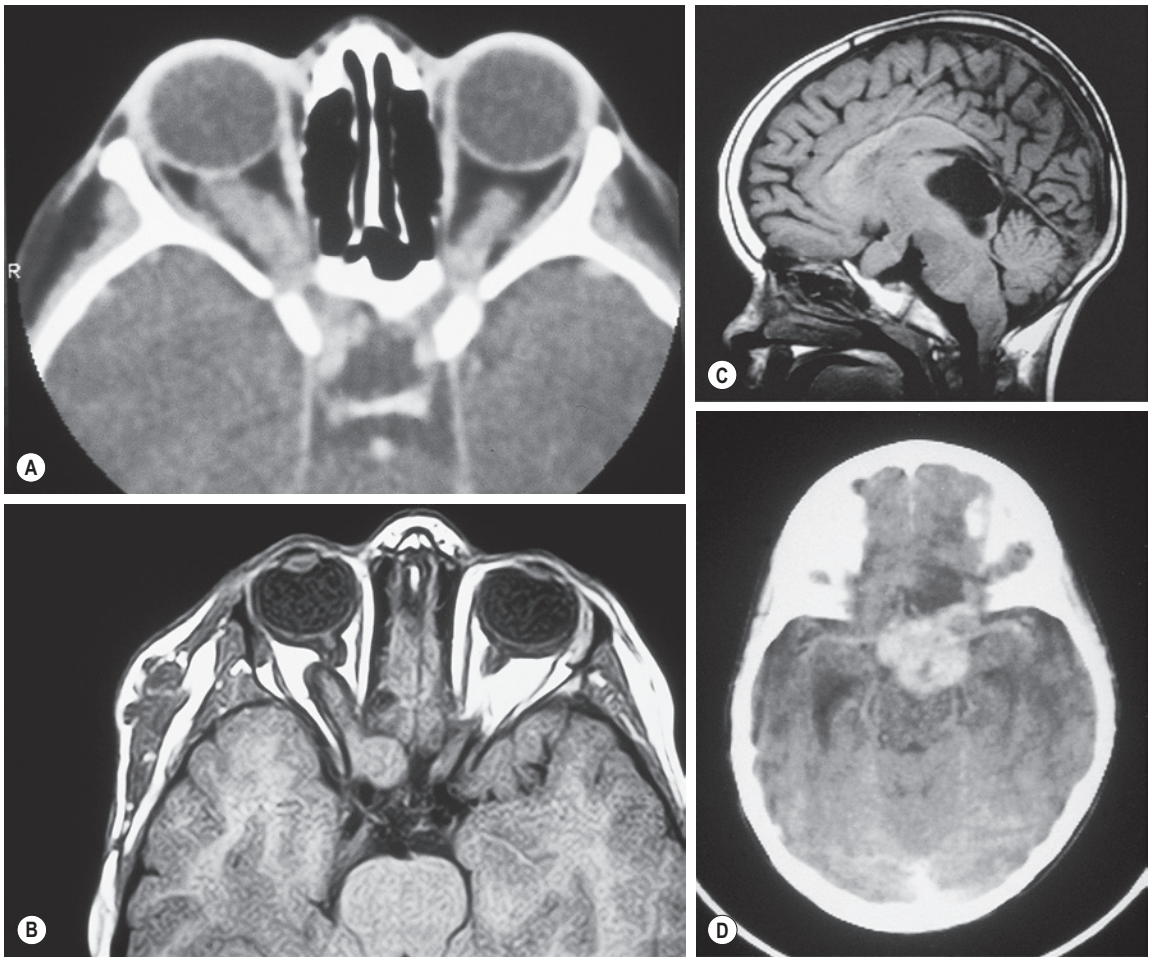

Fig. 57.12 Chiasmal glioma. (A) Computed tomography (CT) scan of bilateral optic nerve gliomas extending to the chiasm. (B) Magnetic resonance imaging (MRI) scan of left optic nerve glioma extending to the chiasm and kinking the intraorbital optic nerve. (C) Sagittal MRI of an optic nerve and chiasmal glioma. (D) CT scan with contrast of a cystic chiasmal glioma. *([A,B] Courtesy of Dr Kling Chong, Great Ormond Street Hospital, London, and Dr Bob Zimmerman of the Children's Hospital, Philadelphia.)*

Craniopharyngioma

These cystic tumors grow slowly and do not usually present until after 3 or 4 years of age. They may present even in old age. Their origin is from the pituitary stalk and they compress the chiasm, classically from behind and above. Hypothalamic disturbances are frequent, and loss of vision may be profound. Young children tend to develop hypothalamic disturbances or hydrocephalus, while older children (first decade) are more likely to present with visual disturbance, strabismus, or nystagmus (see Figs 57.11 and 57.13). The diagnosis is made by CT or MRI scanning (see Fig. 57.13). Calcification occurs in virtually every case in childhood and the tumors are often cystic. Endocrine assessment and management is essential. The tumors are usually treated by surgery with or without radiotherapy; total removal is sometimes possible.

Pituitary adenomas

Pituitary tumors are relatively uncommon in childhood, but can occur in adolescence.[7] In the pubertal period, they are more likely to show extrasellar extension and hemorrhage.[96,97] Children with macroadenomas may develop pituitary apoplexy, characterized by sudden headache, visual deterioration, ophthalmoplegia, and depressed consciousness consequent to hemorrhage into the tumor.[98,99]

Dysgerminoma

Diabetes insipidus is a common symptom of dysgerminomas together with chiasmal defects, including acuity and visual field loss and hypothalamic or pituitary disturbances.[100,101] They are often not large[102] and occur in older children or young adults.[103]

Other chiasmal tumors

Trilateral retinoblastoma is the association of bilateral retinoblastomas and ectopic intracranial primitive neuroectodermal tumor. These midline intracranial tumors most commonly occur in the pineal region, but can occur in the suprasellar area involving the chiasm.[104] The suprasellar tumors can present before the diagnosis of ocular retinoblastoma.[105] Other rare tumors, such as metastatic neuroblastoma, arachnoid cysts, choristomas,[106] ependymomas, epidermoid tumors, leukemic deposits, ectopic pinealomas, and teratomas, can occur.[107]

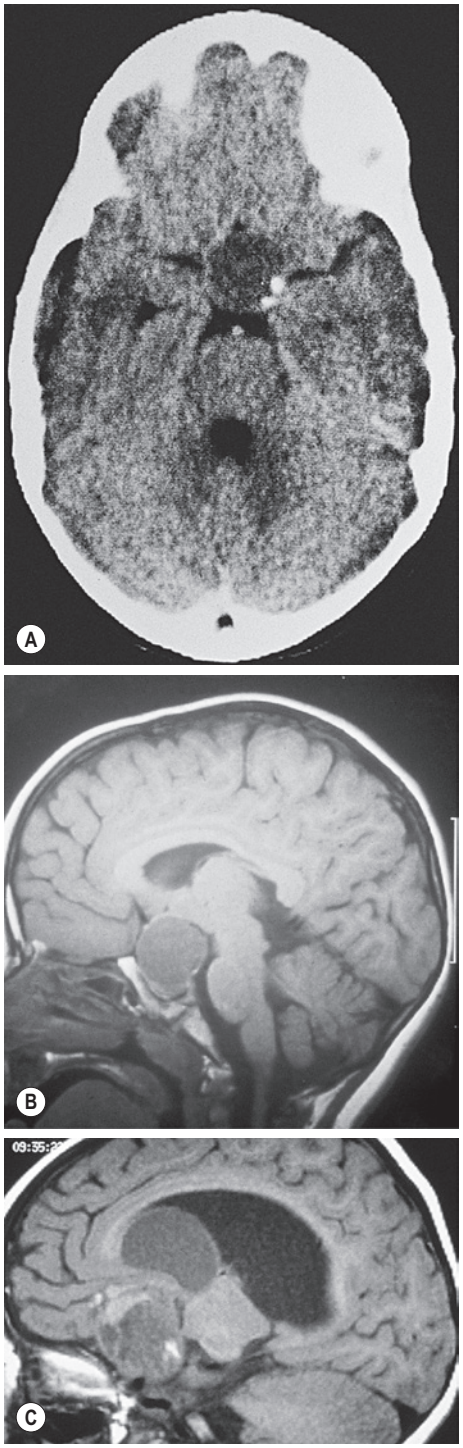

Fig. 57.13 Craniopharyngioma. (A) Computed tomography scan of a small cystic craniopharyngioma with calcification in its wall. (B) Sagittal magnetic resonance imaging (MRI) of small craniopharyngioma. (C) MRI scan of a large cystic craniopharyngioma with calcification in its wall. There is hydrocephalus.

Granulomas and chronic inflammatory disorders

The chiasm and surrounding structures may be involved in abnormalities of the skull base, such as Langerhans cell histiocytosis (see Chapter 27). A variant of this condition tends to present with diabetes insipidus and visual defects. Sarcoidosis, juvenile xanthogranulomas, and pseudotumors may also affect the chiasmal area.

Sphenoid sinus disease

A chiasmal syndrome, or even rapid blindness, may result from the formation and expansion of a mucocele,[108] even in the absence of symptomatic sinus disease.[109]

Chiasmal neuritis

Chiasmal neuritis is characterized by visual loss and bitemporal hemianopia.[98] Most cases are associated with demyelinating disease,[110] although Purvin et al. described a boy with infectious mononucleosis and chiasmal neuritis.[111] MRI shows swelling and enhancement of the chiasm.[110,112]

Optochiasmatic arachnoiditis

Optochiasmatic arachnoiditis with localized thickening of the arachnoid at the base of the brain may surround and compress the optic nerves and chiasm. Tuberculous meningitis, hydatid disease, cysticercosis, and fungal disorders (especially in debilitated, immune deficient children) may affect the suprasellar cistern with damage to the chiasm and surrounding structures.[113–115] Although the diagnosis has come to imply that surgical lysis of intracranial adhesions may be necessary to restore vision, the efficacy of surgical treatment remains unproven. Corticosteroids and cytotoxic agents are reportedly effective in some instances.[116] Modern neuroimaging seems to have rendered the diagnosis of optochiasmatic arachnoiditis an anachronism.

Third ventricle distension

In hydrocephalus, distension of the third ventricle may cause chiasmal damage with visual field defects[117] and profound vision loss due to stretching or compression of the optic nerves and chiasm. Unilateral visual loss from compression of one optic nerve against the internal carotid artery has been reported.[118]

Vascular malformations

Aneurysm is an extremely rare cause of chiasmal defects in children.[119,120] In children, intracranial aneurysms may be large and associated with polycystic kidneys, coarctation of the aorta, and Marfan and Ehlers–Danlos syndromes. Multiple aneurysms (usually small) may also occur in "mycotic" aneurysms with subacute bacterial endocarditis and moyamoya disease.[121–123]

Arteriovenous or cavernous malformations localized to the chiasm may hemorrhage to produce a sudden-onset chiasmal visual deficit accompanied by headache (termed "chiasmal apoplexy").[124]

Radionecrosis

Radiation injury to the optic chiasm is an uncommon, but serious, complication of radiation treatment. When vision becomes impaired, enhancement of the chiasm after gadolinium

injection is a consistent finding. Chiasmal enlargement may also be present. These neuroimaging abnormalities may antedate visual loss by several months.[125] The pathogenesis involves damage to the capillary beds. The risk of radionecrosis appears to be increased by the concomitant use of chemotherapy.

Empty sella syndrome

In empty sella syndrome, the subarachnoid space extends into the sella turcica, and the pituitary gland is flattened against the sellar floor or walls.[126,127] Chiasmal visual field defects occasionally occur.[127,128] Chiasmal prolapse can be caused by a distended third ventricle pushing the chiasm down into the sella, or by scarring and contracture pulling the chiasm into the sella. Aqueductal stenosis is particularly prone to produce ballooning of the third ventricle with downward herniation of the chiasm.[129] Pituitary apoplexy or sellar surgery can produce adhesions and cause downward traction of the chiasm into the sella.[128] Although pseudotumor cerebri is the most common cause of empty sella,[127] it does not seem to be associated with chiasmal prolapse into the empty sella.[128]

SECONDARY HEADACHES
SUMMARY
REFERENCES

Introduction

Headache is a common symptom in children. A landmark epidemiology survey of 6000 school children found a complaint of generalized headache in 37–51% of 7-year-olds, and this proportion gradually increased to 57–82% by adolescence.[1] Accompanying eye or vision signs and symptoms may lead these children for an eye exam. Since serious neurologic morbidity and mortality can be heralded by head pain, it is important for pediatric ophthalmologists to understand the causes of headache in children as well as recognize headache syndromes to help guide the diagnostic work-up and management.

Classification and etiology

Headaches in children can be classified as primary or secondary. The International Classification of Headache Disorders (ICHD-3 beta)[2] defines the headache syndromes, and pediatric criteria were first included in 2004. In adults and children, the most common type of primary headache is migraine with and without aura, and less common syndromes include new persistent daily headache (NPDH), trigeminal autonomic cephalalgia (TAC), and tension-type headache (TTH).[3,4] Medication-overuse headache can often complicate a primary headache syndrome or be a secondary headache unassociated with a headache syndrome. Other primary headaches are listed in Box 58.1.

Migraine

Migraine is common in children; its frequency increases throughout childhood and peaks in adolescence, with a prevalence of 1.2–3.2% in 3–7-year-olds, 4–11% in 7–11-year-olds, and 8–23% by age 15.[5] Migraine is typically more common in boys in the prepubertal ages, but the gender predominance shifts towards girls in the adolescent years. There are three main groups of pediatric migraine: migraine without aura (formerly common migraine); migraine with aura (formerly classic migraine); and childhood periodic syndromes that may be associated with headaches.

Migraine without aura is the most frequent form of migraine in children and adolescents, and accounts for 60–85% of migraine in children.[5] Migraine is defined by recurrent episodes of intense disabling headache separated by symptom-free intervals. The ICHD-3 beta criteria are included in Box 58.2, and typical characteristics in children are bilaterality, a pulsating quality, moderate or severe intensity, aggravation by routine physical activity, and association with autonomic symptoms such as nausea and/or photophobia and/or phonophobia (may need to be inferred from behavior, as in retreating to a quiet dark room). Migraine in children is different than in adults (Table 58.1). For instance, in children, migraine headache is usually frontotemporal, whereas, occipital headache in migraine is rare and should be a diagnosis of exclusion. The prevalence of cranial autonomic symptoms such as aural fullness, facial flushing/sweating, lacrimation, conjunctival injection, ptosis, gritty eye symptoms, nasal congestion/rhinorrhea, and periorbital edema have been well described in children. These symptoms are more frequent than in adults, with at least one cranial autonomic symptom noted in 62% of pediatric migraineurs.[6] Aural fullness was found to be the most common symptom.

Migraine without aura variants

Typically, migraine in children is episodic with symptom-free intervals; however, when the migraine symptom frequency increases to 15 or more days per month for 3 months, chronic migraine is diagnosed. Status migrainosus occurs when there is a debilitating unremitting headache lasting for more than 72 hours.

Causes of primary headaches in children

Migraine without aura
Migraine with aura
Tension-type headache
Trigeminal autonomic cephalalgia
Primary stabbing headache
Primary cough/exercise/cold-stimulus/hypnic headache
New daily persistent headache

Box 58.2

Proposed criteria for pediatric migraine without aura

Diagnostic criteria:

A. At least five attacks fulfilling criteria B through D
B. Headache attacks lasting 2–72 hours (untreated or unsuccessfully treated). Sleep is considered part of the headache duration
C. Headache has at least two of the following characteristics:
   1. Bifrontal/bitemporal or unilateral location (adults unilateral head pain)
   2. Pulsating/throbbing quality (which may need inference from child behavior)
   3. Moderate or severe pain intensity (numerical or FACES scale)
   4. Aggravation by or causing avoidance of routine physical activity
D. During headache at least one of the following:
   1. Nausea and/or vomiting
   2. Photophobia or phonophobia (may need inference from child behavior)
E. Not better accounted for by another disorder

Source: The International Classification of Headache Disorders, 3rd edition (beta version). Cephalalgia. 2013; 33: 629–808.

Table 58.1 Differences between adult and childhood migraine

Feature	Childhood	Adult
Laterality	Bilateral (but may start unilaterally)	Unilateral
Expanding "C" fortification spectrum	Rare	Common
Duration of headache	>2 hours	>4 hours
Systemic symptoms	Variable but often few	Common
Positive family history	Common	Common
Non-visual aura	Common	Infrequent
Visual aura without headache	Very rare	Common

Red flags of migraine without aura

The risks of radiation exposure from computerized tomography (CT) imaging and the risk of anesthesia and sedation needed for magnetic resonance imaging (MRI) can often discourage neuroimaging a child with headache. However, the red flag signs and symptoms of a first or isolated headache listed in Box 58.3 should prompt consideration of urgent imaging of a child with headache. In a child with recurrent headaches, the findings of an abnormal neurologic exam should also prompt imaging the brain. A study of 1562 children with recurrent headaches presenting to nine pediatric neurology clinics in tertiary hospitals found that 77% of these children had brain imaging, but only 9.3% had abnormal findings on the scans. In those with an abnormal neurologic exam, however, 50% of the scans identified a cause.[7] A new-onset headache during pregnancy in an adolescent female is a red flag symptom, given increased risk for an underlying etiology such as cerebral venous thrombosis. Emergent and urgent imaging in children or adolescents with headache is often with a CT scan of the head, but a brain MRI in a child is more ideal if promptly available because of the superior neuroanatomic detail and lack of radiation.

Box 58.3

Red flags of pediatric headache

Focal neurological signs
Seizures (focal or generalized)
Alteration of consciousness/confusion
Papilledema
Fever and/or meningeal signs
Change or deterioration of personality/behavior
Age under 4 (especially with increasing head circumference)
Headaches that are always unilateral (rare in pediatric migraine)
Headaches that wake from sleep or upon wakening
Headaches with coughing, straining, or changing position

Migraine with aura

In 30% of patients with migraine, the migraine attacks are preceded or accompanied by an "aura" characterized by transient focal neurologic symptoms.[8] Migraine with aura (Box 58.4) is defined by recurrent (≥2) attacks, lasting 5–60 minutes, with fully reversible visual, sensory, or other central nervous system symptoms. The aura usually develops gradually over minutes and is followed by associated migraine symptoms and headache. It typically starts before the pain phase begins. However, the aura may begin after the pain starts or continue into the pain phase. If a child meets criteria for typical aura, but has no subsequent headache, the child is diagnosed with typical aura without headache, previously referred to as "acephalgic migraine" or "ocular migraine."

Visual aura is the most common aura in adults and children, although it is less often present in children (see Chapter 100). Positive visual symptoms are most often described as an arc of colored or white zig-zag, jagged, or serrated lines moving to the periphery; however, flashes of light or shapes are also described.[9] The visual symptoms usually disappear after 15–20 minutes. Atypical visual complaints in migraine, but not aura *per se*, such as complex hallucinations, visual snow, and Alice in Wonderland syndrome, are well described in children.

Other non-visual auras

Sensory disturbance is the next most common aura and is usually described as pins and needles or numbness that slowly spreads (seconds to minutes) away from a point of

Box 58.4

Proposed criteria for pediatric migraine with aura

Diagnostic criteria:

A. At least two attacks fulfilling criteria B and C
B. One or more of the following fully reversible aura symptoms
   1. Visual
   2. Sensory
   3. Speech and/or language
   4. Motor
   5. Brainstem
   6. Retinal
C. At least one of the following four characteristics:
   1. At least one aura symptom spreads gradually over ≥ 5 minutes, and/or two or more symptoms occur in succession
   2. Each aura symptoms lasts 5-60 minutes (multiple aura symptoms have cumulative time, i.e. 3 symptoms is allotted 3 x 60 minutes for resolution)
   3. At least one aura symptom is unilateral
   4. The aura is accompanied, or followed within 60 minutes by headache
D. Not better accounted for by another ICHD-3 or other neurologic diagnosis

Source: The International Classification of Headache Disorders, 3rd edition (beta version). Cephalalgia. 2013; 33: 629–808.

origin. Migraine with brainstem aura, previously known as basilar migraine, must include at least two brainstem features (dysarthria, vertigo, tinnitus, hypacusis, diplopia, ataxia, or decreased consciousness). Hemiplegic migraine has an aura that includes motor weakness. If there is a first- or second-degree relative with migraine aura involving motor weakness, then familial hemiplegic migraine from causative gene mutations *CACNA1A*, *SCN1A*, or *ATP1A2* should be considered.

Migraine visual aura complications

The visual aura typically lasts less than 1 hour (although motor aura can last weeks) and is fully reversible; however, on rare occasions an aura can persist for more than 1 week and last for months. If there is no ischemia found on neuroimaging, persistent aura without infarction is diagnosed. Persistent positive visual phenomena differs from persistent aura without infarction in that the visual phenomena are usually continuous, full-field without vision loss, and not visually disabling.[10] Another rare complication of aura is migrainous infarction, defined as a migraine aura lasting more than 1 hour and associated with infarction in the appropriate territory on neuroimaging. In a recent study, however, no increase in hemorrhagic or ischemic stroke risk in children with migraine was found.[11]

Red flags of migraine with aura

Neuroimaging should be considered if there are negative visual symptoms (i.e. hemianopia, black curtain in vision, darkening or graying of vision), symptoms lasting longer than 60 minutes for each of the aura symptoms, and/or other associated neurologic features not associated with typical aura.

Other visual conditions related to migraine

Retinal migraine involves monocular and negative visual symptoms with no other associated aura features. At the time of the attack, there can be constriction of the retinal arterioles and venules.[12] Ophthalmoplegic "migraine" (see Chapter 84) is a rare disorder in children, with typical migraine that occurs before the age of 10, with onset of episodes of ophthalmoplegia preceding a headache by several days. This may be a secondary headache rather than a primary headache disorder.[13] The work-up includes a brain MRI, and a short course of oral prednisone is often tried.

Childhood periodic syndromes

Childhood periodic syndromes may represent early-life expression of genes that later in life manifest as migraine headache, and the phenotype changes as the nervous system develops. These syndromes include abdominal migraine, cyclic vomiting syndrome, infant colic, and benign paroxysmal vertigo of childhood. The children are healthy in between attacks, and there is typically a family history of migraine.[14,15] Childhood periodic syndromes are a risk factor for migraine later in life.

Management of pediatric migraine

Imaging

If the history is suggestive of migraine and the examination is normal, then imaging can be deferred with close follow-up.[16,17] The presence of any red flags (Box 58.3) mandates imaging.

Bio-behavioral strategies

Children suffer less from migraines if they sleep well and eat healthy food regularly. Regular exercise also helps, as does maintaining a healthy weight. Dietary triggers are less common in children but, once identified, should be avoided. Caffeine may aggravate migraines by disrupting sleep and changing mood. Behavior modification education is crucial to all migraine management, and cognitive behavioral therapy has recently been found to be effective in headache reduction.[18]

Acute therapies

Abortive medication is most effective when taken within 30 minutes of onset of the migraine. The non-steroidal anti-inflammatory medications are first-line therapy for most mild-to-moderate migraines.[19,20]

As in adults, there have been many studies showing the efficacy and safety of triptans in children with moderate-to-severe migraines. The Food and Drug Administration (FDA)-approved medications for the pediatric age group include almotriptan maleate and rizatriptan; however, sumatriptan and others are frequently used off-label.[21] Triptans should not be used for hemiplegic migraine or when hypertension or cardiac disease is present. For nausea, chlorpromazine and prochlorperazine (administered with diphenhydramine to prevent akathisia) are effective. Pediatric headache experts have adopted the American Academy of Neurology practice parameters for adult migraine treatment, which recommends against using opioids as first-line treatment, given the concern for medication-overuse headache and medication dependence.[22,23] For chronic migraine, greater occipital nerve injections, and/or a course of intravenous dihydroergotamine are treatment options.

Preventive therapies

If a child or adolescent suffers more than 15 days per month of migraine, preventive measures should be considered. A high rate of placebo effect and small open-label studies in pediatric migraine has created insufficient evidence for efficacy in preventive medications; however, amitriptyline/nortriptyline, propranolol, flunarizine (outside of the United States),[24] and topiramate are most commonly used by headache experts.[25] In children less than 10 years old and of normal weight, cyproheptadine has been used.[26] The supplement riboflavin has been tried in all ages.[27] A minimum of 6–12 weeks is necessary to assess efficacy for all preventive medications.

Etiology of migraine

Previous theories regarding migraine mechanisms that attributed a cascade of events starting with cerebral vasodilation are less favored today.[28] The more contemporary trigeminal–vascular theory suggests that migraine results from a dysfunction of brainstem nuclei involved in nociceptive and other sensory modulation of craniovascular afferents.[29,30] The pain of migraine may have its origin in inflammation of meningeal vessels and "sensitization" of peripheral and central trigeminal afferents. The main structures involved are the cerebral cortex, brainstem nuclei (median raphe, periaqueductal gray matter, locus ceruleus, superior salivatory nucleus, trigeminal nucleus caudalis), and trigeminal nerves that communicate via hormones/neuropeptides (substance P, neurokinin A, calcitonin gene-related peptide) released at these sites. A lower threshold for initial excitation or sensitization may be genetic, possibly causing hyperexcitation from otherwise common internal (i.e. hunger, sleep deprivation, stress) and external (i.e. red wine, riding in a car or boat) events. The genetic influence may cause ion channel dysfunction within the brainstem nuclei as highlighted by the known missense mutation in familial hemiplegic migraine, which leads to a dysfunctional subunit of the voltage-gated calcium channel.[31]

Migraine aura is no longer thought to be caused by vasoconstriction *per se*.[32] Rather, migraine aura is likely neurally driven and caused by cortical spreading depression – a slowly propagating wave of depolarization followed by depression of brain activity from changes in neural and vascular function.[33] There is a short phase of increased regional cerebral blood flow (hyperemia) followed by a decrease (oligemia).[34,35] Flashing and jagged lights in the visual aura may be representative of the hyperemia phase.[36] Although the aura typically precedes the headache, the mechanisms causing the aura and pain phases may even be independent and not sequential. The premonitory nausea has been found to originate from central structures of the dorsal medulla (nucleus tractus solitarius, dorsal motor nucleus of vagus, and nucleus ambiguus) and the periaqueductal gray areas on positron-emission tomography imaging.[37]

Other headache disorders

Tension-type headache (TTH)

These are different from migraine, and are featureless with lack of nausea or vomiting. TTHs are typically episodes of bilateral head pain with a pressing or tightening quality, without worsening from routine physical activity. The pain is of mild-to-moderate intensity and can be associated with photophobia or phonophobia. Teeth grinding has been associated with TTH in 50% of affected children.[38] Bio-behavioral strategies using relaxation techniques and coping skills are most effective.

Trigeminal autonomic cephalalgia (TAC)

This class of cranial autonomic disorders is rare in children. The eye findings and symptoms associated with these may bring patients to the ophthalmology clinic. The cranial autonomic signs include conjuctival injection and/or lacrimation, nasal congestion, eyelid edema, forehead and facial sweating/flushing, aural fullness, miosis, and/or ptosis. TACs all include severe unilateral orbital or supraorbital pain with cranial autonomic signs. Each disorder is defined by a different frequency, length of pain, and treatment response. Cluster headaches are groups of attacks lasting 15–180 minutes. The exquisitely indomethacin-responsive disorders include paroxysmal hemicrania (multiple clusters of daily attacks lasting 2–30 minutes) and hemicrania continua (persistent unilateral head pain persistent, >3 months). Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) attacks last 1–600 seconds, occur multiple time per day, are stab-like, and are typically unresponsive to indomethacin.

Medication-overuse headaches

It is common for children and adolescents to take multiple medications for acute pain, a process that can then lead to a chronic problem of medication overuse. This complication increases the frequency of the primary headache and reduces the effectiveness of acute and preventive medications. Overuse of opioids, ergotamines, triptans, acetaminophen, and barbiturates may even transform a migraine from episodic to chronic. There is no exact recommendation by the headache experts but, in general, these medications should be used less than 10 days per month. The non-steroidal anti-inflammatory medications can actually be protective, and these are preferred acute medications.[39]

Secondary headaches

Box 58.5 sets out the important secondary intracranial causes for headache.

Ophthalmic and dental

Headaches in children are occasionally due to eye conditions. The most common ophthalmic causes of headache include refractive error, eyestrain from convergence insufficiency, glaucoma, dry eyes, uveitis, and optic neuritis. Dental problems such as dental malocclusion, cavities, gingival infection, temporomandibular joint disease, and bruxism can also cause "head pain" in children.

Epilepsy

Headache in patients with epilepsy is common and preictal, ictal, and postictal headaches are often mistaken for migraine.

Box 58.5

Secondary intracranial causes for headache in children

- Dental conditions
- Ophthalmic conditions (infectious, inflammatory)
- Epilepsy (pre-, per- and postictal)
- Raised intracranial pressure and pseudotumor cerebri syndrome
- Brain tumors
- Infections
  - Acute viral illness
  - Meningitis
  - Encephalitis
- Structural brain abnormalities
  - Arachnoid cyst
  - Arnold–Chiari malformation
- Vascular abnormalities
  - Intracranial hemorrhage and arteriovenous malformations
  - Cerebral venous sinus thrombosis
- Acute disseminated encephalomyelitis and multiple sclerosis
- Trauma

In children and adolescents with seizures, preictal headaches have been observed in about 30% and postictal headaches in about 60%.[40] The headache is described as a moderately severe, and throbbing pain 24 hours before a seizure is typical; in general, it is more abrupt (over seconds) in onset than migraine, typically lasting minutes to hours. There can be an aura, which is rapid in onset, brief, and sometimes associated with unusual symptoms, such as a rising abdominal sensation followed by a déjà vu illusion or a visual hallucination that can be associated with nausea and fear. Postictal headaches, in particular, can mimic migraine and respond well to triptan therapy.[41]

Raised intracranial pressure and pseudotumor cerebri syndrome

Raised intracranial pressure (ICP) can cause progressive headaches that may wake a child from sleep and are made worse by exertion or a Valsalva maneuver. Associated findings are nausea, vomiting, lethargy, and personality changes. Tumors, aqueductal stenosis (Fig. 58.1), hydrocephalus, meningitis, edema from stroke, and subarachnoid hemorrhage can increase intracranial pressure, with stretching of the meninges contributing to headache.

Pseudotumor cerebri syndrome (PTCS) (see Chapter 59) refers to the primary and secondary disorders that cause symptomatic intracranial hypertension in patients with normal brain parenchyma and normal spinal fluid constituents, typically presenting with papilledema. Idiopathic intracranial hypertension (IIH) is the primary form of PTCS that occurs most commonly in obese adolescent females; however, in prepubertal children, the prevalence is similar in girls and boys, and they are more often thin.[42] Headaches are a common symptom in adolescents with PTCS, but many of the younger children with PTCS do not have headache. Generalized and focal features of head pain are described and cannot be distinguished from migraine or tension-type headache based solely on the pain characteristics.

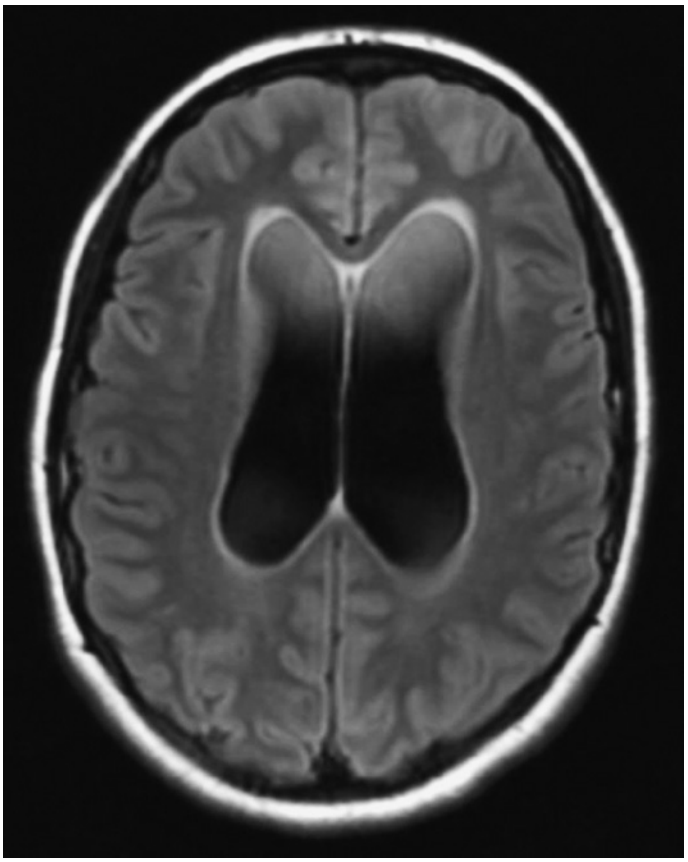

Fig. 58.1 Axial fluid-attenuation inversion recovery (FLAIR) brain magnetic resonance imaging demonstrating non-communicating hydrocephalus due to aqueductal stenosis in a thin 14-year-old girl who presented with headaches and bilateral papilledema.

Brain tumor

This is the diagnosis parents and children worry most about, so it is important to give reassurance that headaches in children are common, and brain tumors (Fig. 58.2) are rare (5.4 per 100,000 person years).[43] Headaches that awake the child from sleep, cause confusion and vomiting, localize to the occiput, are worsened by Valsalva maneuver, are accompanied by new weakness or gait changes, and/or exist in patients with no family or personal history of migraine-like symptoms are worrisome and should be further investigated.

Infections

An acute viral illness is the most common reason that a child will present with a headache to an emergency department. Serious infections such as meningitis and encephalitis account for 5–9% of children with an acute headache presenting as an emergency.[44] As opposed to adults, true "sinus" headaches in children are rare. The dull periorbital, pressure-like pain associated with nasal congestion that adults complain of, rarely gets better when "sinusitis" is treated in children. Instead this is usually an atypical form of one of the primary headaches discussed above.

Structural abnormalities

Arachnoid cysts are collections of cerebrospinal fluid contained in a sac of arachnoid membranes, and are found on imaging

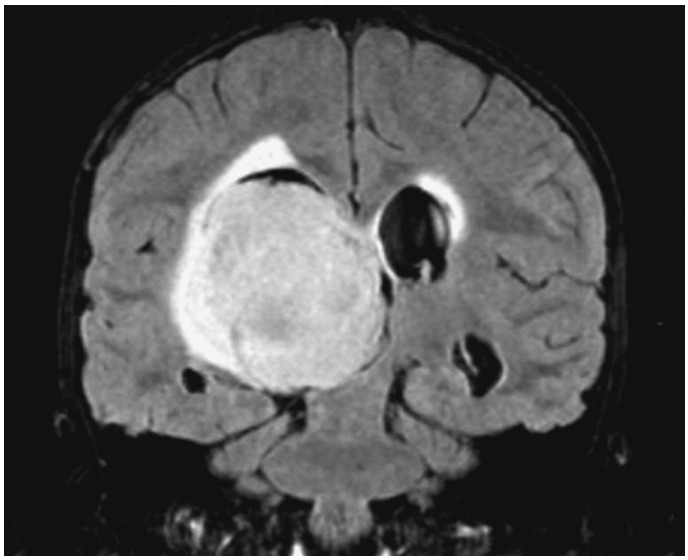

Fig. 58.2 Coronal fluid-attenuation inversion recovery (FLAIR) brain magnetic resonance imaging showing a right thalamic mass in a 9-year-old boy who presented with headache and fatigue. On exam he had a left homonymous field defect and bilateral papilledema.

in about 4% of pediatric patients.[45] They can be congenital or secondary to trauma. Arachnoid cysts are usually incidental, and studies have found 18–41% of children with arachnoid cysts to be symptomatic with headache.[46] The symptomatic cysts are typically those that rupture or hemorrhage, and surgical treatment can include fenestration or shunt insertion.

A Chiari I malformation is the herniation of cerebellar tonsils more than 5 mm below the foramen magnum. Symptoms include headaches, sensory disturbance, neck pain, vertigo and ataxia. 50% to 90% of patients with a Chiari I malformation will be symptomatic with a headache that is similar to migraine; however, there may be a higher incidence of occipital pain that worsens with Valsalva maneuvers.[47,48] Surgical decompression of the posterior fossa is often successful.

Vascular abnormalities

Pediatric hemorrhagic stroke occurs in about 1 per 100,000 children per year.[49] In one study, 77% of children with hemorrhagic stroke complained of headache (mostly sudden onset), and 91% had neurologic symptoms in addition to headache. In these children, 50% were found to have a causative arteriovenous malformation (Fig. 58.3) and 18% had an aneurysm.[50] Other vascular abnormalities include cerebral venous sinus thrombosis in which seizures, coma, and motor weakness are the most common presentations. However, headache occurs in 18% of these children.[51]

Summary

An understanding of the presentation, management, and treatment of primary headaches, as well as a careful history and thorough ophthalmic and systemic neurologic examination, can help identify the children with potentially catastrophic secondary causes. Similarly, this can prevent unnecessary investigations in children with benign headaches.

Fig. 58.3 Non-contrast axial computed tomography scan of the brain demonstrating a right temporoparietal hemorrhage secondary to a ruptured arteriovenous malformation in a 14-year-old girl with sudden-onset headache and a left homonymous hemianopsia.

Introduction

Raised intracranial pressure (RICP) and its potential for causing permanent vision loss requires close monitoring by the eye physician. Pseudotumor cerebri syndrome (PTCS, also known as idiopathic intracranial hypertension), brain tumors, structural brain abnormalities, and acquired infectious/inflammatory conditions are the most frequent causes of RICP in children seen in the ambulatory setting. Understanding the proper ophthalmologic assessment, monitoring, and treatment is essential for optimizing visual outcomes.

Signs and symptoms of raised intracranial pressure

The spectrum of symptoms and their severity can range widely in children with RICP. Children can be relatively asymptomatic when signs of RICP are discovered. The complaint of headache, especially unremitting headache that may worsen while lying flat, reach peak severity in the morning, and/or is relieved by vomiting, should produce a high suspicion of RICP. When caring for infants and toddlers, it is essential to communicate with their primary care physician to determine if there are concerns about an enlarging head circumference or change in developmental trajectory. The presence of other ophthalmologic and non-ophthalmologic symptoms such as transient visual obscurations, pulsatile tinnitus, failure to thrive, cognitive regression, lethargy, or prolonged alteration in mood/personality should prompt the clinician to perform an exhaustive exam investigating for other RICP risk factors and signs. While children with newly diagnosed brain tumors frequently present with headache, an overwhelming majority (>85%) will also demonstrate other neurologic deficits such as a cranial nerve palsy, ataxia, or weakness.

Objective ophthalmologic signs such as elevated optic nerves, vertical gaze palsy, and cranial nerve VI palsy are frequent indicators of RICP. The term "papilledema" should be reserved for elevated optic nerves due to increased intracranial pressure. The presence of additional cranial nerve palsies, bulging anterior fontanel, or/and other neurologic signs requires prompt referral to a neurologist or neurosurgeon, along with the consideration of imaging.

Ophthalmologic monitoring

The afferent vision examination is essential to evaluating a child with suspected or confirmed RICP. Visual field testing, preferably with a quantitative automated or kinetic perimeter, is essential as an enlarged blind spot will be the first sign of RICP. The visual field deficits can expand most commonly to inferonasal loss and generalized constriction. A decline in visual acuity occurs after significant visual field loss as a sign of severe optic nerve dysfunction. Indirect ophthalmoscopy is mandatory, along with photographs to assess longitudinal changes. It is important to recognize that the appearance of the optic nerve, especially in cases of moderate-to-severe swelling, may be incongruous with the functional deficit (Fig. 59.1). Therefore, functional measures of the afferent examination are the most important metric in caring for children with RICP.

Evaluation of the optic nerve sheath diameter and 30° test are two orbital ultrasonography techniques that have been utilized to differentiate between papilledema and pseudopapilledema.[1] While the combination of these two tests have a high sensitivity to detect papilledema, they have lower specificity and require an experienced user to perform and interpret the results. Studies using optical coherence tomography (OCT) to differentiate between papilledema and pseudopapilledema in cases of suspected RICP have demonstrated mixed results.[2,3] In cases of confirmed papilledema, OCT has been suggested as an objective quantitative metric to monitor changes in optic nerve elevation.[4] The use of volumetric OCT imaging in children experiencing relatively small changes in optic nerve elevation over a long time may offer an advantage over fundus photographs and indirect ophthalmoscopy (Fig. 59.2).

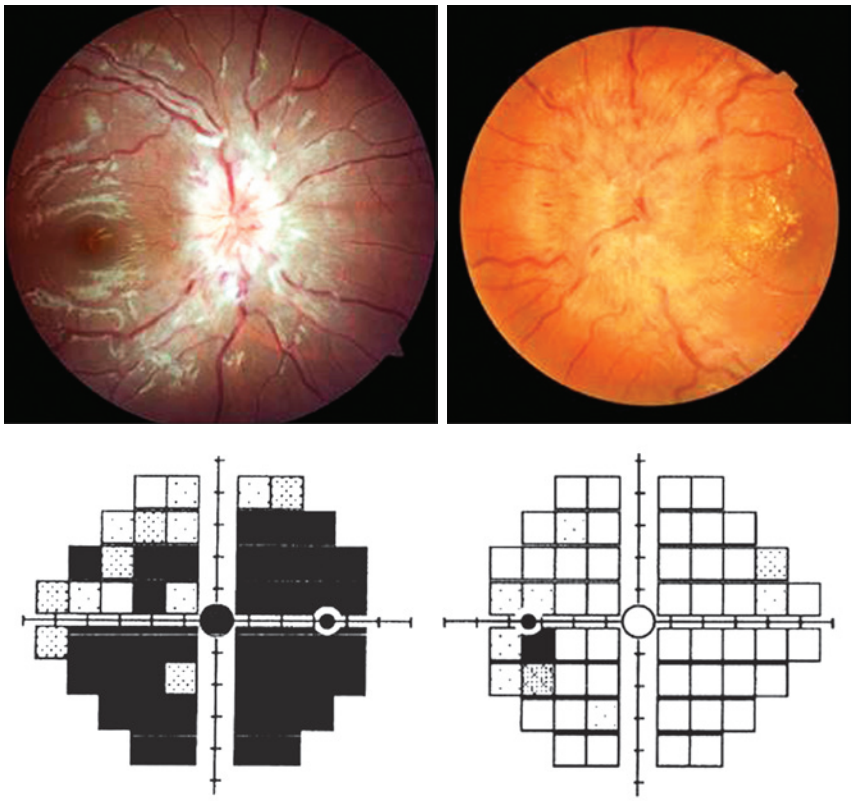

Fig. 59.1 Optic nerve swelling secondary to raised intracranial pressure. (Left panel) Marked swelling, in the setting of 20/30 acuity and severe visual field loss. (Right panel) Marked swelling, hemorrhages, and macular lipid in the setting of 20/20 acuity and very mild blind spot enlargement.

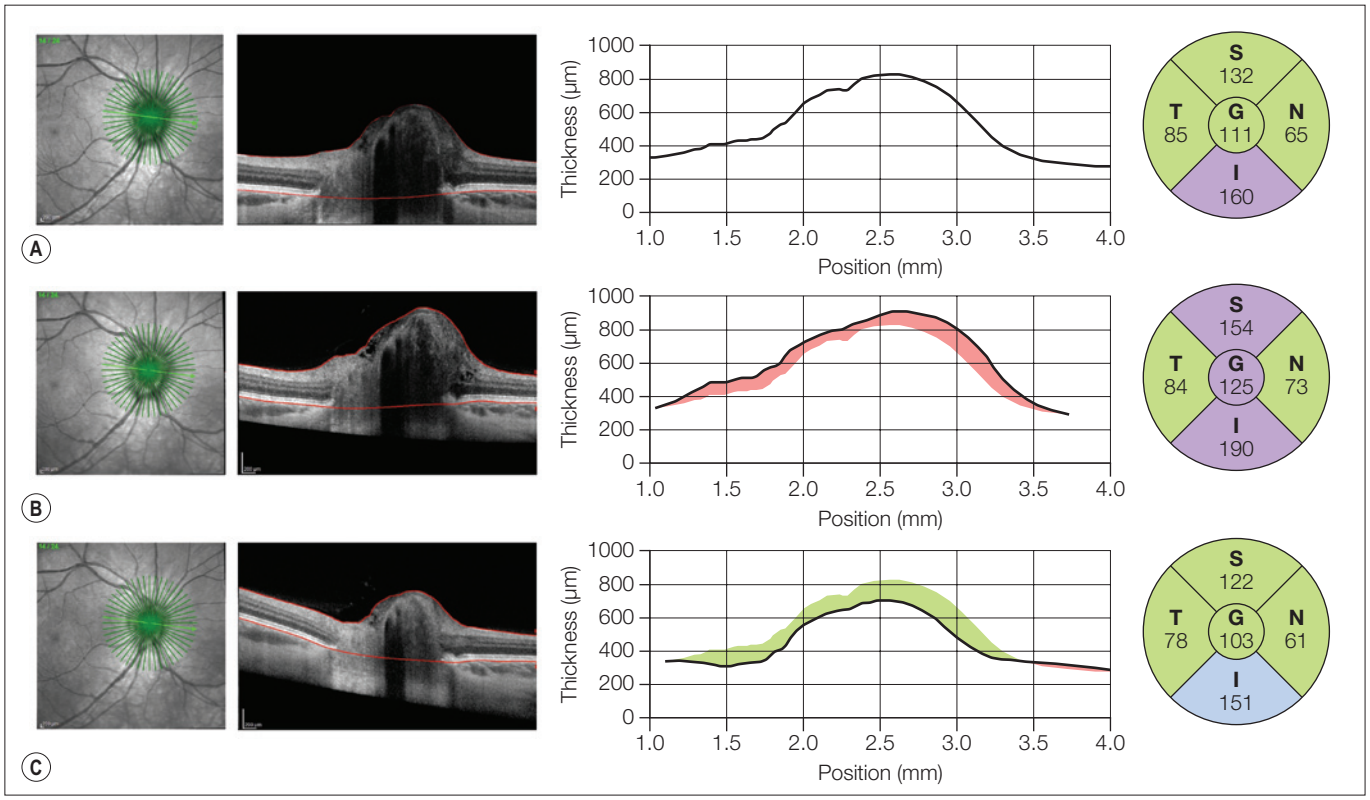

Fig. 59.2 Progressive optic nerve swelling in an asymptomatic child with stable hydrocephalus. (A) A slightly elevated optic nerve and normal retinal nerve fiber layer (RNFL) thickness for all quadrants except the inferior. (B) Visualization of the increasing optic nerve height (red height) along with progressive elevation in the superior and inferior quadrants. After placement of a ventriculoperitoneal shunt, the optic nerve swelling and RNFL thickness declined (C).

Evaluation of raised intracranial pressure

All children with an examination suggestive of RICP should undergo magnetic resonance imaging (MRI) before more invasive intracranial pressure (ICP) monitoring (i.e. lumbar puncture or intracranial monitoring). Magnetic resonance (MR)-venography and MR-angiography sequences can be added if a vascular cause is suspected. Computed tomography (CT) imaging of the brain can be used in emergent cases, although this exposure to radiation should be avoided, if possible. Numerous MRI findings have been reported to be suggestive of RICP including an empty sella turcica (Fig. 59.3), transependymal cerebrospinal fluid flow, flattening of the posterior globe, optic nerve protrusion into the globe (Fig. 59.4), distended optic nerve sheath (see Fig. 59.4), hypoplastic venous sinus, and diffusion restriction of the optic nerve. Some of these MRI features, especially occurring as an isolated finding in a child without neurologic or ophthalmologic signs or symptoms, should not be used to make a diagnosis of RICP.

The cerebrospinal fluid opening pressure measured during a lumbar puncture is the most accessible and least invasive assessment of ICP. Current research suggests an opening pressure below 28 cmH_2O should be considered normal in most children.[5] Depth of sedation and obesity do influence the opening pressure measurement, while patient age and leg position do not have a significant impact.[6] Children with papilledema have an average opening pressure around 41 cmH_2O, although rarely it can be below 30 cmH_2O.[7] An opening pressure above 28 cmH_2O should raise suspicion for RICP, but does not guarantee that the child has RICP, as this indirect measurement of ICP can be influenced by a number of patient and technical factors. Similar to MRI findings, an opening pressure above 28 cmH_2O should not be the sole metric to make the diagnosis of RICP, but instead be interpreted in the context of the clinical history and examination findings. Invasive intracranial monitoring is the most accurate and reliable method to measure ICP as it can vary widely throughout the day.

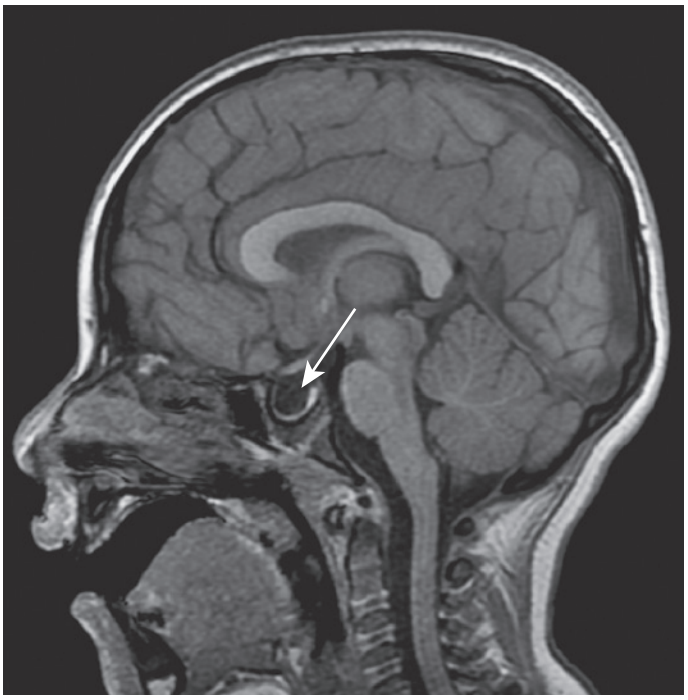

Fig. 59.3 Sagittal T1-weighted magnetic resonance image of an empty sella turcica in a child with raised intracranial pressure.

Fig. 59.4 Axial T1-weighted magnetic resonance image of distended optic nerve sheaths and mild protrusion of the optic nerve in a child with raised intracranial pressure.

Causes of raised intracranial pressure

Impairment of the normal axoplasmic flow throughout the optic nerve from RICP produces swelling of the axons – ultimately resulting in papilledema. Interestingly, not all children with RICP will demonstrate papilledema. Anatomic studies suggest that the subarachnoid space surrounding the optic nerves is a different compartment than the rest of the intracranial subarachnoid space.[8] These separate compartments may explain why not all children with RICP develop papilledema, as well as why papilledema may persist even in the setting of a functional ventriculoperitoneal shunt.

A large number of acquired, structural and congenital problems can disrupt the normal pattern of cerebroshinal fluid (CSF) production, circulation, and absorption. The management and treatment differ according to etiology.

Brain tumors

Brain tumors from any number of locations (i.e. supratentorial or infratentorial) can disrupt the normal flow of CSF, although tumors obstructing the third and fourth ventricles most commonly result in RICP. Not infrequently, tumors without significant cerebral edema and that are located in regions not expected to alter CSF circulation (e.g. frontal lobe) can result in RICP.

Treatment of RICP secondary to brain tumors can be accomplished by surgical resection, although it is not uncommon

for some tumor types to require a ventriculoperitoneal shunt. Tumors that cannot be resected may also require permanent CSF diversion. Due the frequency of ventriculoperitoneal shunt malfunction, pediatric ophthalmologists are frequently asked to evaluate children for signs of RICP. The lack of papilledema or imaging features suggestive of RICP does not exclude the possibility of shunt malfunction. In children with proven shunt malfunction and RICP, only 14% manifest papilledema.[9]

Hydrocephalus

Enlarging ventricle size is frequently due to obstruction of CSF flow from a structural cause (e.g. tumor). In the absence of a structural cause, communicating hydrocephalus is believed to be caused by abnormal reabsorption of CSF. The absence of ventricular enlargement, especially in children with prior central nervous system insults, does not eliminate the possibility of RICP. For infants and young toddlers, the ophthalmologic signs of RICP, such as papilledema, may not be present.

The treatment of hydrocephalus is typically initiated for current or anticipated functional deficits. In the absence of signs or symptoms of RICP, treatment may be deferred for some children with hydrocephalus. Ventriculoperitoneal shunts and endoscopic third ventriculostomy are the most common treatments for hydrocephalus.

Structural abnormalities

Congenital and progressive structural abnormalities can cause RICP, but typically at a lower incidence than brain tumors or other etiologies. Although frequently asymptomatic and benign, arachnoid cysts that are static in size can cause RICP.[10] The descent of the cerebellar tonsils (i.e. Chiari malformation), along with Dandy–Walker malformations and cerebral aqueductal stenosis, are other potential infratentorial structural causes of RICP. Monitoring for signs and symptoms of RICP in children with craniosynostosis and genetic craniofacial syndromes can be challenging due to the young age of presentation and frequency of anomalous optic nerves.

The treatment approach to structural causes of RICP varies depending on the etiology. Surgical correction of the craniosynostosis, bony abnormalities, and obstructive lesions frequently treats the RICP.

Vascular

Although aneurysms and large vascular anomalies (i.e. vein of Galen malformations) can disrupt CSF flow in children, they are relatively rare. The most common vascular problem causing RICP is a cerebral sinovenous thrombosis. Children with acute or chronic mastoiditis are at risk for developing unilateral thrombosis in the transverse/sigmoid venous sinus (Fig. 59.5). Dehydration, infections, head trauma, chronic medical conditions, and prothrombotic conditions are other frequent causes of cerebral sinovenous thrombosis in children. Aggressive intravenous hydration and, when indicated, anti-coagulation are the standard treatments for cerebral sinovenous thrombosis. The use of carbonic anhydrase inhibitors are typically avoided in these cases as they may cause dehydration.

Infectious and inflammatory

Numerous infectious and inflammatory conditions of the central nervous system have been reported to cause RICP, including Lyme disease and demyelinating conditions such as Guillain–Barré syndrome and Miller–Fisher syndrome. The underlying mechanism of RICP in these cases is not well understood, but most respond well to treating the specific etiology. In children with Lyme meningitis, the signs of RICP (i.e. papilledema or sixth nerve palsy) frequently improve with antibiotic treatment. Progressive and severe cases of papilledema have been reported in children being treated for Lyme meningitis; therefore, close monitoring of visual function is required, and treatment with carbonic anhydrase inhibitors should be considered until the papilledema has resolved. Papilledema secondary to demyelinating conditions may also benefit from treatment with carbonic anhydrase inhibitors.

Fig. 59.5 Reconstructed magnetic resonance venogram demonstrating a thrombus that has occluded the left transverse sinus. The thrombus developed after prolonged left-sided mastoiditis resulting in raised intracranial pressure that produced papilledema and bilateral abducen nerve palsies.

Pseudotumor cerebri syndrome/idiopathic intracranial hypertension

RICP in the setting of essentially normal brain imaging and normal CSF composition without infection or malignancy is commonly referred to as either pseudotumor cerebri syndrome (PTCS) or idiopathic intracranial hypertension (IIH). Using the recently updated diagnostic criteria, this condition is best described using the term "PTCS."[11]

PTCS is classified as primary when no medication, vascular abnormality, or medical condition is believed to be causing the RICP. Primary PTCS is typically diagnosed in patients with recent weight gain, obesity, polycystic ovary syndrome, during the peripartum period, or in non-obese children. Secondary PTCS has been attributed to numerous cerebral venous abnormalities, medications, and medical conditions. The most common causes of secondary PTCS in children are listed in Table 59.1, although many rare and weakly associated causes of secondary PTCS can be found in comprehensive reviews.[12]

Table 59.1 Common causes of secondary pseudotumor cerebri syndrome in children

Cerebral venous abnormalities	Medications	Medical conditions
Sinus venous thrombosis	Minocycline	Down syndrome
Superior vena cava syndrome	Isoretinoin	Renal failure
Jugular vein thrombosis	Growth hormone	Anemia
Abnormal CSF circulation/ absorption secondary to previous central nervous system infection or insult	Withdrawal from corticosteroids Vitamin A All-transretinoic acid	Obstructive sleep apnea

As with all cases of RICP, preservation of vision is the treatment goal for both primary and secondary PTCS. When believed to be secondary to obesity or weight gain, treatment of primary PTCS must include weight loss with a goal of 3–5% weight reduction. The addition of acetazolamide to a weight loss plan in cases with mild papilledema demonstrated a greater improvement in the perimetric mean deviation compared to those only on a weight loss plan.[13] A history of allergy to sulfa-based medications does not preclude treatment with acetazolamide.[14] Loop diuretics and medications with carbonic anhydrase activity have been used when acetazolamide cannot be tolerated.

Children may have decreased papilledema after a single lumbar puncture, even before treatment with a carbonic anhydrase inhibitor has begun. Repeated lumbar punctures should not be used as a chronic therapy for PTCS, but instead reserved for those refractory to first-line therapy who are experiencing a rapid decline in visual function and are awaiting more aggressive therapy. In cases of rapid and moderate-to-severe visual loss, high-dose intravenous corticosteroids can be considered as a potential temporizing measure, although the efficacy of this treatment has not been firmly established.

When weight loss and medical therapy fails to resolve or control progressive visual loss, CSF-diversion techniques may be indicated. Optic nerve sheath fenestration has been successfully used in children, and in some centers it is preferred over ventriculoperitoneal shunting, since it does not carry the lifelong risk of infection and obstruction. Cerebral venous stenting has been used in adults, but this treatment has rarely been used in children.

DEVELOPMENTAL DEFECTS
PERINATAL INSULTS
VISUAL RECOVERY IN BRAIN DISORDERS
REFERENCES

Numerous congenital and acquired disorders of the central nervous system affect children's vision and many directly affect vital visual structures with varying disability. Others do not, but are associated with structural eye defects. In many parts of the world, especially in more developed countries, the prevalence of visual impairment in children due to brain disorders equals or exceeds that related to purely ocular disease. Many children with visual impairment due to brain disorders are multi-handicapped and their long-term potential for successful rehabilitation, education, employment, and independent living is limited. Nevertheless, it is essential that their visual deficits and potential be carefully assessed so that appropriate medical, rehabilitation, and educational services may be provided.

Developmental defects

Embryological errors

Cephalocele (encephalocele)

During the first month of embryogenesis, a neural plate is formed which invaginates into the neural groove and then fuses into a neural tube. Cephaloceles (defects in the skull and dura mater with extracranial extension of intracranial structures) are probably the result of a disturbance in the closure of the neural groove. Fortification of staple foods with folic acid and the use of folic acid supplements by women of childbearing age have greatly reduced the incidence of this type of encephalocele in most countries. Alternatively, they may occur as a postneurulation event with brain tissue herniating through the mesenchyme that will give rise to the cranium and dura. Three of the four major types of cephaloceles are of interest to ophthalmologists.

1. *Occipital cephaloceles.* In these, portions of the occipital cortex and the occipital horn of the lateral ventricle herniate into the defect. Severe visual defects are associated both with the anomaly and the results of any surgical correction. Knobloch syndrome is characterized by high myopia, vitreoretinal degeneration with retinal detachment, macular abnormalities, and occipital encephalocele (see Chapters 42 and 52).
2. *Frontal ethmoidal cephaloceles.* These have a geographical predilection for Southeast Asia. They do not usually impinge on any visual structures, but they may be associated with ipsilateral optic nerve dysplasia.
3. *Nasal pharyngeal cephaloceles.* These are uncommon, but visual function is almost always affected. The optic nerves and chiasm may be compromised as they are stretched when they extend into the sac of the defect. Optic nerve hypoplasia and retinal dysplasia and coloboma are frequent associations.

Holoprosencephaly

During the second month of gestation, the forebrain (prosencephalon) is cleaved transversely into the telencephalon and diencephalon and sagittally into the cerebral hemispheres and lateral ventricles. Failure of differentiation and cleavage of the prosencephalon results in a group of disorders referred to as the "holoprosencephalies." The Hedgehog (Hh) signaling pathway mediates spatiotemporally specific aspects of face and brain development. Genetic and teratogenic disruptions of this pathway may produce holoprosencephaly, although mutations in other genetic pathways may also be causative. Maternal diabetes is the most commonly recognized teratogen. Holoprosencephaly can be seen in a number of syndromes including Patau syndrome (trisomy 13), Edwards syndrome (trisomy 18), and de Morsier syndrome. Facial dysmorphism (hypotelorism and midline clefts) and numerous central nervous system anomalies are frequently associated (Fig. 60.1). Surviving children may show visual responses via ectopic striate cortex. Corpus callosum dysgenesis is common, as is optic nerve hypoplasia (see Chapter 53). Indeed, a significant subset of patients with septo-optic dysplasia may have a mild form of lobar holoprosencephaly.

Malformations of cortical development

Between the second and fourth gestational months, the neurons in the ventricular and subventricular zones of the lateral ventricles proliferate and migrate to the cortical plates. This area of cell proliferation is known as the germinal

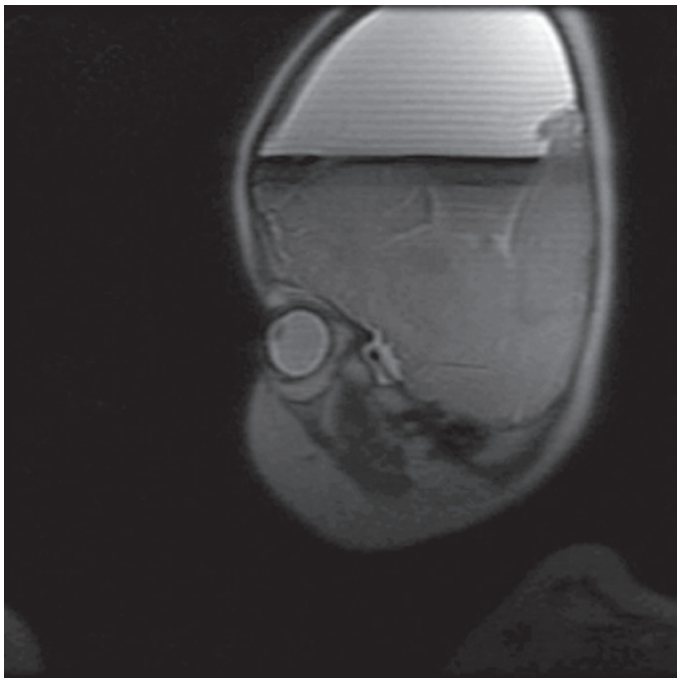

Fig. 60.1 Complex brain anomaly in a 3-year-old girl born at 35 weeks gestational age. She has global developmental delays, intractable seizures, quadraparesis, severe visual impairment, nystagmus, and optic nerve hypoplasia. matrix; here, stem cells give rise to the neurons and glial cells that will form the mature brain. Neurons in early embryogenesis migrate relatively short distances; neurons later in development migrate long distances across the intermediate zones. Neurons arriving first in the cortical mantle assume the deepest locations, while later-arriving neurons assume a more superficial location. Migration is facilitated by radial glial cells acting as guidelines. After arriving in the cortex, neurons form discrete lamina and begin to establish synaptic connection with local and distant neurons. Aberrations in this normal migration and development process result in important neural abnormalities.[1] In general, the resulting malformations can be divided into three categories – those due to:

1. abnormal neuronal and glial proliferation, or apoptosis;
2. abnormal neuronal migration;
3. abnormal cortical organization.

Lissencephaly (smooth brain) is characterized by a paucity of normal gyri and sulci. There are two types: classical and cobblestone. Classical lissencephaly is caused by an arrest of neuronal migration; cobblestone results from over-migration. Over 90% of children with lissencephaly have seizures. Cobblestone lissencephaly occurs in at least three muscular dystrophy syndromes with important ocular features. Mutations in the fukutin-related protein gene account for these three disorders (as well as a broad spectrum of other muscular dystrophies):

- Fukuyama-type congenital muscular dystrophy: affected children develop high myopia and a retinal degeneration (Fig. 60.2A,B);
- the muscle–brain–eye syndrome: this is associated with myopia and early-onset glaucoma and cataracts;

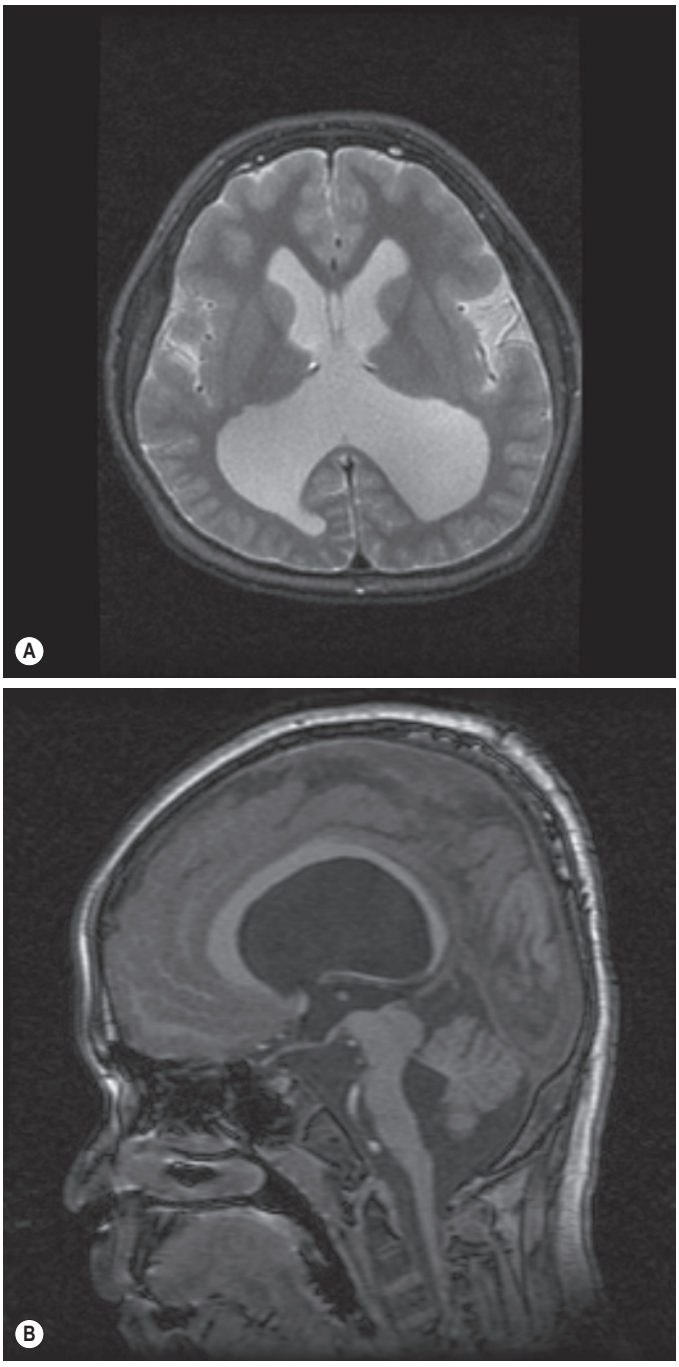

Fig. 60.2 A 10-year-old Vietnamese girl with severe developmental delays and hypotonia presents with bilateral cataracts, glaucoma, retinal detachments, and vitreous hemorrhages. (A) Axial magnetic resonance imaging (MRI) reveals dilated ventricles and pachygyria of the frontal cortex. (B) Sagittal MRI reveals pachygyria and polymicrogyria of frontal cortex, partial agenesis of the septum pellucidum, and hypoplasia of the brainstem. A diagnosis of Fukuyama disease was made. *(Courtesy of Dr. Alejandra de Alba Campomanes.)*

- the Walker–Warburg syndrome (also known as Chemke or HARD syndrome): this comprises microphthalmos, glaucoma, optic nerve anomalies, and retinal dysplasia and non-attachment.

Pachygyria is related to lissencephaly, but occurs at a later stage resulting in reduced numbers of gyri that are thick and underpopulated with neurons (Fig. 60.3). Pachygyria of the

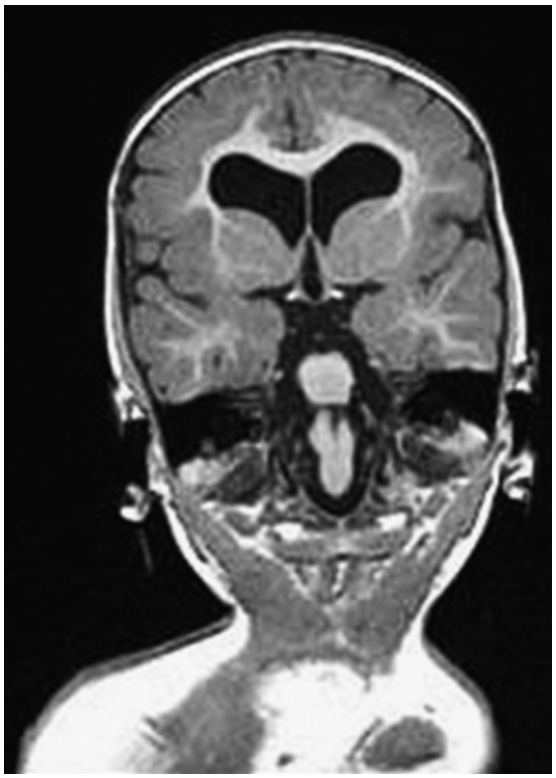

Fig. 60.3 Axial magnetic resonance imaging demonstrating diffuse bilateral pachygyria.

occipital cortex may be associated with congenital hemianopia (see below). Pachygyria of the perirolandic and occipital areas is a prominent feature of Zellweger syndrome. Pachygyria and ocular colobomas are prominent features of Baraitser–Winter syndrome.

Polymicrogyria is the most common malformation of cortical development. It occurs as the result of the interruption of the late stages of neuron migration during the stages of cortical organization. The neurons reach the cortical mantle, but the deep layers are distributed, which results in disorganized, multiple, and small gyri. A disturbance in the formation of the leptomeninges is also an important contributor to this cortical malformation.[2] Its effect on neurological function is less severe than the proliferation and migration anomalies. It may occur as an isolated focal anomaly of little consequence. The most common forms are bilateral perisylvian or frontoparietal. However, it may also occur as a diffuse disorder affecting the entire brain. As an isolated and focal disorder it has been associated with congenital hemianopia (occipital cortex) and dyslexia (left frontal and temporal cortex). It is an important feature of several genetic syndromes including Aicardi syndrome, Joubert syndrome, Zellweger spectrum, Sturge–Weber syndrome, X-linked hydrocephalus, and 22q11.2 deletion syndrome. It is also associated with numerous metabolic disorders and infections, especially cytomegalovirus.

Schizencephaly (agenetic porencephaly) is characterized by full-thickness clefts spanning the wall of the cerebral hemispheres that are lined by gray matter and often surrounded by polymicrogyric cortex. The pathogenesis is incompletely understood although it is thought to represent an *in utero* injury to the germinal matrix during the second trimester before the hemispheres form. The causes of schizencephaly are heterogeneous; they include teratogens, prenatal infections, young maternal age, alcohol use, and *EMX2* mutations.[3] The clefts may be unilateral or bilateral; the lips of the clefts may be open or closed. Seizures, hemiplegia, and mental retardation are the most common symptoms. Involvement of the occipital cortex is unusual but, when it occurs, especially when the cleft's lips are fused, a homonymous hemianopia may occur. In contrast, patients with bilateral clefts are more likely to be severely retarded, severely limited by motor problems and blindness. The blindness is not usually cortical in origin, but due to optic nerve hypoplasia, a frequent accompanying anomaly in all forms of schizencephaly.

Congenital hemianopia

Children with congenital hemianopia show little evidence of visual dysfunction; the visual field defect is often discovered later in life on a routine eye examination. There may be a history of bicycle or auto accidents, but many patients are largely unaffected.

Although the history may not raise suspicions of congenital hemianopia, certain associated ophthalmologic and systemic findings should suggest this diagnosis. Most children with a congenital hemianopia or one acquired early in life, turn their face toward the defective field when fixing on a target straight ahead of them (see Chapter 102).[4] It is not clear how this compensates for the field defect, although the intact field is "centered" on the body by this maneuver. However, a persistent face turn in a child without incomitant strabismus or nystagmus (the common ocular causes of such a turn) should prompt an evaluation of the visual fields. In some cases, the face turn is accompanied by a constant, non-alternating exotropia[5]; the exotropic eye is ipsilateral to the field defect (see Chapter 80). Theoretically, a large-angle exotropia might significantly expand the binocular visual field with the appropriate sensory adaptation (harmonious anomalous retinal correspondence); strabismus with normal retinal correspondence will not be compensatory for a hemianopic visual field defect and may present with diplopia/visual confusion.[5]

In addition to the visual field defect, face turn, and possible exodeviation, the most prominent ophthalmological finding in these children is localized changes in the optic disc and nerve fiber layer – "homonymous hemioptic atrophy" (hypoplasia). There is loss of retinal nerve fibers in the retinal sectors nasal and temporal to the disc in the eye contralateral to the field defect; in the ipsilateral eye, the loss is superior and inferior. This subtle pattern of nerve fiber loss can be seen ophthalmoscopically or with optical coherence tomography (OCT).[6] Examination of the optic discs will reveal a band-shaped atrophy of the contralateral disc and temporal atrophy of the ipsilateral disc. Since the lesions causing congenital hemianopia are almost always posterior to the lateral geniculate body, this points to trans-synaptic degeneration of the retinogeniculate striate pathways. This had been thought to only occur with prenatal or perinatal insults, but recent experiments in non-human primates and OCT and neuroimaging studies (of the optic tract) in patients with acquired hemianopias suggest that this is not the case.[7]

Isolated congenital hemianopias are typically caused by developmental anomalies of the occipital cortex.[8] These include:

- occipital lobe dysplasia: abnormality of neuronal/glial proliferation;

- occipital lobe pachygyria: abnormality of neuronal migration;
- occipital lobe polymicrogyria: abnormality of cortical organization;
- porencephaly with or without polymicrogyria;
- gangliogliomas: neoplastic abnormality of neuronal/glial proliferation;
- cerebral hemiatrophy;
- vascular malformations.

The more extensive the cortical anomaly, the more likely it is that there will be other neurological disorders including hemiplegia, seizures, and developmental delays. The majority of patients with congenital hemiplegias will have an accompanying hemianopia. Hemianopia accompanies congenital occipital cortex lesions in several syndromes including Sturge–Weber and retinocephalic vascular malformation (Wyburn–Mason) syndromes, as well as familial porencephaly.

Asymmetric injury to the periventricular ventricular white matter (periventricular leukomalacia [PVL]) can present as an isolated congenital hemianopia or, more commonly, with hemiparesis. The vast majority of cases of PVL present with bilateral involvement (see below). Rarely, congenital hemianopia associated with absence of the optic tract has been reported. It is uncertain whether these cases occurred as the result of an isolated injury to the optic tract or, more likely, injury to the visual cortex or radiations with severe trans-synaptic degeneration.[7]

Patients with congenital hemianopia are less visually disabled than those with acquired hemianopia. Our understanding of their adaptations and compensations accounting for their minimal disability is incomplete. The possibility that a face turn and/or exotropia could be compensatory has been cited above. A unique saccadic strategy limited to patients with congenital hemianopia allows them to search the blind field. This is distinctly more efficient than the multiple hypometric saccades made by the patient with an acquired hemianopia, but it can occur in congenital lesions. Moreover, in children with acquired hemianopias, the reaction time to initiate a saccade to explore the blind field is prolonged; this is not the case in congenital hemianopia.[9] Some have suggested that the extra-geniculostriate pathways may be playing a compensatory role; others have theorized that re-wiring of the uninjured brain allows it to assume the functions of the injured portion. Mechanisms facilitating visual recovery in children with brain injuries will be discussed in a later section.

Patients with isolated congenital hemianopias, in contrast to those with similar acquired defects, require very little in the way of special ophthalmologic care except to communicate with schools, employers, and government agencies (especially the driving authorities) to reassure them that many of these children are little affected by their visual field defect. If the child has a constant, non-alternating exotropia, strabismus surgery is probably contraindicated.[5]

Acquired hemianopia

Children with acquired hemianopia present in a similar fashion to adults with comparable acquired lesions. The visual acuity is usually normal, but the field defect is easily detected and the disability associated with it declared in the history. Trauma and tumor are the most important causes of acquired hemianopia in children. In contrast to congenital hemianopia, where the lesion is usually cortical, the most common site of injury is the optic radiations. A significant number of children with acquired hemianopias show some spontaneous improvement in the visual field.[10]

Perinatal insults

There are many causes of perinatal brain injury but the vast majority of them are metabolic. They may occur as the result of inherited defects in metabolic pathways, hypoglycemia, or from transient ischemia–reperfusion events. The latter account for most of the visual disability related to brain disorders in infancy. Hypoxic–ischemic brain injury in the newborn results from a simple imbalance between the brain's demand for energy and its supply during the perinatal period. In contrast, the cellular mechanisms accompanying neuronal death are complex, multifactorial, and incompletely defined.[11] The pattern of brain injury and the nature of the resulting visual deficits are determined largely by the age of the infant at the time of the insult, as well as the duration and severity of the hypoperfusion event.

The premature infant

Several types of brain injury may occur in premature infants due to a mild-to-moderate episode of hypoxia and hypoperfusion. These include PVL, periventricular hemorrhagic infarct, germinal matrix hemorrhage, intraventricular hemorrhage, and cerebellar infarction. PVL is the predominant form of brain injury and the leading cause of cerebral palsy and cognitive defects in premature infants.

Periventricular leukomalacia

Advances in neonatology have improved the long-term survival of premature infants and simultaneously reduced the overall incidence and severity of white matter injury in surviving preterm infants, especially those with a birth weight of more than 1500 g. Nevertheless, PVL remains the major brain pathology in preterm infants. It has significant visual consequences and is a major cause of visual disability in many parts of the world.

The pathogenesis of PVL is complex, but most likely involves ischemia–reperfusion in a critically ill premature infant with impaired regulation of cerebral blood flow. The lack of auto-regulation of cerebral blood flow in premature neonates and the high incidence of lung immaturity contribute to the hypoxic perfusion difficulties. In light of these pathogenetic events, the frequent co-existence of PVL and retinopathy of prematurity (see Chapter 44) should not be surprising. The association of maternal infection with PVL suggests that inflammatory mechanisms play an important secondary role in this type of brain injury. The primary cells vulnerable to hypoxic–ischemic injury in the immature brain are the premyelinating oligodendrocytes, oligodendrocyte progenitor cells, and subplate neurons. The resulting myelination disturbances are primarily the result of aberrant regeneration and repair responses of the oligodendrocyte progenitors.[12] Subplate neurons only appear transiently during brain development, but they are essential to the formation of the connections between the thalamus and visual cortex. As a result, the pathology of PVL consists of periventricular necrosis and diffuse gliosis in the cerebral white

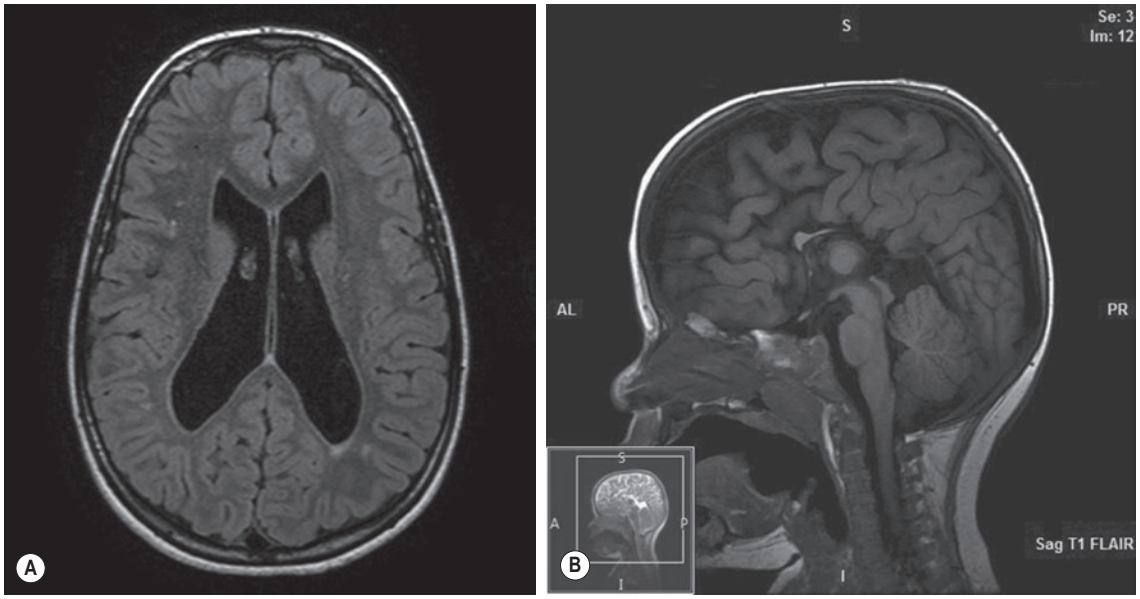

Fig. 60.4 (A) Periventricular leukomalacia in a 9-year-old child born at 25 weeks gestational age. Axial magnetic resonance imaging (MRI) reveals multiple small foci of high fluid-attenuated inversion recovery (FLAIR) signal seen in the periventricular and subcortical white matter representing ischemic changes or gliosis. The ventricles are markedly enlarged with adjacent white matter loss. (B) Sagittal MRI of a different child born at 26 weeks gestational age with periventricular leukomalacia and severe posterior corpus callosum atrophy. *([A] Courtesy of Dr Stacy Pineles. [B] Courtesy of Dr Michael Brodsky.)*

matter and neuronal loss in the thalamus, corpus callosum, and globus pallidus.[13] In long-term survivors with PVL, neuroimaging studies may show reduced cerebral white matter volume, impaired myelination, ventriculomegaly, and reduced volume in the corpus callosum (especially the posterior portion) and thalamus (Fig. 60.4A,B). Although PVL is primarily a disorder of ill, preterm babies, it does occur in near-term infants. With improved neonatal care, the pattern of white matter injury in preterm infants is evolving from cystic necrotic lesions to milder forms.[14]

The motor and visual pathways course through the periventricular white matter that is affected. As a result, motor (commonly "spastic diplegia") and visual impairment are the most common neurologic findings in PVL. The motor fibers serving the lower extremities pass more medially than those of the upper extremity and thus are more likely to be injured by the periventricular injury. The consequences for the motor system may range from a mild spastic diplegia to a severe quadraparesis. Other neurologic symptoms may include athetosis, seizures, cognitive and attention disorders.

Visual impairment is equally variable in its severity, ranging from near-blindness to minor field defects. In many patients, a selective lesion in the superior posterior periventricular white matter is correlated with inferior field loss; in other cases with more extensive damage to the optic radiations, a generalized depression of the visual field results.[15] A normal-sized optic nerve with an enlarged optic cup ("pseudoglaucomatous") is seen in many patients. It is probable that this anomalous optic nerve is not an independent contributing factor to the visual disability, but simply a "marker" for optic radiation damage. This implies that trans-synaptic degeneration has occurred, similar to the case of congenital hemianopia described above. However, the importance of recognizing that a large optic cup in a premature infant is far more likely to indicate PVL than glaucoma cannot be overemphasized. Infantile nystagmus, manifest-latent, or latent nystagmus may occur in children with PVL; most of the children with nystagmus will also have strabismus. As in all cases of cerebral palsy, reduced accommodative facility may occur in PVL. It should be specifically sought and, if found, corrected with glasses.

The long-term visual disability of children with PVL is frequently underestimated by analyzing only the visual field deficits. Visual-perceptual impairment related to PVL may go unrecognized. Dorsal stream (linked to the posterior parietal cortex) dysfunction occurs in PVL and results in a specific pattern of disability.[16] It consists of a deficit in eye–hand coordination, constructional dyspraxia, and impairment of motion perception. Less well studied, but perhaps more important, is the question concerning the visual consequences of the thalamic damage resulting from the injury to the subplate neurons. Injury to two specific subnuclei of the thalamus is found in many children with PVL. The mediodorsal nucleus through its reciprocal connections with the prefrontal lobe plays an essential role in working memory. The mediodorsal nucleus in consort with several cortical centers is vital for attention mechanisms, especially visual attention. Further studies are needed to understand the full range of visual disabilities in PVL.

There is no known treatment for PVL. The role of the ophthalmologist is to assess the visual deficits as fully as possible and counsel the child's parents, other physicians, rehabilitation specialists, and teachers about them. Refractive errors and poor accommodation, if present, should be corrected, even in severely handicapped children. Strabismus surgery may be indicated if the child's general health would not be compromised by an anesthetic and strabismus is not compensatory for a visual field defect.

Many trials are underway to see whether PVL can be prevented or lessened in its severity. Premyelinating oligodendroglia are highly vulnerable to death caused by glutamate, free radicals, and pro-inflammatory cytokines. Pharmacological agents such as memantine that block ischemia-induced glutamate

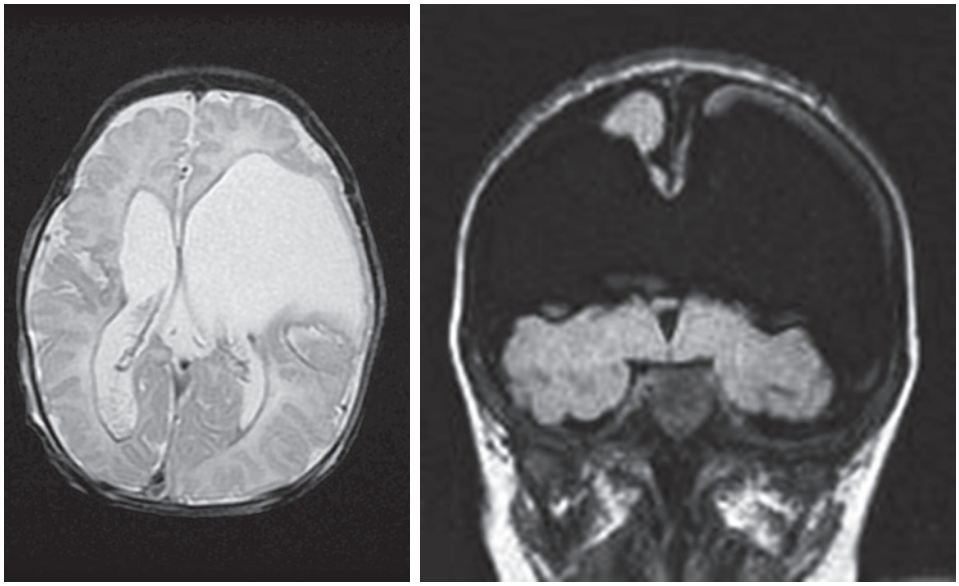

Fig. 60.5 (A) Bilateral hemorrhagic porencephaly seen on magnetic resonance imaging (MRI) in a term infant. The patient has bilateral horizontal gaze palsies and quadraparesis. (B) MRI of an infant with extensive bilateral porencephalic cyst due to perinatal cerebral hemorrhage. This was associated with a *COL4A1* mutation. *(Courtesy of Dr Michael Brodsky.)*

signal transduction may be useful in diminishing the severity of PVL. Other strategies under study include treatment with UDP-glucose and/or glial cell line-derived neurotropic factor (GDNF) that may promote endogenous self-repair by stimulating proliferation of glial cells.[17]

Periventricular and intraventricular hemorrhage

Despite advances in neonatal care, intraventricular hemorrhage remains a major complication of prematurity. It characteristically originates from the periventricular germinal matrix, a highly vascular site where glial and neuronal precursor cells are located at the head of the caudate nucleus beneath the ventricular ependyma. The vessels within the germinal matrix have very thin walls and are especially sensitive to changes in blood flow and pressure. Most intraventricular hemorrhages are an extension of a germinal matrix hemorrhage, which usually occurs within the first 48 hours after birth.[18] Periventricular and intraventricular hemorrhages in premature babies have been divided into four grades:

- grade I: germinal matrix hemorrhage with little or no intraventricular hemorrhage;
- grade II: germinal matrix hemorrhage with extension into the ventricle, but normal ventricle size;
- grade III: intraventricular hemorrhage with ventricular enlargement;
- grade IV: periventricular hemorrhagic infarction.

Grade I and II hemorrhages have a good prognosis for survival and good neurological outcome. Grade III and IV hemorrhages have a significant risk of early death or significant neurological sequelae in the survivors. The neurological complications with important visual consequences include post-hemorrhagic hydrocephalus (see Chapter 55) and infarction, and porencephalic cyst formation in the areas of the occipital-parietal cortex. Significant visual loss may occur even in vigorously treated hydrocephalic neonates as a result of direct damage to the visual cortex and secondary optic atrophy (see Chapter 59).[19] Periventricular hemorrhagic infarctions are associated with significant brain damage and more than 50% of the neonates affected have serious neurological sequelae. In many of these neonates, porencephalic cysts will develop in the area of infarction.

Porencephalic cysts are focal cavities within the cortex that have smooth walls and minimal surrounding glial reaction (Fig. 60.5A). They are the result of focal brain destruction from any cause prior to the 26th week of gestation, after which the potential for glial reactivity is minimal. A familial form of porencephaly (inherited as an autosomal dominant disorder) is associated with mutations in the *COL4A1* gene (Fig. 60.5B). Porencephalic cysts associated with periventricular hemorrhagic infarction commonly involve the optic radiations and occipital cortex and result in homonymous hemianopia and homonymous hemioptic atrophy (hypoplasia) (see above).

The term infant

Neonatal encephalopathy

Neonatal encephalopathy is a serious medical problem; it occurs relatively commonly (1 in 1000 live term births in the United States) with serious neurodevelopmental consequences. The terms "neonatal encephalopathy," "hypoxic–ischemic encephalopathy," and "birth asphyxia" are often used interchangeably. This is unfortunate. Although hypoxia and ischemia are a major factor in most cases of neonatal encephalopathy, intrauterine inflammation increasingly is recognized as a critical contributor to both normal development and injury outcome. Inflammation appears to modulate vulnerability to, and development of, brain injury.[20] Moreover, antepartum risk factors (maternal hypotension, infertility treatment, and thyroid disease) have been identified. However, even if antepartum risk factors are present, prospective magnetic resonance imaging (MRI) studies suggest that at least 80% of term infants who develop neonatal encephalopathy sustain a causative acute brain injury in the perinatal period.

The regions of the brain susceptible to injury due to hypoxia and ischemia change depending on the gestational age of the

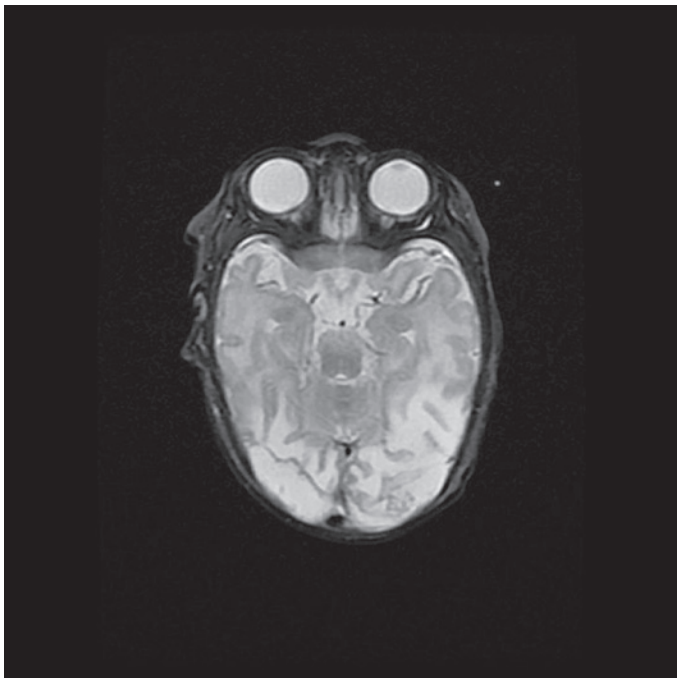

Fig. 60.6 A T2-weighted magnetic resonance imaging scan of a term infant with severe hypoxic–ischemic encephalopathy primarily involving the visual cortex.

infant at the time of injury. Unlike immature oligodendrocytes and oligodendrocyte progenitor cells, mature oligodendrocytes are resistant to hypoxic–ischemic damage. Thus, isolated deep white matter injury is not the primary feature of neonatal encephalopathy in the term infant. Instead, the main site of damage in the term infant is in the cerebral cortex intervascular boundary zones ("watershed areas"). These are the areas between the anterior and middle cerebral arteries and those between the middle and posterior cerebral arteries. The deep gray nuclei and perirolandic cortex are most likely to be damaged. As a result, the most common consequence of mild-to-moderate hypotensive events in the term infant is discrete infarctions in the frontal and parieto-occipital regions of the brain. Watershed cortical damage is the primary site of pathology but, in extensive infarcts, the underlying white matter may be affected. MRI studies may reveal (Fig. 60.6):

1. wedge-shaped infarctions in the watershed zones;
2. cortical thinning and diminution of the underlying white matter in the area of infarction;
3. *ex vacuo* dilation of the lateral ventricles;
4. the development of ulegyria (narrow and distorted gyri, a secondary gyrial anomaly) resulting from the cortical shrinkage.

A different pattern of injury is seen in neonates who suffer profound hypotension or cardio-circulatory arrest. They show injury primarily in the lateral thalami, posterior putamen, hippocampi, and corticospinal pathways, regions of the brain most active metabolically and with the highest degree of synaptic construction at birth. Some of the children develop damage in the lateral geniculate nucleus and optic radiations. Many of these infants die in infancy, but if they survive they will manifest a severe seizure disorder, quadriparesis, mental retardation, microcephaly, and blindness.

It is difficult to predict during the neonatal period which infants with signs of encephalopathy will suffer permanent neurological disability, although the use of amplitude-integrated electroencephalography and diffusion-weighted MRI appear to be promising.[21] Thirty percent of neonates with moderate encephalopathy have clinically normal outcomes. The most common neurological sequelae of neonatal encephalopathy are motor impairment, developmental delays, mental retardation, seizures, and visual impairment. The motor impairment is often a mixture of spasticity, ataxia, weakness, and athetosis. Neonatal seizures occur in the majority of infants with neonatal encephalopathy. Although they are difficult to treat and a poor prognostic sign, they are a persistent problem in only a minority. Cognitive disability occurs infrequently in moderate encephalopathy, but is a common feature in children with severe encephalopathy. Neuropsychological testing identifies memory and attention/executive disabilities as the most common cognitive consequences of neonatal injury.

Infarction of the occipital cortex may result in a wide range of visual disability depending on the location and size of the infarct. The degree of visual impairment may range from "apparent blindness" to barely detectable isolated visual field defects. The majority of these children have detectable residual vision. However, they all have variable and inconsistent visual performance. They function better when well rested and in familiar surroundings. Color perception is frequently superior to perception of form. Detection of motion may be the only consistently documented visual function. The ability to recognize a human face is frequently impaired; this is especially distressing to parents. When reaching for objects, they frequently turn their face away from the object to apparently use their peripheral vision. They may be able to read isolated letters of varying sizes on an acuity test, but unable to read whole words of a similar size.

Examination of the anterior visual pathways is usually normal. Although there is OCT evidence that trans-synaptic degeneration of the geniculostriate pathways does occur with postnatal injuries to the occipital cortex,[6,7] only in a minority of cases of neonatal encephalopathy is mild optic atrophy seen on ophthalmoscopy.[22] Optic atrophy is not a major determinant of visual disability in most cases where it is found. The pupil responses are normal. In contrast to PVL, nystagmus rarely occurs. In a minority of cases, exotropia may occur, but large angle esotropias are rarely seen. Supranuclear ocular motor abnormalities that may occur in children with neonatal encephalopathy include horizontal conjugate gaze deviations, horizontal gaze palsies, and difficulties in ocular pursuit movements. These may contribute to the child's visual disability. Accommodation should be specifically evaluated and, if found to be abnormal, treated with spectacles.

The diagnosis of neonatal encephalopathy with visual loss can usually be established on the basis of the history and other neurologic findings. Neuroimaging studies can be helpful in subtle cases with subtle vision loss and minimal neurologic abnormalities (Fig. 60.7A,B). They are also useful to document the anatomic site(s) and extent of brain damage, but they correlate poorly with functional disability. Magnetic resonance spectroscopy, diffusion-weighted imaging, and diffusion tensor imaging are advanced MRI techniques that go beyond documenting the lesion and its location (Fig. 60.8). They provide useful information on brain metabolism, microstructure, and connectivity, and so may provide quantitative biomarkers

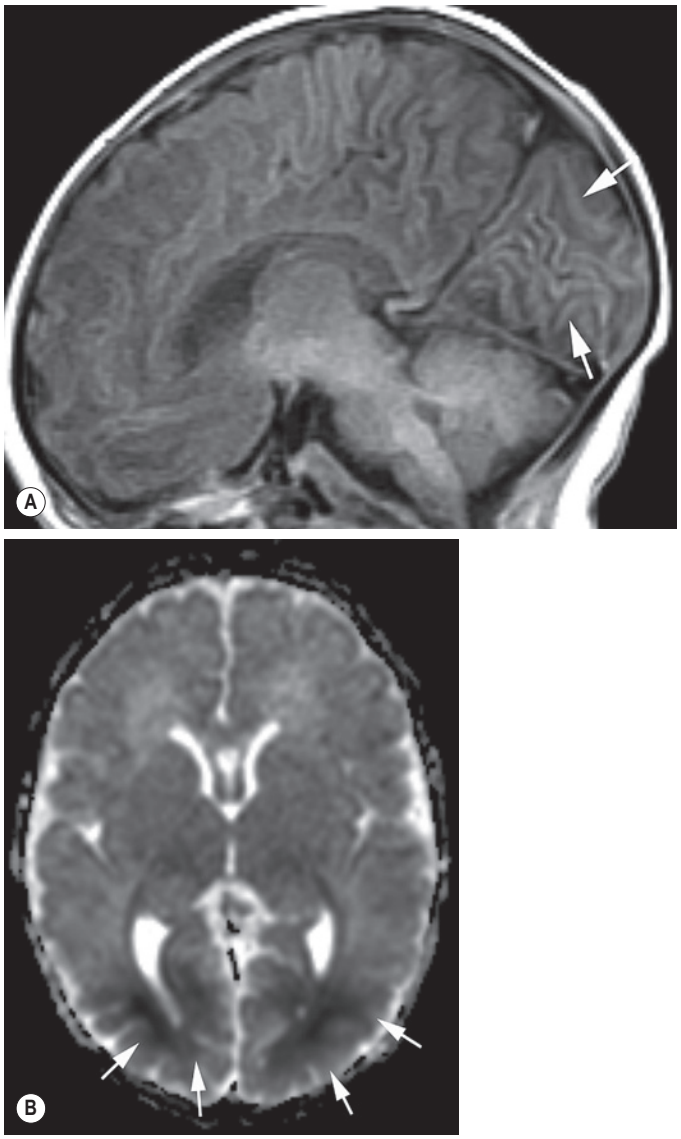

Fig. 60.7 An 8-day-old infant with seizures and profound hypoglycemia. (A) The sagittal T1-weighted image shows abnormal high signal intensity of the occipital cortex. (B) The axial diffusivity map (ADC map) shows markedly reduced diffusion in both occipital lobes (arrows on figures). The child has cortical visual impairment. *(Courtesy of Dr Jim Barkovich.)*

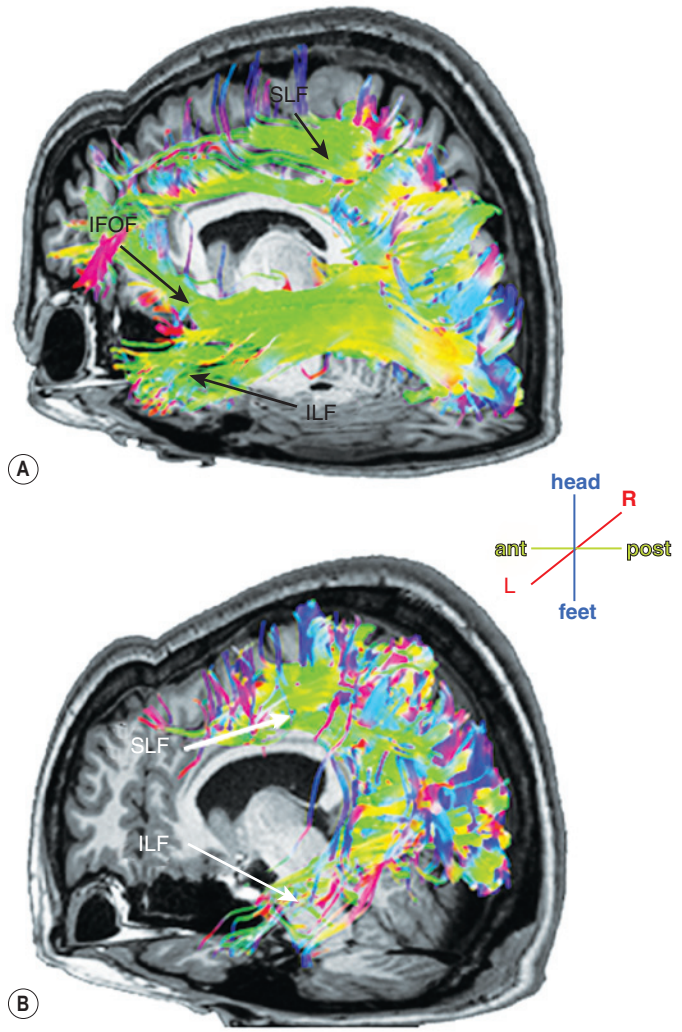

Fig. 60.8 High angular resolution diffusion-weighted imaging (HARDI) of a patient with cortical visual impairment.

for prognostication.[23] Pattern visual evoked potential (VEP) studies can be helpful in diagnosing visual cortex damage, but they are imprecise when quantitatively evaluating visual function in these children. Sweep and step VEPs may be more reliable in quantitative assessments. Vernier acuity VEPs may prove to be the most sensitive electrophysiological technique for quantitative assessment of these injuries.[24]

In caring for the child with neonatal encephalopathy and visual disability, the ophthalmologist's role is two-fold:

1. Periodic assessment of the visual disability and residual visual function.
2. Treatment of any co-existing eye disorder.

Clinical assessment of these children is difficult and time consuming, but vital as a part of the habilitation and education programs for them. Behavioral assessment techniques have been developed to assist ophthalmologists in counseling those caring for these children. The vast majority of affected children show some improvement over time, so re-evaluation is essential. There are no reliable predictors of long-term visual outcome for any specific child. Parents, educators, and other therapists should be encouraged to keep an open mind about the ultimate visual outcome, especially in early infancy when often little or no purposeful visual function can be appreciated. Intensive visual stimulation programs appear to enhance the visual recovery in these children.[25]

Until recently, no treatment was available for the brain damage that occurs in neonatal encephalopathy. However, techniques for neuroprotection of neonates have been developed. External cooling of the head or whole body in the first 6 hours after a hypoxic–ischemic insult is the only treatment currently in clinical use, and only in term infants. Cerebral hypothermia reduces the risk of death and severity of subsequent neurologic disability.[26] There is some evidence that lowering brain temperatures to lower levels than those currently recommended might provide better neuroprotection but the safety of doing so has not been established.[27] Several neuroprotective agents are being evaluated and have shown promise in preclinical and clinical trials. These

include erythropoietin, topiramate, xenon, melatonin, and allopurinol.[11]

Older children

When hypoxia, ischemia, or circulatory arrest occurs in older children, the pattern of brain injury differs from that of neonates. The physiological and biochemical differences that account for this are not yet defined. The differences are relatively minor in injuries from mild-to-moderate hypotension, although the older child is less likely to develop deep white matter injury. With profound hypotension, the older child will show basal ganglia involvement (with sparing of the thalamus) and severe diffuse cortical involvement. The relatively modest injuries suffered by many children as the result of near-drowning events probably are due to the protective effect of hypothermia and the mammalian diving reflex. The mammalian diving reflex is a physiological response to immersion in cold water that shifts blood from the extremities to the central organs. It is especially robust in children less than 6 months old.

Visual recovery in brain disorders

There is considerable evidence to suggest that the capacity of the child's visual system to recover from cerebral injury exceeds that of the adult.[25,28,29] There are several reasons that might explain this superior capacity. First, the child may develop strategies to utilize the remaining visual function. Examples of this include the large single saccade and preserved visual search capacity in cases of congenital hemianopia.[9] A second factor may be that the young brain is endowed with greater endogenous neuroprotection and repair and regeneration capacities than the adult brain.[30] A third possibility is that the child can expand the visual functions normally subserved in uninjured cortical areas outside the primary visual cortex. This has been well documented in experimental animals.[22] This might account for why motion detection (Riddoch phenomenon) is preferentially preserved in so many children with neonatal encephalopathy. There is evidence that the retina–pulvinar–MT cortex pathway that usually regresses during normal development is preserved in children who suffer post-geniculate visual injuries early in life and could, therefore, contribute to visual preservation.[31] Fourth, it is now apparent that the extent of neurological deficit after a focal brain injury cannot be accounted for by the dysfunction attributable just to it. Rather, it is determined by the functional impairment of the connected neural systems that are structurally intact.[32] Diaschisis (inhibition of function in distant portions of the brain anatomically connected to injured brain) is a major factor in determining this, but deactivation, hyperactivity, and hemispheric imbalance also play a role. Children may be more capable of recalibrating these uninjured connected systems.[32] Finally, the possibility that the extra-geniculostriate system might be capable of processing vision even in the absence of the visual cortex (blindsight) seems real. There is some evidence that it plays a role in visual recovery in children with visual impairment due to brain injury. Further defining these recovery mechanisms would be extremely useful in designing habilitation and education programs for these children.

INTRODUCTION
IMPORTANCE OF KNOWING HOW TO DELIVER BAD NEWS
HOW TO DELIVER BAD NEWS
TRAINING IN THE DELIVERY OF BAD NEWS
CONCLUSION
REFERENCES

"We must ask who it is the blindness confronts and what forms this confrontation will take. The parent of a symptomatic mature teenager with a consistent and extensive family history of blindness attributable to retinitis pigmentosa who is surrounded by supportive experience in coping with the disorder, well connected to low-vision and support-group resources, and deeply spiritual in their acceptance of their child's condition will be approached far differently than the socially isolated single parent of an infant newly diagnosed with optic nerve hypoplasia who has overwhelming anxiety, no experience with the disorder, an absence of spiritual connection, anger, low self-esteem, and a life of financial poverty. Rather than simply wait for the blindness to come, we must proactively address the parent's inner needs and concerns to help her or him with more than just a medical prognosis. To do otherwise would only demonstrate our own lack of vision."[1]

Introduction

Pediatric ophthalmologists are faced with the frequent challenge of discussing varying degrees of vision loss. Sometimes decreased vision in children or diplopia in adults may be reversible, while at other times it is permanent. Growing evidence indicates that quality verbal communication between physicians and patients contributes significantly to achieving better health outcomes.[2–6] Therefore, knowing how to deliver bad news effectively and constructively is essential, particularly given the time constraints of the modern medical encounter.[2,5] Furthermore, a patient's overall perception of their care is often based on the conversation surrounding the delivery of bad news.[7–13]

Historically, medical information deemed potentially injurious to a patient was withheld.[14–16] These days in North America, physicians are responsible for disclosing all information a patient wants to learn about their diagnosis and treatment.[14,17] Conveying such "bad news" has been defined as delivering any information that adversely affects a person's outlook about his or her present or future.[18] The negative impact of such news arises from the discord between a patient's expectations of the future and the actual medical situation.[19] In the field of pediatric ophthalmology, this definition might be extended to include any information that unfavorably impacts parental expectations for their child.

Varying levels of bad news exist. Universally bad news, such as informing parents that their child is blind, can be contrasted with news of a more equivocal nature in which the information conveyed leads to undesirable consequences.[20] For example, trabeculotomies might be recommended for a child with primary congenital glaucoma but the treatment and follow-up will require significant family resources while also necessitating a parent's absence from work. Although more diagnostic and treatment options are available than ever before, there are now different and more complex types of bad news to convey, such as positive genetic test results.[14]

How a patient or family receives any information, however, depends upon the life context of that individual patient/family and the unique set of experiences and beliefs they bring to the discussion.[14,18,20] Changing the phrase "breaking bad news" to "sharing life-altering information" was recently proposed to address the subjective nature of how such information is received.[21] In other words, a patient and/or a patient's family are best suited to determine the import of the news delivered in the context of their lives.[21,22] For example, it may be a relief to a family to have a child's blind, painful eye enucleated. We, as caregivers, should not make assumptions about the way the information we provide will be received.

Most of the earlier literature on delivering bad news arose from oncology and palliative care settings and centered on defining bad news, emphasizing the importance of knowing how to deliver bad news, and establishing guidelines for how to break bad news.[14,18,19] Later studies have examined barriers to delivering bad news and outcomes of different strategies for training caregivers to share life-altering information in a variety of settings.[7,20,21,23–25] Current evidence supports a need for physicians to move beyond simply supplying biomedical information into a more patient-centered approach,[2] exploring and addressing psychosocial needs in order to better care for the whole patient.[1,26,27]

Importance of knowing how to deliver bad news

Impact on patients, families, and physicians

The way bad news is delivered affects a patient or family's ability to understand[14,23,28–33] and cope[10,14,20,23,34–42] with the information given, future outlook,[20,41,42] and satisfaction with care.[7,14,23,43–47] Because delivering bad news can be complicated, miscommunication can result.[14] A patient may not understand treatment goals, or take away unrealistic expectations.[14] Quality and coordination of care can suffer as a result of poor communication, and patients' trust in their physician may be diminished.[7–13] Poorly delivered bad news can increase a patient's and/or family's distress at an already difficult time,[20] resulting in anger and increased risk of litigation.[20] On the other hand, well-broken bad news may positively impact care and even outcome.[23,29–33] Well-delivered information can help patients and families to make appropriate quality-of-life decisions,[14] such as whether to subject a child to the risks of general anesthesia or another eye surgery in spite of a limited prognosis for improvement.

In pediatric settings, the parent–child relationship can be re-shaped by how parents are informed of a child's disability.[20,48] Levin has equated news delivered to parents about childhood blindness to a "loss of personhood," as parents must adjust psychologically to adapt their expectations for themselves and their child based on the news delivered.[27] The quality of the initial discussion of a positive newborn screening result for cystic fibrosis has been described as critical to the successful follow up of these children.[49]

Not only can the delivery of bad news be hard on patients, it can also take a toll on doctors.[20] In one review, the difficulties encountered by physicians at many levels of training in various fields included: struggles with telling the truth, emotional stress experienced as a result of giving bad news – including sadness, guilt, feelings of failure – and inadequate training.[20] Anxiety, lack of confidence, fear of compounding a patient or family's suffering, and the desire to avoid a patient's emotional response may cause doctors to defer such encounters or shift responsibility for the conversation to someone else.[7,14,18,20,50–51] Physicians may be tempted to provide an overly optimistic outlook or even consider futile therapies in response to a patient's or family's emotional response to unfavorable news.[14,18,51–52] Physician inexperience,[23] young patient age,[53] poor prognosis, and/or a dearth of treatment options may also lead to heightened anxiety about delivering bad news.[14]

How to deliver bad news

Delivering bad news reflects general communication skills

Good communication "often requires greater thought and planning than a drug prescription, and unfortunately, is commonly administered in subtherapeutic doses."[19] Skills essential for effectively delivering bad news exist as a distillation of the more general set of communication skills that physicians need in order to interact well with patients.[19] Good communication in health care has been shown to increase satisfaction of both physicians and patients.[52] Higher patient satisfaction may correlate more with good communication and family involvement than with medical outcome.[23,54,55] Similarly, the humanistic aspects of the breaking bad news conversation may outweigh the information that is delivered.[52] Overall, physicians must determine an appropriate way to tell the truth, support the patient, and substantiate realistic hopes.[19]

Specific strategies for delivering bad news

While many have recognized the importance of being able to effectively deliver bad news, studies have shown that those who perform the task regularly do not feel well prepared.[14,41] The need for a specific set of communication skills – that are easy to learn and recall – has given rise to multiple paradigms to facilitate these conversations.[14,21,56–58] Such guidelines may provide a strategy to increase physicians' confidence in delivering such news, ease the flow of information, and lessen parental stress.[14] Common to all of these frameworks are techniques that help to determine an individual patient's or family's values and wishes. This information is used to respond appropriately to a patient's emotional response, promoting their active participation in treatment decisions.[14]

Some of the communication strategies established for delivering bad news are the SEGUE,[56] PACE,[57] SPIKES,[14] "The 6 E's,"[58] and SLAI.[21] SEGUE is a framework for teaching and assessing communication skills among US and Canadian medical students that includes: **S**etting the stage, **E**liciting the information, **G**iving information, **U**nderstanding the recipient's perspective, and **E**nding the encounter.[56] PACE was developed as a way to help families learn about their child's chronic condition and includes: **P**lanning the setting, **A**ssessing the recipient's knowledge/needs, **C**hoosing appropriate strategies, and **E**valuating understanding.[57] SPIKES was developed as a six-step protocol for breaking bad news to cancer patients and describes: **S**etting up the interview, assessing the recipient's **P**erception of the situation, obtaining an **I**nvitation to proceed, giving **K**nowledge, **E**mpathizing and addressing patient emotions, and **S**ummarizing the encounter.[14] "The 6 E's" system was established for the pediatric oncology setting and detailed: **E**stablishing agreement about open communication, **E**ngaging the patient, **E**xploring their knowledge, **E**xplaining the news, **E**mpathizing with their emotion, and **E**ncouraging/supporting the patient and family.[58] The SLAI guidelines for "sharing life-altering information" was developed by a multidisciplinary team who modified the SPIKES protocol for a pediatric setting based on recent literature, the consensus of a task force, and experiences of videotaped parents.[21] Changes were made based on the belief that a specialized skill set is needed to effectively deliver bad news in pediatric settings.[21,53]

The well-established SPIKES[14] and pediatric-focused SLAI[21] protocols will be described in more detail here (Table 61.1). When **S**etting up the interview, it is important to determine who will be present. In pediatric ophthalmology, this would include the question of whether or not the child should be present and, if so, how much information the parents want to share with the child.[21] If the child is old enough, he or she should be included in the conversation.[21] To promote establishing a connection with patient and family, interruptions should be minimized and the physician should sit down. Everyone present should be introduced, including his or her role. With regards to assessing a patient or family's **P**erception,

Table 61.1 Recommendations for sharing life-altering information in pediatric settings[14,21]

	Recommendations	Sample questions/ statements
Setting	Minimize interruptions Sit down Introduce everyone in room	Who will participate? To what extent should the child be involved?
Perception	Ask before telling Use open-ended questions Correct misinformation	What is your understanding of your child's condition?
Invitation/ involvement	Repeat some/all of what patient says to show you have been listening	How many details would you like to know?
Knowledge	Warning shot Convey key points at an appropriate level Avoid jargon Cultural sensitivity Check family's understanding	I'm afraid I have some hard news to share.
Emotions/ empathy	Empathize Explore patient's emotions Validate	I know you were not expecting this. Tell me more about that. What do you mean? I can see how you would feel that way.
Strategy/ summary	Treatment recommendations and timeline Teach-back method to verify understanding Provide resources	We will be here to support you.

Adapted from: Baile WF, Buckman R, Lenzi R, et al. SPIKES – A six step protocol for delivering bad news: application to the patient with cancer. Oncologist 2000; 5: 302–11; Wolfe AD, Frierdich SA, Wish J, et al. Sharing life-altering information: development of pediatric hospital guidelines and team training. J Palliat Med 2014; 17: 1011–18.

the importance of asking before telling has been stressed.[14] Physicians should use open-ended questions to determine a patient or family's understanding of the current situation.[14] Inquiring first allows: (1) correction of any misinformation, (2) packaging of information to be delivered according to a patient's ability to understand, and (3) unveiling of unrealistic expectations on the part of the patient or family.[14] For example, is a parent mainly concerned about their junior high school baseball player returning to play immediately following the diagnosis of a hyphema?

Next, it is critical to determine how much information a patient or family would like to know by **I**nviting them to share their desires about this and **I**nvolving them in the care.[14,21] Repeating what a patient or family member has said may facilitate the conversation by showing that the physician has been listening.[19] When delivering **K**nowledge, it is critical to fire a "warning shot" followed by a pause to let a patient or family quickly prepare for the bad news that is coming. Such statements are best preceded by phrases such as, "I am so sorry to tell you that …" Use of the phrase, "There is nothing more we can do for you" should be avoided[14] as, for example, some patients may be helped considerably by low vision evaluation. It is helpful for a physician to be aware of a patient or family's cultural beliefs.[21,59] In general, physicians should deliver information in appropriate amounts,[21] avoiding the use of technical terms and conveying information at a level the patient or patient's family can understand, periodically checking comprehension, or asking the patient to repeat or summarize what they have heard.[14,21]

This recommendation is particularly important in light of recent research in health literacy. This has shown that aspects of the health care setting aside from standard reading skills impact patients' health comprehension and outcomes.[2,60–63] While half of American adults struggle with standard print literacy,[2,64–67] other factors that may limit patients' understanding include the level or complexity of any visual aids, handouts, or videos provided; the demands and assumptions of health care organizations; and the communication skills of health care workers.[2,60–63] Most patients prefer to receive health information in a face-to-face encounter with their clinical providers, but a discrepancy between patient and provider of oral/aural literacy levels creates a barrier to patient learning and is associated with poor health outcomes.[2] Therefore, tailoring the discussion and providing appropriate level educational materials are imperative for effective delivery of life-altering information.

Many physicians find addressing a patient's **E**motions to be the most challenging aspect of delivering bad news.[14,68–69] Responding appropriately requires several steps, including observing and identifying the emotion, seeking the origin of the emotion, and connecting the response with its origin. An empathetic statement might be, "I know you were not expecting this," or, "I was hoping for a different result." Physicians should be willing to ask exploratory questions to determine the root of a patient's response to the news, if it is not clear, for example, "Tell me more about that," or "What do you mean?" It is also important to validate a patient's response using phrases such as, "It is no wonder that you feel that way." A combination of empathy, exploration, and validation can be used to support the patient as the conversation moves into the mutual development of a treatment plan, or **S**trategy.[14] Assisting a patient to develop a clear plan, including treatment recommendations and a timeline, may minimize their anxiety and uncertainty moving forward. Summarizing the conversation should incorporate a "teach-back" method,[2,70] allowing a physician to verify that a patient or family has understood the discussion and plan. Providing information about support services can be helpful at this time.

Training in the delivery of bad news

A 2010 study of 253 pediatric residents, fellows, and attending physicians (consultants) surveyed at one major United States academic center found that half to two-thirds of fellows and attending physicians did not feel "sufficiently knowledgeable" to deliver bad news.[23] Participants cited time limitations, neglect of the subject, absence of positive modeling by instructors, and lack of awareness regarding relevant resources as educational barriers.[23]

Training modules in delivering bad news have been developed for pediatric medical settings. Vail et al. videotaped hospital consultants (attending physicians) from a range of

specialties in the United Kingdom delivering bad news to simulated patients.[26] These conversations, coded using the Roter Interaction Analysis System, revealed that hospital consultants focused mainly on relaying biomedical information and did not actively involve patients in the consultation.[26] Tobler et al. evaluated the impact of a simulation-enhanced breaking bad news workshop in pediatrics and found that teaching these skills in a systematic fashion can be effective.[24] Wolfe et al. introduced the SLAI guidelines with a short didactic session that integrated videotaped parent recollections and group critique of videotaped role-play scenarios demonstrating SLAI encounters.[21] Reed et al. studied pediatric residents and found improvement in the videotaped delivery of bad news during standardized patient encounters immediately and 3 months after the "GRIEV_ING Death Notification Protocol" was reviewed.[25]

Because conversations surrounding the delivery of life-altering information are dynamic,[71] viewing successful demonstration of such skills in real clinical situations and practicing the skills are critical [20–21,23,25] for determining how guidelines can be adapted to each unique clinical encounter.[72] Whether or not such interventions lead to long-term improvements in delivering bad news, however, remains to be seen.[20,73] Awareness of such protocols may not lead to their utilization.[23] Outcomes of many studies to date have relied on participants' self-assessments. Furthermore, while having protocols in place for delivering bad news may lessen stress for those responsible for delivering such news,[20,74,75] it is difficult to evaluate whether or not these guidelines have increased patient satisfaction.

Conclusion

Re-focusing on patient-centered care

The communication skills involved in the delivery of bad news can be taught and learned just like any other clinical skill.[19,76] The essential elements, though, may be "courage, brains, and heart": the ability of a physician to calm his or her own anxiety, convey clinical knowledge and accumulated experience in a user-friendly way, and express real emotion while acknowledging patient emotions and encouraging discussion.[77] *How* a message is conveyed may be even more important than the information that is conveyed,[78] and these difficult conversations must center on the psychosocial needs of the patient. Nothing can change the fact there will always be bad news to communicate, but the way in which life-altering information is shared will heavily influence patient and family perceptions and remembrances of their overall care.[7,8,11,79,80]

Introduction

Visual impairment (VI), defined as a reduction of visual acuity and/or visual field loss, is diagnosed from the combination of history, physical examination, electrodiagnostic testing, genetic evaluation, and neuroimaging. Following counseling of the family regarding the diagnosis, the professional needs to provide support for vision habilitation.

Promotion of vision development

Vision develops as the child matures. However, children with visual impairment in the first year of life have different vision and developmental trajectories. For the majority of these children, vision will improve but, in order to do so, the child requires opportunities to view and identify.

Normally, this process is spontaneous, but infants with VI must be encouraged to use their sight. In addition to limitations in vision, visual interaction can be reduced by defective eye movements, marked developmental delay, or visual attention disorders. Although visual learning continues throughout life, the rate of acquisition of visual skills is greatest during infancy. The development and structuring of the visual brain is influenced by visual input. Ideally, the visual environment should be rewarding, meaningful, and increasingly complex – otherwise, there is a loss of opportunity to fully develop the visual potential. Vision stimulation can improve visual potential.[1] It should start immediately after diagnosis. Professionals working with VI infants must understand the visual abilities. It is important to avoid repetitive visual stimuli, such as flashing lights, and to make interactions increasingly meaningful for learning. The facilitation of visual development can be carried out by family members throughout the day when the infant is alert.

The majority of children with significant congenital visual loss appear to have little or no vision during early infancy, but most develop useful sight later. There are two reasons for this:

1. Visual acuity, fields, eye movements, accommodation, perception, and cognitive factors rapidly improve after birth.
2. The vision may be so severely reduced by the combination of physiologic, ocular, or neurologic factors that they cannot use their vision spontaneously and experience delayed visual development.

Because the maturation of the brain and visual system is stimulus dependent, encouraging these infants to use their sight is critical.

Early interventions

The habilitation (or rehabilitation) of children with visual impairment results from their physical, emotional, and intellectual growth responding to skilled, early intervention.[2] The effect of visual loss and other disabilities on development is complex. A multidisciplinary approach is an effective way to deal with VI children. The team may include ophthalmologists, pediatricians, geneticists, nurses, psychologists, speech–language pathologists, audiologists, physiotherapists, and orientation and mobility specialists. Close co-operation between the professionals dealing with the visually impaired child is important. When the parents are included as part of the team, they become more effective in the management of their children. The parents should receive copies of reports related to their child. In addition, the team should advocate for blind people, educate the community, and participate in research.

The multidisciplinary team will consider many areas of child development. This, in turn, will allow the individual with visual impairment to be better able to participate in activities in the home, school, and community. In addition, these groups are often linked to several community organizations, which help to integrate individuals into varying activities, including sports and social events.

Development in the child with visual impairment

Conceptual development

Visual impairment has a noticeable effect on cognition. Reduced vision results in fragmented processing of information, as only a part of the object can be seen or felt at one time. The relationships to other objects may be lost. In addition, children with visual limitations often are less influenced by the environment. This may lead to limited interaction and exploration, particularly with objects outside their reach. The attention span in VI children is usually shorter than for sighted children.

Given these features, these children may become passive and understimulated if experiences are not brought to them. Therefore, difficulties arise when they are assessed about their knowledge of their environment. They may have challenges in organization and verification of information. There are many other features that may affect concept development. These features include, but are not limited to, object permanence, causal relationship, patterning, classification, and relative sizes. As a result, more time may be needed to establish these concepts. This does not necessarily indicate poor cognitive ability, but insufficient opportunity to acquire the skills and information that would be normal for a sighted child. The development of visual motor skills, arrangement of objects in space, and constructive play are also affected. VI children often avoid activities such as construction toys, puzzles, and drawing. Making experiences available and encouraging them to use their residual vision is essential.

Motor development

VI children who are raised in a rewarding, stimulating environment provided by loving, informed parents who are supported by professionals, develop motor skills faster than those who are understimulated.[3] Even infants with severe visual loss, reared under ideal circumstances, may experience motor delays. Often, there is early delay in hand utilization. Crawling and independent walking may begin late, whereas unsupported sitting and standing may be age-appropriate. Understimulated congenitally blind infants frequently develop generalized hypotonia with poor posture, delayed motor skills and poor coordination, and walk with a gait disturbance. It is the self-initiated mobility that tends to be problematic. When intervention is not started early, these problems become permanent. Moreover, physical fitness in older VI children is often poor from habitually reduced physical activity.[4]

Blind infants without brain damage are usually quiet, passive, and require encouragement to be mobile. They may not acquire skills through "incidental" learning, as do the sighted. Motor tasks such as sitting, pushing, pulling, jumping, and early aspects of orientation and mobility must be taught. Partially sighted children usually learn to move about normally and cannot be distinguished from the sighted, unless they are required to carry out balance activities.

Language development

In order for VI infants to learn from hearing, their environment needs to be optimized by reducing background noise and encouraging the child to listen to meaningful sounds. They learn to recognize voices and anticipate events through sound, smell, and touch. Early language in children with visual impairment tends to parallel their exposure to language.

Without the full range of sensory information, language concepts, and words and phrases retained from overheard conversations are based on auditory memory, not direct observation experience. Language skills become stilted, more self-oriented, and word meanings are limited.[5] Often, children with visual impairment have limited initiation in conversation. There may be a lack of descriptors. Limited vision leads to a lack of language experiences. Children with these types of language difficulties sometimes use sophisticated sentences, without fully understanding their meaning. Intervention services minimize this problem. Self-awareness within the environment may be limited, leading to difficulties in personal pronoun usage.

Social and emotional development

Most young VI infants have poor vision, which may improve with maturation. However, the parents miss the rewarding experiences of mutual gaze and smiling, an important part of bonding. Although these infants smile and respond to voices and touch, the responses are subtle. If not addressed, a child may become less interested in interactions with others. The early intervention specialist must interpret the infant's signals to the parents and encourage them to keep their babies nearby, talking to them often.

Older children with visual impairment have difficulty in sensing their effect on their peers because they may not see "body language" or facial expression. They may not be able to see who is available for play, leading to isolation and persistent egocentric behavior. There may be difficulties in initiating play with peers. Because VI children need more structure and predictability in their environments, they are often resistant to change; their behavior may appear rigid. The introduction of activities of daily living may be challenging. Many independent living skills are introduced by watching. When a visual impairment is present, feeding, self-care, and toileting may be delayed.

Education

Visual disorders have a major impact on education: normally, learning requires good vision. The education of the blind is a specialized field. Educators are important in the lives of VI children. The teachers who plan the curricula and teach the students require special training and experience. In addition to the usual subjects adopted from the sighted curriculum, the education includes concept formation; orientation and mobility; daily living skills; and non-visual communication in reading, writing, speaking, listening, and the use of technical aids. To succeed, educators must understand the ocular or neurologic visual disorders, the cognitive abilities, and the health issues facing their students. This requires good parent–teacher relationships and access to information from treating ophthalmologists.

The distance acuity determines where the students should sit in the classroom and how much board work is required.

Those with homonymous hemianopia must be seated so that their functioning visual field is directed toward the teacher and the class. Children with severe peripheral field loss, but intact acuity, function better if they are further away from the blackboard. Students with photosensitivity (as in aniridia, cone dystrophy, or albinism) must not be placed next to a window where the light is most intense. Appropriate lighting, individually adjusted, is critical. Impaired accommodation, contrast sensitivity, color perception, or eye movements can adversely affect learning. It is helpful for educators to understand the reasons for a head turn or movements associated with nystagmus. When the visual disorder is progressive, the rate of deterioration determines the timing of introduction of Braille and assistive devices. Visual aids are more effective when the educators are involved in the transition and instructions.

Since many VI children have neurodevelopmental disabilities, educators require detailed information about them. Teachers for the visually impaired often accompany students to appointments with ophthalmologists and other physicians; it is helpful when they receive copies of the medical reports. Educators should participate in the multidisciplinary team.

It is important to recognize that a child with visual impairment may not have had the same developmental exposures prior to school entry. Many skills require opportunity and experience. Commonly, there is a greater focus on academic-based activities. Assessment of visual function is important for learning. Visual acuity can offer some information as to the amount of power needed to identify at near.

Children with visual impairment may have difficulties with:

- copying from the board;
- written output;
- reading comprehension (confusing similar words; failure to read full sentence due to restricted fields, skipping lines, losing place when reading);
- performance activities – puzzles, word finding, misalignment in math problems, visual concepts, conservation of size.

There are multiple strategies to assist in academic activities. The first is visual acuity optimization with the use of glasses. Other strategies include:

- environmental conditions (lighting, positioning, access to a slant board to improve posture);
- adaptations (optimizing contrast);
- physical enlargements;
- reading window;
- magnification (low magnification for reading; higher for distant details);
- electronic equipment with application software (text to speech);
- Braille.

In considering strategies, the professional must consider each individual child. Many children with visual impairment may enter school with fragmented skills. This not only includes school-based skills such as written output and coloring, but also other dexterity tasks such as opening containers. Although introduction of low vision aids (magnification) can help with identification, children may have difficulty in effectively using the equipment initially. These difficulties will be compounded on multifaceted activities such as copying information from a distance. Often, the easiest strategy will be to enlarge the material.

The education of children with cortical visual impairment (CVI) and ocular visual loss is different.[6] With purely ocular disorders, visual input may be reduced, but neural processing is normal. Thus, visual enrichment and training to scan efficiently are useful. For children with CVI, this approach does not work: visual input must be controlled, to avoid "overloading." Images should be simple and presented in isolation. In their training, teachers for the visually impaired should be exposed to the management of the neurologically and visually impaired child, since this combination of disabilities is increasingly common.

Previously, severely VI students were educated in segregated schools, but now, in many regions of the world, they are "integrated" into classrooms. This has benefits and disadvantages.[7,8] Full integration may lead to underestimation of the disability and is often detrimental to the multi-disabled visually impaired, who learn best in a carefully controlled classroom.

Orientation and mobility

Orientation is the understanding of one's location; mobility is movement from one area to another. Orientation and mobility (O&M) teaches concepts and skills to children with visual impairment regarding how to travel safely and efficiently in different environments. O&M specialists need to know about the visual disorders, the cognitive and neurodevelopmental disabilities, and the emotional issues of each VI child. They are members of the multidisciplinary team. Successful O&M starts early when basic sensory awareness of the environment is formed. It is much more than just training to use a white stick or cane.

O&M cannot be taught by words or by models. It must be experienced in the real world. While it begins in infancy, instruction continues in preschool years. The most common methods of O&M are sighted guides, cane, mobility devices, guide dogs, electronic and ultrasonic travel aids, and computer-generated alternative training.[9]

Assistive technology

Technology has helped the visually impaired.[10] Assistive or adoptive technology has improved the way they are educated or trained and has increased employment opportunities. When assistive technology is offered, the child's visual and intellectual abilities should be evaluated. This should include the individual's ability to use, adjust, and maintain the device in varying environments. When considering a device, the professional needs to consider the main tasks that the child with visual impairment needs to accomplish. For an exclusive reading-based activity, this may be done with magnification and the use of a reading window. For comprehension of a subject, this may be more effectively managed from an auditory device or computer software.

There are a number of devices listed on the Web, ranging from simple magnifiers to computer screen magnification (or other electronic devices), Windows-based tutorials, Braille translation of software, portable note takers, Braille writing equipment, scanners, voice simulation programs, to a variety of video magnifiers or closed-circuit televisions. It should be

noted that many electronic devices can be used to modify or optimize contrast, color, and lighting. Some devices will enlarge but provide a space for the child to perform dexterity tasks. When possible, distant material should be presented at near. A SMART Board can present information shown at distance directly onto a computer screen (SMART Technologies Inc., Calgary, Canada).

One should remember that there is a wide array of different optical devices to assist in activities outside reading/magnification. These include adaptive strategies such as large print checks or enlarged buttons on phones. There are varying audio devices such as talking calculators, clocks, and label readers. There are accessories to handheld devices, such as global positioning system (GPS) navigators and screen readers. In addition, there are multiple pieces of adaptive equipment for food preparation, to assist in appliance use, and home safety.

The use of adaptive equipment should be co-ordinated with other therapies to optimize their use. Assistive technology is a basic tool, like pencil and paper for sighted students and, as they grow, assistive technology use is a continuous process. It is beneficial to introduce these services before school age, so that young VI children may have a chance to learn with them: early referral is important.

Neurodevelopmental issues and the child with visual impairment

Neurodevelopmental disabilities are associated with a number of ocular disorders. They are seen in most children with cortical visual impairment.[11] Many VI children have additional disabilities, which make habilitation more complex.[12] For intervention specialists, it is suboptimal to have experience only with visual disorders.

As previously mentioned, there are multiple domains of child development that are associated with children with visual impairment. Cognition is frequently affected in VI children.[13] The diagnosis of intellectual deficit is difficult and best made by skilled persons such as child psychologists. Children with severe visual impairment can memorize words and phrases, but without experience, they have less understanding of their meaning. The psychologist must distinguish understimulation from intellectual deficit. Cognitive deficits are even more evident in children with cortical visual impairment.[14]

In addition to developmental disabilities, there are a host of common health conditions. Epilepsy is more common among the visually impaired than in the general population. Uncontrolled seizures may result in visual unresponsiveness, which is temporary if the seizures can be controlled. Sedative anticonvulsant drugs should be avoided since they impair attention and learning. In addition, structural brain anomalies are also more common. Given these features, it is important that patients are assessed for the presence of these conditions, as the optimization of health often can lead to improved visual function.

Hearing loss can also be present in the context of visual impairment. In some genetic conditions, hearing loss is part of the condition, such as Norrie disease, Usher syndrome, and CHARGE association. Some children, such as those born prematurely, are also at risk for hearing loss and visual impairment. Given their greater reliance on hearing and the higher prevalence of hearing problems, Hearing tests are particularly important for this group. When hearing loss is present, children need referral to appropriate services. The development and management of the deafblind child is unique (see Chapter 99).

It should be evident to the ophthalmologist when a child has more than one etiological cause for their visual impairment. In the presence of structural eye or optic nerve disease, there may be a structural anomaly within the brain. For example, children with optic nerve hypoplasia can have several structural brain anomalies, such as a schizencephaly, which may cause a cortical visual impairment. Therefore, when functional vision is not in keeping with a diagnosis, additional investigations may be appropriate.

Blind mannerisms

Many children with severe visual impairment exhibit stereotyped behaviors – body rocking, repetitive handling of objects, hand and finger movements, lying face downwards, and jumping.[15] Blind mannerisms need to be carefully analyzed and appropriately managed. They should not be confused with autism or Tourette syndrome.[16]

Stereotyped behavior involving the visual system includes eye rubbing, pressing, poking, gazing compulsively at light, staring at hands, flicking fingers in front of the eyes against a light source, pulling on eyelids, tapping or hitting their globes, repeatedly blinking, or rolling the eyes. Rubbing, pressing, and poking the eyes are grouped together as "oculodigital phenomena."

Eye rubbing is observed in normal or disabled, fatigued children. Eye pressing occurs with severe bilateral, but usually not total, congenital visual loss, usually of retinal cause. The cause of eye pressing is unknown: it may be stimulatory, requiring functioning retinal ganglion cells. This type of stimulation occurs when the vision cannot provide well-formed, sustained images. It occurs when the child is bored, anxious, or during various activities, such as listening to music. It tends to be prolonged and persistent but is not painful. Orbital fat atrophy may result causing enophthalmos. In order to reduce eye pressing parents should continually keep the child's hands busy and remove them from their eyes during the first years of life, when eye pressing is most intense. Later, the urge to eye press diminishes. Eye poking is deliberate and harmful. Usually, eye poking causes pain and it is not unusual for the child to scream afterwards. Eye poking occurs in severely multi-disabled or emotionally disturbed children, who are not necessarily visually impaired. It can cause corneal scarring, infection, retinal detachment, intraocular bleeding, and cataracts; it may lead to blindness.

Compulsive light gazing is one of the signs of cortical visual impairment. VI children who flicker their fingers in front of their eyes against a light source are also light gazers. Mannerisms in children with visual impairment are often influenced by the underlying diagnosis, the presence of comorbid developmental impairments, and level of visual impairment. In most conditions, as the child ages, the mannerisms tend to decrease in frequency.[17]

Behavioral problems

Professionals who are not familiar with VI children may draw the wrong conclusions from their mannerisms, speech,

posture, facial expressions, and psychological test results. These children may be misdiagnosed as emotionally disturbed or unintelligent. Patients with visual impairment are more prone to social isolation. So, behavioral disorders are more common among the visually impaired than among the sighted, especially with additional disabilities.

The assessment of behavioral deviations may require multiple visits. The cause is often simple, but when more complex, the treatment needs to be directed to the family. The psychologist or psychiatrist needs to be familiar with visual impairment and should preferably be part of the multidisciplinary team.

Sleep

Sleep disturbances are increasingly common in Western societies due to changing lifestyles. In healthy children, these sleep difficulties tend to be transient and respond well to sleep hygiene techniques. In contrast, in children with neurodevelopmental disabilities including visual impairment, they tend to be more frequent, persistent, and severe and may not respond to sleep hygiene interventions.[18] The prevalence has been reported greater than 80% in children with intellectual disability and visual impairment.[19] Circadian rhythm sleep disorders (CRSD) are by far the most common,[20] followed by sleep disordered breathing,[21] parasomnias,[22] and restless leg syndrome.[23] Most of these sleep disorders present differently to those seen in adults.

Adverse consequences of impaired sleep

Sleep is a vital restorative neurological function. It is not surprising that severe, persistent sleep deprivation can lead to gradual loss of neurons in various areas of the brain, but more so in the frontal lobes where executive cognitive functions are generated. The behavioral manifestations of inadequate sleep include inattentiveness, aggressiveness, hyperactivity, impulsivity, and mood changes. Cognitive manifestations are impaired comprehension, deficits in reasoning, and memory formation. School failure is common. Health disturbances are also frequent such as impaired immunologic defenses resulting in more frequent infections and even cancer, cardiovascular difficulties, obesity and endocrine disturbances, tendency to accidents, and increased suicide rates among teenagers.[20]

Causes of sleep disturbances

Excessive or inappropriately timed light exposure, leading to CRSD, is the most common cause of sleep difficulties today, which suggests that increasing attention should be paid to environmental light pollution. Light inhibits pineal melatonin production, while the absence of light promotes it. Visually impaired children can have a special type of CRSD resulting from their ocular visual loss. Total absence of light input into the hypothalamus results in free-running sleep/wake rhythm. This is rare in children because total blindness is infrequent. In the absence of light, the suprachiasmatic nuclei begin to promote rhythmicity according to their own endogenous neuronal rhythms. These are usually longer than 24 hours. Therefore, the pineal melatonin production is progressively delayed every day and with it the sleep/wake patterns. The only treatment that can stop this persistent shifting is timed melatonin administration given at bedtime.[24] Children with cortical visual impairments do not exhibit free-running sleep/wake rhythms because the environmental light input via the retina into the hypothalamus is preserved.

Cognitive processes via the cerebral cortex and the thalamus also have strong regulatory inputs into the suprachiasmatic nuclei and pineal melatonin production. The perception of environmental changes and responses to it very much influence human sleep patterns. When the brain functions are disturbed, the prevalence of sleep difficulties may be as high as 80–100%. These sleep disturbances may present as difficulties falling asleep, frequent nocturnal waking lasting from minutes to hours, early morning awakenings, day/night reversals, or advanced sleep onset.

Management of sleep difficulties

When persistent or recurring sleep difficulties are noted, it is essential to identify the underlying cause. In this way, appropriate treatments can be chosen. Family physicians and a number of different specialists can deal with the management of many sleep problems, but increasingly multidisciplinary sleep clinics are becoming established for children. A detailed sleep history and a physical examination are necessary. The caregivers are often asked to document their child's sleep in a diary for 7–10 days. Most sleep clinics use wrist actigraphs that record limb movements and, therefore, more objectively identify periods of sleep (inactivity) and wakefulness (activity) than parental logs. Polysomnography, nocturnal video recordings, and neurologic and metabolic tests are occasionally needed to secure a diagnosis of CRSD and other sleep difficulties.

Sleep disturbances are not an inevitable part of neurodevelopmental disabilities (including visual impairment), and in most instances they can be treated. They must never be ignored. Behavioral, educational, and other types of interventions are ineffective without correcting severe sleep disturbances. Many physicians have received inadequate training in sleep medicine and they tend to overprescribe hypnotics. Persistent use of hypnotics is not recommended for children because of the high frequency of adverse events and because their benefits are usually short lived.

The treatment of CRSD usually starts with the introduction of sleep promotion techniques.[25] For children who do not have significant neurodevelopmental disabilities, modification of sleep environment and sleep habits usually work very well. For the disabled, the sleep hygiene interventions must be individually tailored to their cognitive strengths and weaknesses. However, with increasing loss of cognition, sleep hygiene is harder to enforce, less effective, and may even be ineffective. Melatonin-replacement therapy is now recommended by the American Academy of Sleep Medicine for the treatment of CRSD. It is simple and highly effective, lacks adverse effects, and acts quickly.[26] Melatonin is not addictive, does not conflict with other medications, and tolerance does not develop.[20] However, the therapeutic evidence for melatonin use in children with visual impairment is limited, as this population is rare, heterogeneous, and fraught with many comorbid conditions.[27–29] In patients with no light perception without neurodevelopmental disabilities, a small dose of 2 mg at night often suffices. In patients with visual impairment and a neurodevelopmental disability, a larger dose may be needed.

Features and definitions of visual conversion disorder

Many terms used are useful (Table 63.1) but none perfectly encapsulates what we refer to as visual conversion disorder (VCD). Children commonly present to ophthalmologists not only with symptoms that do not fit in with known ophthalmic diseases but that also must be *proved* to have characteristics that *definitely cannot be caused by organic disease*. VCD is not just a diagnosis of exclusion but one that is made by positive identification of signs that cannot be due to disease. It is safer to assign those without positive diagnosis to an "unknown cause – to be reviewed" category than to assign them an incorrect diagnosis for any reason.

Many symptoms that children describe are not understandable but they are not necessarily fabricated. A child's naïve description of a normal phenomenon is easily, falsely, taken as an abnormal or fabricated one. The child's interpretation is not usually a conscious deception.[1]

The major characteristics of VCD are as follows (modified from the Diagnostic and Statistical Manual, Fourth Edition [DSM-IV] of the American Psychiatric Association[2]):

- One or more symptoms or deficits are present that affect voluntary motor or sensory function suggesting a neurologic or other medical condition.
- Psychologic factors are associated with the symptom or deficit because conflicts or other stressing events precede the initiation or exacerbation of the symptom or deficit by a variable time. It is often difficult or impossible to find any clearly abnormal stressing event.

The **symptom or deficit** is not *intentionally* produced or feigned (as it is in factitious disorder or malingering[3]):

- After appropriate investigation, it cannot be explained fully by a medical condition, the effects of a substance, or as a culturally sanctioned behavior.
- It causes significant distress or impairment in social, educational, or other important areas of functioning or warrants medical evaluation.
- It is not limited to pain or, in older children, to sexual dysfunction and is not better accounted for by another mental disorder.

Conversion disorder

Conversion disorder was described as a loss or distortion of neurological function not fully explained by organic disease. The patient has an internal conflict, of which they are unaware, which becomes converted into a symptom as a means of expression after dissociation, a mental mechanism whereby underlying feelings and the symptoms are separated. Conversion disorder can be distinguished from other psychiatric disorders mimicking organic loss by its absence of conscious or intentional desire to trick the doctor (or parent). The child with the ocular manifestations of a VCD develops visual loss due to unconscious problems or mental disturbances outside their awareness. Often such children have a history of previous conversion reactions, not necessarily involving the visual system.

Table 63.1 Alternative terminologies used for children with fabricated or exaggerated symptoms

Terminology	Advantages/disadvantages
Conversion disorder (visual conversion disorder, VCD)	The preferred term of the American Psychiatric Association but it implies certain knowledge of the underlying mechanism
Psychogenic blindness	Terms that are still used and can be helpful
Hysterical blindness/ amblyopia	Incorrectly implies instability or "madness" but it is still commonly used
Stress-related visual disorder	Many cases are not apparently stressed by any definition
Conversion neurosis	Implies a certain knowledge of the underlying mechanism and instability
Medically unexplained visual loss	Obscures the meaning from parents and patients and poses a question that must be answered
Amblyopic schoolgirl syndrome	A sexist and pejorative term
Functional visual loss	Meaningless term designed to obscure the meaning from parents and patients
Malingering	A term correctly used for someone who deliberately feigns a symptom for some form of gain – compensation, avoidance of work, military service, etc.[2] This is usually seen in adults
Factitious disorder	A term correctly used for a person acting as if they have an illness by deliberately producing, feigning, or exaggerating symptoms to gain attention or sympathy. Was known as Munchausen syndrome
Factitious disorder by proxy	Used to be known as Munchausen syndrome by proxy. Symptoms or signs produced in a child by a carer to elicit sympathy, etc., for the carer
Non-organic visual loss	Many parents do not understand what "organic" means in this context but it can be useful when explained.

Clinical presentation and symptoms

The child with VCD is typically between 6 and 16 years, most frequently 10 years old, mostly girls. There may be a family history of illness or of eye disease.[4] The symptoms come on gradually in most cases, often following a marginal failure at an eye test. Subsequent examinations reveal varying degrees of acuity and visual field loss, often worsening as time goes on but rarely to the extent that the child becomes bilaterally blind. Most children are little inconvenienced even by an apparently marked visual loss. Repeated objective examinations, neurophysiology, and radiology, are all normal. The condition is usually bilateral, with the most common complaints being "just not seeing," blurred vision,[5] or distorted or small images. Occasionally visual field defects are described, commonly "tunnel vision"; hemianopias are occasionally encountered. Central scotomas are rare and should make one think of associated organic disease. Non-visual defects occasionally also occur,[6] including spasm of the near reflex, headaches, voluntary nystagmus, and eye movement tics, contraversive eye deviation, and accommodation paralysis.

The symptoms of VCD have some of the following characteristics[7,8]:

1. They conform to the child's concept of a symptom or a disorder.
2. They are definable, if somatic, in terms of positive evidence and, if psychologic, by techniques of clinical examination.
3. They are related to emotional conflict.
4. Despite being profound, the symptoms often cause little concern to the affected child.
5. There is usually only one symptom. It is unusual for this to present with multiple symptoms especially in more than one organ system.
6. Conversion disorders are rare under 6 years old, and the gender ratio is equal up to 10 years, then females outnumber males by 3 : 1.
7. In children, both visual fields and acuity are affected; adults tend to be monosymptomatic.[8]
8. Family disharmony is common and abusive or incestuous relationships should be borne in mind as an underlying cause.[9]
9. Patients tend to have equal difficulty with both large and small letters and read down the letter chart very slowly from the top to the lowest they can achieve, often getting further down the chart if cajoled or if the test is done competitively. They read the near vision test excruciatingly slowly, often only to a much worse level than that achieved at distance.
10. A few children have a history of previous psychiatric or psychologic disease,[6] but it is often difficult to elicit the history. Most are normal children.

Depression

Some children develop somatic complaints in response to depression. Therefore, questions that can elicit signs of depression should be raised when depression is suspected. Depressed children may have sleep and eating disturbances, and may have suicidal thoughts. Their peer relationships may have suffered in the preceding months, and they may appear irritable. These need to be addressed, with help from a pediatrician or psychiatrist.

Association with organic disease

Non-organic symptoms are common among referrals to a pediatric ophthalmology service.[10] Prompt, correct diagnosis with appropriate management saves the doctor, the child, and the parents much heartache and time and saves the discomfort and risk of unnecessary investigations.

The fear of missing organic disease makes doctors more cautious about diagnosing non-organic disorders. In VCD, misdiagnoses occur particularly with macular disease and hereditary optic neuropathy in children, but no disease is exempt!

Organic disease may be associated with non-organic disease; the classic situation is the occurrence of pseudoseizures in

epileptics. The same may happen with VCD but, *in childhood*, the symptoms usually occur free of both organic and psychiatric disease.[6]

Psychological background

Inquiry into the background, looking for the underlying stress that produces the symptoms, should center on two main areas:

1. *The home and family.* Conflict between children, sibling rivalry, the child who needs more attention, an unhappy marriage, overcrowding, sexual abuse,[11] harassment or bullying by relatives or others, or conflict with neighbors and their children may be predisposing factors.
2. *The school*. In the school it is often the slow child who is being "overstretched" or the bright child who is being "understretched" who may produce visual symptoms. Unsympathetic or aggressive teachers, teasing or bullying, sexual or other harassment, or abuse[11] all predispose to VCD.

Enlist the help of the parents, tell them explicitly of the possible underlying problems so that they can best help their own child, because relieving underlying factors is the best treatment.

Detection of functional ocular disorders in children

The diagnosis is made positively, with the clear demonstration of signs that are far outside the bounds of physiological possibility. A detailed history, even if time consuming, is often vital to making the correct diagnosis. Certain clinical situations are particularly suggestive of a non-organic disorder as outlined in Box 63.1.

Box 63.1

Presentations and progressions suggestive of visual conversion disorders

1. A severe functional defect in the presence of a normal physical examination, especially when there is a severe unilateral defect with normal pupil reactions and no refractive error.
2. The sudden onset of a disorder related to an emotionally significant event or situation.
3. A step-like deterioration, with the patient's acuity becoming one or two lines worse on each examination but with no objective abnormalities.
4. The ability of a patient to achieve a better acuity or better visual fields with coaxing or cajoling.
5. A monotonous and excessively slow reading of all the letters on a letter chart, regardless of whether they are large or small.
6. A single symptom is most frequent in VCD whereas psychoneurotic patients will tend to have numerous symptoms. Children rarely have substantial ocular complaints.
7. A previous history of ocular or non-ocular VCD, is a recognized predisposing factor to further disorders.
8. The occurrence of visual problems in other members of the family, especially if serious.

Clinical examination in visual conversion disorders

Total blindness

Bilateral

Although unusual, this severe disturbance is usually easy to detect as being non-organic.

1. Direct threat or throwing a ball on a string at the patient while the eyes are open invariably produces a blink (Fig. 63.1). The string can be concealed before the ball is thrown.
2. When facing a mirror, patients involuntarily move their eyes when the mirror is rotated about a vertical axis. The velocity of the eye movement is proportional to the velocity of rotation of the mirror. The only way in which the patient can inhibit the eye movement is by "looking through" the mirror, usually easily detected by a change in convergence and an associated pupil reaction (Fig. 63.2).
3. An optokinetic drum or tape, subtending a large angle at the eye, can be held in front of the patient and the drum rotated to elicit visual evoked movement (Fig. 63.3). It is possible for the patient to look through the tape or drum giving the impression that he/she is not seeing it.
4. A 5- or 25-diopter prism placed base out in front of a seeing eye will normally induce an appropriate, and totally involuntary, fusional movement (Fig. 63.4). This will not occur in severe visual defects.
5. A blind person can easily touch finger tips, one hand to the other, whereas people with VCD sometimes exhibit great difficulty.[12]

Unilateral

The above tests can be used by covering the unaffected eye. In addition:

1. The "confusion–refraction" test (Fig. 63.5). Polaroid lenses or Polaroid projection devices can also be used to trick the patient into reading with the affected eye.
2. Worth's 4 dots and the Frisby or other stereotest (see Chapter 75), appropriately used, will detect if a child is able to use both eyes together even if the responses may be bizarre. With Worth's test, if the patient sees more than three green or two red he/she must be using both eyes. Seeing the Frisby shapes requires a high degree of binocular vision.
3. Either a horizontal prism, as described in the previous section, or a vertical prism may be placed in front of the apparently defective eye. The vertical prism, if over 5 diopters in power, usually involves diplopia and the patient may report this or terminate the examination.
4. It is in this group that pupil reactions are most useful; if one eye is blind and the other is normal there is always a relative afferent pupil defect.
5. Bar reading is a commonly used technique in orthoptics (Chapter 75). To read with a bar placed in an appropriate position between the reading matter and the patient's eyes requires both eyes to work simultaneously to read a complete line.

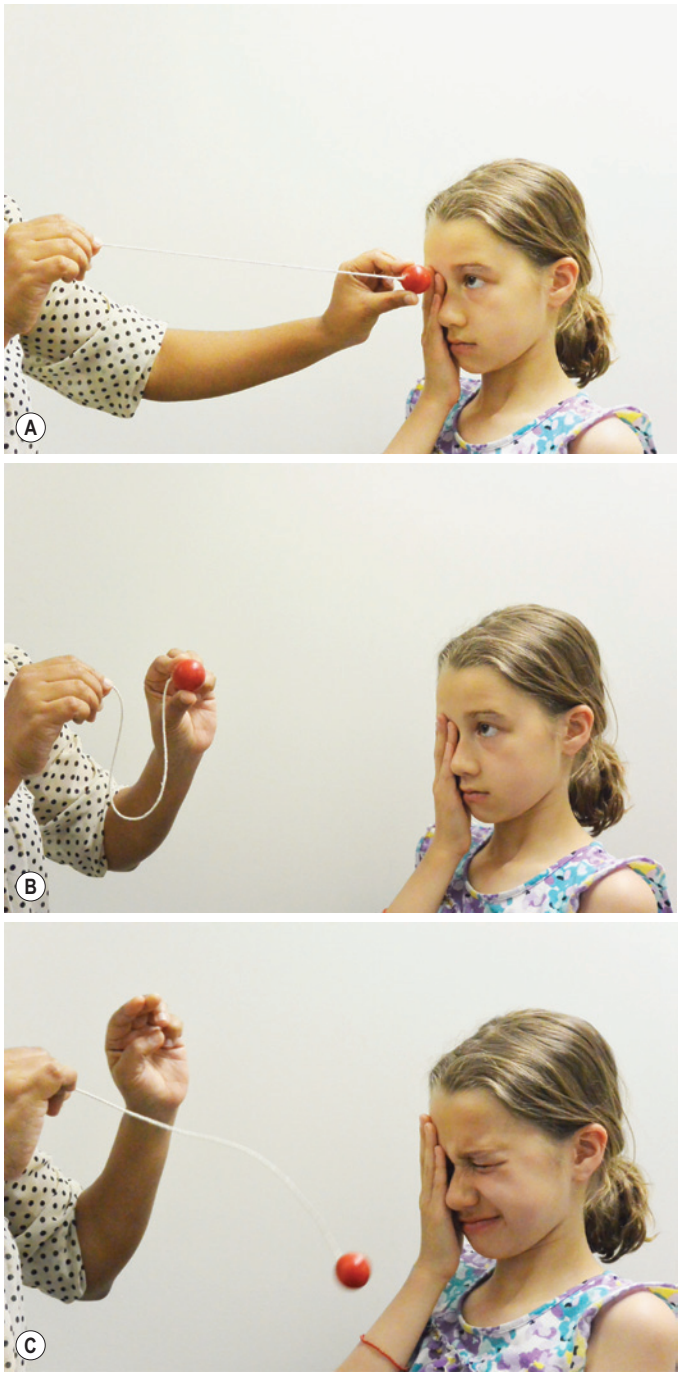

Fig. 63.1 Bilateral non-organic blindness. The ball on a string is measured for distance (A), withdrawn (B), and then thrown at the child, eliciting a blink if they are indeed sighted (C). The first two steps are better performed with the eyes closed. This test needs to be performed meticulously after explanation to the parents the reasons for doing it. It is only really helpful in the unusual instances of complete blindness. *(Image courtesy of Dr CJ Lyons and his completely normal collaborator.)*

Partial acuity loss

If the acuity loss is only partial, it is essential to accept only the most clearly non-organic signs as being true; for instance, a small difference between near and distance acuity is not necessarily non-organic and should not be the basis by itself for such a diagnosis.

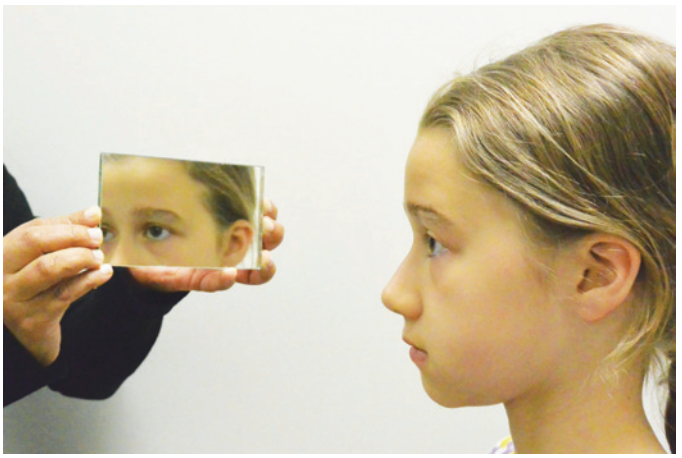

Fig. 63.2 When a blind person looks at a mirror, no movement takes place when the mirror is rotated. The sighted person's eyes will move as the mirror rotates although they believe they are looking straight ahead. *(Image courtesy of Dr CJ Lyons and his completely normal collaborator.)*

Fig. 63.3 Bilateral non-organic blindness. As long as the patient does not "look through" the optokinetic (OKN) tape, the patient's eyes will move with the OKN tape. *(Image courtesy of Dr CJ Lyons and his completely normal collaborator.)*

Unilateral

In this group, the same tests that are used for unilateral complete visual loss are applicable but less easy to interpret. Pupil reactions are rarely helpful. Since there are no clear norms for the correlation between acuity and stereoacuity, these tests are difficult to interpret. The confusion–refraction test is very useful (see Fig. 63.5).

Bilateral

This group is the most difficult to diagnose as non-organic but they nearly always have associated functional field defects that can establish the diagnosis.

1. The finding of an acuity that greatly varies in terms of the angle subtended at different distances is an indicator of VCD. By the use of a second chart with different sized figures or a mirror placed so as to hide the increased distance between the patient and the chart, the patient may be induced to read letters of a size that they were not previously able to read. Similarly, near vision testers,

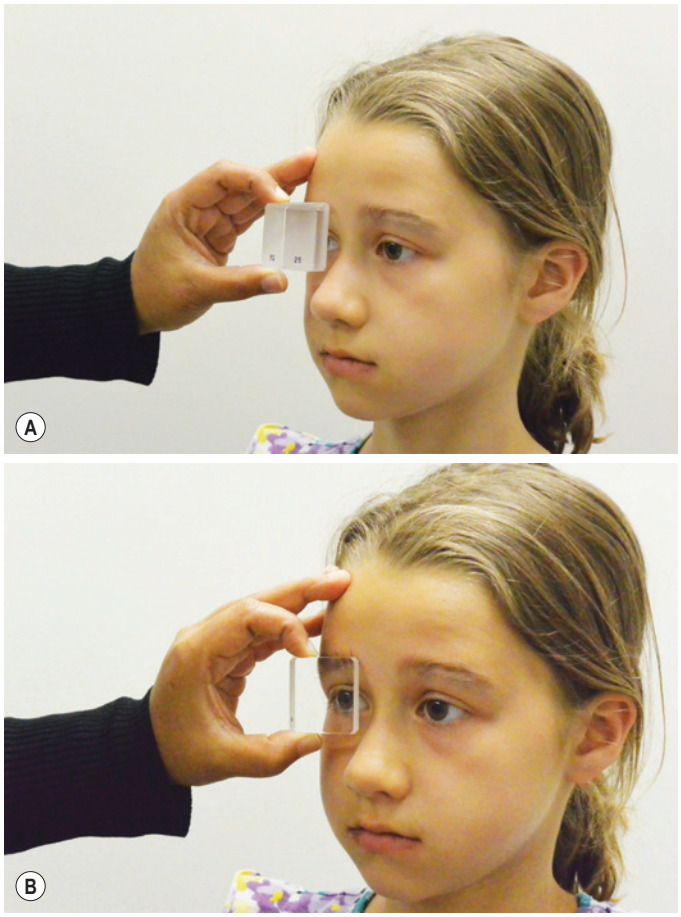

Fig. 63.4 Prism testing. A 25-diopter prism (A) elicits a movement even with only peripheral vision. A 4-diopter prism (B) requires central vision to elicit a movement. *(Image courtesy of Dr CJ Lyons and his completely normal collaborator.)*

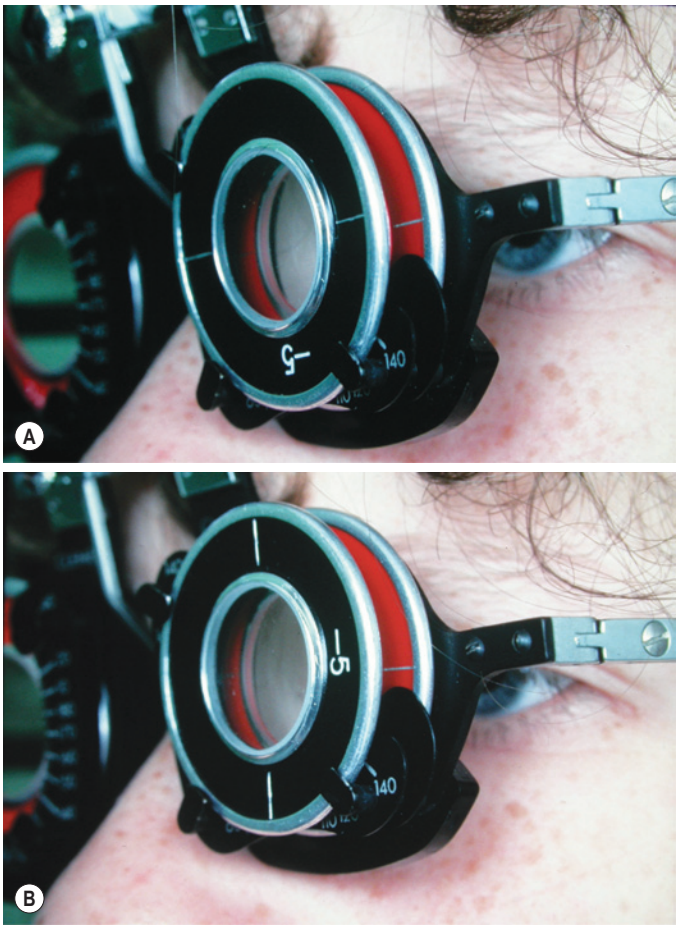

Fig. 63.5 The "confusion–refraction" test. The right eye is suspected of seeing better than the patient indicates. The ophthalmologist puts two canceling 5-diopter cylinders at the same axis in front of the left eye (A), obscures the patient's view of the test type by moving across him, switches the lenses to add to each other (B) and occlude the left eye. As the tester moves away, the patient is urged to read quickly. The left eye is obscured by the lens combination and the right is forced to be used; the patient does not usually detect the change to being forced to use the right eye.

using Snellen near equivalent letters, may show a disparity.

2. Severe bilateral loss of acuity due to organic disease is incompatible with good stereoacuity but a partial loss may be.
3. It is unusual for a patient to make a fusional movement when a 5-diopter prism is placed, base out in front of the other eye, if that eye has organically reduced acuity.

Visual field defects

Children often have fine vision (acuity) symptoms rather than peripheral vision (visual field) symptoms. When testing the visual fields, even normal children may perform in a non-organic manner if the examination is not carefully conducted. Abnormal fields are often associated with an apparently reduced acuity in functional visual loss, or sometimes with other symptoms including reading disability. The presence of a central scotoma should alert the clinician to the co-existence of pathology.[13]

Visual field testing is best done with a tangent screen. Tunnel vision is the most common of the non-organic visual field defects. In tunnel vision, the size of the field is the same at all distances; usually the field is also small. Conversely, purely constricted fields, as in retinitis pigmentosa, are conical, becoming larger as the patient moves away from the testing screen. The defect is always gross; there is an apparently dense defect involving the whole visual field only a few degrees away from the fixation point and this is the same size whether tested at 1, 2 or more meters away from the screen.

The defect, characterized by the "piling" of isopters (isopters all at or near the same eccentricity), is usually "sharp edged" so that both large and small targets are perceived at the same eccentricity, which is often remarkably constant. This "piling" of the isopters may occur even in the face of gross changes in the contrast between the brightness of the background and the target – a distinctly non-physiologic effect!

The absolute nature of the defect makes it easier to detect as being functional. Only clearly abnormal findings should be accepted as indicating a non-organic disorder.

1. In a confrontation technique, the patient alternates fixation between the examiner's eye and a fixation point on a stick held by the examiner, and at a time when he/she is fixing the examiner's eye, the fixation point is moved (Fig. 63.6). If the patient has organic disease with

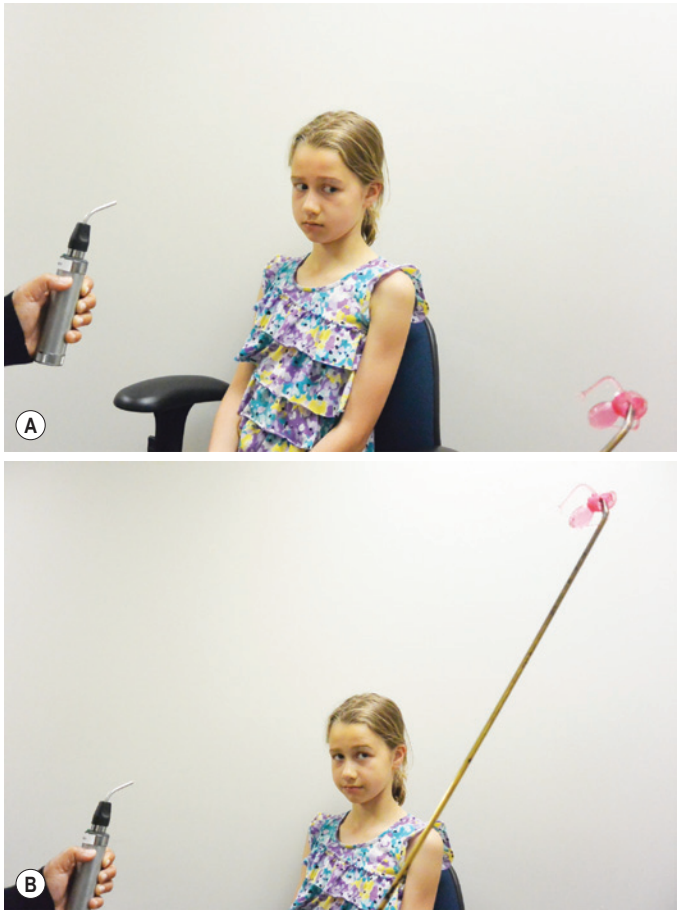

Fig. 63.6 A patient with very constricted visual fields is asked to look at the light (A), then at the figure on a stick, which is kept still. After doing this a few times, when the patient is looking at the light, the figure is moved to another part of the apparently blind part of the visual field (B). If this is done accurately, it is proof that there is a disparity between the tested and the actual visual field, and VCD is a likely diagnosis. *(Image by courtesy of Dr CJ Lyons and his completely normal collaborator.)*

constricted fields, he/she will have difficulty in relocating the spot, whereas a child with VCD finds it accurately.

2. On parting, the examiner fixes the patient in the eye and, without speaking, raises his/her hand from the elbow as though to shake hands. Given the variations of social and cultural backgrounds, most patients with organically constricted fields do not see the examiner's hand, while the child with VCD will.

Using large targets, one may obtain a square visual field, the target when moved inward from one direction being detected in areas previously blind. On successive testing the field may become smaller. If the target is moved inwards as though around a clock-face the target becomes detectable at an ever-decreasing distance from fixation giving rise to "spiraling." This also occurs in patients with organic disease so caution is necessary.

Hemifield defects are rare. A binasal field defect may be a non-organic phenomenon. Functional binasal defects are usually clear-cut; organic ones are not.

In the very rare, true complete bitemporal hemianopic visual field defect, convergence induces a postfixation scotoma, i.e. a wedge of blindness that extends behind the point of fixation. For example, if the patient fixes a point, such as the tip of a pencil held between the examiner's nose and himself/herself, the central features of the examiner's face disappear in the scotoma. This does not occur in a child with VCD.

Blue visual field testing targets are normally detected more peripherally than the red targets of identical size and brightness; the reverse is normal in VCD field testing.

It must be emphasized that an examiner skilled in testing for functional loss should not allow enthusiasm for testing make him/her either overlook co-existing organic disease or encourage the patient to give apparently non-organic results when none are normally present: 9% of 193 normal asymptomatic schoolchildren demonstrated non-organic fields.[14]

Confirmatory studies

VCD tends to be diagnosed late and over-investigated.[15] Once the clinician has made a *positive* diagnosis of non-organic visual loss and has excluded any disease clinically and by selective further investigations, there remains little to do for diagnosis. The more one investigates the child, the more stress one creates and the more one reinforces any underlying problem. If there is any doubt in the mind of the doctor, parent, or the older child about the possibility of organic disease, detailed neurophysiologic studies, including high-quality electroretinograms (ERG): pattern visually evoked potentials (Chapter 9), and fundus imaging studies (optical coherence tomography, autofluorescence, scanning laser ophthalmoscopy, etc., see Chapter 10) may be very reassuring and may inspire sufficient confidence to base the treatment only on reassurance. Non-organic symptoms may also occur in brain disorders, such as Batten disease or adrenoleukodystrophy, many of which, however, are accompanied by detectable neurophysiological changes.

Even with the best neurophysiological studies, it is possible to overlook organic disease, but choosing the optimal test helps avoid this pitfall. For instance, in someone with acuity loss and nothing to find clinically, standard ERGs may be normal but a pattern ERG will detect a commonly missed diagnosis – Stargardt disease. These are useful confirmatory studies in many cases and are risk-free.

Further investigations such as computed tomography or magnetic resonance imaging are not completely risk-free in children, especially if an anesthetic is needed, but they are indicated if the neurophysiological tests are abnormal or if there is real doubt in the doctor's mind.

Management

The exclusion of underlying pathology is the first priority and then the confirmation of the non-organic nature.[16] It is possible to find the underlying psychological cause in some cases; appropriate and sensitive modification of these underlying predisposing factors will abolish the symptom. It is useful to demonstrate the non-organic nature of the defect to the parents and to reassure them strongly that it is such a common problem that it could be regarded as a "normal stress reaction." It is very important to discuss the condition in full with both child and parents, in language appropriate to both.

Most cases can be managed by the ophthalmologist alone. It is important to maintain some contact or follow-up in case the problem does not improve or evolves outside the normal template of non-organic disorders.

The contributions of a psychiatrist or psychologist may be helpful in refractory cases but it is preferable to avoid involvement with too many professionals, because this may reinforce the problem.

The ophthalmologist should maintain a dispassionate approach to the patient. Doctors' emotional reactions to patients can be complex; anger at the patient for "wasting the doctor's time" or frustration are common reactions.

Prognosis

The prognosis is good[14,17] and strong reassurance with minimal follow-up is usually indicated. Psychiatric help may be useful in certain cases and it is likely that "integrative" and family therapy may improve the prognosis.[6] Good prognostic factors are: younger age, treatment compliance, early intervention, healthy family functioning, lack of psychopathology, insight, and acceptance by the family of the psychological nature of the illness.[15] If there is any indication of an underlying psychiatric or psychosocial disorder,[18] or of a more widespread psychoneurosis, for instance, if the patient has recurrent episodes especially affecting more than one system, the psychiatrist's help is mandatory.

Introduction

Pediatric ophthalmologists are often asked to evaluate children who are experiencing difficulties learning to read. Difficulty learning to read occurs in nearly 40% of students in the United States. A number of different factors can cause problems for early readers including deficits in spoken language skills, lack of general knowledge, inadequate instruction, insufficient reading practice, and dyslexia – a learning disability that affects reading.

Although we now know that dyslexia is a language-based learning disorder, historically, dyslexia was thought to be a vision-based disorder. This led to the development of many vision treatments including colored lenses/overlays and vision therapy that are widely promoted to the public today. Pediatric ophthalmologists can detect and treat vision problems, dispel myths, give the family proper information, and help the family find local specialists for educational evaluations and treatments.

Reading

Reading is the complex process of extracting meaning from written symbols. It is the major foundational skill for learning. While speaking is a natural process, reading and writing are neither natural nor easy for many students.[1–3] Strong oral language development is a prerequisite for successful reading.

Currently, the most accepted model for developing the ability to read is the *phonological model*. *Phonological awareness* is the ability to hear and manipulate individual speech sounds.[1–3] It is the main predictor of reading in every language.

Phonemes are the smallest units of sound that are used to form words. When strung together, they form words. Phonemes are not separated in speech; they are co-articulated (spoken together quickly with 8–10 phonemes per second) merging the individual sounds.

Phonics is the understanding of the relationship between the letters and the sounds that they make. Using phonics enables beginning readers to decode new written words by sounding them out and use that skill in reverse to spell or encode words.[1–3] Early readers use phonics to sound out words, but as readers become more fluent, they do not use phonics routinely.

Fluent readers are able to read connected text rapidly, smoothly, effortlessly, with little conscious attention to decoding.

Comprehension is an active complex process that requires automatic decoding and strong higher-order language skills, vocabulary, attention, working memory, inferential thinking, and general knowledge.[1–4]

In 2000 in the USA, the National Reading Panel found that phonemic awareness, systematic phonics, guided oral reading, vocabulary, and comprehension strategies must be taught explicitly in order to promote reading.[4]

Visual functions necessary to read

Reading requires visual acuity, accommodation, convergence, and a series of fixations and saccades. Not used in reading are the vestibular, optokinetic, and smooth pursuit ("tracking") systems.

A visual acuity of 20/20 is not necessary for reading. Accommodation is the ability to focus accurately at near and is necessary for near reading. Accommodative amplitudes are maximal in childhood and decrease naturally with age. The average amplitude of accommodation in children younger than 10 years is 14 diopters, corresponding with a near point of accommodation of 2–3 inches. Seven diopters, or 50%, is available for sustained near activity; thus, young children typically can read comfortably at 6 inches for a prolonged time. Convergence is the inward turning of the eyes used to obtain single binocular vision at near.

Reading uses saccadic eye movements that are of short duration and high velocity. Reading uses both forward

(rightward in English) saccades (85% of saccades) and backward or regression (leftward in English) saccades (15% of saccades). Scanning a line of text requires both right and left saccades.

The saccade length is dependent on the ability to recognize letters, the length of the word before the saccade, and how well the text was understood.[5] Backward saccades are used for verification and comprehension. They increase with the difficulty of the text and are also used to jump to the next line. Visual perception is suppressed during the saccade. Visual information is perceived during foveal fixations, which constitute 90% of our reading time. The duration of a fixation varies with the difficulty of the text.

Dyslexia – reading disability

Definition of dyslexia

The term *dyslexia*, or reading disability, is derived from Greek meaning "difficulty with reading words." The International Dyslexia Association and the USA National Institute of Child Health and Human Development (NICHD) definition of dyslexia[6] is:

> *A specific learning disability that is neurobiological in origin. It is characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede growth of vocabulary and background knowledge.*

Epidemiology of dyslexia

Dyslexia is the most common learning disability and has a prevalence in school-aged children in the United States of approximately 15% to 20%. Reading disability affects males slightly more than females, although schools identify boys at least twice as often as girls. Dyslexia occurs at all levels of intelligence. Children with speech and language delays or impairment often become poor readers. Dyslexia represents the lower portion of a normal distribution of reading ability. Dyslexia, itself, varies in degrees of severity; the majority of children with reading disabilities have relatively mild difficulties, with a smaller number having more severe reading disabilities. It is a lifelong condition, and does not represent a transient developmental lag. Untreated, a poor reader in first grade will, almost invariably, stay a poor reader. Adults with dyslexia continue to read slowly throughout life.[3,7]

Etiology of dyslexia

Dyslexia has a strong genetic basis; family history is one of the most important risk factors. Approximately 40% of siblings, children, or parents of an affected individual will have dyslexia.[3,7,8] Recent genetic linkage studies have identified many loci at which dyslexia-related genes are encoded. The candidate genes are implicated in neural migration and brain development. These brain changes seem to cause phonological and auditory processing abnormalities.

Neurobiology of dyslexia

Recent research using functional magnetic resonance imaging (fMRI) brain scanning has provided extensive scientific evidence that the brains of people with dyslexia are "wired" differently. For typical students, reading takes place predominantly in the left hemisphere. Sites include the inferior frontal (Broca) area, (articulation, naming, and silent reading), areas in the posterior brain, the parietal temporal region (word analysis), the occipitotemporal area (word-form and fluency), and the posterior inferior temporal cortex (word retrieval). People with dyslexia demonstrate a dysfunction in the left hemisphere posterior reading areas and show compensatory use of the bilateral inferior frontal gyri and the right occipitotemporal area.[9] The dyslexia-specific brain activation profile has been shown to improve following successful evidence-based phonologic remedial intervention.[10] In people with dyslexia, the white matter connections between the different brain areas used for reading may be weak and slow functioning. (Fig. 64.1).

Dyslexia is a language-based learning disorder

Most people with dyslexia have a phonologic deficit leading to difficulties identifying the individual sounds that make up words, and/or connecting letters to those sounds. Weak phonological skills make it difficult to decode and identify words causing problems with fluency, comprehension, spelling, and writing.[1–3,7,8] Children with more severe forms of dyslexia may have additional language problems such as deficits in rapid automatized naming, speech perception, verbal short-term working memory, sight word recognition, vocabulary, and comprehension, or have problems with attention.

Children with dyslexia often have trouble with *reading comprehension* because of slow and inaccurate decoding,[1–3,7] while most have average comprehension when listening.

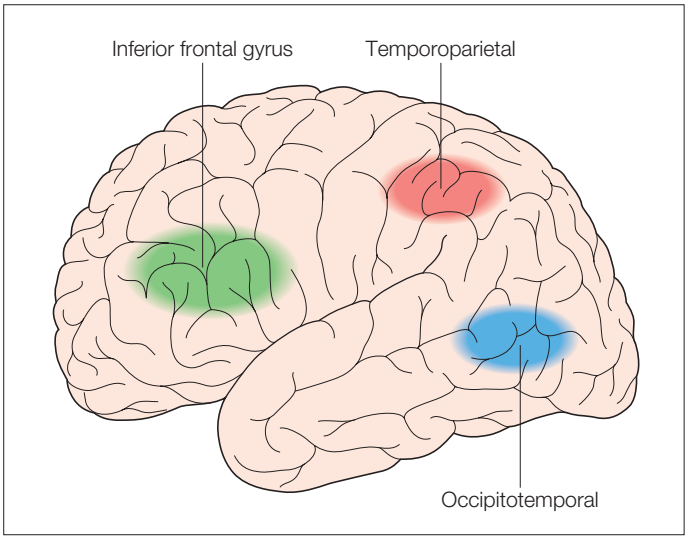

Fig. 64.1 Neural systems used for reading. The three important systems used for reading are in the left hemisphere: (1) Anterior system in the interior frontal region; (2) dorsal temporoparietal system involving the angular gyrus, supramarginal gyrus, and posterior portions of the superior temporal gyrus; (3) ventral occipitotemporal system involving portions of the middle temporal gyrus and middle occipital gyrus. *(Adapted with permission from Shaywitz SE, Shaywitz BA. The science of reading and dyslexia. J AAPOS 2003; 7: 158–66.)*

Approximately 10% of children with reading disabilities show decreased comprehension in the absence of decoding or word recognition problems.

A controversial vision theory of dyslexia – the magnocellular deficit theory

As some children with dyslexia report headaches or visual symptoms,[8] some authors have implicated a deficit in the magnocellular visual system as the cause of dyslexia in this subset of patients. The visual system is composed of two parallel systems: the *magnocellular (large-celled) (transient) system* and the *parvocellular (small-celled) (sustained) system*. The magnocellular system suppresses the parvocellular system at the time of each saccade. This suppression of the parvocellular system prevents activity elicited during one fixation from spilling over into the next. The magnocellular deficit theory of dyslexia proposes that this suppression is lacking, causing confusion and blur.[11]

Most of the evidence supporting the magnocellular deficit theory comes from contrast sensitivity and fMRI studies on visual movement processing. The research evidence in support of the magnocellular theory is equivocal at best. Researchers have calculated that more individuals without dyslexia have magnocellular deficits than those with dyslexia, challenging the view that dyslexia is the result of a magnocellular deficit.

Most investigators reviewing the data have concluded that magnocellular system deficits and associated visual trace persistence are not significant causes of dyslexia.[12–16]

Dyslexia is not a vision-based learning disorder

Vision problems are not more common in children with reading impairment.[17] Eye and vision problems including: high refractive errors, poor vision, nystagmus, saccadic dysfunction, difficulties with "crossing the midline" of the visual field, convergence insufficiency (CI), accommodative insufficiency (AI), strabismus, amblyopia, reduced stereopsis, binocular instability, a magnocellular deficit, or visual perceptual problems do not cause dyslexia and are not more common in dyslexic students.

People with dyslexia do not see things backwards. Difficulty maintaining proper directionality has been demonstrated to be a symptom, not a cause of reading disorders. Contrary to popular belief, the primary sign of dyslexia is *not* reversing letters; rather it is a difficulty sounding out words and also poor spelling.

A child who skips words or lines, or who has choppy reading, may be thought to have a "tracking problem." But *reading tracking* (fluent reading) has nothing to do with *eye tracking*. Both early readers and dyslexic readers use shorter forward saccades, more backward saccades, and fixate for longer periods of time. The saccadic pattern progresses toward the adult pattern as typical readers or dyslexic readers improve their reading skills.

Children reverse words, skip words and lines, or lose their place while reading because of language processing difficulties, not visual or perceptual disorders. Problems with language processing, memory, or attention cause them to struggle to decode a letter or word combination and have poor reading comprehension. Difficulties with fluent reading are the result of dyslexia and not the cause of the reading problem.

Box 64.1

Risk factors for dyslexia

Family history
Prematurity or low birth weight
Fetal exposure to drugs or alcohol
Hearing, speech, or language problems
Developmental delay
Neurological problems
Other chronic health problems

Box 64.2

Possible signs of dyslexia

Difficulty with rhymes
Difficulty learning the names of letters
Trouble connecting letters to their sounds
Difficulty sounding out words
Difficulty with sight word recognition
Slow reading
Poor or erratic spelling

Risk factors for dyslexia

A child should be observed for early indications of dyslexia if he or she has a family history of reading disabilities or has a history of other factors that may be predictive of reading disabilities (Box 64.1).

Possible signs of dyslexia

The signs and symptoms of dyslexia, found in Box 64.2, are indicators, not proof, of dyslexia. Comprehensive testing is necessary to diagnose dyslexia.

Other conditions associated with dyslexia

The comorbidity of *attention-deficit/hyperactivity disorder* (*ADHD*), especially the inattentive type, and dyslexia is common. Approximately 20% to 40% of people with dyslexia also have ADHD and vice versa.[18] Treatment of ADHD may contribute to improvement in the child's reading and overall performance in school.

Dyslexia often co-exists with other learning disabilities, most commonly *dysgraphia* (writing disability), *dyscalculia* (math disability), and dyspraxia (motor skill and coordination difficulties). Students with dyslexia also frequently encounter difficulties learning a foreign language and with organization.

Untreated or inadequately treated dyslexia may lead to frustration, poor self-esteem, and the development of anxiety or depression. Additionally, dyslexic children might be teased or bullied by others.

The importance of early detection of dyslexia

Reading screening tests should be performed on all students in the early elementary grades. Children who are found to be "at risk" for reading difficulties can be given immediate extra assistance in the USA pull-out program called *Response to Intervention* (*RTI*), which can lead to improved reading performance.

Early intervention is often very successful. Students whose dyslexia is identified and addressed in kindergarten or first grade have an approximately 90% chance of improving to grade level. Children identified after third grade have a 74% chance of continuing to struggle through high school. Ideally, it is important to identify and treat children before they leave third grade to have the best chance at academic success, but it is never too late.[19]

Diagnosis of dyslexia

The diagnosis and treatment of a child who has dyslexia depends on the ongoing, coordinated collaboration of a multidisciplinary team that may consist of educators, educational remediation specialists, special services, psychologists, and physicians.

Dyslexia is a clinical diagnosis that requires formal testing. The United States federal law called the *Individuals with Disabilities Education Act* allows parents to request evaluation for a "*Specific Learning Disability*" at their local public school (even if their child attends private school); alternatively, the testing can be conducted privately outside of school. Testing should be used to make the correct diagnosis of the specific type of learning disability and comorbid conditions in order to prescribe the proper therapeutic regimen. Comprehensive evaluation of the causes of a child's reading difficulty can be performed by clinical or educational psychologists, neuropsychologists, or developmental pediatricians, assuming that the clinician conducting the evaluation is properly trained in dyslexia and its assessment. These clinicians can also determine whether there are comorbid conditions, such as ADHD or other psychological issues, which might also interfere with a child's reading. Assessment limited to answering the question of whether the child has dyslexia can be performed by many reading/dyslexia specialists, educational therapists, or speech–language pathologists, again assuming they are properly trained in dyslexia and its assessment.

Family, medical, and school histories are important components in the evaluation. The diagnosis of dyslexia requires a knowledgeable synthesis of clinical history and multiple tests, as there is no single standardized test to identify dyslexia. On testing, most children with dyslexia demonstrate evidence of a phonologic deficit, rapid naming deficits, and/or other language problems.[20]

Treatment of dyslexia

Knowledgeable and skilled teachers are essential for the instruction of children with dyslexia.[2,20–23] Until recently, most elementary education teacher preparation college programs received minimal instruction in language structure, reading theory, reading development, signs of dyslexia, and methods of teaching students with dyslexia.[2,21,23] In 2010, the International Dyslexia Association developed a guide to prepare and certify the professional development of those who teach reading called *The Knowledge and Practice Standards for Teachers of Reading*.[23]

Educational therapists or educators who have been specially trained in reading disabilities can develop and implement intervention plans for children with dyslexia. In public schools, a team determines eligibility for special education and develops an *Individualized Educational Program* (*IEP*) for the student. Severe dyslexia will typically qualify a child for special education, but many children with milder dyslexia may never be properly diagnosed or treated and may "fall through the cracks."

Children with dyslexia learn best in small groups of others who are at the same level. The remediation needs to be tailored to address individual student skill deficits that were detected on the educational evaluation while utilizing their strengths. Practice in oral reading, not silent reading, improves reading fluency.[4] Unfortunately, struggling readers tend to avoid practice, when actually they need to practice much more. Remediation programs must continue long enough, usually 2 years or more, to have a lasting positive effect.

Since dyslexia is a language-based disorder, the educational treatment should target language development. Unfortunately, most schools do not teach reading in a way that is effective for children with dyslexia. Children with dyslexia need reading skills and the structure of language explicitly explained in patterns that are logical, systematic, and multisensory (Boxes 64.3 and 64.4). Multisensory techniques involve the use of visual, auditory, kinesthetic, and tactile pathways simultaneously to enhance learning. The International Dyslexia Association calls multisensory evidence-based reading programs the *Structured Literacy Approach*.[24]

For early elementary school children with dyslexia, *remediations* are very important, while *accommodations* become increasingly important for students in middle school and beyond. Because people with dyslexia continue to read slower throughout life, accommodations can help allow access to higher-level thinking and reasoning skills (Box 64.5).

Children with dyslexia are not one homogeneous group, so there is no single preferred approach to meeting their educational and behavioral challenges. The overall prognosis for a child with dyslexia depends on the severity of dyslexia, patterns of strengths and weaknesses, early diagnosis, and the appropriateness, amount, intensity, and timing of the intervention.

Box 64.3

Explicit teaching of reading skills

Phonemic awareness
Intensive systematic phonics
Fluency training (guided oral reading)
Memorization of sight words
Vocabulary building
Comprehension techniques
Spelling and spelling rules
Writing

Box 64.4

Explicit teaching of the structure of language

Syllable instruction
Morphology (analysis of word parts)
Grammar
Syntax (sentence structure)
Semantics (analysis of meaning)
Pragmatics (interpretation of language in social contexts)

Box 64.5

Important accommodations for people with dyslexia

Extra time
Computers or other technology
Recorded books
Text-reading software
Note-takers
Spell-checkers
Testing alternatives (i.e. verbal testing)
Special quiet room for testing
Preferential seating

Parental involvement is crucial to their child's academic success. Parents need to learn about dyslexia and become their child's advocate. Children with dyslexia need positive emotional support from their teachers and family. Encouragement and positive reinforcement are nearly as important as the instruction itself. It is important to discover the social, athletic, and academic abilities and strengths of children with dyslexia, to encourage, and expand them, because we all succeed on our strengths. Working together, children and parents, in partnership with members of the medical and educational communities, can formulate and oversee a prescription for success.

Controversial treatments

A treatment is controversial if it is sold commercially prior to research, before preliminary research has been replicated, or if the treatment goes beyond what the research data supports.[25]

Colored/tinted lenses and overlays

In 1983, Irlen first proposed using tinted lenses for a specific group of adults with reading problems, which she originally called the *scotopic sensitivity syndrome* (SSS),[26] now also called the *Irlen syndrome* or the *Meares–Irlen syndrome*, or *visual stress*. The initial claims of Irlen were based on observations, students' anecdotal accounts, and no formal experimentation. Supporters contend that the syndrome affects 12% to 15% of the general population and 45% of those with learning problems.

People with this syndrome are thought to suffer from "perceptual dysfunctions" from sensitivities to particular wavelengths of light causing visual distortion, light sensitivity, and "visual stress." This is postulated to interfere with attention and reading, creating symptoms similar to dyslexia. Currently, the magnocellular deficit and cortical excitability theories are considered to be possible causes.

It is important to understand that SSS is *not* a recognized medical syndrome and there are no clearly established criteria for making the diagnosis; the only defining characteristic is the reported benefit of the colored filters themselves.

The Irlen method uses colored lenses or overlays in an attempt to reduce the offending wavelengths to correct "perceptual dysfunctions." Irlen claimed that tinted glasses resulted in instantaneous improvement in reading performance and comprehension. Irlen later clarified that tinted lenses do not treat language deficiencies, dyslexia, specific learning disabilities, or ADHD.

Many studies of the use of colored lenses with good methodology show negative results.[27–29] Others, cited as proof of Irlen lens efficiency, have been found to be inconclusive or invalid upon deeper analysis. Reviews of the literature found little evidence of benefit.[30–33] In spite of the lack of valid supporting evidence that SSS exists or that treatment is effective, Irlen, Wilkins, and Chromagen lenses and overlays are promoted to teachers and directly to the public. Additionally, many children who have worn colored glasses have been teased or bullied, further damaging their self-confidence.

Behavioral optometry

Skeffington was the Director of Education of the Optometric Extension Program from 1928 to 1976. His clinical experience led to the unproven *near-point stress theory*. Skeffington's "near-point stress theory" suggested that the reading demands of our culture are not consistent with the evolutionary development of the visual system, and that such tasks provoke a "biological stress response." The model proposed that binocular anomalies and refractive errors are not primary conditions but products of underlying "near-point stress." Behavioral optometrists believe that this model predicts a group of clinical findings that are not easily explained by other clinical models.[34]

More recently, Scheiman proposed dividing the behavioral optometric evaluation and treatment into three categories: (1) visual acuity, refraction, and eye health disorders; (2) visual efficiency skills of accommodation, binocularity, and ocular motility; (3) visual information processing skills of visual discrimination, visual closure, visual memory, visualization, visual motor integration, and figure-ground perception.[35] (Note: some optometrists include visual acuity and refraction in the category of visual efficiency.)

The optometric literature has implicated problems with "visual efficiency" and "visual information processing skills" as being linked with reading disorders. Optometrists call these problems *learning-related vision problems*. Behavioral optometrists who advocate vision therapy claim that more than 60% of problem learners have undiagnosed vision problems contributing to their difficulties.[36] In opposition, the majority of studies have shown that eye and visual problems do not cause or increase the severity of dyslexia, and, that children with dyslexia have the same visual function and ocular health as typical readers.[17]

Vision therapy

A task force representing the College of Optometrists in Vision Development, the American Optometric Association, and the American Academy of Optometry formulated the following policy statement on "learning related vision problems"[37]:

> *Optometric intervention for people with learning-related vision problems consists of lenses, prisms, and vision therapy. Vision therapy does not directly treat learning disabilities or dyslexia. Vision therapy is a treatment to improve visual efficiency and visual processing, thereby allowing the person to be more responsive to educational instruction.*

Optometrists divide vision therapy into two broad categories: classic orthoptic techniques, to improve "visual efficiency," and "behavioral or perceptual vision therapy," to improve

"visual processing." Behavioral optometrists believe that vision therapy and "training glasses" will make reading more "efficient."

An optometric vision therapy program consists of supervised in-office and reinforcing at-home exercises performed over weeks to months. In addition to "eye exercises," "training glasses," prisms, filters, patches, electronic targets, specialized instruments, balance boards, metronomes, and computer programs may be used.

Vision therapy programs are extremely varied and may include occupational therapy and educational therapy techniques.

Optometrists use various methods to evaluate saccadic eye patterns to detect "inefficient readers." However, there is no basis for testing the saccadic pattern because it is driven by the cognitive needs of reading itself and not from an oculomotor dysfunction. Also, there is no evidence that demonstrates that saccadic training benefits reading. Treating symptomatic CI and/or AI will allow children to read for longer periods of time but will not treat dyslexia. Since no consistent relationship has been demonstrated between visual perception and academic performance or reading ability, there is also no basis for training visual processing.

"Training glasses"

"Training glasses" or "developmental lenses" are low-plus power glasses (+0.25 D to +1.00 D) with or without bifocals or prisms, that behavioral optometrists recommend to help the visual system "develop" and "mature normally," and to relieve reading "stress." They are frequently used with vision training.

In 2000, Jennings reviewed the behavioral optometric literature for the United Kingdom College of Optometrists. This revealed no convincing experimental evidence of any benefits from a low-plus prescription.[38]

Vision therapy and colored/tinted lenses and overlays do not help dyslexia

The optometric literature has been thoroughly reviewed repeatedly over the years,[30,39,40] including several thorough reviews by optometrists[30,38,41]; there is no valid evidence that "training glasses" or vision therapy prevent the development of visual disorders, allow children to be more responsive to educational instruction, or are an effective primary or adjuvant treatment for dyslexia or other learning disabilities. The purported benefits of vision therapy often can be explained by the placebo effect, increased time and individualized attention, maturation changes, or the educational remedial techniques with which they usually are combined.

Because, dyslexia is not a vision problem, methods designed to improve visual function by "training" using "eye tracking exercises," behavioral vision therapy, or colored lenses/overlays have not been found to help children with dyslexia learn to read or improve their long-term educational performance.

The use of these methods contradicts all of the evidence that demonstrates that reading skills depend on language-based processes, such as phonological awareness.

Despite the lack of corroborating research findings with statistical validity, vision therapy and tinted lenses/filters are widely available and directly marketed to parents, teachers, and educational and occupational therapists. These methods rely on anecdotal evidence, instead of scientific evidence, to convince the public and behavioral optometrists often overstate the therapy's effectiveness and the types of problems they may address.

Since using ineffective methods of treatment may give parents and teachers a false sense of security that a child's reading difficulties are being addressed and may delay proper evaluation and treatment, parents and teachers should be advised to evaluate these therapies and become wise consumers.

If vision therapy or colored lenses/overlays have been prescribed, it is recommended that the patient get another opinion by a pediatric ophthalmologist.

The role of the pediatric ophthalmologist

As the first step in reading involves being able to see the printed word, some parents and teachers may understandably suspect that eye problems are the cause of the reading problem. Because routine pediatric vision screening is not designed to detect problems with near vision, children with suspected or diagnosed learning disabilities should undergo a comprehensive eye examination by a pediatric ophthalmologist.

As pediatric ophthalmologists, we are often the first professional evaluating the child, which places us in a unique position to evaluate and treat the child, dispel the myths, give the family proper information, and help them get on the right track. Thus, it is important that pediatric ophthalmologists are well informed on the subject of dyslexia and serve on the dyslexia evaluation team.

Treatable vision problems can occur in addition to a primary learning problem or can masquerade as ADHD or a learning difficulty. Vision problems occur in 5–10% of early elementary students and up to 25% of high school students. Although vision and eye problems may cause trouble seeing the printed word, they rarely result in difficulty learning to read.

Treatable conditions include refractive errors, strabismus, amblyopia, CI, AI, dry eyes, blepharitis, allergic conjunctivitis, and others. Many of these conditions can be treated with corrective eyeglasses and generally will show benefit very quickly. Glasses, however, do not treat reading disorders or dyslexia.

Ophthalmic history and examination

Pediatric ophthalmologists are often asked to evaluate children who are experiencing difficulties learning to read, and this may or may not be the chief complaint. The medical history of school-age children should ask how they are doing in school. You should determine whether there are any difficulties with school, reading, sounding out words, concentration, or attention. The past history should include prior evaluations, diagnoses, and/or treatments for learning disorders, ADHD, or chronic health problems that may have caused school absences. It is important to determine whether there is a family history of dyslexia/reading difficulties or other risk factors for reading difficulties such as premature birth, speech or motor developmental delay, or other neurological problems. The answers to these questions will help guide you as to whether to recommend a dyslexia evaluation for this child.

The ocular history should include any eye or vision complaints, such as blurry vision at distance or near,

diplopia, words that move on the page, headaches, fatigue, or eye itching, burning or tearing. Children with dyslexia whose eyes are normal may present with symptoms such as these. In addition, it is important for the ophthalmologist to recognize that healthy children often have visual complaints from normal visual phenomena, such as physiologic diplopia and relaxation of accommodation.[42] Also, be aware that most children complaining of eyestrain and headaches have a normal eye examination, whereas most children with refractive error, amblyopia, or strabismus have been found to be free of eyestrain, making these complaints a poor marker of eye conditions.[43] Also, ask about the child's use of computers, laptops, hand-held devices, and video games. Be sure to determine if the child experiences similar problems while using these devices. It is unlikely that a near vision abnormality is significant if the child plays on these devices for many hours.

The ophthalmologist should perform a complete dilated eye examination, including cycloplegic refraction. Emphasis should be placed on the evaluation of visual acuity at the distance and near, refractive errors, ocular alignment, amblyopia, versions and ductions, binocular function, stereopsis, accommodation, and convergence. In addition, the child should read out loud a few sentences at their reading level. Even though it is not up to you to diagnose dyslexia, this will give you an indication of the patient's ability to sound out words, and degree of sight word recognition and general fluency. An assessment of the child's activity level, attention span, alertness, cooperation, and ability to communicate should be noted. To obtain correct information in all portions of the examination, it is important to engage the child to obtain his or her full effort. Also, care needs to be exercised to avoid spurious findings.

Visual acuity testing at distance and near with non-letter symbols may be necessary for testing children with dyslexia or other learning disabilities. A child with a significant refractive error may have difficulty seeing the board or reading small print. Refraction using cyclopentolate should be performed to accurately assess refractive errors. The average young school-aged child is mildly hyperopic, averaging between +1.00 D and +2.00 D. Glasses should be considered if the child is greater than or equal to +4.50 D or +3.00 if symptomatic.

The monocular near point of accommodation can be measured by conventional push-up technique using a ruler, the Royal Air Force Rule, or Prince Rule. Before cycloplegia, dynamic retinoscopy can provide a rapid assessment of accommodative function and may be helpful in evaluating a child with high hyperopia, accommodative lag, or AI. The accommodative amplitude can be assessed by using increasing minus lenses in the phoropter while reading at near. Symptomatic AI, an exceedingly uncommon condition in children, can cause blurring and discomfort at near. It is typically associated with uncorrected high hyperopia, occasionally secondary to medications or anxiety, or rarely a primary condition. It can be treated with correction of the hyperopia or with bifocals when indicated. Importantly, children with developmental delay or Down syndrome often hypo-accommodate and may benefit from spectacle correction at lower thresholds of hyperopia.

Accommodative facility can be assessed by alternately applying −1.50 D and +1.50 D lenses in the phoropter (using the 3.00 D coarse adjustment) while the child reads at near.

The near point of convergence should be tested using an accommodative target and measured with a ruler. Distance and near convergence amplitudes can be measured by using a base-out horizontal prism bar or rotary prism while the child is reading.

CI is often asymptomatic. Symptomatic CI can cause discomfort, eyestrain, blurry vision, jumpy vision, diplopia, and headache. It can interfere with a child's ability to concentrate on print and occasionally lead to limited fluency. Because of this behavior in the classroom, CI may be confused with ADHD or dyslexia. Therefore, it is important that ophthalmologists be familiar with CI and its testing to make the correct diagnosis. Depending on the definition chosen, the prevalence of CI varies greatly. It is uncommon in early elementary school children, and patients typically present as teenagers or young adults during extended periods of studying.

Symptomatic CI can be treated with home, computer or office-based orthoptic exercises. Alternatively, for other patients, reading glasses with base-in prism or occlusion during reading can be used to treat the symptoms of diplopia but not the underlying CI.

The treatment of asthenopic symptoms, accommodative difficulties, or symptomatic CI can help reading become more comfortable and may allow reading for longer periods of time, but this approach does not directly improve decoding or comprehension and will not treat dyslexia or ADHD, if present.

A careful external ocular examination should be performed to determine whether the child has problems causing eye irritation that could secondarily interfere with the ability to concentrate and learn. These problems include dry eyes, blepharitis, or ocular allergies. Finally, a dilated retinal evaluation should be performed to detect retinal or optic nerve problems.

Recommendations

The pediatric ophthalmologist on the dyslexia management team should identify and treat any significant vision problem according to standard principles of treatment. The need for additional medical, psychological, educational, or other appropriate evaluations and evidence-based treatments should be discussed with the parents. You should communicate your findings and recommended ophthalmic treatment to the primary care physician and school, and also inform them that you are recommending educational evaluation and remediation as opposed to vision therapy.

Controversial therapies are frequently featured and aggressively promoted by the media, convincing parents to try them. As advocates for patients, ophthalmologists can inform families that dyslexia is a language processing problem, not a vision problem, and that struggling readers need educational evaluation and remediation, not vision-oriented remedies such as eye exercises or colored lenses. Pediatric ophthalmologists should discourage parents from enrolling their children in unproven programs, saving their valuable time and resources for evidence-based educational therapies.

It is *not* enough to reassure the parents that the child's eyes are fine, and that the eyes are not causing the reading problem. The ophthalmologist should give *specific* guidance on how to obtain a reliable diagnosis of the cause of the reading difficulty, and how to obtain evidence-based remediation. If you do not, the parent, who just wants to help their child, may seek help from practitioners offering unvalidated therapies.

To this end, the ophthalmologist should compile a personalized list of local specialists for evaluation and treatment, so that if dyslexia is suspected, you can assist families in finding resources that are available in the community. Ophthalmologists should also help families become educated by giving parents handout information and recommendations for websites, books, and articles (Table 64.1). The American Association for Pediatric Ophthalmology and Strabismus (AAPOS) and the American Academy of Pediatrics (AAP) have patient education brochures on learning disabilities, dyslexia, and ADHD that can assist families.

REFERENCES

Many neurometabolic diseases present in childhood with ophthalmic manifestations. In some conditions, the characteristic ophthalmic features may lead toward an early diagnosis. In others, the ophthalmic complications present later in the course of the disease but can have significant visual effects for the patient. Findings such as vertical or horizontal gaze palsy, characteristic corneal changes, cherry-red spot, retinopathy, or optic atrophy, particularly in the presence of progressive systemic or neurologic disorders, should alert the ophthalmologist to the possibility of a neurometabolic disorder.[1]

Although most of the diseases described here are rare, many are now treatable; it is important that the pediatric ophthalmologist is aware of them.

Lysosomal disorders

Lysosomal storage disorders (LSDs) arise as a result of defects in lysosomal enzymes, receptor targets, activator proteins, membrane proteins, or transporters, causing accumulation of specific substrates within lysosomes. This leads to impairment of cellular and tissue function.[2] Most LSDs have central nervous system (CNS) and systemic defects; untreated, many result in death in infancy or childhood. While each type of LSD is rare, their total incidence is 1 per 7000–8000 live births. There are characteristic ocular features in some of the LSDs (Box 65.1), which should alert the ophthalmologist to their possibility, particularly when seen in a child with suggestive systemic features such as organomegaly, skeletal abnormalities or joint stiffness, coarse facial features, progressive neurologic deterioration, or unexplained pain. The pediatric ophthalmologist has an important role in facilitating early diagnosis so appropriate treatment can be started, as well as in monitoring and managing the ophthalmic complications.

All LSDs have autosomal recessive inheritance except for Danon disease, Fabry disease, and Hunter disease (mucopolysaccharidosis type II), which are X-linked. Some disorders are more prevalent in a particular geographic area or in certain populations, such as Gaucher, Tay–Sachs, Niemann–Pick type A, and mucolipidosis IV, which are 50–60 times more prevalent in the Ashkenazi Jewish population.[2] There is often a wide variation in phenotype, including severity of symptoms, systems affected, and presence of CNS manifestations. In many disorders such as Gaucher and Tay–Sachs, there are infantile, juvenile, and adult forms. Diagnosis of an LSD is usually made using biochemical assay of blood, urine, or skin fibroblasts, and confirmed by molecular genetic testing.

There have been major advances in the treatment for many LSDs. Enzyme replacement therapy (ERT) provides an exogenous source of enzyme by repeated intravenous infusions but it does not cross the blood–brain barrier. Hematopoietic stem cell transplantation (HSCT) provides donor stem cells to produce the deficient enzymes; these cells can enter the brain and ameliorate the neurological problems in some disorders. Trials of intrathecal ERT and gene therapy are being undertaken in some disorders. The drug, miglustat, uses a different approach, reducing production of the substrate for the missing enzyme in Gaucher disease and Niemann–Pick disease type C. Despite these advances, there are many systemic and neurologic complications, requiring medical and surgical management and a multidisciplinary approach.

Mucopolysaccharidoses

The mucopolysaccharidoses (MPSs) are a heterogeneous group of multisystem disorders resulting from accumulation of glycosaminoglycans within ocular and systemic tissues. They are classified according to phenotype, and result from deficiency of different lysosomal enzymes (Table 65.1). They are all inherited in an autosomal recessive manner apart from MPS II, which is X-linked. Visual impairment is common, and can be due to corneal opacification, optic neuropathy, retinopathy, or cerebral visual impairment.[3]

Box 65.1

Ocular manifestations of lysosomal storage disorders

Cornea – diffuse corneal clouding
Corneal verticillata
Lens – characteristic cataract
Macula – cherry-red spot
Bull's eye maculopathy
Vasculature – retinal and conjunctival vascular tortuosity
Optic neuropathy
Ocular motor apraxia (saccadic initiation failure)

Table 65.1 Mucopolysaccharidoses and underlying enzyme deficiencies

Type	Eponym	Stored material	Enzyme deficiency
MPS IH	Hurler	DS, HS	Iduronidase
MPS IS	Scheie	DS, HS	Iduronidase
MPS IH/S	Hurler–Scheie	DS, HS	Iduronidase
MPS II	Hunter	DS, HS	Iduronidase sulfatase
MPS IIIA	Sanfillipo A	HS	Heparan *N*-sulfatase
MPS IIIB	Sanfillipo B	HS	*N*-Acetylglucosaminidase
MPS IIIC	Sanfillipo C	HS	Acetyl-CoA-glucosaminidase-acetyltransferase
MPS IIID	Sanfillipo D	HS	*N*-Acetylglucosamine-6-sulfatase
MPS IVA	Morquio A		Galactosamine-6-sulfatase
MPS IVB	Morquio B		α-Galactosidase
MPS VI	Maroteaux–Lamy	DS	*N*-Acetylgalactosamine-4-sulfatase
MPS VII	Sly	HS, CS, DS	α-Glucuronidase
MPS IX	Natowicz	Hyaluronic acid	Hyaluronidase

CS, Chondroitin 6-sulfate or chondroitin 4,6-sulfate; DS, dermatan sulfate; HS, heparan sulfate; MPS, mucopolysaccharidosis.

Systemic manifestations in MPS

Patients with MPS often present in infancy with recurrent ear infections, inguinal or umbilical hernias. Over the first 2 years, many patients develop coarse facial features, with a flat nasal bridge, thickened skin, and hypertrichosis. Skeletal problems include joint stiffness and kyphoscoliosis (Fig. 65.1); conversely, MPS IV patients have joint laxity and very short stature. Developmental regression and difficult behavior are the main feature in MPS III; learning difficulties are also present in severe cases of MPS I, II, and VII. Valvular heart disease, deafness, and obstructive sleep apnea are also common.

Corneal clouding in MPS

Corneal clouding is a characteristic feature of several of the MPS disorders (MPS I, MPS IV, MPS VI, and MPS VII), and may be present from infancy. Deposition of glycosaminoglycans (GAGs) within the corneal stroma leads to progressive diffuse corneal opacification, described as having a "ground-glass" appearance (Fig. 65.2). Corneal opacification is milder in the less severely affected MPS I phenotype, and is not a feature of MPS II or III. Patients with MPS may have coarsening of facial features with pseudoexophthalmos (Figs 65.3 and 65.4), which can result in corneal exposure and subsequent vascularization.

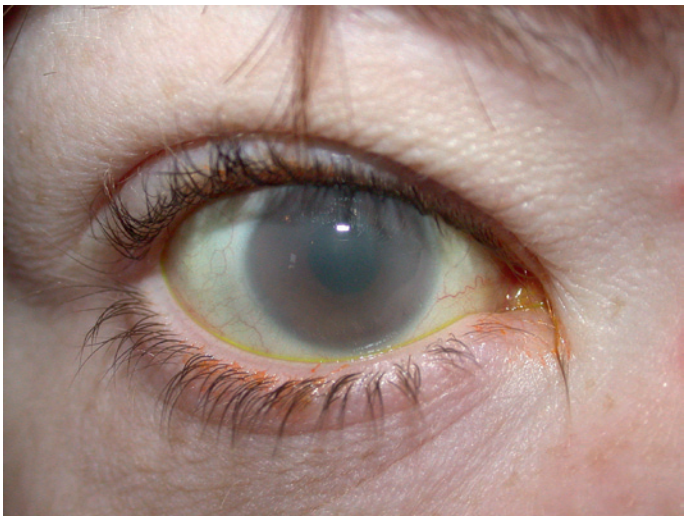

Fig. 65.2 Corneal clouding in a patient with mucopolysaccharidosis I.

Fig. 65.3 Pseudoexophthalmos due to shallow orbits in a 17-year-old patient with mucopolysaccharidosis VI.

A patient with mild corneal clouding may be asymptomatic, but photophobia and reduced vision occur as the opacification worsens. GAG deposition can increase corneal thickness[4,5] and affect corneal hysteresis,[6] thus affecting the accuracy of intraocular pressure measurements. Corneal transplantation (penetrating keratoplasty or deep lamellar keratoplasty) may result in improvement in vision when severe corneal opacification causes visual loss[7,8] with no re-opacification of the graft in up to 11 years follow-up.[7] However, an assessment of potential benefits of corneal transplantation must consider the presence of coexistent retinopathy, optic nerve dysfunction, and cerebral visual impairment, as well as the significant anesthetic risks.

Hypermetropia and strabismus in MPS

The majority of patients with MPS are hypermetropic due to changes in corneal refraction and reduced axial length.[3,9] Strabismus and amblyopia are common.[3]

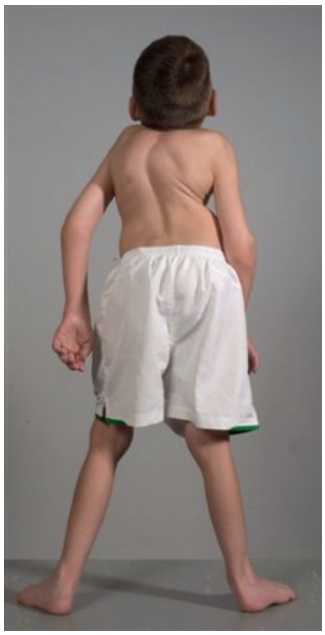

Fig. 65.1 Kyphoscoliosis in mucopolysaccharidosis I.

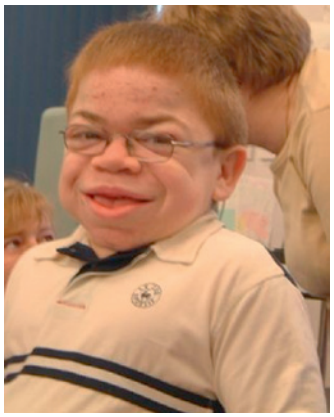

Fig. 65.4 Coarsening of facial features in a 16-year-old patient with mucopolysaccharidosis II.

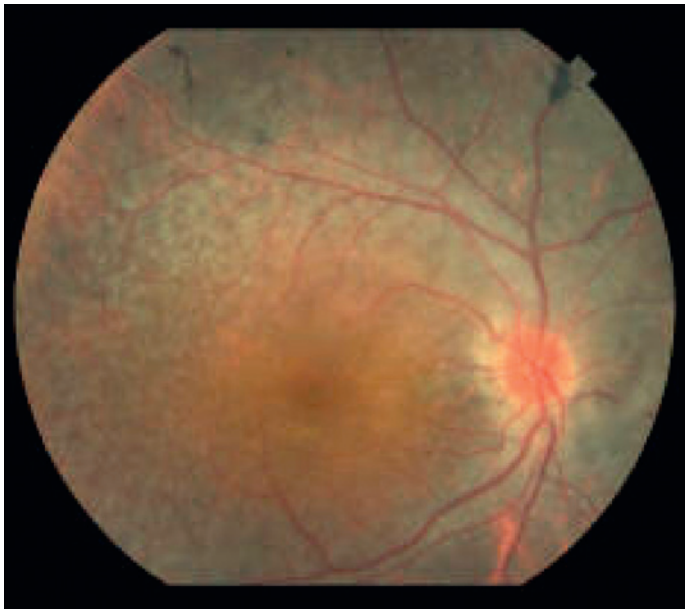

Fig. 65.5 Retinal pigment epithelial changes in a patient with mucopolysaccharidosis I. Vision was 6/60 despite minimal corneal clouding.

Retinopathy in MPS

Progressive retinopathy occurs in MPS I, II, and III, but is not usually a feature of MPS IV or VI.[10] The patient may experience night blindness and problems with peripheral vision, but this may go unnoticed due to the visual loss associated with corneal opacity. Signs of retinopathy include retinal pigment epithelial (RPE) atrophy and pigment clumping (Fig. 65.5), arteriolar narrowing, optic disc pallor, and macula changes. Serial electroretinography (ERG) may show initial deterioration of rod-mediated responses, followed by involvement of cones. Maculopathy and choroidal folds have been described in MPS II associated with a ring scotoma; optical coherence tomography demonstrated extrafoveal photoreceptor loss and cystoid spaces within retinal layers.[11]

Optic disc swelling and atrophy

The optic nerve often has a "full" appearance in patients with MPS (Fig. 65.6A,B). GAG deposition occurs in the ganglion cells and within surrounding sclera causing an enlargement of the nerve and thickening of the sclera[12] (Fig. 65.6C,D). In addition, patients with MPS may develop raised intracranial pressure and the resultant optic nerve compromise may lead to profound visual loss. Visual evoked potential may be useful in monitoring optic nerve function prior to consideration of corneal transplant.

Glaucoma

Glaucoma may arise in MPS due to accumulations of GAGs within the anterior segment resulting in a narrow angle, and within the trabecular cells leading to open angle glaucoma as a result of outflow obstruction. It has been described in MPS I, II, IV, and VI.[10,13] Difficulties in diagnosis and assessment of glaucoma arise in patients with MPS due to inaccuracy of intraocular pressure measurements, corneal clouding hampering assessment of the angle and disc, the presence of coexistent disc pathology, and difficulties with visual field assessment.[13]

Punctate lens opacities occur in MPS IV.

Treatment and prognosis for MPS

The prognosis in MPS is variable depending on the phenotype; some children die before their second decade and others survive into their fifth or sixth decade. ERT is available for MPS I (laronidase), MPS II (elaprase), MPS IV (elosulfase alfa) and MPS VI (galsulfase), but it does not enter the brain and has limited effect on skeletal problems. Early hematopoietic stem cell transplantation (before the age of 2 years) using either matched bone marrow or umbilical cord blood cells is the best treatment for patients with severe MPS I (Hurler).

Management is multidisciplinary, coordinated by a pediatrician with input from many other disciplines, including regular assessment by a pediatric ophthalmologist.

Anesthesia should be undertaken in a department with expertise in the MPS disorders. Children with MPS are difficult to intubate, due to MPS deposition around the airway and vulnerable cervical spinal cords (especially in MPS IV).

Glycoprotein disorders

α-Mannosidosis (α-mannosidase deficiency)

α-Mannosidosis is associated with mild facial coarsening (Fig. 65.7), skeletal abnormalities, a variable degree of learning difficulty, and deafness. A severe form (type I) results in early death from CNS manifestations and recurrent infections. In the attenuated form (type II), hearing loss and skeletal abnormalities become evident usually before the age of 10 years, following which ataxia and mental retardation become manifest. In a multicenter study of 45 patients aged 1–42 years, two had mild corneal clouding, two had cataracts and two had poor vision due to pigmentary retinal degeneration.[14] Other ophthalmologic features include hypermetropia, amblyopia, cataracts, and strabismus.[15] The lens opacities are posterior cortical with multiple discrete clear round vacuoles lying at different depths in the lens, best seen by slit-lamp retroillumination.[16] ERT is being developed for this disorder.

Fucosidosis

Fucosidosis is a progressive neurodegenerative disease with seizures, mild coarsening of the facies, skeletal dysplasia, and angiokeratomas. Affected children have conjunctival and retinal vascular tortuosity. Central "lobulated" corneal opacities may occur at an early age, and later a bull's eye maculopathy.[17] HSCT may improve the neurological outcome if undertaken in the early stages.

Fig. 65.7 A child with mannosidosis showing the mild coarsening of the features. When older, there was an increase in the facial coarsening.

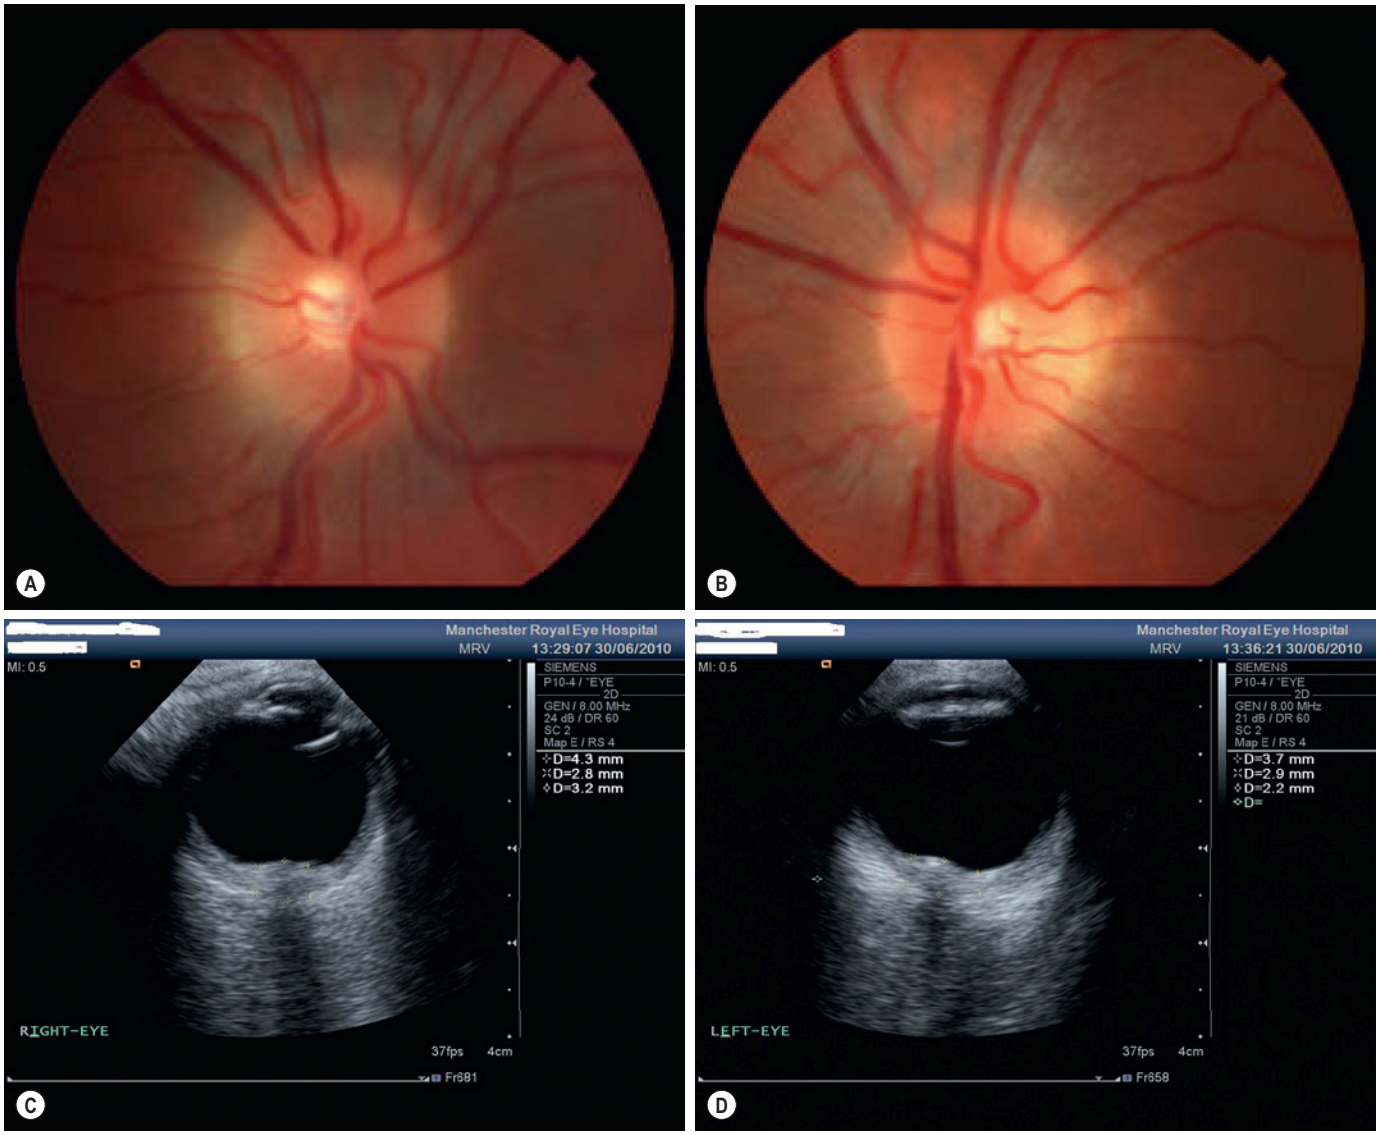

Fig. 65.6 (A,B) "Full" optic discs in a 14-year-old patient with mucopolysaccharidosis II. (C,D) Ultrasound of the same optic nerves as in (A) and (B), showing thickening of sclera and increase in diameter of the optic nerve. *(Courtesy of Mr Vishwanath, MREH.)*

Sialidosis (mucolipidosis type I)

Sialidosis is a result of α-*N*-acetylneuraminidase deficiency; patients excrete sialyloligosaccharide in the urine.

Type 1 sialidosis "cherry-red spot myoclonus syndrome" presents in late childhood with visual loss, myoclonic epilepsy, and ataxia. A cherry-red spot occurs (Fig. 65.8), associated with thickening of the paracentral nerve fiber layer on spectral optical coherence tomography (OCT).[18,19] Type 2 sialidosis has an earlier onset with coarse facies, developmental delay, hepatomegaly, and dysostosis multiplex (Fig. 65.9). In addition to cherry-red spots, patients with sialidoses may have nystagmus, punctate lens opacities, optic atrophy, corneal clouding, and visual field defects.[20–22]

Sialic acid storage diseases

These result from a block in lysosomal efflux of sialic acid as a result of mutations in *SLC17A5*, encoding the lysosomal protein sialin. They range in severity from infantile sialic acid storage disease (ISSD) with coarse facial features and fair complexion, severe developmental delay, hepatosplenomegaly and cardiomegaly, and death in early childhood, to Salla disease with slowly progressive mental retardation, ataxia, spasticity, and epilepsy. In ISSD, children may have albinoid fundi.[23] In Salla disease, strabismus, nystagmus, and optic atrophy may occur.

Mucolipidoses

Mucolipidosis (ML) II and III are autosomal recessive disorders caused by deficiency of *N*-acetylglucosamine-1-phosphotransferase, which phosphorylates carbohydrate residues on *N*-linked glycoproteins. This prevents lysosomal enzymes from entering the organelle.

ML II or "I cell" disease presents at an early age with neurologic degeneration, joint stiffening, facial coarsening, and kyphoscoliosis (Fig. 65.10). Death occurs in childhood. There is retinal degeneration and corneal clouding.

ML III is milder, with a slowly progressive course and survival to adulthood. Ophthalmic features include corneal clouding,

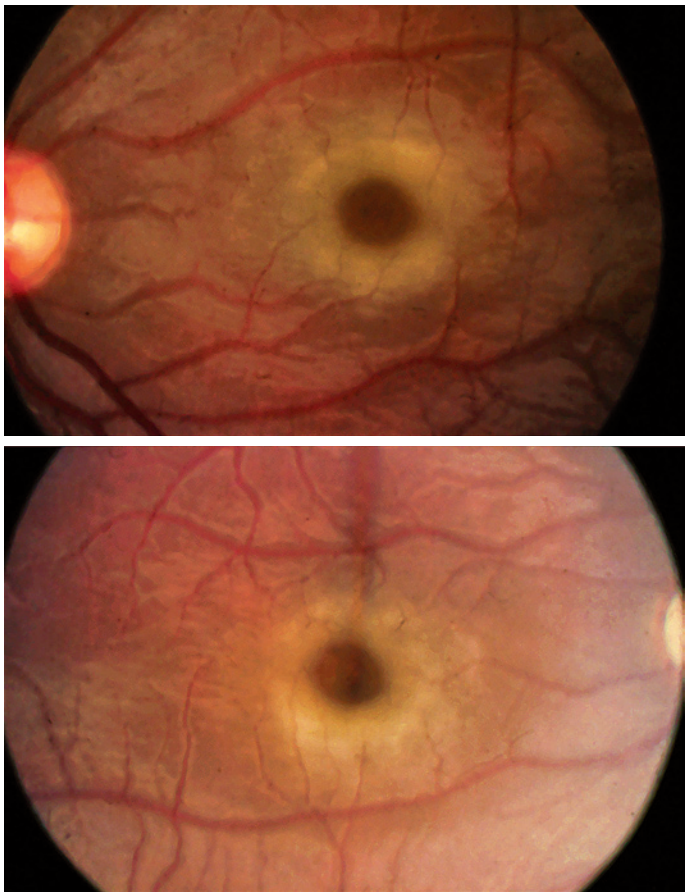

Fig. 65.8 Cherry-red spot in a patient with sialidosis type 1. *(Mr M.D. Sander's patient.)*

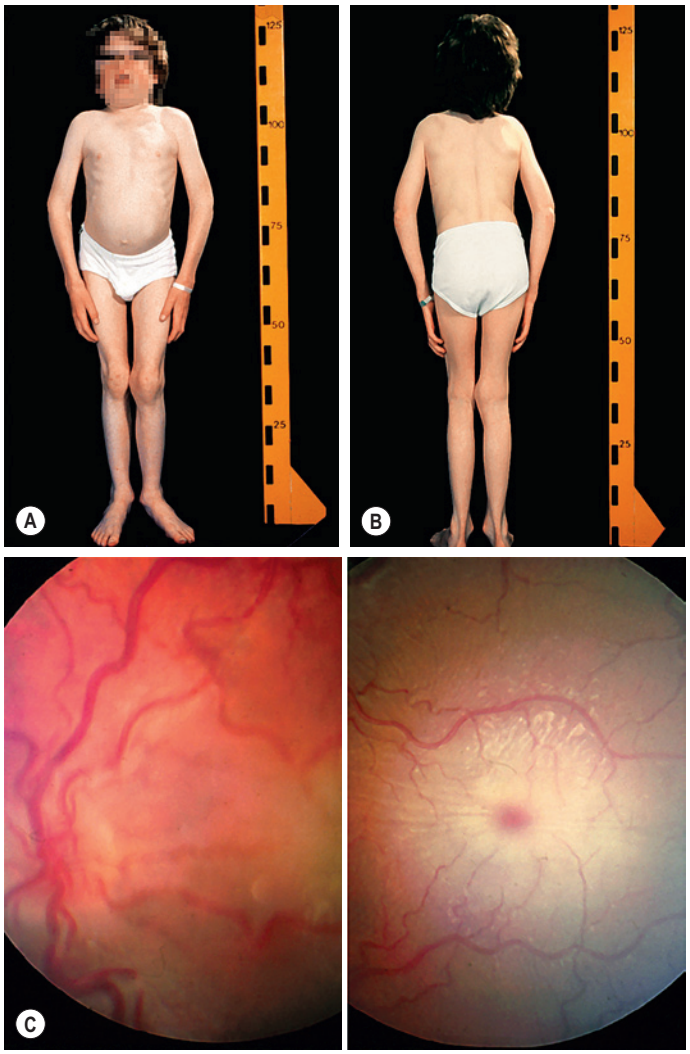

Fig. 65.9 (A,B) Patient with sialidosis type 2. He has kyphoscoliosis and joint changes. (C) Same patient as in (A) and (B), showing a cherry-red spot. The picture is hazy because of corneal clouding.

Fig. 65.10 Mucolipidosis II showing the facial features and the joint stiffening that prevents the patient from fully lifting her arms.

hypermetropic astigmatism, optic disc swelling, retinal vascular tortuosity, and maculopathy.[24] The ERG is normal.

ML IV is an autosomal recessive disorder resulting from mutations in the *MCOLN1* gene, which encodes mucolipin-1. It is seen mainly in Ashkenazi Jews. Clinical features include progressive mental retardation and hypotonia. ML IV patients have corneal epithelial haze, retinopathy with optic nerve pallor, vascular attenuation, and RPE change with electronegative ERG.[25,26] Other ophthalmic features include strabismus, corneal erosion and episodic pain, cataract, and ptosis.[27,28] Mild phenotypes have been described with only ocular manifestations of corneal clouding and retinopathy.[28,29]

Sphingolipidoses

Sphingolipidoses are caused by abnormalities of catabolism of sphingolipids, which form an integral part of cerebral membranes. All show autosomal recessive inheritance except Fabry disease, which is X-linked. The sphingolipidoses have a wide range of presentations and severity, but progressive neurodegeneration and cherry-red spots are characteristic features.

GM2 gangliosidosis

- *Tay–Sachs disease:* hexosaminidase A deficiency, most common in the Ashkenazi Jewish population.
- *Sandhoff disease:* hexosaminidase A and B deficiency.

These are clinically indistinguishable neurodegenerative disorders, with infantile, juvenile, and adult forms. A cherry-red spot is the typical eye finding.[30] There is no effective treatment.

Most patients present in infancy with weakness and an exaggerated startle response, followed by loss of vision, feeding difficulties, seizures, and spasticity. Macrocephaly is common and death usually occurs by 2–4 years.

A cherry-red spot is apparent at an early stage, due to GM2 ganglioside accumulation in the retinal ganglion cells. As the ganglion cells die, the cherry-red spot fades and optic atrophy becomes apparent.[31] The ERG is normal, but the visual evoked potential extinguished.[32]

The juvenile and adult forms usually present with motor symptoms, such as ataxia, followed by dementia. Cherry-red spots are less common in the late-onset forms (Table 65.2) but adults may have saccadic abnormalities.[33]

Metachromatic leukodystrophy (arylsulfatase deficiency)

Metachromatic leukodystrophy usually presents at 1–2 years of age with deteriorating gait, spasticity, and loss of reflexes due to neuropathy. Later, there are speech and feeding problems. Optic atrophy leads to blindness and occasionally there is a cherry-red spot.[30] Juvenile and adult-onset forms may present with deteriorating gait or with behavior problems. HSCT probably slows progression in the late-onset forms[34] and gene therapy is being developed.

Krabbe disease (galactocerebrosidase deficiency)

This is a severe neurodegenerative disorder with infantile, childhood, and late-onset forms. The early-onset form develops symptoms in the first few months with irritability and poor feeding, and progresses quickly to spasticity and a vegetative state. Visual impairment is common in the late stages due to optic atrophy or cortical blindness. There is no treatment

Table 65.2 Cherry-red spot in neurometabolic disorders[1]

Disease	Disease frequency of cherry-red spot
Niemann–Pick type A	Occasional
Niemann–Pick type B	Occasional
GM2 gangliosidosis (Tay–Sachs and Sandhoff)	Frequent
GM1 gangliosidosis, infantile	Occasional
Galactosialidosis	Frequent
Farber lipogranulomatosis	Occasional
Sialidosis type 1	All
Sialidosis type 2	Frequent
Metachromatic leukodystrophy	Occasional

for the infantile form but HSCT may halt progression of the late-onset form.

GM1 gangliosidosis

GM1 gangliosidosis is caused by a deficiency of β-galactosidase resulting in the accumulation of GM1 gangliosides in the brain. Infantile GM1 gangliosidosis causes hypotonia from birth. By 6 months, patients have a coarse appearance with puffy skin, maxillary hypoplasia, hypertrophied gums, and macroglossia. Affected children have hepatosplenomegaly and dysostosis multiplex. Ocular motor apraxia (saccadic initiation failure),[35] a cherry-red spot, optic atrophy, tortuous retinal vessels, retinal hemorrhages, and corneal clouding may occur. Rapid neurologic deterioration is usual, with seizures and swallowing difficulties and death by 2 years. Juvenile and adult forms occur, in which there is neurologic deterioration and dysostosis but no dysmorphism or ophthalmological abnormalities. There is no effective treatment.

Niemann–Pick disease

Disorders in which there is storage of sphingomyelin are called Niemann–Pick disease. Types A and B are due to sphingomyelinase deficiency. Type C is a completely different condition, where ganglioside and sphingomyelin accumulation is due to a disorder of cholesterol transport within the cell.

Niemann–Pick disease types A and B (sphingomyelinase deficiency)

Niemann–Pick type A, the severe part of the spectrum, is commoner in Ashkenazi Jews. Patients present in infancy with failure to thrive and feeding difficulties. Hepatomegaly (Fig. 65.11) is prominent and is more marked than splenomegaly, in contrast to Gaucher disease. Neurologic regression starts at 5–10 months with hypotonia. From around 18 months, there is loss of vision associated with a cherry-red spot (Fig. 65.12) and later optic atrophy. There may be a brown discoloration of the anterior lens capsule, but minimal corneal opacification.[36] There is no treatment and most patients die by 3 years.

Niemann–Pick disease type B is less severe and presents later in childhood with hepatosplenomegaly. Usually there are no neurologic symptoms; some patients may have ataxia but are usually of normal intelligence. Massive splenic enlargement, cirrhosis of the liver, and pulmonary infiltration may occur

Fig. 65.11 An infant with Niemann–Pick type A showing the hepatomegaly and spastic posture.

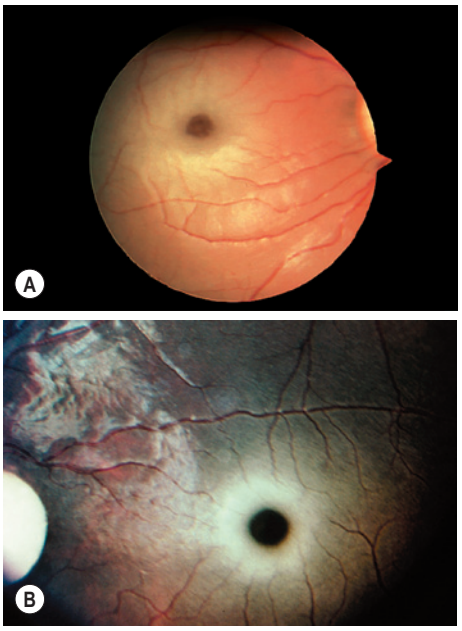

Fig. 65.12 (A) Cherry-red spot in a patient with Niemann–Pick type A: the spot is brownish because of dark pigmentation. (B) Cherry-red spot in a black infant with Niemann–Pick type A. *(Professor C.S. Hoyt's patient.)*

(Fig. 65.13). Eye abnormalities include periorbital fullness, macular granular deposits, and cherry-red spot.[37] ERT is being developed for type B patients.

Niemann–Pick disease type C

Niemann–Pick type C is due to impaired intracellular trafficking of cholesterol as a result of mutations in either the *NPC1* or *NPC2* genes. NPC is pan-ethnic.

Type C has variable presentations including neonatal liver disease, chronic splenomegaly, or neurologic deterioration in children or adults. Neurological features include ataxia,

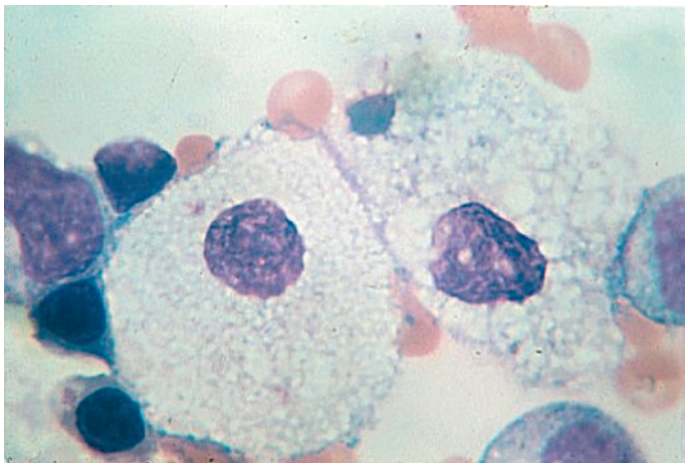

Fig. 65.13 Foam cells. Lipid laden histiocytes seen on bone marrow biopsy in Niemann–Pick disease type B.

cataplexy, seizures, psychoses, and dementia. A vertical supranuclear gaze palsy (Fig. 65.14) is characteristic of this disorder, and may be the presenting feature. There may be horizontal supranuclear eye movement defects or a supranuclear disorder of convergence. A faint cherry-red spot may be seen. Miglustat (an inhibitor of glucosylceramide synthase, which catalyzes the first step of glycosphingolipid synthesis) may slow progression of the neurologic disease.[38]

Fabry disease (α-galactosidase deficiency)

Fabry disease is an X-linked recessive lysosomal storage disease caused by a deficiency of α-galactosidase A. Males with Fabry disease usually present in late childhood or adolescence with pain in the extremities (acroparesthesia) provoked by exertion or change in temperature. Characteristic skin lesions (angiokeratoma corporis diffusum; Fig. 65.15A) are present, with dark red angiectases in the "bathing trunk area" (lower abdomen, buttocks, and scrotum). Later symptoms include a chronic progressive neuropathy (Fig. 65.15B), progressive renal dysfunction, heart disease (hypertrophic cardiomyopathy), and strokes. Heterozygous females may be asymptomatic or suffer the same problems as men, with a later onset and slower progression; the extent of manifestations is determined by X-chromosome inactivation. Fabry disease is treated with ERT, with intravenous infusions of recombinant α-galactosidase, agalsidase alfa, or agalsidase beta.[39]

Corneal verticillata (whorl-like lines radiating from a single vortex; Fig. 65.15C) occur in both males and females with Fabry disease. They do not affect vision but may facilitate diagnosis. Corneal involvement includes corneal haze and fine subepithelial brown lines.[40–42] Conjunctival tortuosity and microaneurysms occur (Fig. 65.15D) and chronic chemosis may occur in affected adults.[43,44] Characteristic lens opacities occur less commonly than corneal and vascular changes: a granular, wedge-shaped, subcapsular cataract, and lines of discrete opacities radiating from the posterior pole of the lens along the sutures (Fig. 65.15E). Retinal vascular tortuosity, particularly of veins, occurs in the second decade. The vessels become beaded, with sheathing, and may develop arteriovenous anastomoses and thromboses. Vascular tortuosity is more frequently observed in patients with greater impairment of renal and cardiac function.[45] Retinal vascular occlusion may be the initial symptom. Optic disc edema or myelinated nerve fibers may occur. Neuro-ophthalmologic problems include nystagmus, third nerve palsy, and strabismus. Optic atrophy and internuclear ophthalmoplegia occur rarely.

Farber disease

This autosomal recessive disease is characterized by the onset in infancy of multiple subcutaneous nodules, lymphadenopathy, a hoarse cry, and variable involvement of lung, heart, and liver. The course is variable with death between 1 and 18 years. Severely affected children may have a cherry-red spot, nodular corneal opacity, or a pingueculum-like conjunctival lesion. There is no treatment.

Gaucher disease (glucocerebrosidase deficiency)

Gaucher disease is an autosomal recessive disease that arises from mutations in the glucocerebrosidase (*GBA*) gene. Gaucher disease is classified according to severity and neurologic involvement into types 1, 2, and 3.

Table 65.3 Classification of the neuronal ceroid lipofuscinoses

Age at onset	Designation	Chromosome location	Deficient protein
Congenital or later	CLN10	11p15	Cathepsin D
Infantile or later	CLN1	1p32	Palmitoyl protein thioesterase 1
Late infantile or later	CLN2	11p15	Tripeptidylpeptidase 1
	CLN5	13q22	Partially soluble protein
	CLN6	15q21	Membrane protein
	CLN7	4q28	Membrane protein
	CLN8	8p23	Membrane protein
Juvenile	CLN3	16p12	Membrane protein
	CLN9		
Adult	CLN4		

Source: Kohlschütter A, Schulz A. Towards understanding the neuronal ceroid lipofuscinosis. Brain Dev 2009; 31: 499–502.

Gaucher type 1 (non-neuronopathic)

This is more common in Ashkenazi Jews, and can present in children or adults with hepatosplenomegaly, anemia, thrombocytopenia, and leukopenia. There may be painful splenic and bony infarctions. Osteopenia may lead to pathological fractures and the distal ends of the femur may develop a typical Erlenmeyer's deformity (so named because it resembles a conical flask). Dark brown-yellow pingueculae occur in the nasal bulbar conjunctivae, which are characterized by numerous Gaucher cells on histologic examination. Macular change, choroidal neovascularization, and peripheral retinal vessel leakage occur.[46–48] ERT with recombinant glucocerebrosidase is very effective, correcting the hematological abnormalities and organomegaly and ameliorating the bone disease. Substrate reduction therapy (miglustat and eligustat) may now be used for maintenance treatment in adults, as an oral alternative to ERT.

Gaucher type 2 (infantile)

This presents within the first 6 months of life with severe feeding problems, spasticity, strabismus, neurologic regression, and hepatosplenomegaly. ERT is ineffective and affected infants die within the first few years.

Gaucher type 3 (chronic neuronopathic)

Type 3 usually presents in childhood with failure to thrive and hepatosplenomegaly (Fig. 65.16). Skeletal problems include osteopenia and progressive kyphosis. Oculomotor apraxia (saccadic initiation failure) may be the first sign of neurologic involvement.[49,50] Intermittent strabismus and vertical gaze palsies may also occur. Retinal, preretinal and vitreous white deposits, and epiretinal membranes have been described.[51,52] Though ERT does not cross the blood–brain barrier, it ameliorates the systemic symptoms and allows many patients to survive into adult life.

Cystinosis

See Chapter 34.

Neuronal ceroid lipofuscinosis

The neuronal ceroid lipofuscinoses (NCLs; or ceroid lipofuscinoses, neuronal [CLN]) are autosomal recessive conditions characterized by progressive neurologic deterioration in children or young adults, epilepsy, and visual deterioration due to retinopathy. All the NCLs are associated with accumulation of an autofluorescent material, ceroid lipofuscin, and degeneration of neuronal cells.[53] There are at least 10 genetically distinct NCLs (Table 65.3). The term "Batten disease" refers to the juvenile-onset form of NCL and occurs most commonly as a result of mutations in *CLN3*, on chromosome 16p21.

Juvenile NCL must be considered when a child presents with rapidly deteriorating visual function, particularly when associated with behavioral changes, neurologic deterioration, or seizures. The ophthalmologist plays a crucial role in early diagnosis of the condition.

NCLs are diagnosed increasingly often by molecular genetic testing, but electron microscopy of skin or leukocyte preparations are still helpful, showing characteristic inclusions. Vacuolated lymphocytes can be seen in blood films from patients with CLN3 and enzyme deficiencies can be demonstrated in leukocytes in CLN1 and CLN2. There are no specific treatments available for the NCLs, but there has been a trial of intrathecal enzyme replacement for late-infantile NCL.

Infantile neuronal ceroid lipofuscinosis (CLN1, Haltia–Santavuori disease)

This manifests as rapidly progressive neurologic deterioration from approximately 6 months of age with seizures and brain atrophy, leading to a vegetative state by about 4 years. There is visual loss with retinopathy and optic atrophy but this is less prominent that other features.

Classical late-infantile neuronal ceroid lipofuscinosis (CLN2, Jansky–Bielschowsky disease)

This presents around the third year of life with epilepsy and developmental regression. Visual loss occurs from retinal degeneration but is relatively late.

Juvenile neuronal ceroid lipofuscinosis (CLN3, Batten disease)

Children with juvenile NCL present with rapid deterioration of vision between 4 and 10 years. Other manifestations such as behavioral problems, cognitive decline, and motor deterioration manifest before or after the onset of visual loss.[53–55] Although neurological manifestations occur early, often predating the visual deterioration, they are often quite subtle. Night blindness

Fig. 65.16 Hepatosplenomegaly in Gaucher type 3.

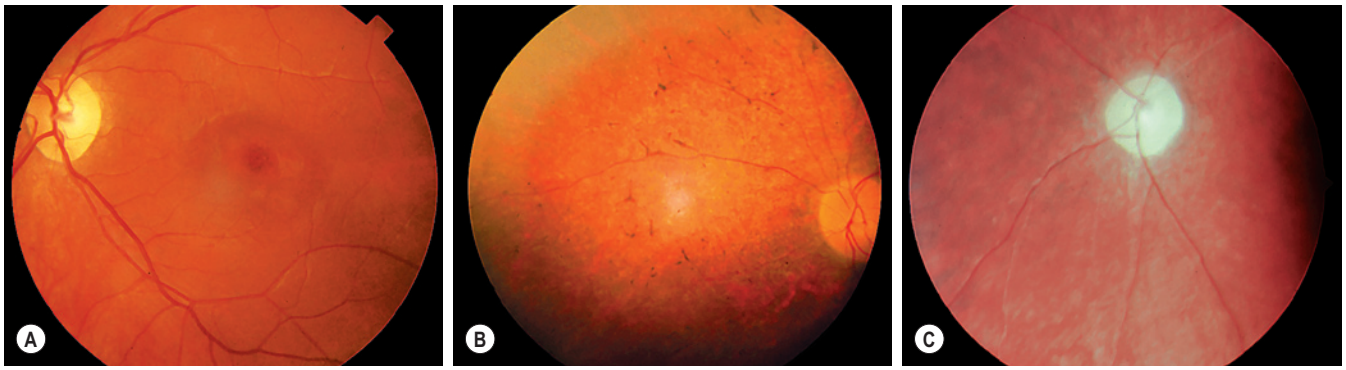

Fig. 65.17 Juvenile Batten disease. (A) Optic atrophy, arteriolar thinning and bull's eye maculopathy. (B) Bone-spicule pigmentation, optic atrophy, and arteriolar narrowing. (C) Late retinal changes, including depigmentation, optic atrophy, and extreme arteriolar narrowing.

and photophobia may be present in addition to visual loss. Eccentric viewing or "overlooking" is often a feature, where children hold their eyes in a raised position while attempting to fixate on a target, presumed due to the relative preservation of the superior peripheral retina.[54,55] Misdiagnosis as macular or retinal dystrophy or even functional visual loss may occur in the early stages.[54] At presentation, the fundus may be normal or show pigmentary maculopathy, atrophic changes, or bull's eye maculopathy. Later there is a widespread retinal degeneration (Fig. 65.17), with sparse bone-spicule pigmentation in the periphery, thinned arterioles and disc atrophy (Fig. 65.17B,C), and the retina eventually becomes avascular. ERG may show an electronegative waveform in early cases with a markedly reduced b : a ratio in the single flash photopic ERG, consistent with inner retinal dysfunction.[53,56] Fluorescein angiography shows diffuse RPE atrophy with stippled hyperfluorescence.[57,58]

The children are usually blind within 3 years, and the disease follows a slow downward path with the onset of seizures between 7 and 16 years of age, dementia in the teens, and death sometimes in the second or third decade.

Mitochondrial disorders

Mitochondrial disorders arise as a result of dysfunction of the mitochondrial respiratory chain. They can present at any age and frequently have ocular manifestations such as ptosis, external ophthalmoplegia, optic atrophy, pigmentary retinopathy, cataracts, and cerebral visual impairment.[59–61] Some mitochondrial disorders have only ocular manifestations (e.g. Leber hereditary optic neuropathy; LHON), but many involve multiple organ systems such as muscle (proximal myopathy), heart (cardiomyopathy), peripheral and central nervous systems (encephalopathy, seizures, dementia, migraine, stroke-like episodes, ataxia, and spasticity), inner ear (sensorineural deafness), and endocrine systems (diabetes mellitus). Several syndromes are described but there is overlap between them and many patients have an atypical pattern.

Mitochondrial disorders can be caused by mutations of nuclear genes (with Mendelian inheritance) or mitochondrial DNA (mtDNA, which is inherited exclusively from the mother). Many copies of mtDNA are present in each cell. In LHON, mutations affect all copies (homoplasmy). In other conditions, mutant mtDNA usually coexists with wild-type mtDNA (heteroplasmy) and the clinical severity depends on the proportion that is mutated; the proportion varies among members of a pedigree, leading to different symptoms and ages of presentation. If the clinical picture is characteristic of a disorder associated with specific genetic abnormalities (e.g. LHON, NARP, MELAS, or Alpers syndromes) then the diagnosis can be confirmed by molecular genetic testing. MtDNA point mutations can be detected in blood or urine but this is not always true for mtDNA deletions. Other tests include measurement of blood or cerebrospinal fluid (CSF) lactate, and biochemical or histochemical studies of the mitochondrial respiratory chain on a muscle biopsy.

Leber hereditary optic neuropathy

See Chapter 54.

Progressive external ophthalmoplegia and Kearns–Sayre syndrome

Progressive external ophthalmoplegia (PEO) occurs in a number of different mitochondrial disorders. The ophthalmoplegia is characterized by ptosis and progressive loss of eye movements; most patients have exotropia but diplopia is rare due to the gradual onset. PEO may be isolated (chronic progressive external ophthalmoplegia) or associated with various additional symptoms.[62] PEO may be sporadic or show autosomal recessive, autosomal dominant, or maternal patterns of inheritance.[63]

Kearns–Sayre syndrome is defined as PEO and pigmentary retinopathy with onset before 20 years of age and at least one of: heart block, cerebellar syndrome, or CSF protein above 1 g/L. Other features may include hearing loss, dementia, cardiomyopathy, and endocrine disorders. The fundus has a "salt and pepper" appearance but visual acuity is seldom severely impaired. Involvement of the orbicularis oculi muscles can lead to exposure keratitis and corneal perforation.[62] Kearns–Sayre syndrome is associated with mtDNA "rearrangements" (large deletions or duplications) but it is sporadic rather than inherited.

MELAS syndrome

MELAS syndrome is characterized by:

M = mitochondrial myopathy
E = encephalopathy
LA = lactic acidosis
S = stroke-like episodes

The stroke-like episodes can start at any age, most commonly between 5 and 15 years, and may cause visual field defects or cortical blindness and hemiplegia; sometimes the symptoms resolve rapidly. Headaches and vomiting may precede the stroke-like episodes and maternal relatives may have a history of severe migraine. Other ocular manifestations may include PEO, "salt and pepper" pigmentary retinopathy and macular RPE atrophy, optic neuropathy, and non-ischemic central retinal vein occlusion.[64,65] The m.3243A>G mtDNA mutation is present in 80% of patients with MELAS syndrome; the remaining patients usually have another mtDNA mutation. MELAS syndrome only occurs if the mutation affects most copies of mtDNA; if it is present at a lower level, patients may have milder problems, such as diabetes and deafness.

NARP syndrome

This is characterized by:

N = neurogenic weakness

A = ataxia

RP = retinitis pigmentosa

It is caused by the m.8993T>G or m.8993T>C mutations. The fundus may have a "salt and pepper" or a "bone-spicule" appearance; some patients develop optic atrophy or maculopathy with severe visual loss.

Leigh syndrome (subacute necrotizing encephalomyopathy)

Leigh syndrome is a severe early-onset neurodegenerative disorder primarily affecting the brainstem and basal ganglia. Problems include dystonia and dysphagia, and death is often due to impaired ventilatory drive. Brainstem involvement can cause ptosis, nystagmus, and strabismus and there may also be optic atrophy.[66]

Alpers syndrome

This neurodegenerative disorder presents with an explosive onset of seizures and developmental regression in early childhood. Involvement of the occipital cortex is common, leading to cortical visual impairment. Terminally, patients often develop liver failure. The condition is caused by autosomal recessive mutations in *POLG1*, which is a nuclear gene involved in mtDNA replication.

Sengers syndrome

Sengers syndrome is characterized by congenital cataracts, hypertrophic cardiomyopathy, skeletal myopathy, and lactic acidosis.[67] The cardiomyopathy may cause early death or the disease may be milder, in which case patients can survive into their second or third decades. It shows autosomal recessive inheritance and is caused by mutations in the gene for acylglycerol kinase (AGK).[68]

Autosomal dominant optic atrophy

See Chapter 54.

Peroxisomal disorders

Peroxisomes are organelles involved in the synthesis of plasmalogens (crucial for myelin), bile acids and isoprenoids, and the oxidation of very long chain and branched chain fatty acids (e.g. phytanic acid).

Peroxisomal biogenesis disorders

In these autosomal recessive disorders, peroxisomes cannot be made properly due to mutations in the *PEX* genes. Peroxisomal biogenesis disorders are classified into the Zellweger spectrum and rhizomelic chondrodysplasia punctata.

Zellweger spectrum (Zellweger syndrome, neonatal adrenoleukodystrophy, infantile Refsum disease)

These disorders vary in severity, with overlap between phenotypes, but with poor vision as a common feature. Zellweger syndrome is the severe end of the spectrum; patients die within a few months of birth. They are dysmorphic with a large anterior fontanelle, high forehead, shallow supraorbital ridges, and epicanthic folds. Hypotonia, seizures, poor feeding, liver disease, impaired hearing, and ocular abnormalities occur (Fig. 65.18). Neonatal adrenoleukodystrophy is a slightly milder phenotype; some patients survive to mid-childhood, although they become deaf, blind, and profoundly retarded. Infantile Refsum disease is the "mild" end of the spectrum; patients have little or no dysmorphism but they still have mental retardation, deafness, and pigmentary retinopathy. Diagnosis is made by demonstrating raised plasma concentrations of very long chain fatty acids (VLCFA) followed by molecular genetic studies.

Retinal dystrophy is almost universal[69] (Fig. 65.19). Patients with neonatal adrenoleukodystrophy and infantile Refsum disease develop macular depigmentation and peripheral leopard spot pigment clumping[70] with loss of peripheral vision that often progresses to complete blindness. Patients with Zellweger syndrome have retinal hypopigmentation and

Fig. 65.18 20-month-old child with a peroxisomal biogenesis disorder. The child presented with hypotonia, deafness, poor vision, and nystagmus and had a pale fundus and extinguished electroretinogram.

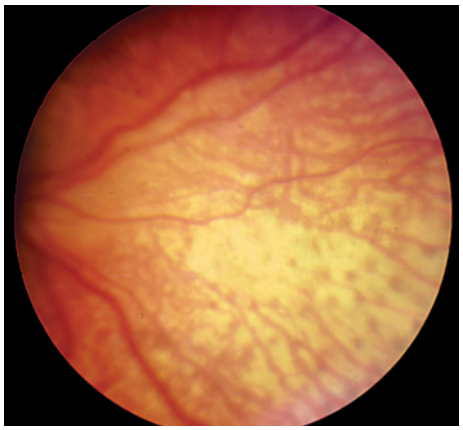

Fig. 65.19 Zellweger syndrome. Retinal dystrophy with mottled retinal pigment epithelium.

a severely abnormal or absent ERG. They may have corneal clouding, congenital cataracts, and glaucoma. Nystagmus and strabismus are common.

Rhizomelic chondrodysplasia punctata

In rhizomelic chondrodysplasia punctata (RCDP), there is severe shortening of the humeri and femora and stippled epiphyses. Most patients have facial dysmorphism and severe neurologic abnormalities: few survive beyond 2 years. Cataracts are very common and are usually congenital (Fig. 65.20) though they may appear at a few months of age. Patients with RCDP have normal plasma VLCFA concentrations but erythrocyte plasmalogen levels are abnormally low.

Refsum disease

Refsum disease is caused by autosomal recessive deficiency of the peroxisomal enzyme phytanoyl-CoA hydroxylase, leading to accumulation of phytanic acid in blood and tissues. Features of Refsum disease include cerebellar ataxia, peripheral neuropathy, and retinitis pigmentosa and cataracts. If started early enough, dietary restriction of phytanic acid can prevent these problems.

X-linked adrenoleukodystrophy

In this X-linked recessive disorder, mutations in the *ABCD1* gene lead to the accumulation of VLCFAs in blood and tissues. There are two main phenotypes, which may occur in the same pedigree. The childhood cerebral form presents at 4–12 years of age with behavioral, cognitive, and neurologic problems, usually leading to a vegetative state within 3 years. Strabismus, visual field defects, and decreased visual acuity are early symptoms. Later, these patients become blind due to optic atrophy and cortical visual loss[71] (Fig. 65.21). The second phenotype, adrenomyeloneuropathy, presents with paraparesis in adults. Adrenal failure occurs in both phenotypes, either before or after the onset of neurologic problems.

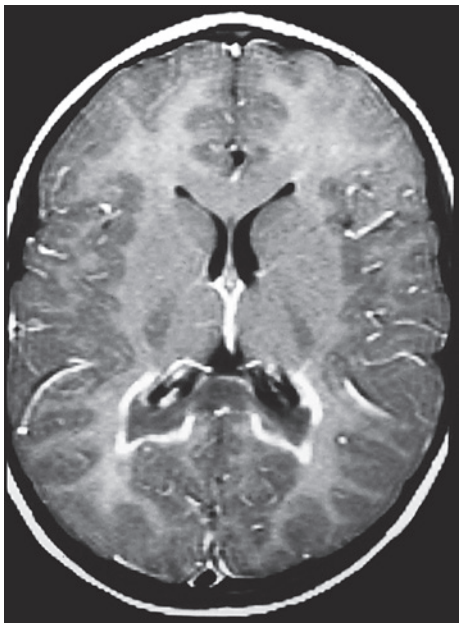

Fig. 65.21 Adrenoleukodystrophy. MRI scan showing characteristically predominant early involvement of the occipital lobes and visual pathway with high signal from the periventricular white matter.

Lorenzo's oil combined with a low-fat diet can normalize plasma VLCFA concentrations and *may* reduce the risk of childhood cerebral disease but it does not alter the clinical course once symptoms have started. HSCT can prevent progression of the childhood cerebral disease if undertaken soon after the onset of problems.

Primary hyperoxaluria type I

See Chapter 50.

Congenital defects of glycosylation

Most extracellular and cell surface proteins and some intracellular proteins are glycoproteins. The oligosaccharide may be attached to the amino acid asparagine in the protein (*N*-linked glycosylation) or to a serine or a threonine (*O*-linked glycosylation). Defects of *O*-linked glycosylation cause various disorders including Walker–Warburg syndrome and muscle–eye–brain disease (see Chapters 42 and 60).

Disorders of *N*-linked glycosylation

Phosphomannomutase-2 deficiency is the commonest congenital defect of glycosylation (PMM2-CDG; previously known as carbohydrate-deficient glycoprotein syndrome [CDG] Ia). Patients present at birth with hypotonia, esotropia, and dysmorphism – long fingers and toes (Fig. 65.22), inverted nipples, and fat pads over the buttocks. Death may occur in infancy from sepsis, pericardial effusions, nephrotic syndrome, or liver failure. Those surviving, or presenting later, show delayed development and ataxia, rarely walking without support. Most patients have esotropia, which is usually present from birth; ocular motor apraxia and nystagmus are common. Pigmentary retinopathy appears after 8 years of age but the ERG may be abnormal much earlier.[72] Other problems include delayed visual maturation, visual field loss, and progressive myopia.[73,74]

The other *N*-glycosylation defects are rarer and the ophthalmologic features are less well defined. Strabismus occurs in a number of disorders and nystagmus, poor acuity, optic neuropathy, congenital cataracts, congenital glaucoma, and colobomas of the iris or retina have been reported.

Inborn errors of carbohydrate metabolism

Galactosemia and galactokinase deficiency

Galactosemia is an autosomal recessive disorder caused by a deficiency of the enzyme galactose-1-phosphate uridyltransferase. It presents in neonates with poor feeding, jaundice, and sometimes sepsis and is treated with a minimal-galactose diet.[75] Cataract formation occurs due to the accumulation of galactitol within the lens, and can be prevented with early diagnosis and implementation of a galactose-restricted diet.[76,77] "Oil-droplet" cataracts occur at an early stage due to refractive change within the lens nucleus (Fig. 65.23). These may

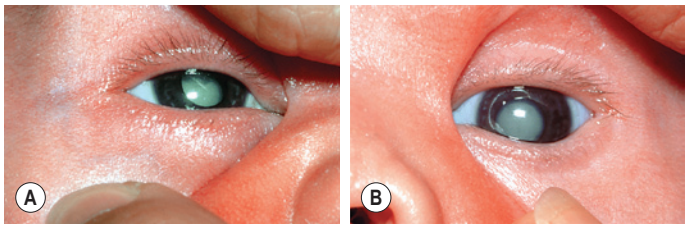

Fig. 65.20 Rhizomelic chondrodysplasia punctata. Bilateral total congenital cataract.

Fig. 65.22 Phosphomannomutase-2 deficiency (carbohydrate-deficient glycoprotein syndrome Ia). (A) Showing long fingers. (B) Showing long toes. (C) 6-year-old boy with esotropia and phosphomannomutase-2 deficiency.

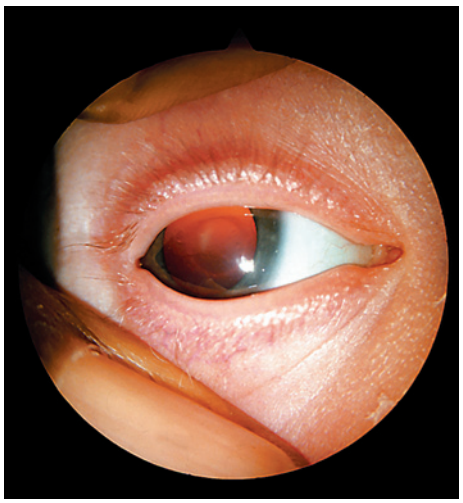

Fig. 65.23 Oil-droplet cataract in galactosemia.

progress to lamellar cataracts in the presence of poor dietary and biochemical control.

Galactokinase deficiency causes early-onset juvenile cataracts, which may stabilize or regress with dietary control; mental retardation has been reported in a few patients.[78] Reducing substances are present in the urine in both untreated galactosemia and galactokinase deficiency. The diagnosis is established by enzyme assays in erythrocytes and molecular genetic studies.

Inborn errors of amino acid metabolism

Homocystinuria

See Chapter 36.

Propionic and methylmalonic acidemias

These autosomal recessive conditions result from defects in the catabolism of branched chain amino acids. Neonates or young children present with vomiting, drowsiness, acidosis, and hyperammonemia. Treatment includes carnitine, dietary protein restriction, and prevention of catabolism; some cases of methylmalonic acidemia respond to vitamin B_{12}. Progressive optic neuropathy (Fig. 65.24) may occur in childhood and may be severe, with central scotomas and optic nerve pallor.[79–81] Visual loss may be exacerbated by episodes of metabolic decompensation.

CblC (cobalamin C) disease

This autosomal recessive disorder of vitamin B_{12} metabolism leads to methylmalonic aciduria and homocystinuria. It may present in infancy with failure to thrive, hypotonia, microcephaly, seizures, and nystagmus. A milder form presents later with neurologic deterioration. Visual loss may occur in childhood due to cone–rod retinal degeneration with an early maculopathy[82] and optic atrophy.[83]

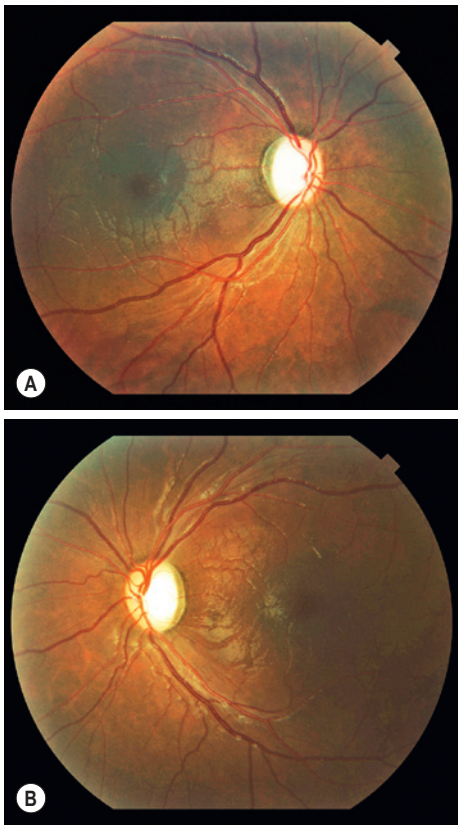

Fig. 65.24 Optic neuropathy in an 11-year-old girl with propionic acidemia. The patient noticed an acute onset of reduced vision in her right eye, and was found to have visions of only counting fingers in the right eye and 1.1 LogMAR in the left, with sluggish pupils, a right relative afferent pupil defect, and bilateral optic nerve pallor.

Maple syrup urine disease

In this autosomal recessive disorder, branched chain amino acids accumulate and are neurotoxic. Most cases present with encephalopathy in the first 2 weeks of life. Patients can be treated acutely by hemofiltration and subsequently with dietary management. Ophthalmoplegia may be a prominent feature of the neonatal encephalopathy.[84] In older children, ataxia is an early feature of encephalopathy and may be accompanied by nystagmus.

Molybdenum cofactor deficiency and isolated sulfite oxidase deficiency

These two autosomal recessive disorders have similar clinical features, with spherophakia and ectopia lentis being common findings. Nystagmus, cortical blindness, enophthalmos, and colobomas may be present.[85] Most patients present in the newborn period with intractable seizures. Subsequently, they develop microcephaly, severe psychomotor retardation, and spastic tetraplegia with early death. Neuroimaging demonstrates multicystic encephalopathy and atrophy. A few patients run a milder course with prolonged survival. Treatment is now available for one form of molybdenum cofactor deficiency but it needs to be started within a few days of birth.[86]

Gyrate atrophy

Gyrate atrophy is an autosomal recessive disorder caused by deficiency of the enzyme ornithine δ-aminotransferase, leading to raised plasma ornithine levels, chorioretinal degeneration, macular edema and progressive loss of vision (Fig. 65.25).[87] Myopia and early cataracts may occur.[88] An arginine-restricted diet may slow the rate of deterioration of the chorioretinal degeneration.[89,90]

Tyrosinemia type 2 (Richner–Hanhart syndrome)

This autosomal recessive disorder is caused by deficiency of tyrosine aminotransferase. It may present with ocular signs and symptoms as the initial manifestation in the first years of life with photophobia, pain, and conjunctival injection. There is a bilateral pseudodendritic keratitis, which may lead to neovascularization and corneal scarring.[91] Patients may have painful erosions and hyperkeratosis of the palms and soles, and cognitive impairment. Plasma tyrosine concentrations are extremely high, and the eye and skin lesions probably result from the intracellular precipitation of tyrosine crystals. Dietary restriction of tyrosine and phenylalanine leads to resolution of these lesions.[92]

Tyrosine concentrations are lower in tyrosinemia types 1 and 3. Type 1 patients treated with nitisinone sometimes complain of sore eyes.

Oculocutaneous albinism

See Chapter 41.

Aromatic L-amino acid decarboxylase deficiency

Eye movement abnormalities are prominent in this rare autosomal recessive disorder, in which the synthesis of catecholamines and serotonin neurotransmitters is impaired. Patients present in infancy with oculogyric crises, hypotonia, and autonomic dysfunction. Convergence spasm, ptosis, and miosis may occur.[93]

Canavan disease

This is an autosomal recessive disorder prevalent in Ashkenazi Jews. Aspartoacylase deficiency leads to the accumulation of *N*-acetyl-aspartic acid. Patients with Canavan disease usually present aged 2–4 months with macrocephaly, hypotonia, and developmental delay. White matter degeneration is seen on neuroimaging. Cortical visual loss, optic atrophy, and nystagmus are common. Most patients die by 3 years of age.[94]

Disorders of fatty acid and fatty alcohol metabolism

Long chain 3-hydroxyacyl-CoA dehydrogenase deficiency

The enzyme long chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) participates in mitochondrial fatty acid β-oxidation, and the autosomal recessive condition, LCHAD deficiency, may present in infancy with hypoglycemia, liver disease, cardiomyopathy and hypotonia.[95] Treatment is with dietary restriction of long chain fatty acids, avoidance of fasting and a regular intake of glucose during illness. LCHAD deficiency

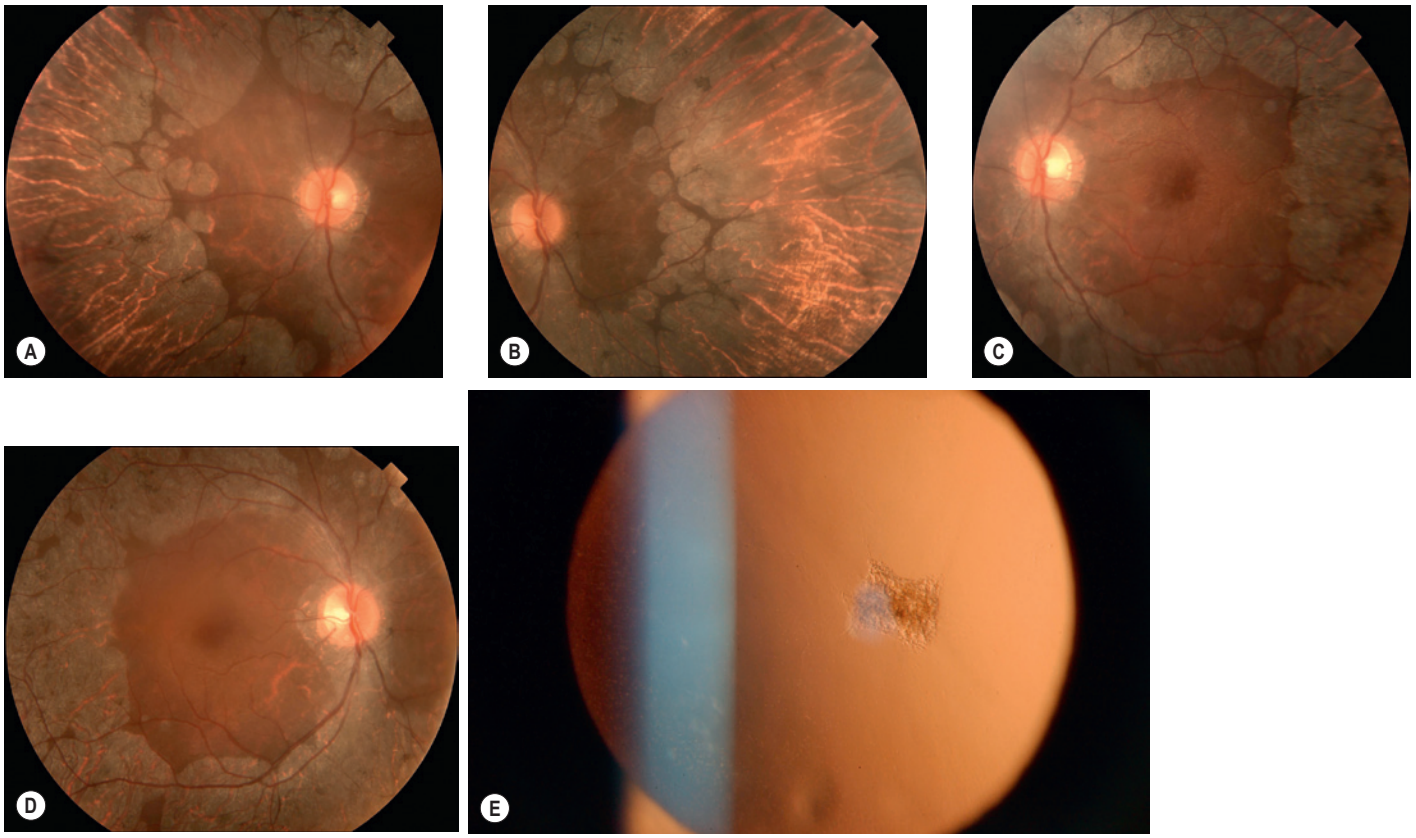

Fig. 65.25 Gyrate atrophy. (A,B) Characteristic sharply demarcated areas of chorioretinal degeneration in the mid-periphery of a myopic patient age 26, with relative sparing of the macula (C,D). The patient had poor dietary control, suffered from significant nyctalopia, and had acuities of 6/24 right and 6/36 left. (E) The patient also had bilateral cataract. *(Courtesy of Mr I.C. Lloyd, Manchester Royal Eye Hospital.)*

causes variable severity of chorioretinal degeneration with visual loss and progressive myopia[96] (Fig. 65.26). Progressive lens opacities may occur.[97] Optimal dietary control may delay the progression of the chorioretinopathy.[98]

Sjögren–Larsson syndrome

See Chapter 50.

Disorders of sterol metabolism

Early-onset cataracts are seen in several disorders of sterol metabolism, including defects of cholesterol synthesis and of bile acid synthesis.

Smith–Lemli–Opitz syndrome

Smith–Lemli–Opitz syndrome is caused by deficiency of 7-dehydrocholesterol reductase, which catalyzes the final step in cholesterol synthesis, resulting in reduced cholesterol and raised 7-dehydrocholesterol levels. It has a spectrum of phenotypic severity with mental retardation and congenital malformations: microcephaly; ptosis; small upturned nose; micrognathia (Fig. 65.27); polydactyly; syndactyly; genital, cardiac, and intestinal abnormalities.[99] One-fifth of patients have cataracts (usually congenital). Other ophthalmologic abnormalities, in addition to ptosis, include strabismus, optic atrophy, and optic nerve hypoplasia. Treatment with cholesterol does not improve intelligence.

Mevalonic aciduria

Mevalonic aciduria is a rare autosomal recessive inflammatory metabolic disorder caused by deficiency of mevalonate kinase, which catalyzes an early step in cholesterol synthesis. Patients present in infancy with dysmorphic features (dolichocephaly, down-slanting eyes, and low-set ears), mental retardation, failure to thrive, cerebellar ataxia, and visual impairment. They have recurrent febrile episodes that are accompanied by hepatosplenomegaly, lymphadenopathy, vomiting and diarrhea, arthralgia, and skin rashes. One-third of patients have cataracts. Uveitis and pigmentary retinopathy occur.[100,101] Many patients die in the first few years.

X-linked dominant chondrodysplasia punctata 2 (CDPX2, Conradi–Hünermann syndrome)

This is an X-linked dominant condition, lethal in males, in which mutations in the emopamil binding protein (EBP) gene lead to deficiency of 3β-hydroxysteroid Δ8,Δ7-isomerase. The main features are skeletal dysplasia, stippled epiphyses, neonatal ichthyosis with subsequent atrophic skin changes in a mosaic pattern, and cataracts, which may be congenital or developmental (Fig. 65.28). Microphthalmos, anterior

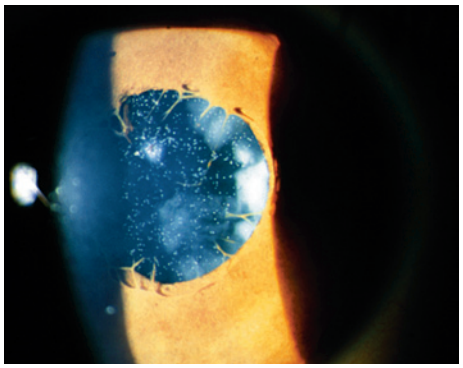

Fig. 65.28 Cataract in a girl with Conradi–Hünermann syndrome.

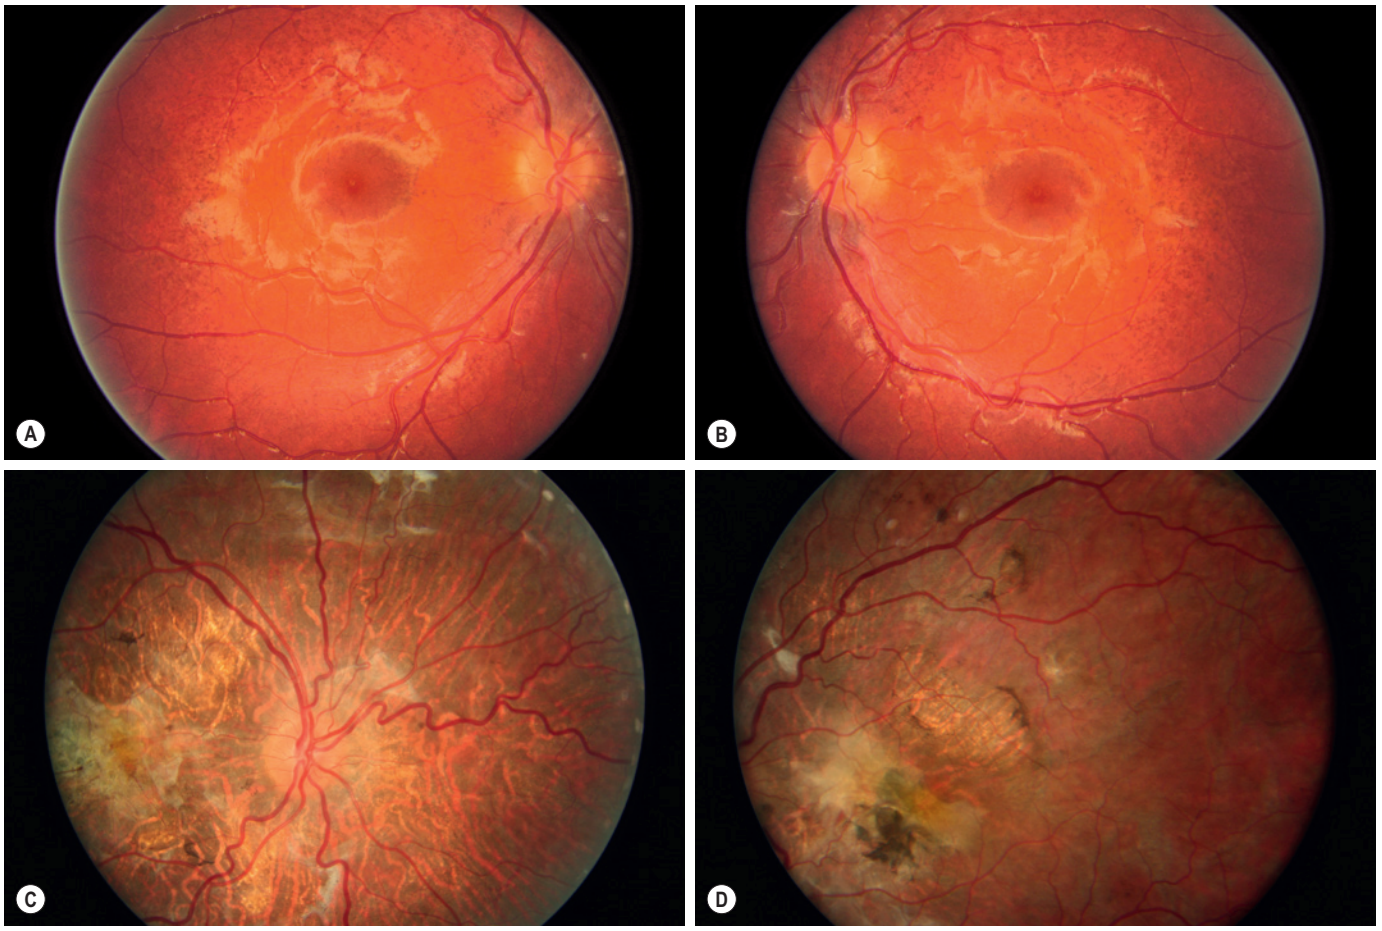

Fig. 65.26 (A,B) Peripapillary and perimacular granular pigmentary changes in an 11-year-old girl with long chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency diagnosed neonatally during the first days of life. The acuity was 0.1 LogMAR right and left eye with correction for a slight myopia and astigmatism. Electroretinogram was of subnormal amplitude. (C,D) Bilateral areolar chorioretinopathy in a 21-year-old woman with LCHAD deficiency diagnosed at 8 months of age. Bilateral pigmentary retinopathy, exotropia, and bilateral myopia had been present since age 3 years, and by early adulthood the vision deteriorated due to chorioretinal fibrosis. The visual acuity was <1.0 LogMAR with myopic glasses. *(Courtesy of Kristina Teär Fahnehjelm, St. Erik Eye Hospital, Stockholm.)*

Fig. 65.27 19-year-old with Smith–Lemli–Opitz syndrome, showing facial features including ptosis.

segment dysgenesis, vitreoretinal abnormalities, and optic atrophy occur.[102,103]

Cerebrotendinous xanthomatosis

Cerebrotendinous xanthomatosis (CTX) is caused by mutations in the sterol 27-hydroxylase gene (*CYP27A1*) leading to the accumulation of cholestanol and cholesterol. Infantile-onset diarrhea may be the earliest clinical manifestation of CTX, followed by juvenile cataracts and neurologic problems (spasticity, ataxia, psychiatric disturbances, dementia, and seizures).[104] Adults develop tendon xanthomas and premature atherosclerosis. Optic neuropathy may occur in addition to cataracts. Treatment with chenodeoxycholic acid prevents deterioration and can reverse some neurologic symptoms.

X-linked ichthyosis (steroid sulfatase deficiency)

X-linked ichthyosis is caused by a deficiency of steroid sulfatase, and results in ichthyosis, usually within the first few months of life, in affected males. Characteristic corneal opacities (fine punctate diffuse opacities in posterior stroma adjacent to Descemet's membrane, or subepithelial granular opacities with epithelial irregularity) are present in 25% of

affected males and also in heterozygous females; they have no effect on vision.[105,106]

Lipoprotein disorders

Abetalipoproteinemia (Bassen–Kornzweig syndrome)

This autosomal recessive disorder occurs due to deficiency of microsomal trigylceride transfer protein (MTP), needed for the production of lipoproteins, resulting in malabsorption of fat and fat-soluble vitamins. It presents with failure to thrive, developmental delay, and steatorrhea in infancy. If untreated, spinocerebellar degeneration develops. It is associated with a progressive retinal dystrophy, which may be mistaken for retinitis pigmentosa; it may be stabilized by a low-fat diet and combined vitamin A and E supplementation.[107]

Lecithin-cholesterol acyltransferase (LCAT) deficiency and "fish eye" disease (partial LCAT deficiency)

Lecithin-cholesterol acyltransferase (LCAT) catalyzes the formation of cholesterol esters in high-density lipoproteins. Complete LCAT deficiency causes adult-onset renal failure, anemia, and corneal opacities. Partial LCAT deficiency ("fish eye" disease) causes no problems except progressive corneal clouding. This is due to extracellular lipid deposition in the corneal stroma. Opacities can be detected in children, although they are often asymptomatic. Some adults require corneal transplantation.

Apo A-I deficiency

Corneal clouding has been reported in a few children with Apo A-I deficiency. Other features of this condition are premature atherosclerosis and xanthomas.

Copper transport disorders

Wilson disease

Wilson disease is an autosomal recessive disorder resulting from mutations in ATP7B, which transports copper into the Golgi apparatus of hepatocytes. Impaired biliary excretion causes copper accumulation in liver, kidney, cornea, and brain. It usually presents with liver disease at 5–20 years of age, or with neurologic problems, typically between 20 and 40 years, but sometimes during childhood. Hepatic manifestations include chronic active hepatitis, cirrhosis, and fulminant hepatic failure. Common neurologic features are dystonia, dysarthria, dysphagia, tremor, and parkinsonism, and psychiatric problems. Rarer problems include hemolysis, arthritis, and Fanconi syndrome.

Deposition of copper in peripheral Descemet's membrane leads to golden-brown pigmentation: the Kayser–Fleischer ring (Fig. 65.29). Slit-lamp examination reveals these rings in 95% of patients with neurologic presentations but they are seldom present in asymptomatic patients and often absent in children presenting with liver disease.[108] Kayser–Fleischer rings may occur with chronic cholestasis from other causes. Retinopathy may occur as a result of dysregulation of photoreceptor copper levels.

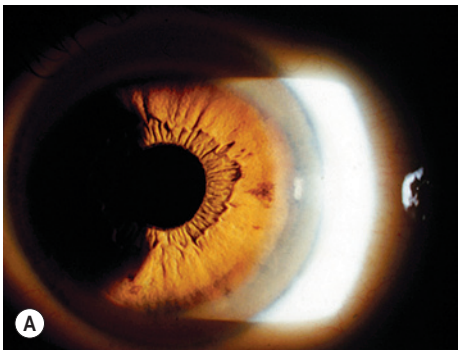

Fig. 65.29 (A) Kayser–Fleischer ring in a child with the neurologic presentation of Wilson disease. A brownish haze can be seen in the peripheral cornea. (B) Continued online.

Treatment with copper chelators (D-penicillamine, trientine) or zinc results in symptomatic improvement and normal life expectancy. Liver transplantation is occasionally required.

Menkes disease

Defects in the copper transporter ATP7A cause this X-linked disease. The main features are infantile-onset neurodegeneration, connective tissue disturbances, and characteristic "kinky" hair (Fig. 65.30). Affected boys present with hypotonia and seizures at 2–3 months of age. They have "pudgy" cheeks, occipital bossing, and sparse, brittle, white hair. Poor visual

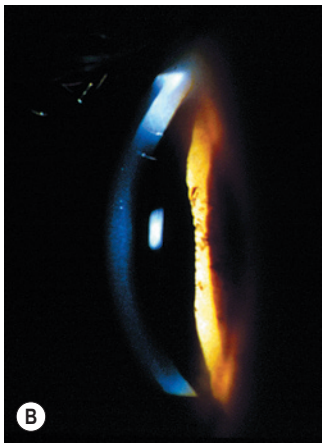

Fig. 65.29 (B) The Kayser-Fleischer ring can be seen in the posterior cornea on slit-lamp examination.

acuity is common with progressive visual loss due to retinal degeneration and optic atrophy. Early-onset myopia, strabismus, blue irides and iris stromal hypoplasia, and aberrant lashes may occur.[109] Patients deteriorate rapidly, with developmental regression, spasticity, and lethargy; most die by 3 years of age. Early treatment with parenteral copper-histidine may improve the neurologic prognosis and enhance survival.

The anatomy (Fig. 66.1), physiology, and pathophysiology of the pupillary pathways are important to the pediatric ophthalmologist but they are dealt with so excellently elsewhere that only aspects relevant to children will be discussed here.

Development (see Chapter 3)

The pupillary light response is absent in infants of 29 gestational weeks or less, but is usually present by 31 or 32 weeks.[1] At birth, the pupil is small. It enlarges in the first months and is probably largest at the end of the first decade, gradually becoming more miotic with age. The pupil reactions of term or premature infants are often small in amplitude and, because of their small resting size, may be difficult to elicit clinically, especially with brown irides. The failure of the pupil grating response in infants under 1 month of age is further evidence of the immaturity of the pupil responses in infancy.[2] Topical cocaine and hydroxyamphetamine are less potent in infants, suggesting that decreased sympathetic tone underlies miosis of the newborn.[3] In very premature babies, the pupil may not have fully formed; during the seventh month of gestation, the vascular pupillary membrane atrophies, and the pupil appears. Before 32 weeks' gestation, mydriasis does not necessarily indicate a central nervous system lesion, nor does an unresponsive pupil necessarily indicate an afferent defect.[3]

Dynamic retinoscopy indicates that infants from 6 days to 1 month of age have no accommodation, but that normal function is achieved by 3–4 months.[4] As a result, higher spatial frequencies are defocused, and younger infants cannot discriminate them. However, photorefraction studies have demonstrated accommodation of over 1 diopter in the neonate, and this ability increases rapidly in the first month and to a lesser extent in the first few years of life, with high amplitudes from 4 years until presbyopia develops.

The near synkinesis

The near reflex is activated when looking from a distant to a near target. It comprises a triad of convergence of the eyes, accommodation of the lenses, and miosis of the pupils; these components are separate in origin, but linked as a synkinetic response. The afferent pathway of the near reflex is probably more ventrally located than the pretectal afferent pathway of the light reflex. Both reflexes share the final efferent pathways of, the oculomotor nerve, ciliary ganglion, and the short posterior ciliary nerves.

In uncooperative children, testing of the near pupil response is more difficult than the light response. A suitable fixation target, for example a small internally lit toy for an infant, a mobile toy with sufficient detail to stimulate convergence, or letters or numbers for a literate child, is the most important factor in testing.

Congenital and structural abnormalities

Congenital, structural, and developmental anomalies of the pupil include the following (many are found in Chapters 33 and 39):

- aniridia;
- micropupil (congenital idiopathic microcoria);
- polycoria and corectopia;
- coloboma;
- peninsula pupil (an inherited partial iris sphincter atrophy with dilated oval pupils);
- persistent pupillary membrane;
- congenital mydriasis and miosis;
- irregular pupils;
- abnormalities of iris color (heterochromia iridis);
- unequal size (anisocoria).

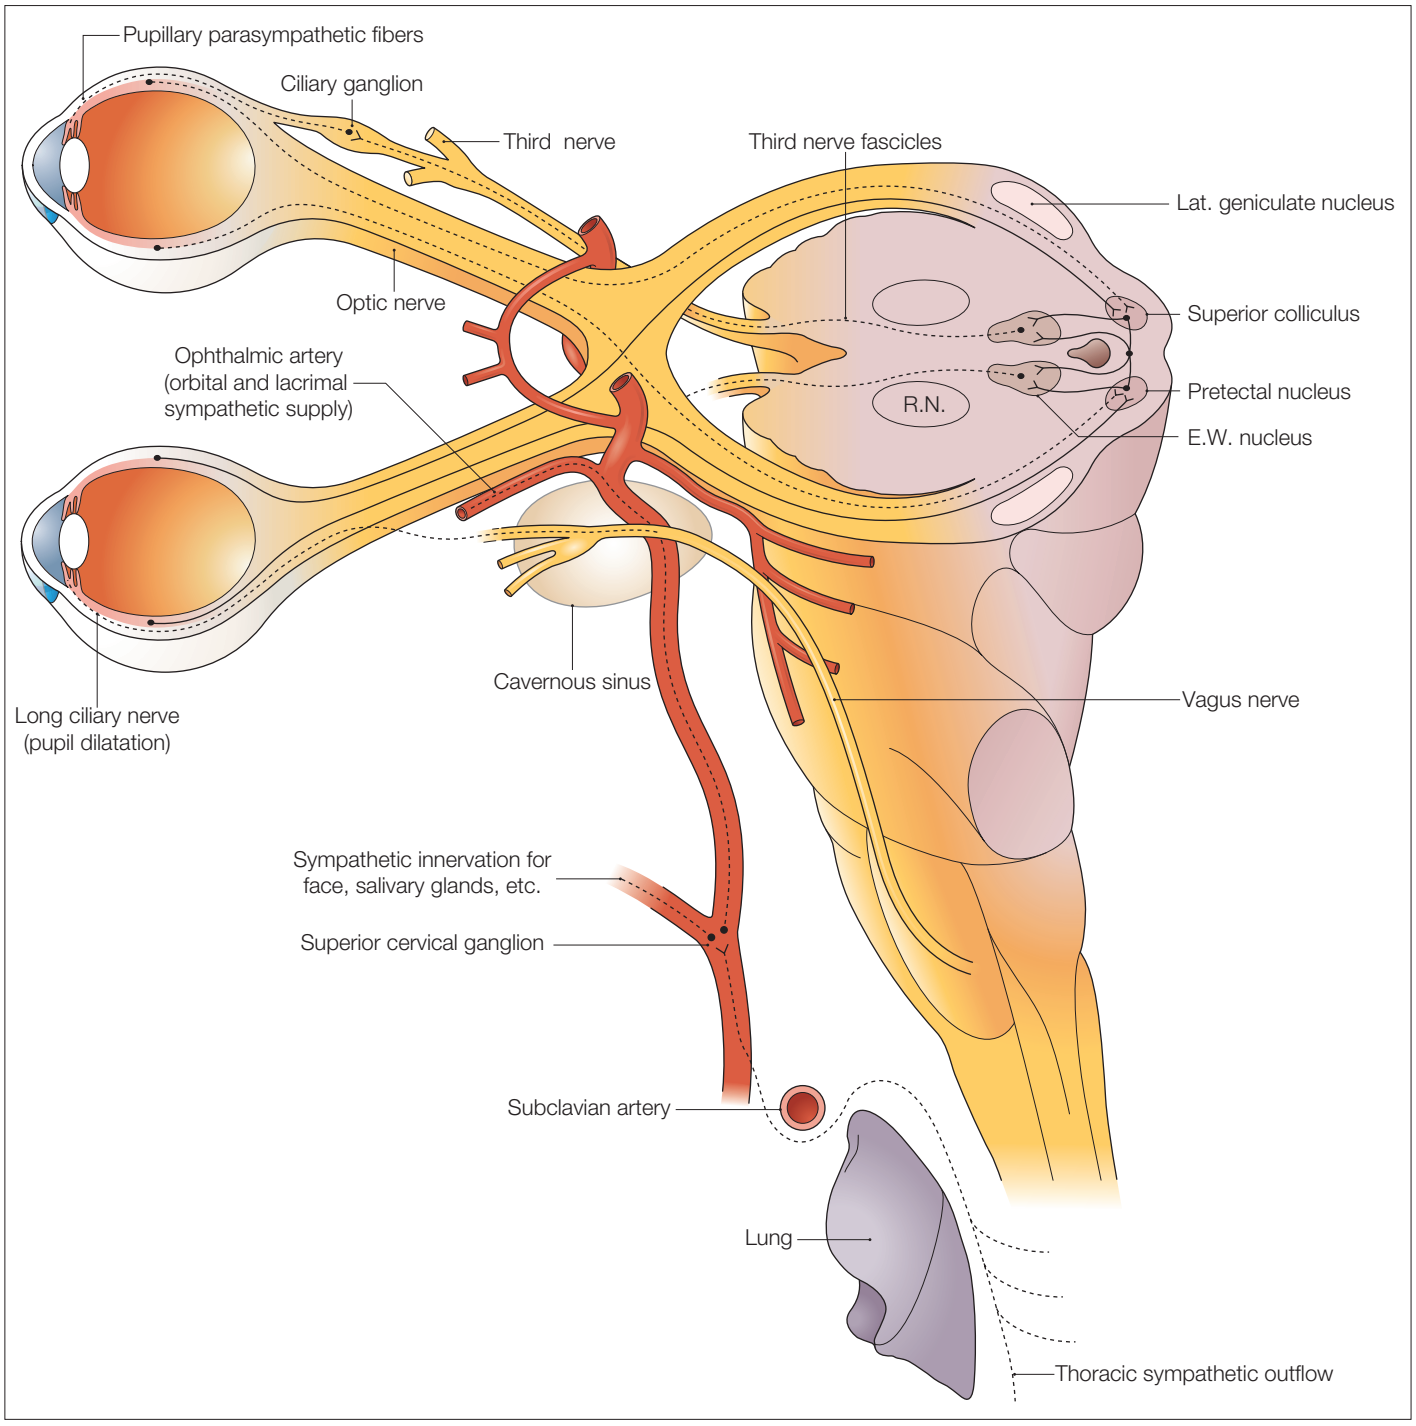

Fig. 66.1 Schematic representation of the efferent and afferent pathways involved in pupillary reactions. Red = blood vessels and parasympathetic; blue = afferent visual pathways; green = sympathetic pathway. E.W. nucleus, Edinger–Westphal nucleus; R.N., red nucleus.

Afferent and efferent abnormalities of pupil reactivity

Afferent pupil defects

Amaurotic pupils

A totally blind ("amaurotic") eye resulting from ocular disease usually has no pupil reaction to a light shone in it (amaurotic pupil), but a normal near reaction if the efferent system is intact. In monocular blindness, the affected eye has no direct pupil reaction but has consensual response to light shone into the unaffected eye (amaurotic pupil reaction). In binocular blindness from anterior visual pathway or retinal disease, both pupils are usually dilated, although they may be nearly normal size in longstanding blindness. If the efferent pupil pathway is intact, then the pupils will still react to near stimuli (light–near dissociation).

Relative afferent pupil defect

When one afferent pathway is affected or if bilateral afferent pathways are affected asymmetrically, the relative afferent pupil defect (RAPD) in the afferent pupil pathway can be detected clinically with the "swinging flashlight" test.[5]

The RAPD is the clinical sign used to detect a defect in the afferent pupillary pathway (i.e. an afferent pupil defect [APD]). The RAPD and the APD should not be used interchangeably; the RAPD is the clinical sign of an APD. Patients with only one eye can still have an APD without an RAPD.

Testing for a RAPD

In dim lighting, the observer shines a bright light into each eye individually. The child should fixate at distance to relax the accommodative pupil response. The light is swung between the two eyes (i.e. "the swinging flashlight test") with one second on each eye. If the afferent pupil pathway of one eye has a defect, the direct response will be less than the consensual reaction driven by the fellow eye, and the pupil of the affected eye will dilate as the light swings from the unaffected to the affected eye (i.e. a relative afferent pupillary defect). The RAPD can be graded subjectively from I through IV, with IV being an amaurotic pupil. Magnification provided by a slit-lamp may help detect a minimal defect in an older, more cooperative child. In situations with a known unilateral efferent pupillary defect or opacity precluding evaluation of one pupil, testing for the RAPD can still be performed. In this setting, a second light is held below the normal pupil. As the light swings from the affected eye to the unaffected eye, the normal pupil constricts, and when the light swings to the affected eye, the normal pupil will dilate. The RAPD is usually attributed to Robert Marcus Gunn who described sequential pupillary assessment with a bright light; the swinging light test is much more sensitive in detecting mild-to-moderate afferent defects.

An RAPD is objective evidence for an asymmetric lesion of the afferent pathway anywhere from the retina to the intercalated neurons of the midbrain pretectal nuclei. Thus, rarely a patient may have an RAPD (tectal RAPD) from a pretectal lesion without any visual loss (i.e. normal visual acuity, normal visual field, and normal fundus exam) because the afferent pupil fibers to the pretectal nuclei exit the optic tract distinctly from the visual pathway to the lateral geniculate nucleus. Although uncommon, a small RAPD may occur in deeply amblyopic eyes.[6] In older children, a useful subjective addition to testing for the RAPD is asking the child in which eye the light is brighter. The child may be asked a question, "If the light in the good eye is worth 1 dollar/pound, how much is the other one worth?" which may give a rough subjective quantification of an RAPD.

Light–near dissociation

Light–near dissociation is present when the pupil reacts better to a near than to a light stimulus. Defects in either the afferent or efferent pupillary pathway can produce light–near dissociation. In patients with symmetrical bilateral afferent disease, an APD might be difficult or impossible to detect. In these situations, it is especially important to look for light–near dissociation as potential evidence of afferent disease helping to localize the lesion.

Efferent pupillomotor defects

Argyll Robertson pupils

In 1869, Douglas Argyll Robertson described a type of light–near dissociation classically seen with tertiary syphilis. The pupils are small, irregular, and constrict more fully and more briskly to a near stimulus than to light (the pupils go from "small to pinpoint"). The iris is often found to be slightly atrophic on slit-lamp examination. The lesion in the Argyll Robertson pupil is presumed to be located in the dorsal midbrain,[7] and patients with such pupils should undergo serologic testing for syphilis.

Sylvian aqueduct syndrome (Parinaud dorsal midbrain syndrome)

Expanding lesions dorsal to the Sylvian aqueduct in children include pinealomas, ependymomas, "trilateral" retinoblastoma, granulomas, hydrocephalus, cystic and other lesions. Compression of the dorsal midbrain produces light–near dissociation that may include a vertical gaze palsy (typically upgaze palsy), lid retraction (Collier sign), accommodation defects, and convergence–retraction nystagmus. The resting size of the pupils is usually larger than normal. Sometimes, probably in more rapidly enlarging tumors, the pupils may be large and poorly reactive to light or near stimuli.

Adie syndrome (tonic pupil syndrome)

Adie syndrome, unusual in young children, is typically idiopathic, but may occur with chickenpox or other viral infections,[8] ophthalmoplegic migraine, and measles vaccination.[9,10] It is more frequent in young women.[11] It is usually unilateral, but many cases become bilateral.[11] Children rarely have symptoms related to the onset, but they may fail a school near vision test or complain of blurred near or, if they are hyperopic, distant vision or photophobia. They may develop anisometropic amblyopia. Many patients are asymptomatic, and parents may be the first to notice.

The acutely affected pupil is usually larger than that of the uninvolved eye (Fig. 66.2), but over time the Adie pupil tends to become miotic ("little old Adie"). There is typically a segmental paralysis of the iris sphincter, which might be extensive or diffuse. Once constricted, the pupil remains constricted longer (the "tonic" pupil). There may also be a transient defect in accommodation, which is often marked at first, but gradually improves over 2 or more years.[11] Corneal sensation may be reduced when tested with an esthesiometer or with a wisp of cotton.

This finding is probably due to damage to the trigeminal fibers that also pass through the ciliary ganglion. Patients with Adie pupil may also have hyporeflexia or areflexia in their extremities, but other neurologic findings are typically absent. Although the Adie pupil is a clinical diagnosis, denervation hypersensitivity of the pupil may be demonstrated by observing pupillary constriction compared to the fellow eye 20 minutes after bilateral instillation of pilocarpine 0.0625%. However, pharmacological denervation hypersensitivity may occur with post- and pre-ciliary ganglionic lesions (Fig. 66.3), and should not be used in isolation to differentiate the etiology for anisocoria (e.g. Adie pupil vs. third nerve palsy).

Loewenfeld and Thompson proposed that the ciliary ganglion is the site of the lesion of the tonic pupil and that

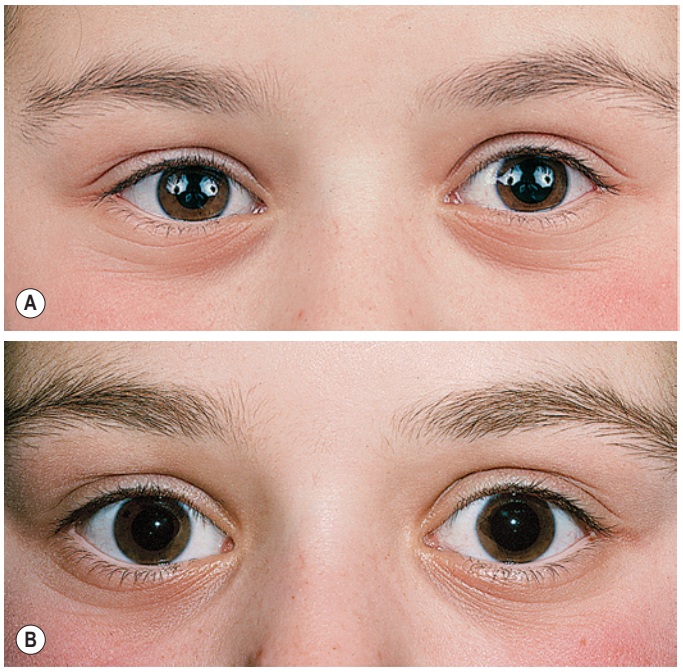

Fig. 66.2 Left Adie pupil. (A) In light; (B) in dark. The pupil size difference is less in the dark.

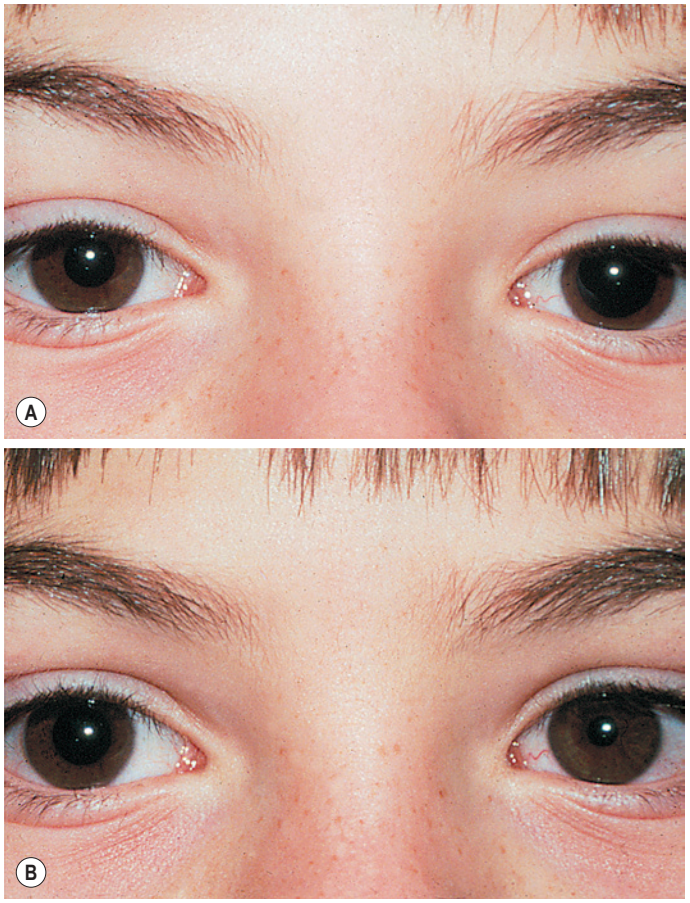

Fig. 66.3 Left Adie pupil (A) before and (B) after instillation of 0.1% pilocarpine. The right pupil is unchanged while the left constricts due to denervation hypersensitivity.

many of its features result from aberrant regeneration.[12] The cause is unknown, but it may be a neurotropic virus. Most patients do not require treatment, but pilocarpine (0.1% three times daily) or another dilute miotic may help with photophobia and occasionally with symptoms secondary to accommodation paresis. In distinction to adult patients, young children with Adie or other tonic pupils should have the unaffected or better eye occluded for a short period each day to avoid amblyopia. Spectacle correction of hyperopia in the affected eye may be necessary to prevent anisometropic amblyopia.

Other causes of tonic pupils

Although Adie syndrome is the classic idiopathic tonic pupil, other etiologies of ciliary ganglion damage cause a similar syndrome. Congenital or acquired tonic pupils have been described in infants with: orbital tumors; traumatic, infectious, or inflammatory diseases; or as part of a variety of widespread neuropathies including syphilis, diabetes, Guillain–Barré syndrome, Miller Fisher syndrome, pandysautonomia, hereditary sensory neuropathy, Charcot–Marie–Tooth disease, and trilene poisoning. Autonomic neuropathy secondary to paraneoplastic disease has also caused tonic pupils.

Iris abnormalities

Damage to the iris by trauma, irradiation, uveitis, ischemia or hemorrhage, or involvement with a tumor such as lymphoma, leukemia, juvenile xanthogranuloma, leiomyoma, or neurofibroma, may all give rise to anisocoria, corectopia, and/or impaired pupil reactions (Fig. 66.4). Slit-lamp examination of the iris can demonstrate the disruption of the iris architecture from the underlying cause.

Benign episodic unilateral mydriasis ("springing pupil")

The syndrome of idiopathic episodic mydriasis is likely a heterogeneous group of conditions that result in parasympathetic insufficiency of the iris sphincter or sympathetic hyperactivity of the iris dilator.[13] In either case, anisocoria usually lasts for several hours and then resolves spontaneously. Other signs of oculomotor or sympathetic nerve dysfunction are absent, but the syndrome is frequently accompanied by headache or orbital pain.[13] Although it affects primarily young women, it has been reported in both genders and many ages.

Midbrain corectopia

Damage to some midbrain pupillary fibers may lead to unequal upward and inward distortion of the pupil and an unequal sinuous pupil reaction to light and near stimuli. The patients described were often, but not always, comatose.

Third nerve palsy (see Chapter 83)

In complete third nerve palsy, the pupil is unreactive (Fig. 66.5), but in partial or recovering third nerve palsy, the ipsilateral pupil reaction may be sluggish or uneven. Patients with a poorly reactive pupil or anisocoria should have motility and lid evaluation to exclude third nerve palsy.

Abnormal pupillary contractions can occur in aberrant regeneration (Fig. 66.6) following third nerve palsy.[14] The

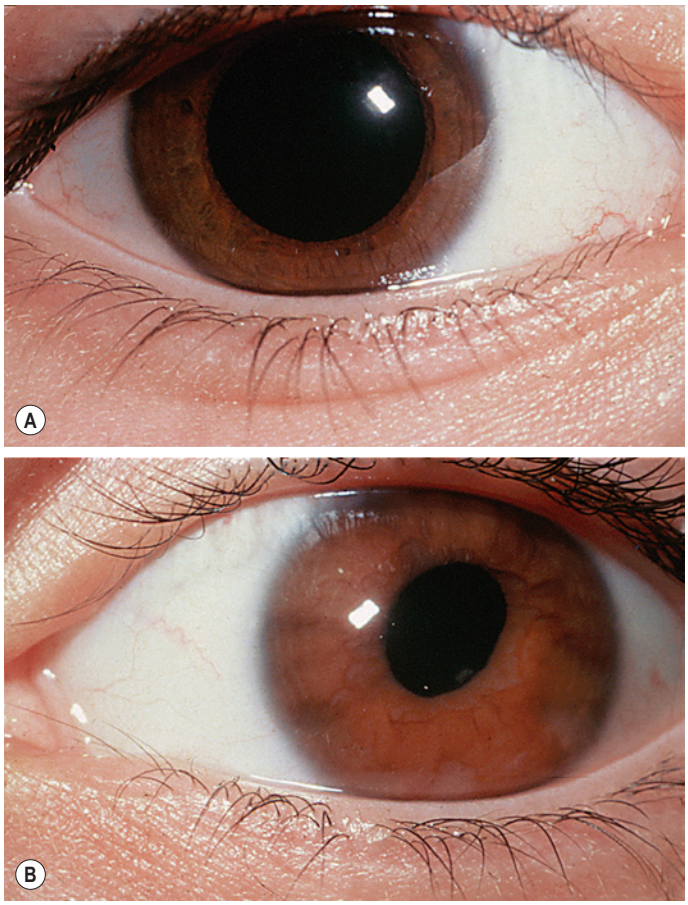

Fig. 66.4 Normal right eye (A) and left iris abnormality with sluggish reactions and small pupil due to leukemic infiltration (B).

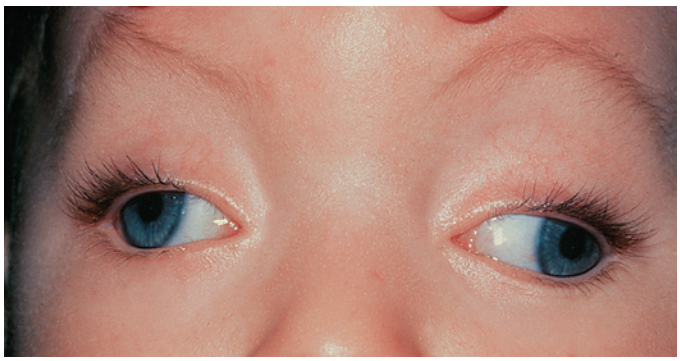

Fig. 66.5 Bilateral congenital third nerve palsy with fixed and unreactive pupils.

pupil may constrict with activation of extraocular muscles or may be smaller on the ipsilateral side (Fig. 66.7).

Riley–Day syndrome

In the Riley–Day syndrome (familial dysautonomia; see Chapters 34 and 54), there is a hypersensitivity to dilute parasympathomimetic agents (i.e. pilocarpine 0.1%).

Iris sphincter or dilator muscle spasms

Spasm of the iris dilator can give rise to "tadpole-shaped" pupils, which usually occurs in otherwise healthy young

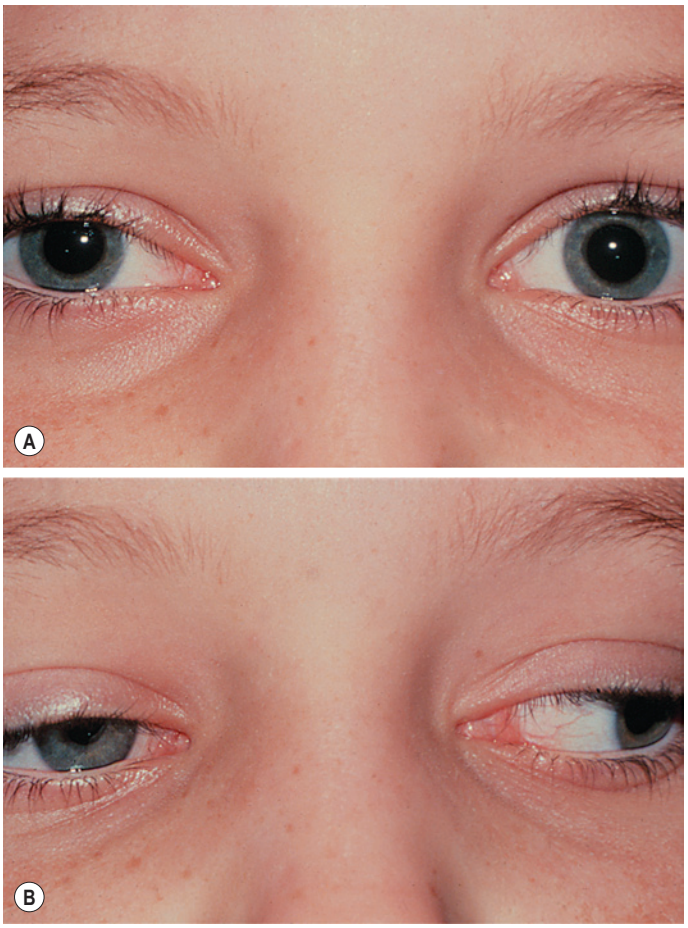

Fig. 66.6 Aberrant regeneration following partial recovery from right traumatic third nerve palsy. The right pupil constricts on attempted adduction.

Fig. 66.7 Left congenital third nerve palsy. In longstanding cases the pupil may be small.

adults.[15] The pupils are peaked in one direction for a few minutes, which may occur on several, separate occasions. This phenomenon may represent a subset of patients with springing pupil.

Paradoxical pupils

In some people with retinal disease, a curious phenomenon occurs in which the pupil size is larger in light than in dark, despite otherwise normal responses.[16] The parents occasionally may remark on it, but it is usually a sign that must be elicited.

When present, it is extremely helpful as it is associated with retinal diseases, typically congenital stationary night blindness (see Chapter 46), but also with cone dysfunction syndromes, such as achromatopsia.[17] It has also been described in Leber amaurosis, dominant optic atrophy (see Chapter 54), optic neuritis, and amblyopia (see Chapter 73).[18] The pupillary responses are brisker in patients with lower acuity and Ishihara scores.[17]

Paradoxical pupils can be recorded using photographs in a fully lit room and in a nearly fully darkened room. The child must be left in the dark for at least a minute; the pupils can be observed using a flashlight for a moment or with an infrared viewing device or videography. In a child with nystagmus, paradoxical pupils suggest obtaining an electroretinogram. The mechanism has not been explained adequately, but it is interesting that dark-rearing normal chicks to maturity causes them to have paradoxically constricted pupils in the dark.

Horner syndrome

Ocular sympathetic denervation (i.e. Horner syndrome [HS]) in childhood is not uncommon, may be congenital or acquired, and may be due to benign or malignant etiologies.

Clinical characteristics

Miosis

The pupils are unequal, with the difference greater in the dark due to the failure of the sympathetically innervated dilator pupillae muscle (Fig. 66.8). The difference depends on the completeness of the lesion, the child's alertness and the ambient lighting conditions. A drowsy child is more likely to have a low resting pupillary tone, and the inequality will be less obvious. There is also a lag in the ipsilateral dilatation, which results in a greater anisocoria at 5 seconds than at 15 seconds after darkening the room. It is best measured by photographs. Pupil reactions to light and near are unaffected.

Ptosis

A 1–2 mm ptosis of the upper lid (due to weakness of Müller's muscle) is typically present in HS, but it may be so slight and variable that it escapes notice or may be absent (Fig. 66.9). Some children present with miosis without ptosis.[19] Parents should watch for the delayed development of ptosis as the onset can be asynchronous. Ptosis can also be present without miosis.[19] The lower lid may also be affected ("reverse ptosis"), giving rise to a more obvious narrowing in the palpebral fissure and a false appearance of enophthalmos (i.e. "apparent enophthalmos").

Ipsilateral anhidrosis

Lesions proximal to the superior cervical ganglion, where the sweat and piloerector fibers branch to travel with the external carotid artery, will damage these fibers and cause ipsilateral facial and conjunctival flushing and nasal stuffiness in acute lesions. In longer-standing lesions, the defect of sweating results in a dry, warm side of the face while the unaffected side is cool and sweaty. In chronic lesions, the affected side may be pale due to denervation hypersensitivity to circulating catecholamines. Most children do not complain of anhidrosis, but parents may describe that one side of the face does not flush, particularly with crying.

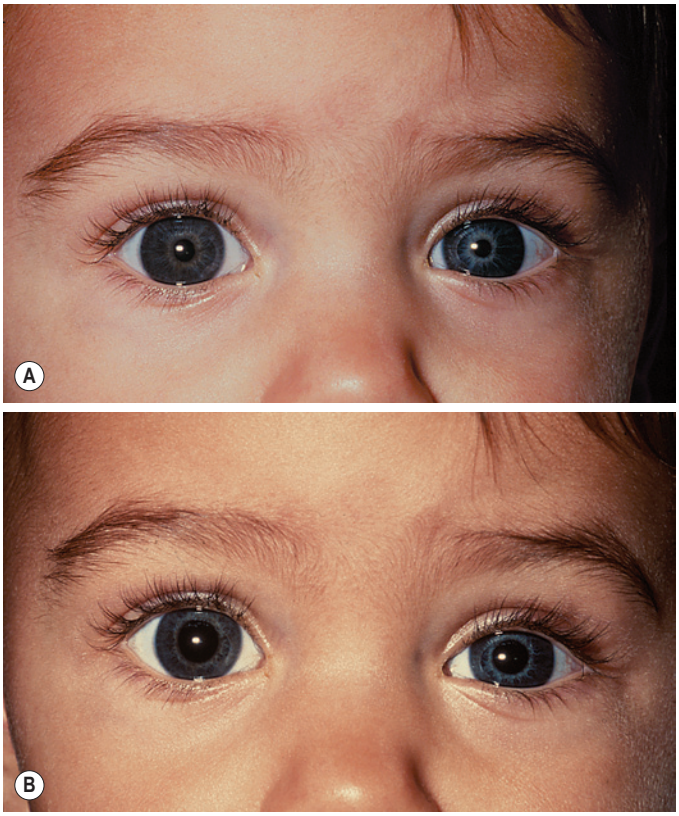

Fig. 66.8 Left Horner syndrome with mild upper and lower lid ptosis. (A) Photograph taken in the light. (B) Same patient 5 seconds after lights turned out showing dilation lag.

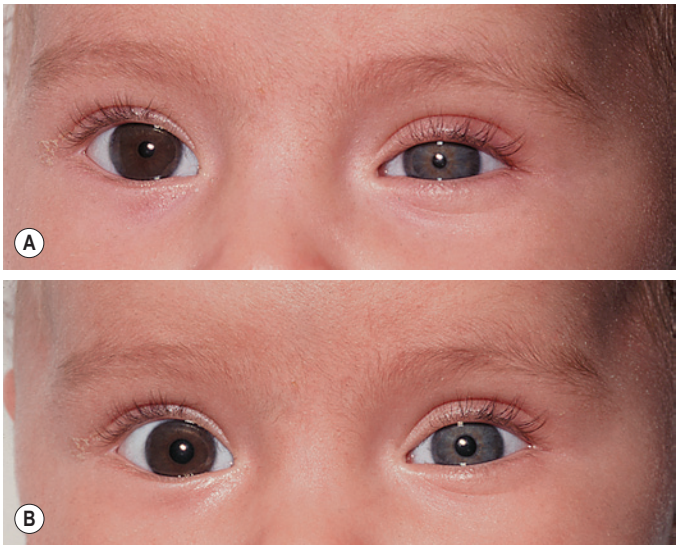

Fig. 66.9 Left congenital Horner syndrome showing upper and lower lid ptosis and an iris heterochromia with the lighter eye being the affected eye. (A) In bright light; (B) in the dark.

Heterochromia

In congenital HS, because iris pigmentation is partially dependent on sympathetic innervation, heterochromia may occur with the lighter iris on the affected side, especially with

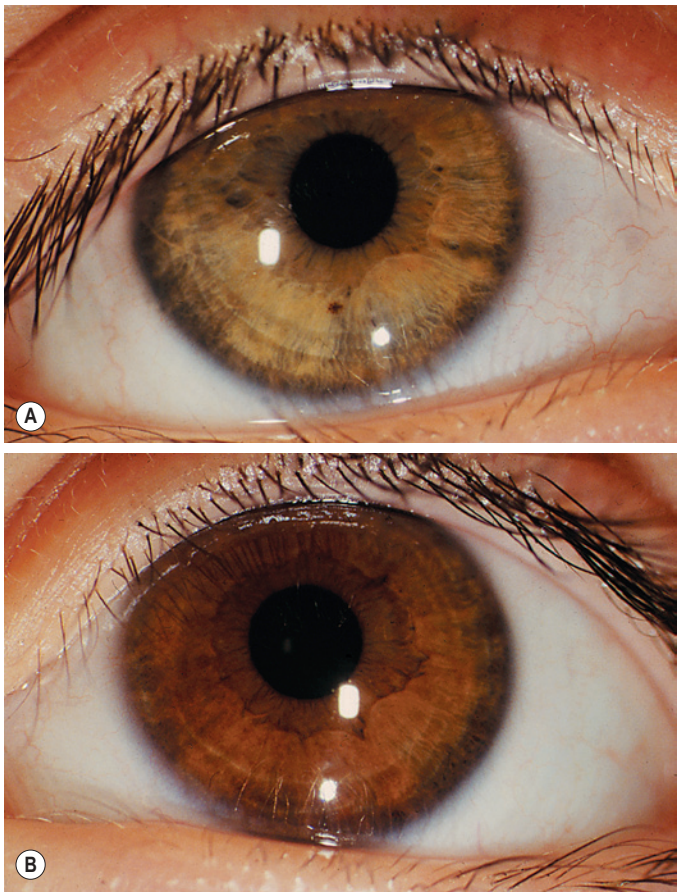

Fig. 66.10 Right congenital Horner syndrome in a teenager. (A) The right iris was noticed to develop a lighter color at the age of 2 years although the ptosis and pupil size were noticed at a few weeks of age. (B) The normal left eye.

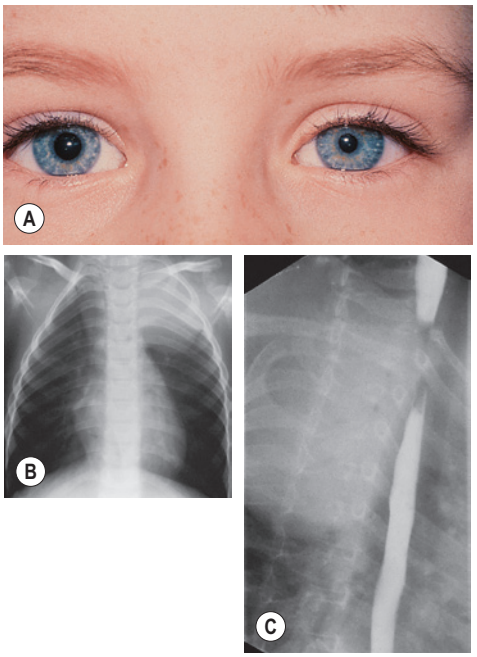

Fig. 66.11 Congenital Horner syndrome. (A) Left Horner syndrome. This child presented with the complaint of a sudden-onset ptosis and small pupil. (B) Chest X-ray showing left apical mass. (C) Barium swallow showing constriction of the esophagus. The cause was a large benign ganglioneuroma.

brown irides (Fig. 66.10). Although believed to be a sign of congenital HS, iris heterochromia occasionally has been described in acquired cases in children[20] and adults.[21] Thus, the presence of heterochromia alone should not be used clinically to define the potential etiology for the HS as benign, especially if the iris heterochromia is progressing rather than static. In addition, heterochromia is not invariably present in congenital HS, especially in already light-colored irides or if insufficient time has elapsed (Fig. 66.11). Histopathologically, in one case, the iris pigment epithelium was normal, there were no iris sympathetic fibers, and the stromal melanocytes were reduced in number, but contained normal melanosomes.[22] The anterior border cells were depleted.

Pharmacological responses

Topical cocaine 10% blocks reuptake of norepinephrine by sympathetic nerve endings, causing dilation of normally innervated pupils. The iris dilator tone depends on an intact oculosympathetic pathway. Lesions of any one of the three oculosympathetic pathway neurons results in decreased norepinephrine release by the postganglionic neuron, so the pupil in the HS fails to dilate as well as the fellow normal pupil, if at all. Topical cocaine can distinguish between normal or physiological anisocoria and anisocoria due to HS.

Hydroxyamphetamine 1% causes release of noradrenaline from presynaptic nerve terminal stores; it should be instilled into the conjunctival sac of both eyes at least 24 hours after the use of cocaine. Where the postganglionic neuron is intact, norepinephrine is present and the pupil dilates; but if the postganglionic neuron is damaged, it contains less norepinephrine and does not dilate as well. Hydroxyamphetamine takes effect in about 40 minutes. However, trans-synaptic degeneration in children limits the sensitivity and specificity of hydroxyamphetamine for localization purposes, and it is not available in many countries.

Low-dose adrenaline (epinephrine) 0.1% (1 : 1000) normally does not dilate the pupil, but in postganglionic HS, the pupil dilates secondary to denervation hypersensitivity. Adrenaline 0.1% has the advantage of being more readily available and is not a proscribed drug.

Apraclonidine 0.5% may be useful in establishing a diagnosis of HS; it causes reversal of anisocoria under both dark and light conditions. Topical apraclonidine is readily available and inexpensive. It is an alpha agonist that normally affects alpha-2 receptors more strongly than alpha-1 receptors. The differential effect on alpha-1 and alpha-2 receptors produces dilation in the smaller pupil and constriction in the normal, larger pupil. Apraclonidine's major site of pharmacologic action is postjunctional alpha-2 receptors in the ciliary body that produces lowered intraocular pressure. Upregulation of alpha receptors that occurs with sympathetic denervation in the HS unmasks the alpha-1 effect, and the smaller pupil dilates. In a recent series of HS in children, apraclonidine 0.5% demonstrated excellent sensitivity and specificity, with the best observation results under light conditions.[23] However, it should be used with caution, if at all, in infants because of possible central nervous system depression.

Pharmacologic testing is usually not necessary to confirm the HS, but because physiological anisocoria presents sometimes with lid abnormalities, and ptosis and miosis can present

asynchronously or in isolation, it may be helpful. Atypical presentations of HS in children can include miosis only, ptosis only, or even intermittent miosis and ptosis.[19] In these cases, pharmacologic testing may aid in the diagnosis.

In children, the main diagnostic difficulty is measuring the inequality and changes in light and dark; it may be aided by photographs. The use of topical testing to differentiate physiologic anisocoria from HS is reasonable for equivocal cases, but most authors believe that children with an unexplained HS should undergo imaging and other testing (e.g. catecholamine testing) of the ocular sympathetic pathway to exclude treatable and potentially life-threatening causes (e.g. neuroblastoma).

Other characteristics

There have been various reports of ipsilateral accommodative increase or decrease, but the difference does not seem to be reliably present or easy to measure in children. The ipsilateral central cornea may be thicker on the affected side.

Congenital Horner syndrome (see Fig. 66.10)

Weinstein et al. divided congenital HS into three causal types[24]:

- Those who suffered obstetric trauma, usually by forceps, to the internal carotid artery and its sympathetic nerve plexus and had a postganglionic HS on drug testing: they did not dilate with 1% hydroxyamphetamine. They had no facial anhidrosis.
- Those who suffered surgical or obstetric trauma to the preganglionic sympathetic pathway including patients with brachial plexus injury (Klumpke palsy). Cardiothoracic surgery is another common cause in children.
- Those without a history of birth trauma but with a Horner syndrome and evidence of a lesion at, or peripheral to, the superior cervical ganglion and anhidrosis. Congenital or early-onset HS with a preganglionic lesion and anhidrosis occurs in patients with neuroblastoma.[25,26]

Congenital HS may also be found with hemifacial atrophy, cervical vertebral anomalies, congenital tumors, arachnoid cysts and holoprosencephaly, and congenital varicella syndrome. Despite the above list of causes, most children with congenital HS have no other abnormalities.[27]

Postnatally acquired Horner syndrome

In contrast to congenital HS, any unexplained acquired HS in children is more significant and usually serious. It may occur in the following:

- "Central" preganglionic lesions due to brainstem trauma, tumors, or vascular malformations, infarcts and hemorrhages, and syringomyelia. Other neurologic dysfunction is usually evident in these cases.
- "Preganglionic" lesions, i.e. of the second neuron between the spinal cord and the superior cervical ganglion, due to neck trauma, neuroblastoma, and other tumors (see Fig. 66.11).
- "Postganglionic" lesions, i.e. of the final neuron after the superior cervical ganglion, due to cavernous sinus lesions (tumors, aneurysms, or inflammatory disease), neuroblastoma, and trauma.

Management

Congenital Horner syndrome

Since birth trauma and early cardiothoracic surgery are the most frequent causes of HS, further investigations are usually unnecessary.[26] However, the albeit rare occurrence of tumors in children with congenital Horner syndrome of no obvious cause may still warrant imaging of the oculosympathetic pathway and a 24-hour catecholamine assay. Several children with unexplained HS were found to have neuroblastoma on imaging, but normal urinary catecholamines[25]; this discrepancy may be due to lower sensitivity of spot urine catecholamine testing as opposed to 24-hour assays. Normal urine studies do not necessarily exclude neuroblastoma. The gravity of this diagnosis may demand both imaging and catecholamine assays as initial investigations. However, given the relatively low incidence of neuroblastoma in children with unexplained HS, performing catecholamine assays and a careful physical examination while reserving imaging studies for children with elevated catecholamines or suggestive examination findings or changes in clinical findings may be an equally suitable approach.[26]

Acquired Horner syndrome

Where there is no obvious cause, such as trauma or surgery, a child with acquired Horner syndrome should be investigated in conjunction with a neurologist, and investigations include imaging of the ocular sympathetic pathway and a 24-hour catecholamine assay (see Fig. 66.9).

Pupil changes from high sympathetic "tone"

Cases have been described in which an intermittent dilated pupil, with or without widening of the palpebral fissure, occurs associated with a cervicomedullary syrinx, post spinal cord injury, lung tumors, seizures, or migraine. In seizures and migraine, there may well be a simultaneous lowering of parasympathetic tone, but sympathetic-induced spasm is suggested by pallor and sweating.

Pupil changes from damage to the parasympathetic system (see Chapter 83)

Internal ophthalmoplegia (paralysis of the sphincter pupillae and accommodation) is occasionally seen without external ophthalmoplegia from nuclear lesions. It is bilateral and often associated with other oculomotor palsies.

Damage to the third nerve in the interpeduncular fossa, where the pupillomotor fibers are confined to the superomedial aspect of the nerve, may occur from aneurysm or tumor and is usually associated with external ophthalmoplegia, but meningitic lesions can cause an isolated internal ophthalmoplegia.

Pharmacological agents

Numerous pharmacological agents affect pupil size and reactivity. Systemic agents usually affect the pupils symmetrically

while topical agents are often instilled into only one eye, causing asymmetry.

Pupil-dilating agents

Parasympatholytic agents

Atropine 0.5–1%, homatropine 2%, cyclopentolate 0.5–1%, and tropicamide 1% are all commonly used agents to dilate the pupil and induce cycloplegia. Homatropine and atropine have prolonged action and are not often indicated diagnostically or therapeutically unless their long action is desirable, as in the case of penalization therapy for amblyopia. Hyoscine 0.5% has an action similar to that of atropine but is shorter acting. These agents may cause respiratory failure in children with congenital central hypoventilation. Inadvertent exposure to topical mydriatrics can produce pharmacologic dilation in children, and parents should be specifically questioned about these agents. In addition, contact with certain garden or wild plants (e.g. belladonna alkaloids, jimson weed) containing parasympatholytic agents can produce mydriasis.

Sympathomimetics

Adrenaline (epinephrine) 0.1–1% or phenylephrine 2.5–10% may be used to dilate the pupil in association with a parasympatholytic. They have no action on accommodation and are not sufficiently effective to produce good dilation. They must be used with great care, and at lowest dilution, if at all, in premature babies, those with cardiac or vascular disease, or those with hypertension.

Pupil-constricting agents

Cholinergic drugs

Pilocarpine 1–4% is commonly used to constrict the pupil. It is now used occasionally in the treatment of glaucoma and has little effect on infantile glaucoma. Some pet flea and tick treatments and collars contain cholinergic agents that produce miosis.

Anticholinesterases

Phospholine iodide (echothiophate) 0.03–0.125% and eserine 0.5% are infrequently used for the treatment of glaucoma. Phospholine iodide is used to cause peripheral accommodation and "unlink" the association between accommodative convergence and accommodation in some cases of high AC:A ratio strabismus. It rarely may cause cataracts and occasionally reversible iris cysts. It interacts with some muscle relaxants used in anesthesia.

Sympatholytic agents

Guanethidine 5% (Ismelin) can be used to counter lid retraction in hyperthyroidism. Thymoxamine 1% may also cause pupil constriction. These drugs are rarely, if ever, used currently in practice.

Systemic agents

Atropine, scopolamine, and benzatropine (benztropine) can cause pupil dilatation and paralysis of accommodation. The seeds of jimson weed, the berries of deadly nightshade, and henbane have all been known to cause a serious or fatal poisoning. The symptoms have been described as "hot as a hare, blind as a bat, dry as a bone, red as a beet, mad as a hatter." Mydriasis from topical atropine or atropine-like drugs is not counteracted by pilocarpine 1%, but in systemic poisoning it may be. Antihistamines and some antidepressants produce mydriasis. Heroin, morphine and other opiates, marijuana, and some other psychotropic drugs cause bilateral pupil constriction.

Abnormalities of the near reflex

Congenital absence

Children may be born with a defect in the near reflex. They have absent accommodation, poor convergence, and the pupil fails to constrict to a near stimulus but constricts to light.[28]

Familial cases of accommodation defect occur.[29] The cause is unknown, but it may be peripheral in origin.

Acquired defects

Sylvian aqueduct (Parinaud) syndrome

Premature presbyopia is one of the signs of tumors encroaching on the dorsal midbrain. Other more classic signs include convergence–retraction nystagmus, vertical gaze defects, eyelid retraction, convergence defect, and pupil light–near dissociation.

Systemic disease

Botulism, diphtheria, diabetes, and head and neck trauma may give rise to accommodation defects either isolated or associated with eye movement and vergence defects. Wilson disease has been shown to be associated with a defect in the near response in some cases.

Pharmacological agents

See above.

Eye disease

Defective accommodation can occur in children with severe iridocyclitis (see Chapter 40), dislocated lenses (see Chapter 36), large colobomas (see Chapter 33), buphthalmos (see Chapter 38), very high myopia, and direct eye trauma including retinal detachment surgery.

Other neurological causes

Adie tonic pupil syndrome and third nerve paralysis may cause defective accommodation. Other orbital diseases, presumably by affecting the short ciliary nerves, may cause cycloplegia and accommodation defect.

Accommodation in school children

A school-aged child normally has a high amplitude of accommodation irrespective of refractive error. It has been suggested that there is a causal relationship between a defective near response and some cases of dyslexia. It is important, however, to distinguish clearly between reading difficulties due to a defective near response, which can be improved by exercises, and dyslexia, which is a defect in the perceptual process involved with reading and writing that cannot be remedied by simple exercises.[30]

Spasm of the near reflex consists of episodes of:

- accommodation-induced pseudomyopia;
- convergence of the eyes (intermittent esotropia);
- miosis.

The symptoms are usually blurred and double vision and ocular pain or headache. These cases are rarely due to organic disease, although closed head trauma is recognized in a number of cases. Upper brainstem pathology is often suspected, but rarely found. In two cases with closed head trauma, magnetic resonance studies revealed no abnormalities in the midbrain, but both had lesions in the left temporal lobe.[31]

In most cases, no organic disease can be found, and it is assumed to be psychogenic. The episodes have a sudden onset and can last many hours and may be variable. There is blurred vision and photophobia. The eyes are crossed and may mimic a bilateral sixth nerve paresis. The essential finding is increasing pupillary constriction as the deviation increases. Pupils that become constricted on attempted lateral gaze are also a clue to the functional nature of the complaint. It is unusual in childhood. Occasionally, symptoms may be recurrent over several years.

The treatment is reassurance of the child and parents. Some patients are helped by miotics, but more often by a combination of cycloplegia and bifocal glasses. Unless there are any neurological signs, no investigations are required, and the prognosis is good.

Introduction

Acute lymphoblastic leukemia (ALL) is the most common cancer in childhood, accounting for more than 30% of cases, with 400–500 new children diagnosed annually in the UK. Acute myeloid leukemia (AML) accounts for 5% of children's cancers, with 60–70 new cases in children in the UK each year. Combination chemotherapy for acute leukemia in children is highly effective; thus, serious ocular involvement is much less common than it was, and routine ophthalmic surveillance is usually unnecessary. Five-year survival rates of over 85% are usual for ALL and up to 60% for AML. The majority of treatment failures are due to recurrent leukemia, and treatment-related deaths have become less common with improved supportive care.

Several clinical and biologic criteria adversely affect ALL prognosis and treatment regimens: age (infants under 1 year and children over 10 years suffer higher relapse rates), high presenting white blood cell count, slow response to initial therapy, and chromosomal changes within the leukemic cells. The following approach has closed the gap in treatment success rates originally identified between the subgroups of patients.

It is now clear that for children receiving optimal contemporary therapy, leukemia cytogenetics and response to treatment as measured by minimal residual disease are the strongest prognostic indicators. Almost all children are treated with 2–3 years of chemotherapy; bone marrow transplantation (BMT) is reserved for the approximately 10% of children with initial very poor prognosis, or following relapse. AML treatment is very intensive over 5 or 6 months, chemotherapy is increasingly effective, and BMT has become less common. Outcome of therapy correlates with chromosomal changes in the leukemic cells and response to initial treatment, which are used to divide children into subgroups in a manner similar to those for ALL.

Common sites of disease at presentation are bone marrow, blood, lymph nodes, liver, and spleen. The eye is the only site where the leukemic involvement of nerves and blood vessels can be directly observed and it may act as a "sanctuary" for leukemic cells against chemotherapy. Eye complications may occasionally be the major residual disability[1] but serious eye involvement is unusual.[2] Ophthalmic manifestations may be dramatic, requiring prompt diagnosis and treatment, and are more a feature of relapse than of initial presentation. The ocular manifestations of acute leukemia are divided into direct (infiltration of the anterior segment, the orbit, or the central nervous system [CNS]) and indirect (secondary to hematologic changes such as hyperviscosity, anemia, thrombocytopenia, and immunosuppression).[3] Ocular manifestations are more common in AML than ALL and the presence of specific orbital or ocular lesions is associated with a higher frequency of bone marrow relapses and CNS involvement.[4]

Orbital leukemia is a small, but significant, cause of proptosis in children.[5] It can be the presenting feature of leukemia[5]; however, it is more likely to be found in uncontrolled disease, in the first decade, and with AML. It is associated with higher mortality. Orbital presentation may occur without eye involvement and it may be the only manifestation, especially in AML. Myeloid leukemia may present as an isolated solid tumor mass (granulocytic sarcoma) at various sites, including the orbit (Fig. 67.1). A greenish tinge to the tissue mass led to the term chloroma: this appearance may be due to myeloperoxidase or altered blood products.

Orbital involvement in leukemia may be due to bone or soft tissue infiltration, tumor formation, or hemorrhage; the lacrimal gland or lacrimal drainage apparatus may be primarily involved, with a more benign diagnosis. Children with orbital involvement present with proptosis, chemosis, and, rarely, extraocular muscle involvement; these may occur early in the disease. Exposure keratitis may occur. It may be difficult to differentiate between primary leukemic infiltration and

Fig. 67.1 "Chloroma" due to myeloid leukemia.

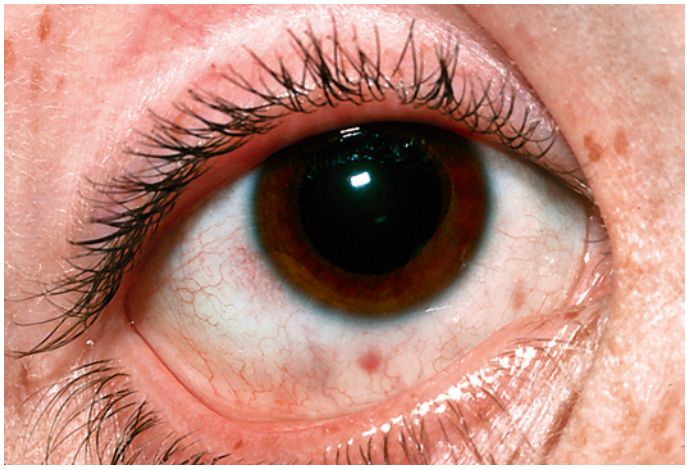

Fig. 67.2 Conjunctival hemorrhages and infiltration in acute lymphoblastic leukemia.

complications such as hemorrhage or opportunistic infection; a biopsy may be necessary.[6] The biopsy should be taken from the center of the abnormal area, not from the periphery where secondary inflammatory changes may occur. Review of the blood count and blood film by a pediatric hematologist, and a thorough clinical assessment prior to biopsy, together with a bone marrow examination at the time of biopsy, are important.

Lids

The lids are usually only involved as a part of orbital infiltration, but lid involvement can occasionally be due to direct leukemic infiltration.[7]

Conjunctiva

The conjunctiva may be involved by hemorrhage (Fig. 67.2), infiltration (Fig. 67.3), or hyperviscosity, when the vessels are tortuous or comma-shaped. Conjunctival mass formation, although rare, can be the presenting sign in acute leukemia.[3]

Cornea and sclera

Being avascular, the cornea is not often involved in the leukemias, but herpes simplex or zoster may occur in the immune-compromised child. Corneal ulcers may be the presenting sign of acute leukemia[8] and perilimbal infiltrates have been described in acute monocytic leukemia.[9]

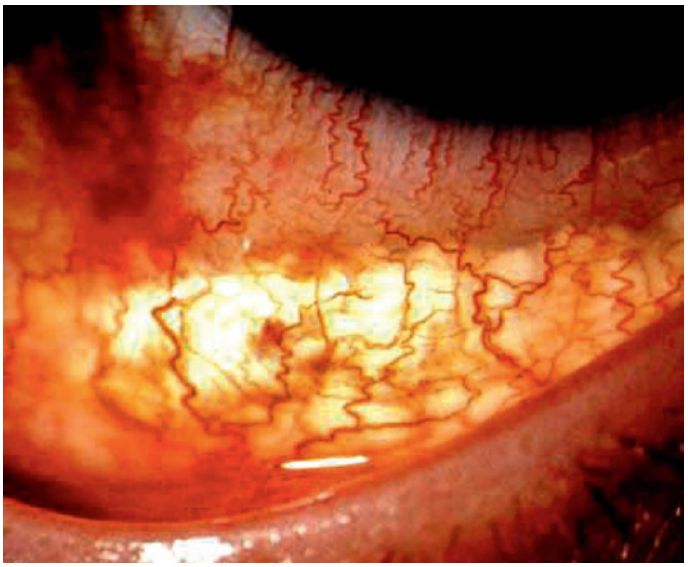

Fig. 67.3 Conjunctival infiltration with leukemic cells (acute lymphoblastic leukemia).

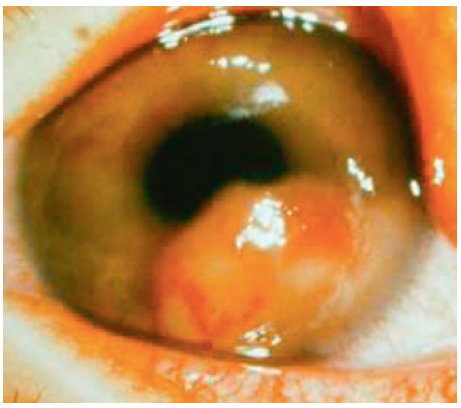

Fig. 67.4 Anterior chamber relapse (acute lymphoblastic leukemia).

Lens

Cataracts develop frequently in patients who have had total body irradiation. Their occurrence is related to the total dose and to the rate and fractionation of administration.[10] The use of steroids to treat graft-versus-host disease may cause or exacerbate cataracts.

Anterior chamber, iris, and intraocular pressure

Most reported cases have been of relapse in ALL (Fig. 67.4) but, rarely, children present with a leukemic hyphema or hypopyon. In ALL, anterior segment relapse accounts for up to 2% of all relapses; it is very rare in AML.[7,11]

The infiltration is most likely to be blood-borne rather than CNS related[10] and the relatively frequent occurrence of isolated anterior segment relapse supports the concept of the eye as a sanctuary site.[12] Because of the blood–eye barrier, chemotherapeutic agents do not penetrate the eye as well as at

many other tissues, allowing leukemic cells to survive, causing recurrence after chemotherapy has stopped. Symptoms include redness, watering, photophobia, pain, and visual loss. The parents may notice changes in the shape or reactions of the pupil or in the color and appearance of the iris (Fig. 67.5). Leukemia accounts for 5% of pediatric uveitis[3] and should always be considered as a possible cause of uveitis in a child with a previous history of leukemia.

Clinical findings are variable; iritis and hypopyon are the most common. Ciliary injection, keratic precipitates, anterior chamber cells, and flare are frequent. Posterior synechiae are unusual, but a grayish hypopyon streaked with blood is common. Secondary glaucoma is common and is associated with corneal edema, pain, and redness.

The iris may be thickened diffusely (Fig. 67.6) or by one or more nodules, or a mass of variable size; the thickening of the iris obliterates the iris crypts resulting in a rather featureless iris. The iris may also be thinned with loss of pigment (Fig. 67.7). The iris color may change, usually by a brownish discoloration. Rubeosis may occur. It is often the failure of standard treatment for uveitis that draws the ophthalmologist's attention to the underlying leukemia. If in diagnostic doubt, anterior chamber paracentesis and iridectomy are helpful diagnostic procedures[11]; a paracentesis alone may not be sufficient to give an accurate diagnosis. Pathologic studies show leukemic infiltration of the iris and trabecular meshwork,[7] and the hypopyon consists of leukemic cells, necrotic tissue, and proteinaceous exudate. Leukemic cells may be difficult to find. Patients with glaucoma have leukemic obstruction of the outflow channels and episcleral vessels.

Fig. 67.5 Anisocoria and mild heterochromia (acute lymphoblastic leukemia).

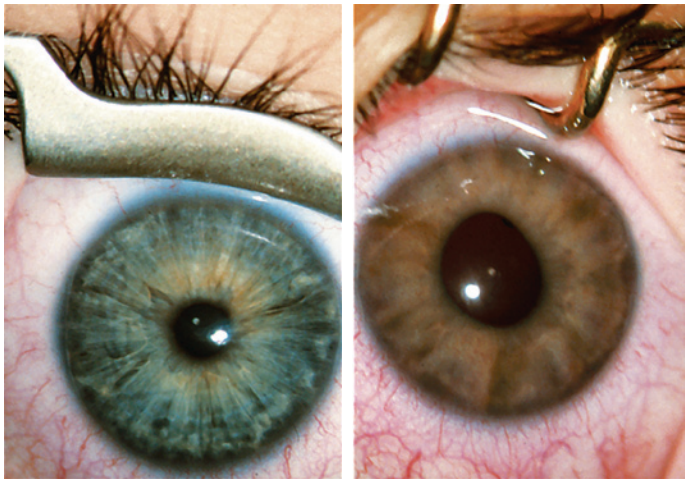

Fig. 67.6 Iris relapse with heterochromia, infiltrated left iris, and sluggish pupil reactions.

Because children with an apparently localized relapse generally have submicroscopic bone marrow disease, retreatment requires full systemic therapy plus local ocular radiotherapy (at least 2000 cGy) and topical steroid treatment. With this approach, long-term survival and likely cure has been achieved in a substantial proportion of patients.[13]

Choroid

The choroid may be the part of the eye most frequently involved in all types of leukemia,[7,14] but it is only rarely clinically apparent. The clinical manifestations are the result of serous retinal detachment or retinal detachment associated with a subretinal mass (Fig. 67.8). Fluorescein angiography demonstrates myriads of diffuse leakage points at the level of the retinal pigment epithelium.[15] Similar fluorescein patterns are seen in serous detachments with melanoma, metastatic tumor, Vogt–Koyanagi–Harada disease, and posterior scleritis. Leukemic choroidopathy can be detected by ultrasound.

Retina and vitreous

The retina, because of its ready visibility, is the part of the eye most frequently found to be involved clinically. Funduscopy is part of the routine follow-up examination of leukemic patients.

Hyperviscosity changes

Hyperviscosity of the blood occurs in many cases of leukemia with very high blood cell counts, especially in monocytic AML. Fluorescein angiography and trypsin digests[3] show capillary saccular and fusiform microaneurysms. Neovascularization, probably related to hyperviscosity,[16] has been seen in chronic myeloid leukemia (Fig. 67.9).

Retinal hemorrhages

Hemorrhages occur as a result of hyperviscosity, coagulation defects, infiltration, damage to retinal vessel walls, and vascular

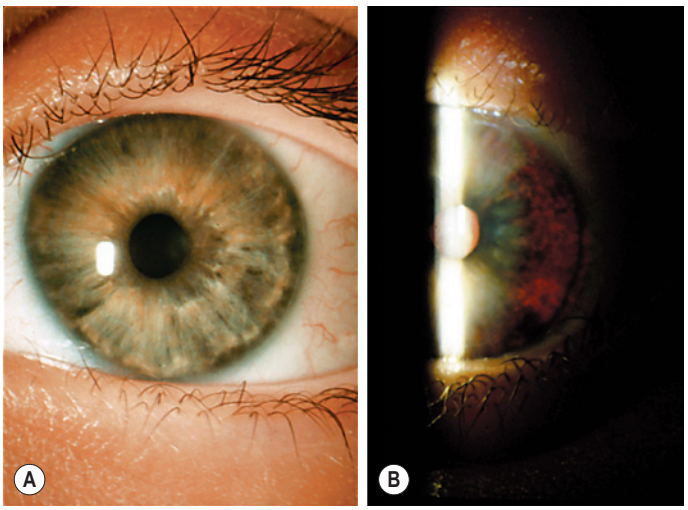

Fig. 67.7 Same patient as in Figure 67.6. After treatment with 2500 cGy there is iris transilluminance. The right eye had become affected.

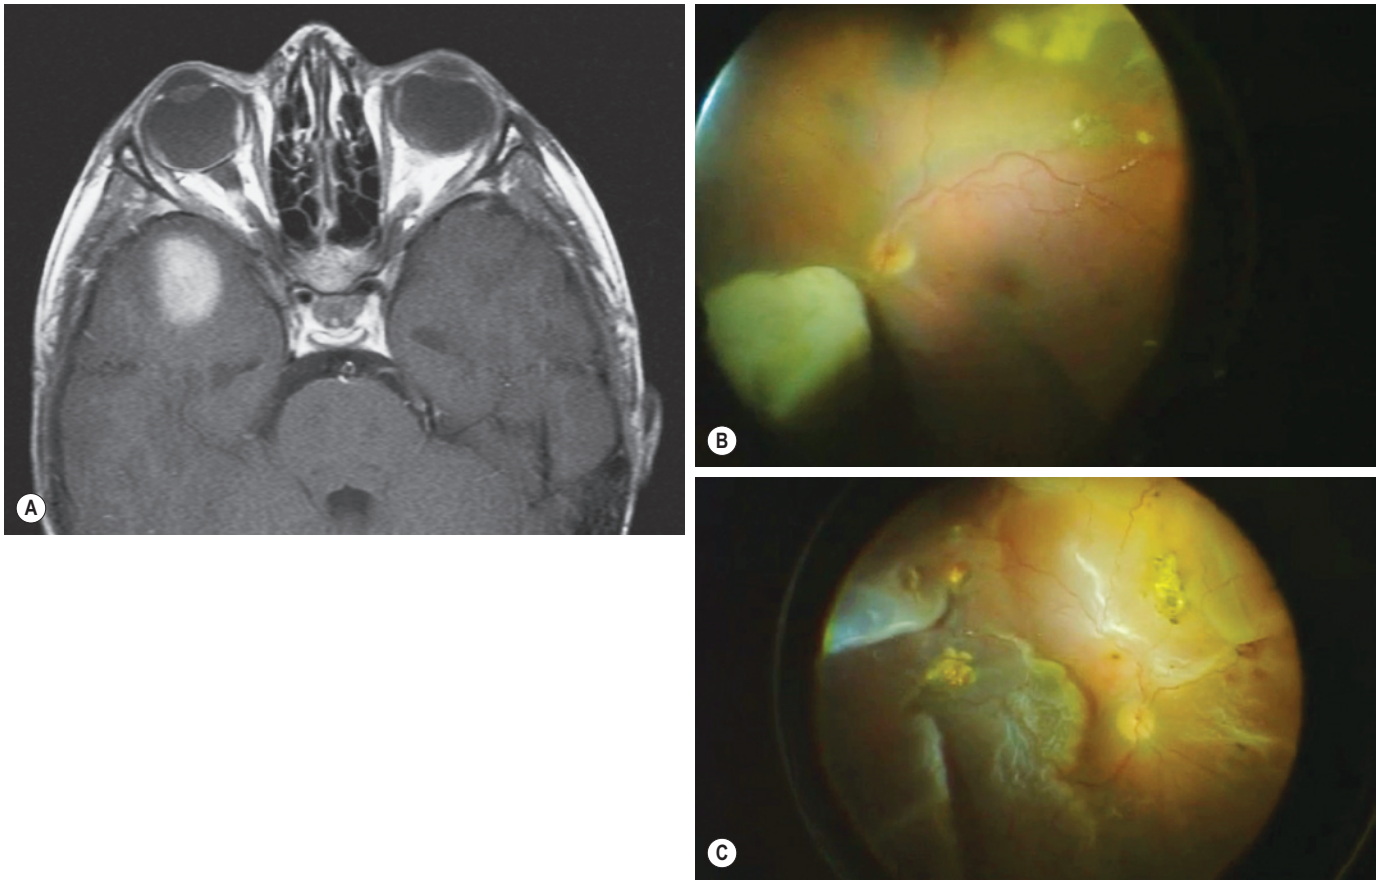

Fig. 67.8 (A) Axial T1-weighted image, after intravenous contrast agent administration, showing enhancing mass lesions on the retina of both globes and in the right temporal lobe. This patient with T-cell acute lymphoblastic leukemia (T-ALL) presented with primary central nervous system and eye involvement. (B) Same patient: intraoperative fundus image of the left eye that shows a large inferior endophytic lesion comprising old blood and inactive leukemia cells. A shallow macula-on retinal detachment is present with subretinal leukemic deposits seen superiorly. (C) Same patient: intraoperative image of right eye. The child had a previous vitrectomy for fundus obscuring vitreous hemorrhage. Subsequent contraction of treated intraretinal leukemic deposits led to macula-off rhegmatogenous retinal detachment. *([A] Mr R Henderson's patient, courtesy of Dr K. Chong.)*

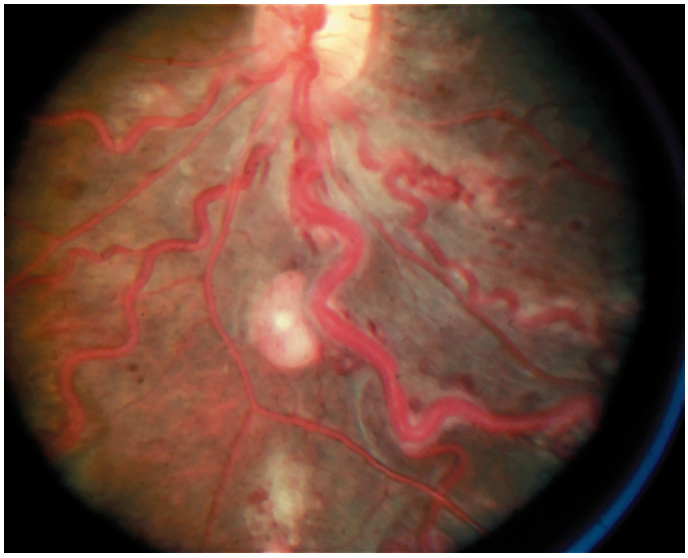

Fig. 67.9 Hyperviscosity changes in chronic myeloid leukemia in a 20-year-old. *(Dr S. Day's patient.)*

occlusion.[17] Sometimes massive, they occur throughout the retina and may involve the vitreous.

Nerve fiber layer hemorrhages are bright red and "flame-shaped." Deeper hemorrhages are less red and usually more rounded. Subhyaloid hemorrhages have sharply defined margins and can form a fluid level with a layer of white cells (Fig. 67.10).

Some hemorrhages are white centered; this should not be confused with the pinpoint white light reflex from the apex of a hemorrhage, or with hemorrhage around a leukemic deposit. The white area consists of platelet and fibrin deposits that occlude the vessel, or septic emboli. The hemorrhage occurs because of infarction and weakening of the vessel wall, which can also be damaged by leukemic deposits, giving the picture of mixed hemorrhage and infiltration (Fig. 67.11).

Retinal infiltrates and white patches

White areas in the retinas of leukemic children may be caused by the following:

1. Vessel sheathing.
2. Retinal infiltrates: these are leukemic deposits (Fig. 67.12), which, before the era of modern chemotherapy, were commonly seen, often with

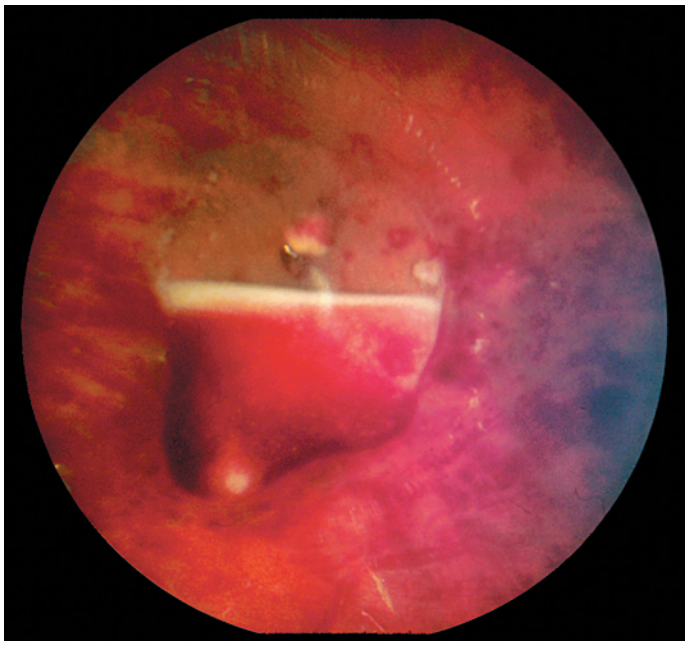

Fig. 67.10 Subhyaloid hemorrhage with a gross leukemic cell content.

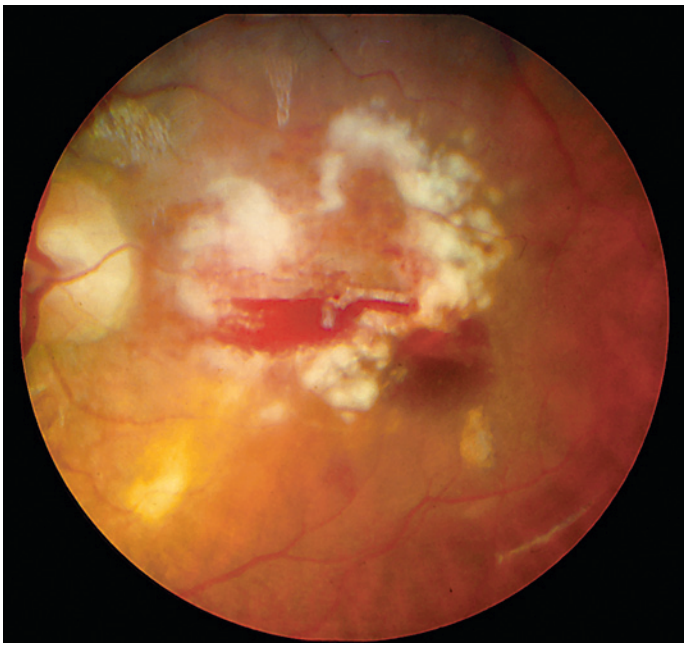

Fig. 67.12 Retinal infiltrates in acute lymphoblastic leukemia.

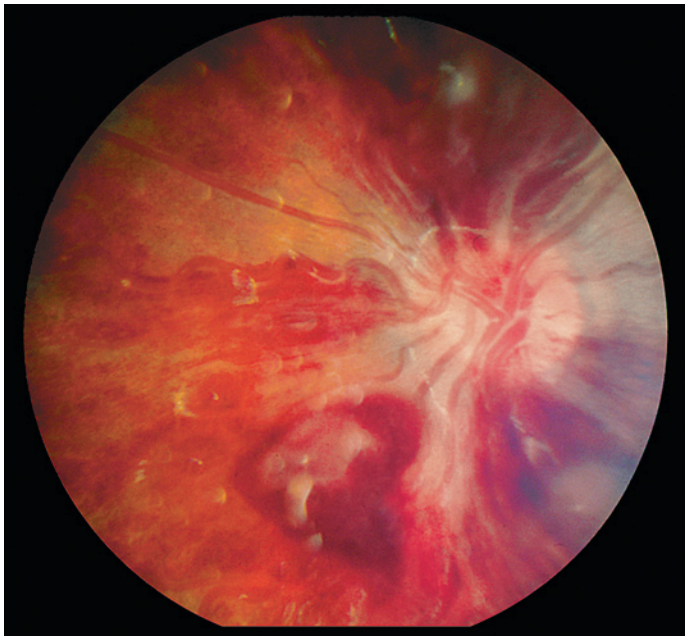

Fig. 67.11 Retinal hemorrhages and infiltrates in acute lymphoblastic leukemia.

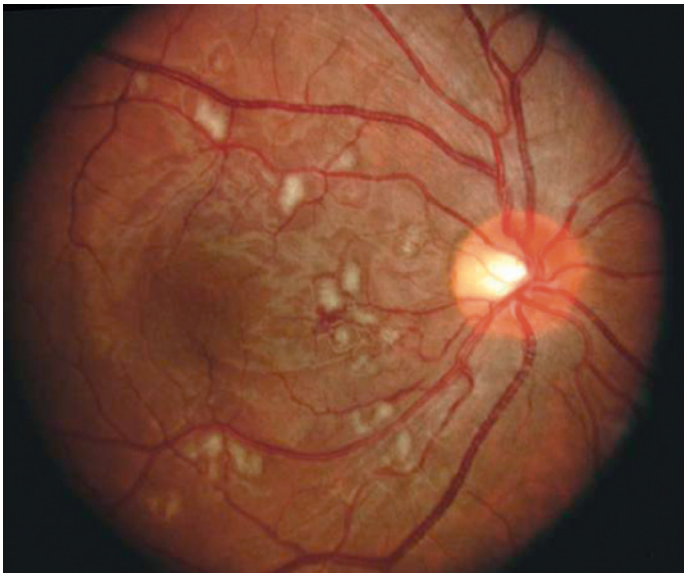

Fig. 67.13 Transient multiple cotton-wool spots after bone marrow transplant.

hemorrhage; they can usually be distinguished from infections by clinical and hematological examination.[18]

3. Cotton-wool spots: these are retinal nerve fiber layer infarcts (Fig. 67.13); they occur frequently in acute leukemia[4] and transiently after bone marrow transplantation. They result from retinal vascular occlusion in patients who have recently received bone marrow transplants, whether or not they have been treated with cyclosporin. They can recover spontaneously and are associated with retinal vascular endotheliopathy.[19]
4. Hard exudates: these small yellowish lesions are seen in relation to vessels that are chronically leaking non-cellular blood elements and are most frequently seen in chronic leukemias with hyperviscosity.
5. Opportunistic infections with cytomegalovirus or fungus in the immunosuppressed.
6. Retinal infarction in the acute stage: this gives rise to large areas of cloudy swelling of the retinal nerve fibers and ganglion cell layer.

Retinal infarction

Occlusion of larger retinal arterioles or of the ophthalmic artery (Fig. 67.14) occasionally occurs as a preterminal event.[1]

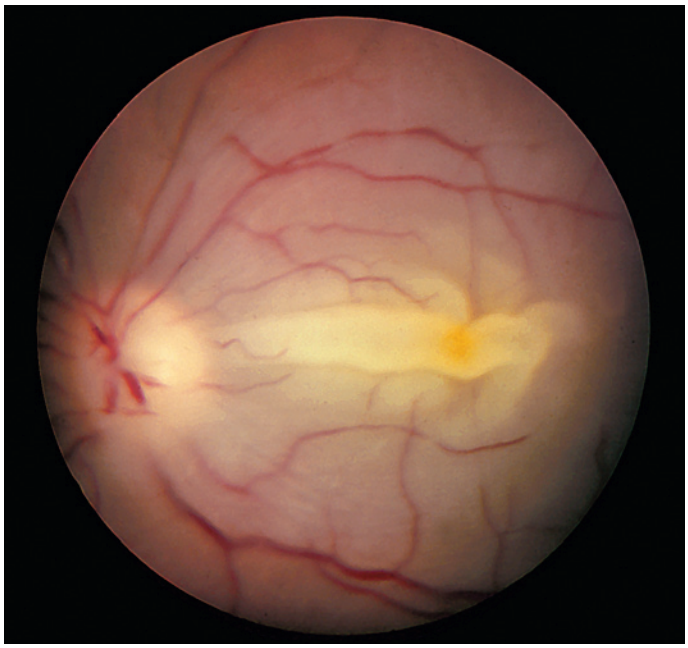

Fig. 67.14 Ophthalmic artery occlusion as a preterminal event.

Vitreous cells

Vitreous involvement with leukemic or blood cells is usually secondary to retinal or choroidal infiltration or hemorrhage.[7] Occasionally, vitreous aspiration may be needed for diagnosis, especially if the patient is apparently in remission and there is a possibility of an opportunistic infection. Vitreous organization is an unusual, but serious, sequela to widespread retinal or optic nerve infiltration.

Other retinal manifestations

Serous retinopathy[15] and retinal pigment clumping occur as manifestations of choroidal ischemia.

Optic nerve

Optic nerve involvement is noted in nearly one-fifth of acute or chronic leukemias postmortem,[4] although in clinical series it is more frequently seen in ALL.[20] Optic nerve involvement, which used to presage death, is now less frequently seen, presumably due to aggressive chemotherapy.[21]

Leukemic optic neuropathy may cause only minimal visual symptoms despite massive involvement, but, often, marked loss of central vision is observed, especially with infiltration behind the lamina cribrosa.[21] With prelaminar infiltration (Fig. 67.15) there is ophthalmoscopically visible fluffy white infiltration with hemorrhage. Occasionally, especially when bilateral, this can be difficult to differentiate from papilledema (which could be caused by idiopathic intracranial hypertension secondary to steroids or steroid withdrawal or CNS infiltration or infection); infectious disease must also be remembered. The response to irradiation at 2000 cGy may be dramatic[22]; whatever the treatment, optic atrophy is a frequent sequel. Optic neuropathy may also be caused by vincristine treatment[23] or by radiotherapy.

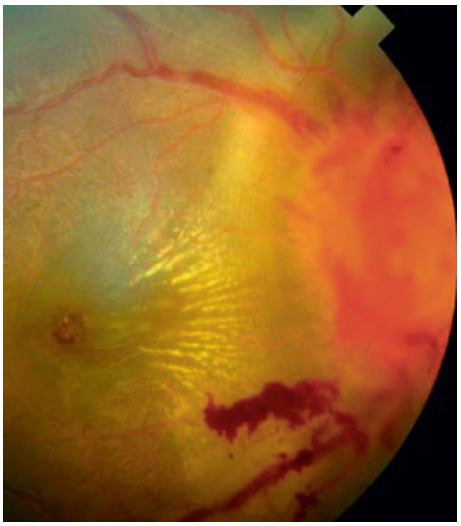

Fig. 67.15 Prelaminar optic nerve infiltration (acute myeloid leukemia) with additional retinal nerve involvement.

Other neuro-ophthalmic involvement

CNS involvement with leukemia manifests as meningeal irritation, with headaches and vomiting, or cranial nerve involvement. Vessel occlusion gives rise to defects ranging from transient deafness to a hypoxic–ischemic encephalopathy. It is usually a feature of leukemia with a very high white blood cell count and hyperviscosity. Communicating hydrocephalus, chiasmal infiltration, and sixth nerve palsies may occur.

In addition to the disease, many of the drugs and radiotherapy used may have CNS side effects, both short and long term, including fits. Rarely, children may develop a leukoencephalopathy due to methotrexate and cranial radiation.

With refinements in therapy, neurologic complications of leukemia and its treatment are now less common. Better supportive care has reduced the incidence of hemorrhage, and improved therapy has reduced leukoencephalopathy. Infection by measles, varicella, or mumps is less common since the introduction of vaccination programs and immunoglobulin prophylaxis in children with proven contacts. Bacterial infections of the CNS are rare.

Complications of treatment

Drugs

Vincristine and related drugs may cause corneal hypoesthesia, ptosis, third, sixth, and seventh nerve palsies, and optic neuropathy, which are reversible if the treatment is stopped early. The neuropathy is dose related and usually starts as a peripheral neuropathy with abnormal deep tendon reflexes. Seizures also occur.

L-Asparaginase may idiosyncratically be associated with a severe, sometimes fatal, encephalopathy. Cytarabine may cause blurred vision from keratoconjunctivitis (prophylaxis with topical steroids has been tried), corneal epithelial opacities, and microcysts. Methotrexate is a significant cause of neurologic problems including arachnoiditis from intrathecal administration, seizures, depression, and leukoencephalopathy with ataxia and

dementia. Steroids may cause posterior subcapsular cataracts; these are often of little visual significance[24] but have a good surgical prognosis, if cataract surgery is necessary. Posterior leukoencephalopathy syndrome has been described as a reversible side effect of immunosuppressants such as cyclosporin, usually presenting with seizures, headache, and cortical blindness.[3] Rapid withdrawal of steroid therapy may cause idiopathic intracranial hypertension (pseudotumor cerebri) (Fig. 67.16).

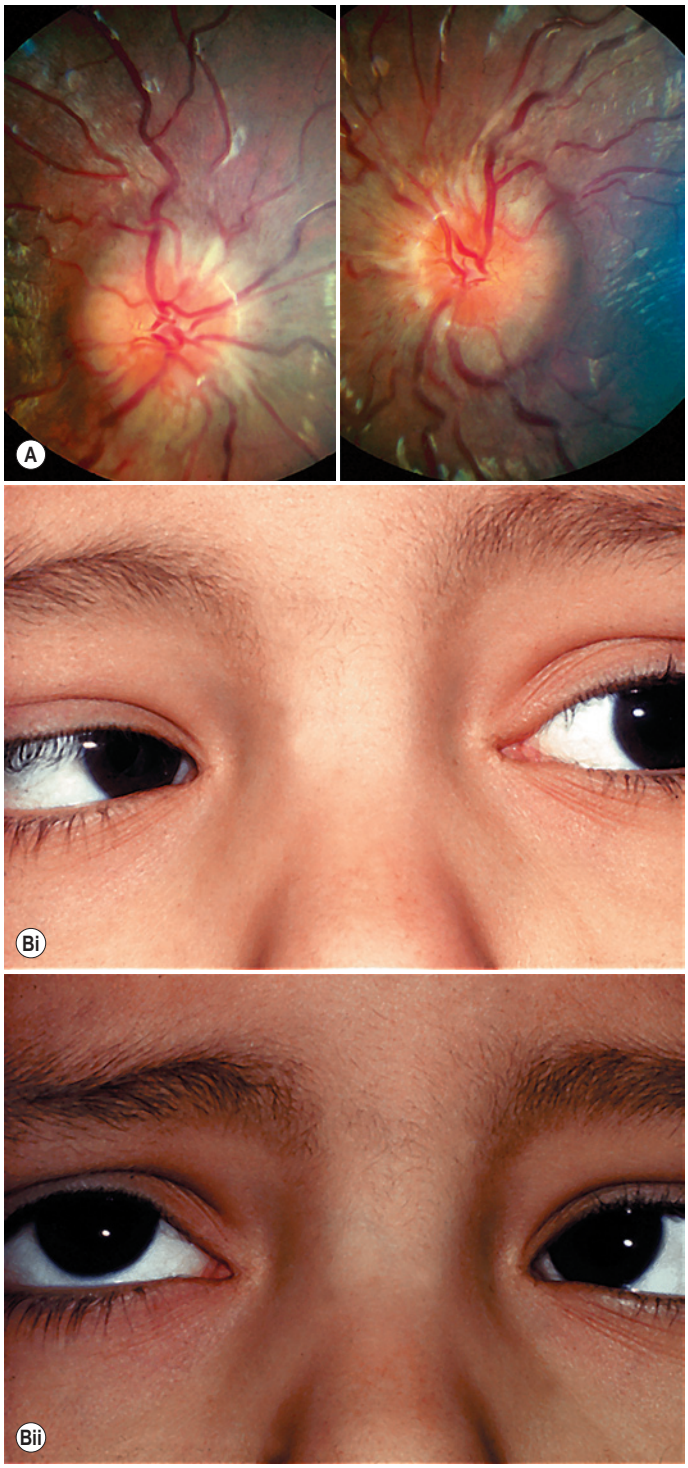

Fig. 67.16 (A) Papilledema and (B) right sixth nerve paresis from idiopathic intracranial hypertension in a patient on withdrawal of steroids in acute lymphoblastic leukemia.

Chemotherapy, steroids, and radiotherapy contribute to immune suppression, which allows infection by opportunistic bacteria, viruses, fungi, or protozoa, some of which do not usually cause significant infection in humans. These complications are related to the intensity of immune suppression and are most likely following bone marrow transplantation. As broad-spectrum antibiotics are now used aggressively for unexplained fever in neutropenic children, uncontrolled bacterial infections have become less frequent, but viruses and fungi have increased. Clinical manifestations may include keratitis, retinitis, endophthalmitis, orbital cellulitis (differentiate from Sweet syndrome/febrile neutrophilic dermatosis[3]), and neuro-ophthalmologic manifestations of CNS infection.

Herpes simplex and zoster affect the cornea (Fig. 67.17), conjunctiva, and lids. Herpes simplex and cytomegalovirus, which have an affinity for neural tissue, may cause a severe necrotizing retinochoroiditis (Fig. 67.18) that may be difficult to differentiate from leukemic infiltrates, a distinction that can be helped by chorioretinal biopsy but can usually be made by culture of urine or saliva.

Yeast and fungal infections are important complications of neutropenia; biopsy is necessary to establish the diagnosis and to plan appropriate treatment. Other infections include mucormycosis, toxoplasmosis, cytomegalovirus, and aspergillosis.

Stem cell transplantation

Bone marrow transplants are sometimes necessary in the treatment of childhood leukemia, but as chemotherapy has become increasingly effective, the number of transplants has fallen. Few children now receive BMT as a first-choice therapy, but it is often considered in relapsed disease.

In recent years, the early hemopoietic progenitor cells required for BMT have been obtained from blood or cord blood collections, and the term "stem cell transplant" (SCT) has supplanted BMT. There are two main types of SCT:

1. allogeneic, when related or unrelated donor stem cells matched by HLA typing are infused;
2. autologous, when the patient's own stored stem cells are used.

Fig. 67.17 Herpes zoster affecting trigeminal division of the fifth cranial nerve (acute lymphoblastic leukemia).

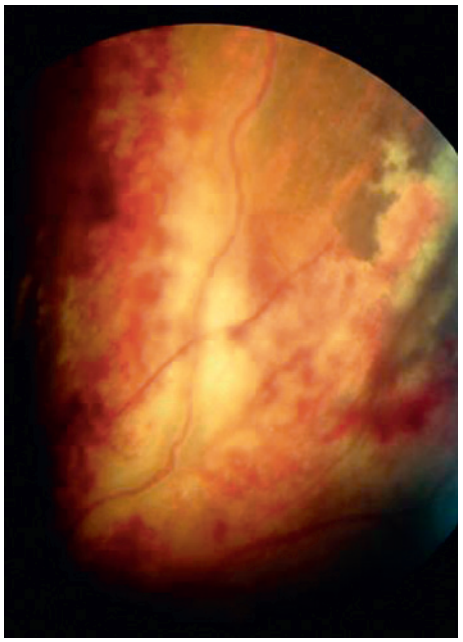

Fig. 67.18 Cytomegalovirus infection in a child with leukemia.

Prior to the SCT, children receive chemotherapy alone or combined with total body irradiation (TBI) as both antileukemia and immune suppressive therapy, to avoid graft rejection. As the marrow regenerates with new transplanted stem cells, all blood cell lineages are donor derived. Ocular changes were found in 50% of children treated with BMT for hematologic disorders.[25] The most frequent findings were dry eye (12%), cataracts (23%), and posterior segment complications (13%). These changes did not seriously compromise vision. Another study[26] identified ocular abnormalities in 82% of children, usually in the anterior segment, usually dry eye.

The incidence of eye complications depends on the treatment regimen, especially the use of TBI, the degree of immune suppression with risk of opportunistic infections, and the occurrence of graft-versus-host disease (GvHD). In one series,[27] cataracts were found in 95% of children given TBI, compared with 23% of children on chemotherapy alone. Low dose rates and fractionated rather than single-dose radiotherapy are associated with a lower incidence of cataracts.[28] It is possible these differences reflect alterations in the latent period before diagnosis, rather than a true reduction in eventual prevalence.

Because of failure to recognize the transplant recipient as "self," the transplanted T lymphocytes may attack the recipient and cause GvHD. Acute GvHD is characterized by the occurrence – within 4 months of the transplant – of any combination of fever, rash, diarrhea, and liver dysfunction. If the disorder occurs or persists after this period, it is termed chronic GvHD (cGvHD). Ocular manifestations are common in cGvHD and include dry eye, cicatricial lagophthalmos, sterile conjunctivitis, and uveitis. The eye problems are frequently severe and their management is demanding. At autopsy, the whole eye is affected including the lacrimal gland. About 10% of patients undergoing BMT develop conjunctival involvement with GvHD.[29] Pseudomembranous conjunctivitis is the most frequent manifestation of conjunctival GvHD and carries a poor prognosis for life. The mainstay of treatment has been topical steroids and lubrication. Topical tacrolimus has recently been reported as an alternative to steroids in children.[30]

Opportunistic infections are a major risk of BMT, especially in mismatched transplants where depletion of T lymphocytes from the marrow graft in order to minimize GvHD results in delayed immune reconstitution.

An interesting occurrence is the transient appearance of multiple white cotton-wool spots in BMT recipients.[31] Retinal complications including retinal or vitreous hemorrhage, cotton-wool spots, optic disc edema, retinitis, lymphoma, and serous retinal detachments occurred in 12.8% of 397 patients after BMT.[32]

Phakomatoses (including the neurofibromatoses)

John R B Grigg and Robyn V Jamieson

Chapter contents

DEFINITION
NEUROFIBROMATOSES
TUBEROUS SCLEROSIS
VON HIPPEL–LINDAU DISEASE
STURGE–WEBER SYNDROME
OTHER CONDITIONS SOMETIMES GROUPED WITH PHAKOMATOSES
REFERENCES

Definition

The phakomatoses are a group of systemic disorders with neurologic, ophthalmic, and cutaneous manifestations resulting from disorders in cell regulation. No precise definition exists for including a condition in this group. A common feature is the development of multiorgan hamartomas. The most important of these conditions are neurofibromatosis, tuberous sclerosis, Sturge–Weber syndrome and von Hippel–Lindau syndrome. Others include Klippel–Trénaunay–Weber syndrome, Wyburn–Mason syndrome, ataxia telangiectasia, diffuse congenital hemangiomatosis, linear nevus sebaceous syndrome, Osler–Weber–Rendu syndrome and blue rubber bleb nevus syndrome. With improved understanding of the genetic, molecular, and cellular biology underlying the phakomatoses, clinical trials with biologic agents have been initiated.

Neurofibromatoses

The neurofibromatoses (NF) are a diverse group of genetic conditions that share a predisposition for tumor development with a predilection for the visual pathways. The two main types are neurofibromatosis type 1 (NF1) and neurofibromatosis type 2 (NF2).

Neurofibromatosis type 1

NF1 is a progressive disease with extremely variable manifestations. Individuals are prone to develop benign and malignant tumors of the central nervous system (CNS) and peripheral nervous system as well as other tumors.[1] Diagnostic criteria have been developed by The National Institutes of Health (NIH) (Table 68.1).[2,3]

Genetics and pathophysiology

NF1 occurs in approximately 1 in 3000 people. Inheritance is autosomal dominant with 100% penetrance, but highly variable expressivity. Up to 42% of cases are due to spontaneous mutations caused by a germline mutation in the *NF1* tumor-suppressor gene.[4] The NF1 protein (neurofibromin) downregulates the rat sarcoma viral oncogene homologue (RAS)–mitogen activated protein kinase (MEK) pathway. This reduces growth of astrocytes. Unopposed RAS activity leads to unopposed cell growth as well as activation of several important downstream signaling intermediates, including the mammalian target of rapamycin (mTOR) protein.[5] The genetic mechanism through which *NF1* mutations give rise to malignant tumors is consistent with the two hit hypothesis.

Clinical presentation

Ocular findings are an important component of the NF1 diagnostic criteria (see Table 68.1).[2] They include Lisch nodules, plexiform neurofibroma, sphenoid wing dysplasia, and optic nerve glioma.

Lisch nodules

Lisch nodules are dome-shaped, discrete lesions occurring anywhere on the surface of the iris or in the angle. They are orange-brown (Fig. 68.1), appearing darker on blue irides but paler on brown irides (Fig. 68.2). Their size varies from pinpoint to involvement of a segment of iris. Histologically, they are melanocytic hamartomas. They are present in one-third of 2½-year-olds, half of 5-year-olds, three-quarters of 15-year-olds and almost all adults over 30 who have the *NF1* mutation.[6] They occur earlier than neurofibromas in children. It is important for ophthalmologists to recognize them, and be able to distinguish them from iris nevi.

Anterior segment and uvea

Congenital glaucoma with buphthalmos is well recognized but rare in NF1. Congenital ectropion uveae, iris heterochromia, angle abnormalities, and posterior embryotoxon may predispose to later-onset glaucoma. Cataract is not a feature of NF1. Pigmentary hamartomas (choroidal nevi) may also involve the posterior uveal tract in up to 35%. Choroidal abnormalities appearing as bright, patchy nodules detected by near infrared imaging frequently occur (82%) in NF1 (Fig. 68.3).[7]

Table 68.1 National Institutes of Health diagnostic criteria for neurofibromatosis type 1 (NF1)

The diagnostic criteria are met if two or more of the following are found:

1. Six or more café-au-lait macules over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals
2. Two or more neurofibromas of any type or one plexiform neurofibroma
3. Freckling in the axillary or inguinal regions
4. Optic glioma
5. Two or more Lisch nodules (iris hamartomas)
6. A distinctive osseous lesion such as sphenoid dysplasia or thinning of long bone cortex
7. A first-degree relative with NF1 by the above criteria

Cutaneous and extracutaneous signs to consider in addition to the "classical" diagnostic criteria when evaluating patients with NF1:

Genetic analysis	Cutaneous signs	Extracutaneous
Molecular analysis of the *NF1* gene	Anemic nevus	Choroidal hamartomas
	Juvenile xanthogranuloma	Large head circumference and hypertelorism
	Mixed vascular hamartomas and cherry angiomas	Unidentified bright objects on neuroimaging
	Hypochromic macules	A peculiar neuropsychological pattern (learning, speech, and behavioral disabilities)
	"Soft-touch" skin	Headache and seizures
	Hyperpigmentation	Neoplasms

Adapted from Szudek J, Evans D, Friedman J. Patterns of associations of clinical features in neurofibromatosis 1 (NF1). Hum Genet 2003; 112: 289–97; and Tadini G, Milani D, Menni F, et al. Is it time to change the neurofibromatosis 1 diagnostic criteria? Eur J Intern Med 2014; 25: 506–10.

Fig. 68.1 Multiple Lisch nodules in neurofibromatosis.

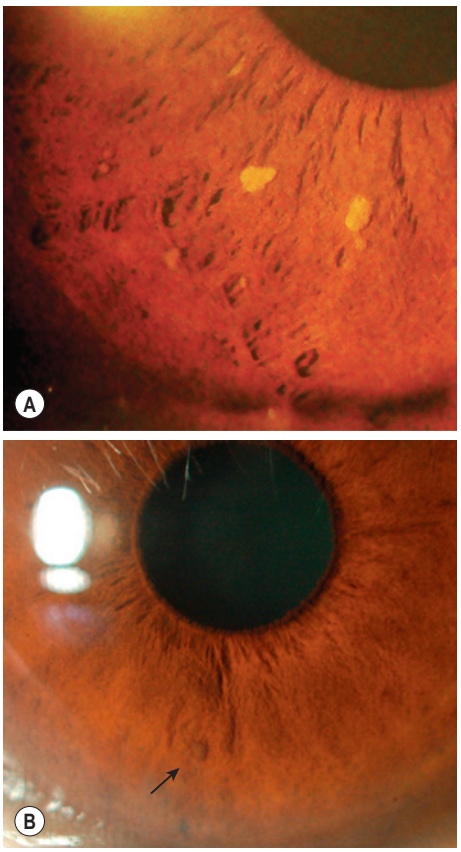

Fig. 68.2 (A) In brown irides Lisch nodules appear light brown. (B) Lisch nodules may be difficult to see in brown irides. *([A] Patient of Dr Shabana Chaudhry.)*

Skin, lids and orbits

Café-au-lait spots are hyperpigmented macular skin lesions. They are often present at birth, and usually appear before the age of 2 years[1]; they tend to enlarge at puberty and are particularly common on the trunk. They are absent from the scalp and eyebrows as well as the palms and soles (Fig. 68.4). Histologically, there is melanocytic hyperplasia with increased pigmentation in the basal layer of epidermis.

Neurofibromas are present in 30–50% of NF1 patients.[8] They are benign Schwann cell tumors.[1] Four types of neurofibroma are recognized (Table 68.2). The presence and growth pattern of neurofibromas is age related. In infancy and early childhood, diffuse plexiform neurofibromas are most active and give rise to cosmetic and visual problems within the orbit (Fig. 68.5). There is a lifelong risk of malignant transformation. In that event, the prognosis for 5-year survival is poor.[9]

Standard chemotherapy is not effective, so surgery has been the treatment option for plexiform neurofibromas. Since complete resection is difficult, surgery is often limited to debulking (Fig. 68.6). Regrowth is common after subtotal resection. Clinical trials with biologic agents including mTOR and MEK inhibitors are underway in these patients.[10,11]

Skeletal anomalies

Sphenoid bone defects occur in association with plexiform neurofibromas, such as hypoplasia of the greater and lesser wings, and widening of the superior orbital fissure (Fig. 68.7). Other osseous abnormalities include abnormal vertebrae, scoliosis, pseudoarthrosis of long bones, and subperiosteal changes.

Optic pathway tumors

Optic pathway gliomas (OPGs) occur in 15–20% of children with NF1; up to half become symptomatic.[12] They are a significant cause of visual morbidity.[13] Nystagmus or strabismus may be the presenting sign of optic nerve or pathway gliomas (Fig. 68.8). The optic disc may be pale or swollen depending on

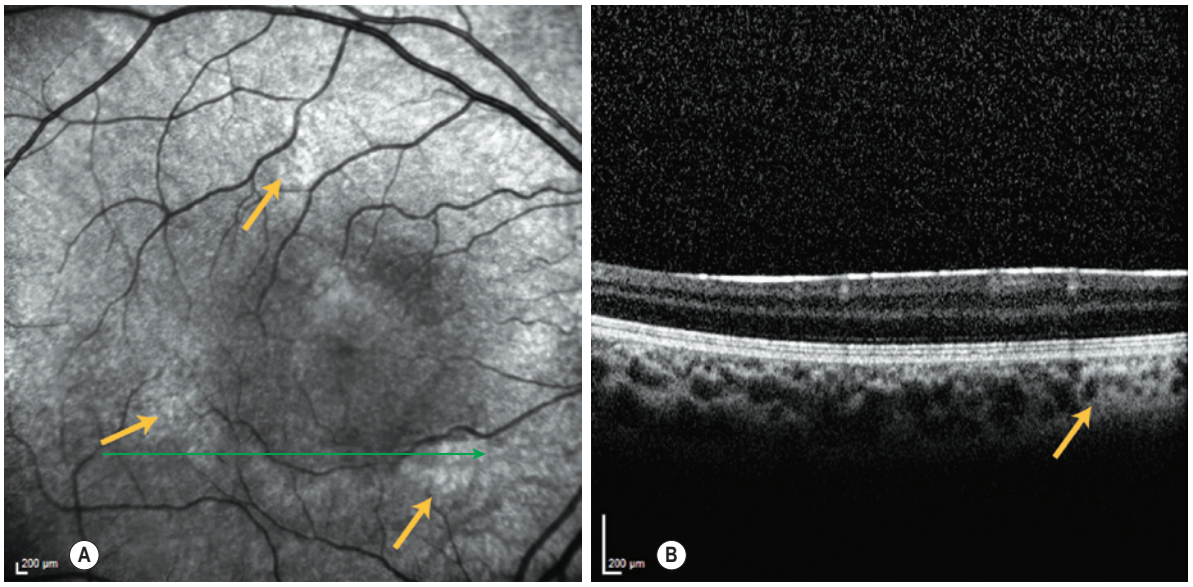

Fig. 68.3 Choroidal nodules detected by near-infrared reflectance (NIR) and ocular coherence tomography (OCT). (A) NIR of the right eye shows bright choroidal nodules. The OCT cross-sectional image obtained along the green line. (B) The corresponding OCT scan shows that these lesions are located within the choroidal tissue.

disease stage. Optic nerve and chiasmal gliomas are discussed in detail in the section on neurogenic tumors (see Chapter 23).

Screening for optic pathway tumors: Visual acuity measurement is the most useful means of detecting changes in OPG that may require treatment[14] (Table 68.3).[15,16]

Central nervous system

The commonest consequence of NF1 in childhood and often the major concern for parents is cognitive impairment. The children are not usually mentally retarded but may have a wide range of learning disabilities manifesting as academic underachievement, and behavioral problems.

Other systems

Tumors of the spinal cord, sympathetic nerves, and adrenals (pheochromocytoma) may occur in patients with neurofibromatosis.

Neurofibromatosis type 2

NF2 affects 1 in 33,000 live births and is characterized by bilateral vestibular schwannomas (VS), multiple CNS tumors, cataracts, and retinal abnormalities.[17] The diagnostic criteria for NF2 are listed in Box 68.1. Two patterns of presentation exist: mild disease presents late (>25 years), with few tumors other than bilateral VS, and slow progression. Those with severe disease have onset before age 25, multiple CNS tumors (at least two of one type), and rapid progression causing severe handicap or death before reproductive age.

Genetics and pathophysiology

NF2 is an autosomal dominant condition with approximately 50% *de novo* mutations (no family history). *NF2* mutations can either be germline (70%) or somatic mosaic (30%) (mutation takes place after conception, resulting in two separate cell lineages).[18] NF2-associated tumors include schwannomas, meningiomas, and ependymomas.[19] There is correlation between nonsense and frameshift mutations and the severe early NF2 phenotype.

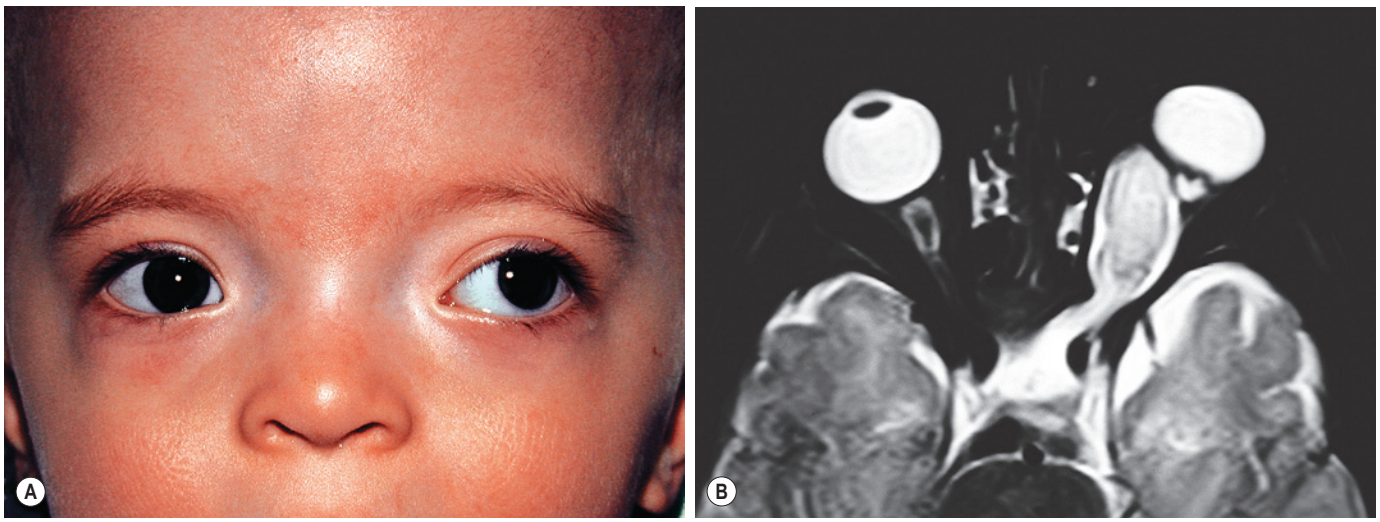

Fig. 68.8 Optic nerve glioma. (A) This 13-month-old girl presented with a history of intermittent exotropia since age 6 months, increasing numbers of café-au-lait spots and increasing proptosis on the left side. She appeared to be blind on the left. (B) A T2-weighted magnetic resonance imaging scan showed a fusiform tumor of the optic nerve extending up to and involving the chiasm.

Table 68.3 Screening for optic pathway tumors in neurofibromatosis type 1 (NF1)

Age and group	Review frequency	Ophthalmology	Neuroimaging
ASYMPTOMATIC CHILDREN WITH NF1 FOR OPG			
Baseline	–	Yes*	No
0–8 years	Annual	Yes*	No**
8–18 years	2 yearly	Yes*	No
Adult	No screening required	Routine eye care	No
EVALUATION OF CHILDREN WITH SUSPECTED OPG			
Ophthalmological abnormality identified: initial assessment	–	OCT if available	Yes***
Follow-up: first year****	3 monthly	Yes* + OCT if available	Yes***
Ongoing follow-up	≥3 monthly	Yes* + OCT if available	Yes***
CHILDREN BEING TREATED FOR NF1-OPG			
Follow-up on chemotherapy	≥3 monthly	Yes* + OCT if available	Yes***
Post-chemotherapy follow-up	3–6 monthly with increasing intervals when evidence of stability or regression	Yes* + OCT if available	Yes***

OCT, Ocular coherence tomography; OPG, optic pathway glioma.
*Ophthalmologic assessment should include age appropriate assessment of visual acuity, confrontation visual field evaluation, color vision testing, and assessment of pupils, eyelids, ocular motility, irises, and fundi.
**In those uncommon situations where reliable eye examinations cannot be obtained, there may be a role for neuroimaging.
***Magnetic resonance imaging of the brain with dedicated views of the orbits.
****Follow-up and management of children with NF1-asociated OPG is complex, they all should be cared for in centers that have significant experience in the treatment of NF1 and childhood cancer.
No universal agreement has been reached on what constitutes "progressive disease" (e.g. radiographic evidence of tumor growth, decreasing visual acuity, or a combination of the two): treatment of symptomatic NF1-associated OPG should be instituted only when there is clear evidence of progressive disease.
Pattern visual evoked potentials (PVEP) are performed in some centers at the same frequency as neuroimaging. PVEP provides additional objective evidence for visual pathway dysfunction when performed in laboratories experienced with visual electrophysiology in children.

Ophthalmological assessment of children with neurofibromatosis type 1. Eur J Pediatr 2013; 172: 1327–33.

Box 68.1

Revised diagnostic criteria (Manchester) for neurofibromatosis type 2 (NF2)*

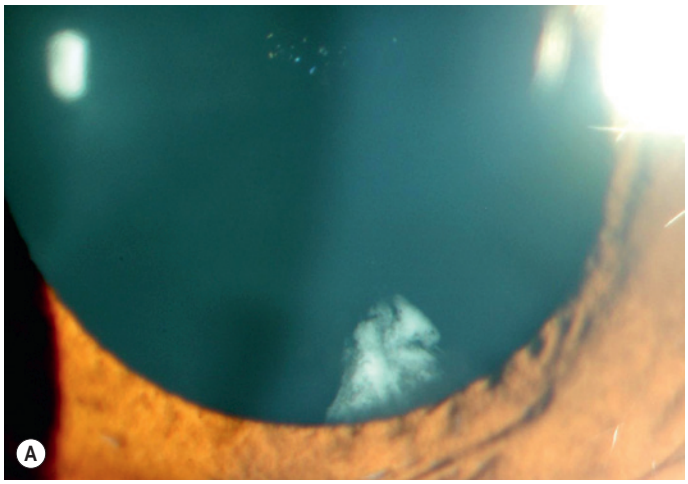
NF2 may be diagnosed in any one of the following situations:

A. Bilateral vestibular schwannomas
B. First-degree family relative with NF2 and either unilateral vestibular schwannoma or any two of: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities
C. Unilateral vestibular schwannoma and any two of: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lens opacities
D. Multiple meningiomas (two or more) and unilateral vestibular schwannoma or any two of: schwannoma, glioma, neurofibroma, cataract

*In the Manchester criteria, "any two of" refers to two individual tumors (not different types) or cataract.
From Lloyd SK, Evans DG. Neurofibromatosis type 2 (NF2): diagnosis and management. Handb. 2013; 115: 957–67.

The *NF2* tumor-suppressor gene encodes merlin, which normally regulates downstream mitogenic signaling pathways. Drugs targeting these pathways (i.e. lapatinib and protein kinase inhibitors) are under evaluation.[20,21] The loss of functional merlin, also unmasks vascular endothelial growth factor (VEGF)-induced angiogenesis. Thus, bevacizumab may be effective in limiting tumor progression for these patients.[22]

Systemic findings



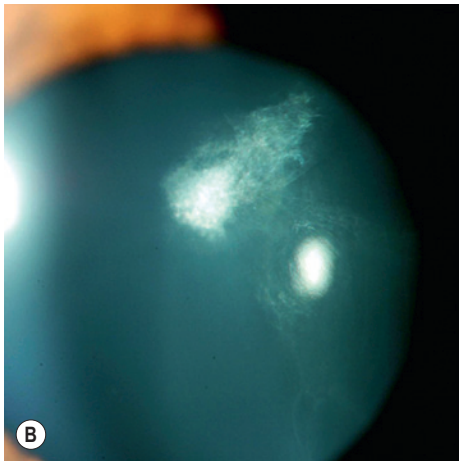
The hallmark of NF2 is bilateral vestibular schwannomas ("acoustic neuromas"), which may only be identified on gadolinium-enhanced magnetic resonance imaging (MRI) (see Fig. 68.10C). The origin of the trigeminal nerve is another frequent intracranial site for schwannomas. They may be found on several cranial nerves in affected patients.

Ocular findings

Most of the ophthalmic findings in NF2 (see Box 68.1) are congenital but may become apparent over time.[23] Visual loss is particularly significant for these children since progressive bilateral hearing loss is so common in this condition.

Anterior segment

The ocular changes of NF2 are early markers of the disease. Between 60% and 81% of patients have presenile central



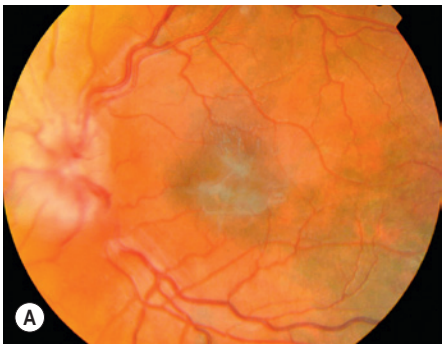


Fig. 68.9

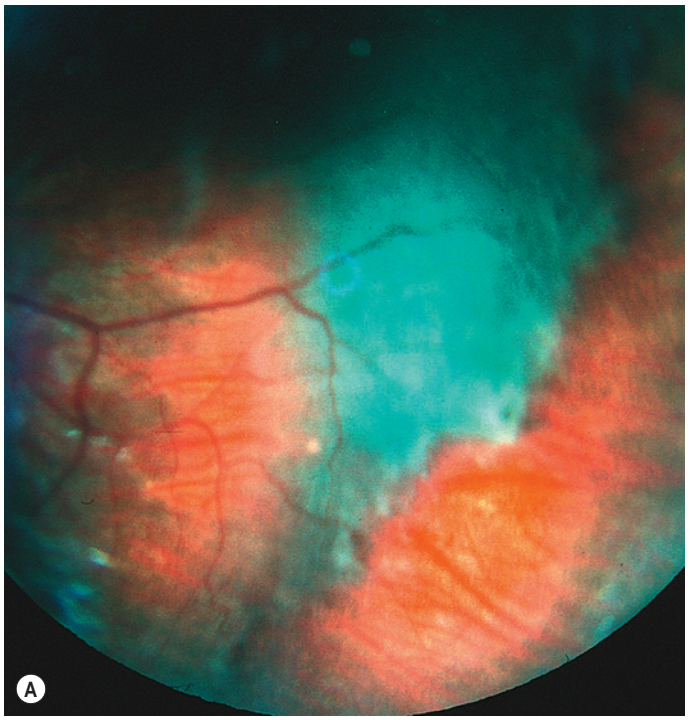
posterior subcapsular lens opacities. These mostly have little effect on vision so other causes for visual loss need to be evaluated first (Fig. 68.9). Corneal hypoesthesia from trigeminal nerve schwannoma, and decreased tear production, reduced blinking, and lagophthalmos from facial nerve palsy may adversely affect the outcome of cataract extraction in patients requiring surgery.

Posterior segment

Epiretinal membranes are seen in 1% of patients. They are translucent or whitish-gray membranes with prominent whitish edges demarcating their borders. They do not usually cause visual loss (Fig. 68.10). Combined retinal and pigment epithelial hamartomas (CRPEH) occur in 6–22% of patients. They are slightly raised masses most frequently identified in the posterior pole (Fig. 68.11). They commonly cause a reduction in visual acuity. Optic nerve sheath meningiomas (see Fig. 68.10C), which may be bilateral, are a significant cause of visual loss. These are described in the chapter on neurogenic tumors (Chapter 23).

Prognosis



Optimum treatment is multidisciplinary because of the complexities associated with management of the multiple and progressive lesions.[24] Screening is essential (Box 68.2).

Box 68.2

Recommended intervals for screening for neurofibromatosis type 2 (NF2) in children of an affected parent

- Ophthalmological examination yearly from infancy
- Neurological examination yearly from infancy
- Audiology with auditory brainstem evoked potentials yearly from infancy
- Presymptomatic genetic testing: one test from 10 years of age*
- Cranial magnetic resonance imaging (MRI) at 10–12 years of age*
- Spinal MRI at 10–12 years of age* (every 2–3 years)

*Earlier than age 10 years in severely affected families and families in which early detection of disease would aid family preparation for future events related to NF2. From Asthagiri A, Parry D, Butman J, et al. Neurofibromatosis type 2. Lancet 2009; 373: 1974–86.

Table 68.4 Diagnostic criteria for tuberous sclerosis complex (TSC)

A. Genetic diagnostic criteria		
Identification of either a *TSC1* or *TSC2* pathogenic mutation in DNA from normal tissue is sufficient to make a definite diagnosis of tuberous sclerosis complex		
B. Clinical diagnostic criteria		
Major features		**Age at onset**
1	Hypomelanotic macules (≥3, at least 5 mm diameter)	Infancy to childhood
2	Angiofibromas (≥3) or fibrous cephalic plaque	Infancy to adulthood
3	Ungual fibromas (≥2)	Adolescence to adulthood
4	Shagreen patch	Childhood
5	Multiple retinal hamartomas	Infancy
6	Cortical dysplasias*	Fetal life
7	Subependymal nodule	Childhood to adolescence
8	Subependymal giant cell astrocytoma	Childhood to adolescence
9	Cardiac rhabdomyoma	Infancy
10	Lymphangioleiomyomatosis (LAM)**	Adolescence to adulthood
11	Angiomyolipomas (≥2)**	Adolescence to adulthood
Minor features		
1	"Confetti" skin lesions (very small white macules)	
2	Dental enamel pits (>3)	
3	Intraoral fibromas (≥2)	
4	Retinal achromic patch	
5	Multiple renal cysts	
6	Non-renal hamartomas	

*Includes tubers and cerebral white matter radial migration lines.
**A combination of the two major clinical features (LAM and angiomyolipomas) without other features does not meet criteria for a definite diagnosis.
From Northrup H, Krueger DA, International Tuberous Sclerosis Complex Consensus Group. Tuberous sclerosis complex diagnostic criteria update: recommendations of the 2012 International Tuberous Sclerosis Complex Consensus Conference. Pediatr Neurol 2013; 49: 243–54.

Tuberous sclerosis

Tuberous sclerosis complex (TSC) is a multisystem disease characterized by hamartomatous growths that most commonly affect the brain, skin, kidneys, eyes, and heart, but may affect almost any organ. Malignant tumors are rare and occur predominantly in the kidney. Incidence of TSC is estimated to be 1 in 6000.[25]

Diagnostic criteria

The clinical features are classified into major and minor features (Table 68.4).[26] The presence of two major features or one major plus two minor features constitutes a definitive diagnosis of TSC. One major plus one minor feature indicates a probable diagnosis of TSC, whereas either one major or two or more minor features suggests possible TSC. It is recommended that the diagnosis should be suspected in patients with epilepsy, developmental delay, or a learning disability in the absence of other known etiologies.[25] Ideal management is for patients to be followed in specialized TSC clinics to enable the comprehensive evaluation of the multisystem complications (Table 68.5).

Genetics and pathophysiology

TSC is an autosomal dominant condition with a high spontaneous mutation rate (66%). Mutations in two genes *TSC1* (hamartin) and *TSC2* (tuberin) cause the condition. TSC is a disorder of cell migration, proliferation, and differentiation. Hamartin and tuberin form a heterodimer that suppresses mTOR. Increased activation of mTOR kinase results in

Table 68.5 Surveillance screening in tuberous sclerosis complex (TSC)

			Child		Adult	
	"Asymptomatic" parent, child or first-degree relative at time of diagnosis of affected individual	Suspected case or initial diagnostic evaluation	Known case, no symptoms	Known case, symptoms or findings previously documented	Known case, no symptoms	Known case, symptoms or findings previously documented

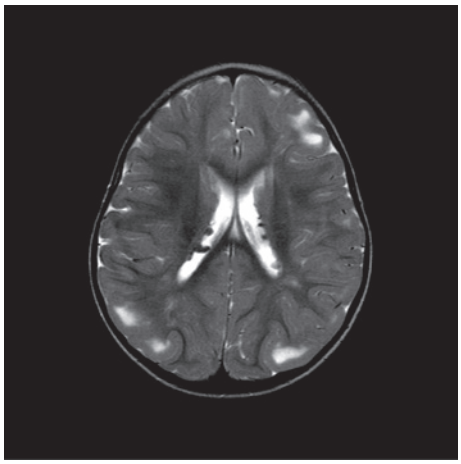

Fig. 68.12 T2 MRI, Tuberous sclerosis. Cortical tubers show as hyperintense signals and the calcified subependymal nodules as hypointense signals projecting into lateral ventricles (T2 axial magnetic resonance imaging scan).

disorganized cellular overgrowth, abnormal differentiation, and the formation of tumors.

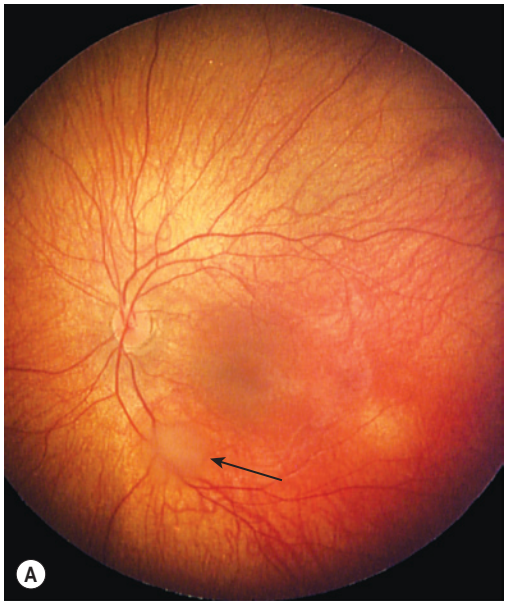
Neurological features

CNS lesions include tubers in the cerebral cortex, and subependymal nodules (SENs) and subependymal giant cell astrocytomas (SEGAs) in the ventricular system (Fig. 68.12). Tubers are focal malformations of embryonal cortical development.[27] They are static lesions directly related to epilepsy, mental retardation, and autism.[28] Seizures are frequent with onset before 2 years of age. Infantile spasms are the predominant form (68%). Vigabatrin (γ-aminobutyric acid [GABA] agonist) is very effective with complete cessation in up to 95% of cases.

Moderate to severe learning disabilities occur in 38–80% of cases; their severity increases with increasing numbers of cortical tubers. However, a child with TSC whose development is normal up to 5 years of age is likely to continue along a normal trajectory.[29] Multiple behavioral problems including sleep disorders, hyperactivity, attention deficit, aggressiveness, and autism may also occur even with a normal IQ.

Clinical trials suggest that mTOR inhibitors (everolimus – a rapamycin analog) might improve both neoplastic features, such as slowing the growth of subependymal giant cell astrocytomas[30], as well as non-neoplastic features including epilepsy and cognitive function.[31]

Dermatological manifestations



Facial angiofibromas (formerly known as adenoma sebaceum) are found in 75% of patients. Their onset is from 5–14 years of age and they are distributed on the face in a butterfly pattern (Fig. 68.13A). Topical rapamycin (0.1–1%) is a safe and effective treatment for facial angiofibroma.[32] Hypomelanotic macules (ash leaf spots) are present in 97% of children. They are present from birth in two-thirds of cases and 90% of cases by the age of 2 years. A Wood's ultraviolet light aids in their detection (Fig. 68.13B). Shagreen patches occur in 50% of cases. The lesions are flattened, yellowish-red or pink, with an orange-skin texture, located on dorsal surfaces, particularly the lumbar region (Fig. 68.13C). Forehead fibrous plaques occur in 25% of cases; these are slightly elevated yellowish-brown or flesh colored plaques. Periungual fibromas occur in up to 50% of cases.

Visceral features

Cardiac rhabdomyomas may be present from the neonatal period and occur in up to 45% of patients with TSC.[33] They are hemodynamically stable and regress in childhood. Renal

Fig. 68.13 Skin manifestations of tuberous sclerosis. (A) Facial angiofibromas (formerly adenoma sebaceum) are typically distributed in a butterfly pattern. (B) Hypomelanotic macules (ash leaf spots). (C) Shagreen patch on the lower back.

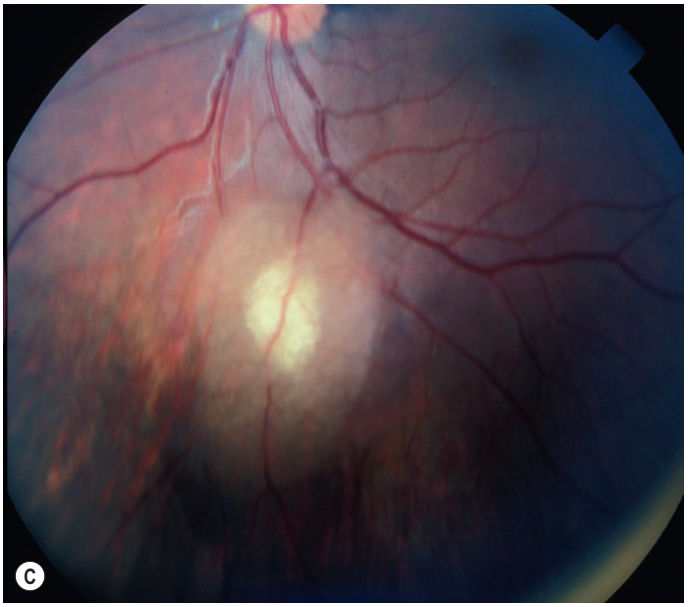


Fig. 68.14 (A) Left translucent retinal astrocytoma along inferior temporal vascular arcade. (B) Both translucent hamartomas and larger calcified hamartomas are shown in this case. The flat translucent lesions in this case are superior to the fovea within and above the superior vascular arcade. (C) A combined lesion with a flat hamartoma and a central nodular area.

lesions occur in nearly all (92%)[33] by age 18. Five renal lesions occur: (1) benign angiomyolipomas, (2) malignant angiomyolipomas, (3) cysts, (4) oncocytomas, and (5) renal cell carcinoma. Benign angiomyolipomas are the most common (70–80%). Other visceral involvement includes liver angiomyolipomas and lymphangiomyomatosis of the lung.[33]

Ocular features

Retinal hamartomas are one of the major diagnostic criteria. Three types are described: (1) a flat, smooth, non-calcified, gray translucent lesion (Fig. 68.14A); (2) an elevated, multinodular, calcified, opaque lesion resembling a mulberry (Fig. 68.14B);

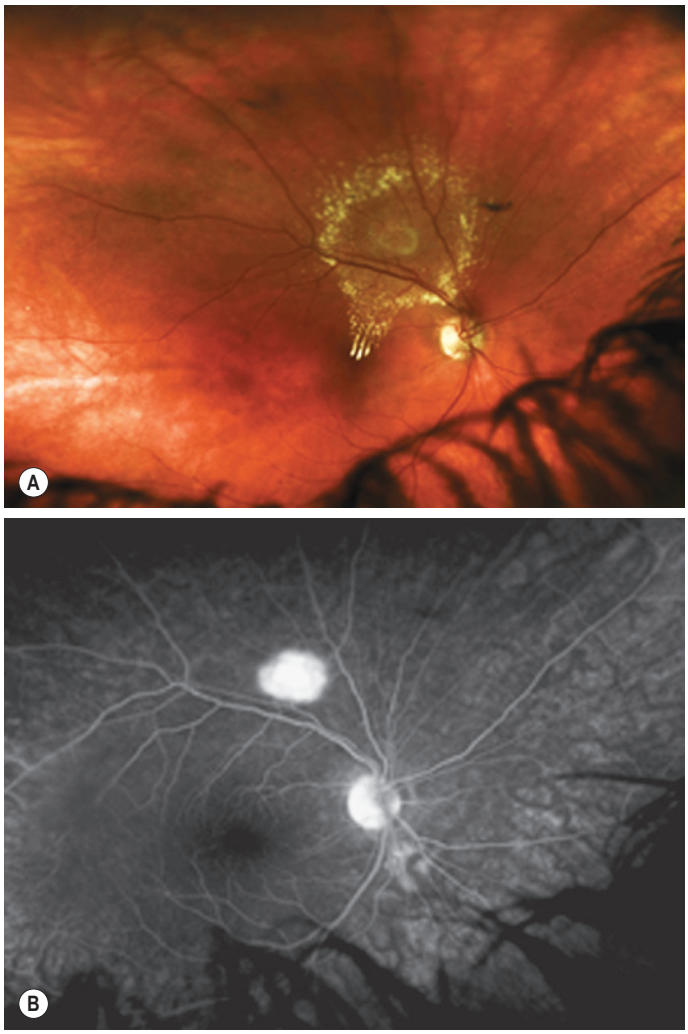

Fig. 68.15 (A) Exudate surrounding retinal astrocytoma with lipid encroaching on macula. (B) Fluorescein angiogram showing vascular leakage associated with retinal astrocytoma.

and (3) a transitional lesion, which has features of both (Fig. 68.14C). They occur in 50% of patients.[34]

The flat, smooth translucent type is the commonest, accounting for approximately 70% of hamartomas seen in TSC.[35] They may be difficult to detect, manifesting as an abnormal light reflex, approximately 0.25–2 disc diameters in size, located in the posterior pole frequently superficial to retinal vessels. The classic multinodular "mulberry" occurs in up to 50% of patients located on or within 2 disc diameters of the optic disc.[35] Ten percent of patients have a combined lesion with a flat hamartoma and a central area of nodular calcification, located at the posterior pole. Retinal hamartomas are not calcified in infancy but become so later in life. In general, the lesions remain static. Rarely vitreous hemorrhage may complicate the lesions, presumably due to abnormal vessels involved with the hamartomas (Fig. 68.15).

Chorioretinal hypopigmented punched-out lesions are also recognized as a retinal finding, occurring in up to 40% of patients.[35] They are less than one disc diameter in size and are distributed in the midperipheral fundus (Fig. 68.16).

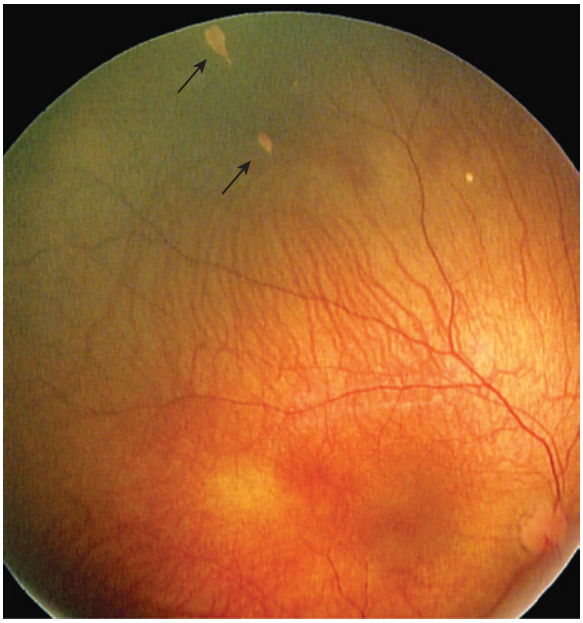

Fig. 68.16 Hypomelanotic punched-out lesions in midperiphery of right eye.

Ocular management

The management of TSC patients requires a multidisciplinary approach (see Table 68.5). The ophthalmologist plays an important role in screening, monitoring visual development, progress of lesions, and in the monitoring of ocular complications of systemic therapy.

Vigabatrin monitoring

Vigabatrin therapy maybe complicated (in 40–50%) by a specific visual field defect resulting in bilateral and concentric constriction within a 30° radius from fixation. This begins with nasal loss extending in an annulus over the horizontal midline, with a relative sparing of the temporal field.[36]

Monitoring is challenging in this group, particularly visual fields. For those unable to comply, a full-field electroretinogram (ERG) (altered cone function) or a multifocal ERG (electronegative b wave) are useful for monitoring therapy.[37] Retinal nerve fiber layer assessment with optical coherence tomography has been shown to provide an accurate estimate of the extent of vigabatrin retinal toxicity.[38]

von Hippel–Lindau disease

von Hippel–Lindau (VHL) disease is a rare familial cancer syndrome causing susceptibility to benign vascular tumors of the eye (retinal capillary hemangioblastomas; RCH) and CNS (angioma or hemangioblastoma), renal cell carcinoma (RCC), and pheochromocytoma. Diagnostic criteria have been developed (see Table 68.6). VHL affects approximately 1 in 36,000 individuals and is an autosomal dominant disorder. Symptoms typically develop from the second to the fourth decade.

Table 68.6 Diagnostic criteria for von Hippel–Lindau disease

Family history*	Required feature
Positive	Any one of the following: Retinal capillary hemangioma Central nervous system (CNS) hemangioma Visceral lesion**
Negative	Any one of the following: Two or more retinal capillary hemangiomas Two or more CNS hemangiomas Single retinal or CNS hemangioma with a visceral lesion**

*Family history of retinal or CNS hemangioma or visceral lesion.
**Visceral lesions include: renal cysts, renal carcinoma, pheochromocytoma, pancreatic cysts, islet cell tumors, epididymal cystadenoma, endolymphatic sac tumor, and adnexal papillary cystadenoma of probable mesonephric origin.
Adapted from Bausch B, Jilg C, Glasker S, et al. Renal cancer in von Hippel–Lindau disease and related syndromes. Nat Rev Nephrol 2013; 9: 529–38.

Table 68.7 Recommended intervals for screening for von Hippel–Lindau disease in at-risk individuals

Test	Start age	Frequency
Ophthalmic examination	0 years	Yearly
Neurological examination	0 years[a]	Yearly
Plasma or 24 h urinary catecholamines and metanephrines	2 years of age	Yearly and when blood pressure is raised
Imaging of CNS (MRI)	11 years of age	Yearly
CT and MRI of internal auditory canals	Onset of symptoms (hearing loss, tinnitus, vertigo, or unexplained difficulties of balance)	
Ultrasound of abdomen	8 years of age	Yearly MRI as clinically indicated
CT of abdomen	18 years of age or earlier if clinically indicated	Yearly
Audiological function tests	15 years	Baseline then when clinically indicated

[a]From 0 to 14 years: annual pediatric examinations are recommended.
Adapted from VHL Alliance. VHL screening protocol 2011. Available from: https://vhl.org/professionals/screening-diagnosis/importance-of-screening/. Accessed 16 June 2016.

Genetics and pathophysiology

VHL disease is caused by a germline mutation in the *VHL* tumor-suppressor gene. The VHL gene product, pVHL, interacts with the hypoxia-inducible factor (HIF). With loss of pVHL activity, HIF is not degraded, leading to overproduction of growth factors encoded by HIF target genes, such as VEGF and platelet-derived growth-factor B chain (PDGF β), contributing to tumor formation.[39] There is high penetrance of the disease, emphasizing the importance of screening, as early detection enables more conservative therapy (Tables 68.6 and 68.7).[40,41]

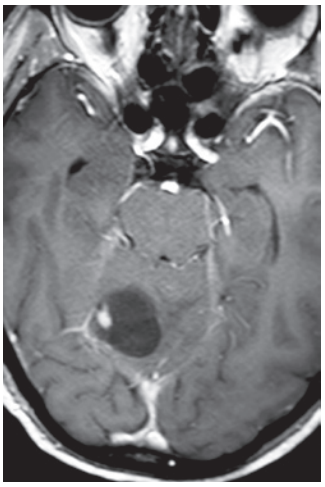

Fig. 68.17 An 11-year-old von Hippel–Lindau patient with cerebellar hemangioblastoma (T1 magnetic resonance imaging axial scan). *(Patient of Dr Mark Dexter, neurosurgeon, Sydney.)*

CNS and visceral features

CNS hemangioblastomas occur in 70% of patients, affecting predominantly the cerebellum (Fig. 68.17), spine, and medulla. Pheochromocytomas occur as a principal manifestation in some families. Renal cysts and tumors are present in 60% of patients.[41] Other systemic involvement includes endolymphatic sac tumors, pancreatic cystic disease, and pancreatic islet cell tumors. CNS hemangioblastomas and renal carcinoma are the main causes for death in VHL.

Ophthalmic features

Ocular involvement occurs in approximately 37% of VHL patients with 58% having bilateral involvement.[42] RCHs are classified on the basis of location (peripheral or juxtapapillary) (Figs 68.18 and 68.19), morphology (endophytic, exophytic, or sessile), and their effect on the retina (exudative or tractional). RCHs usually manifest by 30 years of age. Fluorescein angiography is important to visualize early vascular abnormalities, particularly for juxtapapillary RCHs, and to differentiate the feeder arteriole when laser therapy is considered.

Treatment is indicated if vision is deteriorating.[42] Current therapy for RCHs is based on the principle of tumor ablation and includes laser photocoagulation, cryotherapy, radiation, and photodynamic therapy. Treatment targeting specific growth factors is the goal for therapy.[43]

Sturge–Weber syndrome

Sturge–Weber syndrome (SWS) occurs sporadically in approximately 1 in 20,000–50,000 live births.[44] It is characterized by a port wine stain (cutaneous capillary vascular malformation [capillary malformation, CM]) of the face (Fig. 68.20) and is associated with venous–capillary abnormalities of the leptomeninges and the eye. It is classified into three types: Type I is most common, with the classic facial port wine stain (CM) and intracranial leptomeningeal vascular malformation, ± ocular abnormalities, e.g. glaucoma. Type II involves facial CM ± glaucoma, but no brain abnormalities. Type III is characterized by leptomeningeal angiomatosis without cutaneous lesions or ocular abnormalities.[45]

Pathogenesis

A somatic mosaic activating mutation in *GNAQ* has been found to be associated with both the Sturge–Weber syndrome and non-syndromic port wine stains.[46] *GNAQ* encodes Gαq, which activates downstream MAPK signaling, including endothelin, which has important roles in vasculogenesis.[46]

The International Society for the Study of Vascular Anomalies provides a classification for vascular birthmarks.[47] These skin lesions are termed "vascular malformations." In the ophthalmology literature, vascular malformations present in the choroid and conjunctiva have been termed "hemangiomas." However, the histology shows diffuse choroidal involvement similar to the skin lesions.[48]

Neurological features

Neurological complications are often progressive and include epilepsy, mental retardation, hemiparesis, headache, stroke-like episodes, behavioral problems, and visual field defects.[49] Ipsilateral leptomeningeal vascular malformations are the underlying structural lesions (Fig. 68.21). The extent and degree of the neurological symptoms is related to the area and severity of glucose hypometabolism. A stroke-preventative approach to SWS is important, including good hydration during illness, and low-dose aspirin which may reduce the frequency of stroke-like episodes.

Ophthalmic features and management issues (Table 68.8)[47,49]

Upper-lid skin involvement is commonly associated with intraocular involvement. Glaucoma is the principal ocular complication. It occurs in 58–71% of cases.[44] There is a bimodal presentation with an early-onset group featuring an angle anomaly with trabeculodysgenesis. The late-onset glaucoma group is related to raised episcleral venous pressure.[50] The early-onset group may later worsen due to increasing episcleral venous pressure.

Choroidal vascular malformations ("hemangiomas") are common. They may be localized to the posterior pole or extend to the whole fundus. There is loss of the normal choroidal vascular pattern with a diffuse uniformly red fundus (Fig. 68.22). Bilateral cases can be difficult to detect. Enhanced-depth OCT may assist in determining the extent.[51] These hemangiomas grow slowly and may lead to degenerative changes of the overlying retina with serous retinal detachment (Fig. 68.23).

Glaucoma management is a challenge in SWS. Angle surgery is the procedure of choice in the early-onset group. Anti-glaucoma medications have an adjunctive role in this group. Medications are the initial management for the late-onset group. Filtration surgery, when required, mandates alterations in technique to minimize hypotony and/or hemorrhage. For trabeculectomies, this entails preplaced scleral flap sutures, either viscoelastic or an anterior chamber maintainer, during the procedure. The

Facial port wine stain (PWS) • V1 distribution asymptomatic • V1 with eye and CNS abnormalities • V1 + V2/3 distribution	Dermatology review Ophthalmology evaluation + follow-up Ophthalmology evaluation + follow-up + MRI Ophthalmology evaluation + follow-up + MRI
Seizures	Parental education at diagnosis of PWS Early management with anti-epileptic medication Refractory cases: consider surgical options
Stroke-like episodes	Aspirin (3–5 mg/kg/day) Hydration during illness
Headaches	Standard abortive and preventive agents
Glaucoma	6-monthly ophthalmic review Medical/surgical intervention
Focal neurologic deficit • Hemiparesis • Visual field defect	Multidisciplinary team/rehab input Regular surveillance Adaptive training
Cognitive impairment	Neuropsychological assessment and intervention. Individualized educational programs
Psychosocial	Surveillance and early referral to support services
Endocrine	Monitor growth and thyroid function
ENT	Surveillance for ENT infections and obstructive sleep disorders
Other	Annual influenza vaccination Aggressive management of acute illness optimizing management of fever and hydration

ENT, Ear, nose, and throat; MRI, magnetic resonance imaging.
Adapted from Sudarsanam A, Ardern-Holmes SL. Sturge–Weber syndrome: from the past to the present. Eur J Paediatr Neurol 2014; 18: 257–66.

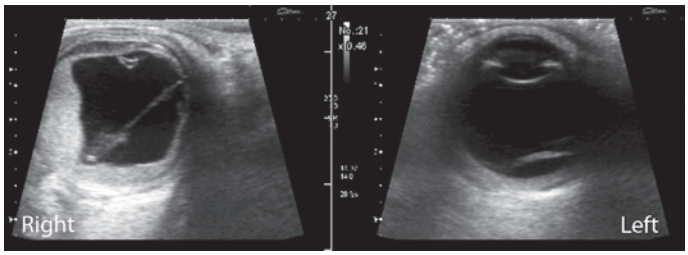

Fig. 68.23 Ultrasound of choroidal vascular malformations ("hemangioma") with associated exudative retinal detachment almost complete in right eye and localized in left eye.

risk of hemorrhage or effusion is proportional to the size of the choroidal vascular malformation. For tube implants, surgical techniques are required to minimize intraoperative and late hypotony including anterior chamber maintainer (25 G), and/or viscoelastic at time of tube insertion, ligation of tube, and the use of a tube stent. Use of a small-gauge needle (25 G) for tube entry into the anterior chamber is advised. If intraoperative choroidal effusions occur (may be dramatic and rapid) then wound closure assisted by elevation of anterior chamber infusion bottle height ± drainage via preplaced sclerostomies is required.[52]

Dermatologic features and management issues

Port wine stains are capillary vascular malformations located in the papillary as well as superficial and reticular dermis. They are present at birth, often darken to a violaceous color, and become raised by middle age. Pulsed dye laser (PDL) is the standard treatment; although complete resolution is rare, this treatment may help to reduce the cutaneous discoloration and associated hypertrophy (see Fig. 68.20). PDL in an animal model resulted in activation of the mTOR pathway, suggesting that angiogenesis pathways play an active role in the skin's blood vessel regeneration and revascularization, contributing to the incomplete effect of PDL. This provided the rationale for the clinical trial that demonstrated that the combination of topical rapamycin with PDL was more effective than laser alone in SWS.[53]

Other conditions sometimes grouped with phakomatoses

Klippel–Trénaunay–Weber syndrome

Klippel–Trénaunay syndrome (KTS) manifestations can be categorized into two groups: group A consists of capillary and venous malformations; and group B is defined by abnormal growth in terms of girth or length. Patients require manifestations in both groups for a diagnosis of KTS[54] (Fig. 68.24). The prevalence is approximately 1 : 100,000.[54] The vascular disorder in KTS is a combined capillary, venous, and lymphatic malformation.[55] Ophthalmic features include orbital varix, retinal varicosities, angioma of the choroid, heterochromia iridium, and ipsilateral optic nerve enlargement. The glaucoma of KTS has many features in common with Sturge–Weber syndrome.

Introduction

Accidental eye trauma in children is a leading public health concern throughout the world. A careful history in cases of eye trauma is important and yet potentially misleading; something unreported could have occurred. Children may try to please adults thereby providing incorrect answers, and may try to deflect blame for an injury with misleading statements. Any history provided by child or parent must fit the physical findings.

Epidemiology

The number of serious eye injuries in children has been estimated at 11.8 per 100,000 per year.[1] At least 35% of serious eye injuries occur in children; the majority occur in children under the age of 12.[2] Eye injuries account for 8–14% of total injuries in children[3] and are the most common cause of unilateral blindness in children. Aside from vision loss, significant disfigurement may accompany a serious eye injury. Several factors place a child at risk for serious accidental eye injury[4]: age between 0 and 5 years, male gender, and a lack of parental supervision. Non-compliance with optical correction and patching is an important factor after childhood perforating anterior eye injury.[5] Amblyopia may limit recovery of vision in children under 7 years of age, even in eye injuries that would carry a good prognosis in older individuals.

Self-inflicted injury

See Chapter 106.

Ophthalmic trauma caused by amniocentesis and birth injury

Eye injuries occur in association with amniocentesis (Fig. 69.1). Of five cases of presumed ophthalmic amniocentesis injury,[6] one had a hemianopia and gaze palsy, two had presumed needle perforation of the eye resulting in a peaked pupil in one case and chorioretinal scar in the other. In the remaining two, one showed a small leukoma and one a limbal scar. After amniocentesis, non-pigmented anterior iris cysts adherent to the posterior cornea with peripheral anterior synechiae are possibly a result of injury with the amniocentesis needle. Congenital aphakia with retinal scar has also been described following *in utero* perforation of the globe. The advent of ultrasonic guidance in the amniocentesis procedure has greatly reduced the incidence of needle injuries to the fetus.

Ocular adnexal injuries occur, albeit rarely, after episiotomy. The possibility of ruptured globe caused by childbirth is discussed below. Forceps should be suspected as the cause of a congenital corneal abnormality in which vertical ruptures in Descemet's membrane (Fig. 69.2) occur with a contralesional occipital depression caused by the other arm of the forceps (Chapter 34).

Eyelid and lacrimal system trauma

In eyelid margin laceration, careful re-approximation of the margins of the eyelid is essential. The etiology is sharp or blunt trauma to the lid margin. Injuries to the canalicular system will occur if the medial eyelid margin is injured, either of the upper or lower lid. These injuries are commonly caused by dog bites in children.[7] They require intubation with silastic tubing passed through both ends of the canaliculus and into the nose, or the use of a monocanalicular stent. With deeper injuries, the deep edges of the wound are closed with fine-grade absorbable suture and the more superficial edges of the wound are closed with fine suture. Additional problems in dog bite injuries may include an inferior oblique palsy or restrictive type of ocular motor problem. Generally, the laceration is closed first, as

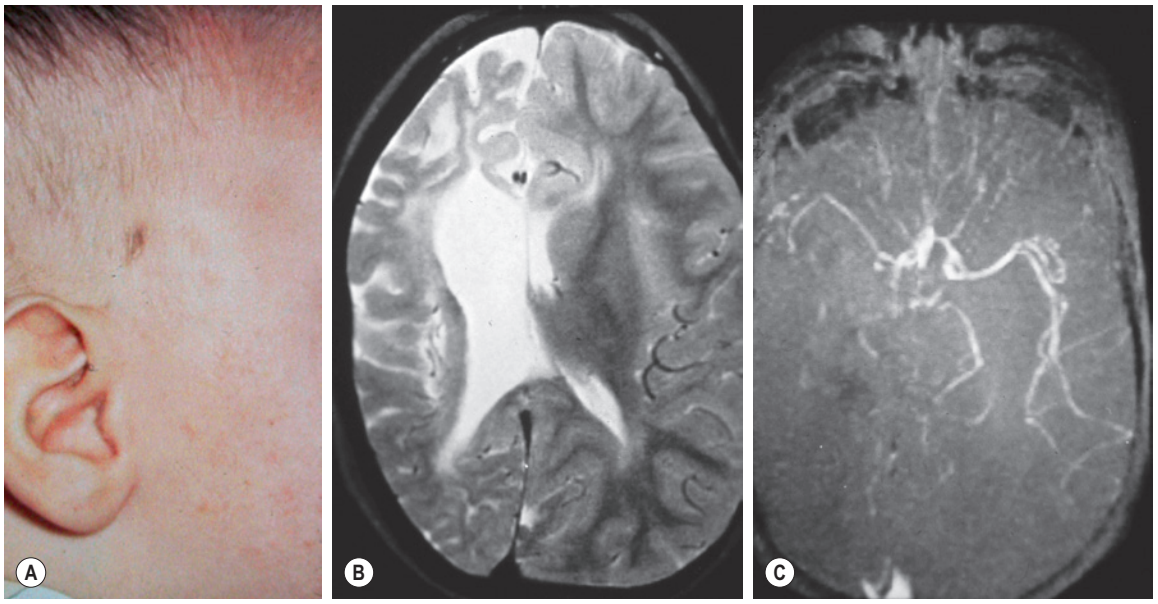

Fig. 69.1 Probable amniocentesis needle injury. (A) A small pigmented dimple on this baby's right temple coincides with radiologic evidence of a needle track. (B) Magnetic resonance (MR) scan showing right cerebral hemiatrophy. (C) MR angiography showing occlusion of the right middle cerebral artery.

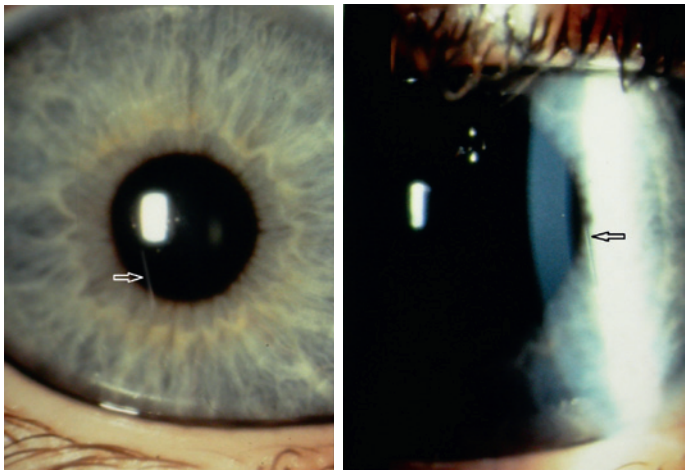

Fig. 69.2 Forceps injury to cornea. The vertically oriented rupture in Descemet's membrane can just be seen to one side of the pupil (arrows).

Fig 69.3 Subconjunctival hemorrhage. In this instance associated with shaking; there were severe intraocular injuries.

described above, followed later by strabismus management as required.

Anterior segment trauma

Subconjunctival hemorrhage (see Chapter 31)

Despite their dramatic appearance, subconjunctival hemorrhages are of virtually no significance except where enough swelling occurs near the limbus to interfere with corneal protection by the eyelids and tear film. In this case, a dellen may occur. A dellen is a non-inflammatory excavation of the cornea with or without epithelial defect, which occurs adjacent to a mass or bump near the corneal scleral limbus. It is probably caused by localized drying. Treatment consists of lubrication until the inciting mass resolves.

Subconjunctival hemorrhages associated with trauma indicate the need for a thorough search for a more serious eye injury (Fig. 69.3). The hemorrhage may mask a penetrating injury; look carefully for other signs of penetrating injury (e.g. uvea in a laceration, distorted pupil, lower intraocular pressure).

Corneal abrasion

Corneal abrasions occur when the corneal epithelium is traumatically removed from its underlying basement membrane. Abrasions can occur from blunt or sharp trauma: they are very painful. Fluorescein transiently stains the underlying basement membrane and fluoresces in a blue light.

The differential diagnosis for corneal abrasion includes viral (e.g. herpes simplex, adenovirus) keratitis and corneal basement membrane disease and dystrophies. Herpes infection is usually suggested by a dendritic appearance, while basement membrane disease occurs in older children and adults and is recurrent, with no history of trauma (see Chapter 16).

Corneal abrasions are managed with a broad-spectrum antibiotic ointment, cycloplegia to reduce pain from iridospasm,

with or without patching the eye for comfort. Most young children do not tolerate a patch, so more frequent dosing with a topical antibiotic ointment becomes the treatment of choice.

Corneal foreign body

Patients with a corneal foreign body complain of pain and a foreign body sensation. The foreign body is removed, usually with irrigation, a rotating "burr," or simply and carefully with a sharp needle brought toward the eye tangentially and used to flick the foreign body away from the surface of the eye. Another safer strategy is to anesthetize the cornea and gently rub off the foreign body on the corneal surface with a moistened cotton tip applicator. After careful examination excludes the possibility of a penetrating eye injury, the eye is managed as a corneal abrasion, once the foreign body is gone.

Eye wall injuries

Etiology

Eye wall lacerations can be categorized as either a simple laceration or a rupture, and either anterior laceration or posterior in location.

In simple lacerations, the eye is cut with a sharp object (Figs 69.4–69.7). Very young children usually suffer injury when they fall on a sharp object. Older children may suffer eye wall lacerations from glass (particularly when they wear spectacles) and projectiles.

Predisposition ("brittle corneas")

Certain eyes may be more likely to rupture with relatively minor trauma. In Ehlers–Danlos syndrome, defective collagen cross-linkage leads to scleral and corneal weakness (Fig. 69.8); in Ehlers–Danlos with blue sclera (due to scleral thinning), hyperextensible skin, and hypermobile joints, spontaneous corneal rupture can occur, and in the brittle cornea, blue sclera and joint hyperextensibility syndrome, spontaneous rupture of the globe may occur. Such patients may have red hair and develop keratoglobus, and, unlike Ehlers–Danlos syndrome, they have normal levels of lysyl hydroxylase. Osteogenesis imperfecta consists of blue sclera, deafness, and bone fractures.

Fig. 69.5 Limbal penetrating injury with iris prolapse.

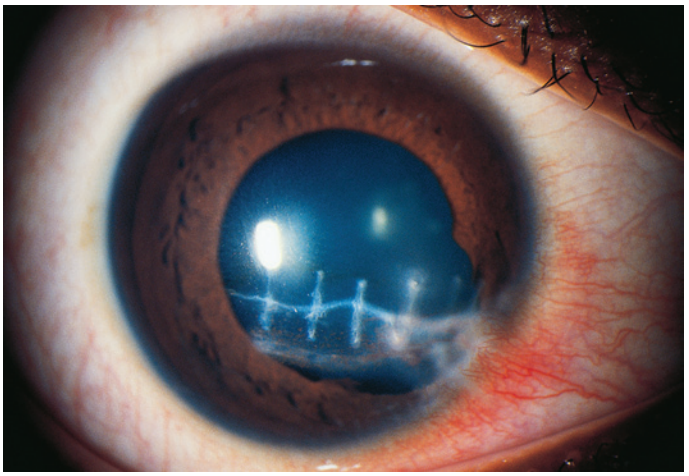

Fig. 69.6 After removal of the corneal sutures a scar persists. Failure to remove suture promptly may cause blood vessel migration and corneal opacification. Note the vessels at the corneoscleral limbus.

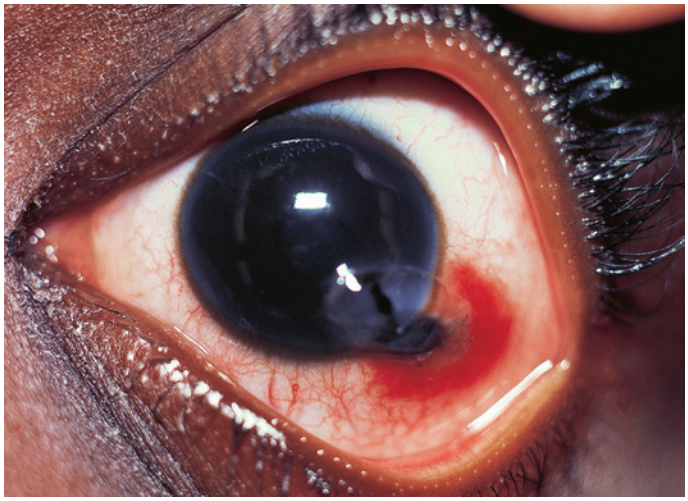

Fig. 69.4 Penetrating injury with iris prolapse and subconjunctival hemorrhage.

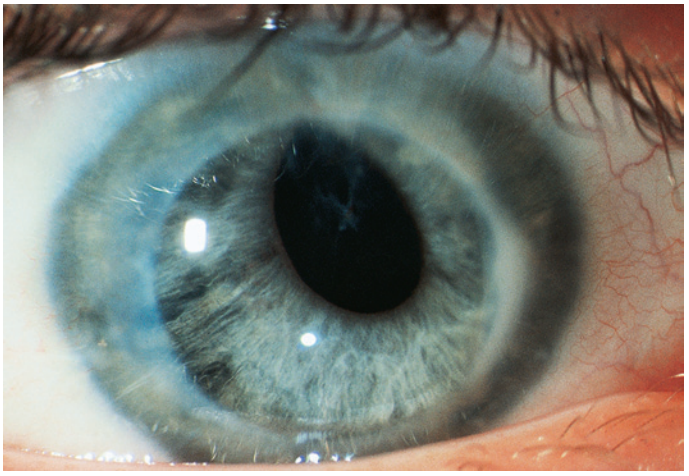

Fig. 69.7 This 5-year-old child had accidental corneal trauma as an infant. Prompt corneal grafting and amblyopia treatment resulted in an acuity of 6/12.

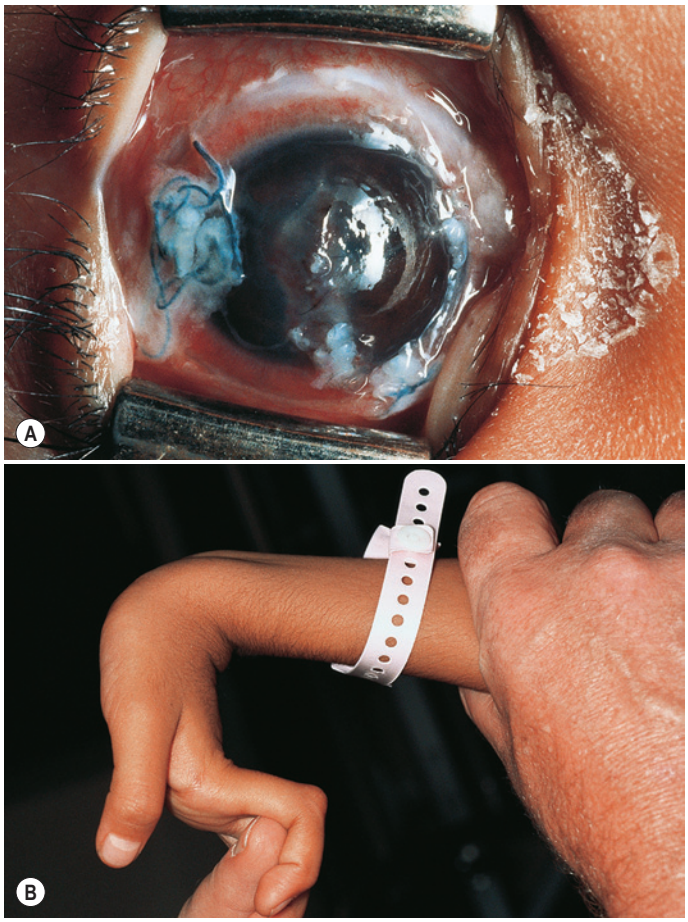

Fig 69.8 Ehlers–Danlos syndrome. (A) Spontaneous rupture of the cornea. This is an autosomal recessive disease. One of this child's siblings, also affected, had a bilateral corneal rupture at the same time during fisticuffs. (B) Hyperflexible joints.

Children with this syndrome may also be more prone to corneal rupture from minor trauma.

Globe rupture

When a globe is ruptured, it is pushed or squeezed so hard that the eye wall breaks under pressure. The results usually are devastating, with partial or complete expulsion of intraocular contents. Expulsion results from increase in intraocular pressure followed by sudden decompression through a hole in the wall of the eye. Events that can cause ruptured globes usually involve encounters with large, blunt objects. In many countries, sporting impacts and automobile crashes (airbag injuries) are major causes of globe rupture in older children.[8] Globe rupture is more common in boys than girls, reflecting the nature of the cause. Eyes are more likely to be ruptured or lacerated in areas where the sclera or cornea are thinnest, i.e. under the rectus and superior oblique muscle insertions and at the corneoscleral limbus.

Anterior versus posterior laceration

Anterior injuries carry a better prognosis, so long as the injury does not also cut the retina. Injuries anterior to the pars plana (5 mm posterior to the limbus) will not cut the retina, and therefore carry a better prognosis. If a cataract occurs with an anterior laceration, the prognosis for recovery of vision is not as good.[9] Posterior injuries cut the retina and often result in a complicated retinal detachment, with a far worse prognosis.

Penetrating eye injuries are those in which the causative agent enters the eye but does not pass all the way through. Perforating eye injuries are those that pass through two walls of the eye. The same definition holds true when referring to different parts of the eye. A penetrating corneal injury penetrates the cornea but does not pass all the way through it. A perforating injury passes all the way through the cornea into the anterior chamber or further.

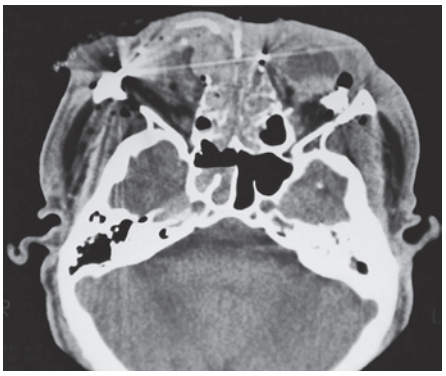

Fig. 69.9 Computed tomography scan showing disrupted right globe following a gunshot wound. The left eye was also injured from the concussive effect. Note the vitreous hemorrhage.

Diagnosis

The diagnosis of penetrating eye injury is obvious when a laceration is apparent. Clues to occult penetration include subconjunctival hemorrhage, distorted pupil, wrinkled lens capsule, and lowered intraocular pressure, particularly compared to pressure in the fellow, uninjured eye, reduced visual acuity, or an afferent pupillary defect.

Management

Prevention

The best form of management for eyeball lacerations is prevention. This includes wearing suitable safety glasses or goggles by players who participate in games involving a small ball, and supervision by parents and teachers when sharp objects (fencing, archery, etc.) are used.

The use of safety glasses in monocular children is valuable, especially at times of particular risk.

Treatment

Once the eye laceration or globe rupture is diagnosed, it is recommended that a protective shield be placed over the eye. Emergency surgery is indicated, but the patient's overall health should not be ignored. The eye laceration may accompany head trauma. An adolescent patient with multiple gunshot wounds needs to be fully assessed as experience has found that it is relatively easy to focus on the eye injury and almost miss a head injury. Systemic antibiotics and control of nausea and vomiting are recommended.

Imaging

In many cases, a computed tomography (CT) scan of the orbits (Figs 69.9 and 69.10) will help to identify the location of expected or unexpected intraocular foreign bodies. Ultrasound biomicroscopic evaluation also can be helpful to detect zonular deficiency, angle recession, iridodialysis, lens dislocation, and

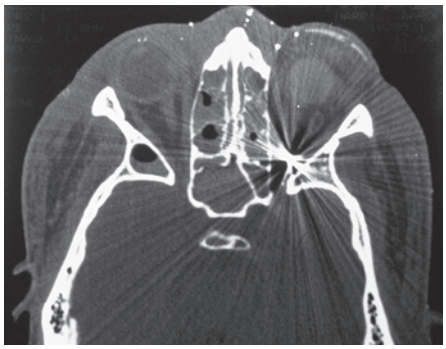

Fig. 69.10 Shotgun injury. Computed tomography scanning is particularly helpful in delineating the presence and location of ocular and orbital foreign bodies. This adolescent was shot in the face with a gun.

iridocorneal adhesions.[10] It is important to avoid contact ultrasound evaluation if a ruptured globe is suspected as any pressure might cause extrusion of intraocular contents.

Anesthesia

Some advocate avoiding a depolarizing agent for fear that the contraction of extraocular muscles (which initially occurs) could expel intraocular contents.

Surgery

Anterior full-thickness lacerations require prompt closure and re-evaluation of the patient's vision and ocular status in the ensuing days. The use of intraocular antibiotics is usually recommended. The prompt closure of an eye wall laceration would seem to be adequate to greatly reduce the incidence of traumatic endophthalmitis. In young children, delay in traumatic cataract extraction runs the risk of inducing amblyopia, but there is often a better chance of successfully implanting an intraocular lens if the eye is closed in two stages. In older children (>7 years of age), it is often an easier decision to plan a second operation with an intraocular lens implant. Although controversial, good results have been reported with combined lensectomy, vitrectomy, and primary intraocular lens implantation as the initial procedure.[11]

Posterior lacerations almost always cut through the retina. Even so, the initial goal of surgery is wound closure. Most authorities do not use cryosurgery or scleral buckling at initial surgery. The trauma alone is enough to cause a retinal scar around a break, and cryosurgery may increase the likelihood of proliferative vitreoretinopathy. A posterior vitreous detachment occurs 7–10 days after trauma; after this detachment has taken place, retinal surgery can be undertaken.

Management continues even after successful surgery. Children under the age of 7 years are at risk of amblyopia. Prompt refractive management with a contact lens over a corneal laceration (or spectacles if appropriate) and patching should be started as soon as possible. Corneal sutures in children attract vascularization and scarring much more quickly than in adults. Sutures may be removed in a few weeks in young children; failure to do this may result in a vascularized cornea, impeding vision.

Prognosis

Anterior lacerations carry a better prognosis than posterior lacerations. But in young children, with the risk of amblyopia, the prognosis may not be good, even with anterior lacerations. When anterior lacerations are combined with a traumatic cataract, the prognosis worsens. The prognosis is highly dependent upon success in the management of amblyopia.

Traumatic cataracts

Traumatic cataracts can occur as a result of a sharp penetrating injury to the lens capsule and/or lens, or a blunt concussive force. They may take days to years to develop. The diagnosis of traumatic cataracts is based on an abnormality in the red reflex. The cataract problem can be confirmed by examining the lens under magnification, either with loupes or a slit-lamp. In some cases, a Vossius ring may occur, i.e. a ring of pigment forms on the anterior lens capsule as a result of the posterior (pigmented) aspect of the iris striking the capsule. Examination should establish that there are no other ocular injuries.

In partial cataracts, an additional important aspect to the examination is an effort at measuring visual function in the involved eye. In older children this can be done with Snellen acuity. In younger children, an estimate must be made based upon experience with lens clarity and visual functioning. Attempts can be made to measure acuity with forced choice preferential looking techniques, but these may be misleading and probably should not be used as the sole determinant to undertaking surgery.

If there is doubt as to the value of removing a lens with a cataract, then it should be observed. So long as the child is beyond the age when amblyopia can develop, the initial repair of a corneal or scleral laceration can be followed at a later date with removal of the lens. This "wait-and-see" strategy has no deleterious effects on the child other than the necessity for a second general anesthetic.

Children with visually significant traumatic cataracts can have good outcomes if managed appropriately.[12] Surgical management consists of removal of the lens with or without preservation of the posterior capsule. If a lens is removed at the same time as the closure of an eye wall laceration, some authorities advocate simultaneous lens implant. One reason for caution is that the implant could foster survival of bacterial organisms that penetrated the eye as a result of the trauma. Another concerns the choice of the intraocular lens power required to correct the aphakia. In young children, eye growth leads to instability of the refractive power of the eye, making implant power selection problematic.[9] Decisions regarding subsequent implants depend on surgeon preference and the presence or absence of corneal refractive problems. If a child has a significant amount of astigmatism and will require contact lens rehabilitation anyway, then in some circumstances, the increased risk of a lens implant can be avoided, since the implant would not avert the need for contact lenses. Contact lenses can be successful in post-traumatic aphakia; rigid gas-permeable lenses seem to be most effective if there was a corneal perforation.[13] Combined keratoplasty and lens implantation may have a role in some cases.[14]

A special type of cataract can occur as the result of electrical injury.[15] A characteristic opacity in the posterior aspect of the lens forms as the result of the transmission of electricity to the eye (Fig. 69.11) itself.

Hyphema

A hyphema is a collection of blood in the anterior chamber of the eye. It occurs as a result of traumatic avulsion of blood vessels at the base of the iris. Bleeding occurs and then ceases

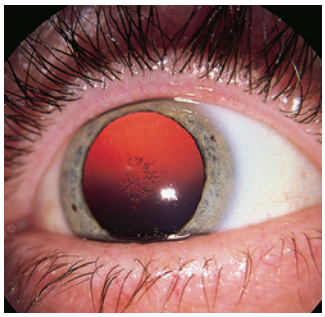

Fig. 69.11 Electric shock. After an electric shock, this young man slowly developed a monocular cataract.

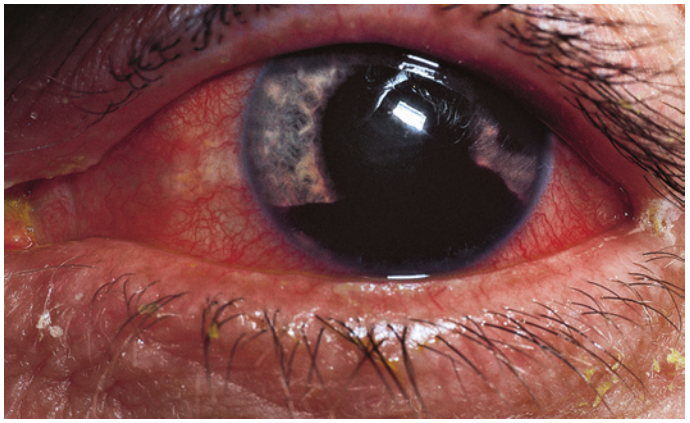

Fig. 69.12 A long-standing hyphema. This is shown by the dark color of the blood in this young man.

after clot formation or an increase in intraocular pressure. A hyphema may be small enough that it can be identified only with a slit-lamp examination, or it can be so extensive as to fill the entire anterior chamber with blood ("8-ball hyphema"). In most instances, a superiorly located meniscus develops due to the effects of gravity (Fig. 69.12).

The major cause of hyphema is trauma; it is much more common in boys than in girls,[16] but there are other etiologies. Herpes zoster iritis can occasionally cause a hyphema. Spontaneous hyphemas also occur with juvenile xanthogranulomatosis (JXG), usually in very young children, and may or may not be associated with cutaneous lesions. The risk of intraocular JXG increases with young age (<2 years), multiple skin lesions, and new diagnosis.[17] Hyphemas may occur rarely in association with tumors of the eye, particularly retinoblastoma, and with iris vascular abnormalities or rubeosis. In a hyphema the clot usually retracts between the third and fifth post-traumatic day, at which point the hyphema may recur. Very small "trickle" hyphemas are less likely to rebleed than larger ones. However, rebleeding cannot be predicted solely on the size of the hyphema if it is visible without magnification. For this reason, some sort of rest regimen for the child is generally advocated. Whether a child should be hospitalized in order to facilitate resting will certainly depend at least on the child's activity level, the family's ability to supervise the child, and perhaps also on the size of the hyphema.[16] A quick, substantial rise in intraocular pressure (a complication of hyphema) can cause nausea and vomiting, an indication for antiemetics. The author uses a long-acting cycloplegic agent in order to put the iris and pupil "at rest" and topical steroids if an inflammatory component (iritis) occurs. Systemic steroids or epsilon aminocaproic acid (which blocks fibrinolysis thereby reducing the risk of rebleeding) have been advocated by some. Topical epsilon aminocaproic acid may be effective in reducing rebleeding and is not associated with an increased risk of nausea and vomiting as is the case in its systemic use.[18]

Complications of hyphema include increased intraocular pressure and glaucoma. How much pressure and for how long it can be tolerated safely has not been determined for children. High pressure runs the risk of causing corneal blood staining and optic nerve damage. To prevent these complications, elevated pressure should be maintained below 30 mmHg. Persistent elevation of intraocular pressure is an indication for surgical evacuation of the hyphema. Elevated intraocular pressure can be managed with topical eye drops such as beta-blockers; it is safer to avoid cholinergic drugs such as pilocarpine because they cause constriction of the pupil and may affect fragile blood vessels. Systemic acetazolamide is often helpful.

When a child has sickle cell anemia or trait, the management of glaucoma caused by hyphema is more problematic. The only agent available is a topical beta-blocker, since other agents may either exacerbate the hyphema (e.g. pilocarpine) or lead to sickle cell crisis. Children with sickle cell with a hyphema are candidates for early surgical intervention. Evacuation of the clot through a limbal incision is generally preferred. Even in children who do not have sickle cell, but in whom glaucoma remains refractory, surgical evacuation is advisable.

Corneal blood staining is caused by erythrocytes crossing the corneal endothelium and Descemet's membrane and staining the cornea when the intraocular pressure is significantly elevated, and when the endothelium is damaged. Corneal blood staining is reversible, but takes several years and may lead to amblyopia. In order to avoid corneal blood staining in the context of a persistent large hyphema with elevated intraocular pressure that is unresponsive to medical management, some have advocated trabeculectomy surgery, closing the scleral flap quite loosely. Although conjunctival scarring will likely lead to bleb failure in the long run, the hyphema will have resolved without accompanying ocular hypertension, thus sparing the child from the profoundly amblyogenic complication of corneal blood staining.

Months and years later, if the angle of the eye has been traumatized and "recessed," "angle recession glaucoma" may develop. For that reason, any patient who has had a hyphema probably should have yearly ophthalmology examinations, with intraocular pressure measurements determined.

Posterior segment trauma

Commotio retinae

Commotio retinae, also known as Berlin edema, frequently occurs after blunt trauma to the front of the eye; in one study it occurred in 35% of cases of contusion or rupture of the globe.[19] The edema, which occurs in the outer retina, has a funduscopic appearance that is white or gray-white. The macula may be involved with or without macular hole formation, in which case central vision will be at least temporarily diminished.[20] Berlin edema can also involve extramacular areas. In most cases, the edema resolves; but in some cases, pigment migration in the

macula results in acuity loss. The differential diagnosis includes retinal infarction, cotton-wool spots, and shallow retinal detachment. No treatment is available for commotio retinae.

Purtscher retinopathy

Severe trauma to the torso or the head can cause Purtscher retinopathy. Airbag and seat belt injuries in automobile accidents account for a significant number of cases.[21] Purtscher disease can be associated with fat or air embolism or pancreatitis.[22] It has the appearance of massive whitening around the optic nerve head associated with hemorrhage. The whitening may represent ischemic areas or exudate. There is no specific treatment for this problem, which may resolve leaving anything from mild to profound vision loss.

Whiplash injury

A macular hole sometimes occurs as a consequence of a severe whiplash injury. Presumably, the head thrusting induces a vitreoretinal interface shearing force, which tugs at the fovea and creates a partial or full-thickness hole.

Choroidal rupture

Another complication of blunt injury to the eye is choroidal rupture, often associated with widespread damage and vitreous hemorrhage (Fig. 69.13). The choroid may be ruptured at the level of the inner choroid and retinal pigment epithelium, and often in the macula. The mechanism is mechanical disruption of tissue. Sometimes the rupture is associated with a serous or hemorrhagic retinal detachment, which obscures the nature of the injury. Once the detachment resolves, the patient may be left with diminished vision if there has been scarring or retinal pigment epithelial migration into the area of the macula. Later, choroidal rupture can predispose to choroidal neovascularization, leading to exudate and hemorrhage under the macula, also diminishing vision.

Retinal hemorrhages

Retinal hemorrhages can be caused by direct head or ocular trauma, or by indirect trauma, as in non-accidental trauma (see Chapter 70).

Hemorrhages occur commonly in normal infants in the perinatal period (Fig. 69.14). They usually resolve completely in less than 1 month, occasionally in up to 3 months. Retinal hemorrhages are uncommon in children born by cesarean section.[23] Hemorrhages may occur in any layer of the retina or in the vitreous. Subretinal pigment epithelial hemorrhages appear dark with an amorphous boundary. Intraretinal hemorrhages are red in appearance, usually small and round. Superficial retinal hemorrhages have a splinter or flame-shaped appearance because they often occur in the nerve fiber layer. Subhyaloid hemorrhages have a characteristic appearance where blood forms a meniscus in a large cystic filled cavity. Finally, vitreous hemorrhages may also occur in the setting of trauma, and may be localized or diffuse depending on their severity. Preretinal hemorrhages are particularly common in children with subdural or subarachnoid hemorrhages. Since central nervous system (CNS) hemorrhage is frequently caused by trauma in children, a traumatic etiology for preretinal hemorrhages should be suspected.

Prolonged obscuration of vision due to severe vitreous hemorrhage can cause deprivation amblyopia, and in some cases is a reason for early vitrectomy, particularly in the first 3–6 months of life.[24]

Traumatic retinal detachment

Blunt trauma to the eye can cause a retinal detachment even if the globe is not cut or ruptured. Typically, the detachment occurs as the result of avulsion of the vitreous base causing a retinal dialysis, which is often in the superonasal quadrant of the eye. Presumably this location is most vulnerable because a blunt blow to the eye arises from 180° away, in the inferotemporal segment; a blunt object strikes the eye and causes a retinal tear which, days to months later, leads to a retinal detachment.

Self-injury in severely mentally retarded children can also cause retinal detachments by similar mechanisms (see Chapter 106).

In atopy, constant rubbing to relieve itching may increase the risk of retinal detachment.

Orbit trauma

Orbital bone fractures

General

Fractures of the orbit frequently involve the eye and demand the involvement of an ophthalmologist.

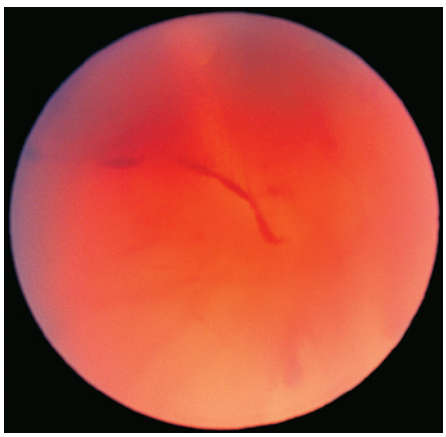

Fig. 69.13 Choroidal rupture. There is a marked vitreous hemorrhage largely obscuring a view of the fundus where a pale organizing clot can barely be made out.

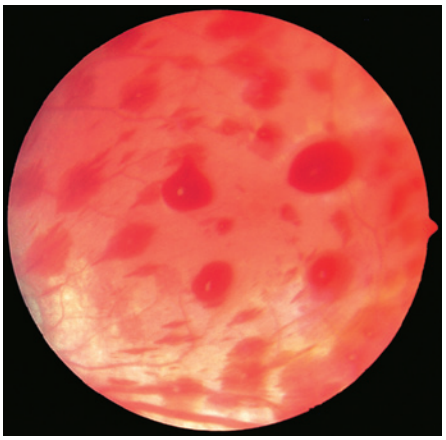

Fig. 69.14 Neonatal retinal hemorrhages in a normal child. *(Photograph courtesy of Dr Andrew Q. McCormick, Vancouver.)*

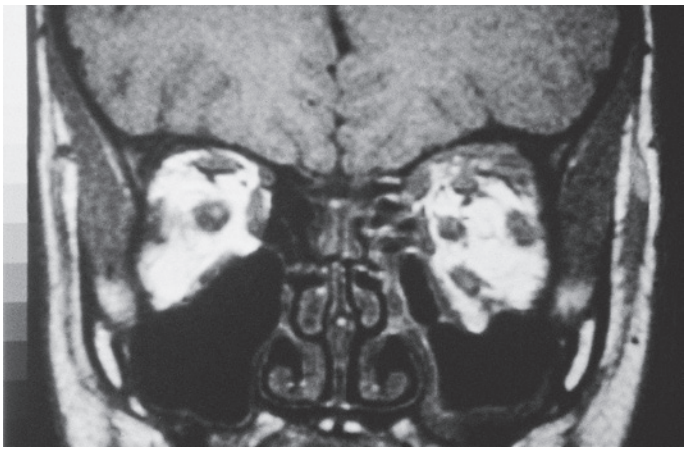

Fig. 69.15 Blow-out fracture. Entrapment of the tissues associated with the inferior rectus in the left orbit.

Blow-out fractures

Blow-out fracture refers to the caving out of one of the orbital bones that surround the eye. In most cases, the floor of the orbit is fractured (Fig. 69.15), but the medial wall of the orbit can also be damaged.[25] "Trapdoor" fractures, usually involving the orbital floor, are not uncommon in children. Blow-out fractures are unusual in young children, before the sinuses have formed.

Etiology

Blow-out fractures are caused either by compression of the orbit, increasing the pressure on the orbital contents, or by direct transmission of the force of a blow to the orbital rim, to the bones of the floor, or to the medial wall of the orbit. Experimental injuries to the orbital rim have demonstrated that a posterior orbital floor blow-out fracture can be induced in this fashion.

Complications

Two types of problems can result from a blow-out fracture. Enophthalmos can occur as a result of expulsion of intraorbital contents into fractures of the floor or medial wall of the orbit. Enophthalmos may not be apparent immediately after trauma due to edema and swelling but becomes apparent by 5–7 days after injury and should be evaluated then. If cosmetically significant, the fracture can be managed by replacing the orbital contents and repairing the fracture in order to return the orbit to its original volume.

A second problem is strabismus, including entrapped or paralyzed extraocular muscles, vertical displacement of the globe, Brown syndrome, and even cranial nerve injury if the force of the blow damage is sufficient. A trapped inferior rectus muscle is the most common cause of strabismus associated with a blow-out fracture (see Fig. 69.15). The muscle or inferior orbital tissues become incarcerated in the floor fracture, tethering the eye in a hypotropic position. Most patients experience vertical diplopia, worsening in upgaze. The incarcerated tissues should be freed as soon as possible to prevent irreversible damage to the inferior rectus, with fracture repair and accompanying strabismus being repaired.

Traumatic optic neuropathy (see Chapter 56)

Etiology

Traumatic optic neuropathy occurs when head or facial trauma causes direct or indirect injury to the optic nerve. In children, it is most commonly associated with motor vehicle accidents or sports injuries.[26] The result is unilateral or bilateral, partial or complete, loss of vision. Frontal bone trauma, occasionally even subtle and apparently insignificant, is most likely to result in optic nerve injury.

One special circumstance bears mentioning. Patients with severe psychiatric disturbances may attempt to enucleate their own eye and in the process sever the optic nerve at some point in its approach to the globe (see Chapter 106). If the severance is posterior near the chiasm, a unilateral blindness may be accompanied by a temporal hemianopia in the fellow eye due to chiasmal damage.[27] Patients who attempt to remove their own eye often experience temporary relief of their psychiatric symptoms if successful; a resurgence of symptoms may lead them to attempt to enucleate their other eye. Such patients should be guarded very closely and their psychotic symptoms should be managed aggressively.

Diagnosis and treatment

The examiner often must rely on signs of unilateral afferent visual dysfunction (afferent pupil defect, diminished color vision, decreased visual acuity). Unfortunately, many patients who experience such trauma may not be able to cooperate with a physical examination. We use high-dose steroids using methylprednisolone at a dose of 30 mg/kg as an intravenous bolus to treat traumatic optic neuropathy. A second option involves surgical intervention. Indications include optic sheath hemorrhage, orbital hemorrhage (focal, diffuse, or subperiosteal), and an optic canal fracture causing compression of the optic nerve. However, there is no convincing evidence that routine medical or surgical treatment alters the long-term visual outcome of patients with traumatic optic neuropathy.[26]

Traumatic retrobulbar hemorrhage

Trauma to the eye or orbit will occasionally cause orbital hemorrhage. Hemorrhage may be the result of blunt trauma, in which case shearing forces on retrobulbar veins or arteries are suspected. Sharp objects can also penetrate behind the eye without actually injuring the globe itself, and may lacerate blood vessels. The affected person will have pain with signs of a rapidly increasing retrobulbar mass: proptosis, an increase in intraocular pressure, chemosis, and diminished eye movements.

Trauma is not the only cause of these retro-orbital signs. Slowly progressive signs may indicate Graves disease, and conditions such as orbital cellulitis and traumatic carotid–cavernous fistula can also present similarly. Cellulitis may be diagnosed when other signs of infection are present (redness, heat in the area, considerable pain). Neuroimaging usually demonstrates sinusitis extending into the retro-orbital space, and the patient may have fever and leukocytosis. Carotid–cavernous fistula is suspected when there is pulsating exophthalmos and vessels that appear arterialized in the conjunctiva and retina.

Traumatic retrobulbar hemorrhage occasionally is an ophthalmic emergency.[27] When the intraocular pressure

is elevated and affecting optic nerve function the pressure must be lowered immediately. The author lowers intraocular pressure with carbonic anhydrase inhibitors (acetazolamide) and hyperosmotic agents. A lateral canthotomy and inferior cantholysis can relieve retrobulbar pressure almost immediately. He seldom uses aqueous paracentesis because it has only a short-term benefit and exposes the patient to the risk of cataract or intraocular infection.

Central nervous system trauma (see Chapter 60)

Prolonged cortical visual impairment following trauma

Many possible mechanisms can account for prolonged cortical visual impairment after head trauma.[28] A seizure could lead to cortical impaired vision. A cerebral contusion could result in generalized cerebral edema, causing either transient or prolonged cortical visual impairment. Increased cerebral edema can compress the posterior cerebral arteries leading to vascular insufficiency to the visual cortex. CNS hypoxic ischemia could be a sequel to either generalized trauma with blood loss or CNS vasospasm. The occipital region is quite susceptible to hypoxia and may be selectively involved (see Chapter 60).

Post-traumatic transient cortical visual impairment

Cortical visual impairment can be defined as complete or nearly complete, loss of vision with normal pupillary reflexes, and a normal fundus examination. Cortical visual impairment in children may differ in its manifestations from cortical blindness in adults. Children show fluctuating vision, a preference for observing color (versus black and white), light gazing, and, occasionally, photophobia. A relatively minor blow to the head can cause transient cortical blindness.

Traumatic cranial neuropathy (see Chapter 84)

Thirteen percent of non-fatal head injuries result in cranial neuropathy. The sixth cranial nerve is most commonly traumatized and the most common cause of multiple acquired cranial nerve palsies is trauma.[29] Most cases occur between the ages of 16 and 25 years, but even very young children can be affected.

Diagnosis

In sixth nerve palsy, difficulty or inability to abduct the involved eye is noted. The patient demonstrates a large-angle esotropia in primary gaze greater for distance than near; they can be bilateral.

Complete third nerve palsies cause a dilated pupil, complete ptosis, and an inability to adduct, depress, or elevate the eye. The resulting eye position is one of exotropia and hypotropia. Partial third nerve palsies may occur.

Traumatic fourth nerve palsies may be unilateral or bilateral. Unilateral cases typically show a hypertropia in primary gaze with inferior oblique overaction. Patients may demonstrate excyclotorsion of the eye, and cyclotorsional double vision up to 8°. Bilateral fourth nerve palsies occur in as many as 30% of cases. Bilaterality is suggested by the following physical findings:

- a "V" pattern esotropia greater than 25 prism diopters;
- alternating hyperdeviation (right hypertropia on right head tilt and left hypertropia on left head tilt);
- an excyclotorsion in primary gaze which exceeds 15°.

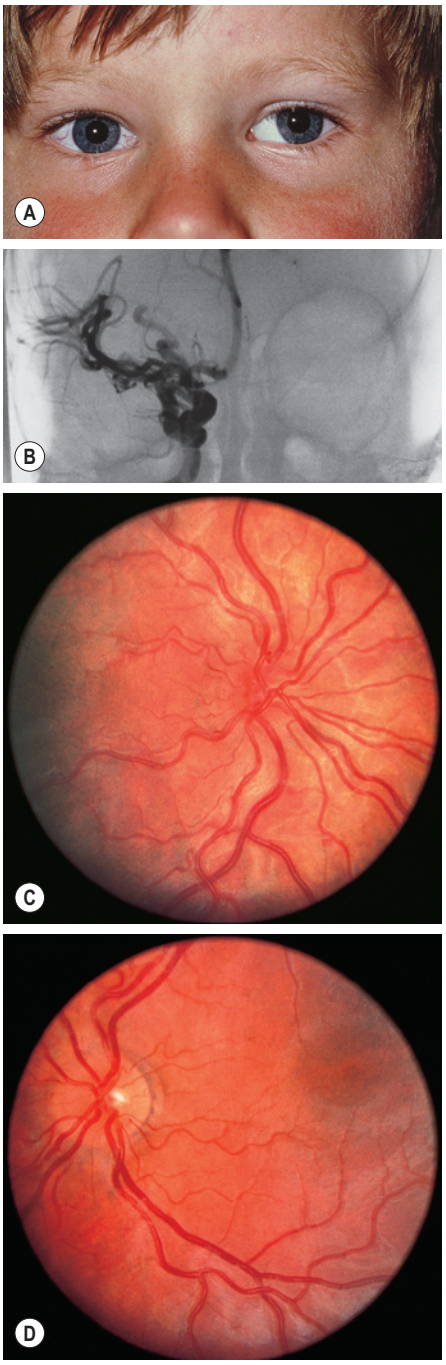

Fig. 69.16 Severe trauma. (A) This 5½-year-old boy developed right proptosis and a squeaky bruit a week after a severe road traffic accident. Dilated episcleral veins can be seen on the right. (B) Carotid angiogram showing the shunt that was later closed with a balloon catheter. (C) Retinal venous congestion and tortuosity with optic disc edema on the right. (D) Normal left fundus.

Management

In about 40% of cases, resolution may spontaneously occur. Neuroimaging is indicated when a cranial neuropathy is present, particularly when the trauma is slight and would not normally be expected to cause a nerve palsy: tumors present in this way. Magnetic resonance imaging is probably more sensitive

in detecting subtle intraparenchymal lesions or hemorrhages. After 6 months we consider surgical management.

Disorders following concussion

A surprising number of patients will complain of trouble focusing their eyes following head trauma.[30] Other concussive symptoms include photophobia and convergence insufficiency.

Carotid–cavernous fistulas are rare in children but may occur following severe trauma[31] (Fig. 69.16).

Introduction

Ophthalmologists working with children should have the knowledge and skills to identify abuse and neglect. They should be aware of local safeguarding policies to protect children and promote their welfare.[1,2] Child maltreatment covers both child abuse and neglect.[3]

Child maltreatment is defined as any act or series of acts of commission or omission by a parent or caregiver that results in harm, potential harm, or threat of harm to a child (Box 70.1).

Epidemiology

In the year 2012, it was estimated that there were 686,000 victims of child maltreatment in the US.[4] However, it is well recognized that child maltreatment is often missed and this figure may represent only a small part of the problem. Neglect in various forms is the most common type of child maltreatment, followed by physical abuse, sexual abuse, and emotional abuse.

Currently 1 in 80 children in the UK, less than 11 years old (1.3%) have experienced physical violence at the hands of a parent or guardian.[5]

Ophthalmological features are commonly associated with abusive head trauma, which represent 1.8% of physical abuse.[6] The incidence of abusive head trauma ranges from 14.2/100,000 to 33.8/100,000 infants in the UK and is commonest in infants less than 6 months of age.[7,8] Abusive head trauma accounts for the majority of fatal life-threatening injuries due to abuse in infants.[9]

Risk and protective factors for child maltreatment

A combination of individual, relational, community, and societal factors may contribute to the risk of child maltreatment. Although children are not responsible for the harm inflicted on them, certain characteristics are associated with an increased risk of abuse. Parents either acting alone or with another person account for 71% of abuse of children in their care. Though there is no single profile that fits all perpetrators, a number of common characteristics are reported in many studies (Box 70.2).

There is scientific evidence that protective factors for child maltreatment include a supportive family and supportive social networks.

Presentation of child abuse victims to the ophthalmologist

Children are most commonly referred from child protection teams to an ophthalmologist when abusive head trauma is suspected. However, if the initial presentation is to an ophthalmologist, who suspects maltreatment, he/she should be familiar with local child protection proceedings and refer to the child protection team.[10]

The presenting features alerting the professional to child maltreatment include the following:

1. Physical signs of unusual bruising in non-mobile infants for which there is no explanation (Fig. 70.1A–C). Bruising in pre-independently mobile infants is

very rare (<1%)[11] and bruising that is periocular in infants should be investigated when there is no innocent explanation. Other signs include bites, burns, scalds; ligature or strangulation marks and abrasions may accompany a story that does not seem a plausible explanation.

2. Anogenital injuries and sexually transmitted diseases in children point to sexual abuse.
3. Clinical presentations include an apparent life-threatening event (where the child presents floppy and apneic), seizures, ingestion of poisonous substances, epistaxis, near drowning, unusual or poor attendance at medical services, and poor school attendance due to ill health.
4. Unkempt child with infestations and/or tooth decay may signify neglect.
5. Behavioral signs include sexualized behavior, the "frozen watchfulness" of a withdrawn child, overt hostility or friendliness of the caregivers, and an aggressively acting child.

Box 70.1

Classification of child maltreatment

Child abuse classified as acts of commission (words or overt actions) include:

- Physical abuse
- Sexual abuse
- Psychological abuse
- Fabricated or induced illness

Child neglect classified as acts of omission include:

- Failure to provide: physical, emotional, educational, medical/dental neglect
- Failure to supervise: inadequate supervision, exposure to violent environments

Management

Clinical records

Completion of a standardized ophthalmology clinical record[12] supplemented with wide-field retinal photography (Retcam 130) improves documentation that will help when giving evidence in family or criminal court[13,14] (Fig. 70.2).

Studies have described a number of ways of describing the distribution, location, and types of retinal hemorrhages.

Box 70.2

Risk factors for child maltreatment

Perpetrator individual risk factors[3]

- Poor parenting skills, lack of understanding of child's needs and development
- Family or parental history of abuse
- Mental health problems, depression, and history of substance abuse
- Young age, low income, single parents
- Mother's male partner
- Maltreatment not considered abusive and justified

Children at risk

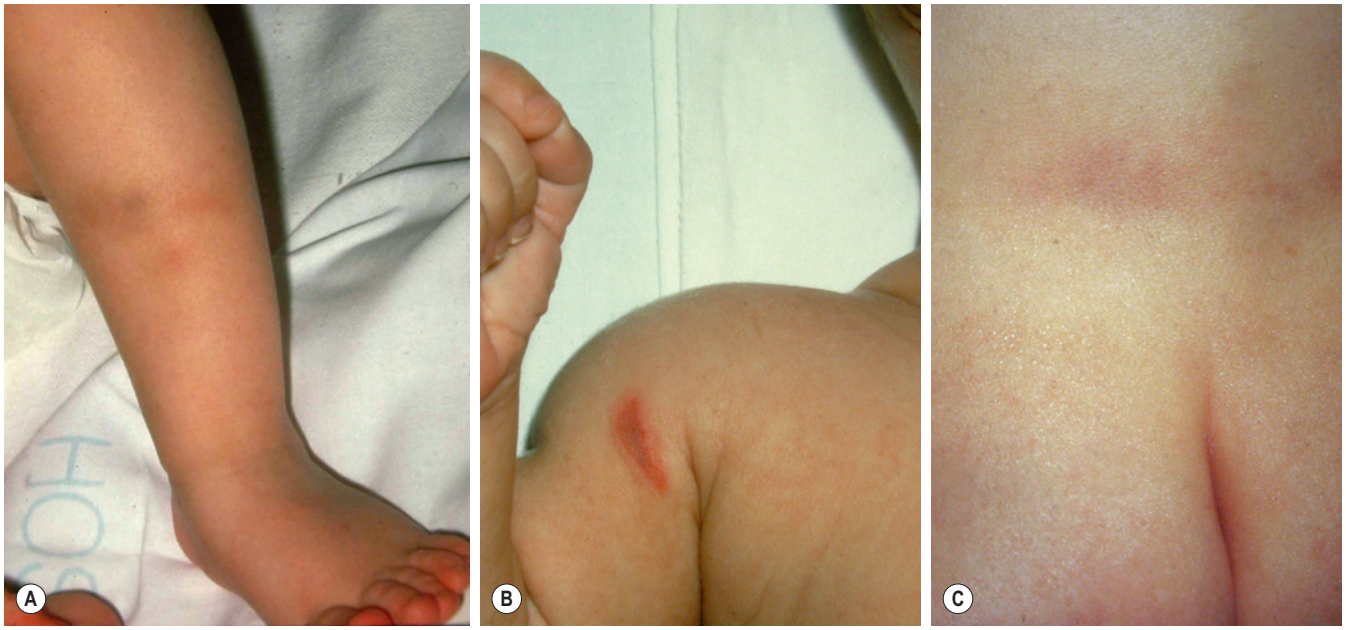
- Children less than 4 years
- Special needs children

Family risk factors

- Social isolation
- Family disorganization, dissolution, and domestic violence
- Parenting stress, poor parent–child relationships, and negative interactions

Community risk factors

- Community violence and concentrated neighborhood disadvantages (poverty, unemployment, residential instability)



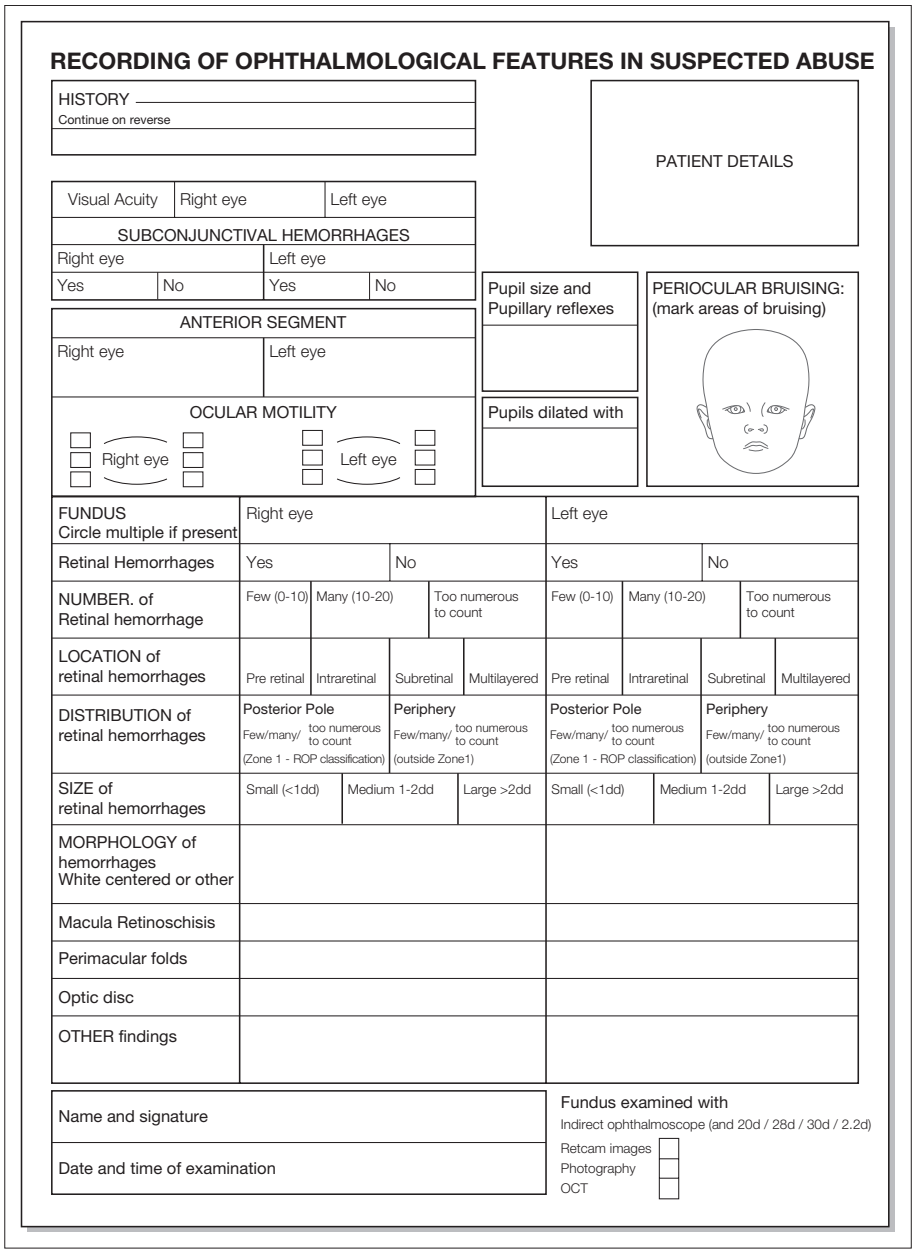


Fig. 70.1 Bruises on the left shin (A), right arm (B), and small of the back (C) in a non-independently mobile infant are suggestive of inflicted injury.

Fig. 70.2 Ophthalmology clinical record in suspected abusive head injury.

Their use in routine clinical practice, however, has not been evaluated.[12,15–19] Recent systematic reviews of retinal hemorrhages in abusive injury identified the need for consistent and standardized description of retinal findings that would hold under scrutiny in medico-legal cases and help with future research in differentiating patterns of retinal hemorrhages from various causes.[20,21]

Fluorescein angiography to demonstrate retinal vascular non-perfusion[22] and optical coherence tomography elucidating vitreoretinal interface pathology[23–25] may help explain the mechanisms of retinal hemorrhages and help to elucidate whether the cystic lesions in the macula, are sub-hyaloid or intraretinal (retinoschisis).

Each entry in the clinical record should be labeled with the child's name, date of birth, clinician's name, designation, signature and date and time of examination. The clinical record should include a differential diagnosis list, which may suggest further investigations if considered appropriate by the lead child protection doctor. A standard list of investigations in suspected cases of abusive head injury has been suggested with a multidisciplinary assessment involving appropriate medical teams, social services, and the police[26] (Table 70.1).

A date for a follow-up examination should be clearly indicated on the clinical record.

History

When possible, a detailed history from the caregivers of the child is recorded. The ophthalmologist often relies on the history taken by other health care professionals, as the caregivers of the child may not be present when the child is examined. When they are present, the history of the presenting condition should be elicited and whether any prior eye disease (e.g. retinopathy of prematurity) or visual concern had been expressed about the child prior to presentation. A family history of eye disease or a bleeding disorder should be ruled out.

Table 70.1 Essential baseline investigations of an infant or young child with abusive head trauma[26]

1	Multi-agency assessment	Pediatrician with expertise in child protection Pediatric neurologist and neurosurgeon Neuroradiologist Ophthalmologist Social services and police
2	Clinical history	Complete pediatric history and documentation of all explanations of trauma
3	Social and police history	Any previous concerns, criminal records of caregivers
4	Examination	Thorough examination, documentation, photographs of injuries, monitor head circumference
5	Ophthalmology	Ophthalmologist to examine both eyes using an indirect ophthalmoscope through dilated pupils
6	Radiology	Initial magnetic resonance imaging of head repeated in 7–14 days Discuss with neuroradiologist Full skeletal survey – repeat between 10–14 days
7	Serology	Full blood count – repeated in 24–48 hours Coagulation screen, urea and electrolytes, liver function tests, and blood cultures

In abusive head trauma, the history may not be consistent in the timing and date of the events when taken by a number of health care professionals. The injury sustained may be incompatible with the explanation given.

Examination

It is good practice to examine the child within 24 hours of referral and as close as possible to the admission of the child to hospital.

- External eye examination should include descriptions, drawings, and photographs of any periocular injury or subconjunctival hemorrhages.
- If possible, the visual acuity and ocular motility should be recorded.
- The pupillary reactions, anterior chamber and lens position should be examined before the pupils are dilated. Poor pupillary responses are strongly associated with increased mortality and poor visual outcomes.[27]
- Examination of the retina should be with an indirect ophthalmoscope and a wide-field lens (28 or 30 diopter, or a 2.2 lens) following dilation of the pupils with short-acting mydriatics (phenylephrine 2.5% and tropicamide 1%). Pupillary dilation will affect neurological observations; this should occur after discussion with the admitting physicians. Descriptions of retinal hemorrhages should include their distribution, their location in terms of the retinal layers, their morphology, their number, and size.

Medico-legal issues[28]

The conduct of a case in court will depend on the operating legal framework but, universally, the underlying principal concern is the welfare of the child.

In the UK, a case may be considered subject to the following:

1. Care proceedings in a civil or family court: A verdict reached by the court is based on the "balance of probability."
2. Criminal court proceedings: A verdict is reached when it satisfies the statement of "beyond reasonable doubt."

Expert witness

When writing a report or giving evidence as a witness, the expert's duty is to the court and not to any side or to the lawyers who commissioned the report. Common threads of inquiry include the causes of positive findings, the differential diagnosis, the forces required to produce the injuries sustained, the mechanisms of injury, the timing of injury, and the contribution of confounding issues such as seizures, cardiopulmonary resuscitation, apparent life-threatening events, and coughing, which frequently co-exist in a child with traumatic brain injury. The report should take into account all material sent to the witness and should be well researched. A summary of publications addressing pertinent issues is often useful in providing a balanced view of the literature.[29–31]

The court will look for clarity in presentation and conclusions. The following issues are required by the court in any expert report[28]:

1. issues it has asked the expert to address;
2. the material the expert has considered;
3. the conclusions reached;
4. the reasons for reaching these conclusions.

Evaluation of child maltreatment literature

Ophthalmology literature frequently lacks strict definitions of abuse. This introduces circular reasoning where the certainty of the findings being truly due to abusive injury cannot be confirmed. Evaluation of the literature should be supported by the use of a ranking system of various levels of certainty of abuse based on criminal or family court proceedings, perpetrator confessions, multidisciplinary team assessments, and defined clinical criteria. The various levels of certainty of child abuse may be defined as definite, probable, or possible, or ranked 1 to 5, where rank 1 represent the highest level of certainty and 5 the least[32,33] (Table 70.2). This will not eliminate circularity, but makes it less likely if conclusions are based on studies that rely on cases that were "definite" or a high ranking (1 or 2) abuse.

Ophthalmic features of physical abuse

Direct injury

Reports from early literature suggest that direct injury to the eye and orbit may manifest with periocular swelling and bruising (Fig. 70.3), burns, lid lacerations, hyphema, cataracts, retinal dialysis, and retinal detachments.[34,35]

Indirect injury

Subconjunctival hemorrhages

Subconjunctival hemorrhages have been reported in abusive head trauma with or without intraocular injury and should

prompt a full child protection investigation and ophthalmology assessment in suspected cases of abuse[36] (Fig. 70.4).

Retinal hemorrhages

Retinal hemorrhages are highly suggestive of abusive head trauma (AHT), although they may be absent in confirmed cases of abusive injury. There is no pathognomic type (flame shaped, dome shaped, dot, blot, white centered), size, distribution, or location of retinal hemorrhages seen exclusively in abusive head injury[37] (Fig. 70.5A,B). Bilateral hemorrhages are reported in 74% of cases with a sensitivity of 75% and specificity of 94% for abusive head trauma.[38]

Retinal hemorrhages in the presence of head injury have a 71% positive predictive rate of abusive injury[39] (Fig. 70.6A–C).

Table 70.2 Ranking of abusive injury

Ranking	Criteria used to define abuse[33]
1	Abuse confirmed at case conference *or* civil *or* criminal court proceedings *or* admitted by perpetrator *or* independently witnessed
2	Abuse confirmed by stated criteria including multidisciplinary assessment (social services/law enforcement/medical)
3	Abuse defined by stated criteria
4	Abuse stated but no supporting detail given
5	Suspected abuse

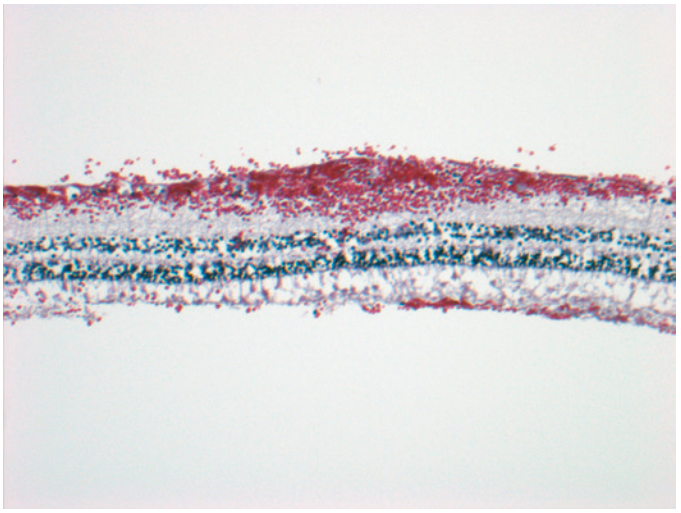

Fig. 70.8 Histology of the retina showing bleeding in multiple layers. *(Courtesy of Dr R. Bonsek.)*

The prevalence of retinal hemorrhages in abusive head injury varies between 77% and 83%.[27] Preretinal hemorrhages, dome-shaped hemorrhages situated in the posterior pole, are seen commonly in abusive head injury[37] (Fig. 70.7). Retinal hemorrhages in AHT may range from a few scattered hemorrhages to widespread hemorrhages extending from the posterior pole to the periphery and situated in multiple layers of the retina[40] (Fig. 70.8). Extensive retinal hemorrhages correlate with severe intracranial injury and poor visual outcome.[41] A recent systematic review reported that in the presence of head injury, retinal hemorrhages have a 91% probability of abusive etiology (odds ratio 14.7).[20]

Retinal folds

Perimacular folds are an important sign, seen in 6–8% of live cases (Fig. 70.9) and 23% of postmortem cases of inflicted injury[27,38,42] (Fig. 70.10). There have been isolated case reports of these in Terson syndrome in a child,[43] adult patients,[44] and accidental head injury in children.[45–48]

Retinoschisis

Cystic intraretinal cavities (Fig. 70.11A,B) in the macular area are recognized by vessels coursing over the surface or an electronegative ERG. Schisis cavities are seen in 14% to 23%

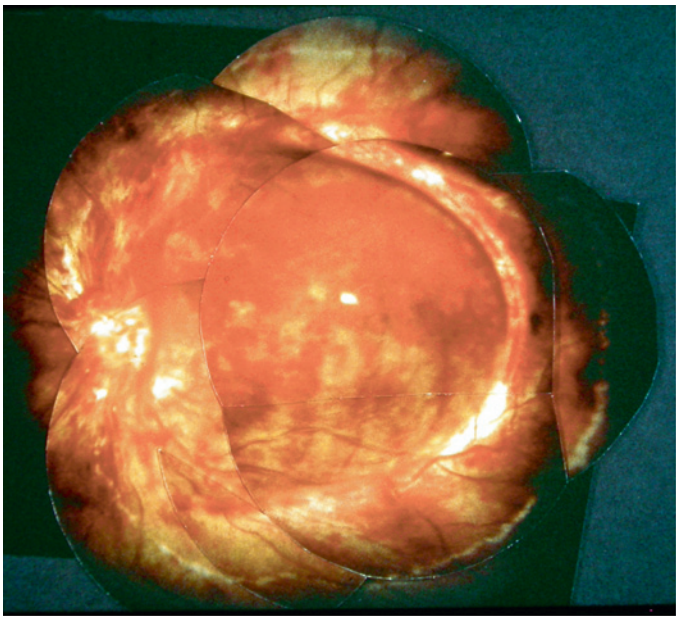

Fig. 70.9 Photomontage of a child with abusive head trauma showing a perimacular retinal fold with extensive retinal hemorrhages.

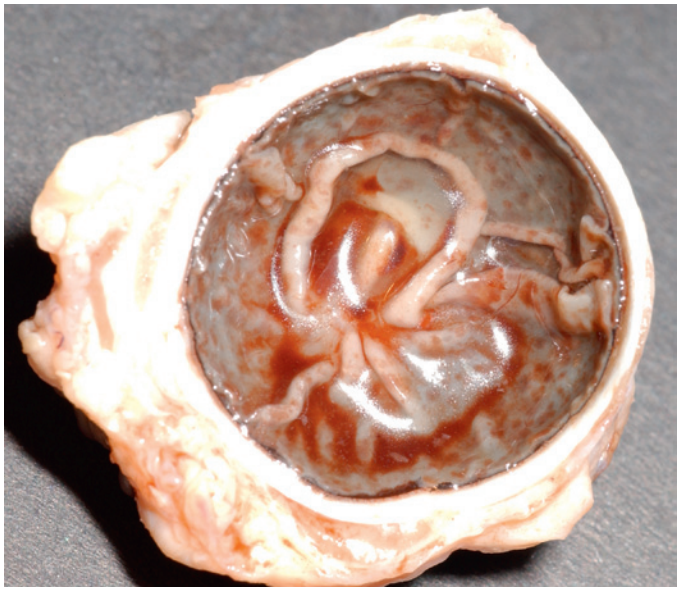

Fig. 70.10 Postmortem specimen showing numerous retinal hemorrhages and postmortem retinal folds.

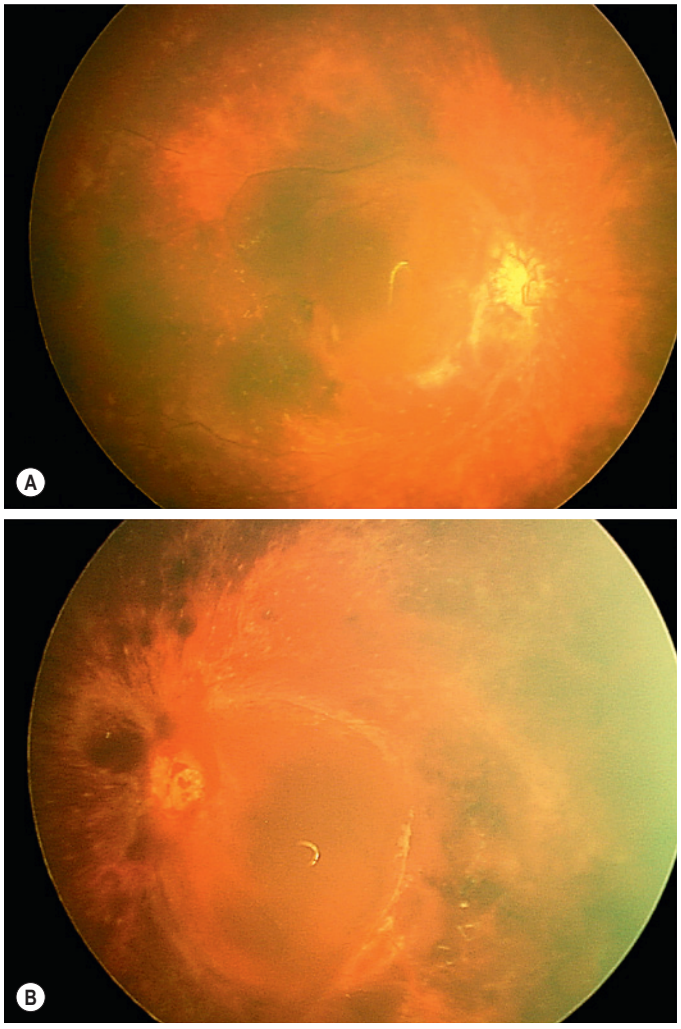

Fig. 70.11 Schisis cavities in the posterior pole in the right (A) and left (B) eye with extensive retinal hemorrhages.

of case studies involving live and postmortem findings. It has been previously stated that traumatic hemorrhagic macular schisis in not seen in any condition other than abusive head injury,[49] but recent case reports suggest similar cavities occur with severe trauma or crush injury.[47,48]

Vitreous hemorrhage

Hemorrhage in the vitreous cavity occurs in 14% of abusive head trauma cases and is seen more frequently in autopsy specimens.[27] It is believed to occur with breakthrough of the dome-shaped preretinal hemorrhages into the vitreous cavity (Fig. 70.12). Vitreous hemorrhages carry a poor prognosis for visual recovery, as they are frequently associated with cerebral visual impairment. Surgery to remove a non-clearing vitreous hemorrhage may be associated with minimal visual improvement.[50]

Optic disc edema

This is rare in clinical reports of children who have been abused, as the severity of the retinal hemorrhages frequently prevents a clear evaluation of the disc.[51] Optic disc swelling is seen histopathologically in many cases in postmortem studies.[52,53] Delayed papilledema in abusive head injury has been reported in a case that developed systemic hypertension and another case that developed communicating hydrocephalus weeks after the initial presentation.[54,55]

Orbital and optic nerve sheath hemorrhage

Hemorrhages have been demonstrated in the optic nerve sheath (Fig. 70.13), the orbital fat, the extraocular muscles, and motor nerve sheaths (Fig. 70.14). These findings have not been seen with non-abusive head trauma.[52,56]

Cranial nerve palsies

The development of acute third, fourth, and sixth cranial nerve palsies as a result of intracranial injury has been reported in abusive head injury.[27,57]

Ophthalmology outcome on follow-up of abusive head injury

1. Visual acuity: The prognosis for visual acuity at follow-up is poor for those with severe hemorrhagic retinopathy,

Fig. 70.13 Cross-section of optic nerve behind the globe showing intra-sheath hemorrhage.

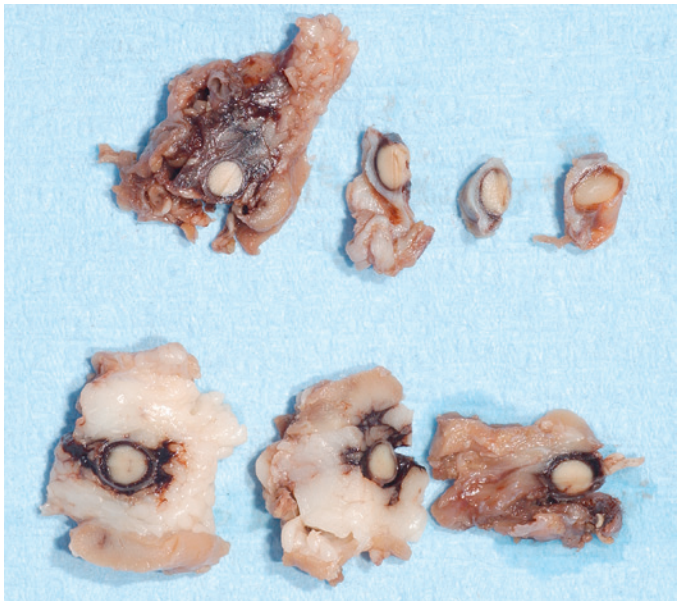

Fig. 70.14 Cross-section of the orbit from behind the globe showing optic nerve, orbital fat, and extraocular muscle hemorrhage.

vitreous hemorrhage, or poor pupillary responses. Fifty percent of children followed up have severe visual impairment due to retinal scarring, optic atrophy, or cerebral visual impairment.[27]

2. Ocular motility: This may be impaired due to: nystagmus, nerve palsies, or secondary strabismus due to visual loss.
3. Retina and optic nerve: Macular holes, epiretinal membranes, giant retinal tears, retinal detachment, optic atrophy, neovascularization of the disc, retinal scarring, and choroidal atrophy have been observed after the retinal hemorrhages have cleared[58–61] (Fig. 70.15).

Differential diagnosis of retinal hemorrhages

The ophthalmologist should be aware of the causes of retinal hemorrhages that may or may not have overlapping features

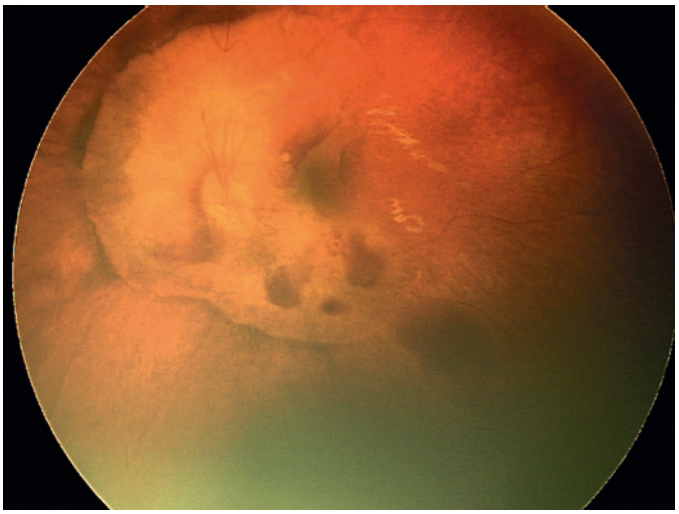

Fig. 70.15 Retinal folds and scarring with residual vitreous and retinal hemorrhage seen 3 months after absorption of extensive retinal and vitreous hemorrhage.

Fig. 70.16 Retinal hemorrhages. Seen with white centered hemorrhages in a full-term child born vaginally with the aid of vacuum extraction.

of abusive injury. In order to safeguard the child and prevent the wrongful conviction of innocent guardians of the child, it is vital to consider all relevant etiologies and eliminate them clinically or through the child protection team. This includes both clinical entities and disease states; confounding conditions seen at the time of evaluation of a sick child are frequently used by the defense team to explain the retinal findings.

Clinical entities or disease states

1. Birth-related hemorrhages:

A systematic review of retinal hemorrhages in the newborn reported retinal hemorrhages in 25% of spontaneous vaginal deliveries, 42% of vacuum-assisted deliveries, 52% of combined forceps and vacuum deliveries, and in 7.7% of cesarean sections.[62] The majority of retinal hemorrhages resolve within 10 days of birth leaving no sequelae[62–64] (Fig. 70.16). Macular retinal hemorrhages may persist for 4–5 weeks. Exceptionally, intraretinal hemorrhages can remain evident for 58 days.[64]

2. Accidental trauma:

This mechanism of injury includes motor vehicle accident, falls, and crush injuries. While no pattern of retinal hemorrhage consistently suggests accidental injury, the hemorrhages tend to be unilateral, few in number, and limited to the posterior pole.[65–71] Retinal hemorrhages are reported in 5% of accidental injuries which were mostly falls from heights less than 4 feet.[20] Associated findings of retinal folds and retinoschisis are rare in accidental injury. Retinal folds have only been reported in this context in single case reports of crush injury and a fall.[45–48]

3. Metabolic disorders[72–76]:
   - a. Galactosemia
   - b. Glutaric aciduria
   - c. Methylmalonic aciduria
4. Bony disorders[77,78]:
   - a. Osteogenesis imperfecta
   - b. Osteoporosis-pseudoglioma syndrome
5. Bleeding disorders:
   - a. Leukemia
   - b. Anemia
   - c. Thrombocytopenia
   - d. Protein C deficiency
   - e. Hemorrhagic disease of newborn
   - f. Platelet dysfunction in Hermansky–Pudlak syndrome
   - g. Low fibrinogen levels
6. Vascular disorders[43,55,79–81]:
   - a. Intracranial aneurysms with Terson syndrome
   - b. Fibromuscular dysplasia
   - c. Hypertension
   - d. Spinal cord arteriovenous malformations
7. Infections/infestations[82–84]:
   - a. Meningitis
   - b. Malaria
8. Carbon monoxide poisoning[85]
9. Asphyxia and strangulation[86,87].

Fifteen percent of critically ill children admitted to the intensive care unit have been reported to have retinal hemorrhages. However, the underlying causes were accidental injury, leukemia, and hemorrhagic disease of newborn, and not the fact that they were submitted to intensive care interventions.[88]

A recent systematic review reported a group of nine conditions that have overlapping features with abusive injury.[21] (Table 70.3).

Pre-existing eye disease

Retinal hemorrhages have been described in the vascularized retina of retinopathy of prematurity following cardiopulmonary resuscitation, and in a premature infant following a screening examination with a contact retina camera.[89,90] Hence, due consideration to pre-existing retinal disease should be given when evaluating infants with retinal hemorrhages.

Confounding conditions (Table 70.4)

Children who have sustained abusive head trauma frequently present either collapsed with apnea and requiring

Table 70.4 Retinal hemorrhages in confounding conditions of seizures and cardiopulmonary resuscitation (CPR)

	Retinal hemorrhage description			
Confounder	**Severity**	**Location**	**Layer**	**Laterality**
Seizures	Multiple	Posterior pole	Intraretinal Superficial flame shaped	Unilateral or bilateral
CPR	Multiple	–	Intraretinal small dot	Bilateral

Table 70.3 Retinal hemorrhages in conditions with clinical overlap for child abuse[21]

		Retinal hemorrhage description			
Condition	**Features of abuse**	**Severity**	**Location**	**Layer**	**Laterality**
Glutaric aciduria	ICH	Multiple	Posterior pole	Intraretinal (with unilateral vitreous right)	Bilateral and unilateral
Methylmalonic aciduria with homocysteinuria (cobalamin C deficiency)	ICH	Scattered	Posterior pole and post-equatorial	Intraretinal and vitreous hemorrhage	Bilateral
Osteogenesis imperfecta	ICH, bruise, fracture	Multiple	Posterior pole	Preretinal, intraretinal, vitreous hemorrhage	Bilateral and unilateral
Platelet function defect (Hermansky–Pudlak syndrome)	ICH	Few	Posterior pole	Subretinal, intraretinal and subhyaloid	Bilateral
Protein C deficiency	ICH, bruise	Florid and minor	N/A	Subretinal with vitreous hemorrhage	Bilateral and unilateral
Low fibrinogen levels	ICH, bruise	N/A	N/A	Intraretinal, subretinal	Bilateral
Hemorrhagic disease of the newborn	ICH, bruise	Multiple	N/A	Intraretinal, vitreous hemorrhage	Bilateral
Fibromuscular dysplasia	ICH	Extensive	Widespread	Intraretinal and subhyaloid	Bilateral
Spinal cord arteriovenous malformation	ICH	N/A	N/A	Intraretinal and preretinal	Bilateral

ICH, Intracranial hemorrhage; N/A, not available.

cardiopulmonary resuscitation, or with an encephalopathy or seizures. In addition, they may have acute coagulation abnormalities that resolve over a period of a few days. These following confounding events or conditions are often proposed in court as explanations for retinal hemorrhages, introducing uncertainty in the diagnosis of abusive head injury.[21]

Apparent life-threatening event (ALTE)

An ALTE is defined as a combination of apnea, color change, marked change in muscle tone, and choking or gagging, which is frightening to the observer. Children with abusive head trauma may present with ALTE; however, retinal hemorrhages have not been reported in ALTE in the absence of abusive injury.[91]

Prolonged coughing

Studies of prolonged coughing have not reported retinal hemorrhages.[92–94]

Seizures

Retinal hemorrhages are rarely reported with seizures. A number of studies revealed 2 of 218 cases with retinal hemorrhages, one case with tonic–clonic seizures for 5 minutes had unilateral hemorrhages around the disc, and the second case with hyponatremia had multiple bilateral hemorrhages at the posterior pole.[95–98]

Cardiopulmonary resuscitation (CPR)

A well-conducted prospective study of 43 pediatric cases (33 infants) who had received CPR found retinal hemorrhages were present in a 1-month-old infant who had received 60 minutes of open heart massage with co-existing coagulation defects. The hemorrhages were bilateral small multiple dot retinal hemorrhages.[99] Three other cases – a 6-week-old infant after 75 minutes of CPR had bilateral retinal hemorrhage; a 2-year-old after 40 minutes of CPR had a large unilateral hemorrhage next to the optic disc; and an 18-month-old infant with coagulation abnormalities and arterial hypertension – had a retinal hemorrhage. Hence, isolated prolonged CPR is rarely associated with retinal hemorrhages.

Use of extracorporeal membrane oxygenation (ECMO)

Retinal hemorrhages are rare in infants receiving ECMO. One study found a prevalence of 5%[100]; however, many of these children were premature and birth-related hemorrhages cannot be ruled out.[101,102]

Coagulopathy of abusive head trauma

Head injury is associated with acute coagulation abnormalities with prolonged prothrombin time, decreased platelets, and fibrinogen levels. These abnormalities are accentuated in children with parenchymal brain injury, where 54% have a prolonged prothrombin time. Of children who die with abusive head trauma with parenchymal brain injury, 94% display prolonged prothrombin time.[103] These abnormalities in coagulation seen in abusive head injury are not due to a preexisting hemorrhagic diathesis. The abnormalities are temporary, and do not explain retinal hemorrhages, which are also seen in children without coagulation abnormalities.[8]

Dating of retinal hemorrhages

Current evidence indicates that it is not possible to accurately date bruises in children.[104] Similarly, it is not possible from examination of the retina to estimate the duration of the retinal hemorrhages. There is some indirect evidence from birth-related retinal hemorrhages that most superficial retinal hemorrhages resolve in 10 days but that large macular hemorrhages may take up to 58 days to disappear.[62] In children with abusive head trauma, retinal hemorrhages took between 1 and 11 months to disappear.[105]

Systemic features of abusive head injury

Neurological

Brain injury may manifest acutely with symptoms and signs ranging from general malaise with drowsiness and lethargy to critically ill infants with impaired consciousness and death.[8] Head injury includes the presence of extra-axial blood (subdural, subarachnoid), intraparenchymal hemorrhage, diffuse axonal injury, hypoxic–ischemic injury, or any combination of the above (Fig. 70.17A–D). Although seizures and skull fractures are seen in abusive head injury, they are not discriminatory for abuse.[39] Neurological sequelae of parenchymal brain injury manifest later as cognitive and behavioral disturbances, cerebral palsy, seizures, and blindness, with a severe disability reported in 61% of children. Neuroradiological features suggestive of an abusive injury are: multiple complex wide fractures (diastatic), multiple-site subdural hematomas, inter-hemispheric blood, and loss of gray–white matter differentiation. The finding of blood around the spinal cord on magnetic resonance imaging (MRI) and postmortem (Fig. 70.18) in abusive trauma suggests that scanning of the spine should be included in the radiological investigations.

Fractures

Abusive injury should be suspected in children less than 3 years of age with multiple fractures. Abusive fractures involving the femur are more likely to be seen in non-ambulant children and fractures of the humerus involve the mid-shaft rather than the supracondylar region. Fractures that have the highest probability of abuse are posterior rib fractures.[106] Rib fractures are rare with cardiopulmonary resuscitation in children and are usually located anteriorly at the costochondral junction.[107]

Bites

A human bite is one of the only signs with which there is a possibility of identifying the perpetrator, both from the imprint of dental characteristics and the salivary DNA.[108] The hallmark of a human bite is the compression of tissue in two opposing concave arcs. The arcs are measured by the inter-canine distance, at about 3–4.5 cm in an adult and 2.5–3.0 cm in a child. An inter-canine distance of less than 2.5 cm suggests a child's deciduous teeth. Animal bites usually tear flesh, whereas human bites compress the flesh leaving an imprint.

(B) Bilateral subdural hemorrhage on magnetic resonance imaging (MRI) T2 scan (white arrows). (C) Subdural (black arrow) interhemispheric bleeding with scalp hematoma (white arrow). (D) MRI scan showing blood around the spinal cord. *(Courtesy of Dr A. Liu.)*

Burns and scalds

Burns and scalds are less common than other forms of physical abuse. Intentional scalds (immersion into hot water) are seen more frequently in abusive injuries. When intentional, they follow certain patterns of symmetry: on the extremities they have a clear upper margin and may have a glove- or stocking-like pattern; if involving the buttock, sparing of the perineal fold is seen.[33]

Unintentional cigarette burns are usually superficial, as contact with the lighted end, for example a child walking into a cigarette, initiates a prompt withdrawal response. Superficial burns should be observed over a period of 3 weeks, as they heal without a scar. Deep burns require a contact time of more than 2 seconds; they heal with a scar and are more likely to be intentional (Fig. 70.19).

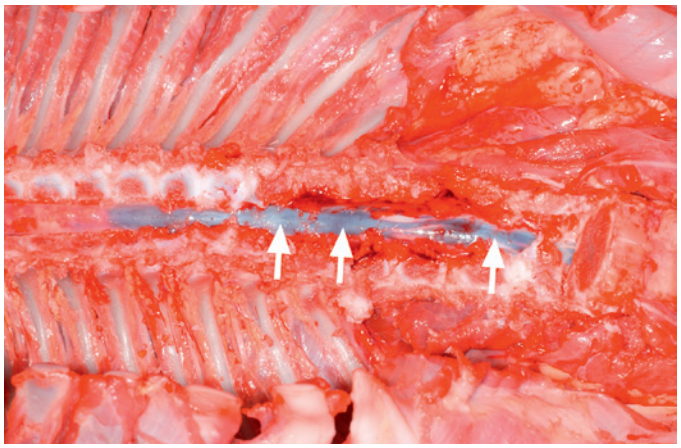

Fig. 70.18 Postmortem dissection of the spine of a child subjected to abusive head trauma. White arrows indicate subdural blood.

Fig. 70.19 Abusive cigarette burns on the left side of forehead.

Fig. 70.20 An abusive bruise on left cheek demonstrating the imprint of fingers.

Bruises

Bruising is the commonest presenting sign in abusive injury. Certain patterns of bruising help to distinguish abusive from accidental bruises: bruising in non-independently mobile infants; bruising away from bony prominences (e.g. face); large, multiple, occurring in clusters and bearing the imprint of an implement are highly suggestive of abusive injury[11] (Fig. 70.20).

Biomechanics of retinal hemorrhages

Theoretical considerations include:

1. vitreoretinal traction;
2. impaired retinal venous return from acute raised intracranial pressure;
3. hypoxic ischemia of retina.

Although controversies still exist as to whether a shaking injury alone or one with impact exceeds the threshold of force required to produce head injury, retinal hemorrhages are seen in both impact and non-impact head injuries.[109,110] Experiments with primates demonstrate that angular and rotational accelerations of the head rather than linear acceleration cause brain injury.[111,112] Until recently, the evidence for retinal injury was extrapolated from mechanisms underlying brain injury, which have been excellently reviewed in previous publications.[29,113] Current research does not provide conclusive evidence for the underlying mechanism of retinal hemorrhages in abusive injury.

Retinal hemorrhages are rare in neurologically normal children. Although they have been reported in children whose initial computerized tomography (CT) scans were normal, these children were not neurologically normal and were subsequently found to have abnormal MRI.[114,115] A single case report reported retinal hemorrhages with normal CT and MRI imaging; however, the patient had a gaze palsy and hemiparesis.[116]

Acute elevation of intracranial pressures from ruptured aneurysms has been shown to cause retinal hemorrhages in two infants.[43,117]

Experimental and naturally occurring animal models have failed to replicate the findings seen in abusive head trauma in infants.[118–120] Computer modeling using finite element analysis demonstrate that the majority of forces during simulated shaking cycles is exerted on the posterior retina or the vitreoretinal interface, suggesting that traction of the vitreous on the retina causes retinal hemorrhages.[121,122] In addition, clinical and postmortem studies and the use of optical coherence tomography have demonstrated vitreous attached to schitic cavities and folds in the retina, extrapolating this to vitreoretinal traction causing retinal hemorrhages.[123,124] Postmortem studies have suggested that retinal ischemia may explain the retinal findings in abusive head injury.[125] Although hypoxic–ischemic brain injury demonstrated on diffusion-weighted MRI (DW-MRI) in children with head trauma is associated with severe retinal hemorrhages, retinal

hemorrhages are also seen without hypoxic ischemia on DW-MRI in abusive head injury.[126]

Prevention

1. Primary prevention: Educational programs have been developed to address a broad segment of society, which should includes parents and other child carers. These programs include coping strategies to deal with inconsolable crying, known as the period of purple crying.[127]
2. Secondary prevention: This involves targeted programs for populations at higher risk of abusive injury, which include parents or carers from lower socioeconomic classes, young parents, or those with previous social services contact.
3. Tertiary prevention: this relates to programs directed at perpetrators to prevent recidivism.

The programs developed are educational and have been shown to reduce the prevalence of abuse in defined populations.[128]

Munchausen syndrome by proxy

This is an illness fabricated by the caregiver of the child for personal gain or attention. The perpetrator, who is frequently the mother, simulates or induces an illness in a child who is not capable or unwilling to identify the offender. The offender may fabricate the history; cause physical signs by exposing the child repeatedly to infectious agents, toxins, or physical trauma; or alter laboratory tests by tampering with the child's specimens. The following should alert the clinician to this possibility:

1. Over-attentive caregiver or caregiver does not seem to be as worried about the child as medical staff.
2. Investigations that do not tally with clinical signs.
3. Clinical signs that do not respond to treatment.
4. The child's condition improves when isolated from the caregiver and recurs in his/her presence.

Ophthalmic manifestations are rare, although case reports of recurrent conjunctivitis,[129] unilateral orbital cellulitis, and keratoconjunctivitis[129,130] induced by toxins have highlighted the difficulties in diagnosis (Fig. 70.21).

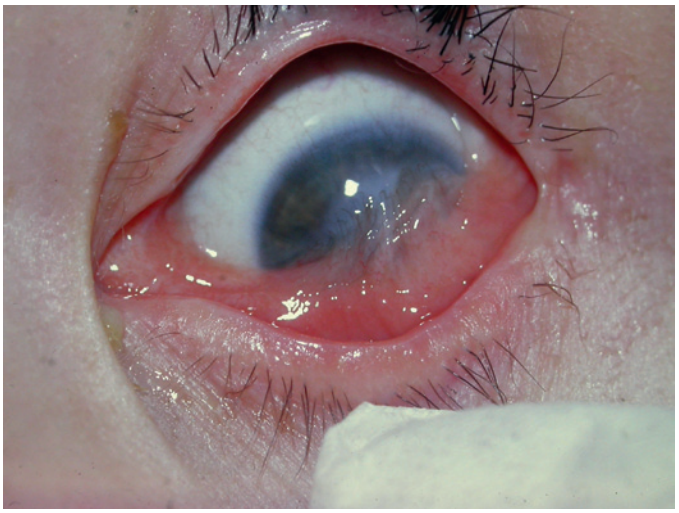

Fig. 70.21 Munchausen syndrome by proxy. Keratoconjunctivtis with vascularization and pseudopterygium of the inferior cornea seen in a child from repeated toxin instillation by her caregiver.

The ophthalmologist and child maltreatment

In summary:

- When confronted with suspected cases of child abuse or neglect, the ophthalmologist's overriding duty is to safeguard the child.
- An ophthalmologist should not intervene individually; all cases suspected of abuse should be discussed with a designated or named child protection physician/nurse.
- Knowledge of local child protection protocols and procedures is essential.
- The ophthalmic evaluation should never be considered in isolation but in conjunction with the findings of other specialties, fostering a close working relationship with multidisciplinary teams and child maltreatment experts.
- Meticulous documentation of evaluation, supplemented where possible with photography, in date and time order is paramount.
- Remember: there are no pathognomonic ocular signs of child abuse.
- As an expert witness, it is important to be well versed with all the documentation provided and with current literature. Do not be drawn by the counsel into giving opinions outside your area of expertise. Evidence is presented for the court and not to a particular side.

Introduction

Excimer laser refractive surgery for high refractive error associated with amblyopia has been performed for almost two decades in children, with good visual acuity and refractive results and minimal complications.[1–26] Intraocular refractive procedures have been performed in smaller numbers in children for higher refractive errors for about a decade, also with good visual and refractive outcomes and few complications. Most recently, excimer laser refractive surgery has been performed for accommodative esotropia with reasonable results.

Conventional amblyopia therapy consists of the following:

1. clearing the ocular media of visual obstructions such as leukoma, cataract, or vitreous hemorrhage.
2. correcting significant refractive errors either with spectacles or contact lenses.
3. encouraging use of the amblyopic eye through occlusion or pharmacologic and/or optical penalization of the fellow eye (see Chapter 73).[27–29] This conventional therapy is successful in the majority of children with amblyopia.

There are, however, several subsets of children with amblyopia that often fail this standard therapy. These groups are:

1. children with severe isoametropia (bilateral high ametropia) who are spectacle non-compliant or intolerant;
2. children with severe anisometropia who are non-compliant or intolerant of spectacle and contact lens wear;
3. children with high ametropia, either anisometropia or isoametropia, who have other special circumstances such as craniofacial anomalies, ear deformities, or neck hypotonia that preclude the proper use of refractive correction.

There are many reasons for poor compliance with spectacles or contact lenses. Spectacles for the treatment of extreme myopia or hyperopia can cause prismatically induced optical aberrations, a narrow visual field, and social ostracism due to unattractive thick lenses. Group 1, above, consists primarily of children with neurobehavioral abnormalities and cognitive disability. They have severe tactile aversion and thus refuse to wear glasses or contact lenses in spite of being functionally blind without the refractive correction. Their visual impairment may impede their attention and social interaction, exacerbating significant behavioral and social problems, and further interfere with the development of normal communication skills. This group is mostly comprised of former premature infants with severe retinopathy of prematurity and high myopia, children with genetic mutations, or with autism spectrum disorder. In group 2, spectacle-induced aniseikonia and anisovergence impede stereopsis and binocular vision, and may cause asthenopia.[30]

Contact lenses, more than spectacles, improve the quality of vision, reduce the minification effect of high myopic spectacles, give better contrast sensitivity, and reduce social discomfort. Contact lenses, however, in children are often impractical due to difficulty with insertion, cost, intolerance, non-compliance, and frequent loss.

In the past, no other treatment options existed. The result was variable levels of visual impairment in the affected eye(s) depending on the severity of the refractive error. If the condition was bilateral, severe blur-induced amblyopia was the result. Refractive surgery, just as in adults, reduces refractive error in these children and thus reduces or eliminates these other related issues. Additionally, it greatly improves their quality of life.

A new mindset is needed when we think about the management of severe refractive error in children. Untreated high refractive error in young children can result in severe levels of blur-induced amblyopia akin to that found with a dense congenital cataract or leukoma. We should approach this form of amblyopia as aggressively as we would treatable

causes of form vision deprivation such as cataract. Surgery is effective in treating high refractive errors when standard therapy fails, with few complications.

Lastly, refractive surgery may prove to be a viable alternative in older children with accommodative esotropia if longer-term follow-up in children who have undergone refractive surgery for this indication demonstrates stability of ocular alignment. Some recent studies have shown refractive surgery to be effective though the sample sizes in the studies were small.[31–33]

Types of refractive surgery used in children

Corneal and intraocular procedures can reduce refractive error. Today corneal procedures are performed with the excimer laser and include photorefractive keratectomy (PRK), laser-assisted subepithelial keratectomy (LASEK) (these two procedures together will henceforth be referred to as advanced surface ablation [ASA]), and laser-assisted *in situ* keratomileusis (LASIK). ASA can be used to treat up to 10–12 diopters of myopia, 6 diopters of hyperopia, and 4 diopters of astigmatism. These numbers are typically reduced by about one-third for treatment using LASIK.

PRK and LASEK are surface ablations, with minor differences between them, that permanently change the shape of the cornea by ablating (via vaporization) tissue from the anterior corneal stroma, just under the corneal epithelium.

1. In PRK, the corneal epithelium is removed and Bowman's membrane and anterior corneal stroma are ablated with laser.
2. In LASEK, the epithelium is not removed, but an alcoholic solution is used to loosen the epithelial cells; the surgeon folds the epithelial layer out of the treatment field, performs the laser ablation on Bowman's membrane and anterior corneal stroma, and then replaces the epithelial layer.

In LASIK, a partial-thickness corneal flap, composed of epithelium, Bowman's membrane, and anterior stroma is created using either a mechanical microkeratome or a femtosecond laser microkeratome. A hinge is left at one end of this flap. The flap is folded back and the laser ablation is performed on the deeper corneal stroma. The LASIK flap is then positioned back in place over the treated corneal stroma. The flap is held in position after the procedure by natural adhesion. Current intraocular refractive procedures change the existing lens power and include phakic intraocular lenses (phIOLs), refractive lens exchange (RLE), and clear lens extraction (CLE). These procedures are used to treat higher refractive errors that fall outside the treatment parameters for the excimer laser, or in cases where the cornea is too thin for the excimer laser. Phakic IOL procedures can add or reduce lens power.[34] In these procedures, an intraocular lens (IOL) is placed into the anterior or posterior chamber, thus preserving the natural crystalline lens. Anterior or posterior chamber phIOLs can be used to treat extremely high myopia if the anterior chamber is deep enough to tolerate the lens (≥3.2 mm). It is rare that a highly hyperopic eye has a deep enough anterior chamber depth to be able to have a phakic IOL procedure. One significant advantage of phIOL over the other intraocular refractive procedures is the preservation of accommodation.

The other procedures that change lens power are refractive lens extraction (RLE) and clear lens extraction (CLE). They are technically identical to pediatric cataract surgery except the crystalline lens being removed is clear. In RLE, an appropriately powered IOL is placed in the eye after removing the crystalline lens; in CLE, the eye is left aphakic. Currently, both corneal and intraocular refractive procedures are utilized "off-label" in children and are not approved by the Federal Drug Administration (FDA) in the United States.

Safety of ASA versus LASIK

Box 71.1 outlines the risks of ASA and LASIK. While LASIK has been shown to be effective in children to correct refractive error, ASA has several advantages. First, no corneal flap is created, so there is no risk of flap loss, epithelial in-growth, or flap striae as with LASIK. In LASIK, the flap is held in position by natural suction; however, the flap never heals back to the posterior stroma completely and can be lifted years later. Second, since ASA is performed on the surface of the cornea, the remaining posterior stroma is thicker, with less risk of late keratectasia. Because most children who fail standard amblyopia therapy and are treated with excimer laser procedures require large excimer treatment doses, the depth of the corneal ablation is greater than in most adults. Keratectasia following ASA in adults in extremely rare and has never been reported in children. The main long-term risk of ASA is corneal haze, but, in the author's experience, it is uncommon and usually mild when it occurs. It is typically persistent when the topical steroid (fluorometholone or loteprednol) is discontinued too soon. Topical steroid must be used for 6 months following PRK to minimize the risk of this serious complication. Corneal haze can be further reduced by limiting ablation treatments to within the FDA-approved (in the USA) parameters and by the child ingesting vitamin C 250–500 mg daily for a year after the procedure Recently, the use of topical mitomycin has been reported to reduce the risk of corneal haze and regression in children.[35] The last issue with excimer laser procedures is refractive regression. Most of the regression following excimer refractive procedures occurs in the first year, but it can continue longer; it is more significant with higher excimer treatment doses.

Phakic intraocular lens safety

Phakic IOL implantation is not subject to refractive regression and may be the preferred surgical correction of pediatric

Box 71.1

Risks of ASA versus LASIK

ASA	*LASIK*
Dry eyes	Dry eyes
Mild to moderate discomfort for 3–4 days	Flap dislocation
Corneal haze	Flap loss
Long healing time	Epithelial ingrowth
	Keratectasia
	Posterior vitreous detachment
	Retinal detachment

ASA, Advanced surface ablation; LASIK, laser-assisted *in situ* keratomileusis.

myopia and hyperopia beyond the range of ASA.[36] Other major advantages are reversibility and the possibility for IOL exchange if needed with eye growth. The anterior chamber depth required for an "iris-enclaved" IOL precludes the use of this lens in some children. Children with high hyperopia, and those who have high lenticular myopia after retinopathy of prematurity may be unsuitable because of shallow chambers.[37] The major concern with a phIOL in a child is the long-term effect on the corneal endothelium. Experience indicates that thus far endothelial cell loss has been low[36,38,39] and no greater than after adult implantation; however, accurate endothelial cell counts are difficult to obtain in the children.[36] Any refractive surgical procedure, including ASA, LASIK, and RLE/CLE, will cause some reduction of endothelial cell density. We just need to know what the loss is in comparison to that in adults. Posterior chamber phIOLs have also been implanted in children[40–42]: Because they lie adjacent to the iris pigment and lens, the risks of pigment dispersion, secondary glaucoma, and cataract formation are the concern. These potential risks are important, but they must be weighed against the certainty of permanent blur-induced visual impairment if the child continues uncorrected. These potential complications, if they occur, will occur many years in the future, and there are effective treatments for them if they do.

Refractive lens exchange and clear lens extraction safety

RLE and CLE are useful in children who have severe refractive error that is beyond the range of effective ASA or who have anterior chambers that are too shallow for phIOLs.[43,44] An important disadvantage of removing the natural lens is that it abolishes accommodation. This can be rectified by implantation of a multifocal IOL, but multifocal IOLs have their own risks and complications. The major long-term risk of RLE/CLE are the same as for cataract extraction and include glaucoma, endophthalmitis, corneal decompensation, and retinal detachment (estimated prevalence of approximately 3%). If the axial length exceeds approximately 29 mm, prophylactic diode laser therapy may be considered, to reduce the risk of retinal detachment.[45,46] All of these risks must, again, be weighed against the certainty of severe blur-induced amblyopia in the affected eye(s) if the child is left uncorrected.

Strategy for pediatric refractive surgery

If standard therapy fails, children with hyperopic isoametropia or anisometropia of 3–6 diopters, or myopic isoametropia or anisometropia of 3–10 diopters, can be treated with ASA. Children with refractive errors beyond these ranges can be treated with a phIOL if the anterior chamber depth is ≥3.2 mm or with RLE/CLE if the anterior chamber depth is shallower than this. These procedures require general anesthesia in children.

Improvements in visual acuity and visual function

Is refractive surgery effective in children? Yes, with qualification. One must remember that the measure of effectiveness in children non-compliant with spectacles is uncorrected visual acuity (UCVA). Substantial gains in UCVA and best corrected visual acuity (BCVA) have been demonstrated using ASA, LASIK, phIOLs, or RLE/CLE in children. Impressive visual gains have been achieved in isoametropic children for both high hyperopia and high myopia[3–6,21,22,36,44,47] (Tables 71.1 and 71.2). More modest, but consistent, gains have been achieved in the amblyopic eyes of anisometropic children using ASA, LASIK, phIOLs, and RLE/CLE.[2,6,8,9,15,18,22,23,48–52] (Tables 71.1 and 71.3). Most reports on pediatric refractive surgery have used ASA to treat anisometropic amblyopia.[1–3,5–7,9,14,15,17,18,22,23,26,53–55] These series show an initial refractive correction of ±1.5 diopters from emmetropia in approximately 90% of treated eyes. The qualification for all pediatric refractive visual acuity results is that tolerances are wider than in adult refractive surgery. Seldom does one achieve the precision commonplace in adult refractive surgery where the treatment doses are much smaller as a rule. The goal in children is the prevention of high levels of refractive amblyopia. The gains in UCVA and BCVA range from mild to excellent (2–7 lines improvement), with only rare reported losses of acuity. Roughly, 50% of the children treated have improved binocular fusion and stereopsis after refractive surgery.[2,9,15,18,23]

Beyond the gains in acuity or binocularity, refractive surgery has positive effects on children's day-to-day visual function.[36,47] Enhanced visual awareness, attentiveness, and social interactions have been reported in approximately 80% of children treated for high isoametropia. When measured using Likert scale visual function questionnaires, before and after refractive surgery, scores for eye contact, tracking, observing and reacting, judging depth and distance, and reading improved by an average 73% in isoametropic children and 58% in anisometropic children.[36,56,57] Recently, improvements in development have been reported in two studies where children with cognitive disabilities and severe isoametropia underwent PRK. Using a battery of well-known standardized developmental tests, the developmental quotient, calculated as the mental age divided by the biological age ×100, was shown to significantly improve in many areas of development at 6 and 12 months after PRK.[47] These results were shown to persist 3 years after PRK.

Controversies in pediatric refractive surgery

Controversies exist regarding pediatric refractive surgery, even among its advocates. The main issues are the ideal age at which to perform refractive surgery and what procedure is optimal. Most experts recommend the procedure be performed early in the visual neuroplastic years when the possibility of reversal or even prevention of amblyopia is greatest. The disadvantages of doing the procedure at an early age, however, are similar to those with placing an IOL in a child. The eye is still growing and determination of the proper treatment dose can be difficult, as the refractive error will change with eye growth. In the majority of studies thus far, the refractive error treated was greater than 9 diopters of myopia or 4 diopters of hyperopia, so the risk of overtreatment is low. Another potential disadvantage is difficulty with centration of the excimer treatment as young children generally require the treatment to be performed using general anesthesia. Experience, however, has shown that centration is not problematic.[4–6,8,10,11,13,14,16,18–20,22–25,34]

Summary

Refractive surgery in children with high refractive error and amblyopia, unresponsive to standard therapy, appears to be safe and effective after nearly two decades of follow-up. Interventional case series and case-control studies of excimer laser refractive surgery, phIOLs, and RLE or CLE in children have reported few complications and demonstrated improved visual acuity, refractive error, and developmental quotient, with significant improvements in social functioning, coping skills, and verbal and nonverbal communication. While the majority of children with refractive error, either unilateral or bilateral, do well with contact lenses or spectacles, for the small subset that do not, refractive surgery is a useful treatment and a reasonable option to prevent a lifetime of severe visual impairment. Randomized clinical trials should be conducted to further validate efficacy.

Introduction

Our two eyes view the world simultaneously from slightly different angles. The visual fields of the two eyes receive largely overlapping images on their two-dimensional retinal surfaces. The information contained in the separate and slightly dissimilar images arising in each eye is appreciated as a single image by the process of fusion, which blends sight from the two eyes to form a single percept. This process of normal binocular single vision depends on clear visual axes with reasonably good visual acuity in each eye, the ability of the visual cortical elements to appropriately combine the slightly dissimilar monocular inputs (*sensory fusion*), and the precise coordination of the two eyes for all directions of gazes, so that corresponding points on the two retinas are aligned (*motor fusion*). In addition to binocular single vision, our visual cortex has the ability to disambiguate the minute dissimilarities from the pair of two-dimensional retinal images and reconstruct the third dimension (*stereopsis*).

Normal development of binocular vision

Milestones in the normal maturation of binocular vision are achieved rapidly during infancy. By the time they are 2 months old, nearly all infants have orthotropic alignment, except for "very infrequent" misalignment.[1–3] While there is clear evidence that infants as young as 1 month are capable of motor fusion,[4,5] it is not until 2–4 months that consistent motor fusion responses are observed in nearly all infants.[5,6]

Sensory fusion has been assessed using a wide variety of test paradigms, from the clinical 4-prism diopter (PD) test to forced-choice preferential looking fusion-rivalry discrimination and visual evoked potentials to dynamic random dot correlograms. Overall, the results are consistent. Few normal infants demonstrate sensory fusion before they are 2 months old, whereas most 4-month-olds and older infants demonstrate sensory fusion (Fig. 72.1).[1,7–11]

Likewise, the onset of stereopsis has been investigated using a number of different paradigms, including forced-choice preferential looking with contour stereograms and random dot stereograms, and visual evoked potentials to dynamic random dot stereograms.[12] Again, despite the differences in stimuli and response measures used, there is general agreement across studies that the onset of stereopsis occurs at approximately 4 months (Fig. 72.2).[7,13,14] After the onset of stereopsis, the rate of stereoacuity maturation is rapid (Fig. 72.3)[13–15]; further slow improvement of stereoacuity continues for several years.[16–18]

Unlike visual acuity development, where preterm birth has been shown to have only a slight or no accelerating effect on the rate of maturation, binocular vision shows an intriguingly different pattern of results. For visual acuity, preterm infants typically achieve the same level of maturation as would be expected for their adjusted age, i.e. if the child was born 2 months preterm and is now 6 months old, we would expect to see visual acuity at the 4-month-old level. This finding suggests that, in an otherwise healthy infant, visual acuity is limited by a pre-programmed course of visual maturation that cannot be accelerated by precocious visual experience. On the other hand, recent research suggests that it is postnatal age that determines when binocular vision matures, with both preterm and term infants developing binocular vision around 4 months after birth (Fig. 72.4).[19] Thus, infants appear to acquire binocular vision as a result of visual experience, not solely due to pre-programmed visual maturation.

Testing binocular vision in infants and children

Measurement of fusion and stereoacuity in the clinic can provide important information about the status of the visual system that contributes to management decisions. Stereoacuity

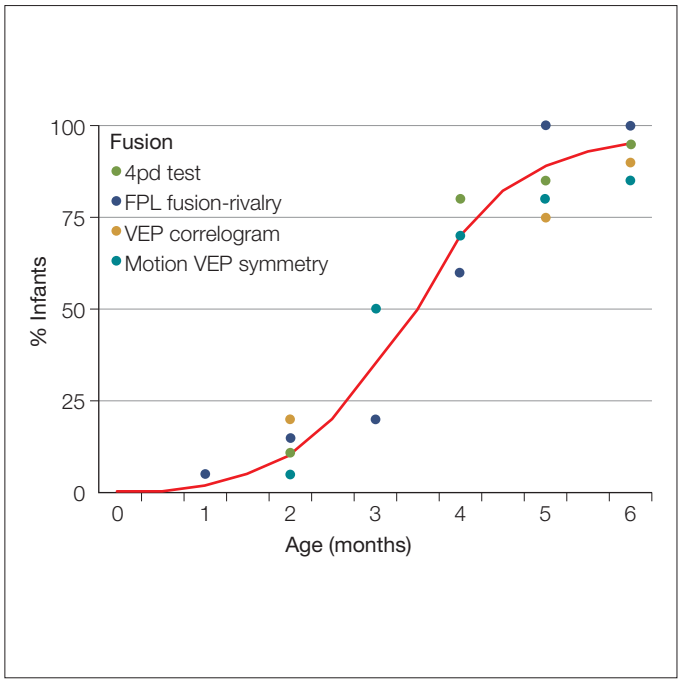

Fig. 72.1 Percentage of infants demonstrating fusion on clinical (4-PD base out) and laboratory-based tests, including forced-choice preferential looking (FPL) and visual evoked potentials (VEP).[1,7–11]

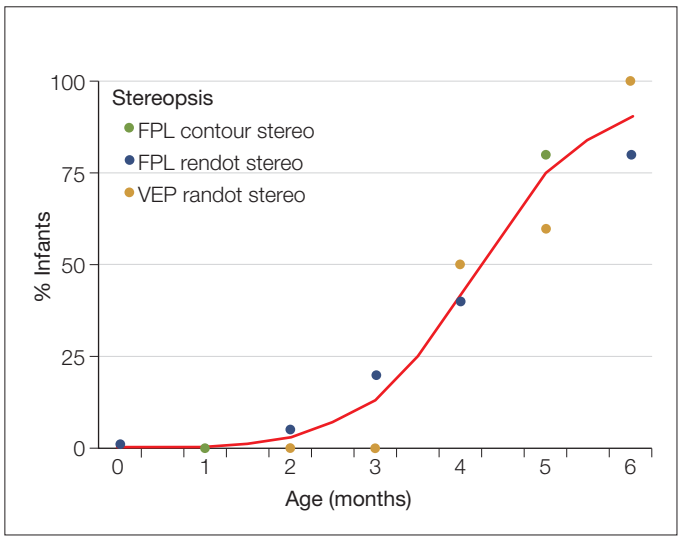

Fig. 72.2 Percentage of infants who demonstrate stereopsis when tested with forced-choice preferential looking (FPL) or visual evoked potentials (VEP) using contour or random dot stereograms with ≤3600 arcsecs disparity.[7,13,14]

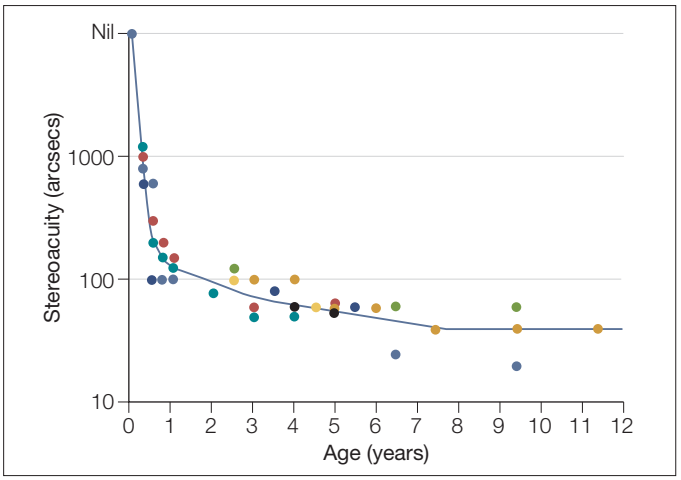

Fig. 72.3 Stereoacuity as a function of age for infants and children with normally developing vision.[13–15]

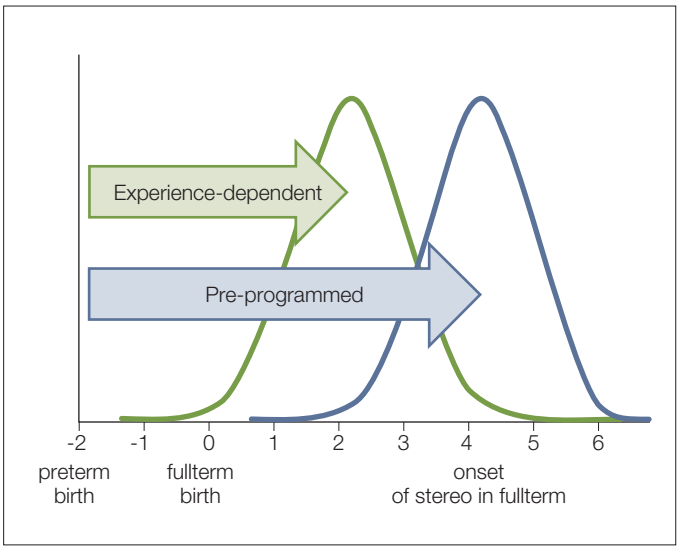

Fig. 72.4 Binocular vision is absent at birth and seems to switch on when a baby is about 4 months old. Jandó et al.[19] monitored the activity of the visual cortex region of the brains of babies who were born at term (9 months post-conception) and babies who were born 2 months prematurely to determine when they first displayed a binocularly evoked response. Binocular vision developed at 4 months after birth in both cohorts. This suggests that 4 months of postnatal visual experience is a key determinant of the onset of binocular vision (green curve). This is in contrast to the alternative scenario of a pre-programmed onset age that is guided by genetically encoded molecular and neuronal signals. In this case, additional visual experience should not alter the rate of maturation, and binocular onset would be expected to occur 6 months postnatally in the premature babies (blue curve).

depends on good vision in both eyes, accurate and stable alignment of the visual axes, and intact binocular cortical mechanisms. Abnormal binocular experience early in life associated with anisometropia or strabismus may result in maldevelopment of binocular vision, suppression, and reduced or no stereoacuity. Moreover, there is evidence to suggest that abnormal experience that is prolonged (>3 months duration) during the first years of life is likely to lead to permanent deficits in binocular visual function.[20–22]

The most widely used test of sensory fusion in the pediatric age range is the Worth 4-dot test. The child views four lights arranged in a diamond formation, with a red light at the top, two green lights at either side, and a white light at the bottom, while wearing anaglyphic glasses. If the child has normal binocular vision, they see all four lights, but if they suppress one eye, they will see only two or three lights. Diplopic children report five lights. There is also a version of this test that uses shapes rather than dots, called the Worth 4-shape test, designed for use with young children who have difficulty with color-naming and counting.[23] Before starting any assessment of sensory fusion, the angle of deviation should be neutralized with prisms. Note that, even with the use of prisms, absence

of sensory fusion may not reflect the potential outcome following surgical alignment. Use of a haploscopic device, such as the synoptophore, can correct for horizontal, vertical, and cyclorotational deviations simultaneously to direct stimuli onto each fovea and allow a truer assessment of the potential for sensory fusion.

Another limitation of the Worth 4-dot test is that the anaglyphic glasses could be dissociative. Because they are potentially an impediment to binocular vision, demonstrating fusion on the Worth 4-dot test can be interpreted as strong evidence that fusion is present but a test failure may be inconclusive. The Worth 4-dot test may also be used to estimate the size of a suppression scotoma by presenting the flashlight targets at different distances from the child. The size of the scotoma can be calculated in visual angle (degrees) using simple trigonometry (Table 72.1). The degree of fusion may also be classified as peripheral, macular, or foveal, based on the size of the scotoma (see Table 72.1). The 4-PD base out test is commonly used to detect small suppressions scotomas associated with monofixation syndrome or presence/absence of bifoveal fixation.

Motor fusion is the ability to maintain alignment of the eyes through a range of movements and consists of tonic (smooth movement when tracking an object) and phasic (quick changes in fixation from one object to another) components. The stimulus for motor fusion is peripheral retinal disparity outside Panum's area and the motor response is vergence. While the presence of motor and sensory fusion are linked, the amplitude of motor fusion is not related to the amount of sensory fusion.[24] Assessment in young children primarily consists of identifying the ability to maintain motor fusion in the presence of a 20- or 15-diopter base out prism (prism reflex test). While this does not quantify the fusional ability, it may identify a lack of motor fusion, or confirm the presence of binocular vision in a young child with suspected strabismus. In older children, quantification of motor fusion (prism fusion range) can be accomplished by measurement of a *break point*, at which vergence demand exceeds fusional reserve and a deviation becomes manifest, and a *recovery point*, where motor fusion can be recovered as vergence demand is lessened. In practice, the child is asked to observe a target at a fixed distance (typically ⅓ and 6 m) through a prism of increasing strength, while attempting to maintain a single image. The phasic range is assessed using a prism bar, with discrete intervals between prisms, and tonic is assessed using either a Risley rotary prism or the synoptophore, both of which allow a continuous increase in the prism strength. There is variation in the reported normative values, likely attributable to a precision of test distance, differences in target size, prism placement, and speed of prism change. Total fusion range (convergence and divergence combined) is normally about 25 diopters for phasic and 20 diopters for tonic measurements.[25]

Table 72.1 Estimating the extent of the suppression scotoma with the Worth-4 flashlight*

Viewing distance	Scotoma size (degrees)	Fusion quality
16 cm	12	Peripheral fusion
33 cm	6	
50 cm	4	
1 m	2	Macular fusion
1.5 m	1.3	
2 m	1.0	Foveal fusion
2.5 m	0.8	
3 m	0.7	

*On the face of the standard Worth 4-dot flashlight are spaced equidistant targets on a 35 mm diameter circle.

Two types of stereoacuity tests are widely available, contour tests and random-dot tests. Contour tests have the disadvantage of providing cues that enable some children with no stereoacuity to pass the initial 2–4 levels on the basis of monocular or nonstereoscopic binocular cues. Random-dot tests contain no monocular or non-stereoscopic binocular cues; depth can only be appreciated by global binocular evaluation of corresponding points and disparate points. Most stereoacuity tests are conducted at a near viewing distance, usually at 40 cm. Because stereoacuity is sensitive to blur, especially anisometropic blur, it is important to optically correct the child. It is always best to perform stereoacuity testing early in the examination, before the child's eyes are dissociated for other testing. For infants and preverbal children, preferential looking can be used with the Preschool Assessment of Stereopsis with a Smile (PASS) Stereotest. For children age 3 years and older, stereoacuity can be tested with the matching, pointing, or naming tasks available in the PASS, Randot Preschool, Toegepast Natuurwetenschappelijk Onderzoek (TNO), and Frisby Stereoacuity tests. Normative data for the infant and pediatric stereoacuity tests have been published (Table 72.2).[15–18] Despite the difficulties associated with interpretation of performance on the Titmus Fly, Titmus Animals, and the first 4 levels of the Titmus circles and Randot circles, results from these stereoacuity tests are commonly reported as outcome measures in pediatric ophthalmology. Passing the Titmus Fly test without stereopsis may be possible because the child knows it is a fly and expects the wings to be elevated, because the child has been repeatedly exposed to the same test with only two possible responses, or because the child alternates fixation and observes image jump in disparate portions of the test.

One limitation of currently available random dot stereoacuity tests for children is the maximum disparity available, e.g. 800 arcsecs for the Randot Preschool Stereoacuity Test and 440 arcsecs for the PASS. Thus, it is possible that some children who appear to have no stereoacuity are simply not within the measurable range of disparities available. A second factor that may limit performance on current random dot stereoacuity tests is dot size; most random dot tests require visual acuity of 0.4 LogMAR or better, in order to be able to appreciate the dot texture sufficiently to extract disparity information. In addition, the clinical tests consist of relatively small images that are static; there is some evidence to suggest that larger, dynamic stimuli provide additional information that may allow children who appear to have no stereoacuity on standardized tests to appreciate depth.[26,27]

There are also distance stereoacuity tests available, including the FD2, which has moveable real depth targets, and the Distance Randot; normative data are available for both of these tests (see Table 72.2).[28,29] Children and adults with normal

binocular vision generally have poorer stereoacuity at distance than at near. In addition, many electronic visual acuity test systems have implemented optional distance stereoacuity tests with liquid-crystal display (LCD) shutter glasses, polarized filter glasses, or anaglyphic filter glasses; few have been formally evaluated and most lack normative data. Distance stereoacuity may be especially useful for detecting deterioration of control of intermittent exotropia.[30–32]

Strabismus and stereopsis

Near the time of onset of esotropia, children with infantile esotropia show a capacity for stereopsis; deficits become apparent only after the onset of stereopsis, suggesting that they result from prolonged abnormal binocular experience.[33] This hypothesis is consistent with data from animal models in which there is an experience-independent initial phase of sensory development, followed by a period of susceptibility to abnormal experience that peaks just after the onset of stereopsis.[34] There is substantial evidence that early surgical correction improves binocular sensory outcomes for infantile esotropia, probably because the duration of constant esotropia is minimized.[20–22] Surgical alignment after the age of 24 months results in only 12% of children achieving any stereo vision[35,36]; whereas 75% of children aligned before 6 months of age achieve stereopsis (Table 72.3).[21,22,37–40] A few case series have reported excellent stereoacuity outcomes in a few infants who were surgically corrected by 6 months of age.[40–42] However, these case series may have inadvertently included some infants who had the potential for their esotropia to resolve spontaneously. When the Congenital Esotropia Observational Study (CEOS)-defined clinical profile[43] is used to identify a cohort of infants for whom spontaneous resolution was very unlikely (<2%), stereoacuity outcome data from six longitudinal studies of esotropia finds that more than 80% who were surgically aligned by 6 months achieved stereopsis but only 4% achieved normal stereoacuity (see Table 72.3).[21,22,37–40] Thus, the potential for preservation or rehabilitation of stereopsis via early surgery for infantile esotropia is good but the likelihood of achieving fine stereoacuity is almost nil.

Table 72.3 Summary of stereoacuity outcomes from six longitudinal studies using the CEOS definition of infantile esotropia[21,22,37–40] to evaluate outcomes only among children for whom spontaneous resolution was very unlikely (<2%)

Age at alignment	Stereoacuity outcome (months)		
	Nil	100–3000 arcsecs	≤60 arcsecs
≤6 months	24%	75%	<1%
7–12 months	64%	35%	<1%
13–18 months	61%	38%	<1%

CEOS, Congenital Esotropia Observational Study.

Children with late-onset accommodative esotropia might be expected to have good stereoacuity outcomes once their eyes are aligned, because the onset of esotropia occurs well after the infantile period of rapid stereoacuity maturation. However, even when children with accommodative esotropia are tested very early, while the esotropia is intermittent, more than 40% have reduced or no abnormal stereoacuity.[20] This finding suggests that stereodeficits may be primary in some children

with accommodative esotropia. In this subset of children, there may be a genetic factor or the stereodeficit may be due to other factors that were present prior to the onset of esotropia, such as hyperopic anisometropia (frequently associated with accommodative esotropia).[44] For some children, moderate hyperopic refractive error may need to occur in conjunction with abnormal stereoacuity to precipitate the onset of accommodative esotropia; most children with ≥+4.00 D never develop accommodative esotropia. The remaining 50–60% of children with accommodative esotropia initially present with normal stereoacuity, and prompt treatment to restore alignment is associated with excellent stereoacuity outcomes.[20]

Intermittent exotropia is usually associated with normal stereoacuity at near. However, distance stereoacuity, measured at ≥3 m viewing distance, may be normal or abnormal. The frequency with which intermittent exotropia deteriorates to constant exotropia is unclear, with some reports suggesting a high frequency and others describing long-term stability. Distance stereoacuity can be used to assess the severity of intermittent exotropia and to monitor for deterioration of control.[30,31] Moreover, deterioration in distance stereoacuity has been suggested as an indicator for surgery prior to the onset of constant exotropia and as an outcome measure to assess the success of surgery.[30–32,45] Improvements in distance stereoacuity have been reported using both the Distance Randot and FD2 stereoacuity tests in patients who had surgery for intermittent exotropia.[32,45]

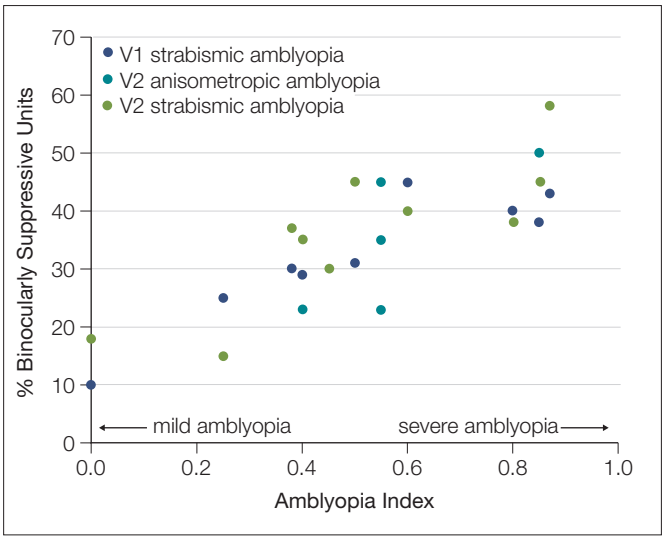

Fig. 72.5 Relationship between the proportion of binocularly suppressive neurons in two visual cortical areas and the depth of amblyopia in primate models of strabismic[46] and anisometropic[47] amblyopia. The amblyopia index is a similar but more comprehensive index of spatial vision deficits than the interocular acuity difference; it is calculated by integrating the area between the contrast sensitivity functions for the amblyopic and fellow eyes and dividing it by the area for the amblyopic eye. This index ranges from 0.0 (no measureable spatial vision deficit) to 1.0 (no measurable spatial vision in the amblyopic eye).

Binocular vision and amblyopia

When the input from the two eyes is significantly different in visual direction (strabismus) or focus (anisometropia), sensory fusion is impossible and the visual cortex relies on interocular suppression to block the discordant input from one eye. Amblyopia is a manifestation of this binocular barrier to normal development of the central visual pathways. Research on primate models of both strabismic and anisometropic amblyopia have shown a clear relationship between the severity of amblyopia and the percentage of binocularly suppressive neurons in the visual cortical areas V1 and V2 (Fig. 72.5).[46,47] Similarly, there is correlation between the severity of interocular suppression and amblyopic eye visual acuity deficit in amblyopic children and adults.[48–51]

Viewing amblyopia in the context of interocular suppression has important implications for treatment. Monocular treatment with patching cannot be expected to fully rehabilitate the child with amblyopia because the primary binocular dysfunction persists. In fact, most children treated for amblyopia have improvements in visual acuity with various monocular treatment modalities alone or in combination, but 15–50% fail to achieve normal visual acuity even after extended periods of treatment. Even among the children who do achieve normal visual acuity with amblyopia treatment, the risk for recurrence of amblyopia is high. In a series of prospective, longitudinal studies of infantile and accommodative esotropia conducted at one site,[20,22,38,39,44] 80% of esotropic children were treated for amblyopia at least once during the first 5 years of life and 60% had recurrent amblyopia that required re-treatment. The Pediatric Eye Disease Investigator Group (PEDIG) reported that 25% of successfully treated amblyopic children experience a recurrence within the first year of treatment.[52]

Patching treatment for amblyopia has only a modest benefit for stereoacuity. Two recent large clinical trial reports by the Monitored Occlusion Treatment of Amblyopia Study (MOTAS) and PEDIG groups[53,54] found that 37–66% of amblyopic children had no stereoacuity at baseline and after treatment 24–44% still had no stereoacuity. Only 28% had improved stereoacuity after amblyopia treatment in each study. We do not know exactly how patching works to improve visual acuity in amblyopia but, given how little effect it has on binocular vision outcomes, it likely affects only monocular mechanisms and has little or no effect on interocular suppression.

Current scientific consensus is that amblyopic individuals have a structurally intact binocular visual system that is rendered functionally monocular by interocular suppression, i.e. the two eyes are not working together. This has been demonstrated by using dichoptic presentation with reduced fellow eye contrast to allow the amblyopic eye to "break through" and participate in binocular vision.[55] The reduced fellow eye contrast approach has also provided a basis for crafting a new approach to amblyopia treatment. Repeated binocular visual experience with reduced fellow eye contrast (for example, in the context of an anaglyphic game on an iPod or iPad platform) allows the two eyes to work together. As amblyopic eye visual acuity and binocular vision improves, the interocular contrast difference can be gradually decreased day by day, with the goal that binocular vision will be functional even when contrast is equal in the two eyes. To date, results from short-term treatment (4 weeks) of 90 children have been reported in the literature; these were summarized in a recent review.[56] The children enrolled had all been treated with spectacles prior to enrollment, had moderate or severe amblyopia, and most had prior treatment with patching and had residual amblyopia following standard therapy. All of the children were aligned within 8 PD of orthotropia with surgery

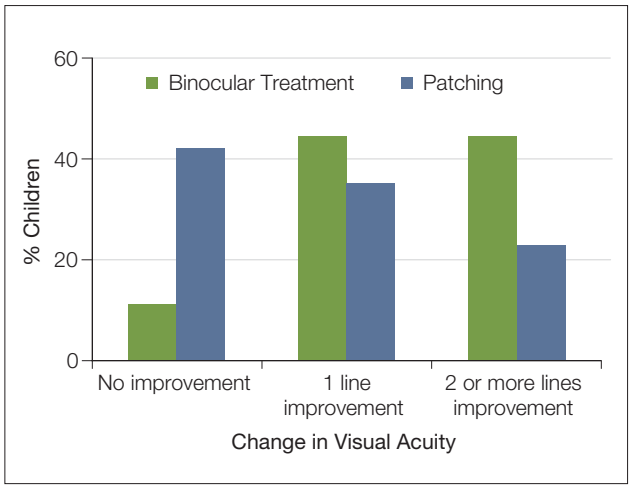

Fig. 72.6 Combined visual acuity outcome data from 90 amblyopic children across a number of binocular treatment studies (adapted from Hess and Thompson 2015[56]) and from children in the 2 hour/day patching arm of several Pediatric Eye Disease Investigator Group (PEDIG) randomized clinical trials.[57–61] All studies in the figure included children aged 3–17 years with moderate or severe amblyopia, who wore spectacles for approximately 12 weeks prior to treatment with binocular games or patching, and included a significant number of children who had residual amblyopia after prolonged treatment with standard therapies. Children were treated for 2–6 weeks in the various studies.

and/or spectacle prescription prior to beginning the binocular treatment. Overall, the mean improvement for children aged 3–17 years was 1.6 lines in 4 weeks; 44% improved ≥0.2 LogMAR (≥2 lines) and only 11% failed to improve (Fig. 72.6). Similar cohorts of children treated with 2 hours/day patching drawn from PEDIG randomized clinical trials[57–61] (aged 3 to 17 years, prior treatment with spectacles, moderate or severe amblyopia, and some with prior patching and/or residual amblyopia at entry; 4–10 weeks treatment) did not fare as well. Only 23% improved ≥0.2 LogMAR and 42% failed to improve with treatment (see Fig. 72.6). A recent study has reported a similar benefit obtained from watching dichoptic feature films with reduced fellow eye contrast.[62] Thus, active game play may not be a required component of the treatment; contrast-balanced visual experience may be sufficient. No adverse effects (e.g. diplopia) have been reported using a contrast-balanced binocular treatment approach in either the game or feature film format.

Why do we care about binocular vision?

Impaired binocular vision can result in debilitating symptoms, such as headaches, eye strain, and diplopia, impacting on quality of life, with lifelong consequences related to a child's future occupation choices. Symptoms can arise from reduced or absent motor fusion, resulting in asthenopia, diplopia, or absent stereoacuity.[63] In addition, sensory fusion and binocular summation are impaired in the presence of strabismus[64] and, if binocular inhibition develops, there is a significant impact on quality of life,[65] but improvements in binocular summation and quality of life are reported following surgical alignment of strabismus.[66]

It may seem only a minor inconvenience that a child with no stereoacuity cannot appreciate the vivid depth experience of a three-dimensional (3D) feature film, but this experience highlights how binocular deficits change the child's ability to perceive space. As the use of 3D technology is becoming more widely incorporated into homes and educational environments, a lack of binocular vision increases in significance. Visualization of structures can aid understanding, highlighted by the implementation of 3D technology in the classroom in subjects such as astronomy and biology; not being able to access these resources has the potential to impact on educational progress. From a social perspective, not being able to engage with the immersive, interactive 3D virtual worlds that children enter via games, children with abnormal binocular vision are not able to interact with their peers in this context.

Deficits resulting from a lack of binocular vision are not restricted to the accessibility of 3D technologies. Binocular vision disorders can impact on many aspects of motor functions, with studies demonstrating deficits in a range of fine motor skill tasks, resulting in decreased speed and/or reduced accuracy. People with stereoacuity are better at threading beads,[67] catching balls,[68] and completing a battery of timed manual dexterity tasks (sorting, drawing, placing pegs, etc.) than people with no measurable stereoacuity.[67,69] The reasons for the increased time or greater errors have been examined by assessing the kinematics of movement under binocular and monocular conditions. Figure 72.7 summarizes key elements of the movement that are affected in simple reaching and grasping tasks, with changes in the hand aperture, velocity of approach to the target, and errors in grasping.[70–74]

In addition to the errors in fine motor skill tasks, gross motor skills can be affected. Evidence shows an impact on gait, where reduced stereoacuity is associated with slower speed[75] and a more hesitant penultimate step and higher toe clearance when walking among obstacles, suggesting a more careful strategy for obstacle avoidance.[76] Additionally, there is evidence to suggest that monocular cues are potentially sufficient to localize ground level but stereoacuity is necessary to localize heights of steps and obstacles above ground level.[77] Later in life, there is evidence to demonstrate that reduced stereoacuity is risk factor for recurrent falls among the elderly.[78,79]

Overall, the best (quickest/most accurate) motor responses in all modalities are associated with high-grade stereoacuity, but those with reduced stereoacuity consistently perform better than those with no stereoacuity. While the precise relationship between binocular vision and functional ability is unclear, there are data to suggest it is not a linear pattern, where the presence of reduced stereoacuity has a slight impact but the absence of stereoacuity has a much larger impact.[80]

The consequences of abnormal binocular vision have also been reported by patients (and proxies) through quality of life questionnaires. The introduction of questionnaires designed specifically for strabismus, amblyopia, and diplopia address both functional and psychosocial impact, allowing analysis of these factors and the impact of treatment. There is now a significant body of evidence demonstrating improvements in patients following strabismus surgery. Most of the questionnaires are not designed specifically for children, and therefore address activities they will not or cannot do. However, there is consistent evidence in the literature for improvement in quality of life following treatment for disorders that disrupt binocular vision in adults.

Potential benefits of having binocular vision extend beyond those measured in motor task assessments and quality of life

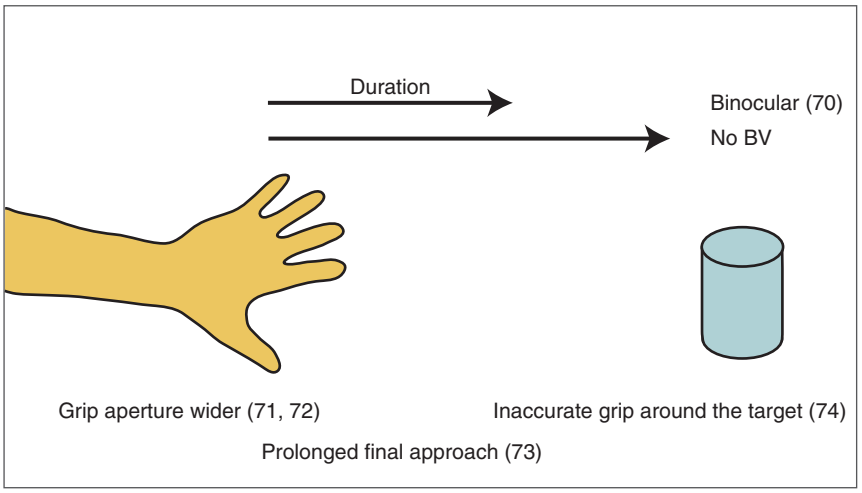

Fig. 72.7 Schematic of the deficits in reaching and grasping tasks in subjects without binocular vision (BV).[70–74]

questionnaires. Long-term management of strabismus often requires multiple surgeries, but the presence of stereoacuity is associated with more stable long-term eye alignment and fewer surgeries. Among children with infantile esotropia, those who had no stereoacuity after the initial surgical alignment procedure were 3.6 times more likely to require additional surgery later in childhood.[37] Similarly, children with accommodative esotropia whose alignment was corrected to within 4 diopters of orthotropia with the initial spectacle prescription but no stereoacuity, were 17 times more likely to decompensate and require surgery to restore alignment than those with stereovision.[37] Because there is a lower risk for recurrent and consecutive deviations, good eye alignment related to stereopsis is also associated with improved long-term quality of life, including self-image, employment opportunities, and success in school and sports.[81] Stereopsis is also associated with reduced risk for and severity of amblyopia, and amblyopic eye visual acuity is known to be an important determinant of quality of life.[82]

Conclusion

Given the wide-ranging impact that disorders of binocular vision can have, the restoration of high stereoacuity should be a primary goal of treatment. Early diagnosis and prompt surgery are imperative for maximizing stereoacuity outcomes. Even the attainment of reduced stereoacuity is associated with significant benefits, including long-term stability of alignment, better fine motor skills, and improved long-term quality of life. Management of other aspects of binocular vision in the treatment of pediatric eye disorders is less well understood. Most reports in the literature focus on optical management of associated refractive errors or surgical management of strabismus. Thus, one significant gap in our evidence base is the management of children with poor control of alignment (e.g. intermittent exotropia) or weak motor fusion (e.g. convergence insufficiency). These children are often treated with exercises designed to strengthen motor and sensory fusion to alleviate symptoms, but little evidence exists to evaluate their efficacy. Another key development to enhance management of pediatric binocular disorders will be the development of new tests that accurately identify and quantitatively evaluate each aspect of binocular vision.

Amblyopia is the most common cause of visual impairment in children; it often persists into adulthood. The prevalence in childhood is estimated to be 1–4%, depending on the population studied.[1,2] It is considered to be the leading cause of monocular vision loss of people between the ages of 20 and 70 years.[3] The prevalence of visual loss from amblyopia was 2.9% in one study of adults, indicating the need for improved detection and treatment.[4] Amblyopia is defined as a "decrease of visual acuity caused by pattern vision deprivation or abnormal binocular interaction for which no causes can be detected by the physical examination of the eye and which, in appropriate cases, is reversible by therapeutic measures."[5] Amblyopia may be unilateral or, less often, bilateral. Most cases are associated with eye misalignment, usually esotropia in infancy or early childhood, anisometropia, or a combination of strabismus and anisometropia (Table 73.1).

Visual loss in amblyopia varies from mild to severe. About 25% of cases have visual acuity worse than 6/30 and about 75% 6/30 or better.[6–9] The extent of the deficit may not be equivalent, but vary by cause. Strabismic amblyopia may represent a more severe physiologic deficit than isolated anisometropic amblyopia, and combined strabismic and anisometropic amblyopia is a more serious deficit still.[10]

Methods of detection

The gold standard for detection is measurement of visual acuity using a crowded or linear letter optotype test. Single optotype presentation and picture optotypes are less sensitive and should be used only when a child is unable to perform a test using surrounded or line optotypes. Tests based on the four letters "H," "O," "T," and "V" in a box or with contour surround bars are the basis of several popular test strategies.[11,12] A defined protocol for testing children with single-surround HOTV has been developed by the Pediatric Eye Disease Investigator Group (PEDIG).[12] The strategy includes a second chance at threshold determination and a portion designed to get the child back on track with some larger above-threshold stimuli. It has good testability, test–retest reliability, and has been automated.[13] The Amblyopia Treatment Study HOTV (ATS-HOTV) protocol slightly overestimated visual acuity relative to the electronic Early Treatment Diabetic Retinopathy Study (ETDRS) visual acuity protocol (0.68 lines for amblyopic eyes; 0.25 lines for fellow eyes).[14]

For children unable to perform with letter optotypes, clinicians have commonly used picture optotypes. However, standard picture optotypes overestimate the visual acuity of amblyopic eyes and are not recommended for screening or diagnosis of amblyopia. Dr Lea Hyvärinen designed four picture-like optotypes[15] to have similarities between optotypes and have contours like the Landolt C making them more difficult to successfully recognize. The objects (apple, circle, house, square) chosen are common in Western children's experience and eliminate cultural biases in that population. In one study, the single-surrounded Lea tests systematically overestimated acuity by 1.9 lines compared to the crowded Landolt C in normal eyes.[16] A comparison of the Lea symbols to line optotypes in amblyopic eyes has not been thoroughly studied.

Fixation preference testing may be used for children unable to perform any optotype-based testing. For strabismic children, the clinician compares the ability to hold fixation with each eye. The child may alternate, be unable to hold fixation after a blink, or be unable to hold fixation. For a patient with no misalignment, perform the test by placing a 10-diopter prism base down before one eye, having the child fixate a detailed target at distance or near, and assessing fixation preference. If there is a fixation preference for the eye without the prism, switch the prism to the fellow eye and again assess

Table 73.1 Association of amblyopia with strabismus, anisometropia, or both combined

	Woodruff et al.[6]	Shaw et al.[98]	PEDIG[99]
Number of cases	961	1531	2635
Strabismus as the cause	57%	45%	31%
Anisometropia as the cause	17%	17%	41%
Combined strabismus and anisometropia	27%	35%	28%

Precise percentages vary depending on how amblyopia is defined.

fixation preference. The prism might cause the other eye to be preferred. If the same eye is preferred under each testing condition, then the fellow eye is assumed to have amblyopia. A patient who fixates with the eye without the prism is alternating. Comparing fixation preference testing to optotype testing has shown fixation preference testing is unreliable as a means of diagnosing amblyopia, generally leading to an overdiagnosis of amblyopia. Optotype testing confirmed only 17 of 52 patients (33%) diagnosed with amblyopia by fixation preference testing.[17] In another study, 53 children had two or more lines of difference in visual acuity, yet 45 were graded as normal by fixation preference.[18] Amblyopia therapy is typically prescribed for a strong fixation preference, as discussed in the sections on treatment.

On occasion, visual acuity testing consists of noting whether the child can centrally hold fixation, has steady eye movements, and is able to maintain fixation on a target. This is noted as CSM (central, steady, maintained) when present. The clinician uses this scale to compare the two eyes.

Forced choice preferential looking using Teller acuity cards has been used as an alternative method for infants and non-verbal children.[19] This test is time consuming and requires an experienced tester to assure reliable results. Unfortunately, this test systematically underestimates amblyopia, reducing its clinical utility as a means of screening or detecting a successful treatment endpoint.

Methods of treatment

There are few data comparing the outcomes of amblyopia treatment to the natural history. Clinicians have noted improvement of acuity when children complied with therapy, but found little improvement when no therapy was actually completed. Simons and Preslan reported that among a case series of amblyopic patients who were not treated, there was no improvement in visual acuity.[20] However, demonstration of improvement in acuity of the amblyopic eye in a study without concurrent untreated or natural history controls is not sufficient to prove a benefit of therapy. This deficiency led to a recommendation in the United Kingdom to stop screening for amblyopia as well as treating it because of a lack of a proven benefit.[21]

Recent prospective studies have shown value in terms of visual acuity improvement. Two hours of daily patching modestly improves amblyopia in children 3–7 years of age compared to no patching, which is sustained.[22,23] Another study (Amblyopia Treatment Trial, UK) randomized a group of non-strabismic children with anisometropia to no treatment, treatment with glasses, or treatment with glasses and occlusion. This study found about one line of visual acuity improvement at outcome comparing glasses and occlusion treatment with no treatment.[24] Some limitations were present; not every child had amblyopia. In addition, the control group's visual acuity at baseline and at final measurement was without correction, whereas the treatment group was measured with best spectacle correction.

Refractive correction

The initial intervention for amblyopia of any type is to prescribe necessary refractive correction. The diagnosis is not made until refractive correction is prescribed, the glasses obtained, and the visual acuity deficit confirmed with the correction. The practice of prescribing spectacles for amblyopia varies with severity and age of the child, but most guidelines suggest correction of an anisometropia greater than 0.50 D and astigmatism of 1.50 D when amblyopia is suspected. Hypermetropia should be fully corrected in younger strabismic patients and corrected with the plus sphere reduced by up to 1.50 D in orthotropic patients. Myopic errors should be fully corrected during office testing with trial frames to confirm the diagnosis, although prescribed minus sphere may be cut in some cases, especially with younger children.

When should additional therapy such as occlusion be started? Some clinicians prescribe such therapy immediately, some wait a pre-specified time, others wait until improvement with spectacles alone ceases. Moseley et al. found that 8 of 12 patients prescribed spectacles for the first time improved three or more lines in the amblyopic eye.[25] PEDIG reported that amblyopia improved in previously untreated anisometropic patients (n=84) with optical correction by at least two lines in 77% of the patients and resolved in 27%.[26] Improvement took up to 30 weeks. A subsequent study (n=146) of the impact of refractive correction on strabismic or combined amblyopia found a nearly identical outcome: 75% improved at least two lines and 32% resolved.[27] This was in spite of not requiring alignment with the correction.

Based on these findings, the author prefers to prescribe any necessary spectacle correction and then wait for at least 6 weeks to re-evaluate visual acuity. The visual acuity is measured in trial frames when the glasses are prescribed at the initial (baseline) visit so it may be compared with the vision measured at the first follow-up visit. As long as the visual acuity is improving, the child may continue with just glasses before prescribing additional therapy. This staged approach may improve patient compliance with each portion of the therapy.

Occlusion therapy

Occlusion has been the mainstay of treatment for a century despite the lack of meaningful data demonstrating superiority over other modalities. Treatment commonly employs an adhesive patch placed over the fellow eye so that the amblyopic eye must be used. Opinions vary on the number of hours of patching per day that should be prescribed, ranging from a few hours to all waking hours in many textbooks.[5,28–31]

Flynn et al. found that the success rates were the same for part-time and full-time occlusion therapy based on reported outcomes in 23 studies.[32] Several authors have reported significant improvement in visual acuity using brief daily periods of occlusion (20 minutes to 1 hour).[33,34] Campbell et al. noted that 20 minutes per day was effective in improving the vision of 83% of children to 6/12.

The dosages prescribed by clinicians during the last few decades vary greatly and seem to be largely a matter of region or training.[35] For instance, more hours are prescribed in German-speaking countries than in the United Kingdom, yet the same outcome is expected.[36] These prospective multicenter randomized controlled clinical trials have included only patients with strabismic and anisometropic forms of amblyopia.[37–40] The first study compared occlusion to atropine treatment. The dosage of occlusion prescribed was a minimum of 6 hours up to full-time, but the investigator chose the actual occlusion dosage. Patients with acuity of 6/24 to 6/30 improved faster when more hours of patching were prescribed, but after 6 months the improvement was not significantly greater than that occurring with fewer hours of patching or with atropine (Fig. 73.1).[37]

Additional prospective randomized trials compared the efficacy of different occlusion dosages. There are two distinct studies, one for moderate amblyopia 6/12 to 6/24, and one for severe amblyopia 6/30 to 6/120, caused by strabismus, anisometropia, or both.[38,39,41] The studies found that 2 hours of daily patching produces an improvement in visual acuity of similar magnitude to the improvement produced by 6 hours of daily patching in treating moderate amblyopia in children 3 years to less than 7 years of age.[39] Each treatment group improved 2.4 lines over 4 months. More interesting was the lack of any benefit in terms of the rate of improvement from more hours (Fig. 73.2). When reviewing this study, it is important to consider that the visual acuity gain after 4 months likely does not represent the maximum improvement possible from either treatment.

The study for severe amblyopia compared 6 hours with full-time occlusion. The investigators found the improvement in the amblyopic eye acuity from baseline to 4 months averaged 4.8 lines in the 6-hour group and 4.7 lines in the full-time group (P=0.45).[38] In a recent study, children with severe amblyopia improved a mean of 3.6 lines with just 2 hours of daily patching for 17 weeks.[42]

Children's dislike of occlusion therapy is well known.[43] Reported compliance rates range widely. Parents have used coercion and clinicians have, on occasion, prescribed punitive measures such as elbow splints to enhance compliance. Lack of parental understanding seems to play a large role. In the United Kingdom, failure to comply with the prescribed regimen at least 80% of the time occurred in 54% of patients: the failure to comply related to the parents' lack of understanding that there is a "critical period" for effective therapy.[44]

Side effects from occlusion are uncommon, usually minor skin irritation or the social stigma of a patch.[40] Adhesive sensitivity to the patches does occur. The clinician should discontinue the patch and treat with an emollient facial cream. Rarely, topical hydrocortisone may be needed.

More serious is occlusion (or "reverse") amblyopia – a decrease in vision in the fellow (patched) eye of more than one line. It is more common with more intense therapy and longer treatment intervals, especially if the patient is lost to

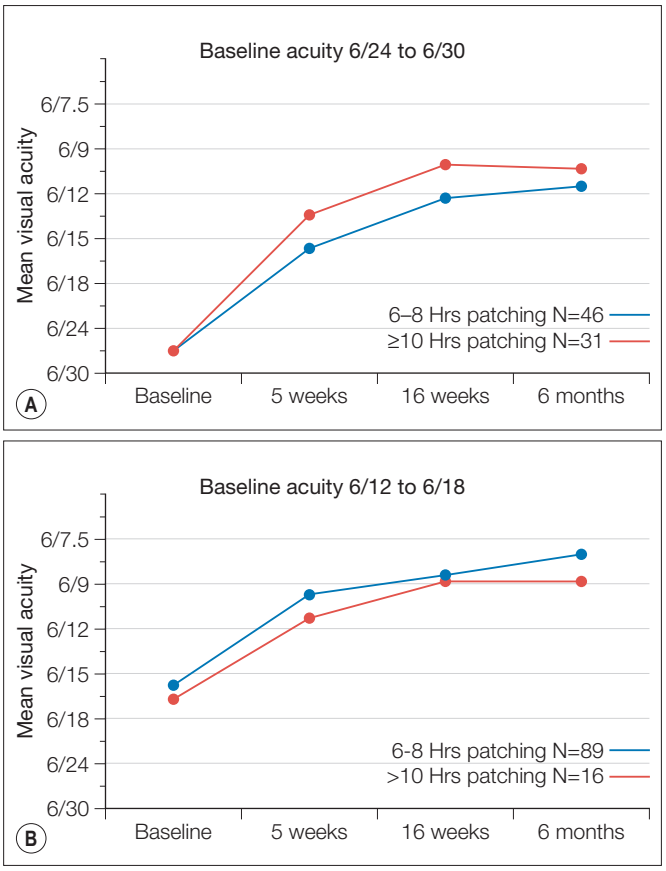

Fig. 73.1 Initial prescribed dosage of patching versus mean visual acuity from a randomized controlled trial.[40] Eighty percent of patients remained on their initial dosage throughout the study. Unsuccessful patients in each subgrouping had patching of 12 or more hours prescribed at the 17-week visit. (A) Patients with amblyopic eye acuity of 6/24 and 6/30: The patients initially treated with 10 or more hours compared to 6 or 8 hours per day had a faster rate of improvement, but by 6 months there was no significant difference in outcome. (B) Patients with amblyopic eye acuity of 6/12 to 6/18: There was no difference in the rate or magnitude of improvement between those initially treated with 10 or more hours compared to those with 6 or 8 hours.

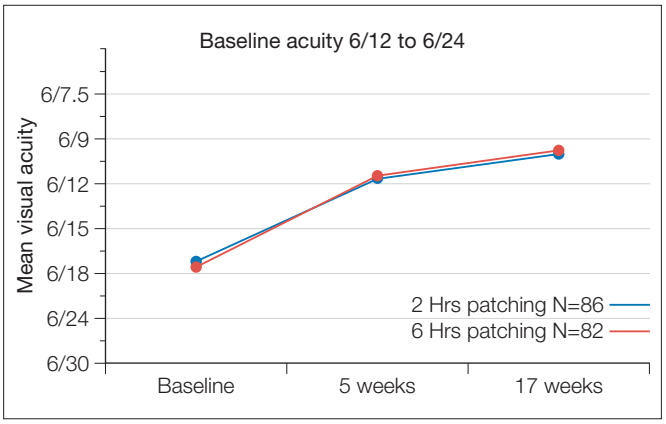

Fig. 73.2 Occlusion dosage of 2 versus 6 hours compared in a randomized controlled trial.[39] No increase in therapy was allowed by the protocol. There was no difference in the rate or magnitude of improvement during the 4 months of prescribed treatment.

follow-up. In one prospective study in which the majority of patients were treated with 6 or 8 hours of occlusion per day, only 1 of 204 patients was diagnosed with reverse amblyopia.[40] In most cases, occlusion amblyopia is reversible simply by stopping the treatment. Rarely, amblyopia therapy is needed for the original non-amblyopic eye.

The value of occlusion therapy is well established for anisometropic and strabismic amblyopia. The clinician and the parents should discuss the dosage of occlusion to be prescribed. The number of hours prescribed should be based on many factors including compliance and lifestyle.

An opaque adhesive patch is the best method currently available. Temperature-sensitive patches to monitor compliance may be available in the future.[45] Spectacle-mounted patches and non-adhesive patches may be less successful because they are easily removed. Once an occlusion dosage is prescribed, the patient must return for visual acuity monitoring. Traditionally, these intervals have been 1 week per year of age (i.e. a 3-year-old patient would return in 3 weeks). This approach is necessary when full-time occlusion is prescribed, but should be lengthened with part-time occlusion. An initial follow-up interval of 2 months for 2–6 hours per day patching is sufficient. If the amblyopic eye has improved and the fellow eye has not been impaired, the treatment interval can be increased. Therapy should be continued until no improvement occurs between two visits. Re-testing is warranted to be certain of the lack of improvement.

Most data on the treatment of amblyopia is derived from subjects who have strabismic, anisometropic, or both combined forms of amblyopia. An important group of patients experience form deprivation amblyopia, e.g. from a cataract or media opacity. For these patients, the amblyopia is often severe. Occlusion remains the best choice. The occlusion dosage should be individualized, as there is no clinical trial available to guide the clinician. For patients with unilateral deprivation amblyopia, occlusion dosages of half waking hours are reasonable to avoid damage to the binocular system or to the fellow eye. This dosage can be tapered as the child plateaus to maintain the improvement.

"Penalization" therapy

Penalization is an alternative to occlusion therapy for amblyopia. Both pharmacologic and optical means are used to blur the vision in the better eye for near and/or distance. Penalization was first advocated in 1903 by Worth.[46] It has mainly been employed as a second-tier treatment, for use with occlusion non-compliance, and for post-occlusion maintenance or titration.[47–51]

Pharmacologic penalization involves the instillation of a long-acting cycloplegic agent into the fellow eye. Most often, atropine 1% ophthalmic solution has been used, but sometimes shorter-acting cycloplegic agents. Cycloplegia prevents accommodation, thus blurring the eye at near fixation. The patient uses the amblyopic eye at near. Some clinicians have augmented the therapeutic effect by reducing or removing any plus sphere from the spectacle correction of the fellow eye, effectively blurring the fellow eye at all fixation distances.[40,52,53] Pharmacological penalization has been recommended for moderate amblyopia, but has also been found somewhat effective for amblyopia 6/30 to 6/60.[54] Compliance with pharmacologic therapy is easier for caregivers: 78% of patients had excellent compliance.[40] The treatment appears to take longer to reach a successful outcome compared with occlusion, but appears to be equally effective.

Optical penalization involves placement of "plus" fogging lenses over the fellow eye, blurring that eye at near, causing the patient to shift fixation at near to the amblyopic eye. Optical penalization has generally been advocated for only mild amblyopia (6/18 or better).[48,49] The power of the additional plus before the fellow eye may be arbitrarily chosen, usually +2.50 or +3.00 D. It is very convenient for a child wearing bifocals to simply extend the power of the bifocal throughout the entire lens creating an "over-plussed" single-vision lens. An alternative is to have the patient fixate a distance vectographic target and increase the plus sphere before the fellow eye until the fixation at distance switches to the amblyopic eye.[55] Compliance is a concern with optical penalization since it is dependent on the child wearing the glasses and not "peeking" around them. For that reason it is a method best reserved for older children and those with milder degrees of amblyopia. The clinician should be prepared to continue this treatment for 2 or more years.

Penalization with either optical or pharmacological blur appears effective because the blur produced selectively removes the high spatial frequency components of the image to the fellow eye, eliminating their suppression of the high spatial frequency components perceived by the cortex responsive to the amblyopic eye.[56] This appears to be critical because amblyopia is a deficit of neuronal responses to high spatial frequencies. With penalization, the high spatial frequencies become more dominant in the neurons to the cortex of the amblyopic eye.

Occlusion compared to penalization

Some studies have compared penalization with occlusion.[57–59] The first Amblyopia Treatment Study was a randomized controlled trial that enrolled 419 patients comparing occlusion to pharmacologic penalization.[40] Both daily patching (6 or more hours) and daily atropine were effective initial treatments for amblyopia throughout the range of 3 years to less than 7 years of age and the acuity range of 6/12 to 6/30. Each method produced nearly the same improvement of about 3 LogMAR lines over 6 months. Follow-up through age 15 years has found the improvement of the amblyopic eye to be maintained, although residual amblyopia is common.[23] The outcome was similar regardless of initial treatment.

Fogging

An alternative to occlusion or penalization is fogging. This may be done with Bangerter foils or even adhesive tape, which reduce the visual acuity in the fellow eye. The foils are available in graduated densities. The selected filter is typically one that is expected to reduce the fellow eye vision to less than the amblyopic eye. An alternative is to use a fairly dense filter for all patients. A randomized study compared Bangerter filter density of 0.3 (for 6/12–6/18 amblyopic visual acuity) or 0.2 (for 6/24 amblyopic acuity) with patching for 2 hours per day.[60] At 24 weeks, amblyopic eye improvement averaged 1.9

lines in the Bangerter group and 2.3 lines in the patching group. Similar percentages of subjects in each group improved three lines (Bangerter group 38% vs. patching group 35%; P=0.61) or had 6/7.5 amblyopic eye acuity (36% vs. 31%, respectively; P=0.86).

A readily available and inexpensive alternative is the use of an opaque adhesive tape placed on the glasses. Each of these is barely visible beyond 0.5 m. This method is ideal for mild visual deficits, long-term maintenance therapy, and in school-age children in which compliance with the glasses wear is possible.[61]

Active therapy

Active treatment has been suggested as an important supplement to occlusion therapy. Duke-Elder emphasized the importance of interesting play during occlusion.[62] Physicians have suggested that while patching, patients should be involved in some activity that promotes visual interaction. The simplest forms have been home-based activities, performed in conjunction with the occlusion, usually involving activities such as tracing, dot-to-dot tasks, coloring, stringing beads, reading, and playing computer/video games. These therapies may be helpful because they: (1) help overcome compliance problems with occlusion; and (2) may help to improve accommodation and fixation patterns. A study compared 100 patients who were occluded with another 100 who underwent occlusion with active home therapy twice weekly. They achieved the same visual acuities, but the actively stimulated group reached maximum improvement 2 months earlier.[63] Campbell and coworkers added intensive close work to 20 minutes per day of occlusion and found that 83% of children improved to 6/12.[34] Active therapy has been shown to be helpful when patching alone did not improve the visual acuity. Shippman added 1 hour of video game play to patients previously unsuccessfully treated with occlusion.[64] Fifteen of 19 (78%) had an additional two lines of improvement, and nearly 50% improved by three lines of acuity. Similar success in older children has been reported in uncontrolled studies.[65,66]

The Cambridge amblyopic vision stimulator employed intensive visual activities.[34] The initial report suggested excellent results. However, subsequent studies including sham stimulation found no significant difference in acuity outcomes.[67–69]

PEDIG studied adding 1 hour of near activities to 2 hours prescribed patching in children 3 years to less than 7 years of age.[70] After 8 weeks of treatment, improvement in amblyopic eye visual acuity averaged 2.6 lines in the patching-only group and 2.5 lines in the near activities group. At this time, the absence of a benefit means this approach may only be of use in some children as a compliance tool.

Binocular visual experience as treatment

Hess and his colleagues reported treating unilateral amblyopia in adults with a binocular approach using dichoptic stimuli.[71] This approach was translated to amblyopia treatment in children on an iPod (Apple, Inc.) using a Falling Blocks game.[72] Li and colleagues treated amblyopia with dichoptic stimuli, using red–green glasses with reduced contrast for the non-amblyopic eye, for 4 hours/week for 4 weeks.[73] The authors reported an average improvement from 0.47±0.03 LogMAR at baseline to 0.39±0.03 LogMAR (P<0.001) after 4 weeks in 50 children 4–12 years of age. In another study of preschool children 3 to < 7 years of age (n=35) treated 4 hours per week on an iPad (Apple, Inc.) platform at home, they improved about one line on average over 4 weeks of therapy, while there was no improvement for sham treatment.[74] Confounding analysis was the ongoing use of patching and a limited size control group (n=5). Greater treatment effect was seen in those children with better compliance.

PEDIG is conducting a prospective randomized study of this treatment in children and teens 5–16 years of age. The trial is using 1 hour per day of the game and no other treatment except glasses for 4 months of treatment. There is a 2 hours per day of patching control group.

Systemic therapy

Catecholamine neurotransmitters play a role in maintaining plasticity of the visual cortex during development. The administration of oral levodopa–carbidopa (L-dopa) combination therapy improves the acuity of amblyopic eyes.[75] Levodopa is converted to dopamine, which appears to play an important role in retinal function and in central visual processing.[76] Carbidopa is added to reduce the systemic effects of the levodopa by allowing a lower dose. When this pharmacologic therapy is combined with occlusion therapy the visual acuity improvement was greater than that with occlusion alone.[77] These studies noted regression after the treatment was stopped, but the outcome acuity was felt to be better when occlusion was combined with L-dopa.[75]

Three randomized placebo-controlled studies of levodopa with patching for residual amblyopia have been conducted.[78–80] Each of the studies found more improvement in the levodopa group compared with the placebo group. Two earlier studies were of 1 week or shorter duration. PEDIG has recently completed a larger randomized trial of levodopa (0.76 mg/kg/tid) plus occlusion compared with placebo plus patching for residual amblyopia in children 7–12 years of age.[80] Although both groups improved about one line, there was no meaningful benefit from adding oral levodopa to patching.

Side effects of nausea, dizziness, decreased respiration, and decreased body temperature have been reported with the use of levodopa, although they are reported by a minority of study participants.[80–82]

Citicoline (cytidine-5′-diphosphocholine) had some success in a study of 50 amblyopic patients.[83] Treatment involved daily intramuscular injections of the medication for 10 days. Both the fellow and amblyopic eyes improved and were stable with 4 months of follow-up. This drug has been less widely used because of the requirement for parenteral administration, but few side effects have been reported. An oral preparation is currently under study.

The lack of compelling evidence of success greater than that found with conventional treatments and the use of neuroactive drugs for a condition that does not threaten life or general health make it impossible to recommend systemic therapy at this time.

Combined therapies

Some clinicians simultaneously treat amblyopia with more than one approach. A common approach is to patch part-time and to prescribe topical atropine, thus allowing the child to be continuously treated. The child will use the patch when not in school or at other activities where the patch will not make them self-conscious. The effectiveness of this approach is uncertain. An alternative is to prescribe topical atropine and reduce the plus sphere in the fellow eye to plano (or some other reduction of plus power), thus blurring the fellow eye at all fixation distances.[52] In a randomized trial of 18 weeks of such treatment, amblyopia improvement averaged 2.8 lines in the group that received atropine plus a plano lens, and 2.4 lines in the group that received atropine alone.[84] More patients in the group that received atropine plus a plano lens had reduced fellow eye visual acuity at 18 weeks; however, there were no cases of persistent reverse amblyopia. Nonetheless, monitoring these patients for decreased vision in the fellow eye is prudent.

Discontinuation of treatment/ maintenance therapy

Most clinicians stop intensive therapy when the patient no longer shows improvement. However, the duration of treatment before cessation of therapy is unclear, but 3 months with no improvement before stopping or reducing therapy is a reasonable approach. Once therapy is thought to have reached its maximum benefit, the author begins to "wean" the patient over many months or even a year, reducing the treatment by 50% every 3 months. However, there are no data available to prove that weaning is superior to immediate cessation in retaining the treatment benefit. In any case, ongoing monitoring is needed until 7 or 8 years of age without any active treatment besides glasses to detect a recurrence, which is inconvenient but medically necessary.

The long-term stability of improved acuity in amblyopia therapy is an important public health goal if we are to reduce the high prevalence of amblyopia in adults. The chance of maintaining all, or a portion of, the improvement into adulthood is at least 75% in retrospective studies.[85–87] In a prospective study, most children treated for moderate amblyopia when younger than 7 years of age had good visual acuity, although mild residual amblyopia was common.[23] The results indicate that improvement occurring with amblyopia treatment is maintained until at least 15 years of age without evidence of regression.

Compliance

Compliance with amblyopia therapy is a key factor in the success of the therapy. However, compliance with occlusion therapy varies widely, from 30% to more than 90%.[88–91] Reasons for the inability to complete the prescribed occlusion regimen include visual impairment, skin irritation, and psychosocial reasons. Pilot studies of occlusion therapy with occlusion dose monitors have shown the expected correlation of treatment compliance with outcomes.[92,93] Compliance with topical pharmacologic therapy is simpler, having to put the drop in only once per prescribed day. Compliance was reported to be excellent or good in 96% of patients.[40]

Although children may reject amblyopia therapy, lack of understanding about the disease and the timing of therapy also seem to play a role.[44] Compliance may be improved with better education of the parents and some explanatory materials to take home.

Reverse amblyopia

Reverse amblyopia (occlusion amblyopia) is a form of deprivation amblyopia. It is a reduction of vision in the fellow eye of more than one line due to a treatment prescribed for amblyopia in the fellow eye. Reverse amblyopia has been associated with most forms of therapy of amblyopia. It seems to be most commonly associated with full-time occlusion. It occurs much less often with part-time occlusion and cycloplegic and optical methods of treatment.

Reverse amblyopia generally recovers quickly, although there are reports of permanent visual impairment or change in fixation.[94] Each patient thought to possibly have reverse amblyopia should be reassessed: Confirm the refractive correction being worn. Examine the patient for signs of optic neuropathy including the pupillary light reflex for evidence of an afferent pupil, color vision, and appearance of the optic nerve and nerve fiber layer. Check the refraction with cycloplegia. Re-test the vision. If the acuity reduction is confirmed, either stop the active amblyopia therapy and re-examine the patient in several weeks or continue the therapy with careful monitoring of the fellow eye. If the fellow eye is worse than the amblyopic eye, stop therapy and schedule a return visit. If the vision in the fellow eye is still reduced on the subsequent visit, consider treating the formerly fellow eye.

Treatment of older children and adults

Amblyopia therapy is widely thought to be more successful in younger patients, especially when less than 7 years of age. This is consistent with the demonstration of age-specific sensitive periods in neurologic development. Recent findings challenge this tenet.

PEDIG conducted a randomized trial comparing optical treatment to optical plus other active therapies.[95] Improvement with optical correction alone occurred in about a quarter of children 7–17 years of age; although most patients benefited from additional treatment for amblyopia, most patients were left with a residual visual acuity deficit. For patients 7–12 years of age, 2–6 hours per day of patching with near visual activities and atropine improved visual acuity even if the amblyopia had been previously treated. For patients 13–17 years of age, prescribing patching 2–6 hours per day improved visual acuity only when amblyopia had not been previously treated (Fig. 73.3). While there appears to be much less improvement in older children and teens, it is reasonable to conclude from this work that any amblyopic patient who has never been treated should be offered at least one cycle of therapy.

In several retrospective studies and two clinical trials for occlusion and pharmacologic therapy in patients less than 7 years of age, no age effect could be demonstrated.[6,39,40,96] Although somewhat surprising given long-standing consensus

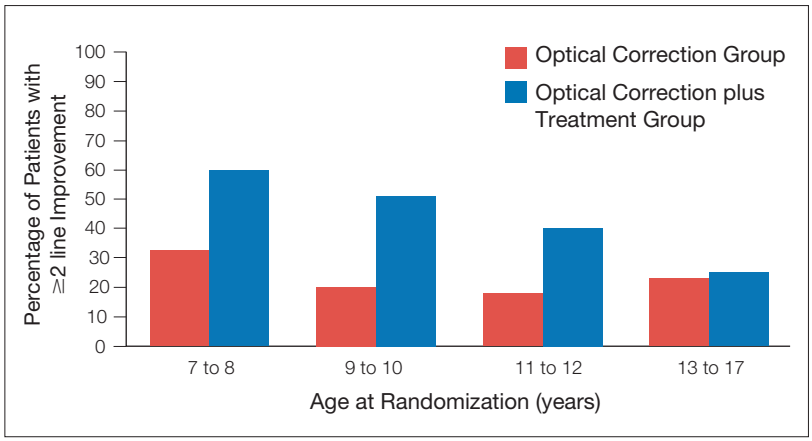

Fig. 73.3 Improvement in visual acuity of children 7–17 years of age with optical correction with or without additional treatment. Treatment for children 7–12 years of age was optical only or optical plus prescribing patching 2–6 hours per day with near visual activities and atropine ophthalmic solution 1% daily. For teens 13–17 years of age, treatment was optical only or optical plus prescribing patching 2–6 hours per day with near visual activities. *(Modified from Pediatric Eye Disease Investigator Group. Randomized trial of treatment of amblyopia in children aged 7 to 17 years. Arch Ophthalmol. 2005;123(4):437–47, with permission from the American Medical Association.)*

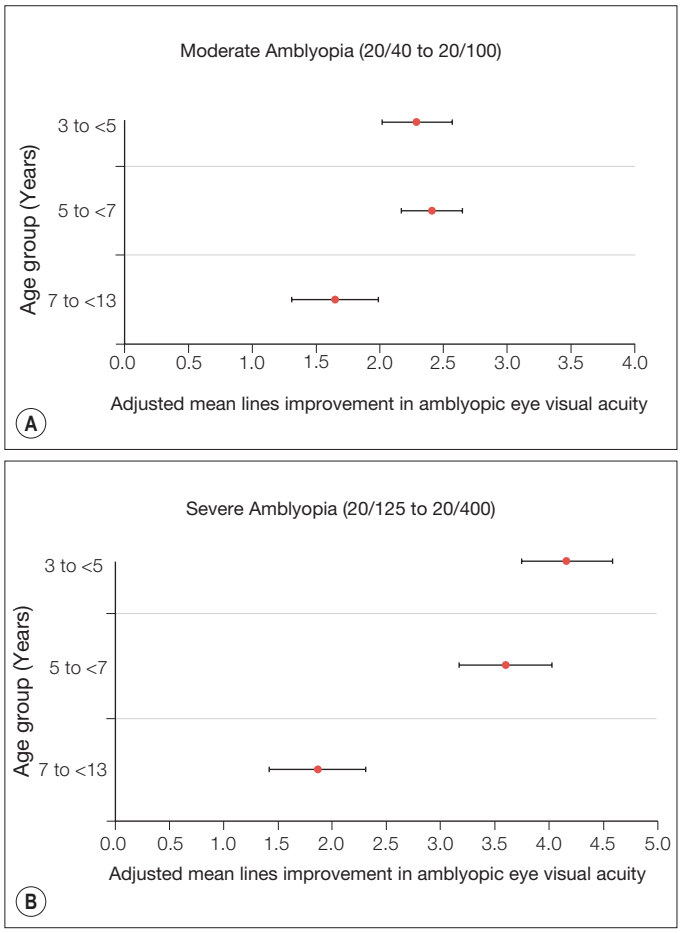

Fig. 73.4 Treatment effect by age for pooled Pediatric Eye Disease Investigator Group (PEDIG) studies data. Mean effects for each PEDIG trial weighted for sample size with 95% confidence intervals. (A) The treatment of moderate amblyopia shows no age effect below 7 years of age, but a striking reduction in the benefit after that age. (B) The treatment of severe amblyopia shows an age effect for each of the age cohorts with the youngest children able to achieve the greatest improvement.[97]

that there is an age effect in childhood, this finding may have been related to the relatively small ranges of age enrolled in each trial. A meta-analysis of PEDIG trials over a much wider age range found amblyopia more responsive to treatment in children younger than 7 years of age compared with children 7 years to less than 13 years of age[97] (Fig. 73.4). For moderate amblyopia, there was no difference in response seen among children less than 7 years of age, but for children with severe amblyopia, children 3 years to less than 5 years of age were likely more responsive than children 5 years to less than 7 years of age. These data would support the earlier identification and initiation of amblyopia treatment.

Introduction

Diagnosis and surgical correction of strabismus require anatomic knowledge of the extraocular muscles (EOMs) and their relationships with other orbital tissues. This chapter summarizes this anatomy and some surgical applications.

Overview of the extraocular muscles

The historically understood six EOMs are the effector arm of the ocular motor system.[1,2] The EOMs are loosely organized as "yoked pairs" of agonists and antagonists. These EOMs are highly specialized, and each EOM consists of two kinds of compartments.[3] The global layer (GL) controls oculorotary tension, while the orbital layer (OL) controls the pulling direction by regulating the position of the connective tissue pulleys. The GL and OL contain fiber types with different metabolic and structural properties. A second kind of compartmentalization divides the GL of each transversely according to specialized motor nerve arborizations that enables differential contraction. The pulleys, connective tissue EOM encirclements that are actively controlled by the OLs of the rectus EOMs, mechanically regulate most aspects of ocular kinematics, including Listing's Law (LL) of torsion. Exceptions to LL are implemented actively by the oblique EOM OLs. However, transverse compartmentalization allows for fine tuning EOM pulling direction, and is critical to ocular motor control during vergences, and to the interactions with vestibulo-ocular reflexes (VORs).

Details of the extraocular muscles

The six classical oculorotary EOMs pair as antagonists.[1] The medial rectus (MR) adducts and the lateral rectus (LR) abducts. The superior rectus (SR) and inferior rectus (IR) muscles form a vertical antagonist pair, with the SR supraducting and the IR infraducting. However, vertical rectus EOMs have additional actions. The superior oblique (SO) and inferior oblique (IO) muscles form a torsional antagonist pair: SO incycloducts, while IO excycloducts, but their additional actions are not strictly antagonistic.

Orbital and global layer compartmentalization of extraocular muscles

The oculorotary EOMs consist of two layers subserving distinct functions (Fig. 74.1).[1] The GL, containing approximately 10,000–15,000 fibers in the mid-length, is located adjacent to the globe in rectus EOMs and in the central core of the oblique EOMs.[4] In the rectus EOMs and the SO, the GL anteriorly becomes contiguous with the terminal tendon and inserts on the sclera.[5] In the IO, the GL inserts directly on the sclera. The OL of each rectus EOM contains 40–60% of its fibers. The OL does not insert on the eyeball at all, but instead inserts on connective tissue pulleys. The OL is located on the orbital

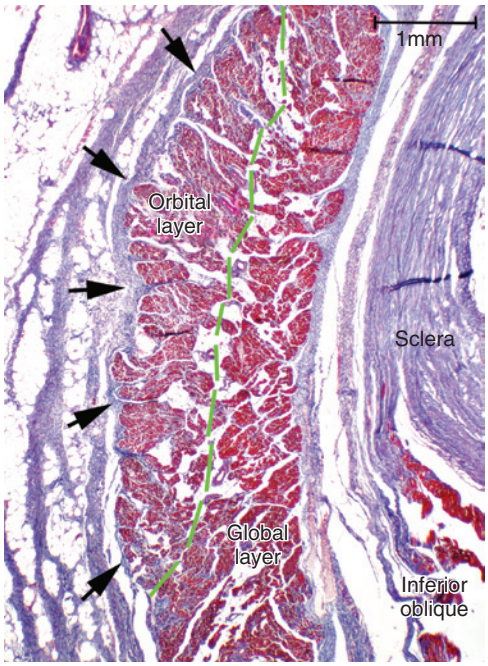

Fig. 74.1 Transverse histological section of 17-month-old human lateral rectus (LR) muscle stained with Masson's trichrome showing the smaller, darker-red staining fibers of the orbital layer (OL) to the left of the larger, brighter-red staining fibers of the global layer at right. Note insertion of OL fibers into the dense blue-staining collagen of the LR pulley (arrows). The inferior oblique muscle insertion into the blue-staining collagen of the sclera is seen at lower right.

surface of the rectus EOM, but constitutes the concentric outer layer of the SO.

The OL contains two muscle fiber types.[6] About 80% of fibers in the orbital layer of each EOM are fast, twitch-generating, singly innervated fibers (SIFs) resembling mammalian skeletal muscle fibers, while 20% are multiply innervated fibers (MIFs) that either do not conduct action potentials or do so only in their central portions.[6] Orbital SIFs have small diameter and numerous mitochondria. The metabolism and blood supply of orbital SIFs are tailored to their mechanical loading and nearly continuous activity, and thus specialized for intense oxidative metabolism and fatigue resistance.[6] The vascular supply in the OL is higher than in the GL.[7] Orbital SIFs express unique myosin isoforms.[6] The relatively sparse and primitive orbital MIFs may be proprioceptive.[8]

The GL contains one MIF type and three SIF fiber types.[6] The largest SIF is similar to the orbital SIF, while mitochondria are less abundant in the other two SIFs. Global MIFs resemble orbital MIFs. While spindles are absent in the GL, there are palisade endings along the width of each rectus tendon where the GL fibers terminate, perhaps subserving a proprioceptive function, although this is controversial.[8]

Several myosin isoforms occur in EOMs, with the predominant one in orbital SIFs, EOM-specific myosin, occurring uniquely in EOMs.[6] Neonatal and embryonic myosin isoforms persist throughout adult life at the anterior and posterior ends of SIFs. Differences in myosin expression may underlie the susceptibility of the EOMs to disorders such as thyroid ophthalmopathy, as well as their resistance to other disorders such as muscular dystrophy.[7]

Gross structure of the extraocular muscles[1]

Rectus EOMs originate in the orbital apex from the annulus of Zinn. The SO muscle originates from the periorbita of the superonasal orbital wall. The rectus EOMs course anteriorly through loose, areolar lobules of orbital fat until they enter their connective tissue pulleys that ensheath them as they penetrate posterior Tenon's fascia. Contrary to implications of many texts, there is no "muscle cone" of connective tissue among the adjacent rectus EOM bellies in the mid-to-deep orbit. The SO muscle remains tethered to the periorbita via connective tissues as it courses anteriorly, then thins to become continuous with its long, thin tendon. The concentric OL of the SO terminates posterior on a peripherally located sheath; the SO's GL terminates on parallel tendon fibers similar to rectus EOM tendons, but rolled up into a cylinder as it transits the trochlea, a cartilaginous rigid pulley attached to the superonasal orbital wall. After reflection in the trochlea, the SO tendon passes beneath the SR, thins, and flattens as it spreads out to its broad scleral insertion posterolaterally on the globe, while the sheath inserts on the SR pulley. The IO muscle originates from the inferonasal orbital rim, and runs laterally to enter its connective tissue pulley immediately inferior to the IR at the point the IO penetrates Tenon's fascia.

The axes of the bony orbits are angled about 23° laterally from the midsagittal plane. The array of the rectus EOMs and the SO is conical. As they continue anteriorly, the rectus EOMs thin to become strap-like bands about 10 mm in width, and ultimately their GLs become continuous with tendons that insert on the globe. The SO would do the same, except that its tendon rolls up within the trochlea and then unrolls anteriorly.

The rectus EOMs do not follow straight-line paths from their origins to their scleral insertions. In eccentric gazes, rectus paths are inflected sharply in the anterior orbit (Fig. 74.2). The inflections, due to the pulleys, cause the anterior paths of rectus EOMs, and thus their pulling directions, to change with eye position. Figure 74.2 is a set of axial magnetic resonance images (MRI) illustrating that the anterior IR path changes by half the change in duction angle. All four rectus EOMs behave in this manner.

Structure of pulleys

The rectus EOM inflections in the anterior orbit constitute the functional pulleys. Anterior to the pulleys, rectus EOM paths directly track to the scleral insertions. The pulleys thus act as mechanical origins of the rectus EOMs. The line segment between the scleral insertion and pulley thus defines the EOM's pulling direction. Pulleys consist of rings of dense collagen about 2 mm in length, co-axial with less substantial collagenous sleeves around the EOMs (Fig. 74.3). Anteriorly, these sleeves thin to form slings convex to the orbital wall and, more posteriorly, the sleeves thin to form slings convex toward the orbital center. The anterior pulley slings have also been called the "intermuscular septum," a time-honored but relatively vague term. Fibrils of pulley collagen in the pulleys have a crisscrossed configuration suited to high internal rigidity.[9] Elastic fibers in and around pulleys[10] provide reversible extensibility, particularly in bands that connect the pulleys

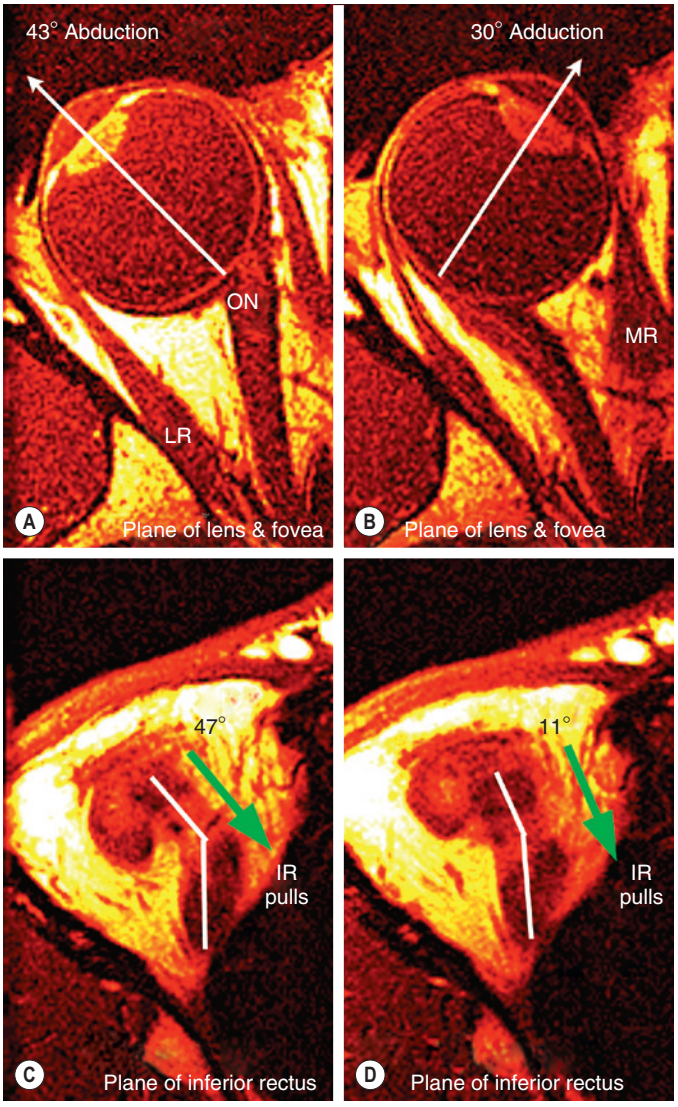

Fig. 74.2 Axial magnetic resonance imaging scans (2 mm thickness, T1 weighted) of a right orbit taken at the level of the lens, fovea, and optic nerve (A,B), and simultaneously along the path of the inferior rectus (IR) muscle (C,D), in abduction (A,C) and adduction (B,D). Note the bi-segmental IR path. For this 73° horizontal gaze shift, there was a corresponding 36° shift in IR muscle path anterior to the inflection at its pulley. This is a direct demonstration of half-angle shift of IR pulling direction with ocular duction.

to bony anchors on the orbital rim, suspending them under elastic tension that draws them anteriorly. Smooth muscle is present in pulley suspensions, particularly in a distribution called the inframedial peribulbar muscle between the MR and IR pulleys.[11]

The IR pulley is intimately coupled with the IO pulley in a bond that forms part of Lockwood's ligament where the IR and IO pulleys share a common collagenous sheath stiffened by a heavy elastin deposit at their point of crossing. The IR's OL inserts on its pulley. The IO's OL inserts partly on the conjoined IO-IR pulleys, partly on the IO's connective tissue sheath, and partly on the inferior aspect of the LR pulley. IO contraction displaces the conjoint IR/IO pulley nasally and the LR pulley inferiorly.[12] The overall arrangement of the entire pulley system is illustrated in Figure 74.4.

Although the rigid SO pulley – the trochlea – has been known since antiquity, the SO's OL inserts via the SO sheath on

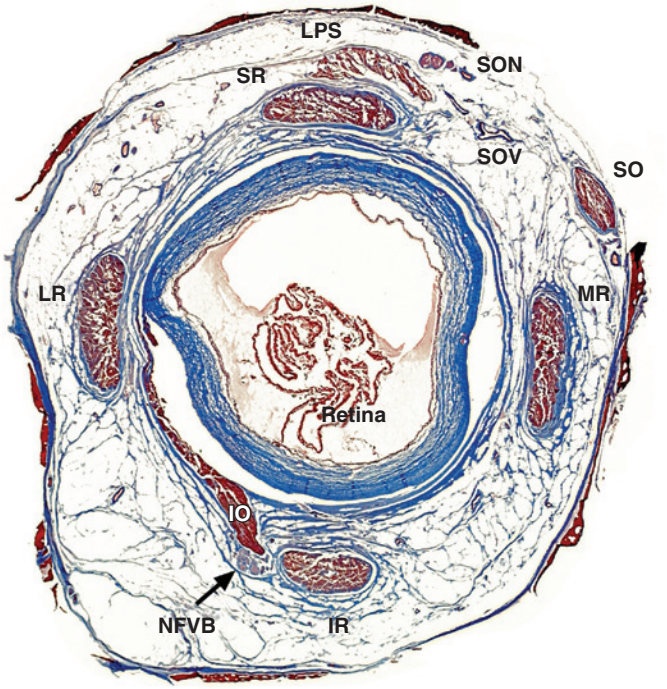

Fig 74.3 Quasi-coronal (perpendicular to orbital axis) histological section of 17-month-old whole human orbit stained with Masson's trichrome showing encirclement of the inferior rectus (IR), lateral rectus (LR), medial rectus (MR), and superior rectus (SR) muscles by the dense, blue-staining collagenous rings of their pulleys. The main part of the inferior oblique (IO) pulley is slightly anterior to this section, but can be seen in part as a dense collagenous mass adjacent to the muscle belly and its neurofibrovascular bundle (NFVB). The retina is detached as a postmortem artifact. LPS, Levator palpebrae superioris muscle; SO, superior oblique muscle; SON, supraorbital nerve; SOV, superior orbital vein.

the medial aspect of the SR pulley.[10] The SO pulling direction changes half as much as ocular duction despite an immobile pulley, because of the uniquely broad, thin insertion of the SO tendon as it wraps over the globe.

The foregoing anatomical relationships can be demonstrated in surgical exposures. Following engagement of a rectus EOM on a surgical hook, the white anterior pulley slings are visible. These tissues play little role in constraining EOM paths. The anterior pulley slings can usually be displaced posteriorly by blunt dissection, after which fine fibrous bands constituting the insertion of the OL of the EOM on the glistening white pulley suspension can be visualized (Fig. 74.5). This insertion is anterior to the pulley ring, which is obscured by the overlying white tissue of Tenon's capsule. After transposition of a rectus tendon for the treatment of, for example, LR palsy, the path of the transposed EOM continues to be toward the original pulley (Fig. 74.5). The clinical effect of rectus transposition can be improved by suture fixation from a posterior point on the transposed EOM belly to the sclera adjacent the palsied EOM.[13] This operation displaces the pulley further towards the transposed direction.[14]

Functional anatomy of pulleys

The insertion of each rectus EOM's OL on its corresponding pulley translates (linearly moves) that pulley posteriorly during

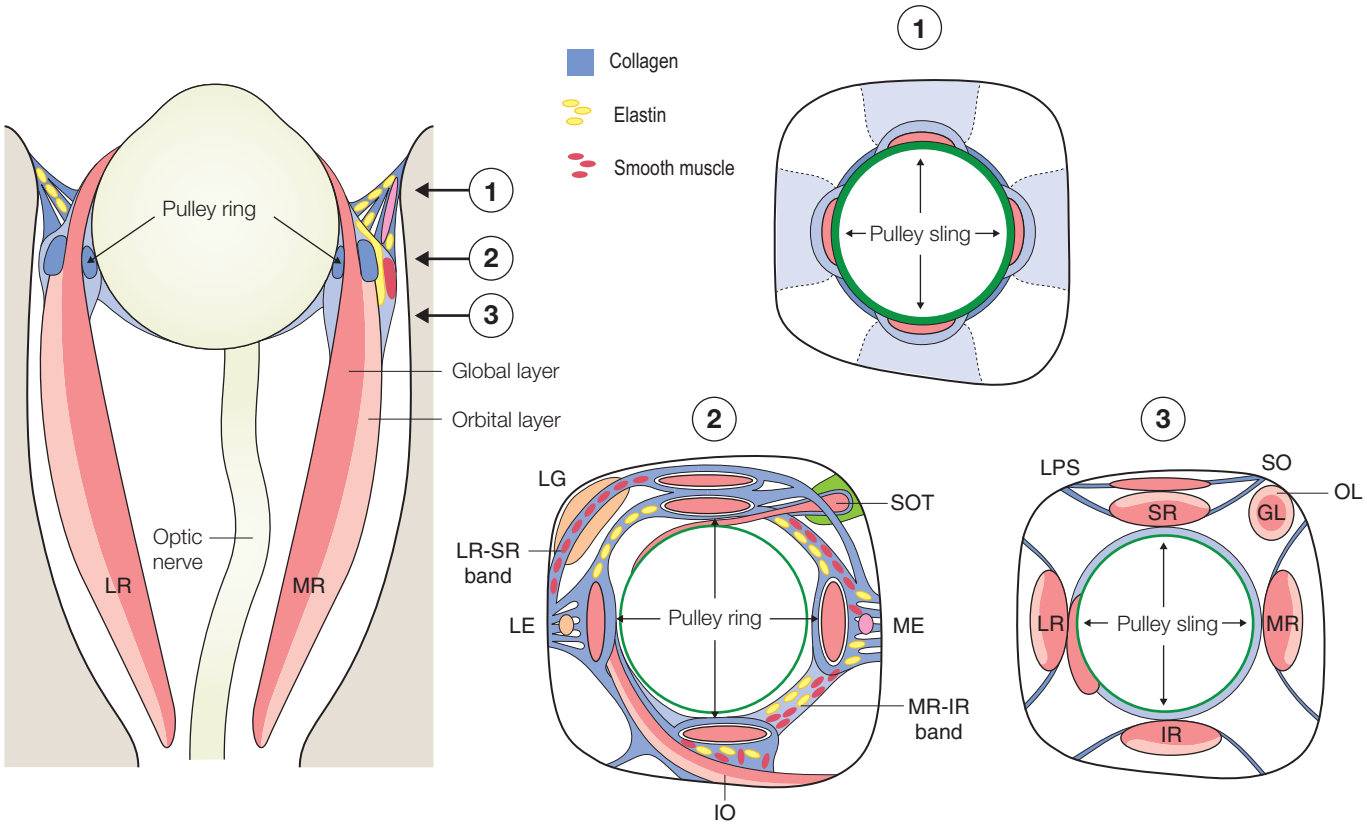

Fig. 74.4 Schematic of orbital connective tissues. Coronal views are depicted at three levels from the axial view. The functional pulleys are at the level depicted at lower right. Tissue composition is color coded as shown at right. GL, Global layer; IO, inferior oblique muscle; IR, inferior rectus muscle; LG, lacrimal gland; LE, lateral enthesis, the attachment of the pulley suspension to the orbital wall; LPS, levator palpebrae superioris muscle; LR, lateral rectus muscle; ME, medial enthesis, the attachment of the pulley suspension to the orbital wall; MR, medial rectus muscle; SO, superior oblique muscle; SOT, superior oblique tendon; SR, superior rectus muscle.

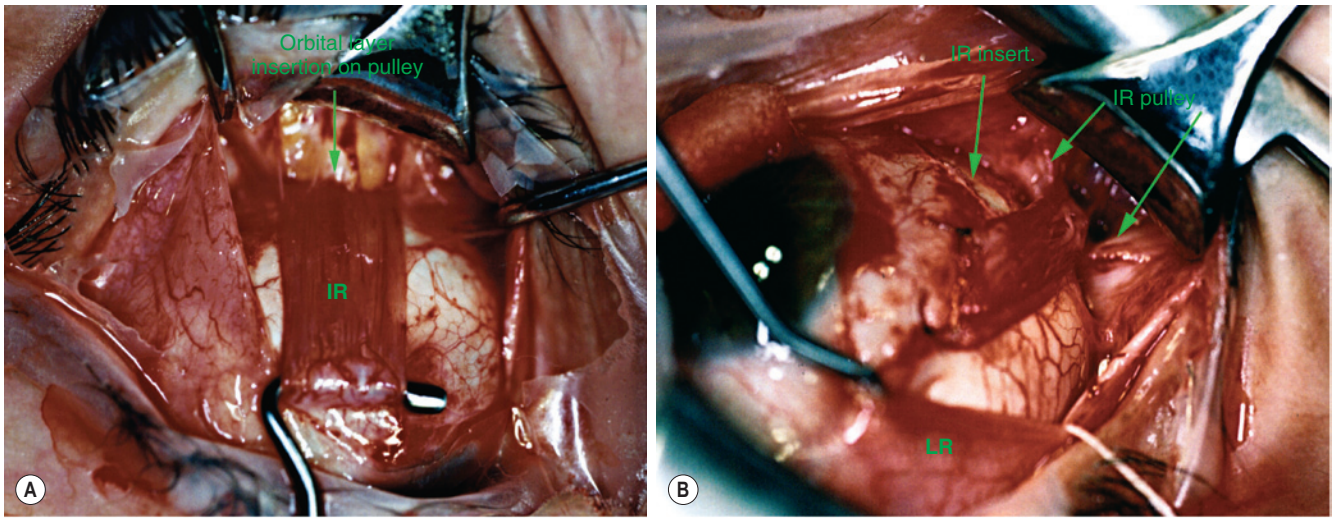

Fig. 74.5 Surgical exposure of right inferior rectus (IR) region, as seen from above the patient, using incision at the conjunctival limbus. The lateral rectus (LR) of this patient was palsied; magnetic resonance imaging showed that the deep LR belly was markedly atrophic. (A) Inferior rectus muscle, engaged on hook, courses posteriorly into the glistening white tissue of the IR pulley. Note fine connective tissue bands marking the anterior part of the orbital layer insertion into the pulley. (B) The IR tendon has been disinserted from the sclera, leaving a white line at the original insertion site. The IR tendon has been transposed temporally to adjoin the inferior pole of the insertion of the paralyzed LR muscle. Note the diagonal path of the transposed IR towards the original location of the IR pulley, now more visible as a discrete structure.

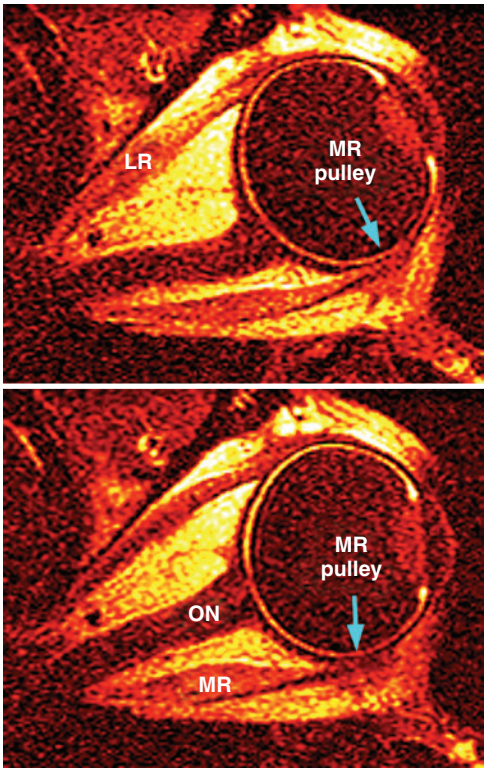

Fig. 74.6 Gadodiamide contrast-enhanced axial magnetic resonance image scans of a right orbit in central gaze and in abduction. Note that the medial rectus (MR) pulley moves anteriorly in abduction by the same amount as the MR insertion. LR, Lateral rectus muscle; ON, optic nerve.

EOM contraction. This may be seen in the axial, contrast-enhanced MRI scans in Fig. 74.6. Pulley tissues move in coordination with the insertion and sclera, although histological examinations show the absence of connections between these tissues. Coronal MRI scans shows changes in the anteroposterior position of the inflections in rectus EOM paths in tertiary gaze positions.[15] This behavior has been confirmed that all four rectus pulleys.

The IO pulley shifts anteriorly in supraduction, and posteriorly in infraduction. This shift is easily appreciated from the obvious change in the IO's path observed by MRI in the quasi-sagittal plane parallel to the long axis of the orbit (Fig. 74.7). As is also evident from Fig. 74.7 the IO pulley moves by half as much as the IR insertion,[12] as necessary to for optimal control of the IO's pulling direction.

The SR pulley also has discrete mechanical couplings to other pulleys.[10] The most prominent such coupling is a dense band extending from the lateral border of the conjoint SR/LPS pulley to the superior border of the LR pulley. This band contains dense collagen and elastin throughout, and divides the orbital lobe of the lacrimal gland.

Although the rectus and IO pulleys are mobile along the lengths of their EOMs, pulleys are located quite stably and stereotypically in the transverse directions. Since EOMs must transit their pulleys, and the pulleys encircle the EOMs, pulley locations may be inferred from EOM paths. Even the anteroposterior pulley locations can be determined by imaging EOM path inflections produced by the pulleys in eccentric gaze positions. In describing pulley location, it is essential that a coordinate reference be defined. Table 74.1 specifies the coordinates of the rectus pulleys of normal young adults in a coordinate system originating in the globe center. Remarkably, the 95% confidence intervals for normal rectus pulley coordinates range over less than ±0.6 mm.[16] Precise

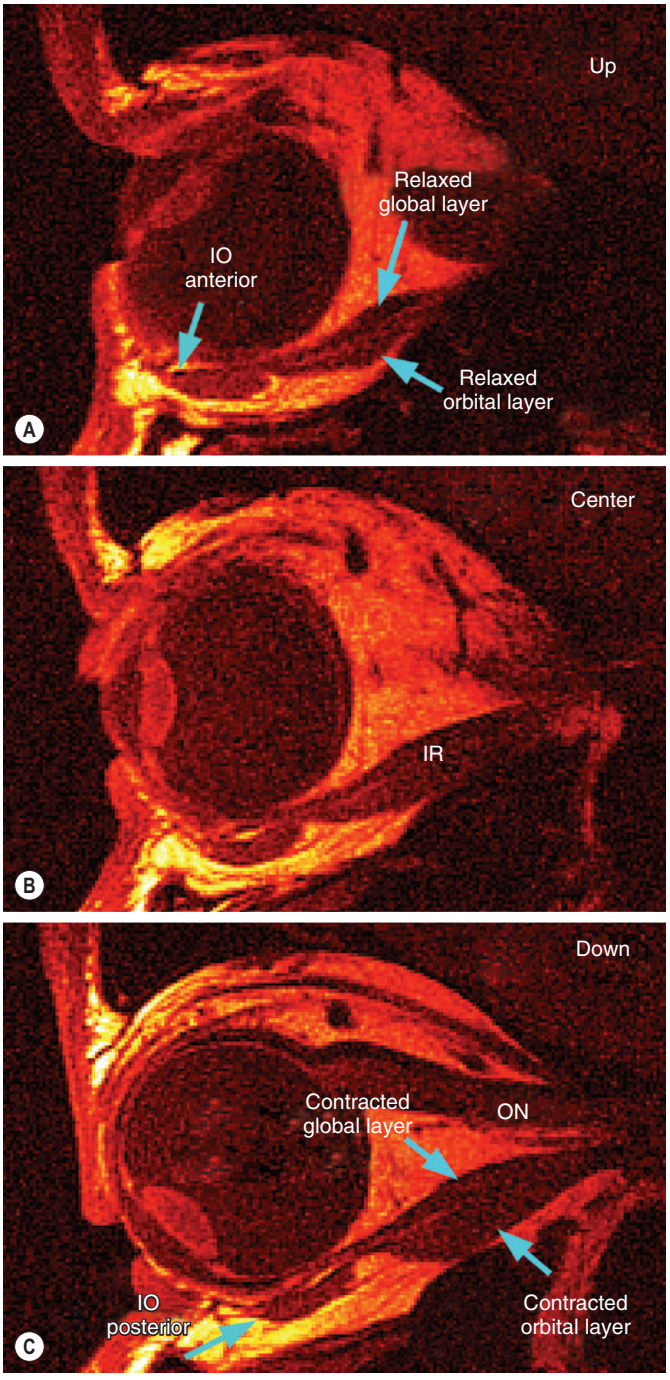

Fig. 74.7 Quasi-sagittal (parallel to the orbital axis) magnetic resonance images (2 mm thickness, T1 weighted) of orbit in three gaze positions. Note demarcation of the orbital and global layers of the inferior rectus (IR) muscle by a thin, bright, fatty septum. The global layer, in continuity with the scleral insertion, exhibits modest contractile thickening in infraduction. The orbital layer, terminating in the IR pulley (not directly seen), exhibits marked contractile thickening in infraduction. The inferior oblique (IO) muscle shifts posteriorly with infraduction, but only half as far as the lens and other ocular structures. ON, Optic nerve.

pulley placement is important since the pulleys serve as the functional mechanical origins of the EOMs, and since the pulleys are close to globe center. Normal aging causes cause inferior sagging of the horizontal rectus pulleys by 1–2 mm, and more in the sagging eye syndrome,[17] as described below. Vertical rectus pulley positions change little over the lifespan.[17]

The globe itself makes translations – linear shifts – during ocular ductions.[16] The globe translates 0.8 mm inferiorly from 22° infraduction to 22° supraduction, for example. The globe also translates slightly nasally in both abduction and adduction. These small translations affect EOM pulling directions since the globe center is only 8 mm anterior to the rectus pulleys.

Rectus pulleys make small transverse shifts under physiologic conditions.[16] The MR pulley translates 0.6 mm superiorly from 22° infraduction to 22° supraduction. Due to the insertion upon it of the IR's OL, the LR pulley translates 1.5 mm inferiorly from infraduction to supraduction. The IR pulley, due to the insertion upon it of the IO's OL, is drawn 1.1 mm medially by IO contraction in supraduction, but 1.3 mm temporally during IO relaxation in infraduction. The SR pulley is relatively stable in the mediolateral direction,[16] but moves inferiorly in supraduction as it is posteriorly displaced by the SR OL, and superiorly in infraduction as the SR OL relaxes. The small gaze-related shifts in rectus pulley positions are also highly uniform among people with normal eyes.

Table 74.1 Rectus pulley locations

	Millimeters from globe center		
Extraocular muscle	**Lateral**	**Superior**	**Anterior**
Medial rectus	−14.2 ± 0.2	−0.3 ± 0.3	−3 ± 2
Lateral rectus	10.1 ± 0.1	−0.3 ± 0.2	−9 ± 2
Superior rectus	−1.7 ± 0.3	11.8 ± 0.2	−7 ± 2
Inferior rectus	−4.3 ± 0.2	−12.9 ± 0.1	−6 ± 2

Rectus pulley positions averaged over 11 normal young adults. For lateral and superior positions, error limits represent 95% confidence intervals. For anteroposterior position, the error limits represent the magnetic resonance image plane thickness (2 mm).
Data from Clark RA, Miller JM, Demer JL. Location and stability of rectus muscle pulleys inferred from muscle paths. Invest Ophthalmol Vis Sci 1997; 38: 227–40.

Kinematics of pulleys[18]

Rectus pulleys are fundamental to ocular kinematics – the rotational properties of the eye. Successive rotations are not mathematically commutative, in that final eye orientation depends on the order of rotations.[19] Each combination of horizontal and vertical orientations of an arbitrary sphere could be associated with infinitely many torsional positions.[19] The eye, however, is constrained (when the head is upright and immobile) by a relationship known as Listing's Law (LL), a statement of classical observations that the torsion of the eye in any gaze direction is that which it would have if it had reached that gaze direction by a single rotation from primary eye position about an axis lying in a plane, Listing's plane.[19] LL is always satisfied if the ocular rotational axis shifts by exactly half of the shift in ocular duction.[20] For example, if the eye supraducts by 20°, then the vertical axis about which it rotates for subsequent horizontal movement should tip back by 10°. This is called the "half-angle rule." Conformity to the half-angle rule makes the sequence of ocular rotations appear commutative to motor control centers in the brain.[21]

Appropriate rectus pulley position implements the half-angle kinematics required by LL. Consider the horizontal rectus EOM schematized in Fig. 74.8A. It is seen from small angle trigonometry that the EOM's pulling direction tilts posteriorly by half the supraduction angle if the pulley is located as far posterior to globe center as the insertion is anterior to globe center. All four rectus EOMs behave identically in this regard.[19] Since the rotational axis of each EOM force rotating the globe observes half-angle kinematics, overall ocular rotation conforms to LL.

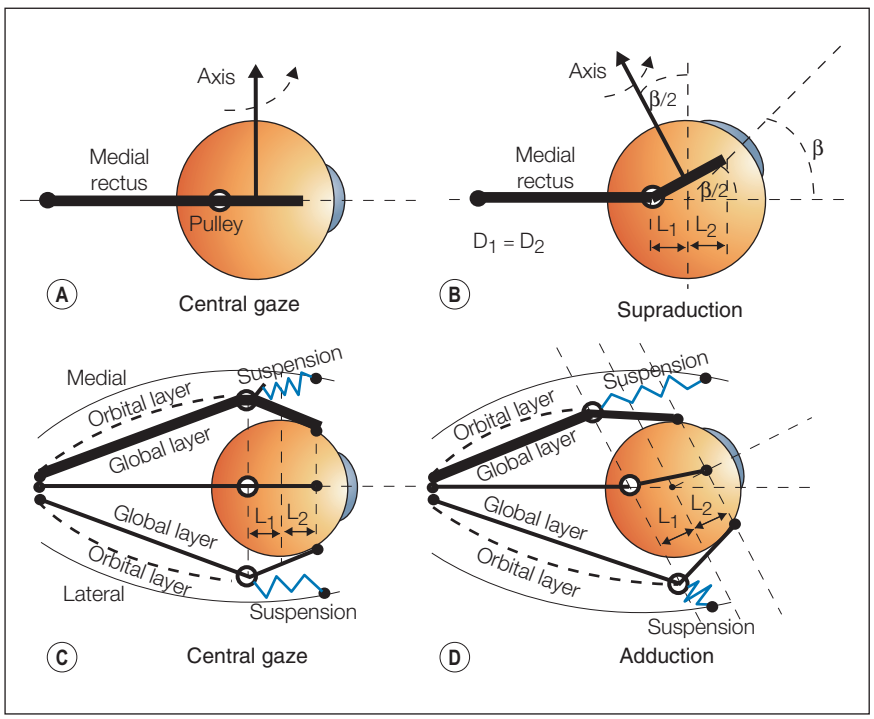

Fig. 74.8 Relationship of pulleys to the rotational axis of horizontal rectus muscles. (A) The medial rectus muscle's rotational axis is perpendicular to the segment between the pulley and the scleral insertion, and is thus vertical in central gaze. (B) In supraduction of angle β, the distance L1 from the pulley (ring) to globe center is equal to distance L2 from globe center to the insertion. This causes the muscle's rotational axis to tilt posteriorly by approximately angle β/2, the half-angle rule to implement Listing's Law. (C) Axial view showing pulleys (depicted as rings) of the horizontal rectus muscles in central gaze. (D) In adduction, the contracting medial rectus orbital layer shifts its pulley posteriorly, while the relaxing lateral rectus orbital layer allows its pulley to move anteriorly.

Were primary and secondary gazes the only ones required, rectus pulleys could be rigidly fixed. However, tertiary gazes such as adducted supraduction require the rectus pulleys actively to shift anteroposteriorly in the orbit along the EOM's length, so that the relationship is maintained in an oculocentric reference (Fig. 74.8B,C). This is the reason for coordinated anteroposterior motion of rectus pulleys described above. The *active pulley hypothesis* (APH) states that these shifts are generated by the contractile activity of the OLs of each EOM acting against the elasticity of the pulley suspensions.[1,19]

Under coordinated control, rectus pulleys shift anteroposteriorly in the orbit by the same distance as the scleral insertions. Nevertheless, the OL and GL require different neural commands. The GL's mechanical load is predominantly the viscosity of the relaxing antagonist EOM, a load proportional to the speed of eye rotation, and thus slight during sustained eccentric gaze.[1] The OL's mechanical load, however, is due to the elasticity of the pulley suspension. This elastic load is independent of speed, but proportional to gaze angle. Electromyography (EMG) in humans correspondingly shows high, phasic GL activity during rapid saccadic eye movements, with only a small, sustained activity change in eccentric gaze. In the OL, EMG shows sustained, high activity in eccentric gaze, but no phasic activity during saccades. Differing mechanical loads on OL and GL are associated with the corresponding biological specializations. The ratio of motor nerve to muscle fiber is exceedingly low in the GL, averaging about one for human rectus EOM,[1] and reflecting the high precision required of ocular rotation. The ratio is higher in the OL, averaging five fibers per axon in horizontal rectus and 2.5 in vertical rectus EOMs, reflecting less precision for pulley control.

While rectus EOMs alone can implement all the eye movements conforming to LL, some eye movements do not conform. Violations of LL occur during the vestibulo-ocular reflex (VOR)[22] and during convergence,[19] and involve the oblique EOMs.

Considered by itself, the IO muscle also observes half-angle kinematics. As noted above, the IO pulley shifts by half of vertical ocular duction because the IO OL inserts on the IR and LR pulleys.[12] In primary position, these two OL insertions constrain the distal IO to be co-planar with the IR and LR pulleys, so that IO rotational axis is perpendicular to the primary gaze line, and perpendicular to the rotational axes of the rectus EOMs. In the Listing's coordinate system, this gives the IO a purely torsional action, capable of nothing other than violating LL. (In other coordinate systems, particularly the coordinate system employed for clinical examination, the IO also exhibits the familiar supraducting and abducting actions.) With oblique gaze shift from supraducted adduction to infraducted abduction, the IO pulley moves anteroposteriorly by half the movements of the IR pulley.[12]

The SO, with its immobile pulley at the trochlea, is actually the exceptional case. The broad, thin SO insertion on the sclera resists sideslip by virtue of its fan-like shape as it courses from the narrow trochlea. The SO approximates half-angle kinematics because the distance from trochlea to globe center is approximately equal to distance from globe center to insertion, the SO rotational axis shifts by half the horizontal duction.[19]

In addition to convergence, stereopsis requires torsional eye rotations such as excyclotorsion in convergence that violates LL.[19] During asymmetrical convergence to a target aligned to one eye, this extorsion occurs in both eyes, independent of eye position.[23] MRI during 22° asymmetrical convergence in the orbit aligned to the target, analysis of IR, MR, and SR muscle paths demonstrated 0.3–0.4 mm extorsional shift of the their pulleys in the coronal plane.[23] Thus, during convergence, the rectus pulley array rotates in the coronal plane in coordination with ocular torsion, changing the pulling directions of all of the rectus EOMs without altering their fundamental half-angle kinematics. The torsional rotation of the pulley array is implemented by the oblique EOMs. Contraction of the IO, directly demonstrated by MRI during convergence, excycloducts the positions of the LR and IR pulleys.[23] Inferior LR pulley shift is coupled to lateral SR pulley shift via the dense connective tissue band between them.[10] The SO's OL inserts on the SO sheath posterior to the trochlea, with both the tendon and sheath reflected via that rigid pulley. Anterior to the trochlea, the SO sheath inserts on the SR pulley's nasal border. Relaxation of the SO OL during convergence is consistent with electrophysiologic recordings in the monkey trochlear nucleus. The inframedial peribulbar smooth muscle might also contribute to rectus pulley extorsion in convergence.

Physiologic ocular counter-rolling (OCR) is a torsional VOR responsive to changes in head orientation relative to gravity, as sensed by the inner ear. Since OCR can change torsion independent of horizontal or vertical eye position, it violates LL. MRI in right versus left lateral decubitus positions demonstrates shift in torsional position of the rectus pulley array directionally consistent with the OCR, and associated with SO contraction and IO relaxation.[22]

Thus, all six EOMs have pulleys that cause their force directions to vary by the half the angle of ocular duction. This "half-angle" behavior makes the sequence of ocular rotations effectively commutative. For visually guided eye movements with the head upright and stationary, half-angle behavior gives the incidental benefit of conformity of ocular torsion to LL. In special situations, non-LL torsion is advantageous: in convergence, torsion facilitates stereopsis, and for the VOR, torsion facilitates retinal image stability during head motion. Rectus pulley reconfiguration coordinated with ocular torsion maintains the half-angle behavior required by commutative ocular kinematics even during deviations from LL.

Transverse compartmentalization of extraocular muscles

It is paradoxical that the robust kinematic behavior of the pulleys appeared to prohibit one prominent violation of LL: the VOR velocity axis changes by one-fourth eye position, not half as for LL,[24] yet motoneurons controlling cyclovertical EOMs do not command the violation.[25] Since these violations of LL require torsion generation without cyclovertical EOM action, horizontal rectus EOMs must somehow generate ocular torsion. This insight motivated the discovery of transverse compartmentalization,[26,27] a general feature of most EOMs.

Anatomy of compartmentalization

The abundance of fibers in each rectus EOM[28] suggests that individual EOMs could perform several functions using

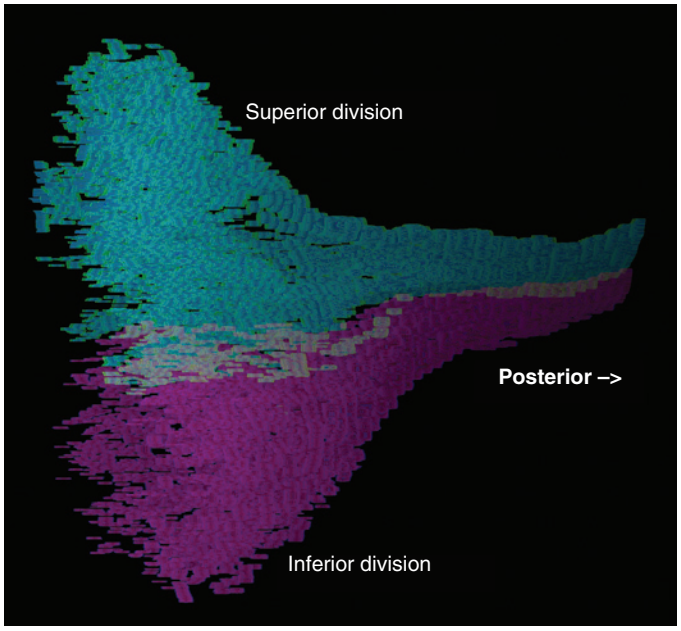

Fig. 74.9 Reconstruction of the intramuscular abducens nerve within the human lateral rectus muscle demonstrating non-overlapping superior and inferior divisions of the nerve innervating the corresponding compartments of extraocular muscles fibers.

specialized fiber groups. Motor nerves innervating horizontal rectus EOMs bifurcate into about equal regionally segregated intramuscular arborizations (Fig. 74.9).[27] Longitudinal LR splitting is evident in several congenital cranial dysinnervation disorders.[29–31]

The abducens nerve often divides into two or more trunks,[32,33] sometimes widely separated at the cavernous sinus.[32] The MR motor nerve also bifurcates into superior and inferior divisions.[27] The IO is also innervated in compartmental fashion by separate motor nerve trunks.[34] The IR has a selective lateral trunk overlapping arborization of another trunk throughout the entire EOM.[27] However, the SR lacks selective compartmental innervation.[27]

The SO is innervated in non-overlapping medial and lateral compartments by two divisions of the trochlear nerve, medial and lateral.[34,35] While its tendon insertion is broad, SO fibers roll into cylindrical configuration passing through the trochlea and unroll posterior to the trochlea where they become contiguous with muscle fibers.[34,35] The medial SO compartment is contiguous with tendon fibers inserting predominantly on the equatorial sclera that would have best mechanical advantage to produce incycloduction. The lateral SO compartment is contiguous with tendon fibers inserting predominantly on posterior sclera that would have best mechanical advantage to produce infraduction.

Compartmental biomechanics

EOMs and tendons are composed of parallel fiber bundles having sparse transverse interconnections. Tensile force transmission in arbitrary groupings of fibers is >90% independent of adjacent fibers,[36] as confirmed after marginal myotomy or tenotomy.[37] This supports empirically based EOM surgeries involving portions of rectus[38] or SO tendons,[39] and implies that EOM fiber groups can transmit tension independently, subject only to coordination of neural commands.

Strabismus surgeons have recognized that transverse shifting of rectus EOM insertions imparts cyclotorsion.[40,41] Computational simulation using the *Orbit 1.8* model suggests such shift could redirect 13–15% of LR force to vertical action, and 16–22% to cycloduction.[42] Compartmentalization could, therefore, create the torsion required to produce the LL violations that occur during the VOR.

Functional anatomy of compartmentalization

A similar ratio of inferior compartment to total LR transverse dimension prevails in cases where structural demarcations are evident,[43] consistent with postmortem nerve tracing from histology showing the ratio ranging from 0.4 to 0.6.[27]

During contraction, total EOM volume[44] and peak cross-section increase, and the peak shifts posteriorly,[43] usually by ~2 mm.[45] The best contractility index is change in posterior partial volume (PPV),[45] which robustly correlates with duction for horizontal rectus EOMs.[45] Correlations for maximum cross-section are almost as strong.[45] MRI studies have divided these EOMs into inferior and superior halves that are considered to represent the compartments. For both LR and MR, the inferior compartments are slightly larger than the superior compartments.[26] Contractility is similar for convergence and conjugate adduction in both inferior and superior LR compartments, and for the inferior MR compartment. However, the superior MR compartment exhibits much greater contractility in adduction than in convergence.

In normal subjects tilted on-side to produce ocular counter-rolling, MRI has demonstrated contractile PPV changes in the inferior but not superior LR compartments, and borderline contractile changes in superior MR but not inferior compartment.[26] These differential compartmental changes presumably contribute to cyclotorsion.[26] Differential compartmental changes in PPV were absent in vertical rectus EOMs.[26] During vertical duction, there are contractile changes in maximum cross-section and PPV of the superior MR compartment, without changes in the inferior MR compartment, or in either LR compartment.[46] Differential compartmental MR contractility might thus augment vertical duction.

Vertical fusional vergence

During vertical fusional vergence (VFV) in normal subjects induced by a monocular 2Δ base up prism, the LR exhibits differential compartmental contraction, along with a complex pattern of differential contractility in the SO compartments.[47] Differential contractile behavior of the LR during VFV suggest that the EOM mechanisms that normally compensate for vertical heterophoria are highly complex, presumably because of the necessity to regulate horizontal and torsional eye orientation.

Compartmental brainstem control

Differential compartmental behavior of EOMs requires control by selective motoneuron pools. The A and B groups of MR

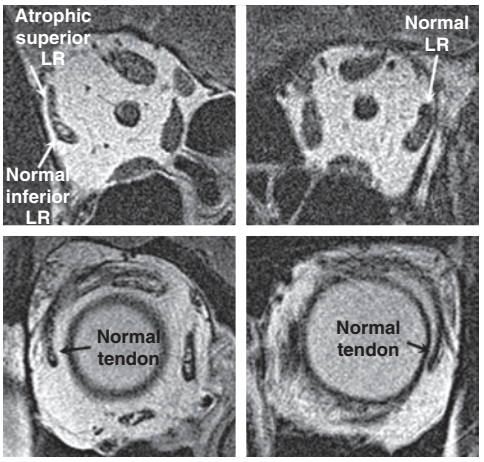

Fig. 74.10 Quasi-coronal magnetic resonance imaging (MRI) demonstrating right superior compartment lateral rectus (LR) palsy causing selective atrophy of the ipsilesional superior LR compartment.

motoneurons in the oculomotor nucleus are widely separated by the vertical rectus and IO motoneurons.[48] Both version and vergence signals are observed in MR and LR motoneurons.[49] The abducens nucleus has cyclovertical premotor inputs, including vestibular inputs from vertical eye movement pathways.[50] Neuroanatomic studies have suggested topographical segregation of motoneuron pools to the two LR compartments in monkey.[51]

Compartmental extraocular muscle pathology

Denervated human EOMs exhibit atrophy of cross-section and volume, and loss of contractile thickening.[52] About 30% of abducens palsy cases exhibit greater atrophy of the superior than inferior LR (Fig. 74.10), usually with ipsilesional hypotropia suggesting preserved inferior compartment function.[53] Many patients with paretic abduction deficiency have selective superior compartment LR weakness.[53] Many cases of isolated LR palsy exhibit hypertropia that increases in abduction, suggesting relationship to residual LR contraction.[54]

Pathologic anatomy of pulleys

Three forms of pulley pathology cause strabismus: heterotopy, instability, and hindrance. Heterotopy may be congenital or acquired.

Congenital pulley heterotopy

Many congenital cases of incomitant cyclovertical strabismus are associated with heterotopy of one or more rectus EOM pulleys >2 standard deviations from normal. Patterns of incomitance in individual patients consistently match those predicted by computer simulation based on pulley locations, suggesting that pulley heterotopy *caused* the strabismus.[55] In most of these cases, the strabismus exhibits "A" or "V" pattern. In a "V" pattern, for example, there is greater esotropia or less exotropia in downward gaze, with overelevation and overdepression in adduction (Fig. 74.11B). While this pattern of versions has been described as exhibiting "IO overaction" and "SO underaction," the pulley locations fully explain it, without necessity of abnormal contractile behavior by the oblique EOMs. Conversely, in "A" pattern strabismus, there is more esotropia or less exotropia in upward than downward gaze, and one or both LR pulleys are typically located superior to the MR pulleys (Fig. 74.11A). While this pattern of versions has been described as exhibiting "IO underaction" and "SO overaction," pulley locations fully explain the strabismus pattern, without necessity of abnormal contractile behavior by the oblique EOMs. The foregoing imaging findings suggest that clinical nosology be revised to avoid erroneous implications of oblique EOM contractile dysfunction, which can also be excluded directly by MRI observations of EOM function. For example, MRI demonstrated absence of correlation between IO size and contractility, and absence of correlations with variations in elevation in adduction in SO palsy. Evidence suggests that ocular torsion strabismus did not cause the pulley heterotopy: (1) typically only one or two pulleys were heterotopic; (2) ocular torsion was quantitatively insufficient to account for the pulley heterotopy; and (3) patients with similar ocular torsion due to SO palsy lack pulley heterotopy. Extreme pulley heterotopy is associated with esotropia and hypotropia in axial high myopia, the "heavy eye syndrome."[56]

Acquired pulley heterotopy

This may be the simple consequence of aging. The horizontal rectus pulleys of normal older people symmetrically sag inferiorly, probably causing the typical reduced supraduction range.[17] Histological examination shows that the dense connective tissue in the pulley tissues of children becomes attenuated in the elderly, with particularly striking age-related degeneration of attachments of the IO OL to connective tissues.[10]

Most cases of acquired pulley heterotopy are due to sagging eye syndrome (SES). Patients with SES typically exhibit adnexal laxity, including blepharoptosis, superior lid sulcus defect, and floppy lower lids.[17] Many have a history of blepharoplasty, brow lift, or facelift surgery. These changes are consistent with histologically demonstrable connective tissue degeneration.[10,57] MRI findings in SES are stereotypic. While orthotropic older controls exhibit 2 mm more LR pulley sag than young adults, LR pulley sag exceeds 6 mm in SES. LR sag is symmetrical in age-related distance esotropia (Fig. 74.11C), but in cyclovertical strabismus LR sag in the hypotropic eye exceeds its fellow by >1 mm (Fig. 74.11D). Degeneration of the LR-SR band in SES frequently causes temporal tilting of the superior aspect of the normally vertically oriented LR. Other rectus pulleys are also displaced in SES. EOMs are also elongated in SES. For example, the LR is elongated by ~50% from the normal value of 30–45 mm! This may be why surgery for age-related distance esotropia by MR recession requires dose augmentation in SES.[58]

Pulley instability

Pulleys may become unstable and shift markedly with gaze to alter EOM action, sometimes in one gaze position only. Inferior LR pulley shift in adduction may be acquired, and

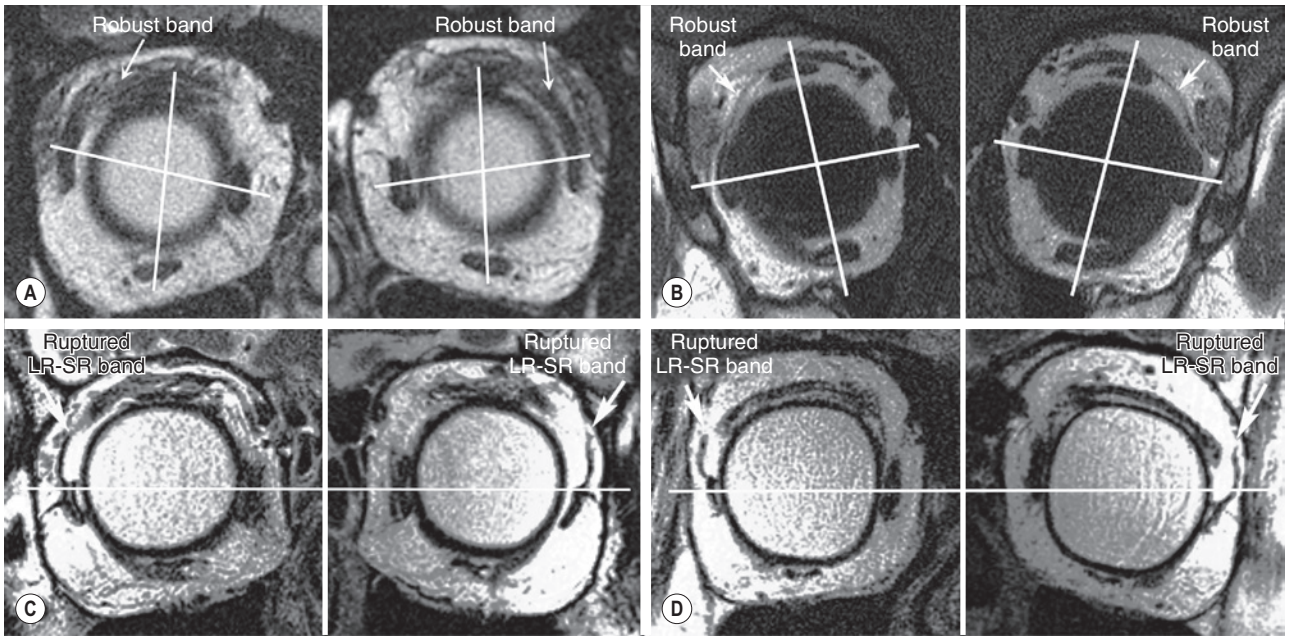

Fig. 74.11 Coronal plane MRI in strabismus due to pulley heterotopy.[63] (A) Typical pattern associated with congenital A pattern strabismus and over-depression in adduction, with LR pulley located superior to MR pulley. (B) Typical pattern associated with V pattern strabismus and over-elevation in adduction, with medial rectus (MR) pulley located superior to lateral rectus (LR) pulley. (C) Typical pattern of symmetrical LR pulley sag due to bilateral rupture of the LR-SR band ligament resulting in symmetrical inferior displacement of the LR, and presenting as age-related distance esotropia. (D) Typical pattern of asymmetrical LR pulley sag due to bilateral rupture of the LR-SR band ligament resulting in asymmetrical inferior displacement of the LR greater on the left than right, and presenting as left hypotropia and left excyclotropia. *(From Demer, JL. The Apt lecture: Connective tissues reflect different mechanisms of strabismus over the life span. J AAPOS 2014; 18: 309–315.)*

can mimic the restrictive hypotropia in adduction traditionally attributed to SO tendon sheath pathology (Brown syndrome), or "X" pattern exotropia.[59] An exaggeration of the physiologic excyclo-rotation of the rectus pulley array in convergence may produce a marked "Y" or "T" pattern exotropia, one present only in elevated gaze. Pulley instability can be diagnosed only by orbital imaging in multiple gaze positions. The most common instability is downward shift of the LR in supraduction or adduction,[60] the latter producing a restrictive hypotropia clinically identical to Brown syndrome of the SO tendon sheath.[60] Temporal shift of the SR is occasionally associated with inferior LR shift.

Pulley hindrance

Abnormally anterior pulley location, or failure of a pulley to move posteriorly during EOM contraction, can result in pulley collision with the scleral insertion and hinder duction. This is also the case after fadenoperation, where there is restriction to passive forced duction of the eye. Hindrance to posterior IR pulley shift due to scarring from inferior orbital[61] or lid surgery creates incomitant, restrictive hypertropia.[62]

Introduction

"I have double vision"… "I sometimes have double vision"… "Images overlap"… "Images tilt"… "Images shake"… "My eyes are crossed"… "My eyes are strained"… "My neck is sore"… "My eyes just don't work together!"

Disorders of binocular vision, disruption of ocular alignment and motility can induce numerous subjective symptoms; sorting through these falls within the domain of the orthoptic evaluation.

The aim of this chapter is to:

- describe the concept of orthoptic evaluation and orthoptic status;
- outline indications for conducting an orthoptic evaluation;
- outline an approach to the basic orthoptic evaluation;
- highlight important factors when designing a patient-specific evaluation.

Descriptions of strabismus are usually technically driven and communicate information to the clinician about the patient's binocular status. This chapter covers the principles underlying a basic orthoptic evaluation.

This is not a "how to" chapter. Excellent resources are available describing tests and how to perform them.[1–4] Nor does it deal with the neurophysiology of binocular vision and associated cortical pathways. The reader is again directed to other excellent sources.[3,5] This chapter also assumes that the reader is familiar with strabismus terminology (e.g. manifest, latent, comitant, incomitant, etc.) and a basic understanding of binocular vision and amblyopia.

Defining the concept of orthoptic evaluation and orthoptic status

The orthoptic paradigm for disorders of binocular vision involves generating clinical data through a standardized *orthoptic evaluation*, interpreting the results to define the *orthoptic status* of the patient, and to use this information to formulate the best management approach.

The orthoptic evaluation

The *orthoptic evaluation* consists of three essential components (Fig. 75.1):

- motor evaluation;
- sensory evaluation;
- vision evaluation.

The terms "motor evaluation" and "sensory evaluation" have been used before.[1] "vision evaluation" has been added as a separate component. Each component has main themes (Fig. 75.2).

The vision evaluation

Symptoms relating to the subjective clarity of vision are elicited from the history and the central visual acuity is determined under monocular and binocular conditions.

As well as the ocular and visual pathway integrity, it is also influenced by the sensory and motor systems. For instance, a patient may use accommodation-convergence to help control an exodeviation, thus blurring their binocular distance visual acuity. Conversely, vision can affect the motor and sensory evaluation. Reduced vision weakens the effectiveness of these systems and can lead to a degradation of the orthoptic status.

An accurately performed vision evaluation can:

- determine selection of appropriate motor and sensory tests and the reliability of the results; poor vision in one or both eyes reduces accuracy of quantifying strabismus and negatively impacts sensory testing;
- assess the significance of amblyogenic mechanisms when present;
- determine the outcome of management, e.g. correction of refractive error or amblyopia therapy
- distinguish between suppression and amblyopia when evaluating sensory adaptations.

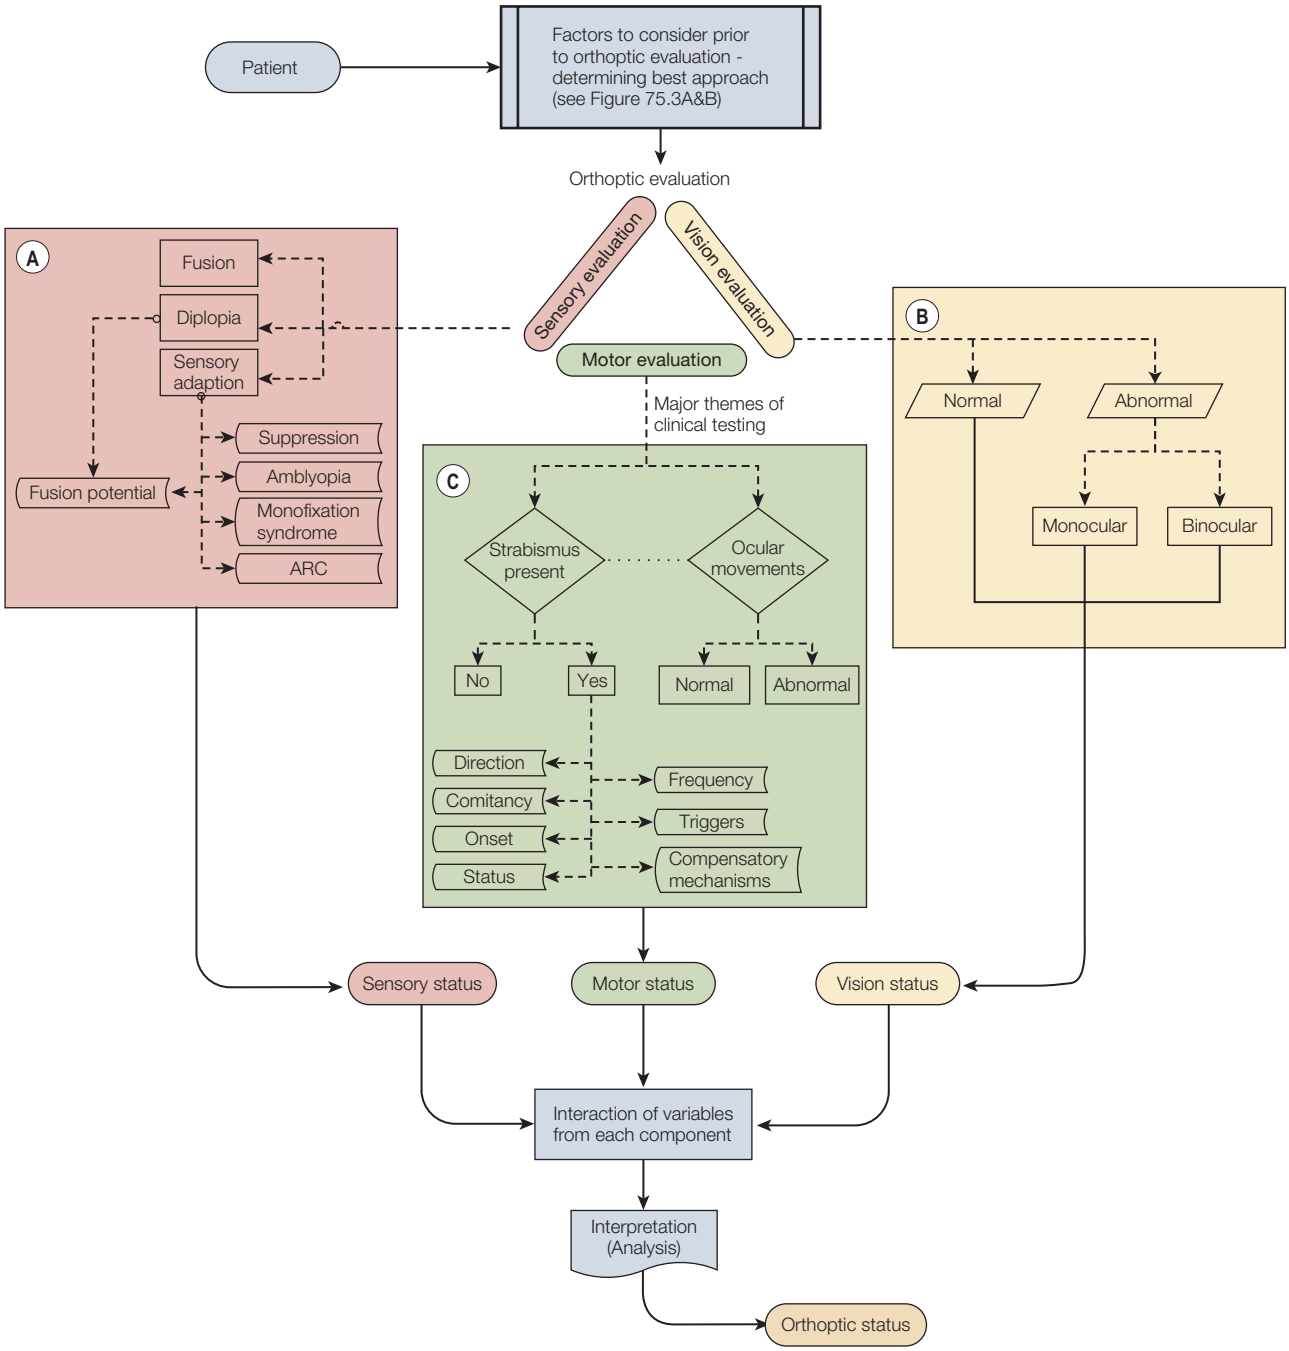

Fig. 75.2 The orthoptic paradigm pathway: main themes and determination of orthoptic status. Defining the orthoptic status involves a series of steps that ensures efficiency and accuracy. The first step identifies factors to help determine the best approach for a given patient or situation. Next involves specialized clinical testing to assess major themes within each of the core components (A, B, and C). The interaction between each component is analyzed and interpreted. The outcome constitutes the orthoptic status of a patient. This information is used to determine best management approach. (Additional details provided in Table 75.1.) ARC, Abnormal retinal correspondence.

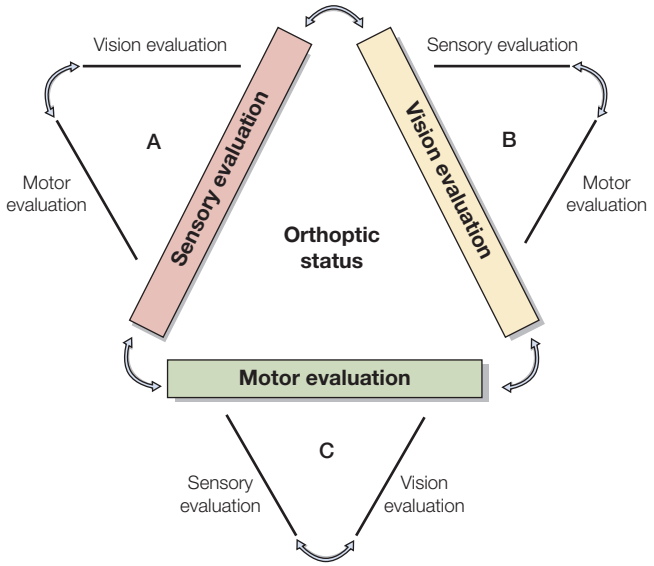

Fig. 75.1 Core components of the orthoptic evaluation. The orthoptic evaluation is represented as a triangle (or prism!). Each side represents one core component. Defining the orthoptic status of a patient requires information from each side of the intact triangle. A triangle with symmetrical sides (i.e. the inner triangle with colored sides) represents an evaluation requiring full assessment of all components. However, the dimensions may shift depending on clinical needs: (A) An orthoptic work-up weighted to a sensory evaluation. (B) An emphasis on a vision evaluation, e.g. amblyopia follow-up appointment. (C) An emphasis on a motor evaluation.

The sensory evaluation

The sensory evaluation represents the brain's processing of information coming from the two eyes. It is defined by the patient's subjective interpretation of this response. It is often the least understood component of the orthoptic evaluation and its important conclusions may be overlooked. The sensory evaluation has three main components: fusion, binocular diplopia, and sensory adaptions (Table 75.1).

Fusion

Fusion is the blending of an image from each eye into a single image. This necessitates the stimulation of corresponding retinal elements and occurs within the visual cortex.[5]

In order for fusion to occur, appropriate alignment of the visual axes and reasonable vision in each eye are necessary. However, several other clinical situations need to be recognized (Table 75.2). It is crucial to understand these to interpret how the eyes work together in order to avoid inappropriate management.

Diplopia

Binocular diplopia occurs when non-corresponding retinal elements of each eye are stimulated by the same object of regard in free space. As with fusion, it also represents a normal sensory system; however, one that is operating within an abnormal motor status, e.g. manifest deviation. Localization of diplopic images provides information about the direction and

Table 75.1 Sensory evaluation – assessment of the main themes

OBJECTIVES:

- To determine how the brain uses information from both eyes
- To determine what binocular information the brain permits the patient to perceive
- To determine if a normal sensory status (single vision with fusion) can be achieved (under the right setting)

SUBCOMPONENTS (MAIN THEMES):

- Fusion (including stereopsis)
- Diplopia
- Sensory adaptation (occurring secondary to disruption of motor system or vision during visually immaturity)

Specific items	Questions to be answered/comments
Fusion*	Present: yes or no? Actual versus potential? Actual fusion: • Occurs under normal binocular viewing conditions • Demonstrable with standard sensory tests e.g. Worth 4-dot test, Titmus stereotest, etc. Potential for fusion: • Fusion only achievable with use of prisms or major amblyoscope Quality? • Bifoveal fusion/central fusion: generally associated with high level stereopsis • Peripheral fusion: generally associated with reduced stereopsis and central suppression of one eye • Gross fusion: absence of stereopsis on clinical testing; binocular cooperation only demonstrable with minimally dissociated tests such as Bagolini striated lenses Strength? • Size of fusional amplitudes • Be aware of fragile or large amplitudes Quality and strength are regarded as stabilizing influences to maintain proper ocular alignment. Low-grade fusion (e.g. reduced or absent stereopsis on clinical testing) and fragile fusional amplitudes suggest a higher risk of losing control of an existing phoria or intermittent tropia or represent a suboptimal sensory outcome following previous strabismus management

Table 75.1 Sensory evaluation – assessment of the main themes—cont'd

Specific items	Questions to be answered/comments

Diplopia*	Is it true binocular diplopia?
	• Two images present both eyes open
	• Separation between images (exception can be torsional diplopia or with central fusion disruption)
	• One image eliminated with closure of either eye
	
	Image separation?
	• Horizontal, vertical, torsional, or combined
	
	Constant or intermittent?
	
	Is there appropriate localization of diplopic image?
	• Homonymous (uncrossed) diplopia with esotropia etc.
	• Confirms normal retinal correspondence
	
	Is diplopia eliminated by offsetting the deviation with prisms or major amblyoscope?
	• Does this permit fusion or utilize a pre-existing suppression area?
	• What components of the deviation and how much needs to be corrected?
	  • Horizontal, vertical, torsional component, or a combination
	  • Full correction vs. partial correction required

Sensory adaptation†	Does the patient have any binocular symptoms with both eyes open?
	If no, suggests presence of sensory adaptation in the setting of a manifest deviation
	
	Type of adaption?
	Suppression*
	• Only persists under binocular conditions
	• Area of suppression (in non-preferred eye) may include:
	  • visual field overlapping the preferred eye
	  • central suppression (macular area) with fusion involving peripheral retinal elements, e.g. monofixation syndrome
	• Depth of suppression
	  • diplopia appreciated under minimally dissociative conditions is considered fragile
	• Determine if there is fusion potential
	  • offset angle of deviation with major amblyoscope to simulate straight eye viewing condition
	Abnormal retinal correspondence*
	• Only persists under binocular conditions
	• Determine if fragile or well established – strabismus surgery may be contraindicated if well established
	Amblyopia*
	• Similar binocular sensory tests as suppression but with reduced monocular vision with closure of preferred eye
	• Responds to appropriate management if still within critical period

Sections correspond to Fig. 75.2A.
*Can exist with other sensory findings in the same patient.
†Specific to manifest or intermittent deviations.

Table 75.2 Defining the orthoptic status: examples of interactions between sensory and motor features (fusion and strabismus)

Situations when fusion occurs in the setting of a manifest deviation	
Small-angle heterotropia	Manifest deviation (less than 10 prism diopters) associated with peripheral fusion and mild amblyopia, e.g. monofixation syndrome
Well-established ARC	Fovea of fixating eye corresponds to a non-foveal point in the deviating eye Fusion, at best, is peripheral and usually fragile Clinical concern is for binocular relationship to persist after surgical correction resulting in postoperative diplopia
Fusion potential	Fusion under normal viewing conditions is not present; however, it can be demonstrated by "simulating" normal alignment with the use of prisms or major amblyoscope
Intermittent manifest deviation	A normal sensory status (presence of fusion) when the deviation is controlled (i.e. not manifest) Re-evaluation of alignment is warranted in presence of a presumed manifest deviation but a sensory status that indicates fusion
Situations when fusion occurs only in certain positions of gaze	
Incomitant strabismus with limited ocular movement	Visual axes become aligned in a certain gaze direction permitting fusion; diplopia/suppression may be evident in all other positions where the deviation is manifest, e.g. normal alignment in left gaze with a right abduction deficit Patients with this motor finding are not expected to have amblyopia or ARC
Incomitant strabismus without limited ocular movement	Includes strabismus patterns with: Distance/near disparities e.g. convergence excess type esotropia where esotropia may only be present at near "A" or "V" pattern with no manifest deviation in one vertical gaze position and a significant deviation in opposite direction

Continued

Table 75.2 Defining the orthoptic status: examples of interactions between sensory and motor features (fusion and strabismus)—cont'd

Situations when fusion may be influenced by refractive status	
Fully refractive accommodative esotropia	Esotropia eliminated by full correction of hyperopic refractive error
Intermittent exotropia	Improved control of an exodeviation after correction of myopia, i.e. improved vision and/or stimulation of accommodation helps control the deviation and promotes fusion

Above examples illustrate the ability to achieve fusion in the setting of an abnormal motor status.
ARC, Abnormal retinal correspondence.

comitancy of the ocular misalignment. Table 75.1 describes other important issues related to the evaluation of diplopia.

Sensory adaptions

A sensory adaption is a cortical defense mechanism. The goal is to prevent the appreciation of an unwanted image in the setting of abnormal binocular alignment. These develop during the visually immature period but, once established, can persist throughout life. In some cases, a crude level of binocular cooperation still exists. Strabismus during visual immaturity is a common stimulus for sensory adaptations. Thus, the absence of diplopia in the presence of a manifest deviation is an important clue to the age at onset. The commonest sensory adaption is cortical suppression where the visual field of the deviating eye that overlaps with the fixating eye is suppressed.[6] Other adaptions include: central suppression scotoma with peripheral fusion (e.g. monofixation syndrome), amblyopia, and abnormal retinal correspondence (see Fig. 75.2A). Identification of a sensory adaption is crucial to strabismus management and to predict the prognosis for restoring a normal sensory and motor status.

An accurately performed sensory evaluation can:

- define binocular symptoms (or lack of expected symptoms) in the presence of an abnormal motor or vision status;
- determine the actual and potential ability for the two eyes to work together;
- identify potential barriers for the eyes to work together, e.g. torsion, central fusion disruption;
- predict if surgical correction of strabismus will re-establish fusion and/or eliminate binocular symptoms, or identify risks of creating binocular symptoms.

The motor evaluation

The motor evaluation determines the presence and degree of a strabismus or ocular motility problem. These features are defined by their characteristics, e.g. comitant versus incomitant, and are discussed in detail in Table 75.3.

An accurately performed motor evaluation can:

- determine if a patient's symptoms are due to strabismus;
- determine function of the extraocular muscles, as well as the integrity of the neurological pathways and the other structures involved in movement of the eyes;
- identify strabismic patterns to help select best management strategies.

Defining the orthoptic status: putting it all together

The interplay between vision, sensory, and motor evaluations defines the *orthoptic status* of the patient. Correctly interpreting these interactions is crucial to understanding the test results. It is essential to correlate clinical findings with the patient's symptoms, or, in some cases, lack of symptoms. Figure 75.2 outlines this process, while Fig. 75.3A,B illustrates important pre-testing factors that also influence the final orthoptic status. Clinicians need to have an in-depth understanding of the synergy between these features and the various outcomes that can arise to ensure appropriate management. Table 75.2 gives some examples of these interactions.

Defining the orthoptic status can be a daunting task. This can be particularly confusing in patients who may have more than one motor and sensory finding (see Table 75.2: "intermittent manifest deviation" and "incomitant strabismus"). A useful approach to this process is to use an algorithm. One suggestion is to begin by determining the ocular alignment (motor status) with a simple cover test. The subsequent algorithm pathways are determined by the sensory responses that arise as the evaluation continues. Figure 75.4 illustrates this algorithm. Table 75.4 provides details for each section of the algorithm.

Indications for an orthoptic evaluation

Any patient with a known or suspected *abnormality of ocular motility* should undergo an orthoptic evaluation. The goal is to document the presence of the strabismus, to identify the presence and pattern of incomitance, and to note other features that may contribute to classification.

An orthoptic evaluation is also indicated in the presence of *visual symptoms*. These may be specific or vague and can represent a new sensory or motor problem. The goal is to determine the motor and sensory basis of the symptoms. Table 75.5 lists symptoms that warrant an orthoptic evaluation.

The presence of *specific signs* also warrants an orthoptic evaluation. Ophthalmologic, neurologic, or systemic disorders affecting binocular vision may not always be associated with visual symptoms. This is particularly true in patients with pre-existing childhood strabismus or very slow evolving strabismus (e.g. chronic progressive external ophthalmoplegia). Therefore, it is imperative for the clinician to be aware of certain signs suggestive of underlying pathology. Clinical signs that warrant an orthoptic evaluation are described in Table 75.5.

The basic orthoptic evaluation

Figure 75.5 outlines a simple flow chart for conducting a basic orthoptic evaluation. The steps within the flowchart are discussed here.

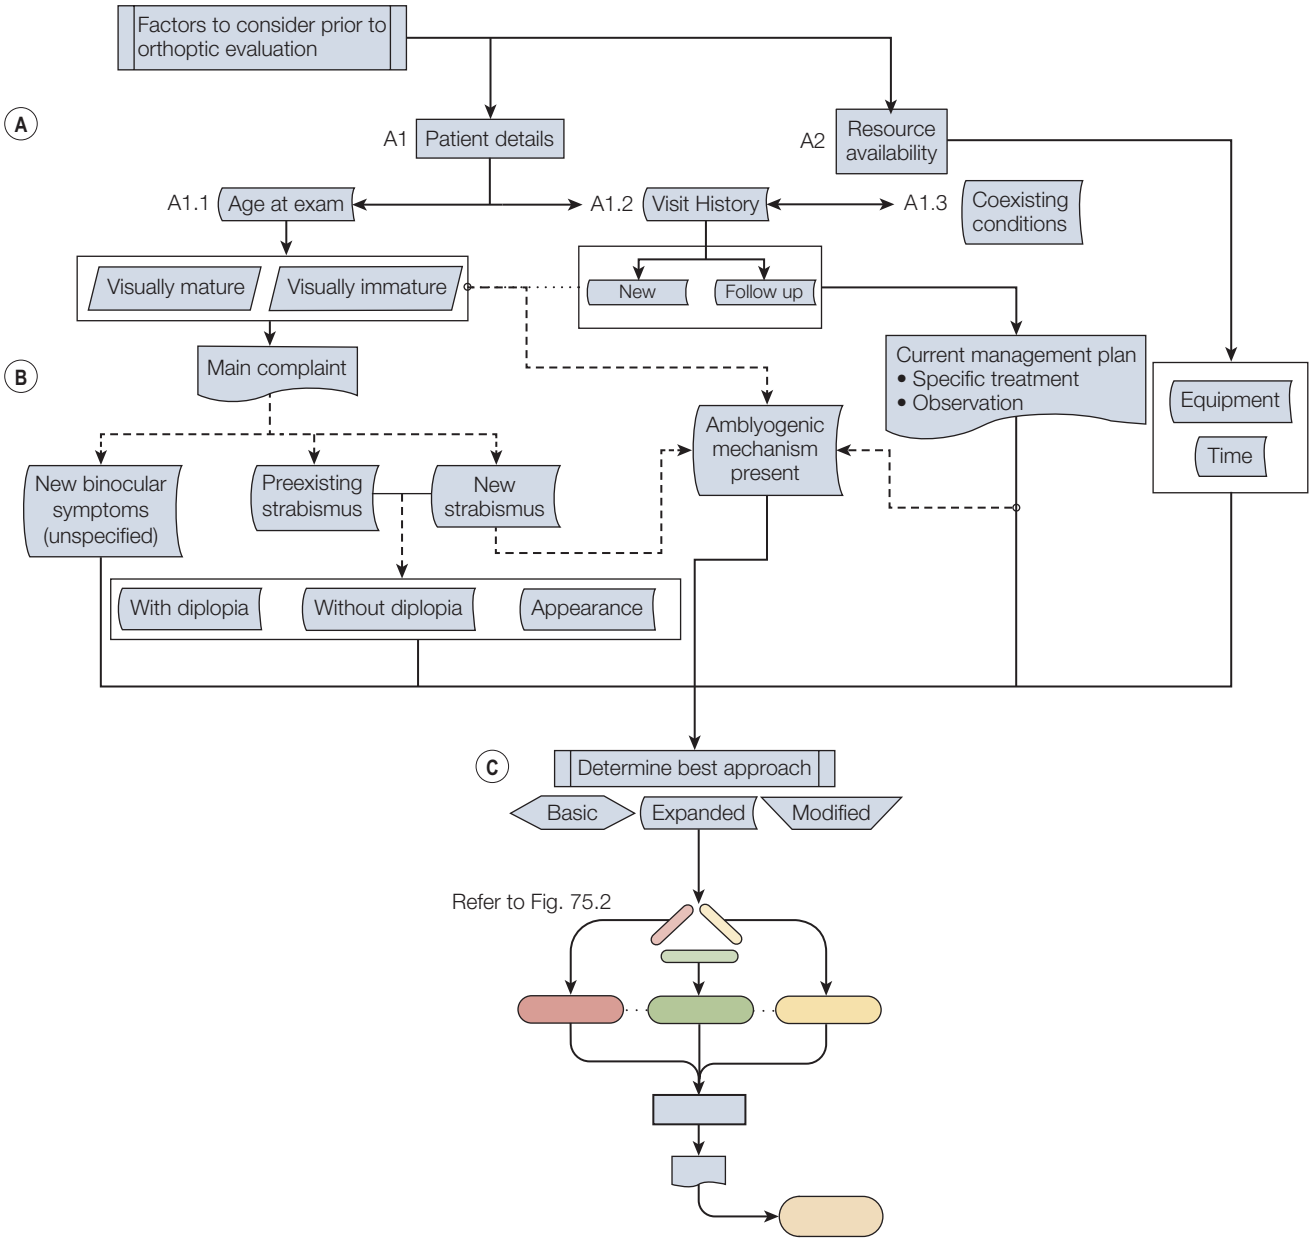

Fig. 75.3 Pre-testing factors to consider when determining best approach to the orthoptic evaluation. Section (A) and (B) expands step 1 in Figure 75.2. These are essential when designing the best approach to the orthoptic evaluation (C).

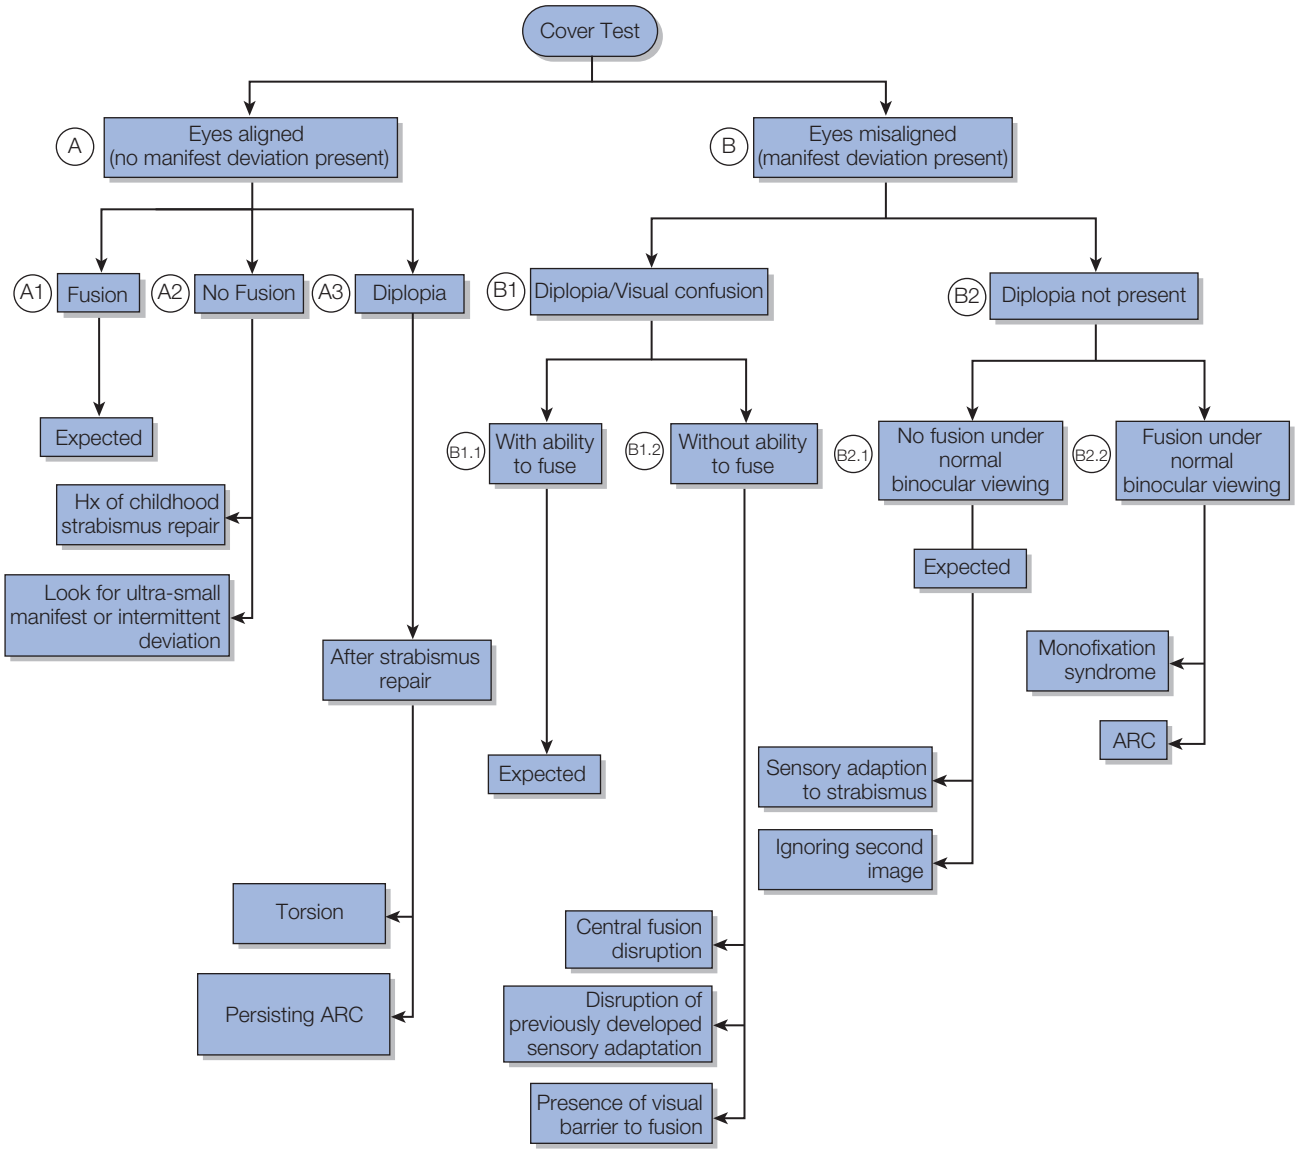

Fig. 75.4 Putting it all together – algorithm to determine the orthoptic status. A flowchart to facilitate determination of the orthoptic status. Pathways are determined by the sensory responses for a given ocular alignment as determined by the cover test. It already takes into account underlying influences of vision. Table 75.4 provides full details of each arm of the flowchart. ARC, Abnormal retinal correspondence; Hx, history.

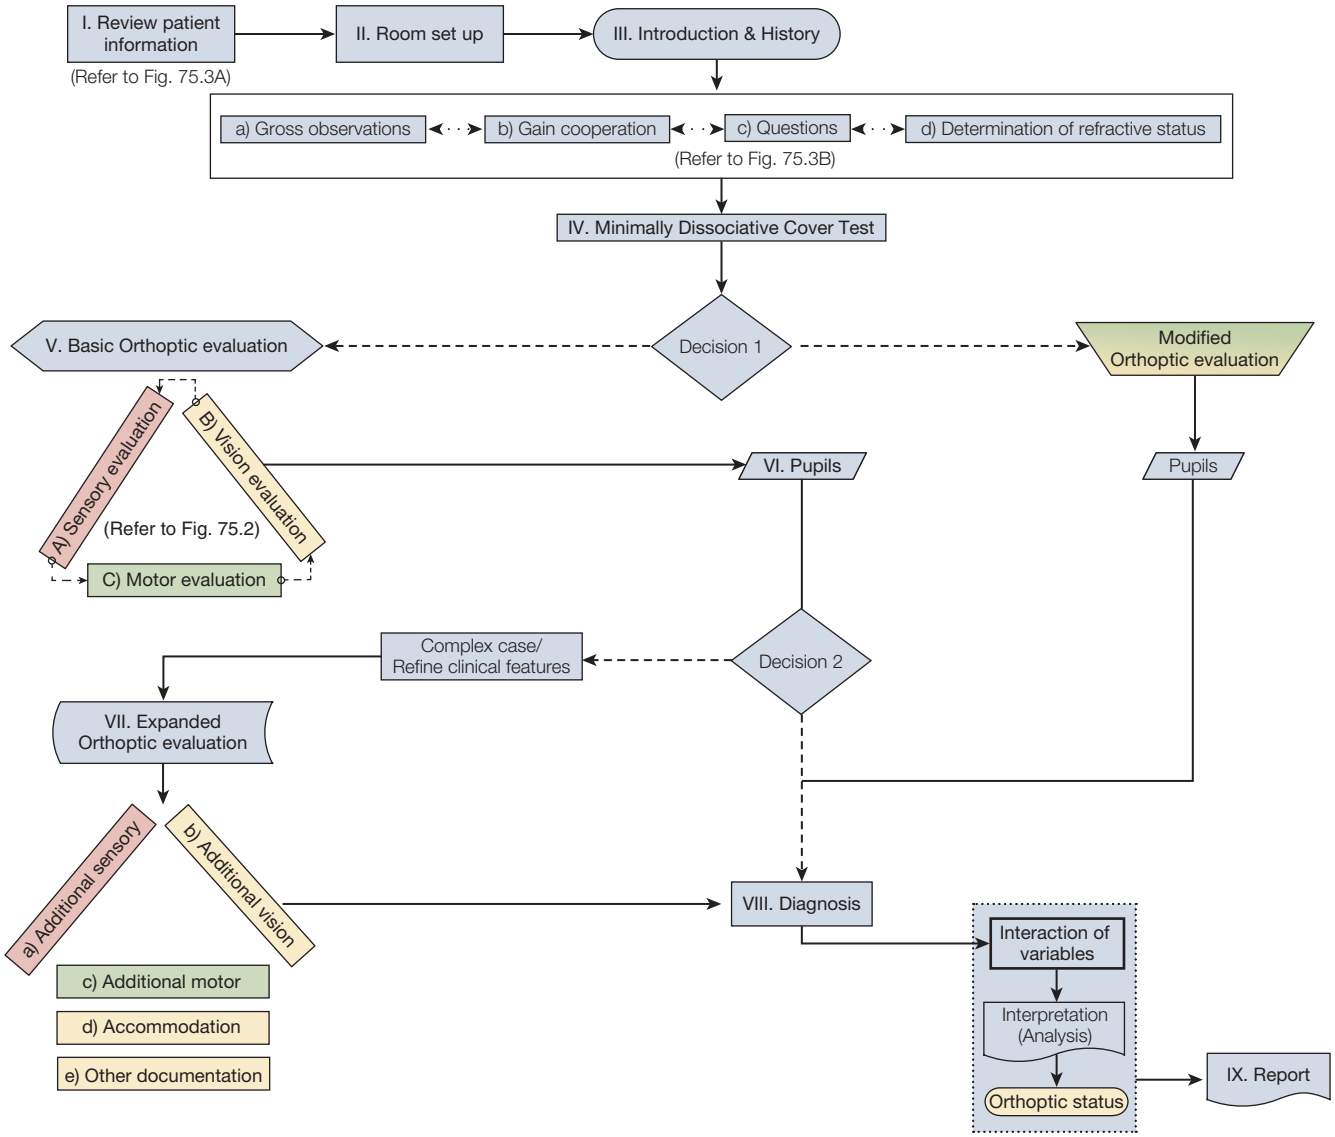

Fig. 75.5 The orthoptic evaluation: pathway for clinical testing. Refer to section "The basic orthoptic evaluation" for full details.

Table 75.3 Motor evaluation: assessment of the main themes

Determine if strabismus is present
Assess ocular alignment

If present
Assess the following characteristics

Direction:
Determine direction of the deviation, e.g. horizontal, vertical, torsional, or combination
- First step to generating differential diagnosis
- Combine with ocular movements to refine diagnosis, e.g. distinguishing exotropia with an adduction deficit from exotropia with full ocular movements

Frequency (control):
Refers to control of the strabismus, i.e. how often the eyes are aligned or misaligned
Determine if constant or intermittent
Dictates need and/or timing of treatment
Influences sensory status and vision status, particularly in visually immature patients

Comitancy:
Determine if angle is same (comitant deviation) or increases/decreases (incomitant deviation) in different gazes and distances. Used to classify the strabismus
- Assessment only in primary position can miss critical information leading to an erroneous diagnosis and poor management planning
- Incomitant strabismus can identify subtle limitations of ocular motility that might otherwise go unnoticed during gross evaluation of the eye movements

Triggers:
Determine if a strabismus can be induced or the size increased
- Examples: Looking up and in with Brown syndrome; or other factors such as fatigue
- These may be first identified in the history but must be documented in the motor evaluation

Compensatory mechanisms*:
Determine if a strabismus can be reduced or eliminated
- This is converse to identifying triggers that exacerbate strabismus
- This might be a conscious or unconscious effort by the patient to improve binocular functioning

Onset of the deviation:
Determine if newly acquired, longstanding, or congenital. Clues within the motor evaluation can help answer this.
- Examples: primary and secondary deviations; degree of incomitance; and fusional amplitudes

Status of the deviation:
Determine if deviation is worsening, improving, stabilizing, or variable over serial visits. This is influences management decisions
Examples:
- Observe and wait for resolution (getting better each visit)
- Proceed with medical investigation (worsening each visit)
- Proceed with strabismus surgery (unresolved stable angle)

Careful history taking can assist in this area but it is most accurately determined by serial orthoptic evaluations providing objective documentation

If *not* present

Confirms *pseudostrabismus*
Rules out disruption of motor system in patient with a vague unspecified binocular symptom
Attention to be directed to other areas such as accommodation, refractive status, media, or retina
Media or retinal anomalies may create monocular image distortion affecting binocular cooperation, e.g. *metamorphopsia* and *aniseikonia*. These are assessed within the sensory and vision components of the orthoptic evaluation

Determine if the eyes move normally
Evaluate the following features

Extent of ocular excursion in all directions of gaze:
Involves assessing versions and then ductions
- Greater ductional movement suggests innervational mechanism
- Equal limitations suggests restrictive mechanism

Quality of eye movements
Integrity of the eye movement subsystems must also be assessed, e.g. saccades, smooth pursuit, vestibular, OKN, and even presence of Bell's phenomenon

Other points:
Some forms of strabismus come with full ocular movements (e.g. comitant)
Absence of strabismus does not always rule out the absence of ocular motility deficits
- Supranuclear pathway anomalies that only affect the quality of eye movements (e.g. ocular motor apraxia)
- Nuclear or supranuclear anomalies resulting in bilateral symmetric limitation of eye movement (e.g. gaze palsy)

Sections correspond to Fig. 75.2C.
*Table 75.4 gives examples of commonly employed compensatory mechanisms, of which not all are related to strabismus.

Table 75.4 Putting it all together: working through an orthoptic algorithm to define the orthoptic status

Cover test finding*	Response by the sensory system	Explanation
A. Eyes aligned (no manifest deviation present)	A1. Fusion	The expected sensory finding The quality of fusion/stereopsis should then be assessed
	A2. No fusion	Alternative explanations must be sought This can include presence of poor vision or a history of having late surgery for a childhood strabismus These cases rarely come with completely straight eyes and the clinician should be vigilant for an ultra-small manifest deviation
	A3. Diplopia	May occur after strabismus repair Examples can include: Torsion • Residual torsion acting as a barrier to fusion following correction of vertical strabismus, e.g. superior oblique palsy • Torsional malposition of the globe cannot be visualized by cover test and eyes will appear aligned Persisting abnormal retinal correspondence (ARC): • Continued correspondence of fovea of one eye and a pseudofoveal point in fellow eye under binocular viewing conditions can result in appreciation of diplopia despite normalized ocular alignment
B. Eyes misaligned (manifest deviation present)	B1.1. Diplopia/visual confusion present – **with** ability to fuse	Diplopia is the expected sensory response in a visual adult with normal retinal correspondence. Some patients may alternatively appreciate visual confusion Fusion of the images is also expected if the deviation is offset by prisms or with the use of a major amblyoscope Important to identify an etiological mechanism such as incomitant strabismus or decompensation of pre-existing heterophoria or monofixation syndrome
	B1.2. Diplopia/visual confusion present – **without** ability to fuse	Fusion of images is not possible with use of prisms, major amblyoscope, or surgical re-alignment of the visual axes Potential explanations: **Central fusion disruption** following: • Severe closed head trauma • Restoration of vision after prolonged monocular visual disruption and development of a sensory strabismus, e.g. correction of longstanding aphakia with a contact lens or intraocular lens implant **Disruption of a previously developed sensory adaption:** Diplopia is appreciated if disruption occurs as a visual adult. Examples: • Surgical overcorrection of a childhood strabismus • Occlusion of dominant eye, e.g. aggressive amblyopia therapy in visual adults. Diplopia will be appreciated at all times • Reduction of vision in dominant eye, e.g. new cataract, corneal scar. Diplopia only present when fixing with previously non-dominant eye, i.e. fixation-switch diplopia **Presence of visual barriers to fusion:** Preceding or concurrent to onset of deviation visual barriers may prevent fusion of images. For example, dissimilar appearance of image from each eye such as aniseikonia or metamorphopsia
	B2.1. Diplopia not present – **no** fusion under normal binocular viewing	Awareness of this category is essential when evaluating an asymptomatic patient seeking correction of a longstanding childhood strabismus Absence of diplopia in the setting of a manifest deviation is not an expected sensory response. Potential explanations: **The patient has developed a sensory adaption:** • Expected if onset of strabismus was during visual immaturity • Once developed can persist into adulthood Examples: • Suppression • Amblyopia **Diplopia is present but not readily appreciated (i.e. ignoring second image):** • Marked image separation due to large angle strabismus • Significantly reduced vision (rare). Clinician should be cautioned that poor vision (excluding amblyopia) rarely inhibits the appreciation of diplopia. Patients with count fingers vision can still have binocular symptoms although they may not actually be able to identify the second image

Table 75.4 Putting it all together: working through an orthoptic algorithm to define the orthoptic status—cont'd

Cover test finding*	Response by the sensory system	Explanation
	B2.2. Diplopia not present – fusion **present** under normal binocular viewing	This category represents other sensory adaptions that may occur **Monofixation syndrome:** • Represents as subgroup of patients with a small manifest deviation (<10 prism diopters) who have developed peripheral fusion with a demonstrable central suppression scotoma under binocular conditions • Typically occurs following surgical correction of a larger deviation • Patients generally have good ocular cosmesis and do not seek further correction surgery **Abnormal retinal correspondence (ARC):** • Rare situation in which some degree of fusion develops in the presence of a modest sized manifest deviation (~12–20 PD) • A non-foveal point in the deviating eye now has a common visual direction with the fovea of the fixing eye. This relationship only occurs under binocular viewing • A patient with ARC generally presents without binocular symptoms and is usually seeking surgical correction to improve appearance of the ocular alignment • This sensory finding should raise a red flag for the clinician. Patient requires additional testing to evaluate the likelihood of inducing postoperative diplopia if surgical correction is done

Alphanumeric codes correlate to Fig. 75.4.
*Only considers primary position, therefore sensory status may differ in different positions of gaze.

Table 75.5 Indications for an orthoptic evaluation

Indication	Objective
Suspected motor system anomaly	Identify presence of true strabismus Classify type of strabismus (comitant vs. incomitant)
Known motor system anomaly	Provide evidence for etiological mechanism (e.g. innervational, mechanical, or sensory forms) Determine role of non-surgical management (e.g. prisms, monocular occlusion, utilizing head postures) Document stability of deviation over time Provide information to help selection of surgical plan Aim is to maximize outcome and minimize postoperative surprises (e.g. identifying incomitance that may need to be addressed – "A" or "V" patterns, lateral incomitance, distance/near disparities) Identify presence of a sensory adaption Determine effect of treatment e.g. postsurgical or medical intervention
Visual Symptom	
Double vision (diplopia)	Confirm true binocular diplopia arising from manifest or intermittent deviation
Two different images overlapping (visual confusion)	Alternate symptom to diplopia Objective same as above
Image moving or shaking (oscillopsia)	Confirm symptom is the subjective perception of moving or shaking images Identify presence of nystagmus as this symptom is typically due to acquired nystagmus as a visual adult Confirm if isolated symptom or in conjunction with diplopia
Eye strain or browache (asthenopia)	Determine if nonspecific symptom is due to increasing difficulty to control a pre-existing heterophoria This may occur in a patient who is increasing accommodative effort to improve control of an exodeviation This effort may also arise with new hypoaccommodation. An effort to increase accommodation can lead to this symptom as well as worsen control of an esodeviation as a result of increased accommodative-convergence
Changing clarity of binocular vision	Determine if this accommodation is being used to help control a deviation, either for an esodeviation (relaxes accomodation) or an exodeviation (increases accommodation) Determine if due to non-corrected, uncorrected, or inappropriately corrected refractive error
Vague visual symptom occurring with both eyes open	Useful in situations where a patient is unable to clearly articulate their binocular symptom Determines if symptom can be attributed to a motor, sensory, or vision anomaly for which appropriate investigation can be directed
New unexplained vision loss (suspected malingering or functional visual loss)	Generate information about the integrity of the afferent visual system by indirect means (e.g. document high-grade stereopsis)

Continued

Table 75.5 Indications for an orthoptic evaluation—cont'd

Indication	Objective
Specific Signs	
Eye appears deviated	Confirm presence of true strabismus and evaluate the resultant effect on the sensory system, i.e. does the patient have diplopia, ignores the second image, or developed a sensory adaption? Confirm pseudostrabismus and possible etiologies, e.g. quantify palpebral fissure asymmetries, lid malposition, and angle kappa
Eyes appear different sizes	Quantify exophthalmos and enophthalmos that may suggest orbital or systemic disease
Malposition of lid	Quantify ptosis or lid retraction Determine potential association with motor system anomalies. Examples: • constant ptosis arising from cranial nerve III palsy (innervational disturbance) • variable ptosis arising from myasthenia gravis (neuromuscular junction defect) • lid retraction from thyroid orbitopathy (myopathic disease)
Anisocoria	Confirm presence Determine which pupil is abnormal Document evidence of other signs of a cranial nerve III palsy in the setting of a non-reactive dilated pupil
Abnormal head posture	Confirm presence Determine reason for utilizing, i.e. is this attributable to an ophthalmological problem?
Monocular eye closure	Determine if frequent closure of one eye is to eliminate a diplopic image or if associated with intermittent exotropia
Detection of amblyogenic mechanism in visually immature patients	Determine the presence of a deviated eye (strabismus); defocused eye (refractive error or accommodative anomaly); or a deprived eye (blockage of visual axis by ptosis or media opacity)
Detection of amblyopia	Determine vision status in the presence of an amblyogenic mechanism
Change in vision status	Determine the effect on binocularity when there has been a change in refractive status, loss of vision, or even improvement in vision Elucidate symptoms arising from difference in image size (aniseikonia) and clarity or distortion of vision (metamorphopsia)
Vision assessment in difficult populations	Not specific to the orthoptic evaluation; however, assessment of vision in difficult patients frequently falls within the domain of the orthoptic evaluation

Review patient information (I.)

Reviewing all available patient information prior to bringing the patient into the exam room will save time and help to focus your questions, identify the main goals of the evaluation, and determine if additional testing may be indicated. Figure 75.3A illustrates factors to consider prior to initiating clinical testing.

Room set up (II.)

The next step is to prepare the exam room and make appropriate alterations. These may range from preparing the preverbal acuity chart for a young patient to distributing furniture for wheelchair access and ensuring equipment is clean and working properly.

Preparation helps ensure the exam is efficient and focused. This is important in young patients who may quickly lose concentration.

Introduction and history (III.)

The initial interaction with the patient and family sets the stage for the rest of the evaluation and provides an opportunity to determine the best approach.

The process includes:

Making gross observations (III.a)

These include:

Disposition:

- Is the patient cheerful, upset, or shy? Useful when determining best way to gain cooperation.

Body:

- Gait abnormality that may suggest cerebellar or neurological involvement.
- Obvious physical deformities suggesting previous trauma or congenital malformation.
- Neck or upper body anomaly that may prevent testing in some positions (e.g. prism cover test) or the need to avoid a test (e.g. vestibulo-ocular reflex [VOR]).

Head:

- Skull deformity or orbit anomaly (e.g. plagiocephaly).
- Abnormal head posture.
- Facial symmetry or weakness.
- Wearing glasses or hearing aids.

Periocular:

- Signs of injury suggesting orbital trauma (e.g. scars).

Palpebral fissure/lids:

- Upward or downward slant of the lid fissure (orbit position information).
- Ptosis or lid retraction.

Globe/ocular:

- Displacement of the globe (e.g. proptosis, enophthalmos, or hypoglobus).
- Chemosis, irregularities of conjunctiva, cornea, iris, or pupil.

Identification of any of these features can provide an early clue as to what to expect on clinical testing. For example, seeing a partial unilateral ptosis without a compensatory chin-up head posture in a young child raises the possibility of amblyopia.

Gain cooperation (III.b)

This part of the exam is an opportunity to build a rapport with the patient in order to gain cooperation for the rest of the visit. The degree of cooperation will determine the speed and complexity of testing that can be performed. This is generally considered when dealing with toddlers; however, it is just as important to gain rapport with the child's parents, and even extends to adult patients, to relieve any anxiety. Gaining trust can be achieved in young children by providing a brief explanation what to expect: "We're going to play lots of games looking at pictures!" Remind them that nothing in your room is going to hurt them, and give them your full attention (i.e. listen to what they are saying).

This is also an opportunity to get a sense of a patient's ability to participate with subjective testing. The first few minutes should help you decide the best way to interact with the patient, (e.g. how to explain tests, what is the best volume to speak, are there gestures or actions that seem to startle them, such as moving quickly, bringing things close to their face, etc.). Your ability to make any necessary adjustments will greatly increase the quality of information generated from the exam.

Questions (III.c)

Take the history while observing the patient and building rapport. The importance of a good history cannot be overemphasized. Detailed, relevant questions streamline the evaluation and help to predict the results of testing. The following are some key areas to address:

Age: Determine if the patient is visually immature (~birth to age 7). Age at time of testing combined with the reported age at onset of the problem predicts the sensory adaptations that may have ensued.

Main concern: Establish if the patient's concern is visual or appearance. This often helps in making decisions about the management of a problem. Be sure to ask the patient as well as any family members present. Patients may have difficulty distinguishing between image blur, image jump, image overlap, or even oscillopsia. However, the distinction is important since each symptom represents an anomaly of a different sensorimotor system. In this situation, clinical testing may, in fact, help the patient understand their visual symptoms.

Expectations: It is important to understand what expectations the patient may have. This includes their expectations of the orthoptic evaluation, as well as what they hope can be achieved by the treating ophthalmologist. Patient expectations need to be documented, and then addressed at the right time by the right person. This may be by the orthoptist at the completion of their evaluation or delayed until results of other investigations are available and discussed with their ophthalmologist.[7] It is important to avoid providing the patient and family with conflicting information.

Other pertinent details: Ask about: general medical history; family history of strabismus and any ophthalmic disorder; precipitating events if cause unknown; past ophthalmic treatment; and if there is any ongoing management, as well as compliance to treatment (e.g. use of prescribed optical correction, hours of occlusion for amblyopia, etc.).

At the end of taking a history, you should be able to generate a shortlist of differential diagnoses and determine the main emphasis of the evaluation. For example, the likely diagnosis in a 55-year-old diabetic with a 2-day history of horizontal double vision in right gaze is an acquired right sixth nerve palsy. Emphasis will be on the motor evaluation to document and quantify the right abduction deficit (see Fig. 75.1C). Conversely, emphasis should be shifted to a careful sensory evaluation in an adult complaining of a longstanding inturning eye without double vision (see Fig. 75.1A).

Determination of refractive status (III.d)

This is an ideal time to perform lensometry to determine the optical correction worn by the patient. This too can be accomplished while building rapport and taking a history. Knowing the power of the glasses, near correction, and prismatic correction is essential prior to orthoptic testing.

Formal clinical testing now begins.

Minimally dissociative cover test (IV.)

A useful starting point for clinical testing is to perform a cover test to determine ocular alignment. Brief occlusion of an eye avoids disrupting fusion in patients with fragile control while providing the clinician with valuable information to help interpret findings on upcoming tests (see Fig. 75.4 and Table 75.4). It should be performed at least in the straight-ahead position at near (⅓ m) and distance (6 m). The patient should be wearing their current optical correction (if any) while looking at an accommodative target. Additional positions and viewing situations (e.g. manipulating optical correction, using a light as a fixation target) can be reserved for later in the exam.

If strabismus is identified other characteristics should be noted:

- What is the direction of the deviation?
  - Is it horizontal (eso/exo), vertical (hyper, hypo, dissociated vertical deviation [DVD]) or a combination?
- What is the control?
  - Is it constant (manifest), intermittent, or always controlled under binocular viewing (latent)?
  - If intermittent, how easy can control be disrupted and then regained?

The cover test also provides other helpful information. Some examples include:

- Observing brisk recovery of ocular alignment after the occluder is removed, suggesting the presence of fusion and good vision.
- Occlusion of one eye with poor, inaccurate refixation of the fellow eye, suggesting reduced vision in that eye.
- No movement of an "apparently" deviated eye following occlusion of the fellow eye, suggesting a severe motor deficit or angle kappa.

Collecting this information early in the exam is helpful, particularly when cooperation may falter at any time (particularly in toddlers). It also predicts results on other tests and helps determine if modification of the exam may

be necessary. For example, if poor vision is suspected in one eye based on the inability for the non-covered eye to pick up fixation, poor results will be expected on all sensory tests; and measurement of the strabismus will need to be done with a Krimsky test rather than the prism cover test. Alternatively, if the initial cover test rules out a manifest strabismus and excellent visual acuity is present, it suggests that more coaxing is warranted if suboptimal results occur on subjective sensory tests.

Other benefits of an early cover test:

- Determines the patient's ability to follow instructions. Difficulty gaining cooperation with this test suggests subjective testing may be limited or at least warns the clinician extra effort may be required.
- Another opportunity to build a rapport with the patient. This will "warm them up" prior to conducting more detailed subjective tests.
- Confirms if symptoms identified in the history are binocular if they disappear with monocular occlusion.
- Provides the first formal opportunity to investigate an abnormal head posture or any other "compensatory" mechanism suspected during initial observation of the patient. Examples of are given in Table 75.6.

Nowhere else in the exam can so much information be obtained with only a few moments of testing!

Decision 1

If cooperation with the cover test is limited, a *modified* orthoptic evaluation may need to be considered. However, proceeding with the *basic* orthoptic evaluation can be as follows:

Sensory evaluation (V.A)

Sensory tests should be performed at a minimum of near and distance in the straight-ahead position. Additional positions should be considered if you suspect that the sensory status may be different there; for example, incomitant strabismus where normal alignment is present in one direction permitting fusion, or with nystagmus where the presence of a null zone improves vision to permit or improve stereopsis. It is important to explore and document multiple sensory findings in such patients. The sensory evaluation requires subjective responses that occasionally make accurate determination of the sensory status difficult. Reliability is improved by gaining cooperation, ensuring appropriate tests are selected, and that instructions are given at an appropriate level. Finally, be vigilant that the sensory results correlate with other findings. For example, high-grade stereopsis (normal sensory) with a manifest strabismus (abnormal motor) should raise a cautionary flag, and testing may need to be repeated. Table 75.7 provides a list of common sensory tests and the information they provide. Figure 75.6 illustrates some of these tests.

Vision evaluation (V.B)

The assessment of visual acuity as part of the orthoptic evaluation is generally restricted to quantifying high-contrast central acuity using optotypes. In some cases, it may need to be limited to observing visual behavior (e.g. young infants) (Fig. 75.7). The acuity with each eye should be tested at distance and near. Some impression of acuity level can be obtained in all patients, regardless of age and cooperation. To compare acuity at consecutive visits, the same test should be used. Optotype acuity tests should be introduced as early as possible. When "graduating" from one test to another, e.g. from "fix & follow" to Lea symbols, it is beneficial to test with both methods at the transition visit. Figure 75.8 illustrates several commonly employed vision tests and associated tools. Table 75.8 provides a description of these tests and tools.

Motor evaluation (V.C)

The motor evaluation is generally the most time-consuming portion of the work-up. Most tests are objective, but still require concentration by the patient and are influenced by the vision status of the patient. Table 75.9 provides an overview of the commonly employed clinical tests. The combination of tests used will depend on the approach taken for a particular patient (i.e. a *basic* evaluation versus an *expanded* or truncated [*modified*] one).

Pupils (VI.)

Examination of pupils is typically reserved for the end of the examination, or at least after vision tests have been completed. Standard assessment should be performed.[8] Attention should also be given to the presence of light-near dissociation, miosis associated with spasm of the near reflex, or aberrant regeneration following a third nerve palsy. In rare cases, patients with severe horizontal gaze anomalies may try to utilize convergence in an attempt to achieve some side gaze, resulting in pupillary miosis.[9,10]

Fig. 75.7 Clinical methods to assess vision in infants and young children. Examples of objective methods for assessing vision, i.e. observing visual behavior. Image (A) Teller acuity cards, (B) Cardiff card, (C) Heidi paddles, (D) optokinetic nystagmus (OKN) drum, (E) 10-diopter prism. Image (A) and (B) are examples of forced preferential looking techniques that require the child to detect the presence of a stimulus and direct his/her attention towards it. Other methods involve tracking a slow-moving fixation target (C); detecting a rotating stimulus (D); or determining the ability to hold fixation with an eye, which in this case requires inducing a manifest deviation with a small vertical prism. Here the patient is fixing with left eye. Note the central position of the corneal light reflex in the left eye and the vertically displaced reflex in the right eye (E).

Table 75.6 Examples of compensatory mechanisms

Strategy	Reason	Clinical examples
Abnormal head posture Any direction	Utilize null zone to improve visual acuity	Nystagmus
Abnormal head posture Head turn toward limited field of movement	Avoid gaze position to achieve binocular single vision (fusion) or eliminate diplopia	Unilateral sixth nerve paresis; unilateral Duane syndrome
Abnormal head posture Head tilt contralateral to higher eye	Avoid gaze position to achieve binocular single vision (fusion) or eliminate diplopia	Unilateral fourth nerve paresis
Abnormal head posture Chin up Increased frontalis effort	Avoid blockage of visual axis by a ptotic lid to maintain monocular vision and/or binocular single vision	Ptosis
Head thrusting; ± eye closure	Quickly move eyes to another fixation target to overcome lack of saccadic initiation	Ocular motor apraxia
Head movement	To substitute head movement for absent or severely restricted eye movement to view objects	Severe restriction of bilateral eye movement; bilateral horizontal gaze palsy
Under-accommodate	Avoid inducing an esotropia	Accommodative esotropia
Over-accommodate	Maintain control of deviation to eliminate diplopia or loss of fusion	Exophoria or intermittent exotropia
Close one eye; avoid near work	Avoid diplopia or asthenopic symptoms associated with near work	Convergence insufficiency
Squinting (narrow palpebral fissures)	Induce a pinhole effect to improve vision	Myopia
Adjusting glasses	Improve vision	
	• Achieved by titling glasses (or head)	Astigmatic correction off axis
	• Decreasing vertex distance with myopic correction or increasing vertex distance with hyperopic correction	Increases minus power Decreases plus power
	• Look over glasses with hyperopic correction	Accommodative esotropia (not tolerating new hyperopic correction)
	• Look over glasses with a myopic correction at near	Presbyopia (or any cause of inadequate accommodation)

To be considered a partial list of examples. Main objectives are to improve vision, maintain alignment of visual axis to avoid diplopia/gain fusion, or to achieve fixation with one or both eyes.

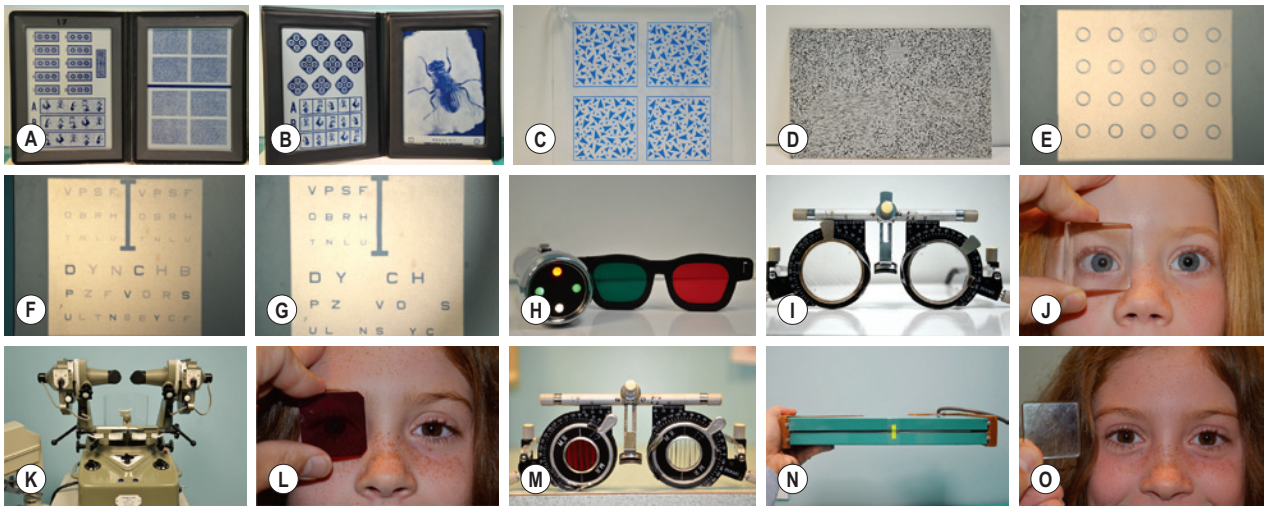

Fig. 75.6 Commonly employed sensory tests. (A) Randot stereotest. (B) Titmus stereotest. (C) Frisby stereotest. (D) Lang stereotest 2. (E) American Optical (AO) vectograph slide for distance stereopsis. (F) AO vectograph slide for suppression. (G) Same slide as in (F) illustrating unilateral suppression. (H) Worth 4-dot test, flashlight, and glasses. (I) Bagolini striated lenses in trial frame. (J) Introduction of a 20-diopter base-out prism eliciting bilateral convergence suggesting the presence of fusion. (K) Major amblyoscope (Synoptophore). (L) Red filter test. (M) Maddox rod lenses in trial frames, i.e. the double Maddox rod test. (N) After-image device. (O) Pre-introduction of a 4-prism diopter base-out prism. Absent movement noted in left eye suggests a central suppression scotoma of the right eye. (Table 75.7 provides information for these tests.)

Table 75.7 Sensory evaluation: common tests and key information

Test	Key information
Cover test	Alignment status: presence of manifest, intermittent, or latent deviation to predict expected sensory finding Recovery of alignment after dissociation suggests presence of fusion
Bagolini striated lenses	Retinal correspondence: fovea to extra-fovea Presence of central suppression scotoma Minimal dissociation making it useful in cases of fragile fusion/deviation control
After-image	Retinal correspondence: fovea to fovea
Worth 4-dot test (W4DT)	Retinal correspondence: fovea to extra-fovea Presence of central suppression scotoma Dissociative test – control of deviation through glasses suggests modest control or better
Titmus,* Randot,* Frisby,† Lang I and II†	Near stereopsis Indirect information about fusion and vision
AO Vectograph,* Mentor B-Vat system[β]	Distance stereopsis Indirect information about fusion and vision
Major amblyoscope (Synoptophore)	Retinal correspondence Fusion potential Fusional amplitudes Stereopsis Torsion
4-Diopter prism test	Presence of bifoveal fixation/central suppression scotoma
20-Prism diopter base-out test (aka: prism vergence test)	Objective test of motor fusion Useful in infants/patients with limited cooperation for subjective testing
Red filter test	Confirmation of true binocular diplopia Image localization
Double Maddox rod	Confirms subjective symptoms of torsional diplopia by detecting torsion (therefore also considered motor)
Prism adaption test	Fusion potential
Postoperative diplopia test	Confirmation of suppression region and presence of abnormal retinal correspondence
Important Concepts	
Testing done with optimal correction of refractive errors	Uncorrected refractive error that results in a reduction of vision will negatively impact sensory results
Appropriate selection of test for age and level of cooperation	To maximize reliability of results
Results to correlate to motor and vision status	Good vision and normal alignment should come with good sensory findings Reduced vision should inhibit good scores on sensory testing
Level of dissociation	More dissociative tests like W4DT may break control of a deviation in patients with fragile fusional ability
All tests do not assess same level of binocularity	Appreciation of random dot stereopsis requires a greater level of development of the cortical binocular system versus seeing an "X" with Bagolini lenses

*Requires the use of Polaroid glasses.
†No special testing glasses required.
[β]Requires liquid-crystal shutter glasses.

Decision 2

This is another opportunity to decide how to proceed with the rest of the evaluation. At this stage you must decide if sufficient data has been collected to make a clinical diagnosis and generate a report. Alternatively, if the case is complex or certain clinical features require further refinement, an expanded orthoptic evaluation can be pursued. However, it should be noted the orthoptic evaluation is a dynamic process and a decision to modify (limit testing) or expand (additional or specialized testing) the evaluation can be made at any time. This may be at the time of the chart review (see Fig. 75.3A) or after first interactions with the patient (see Fig. 75.3B).

Expanded orthoptic evaluation (VII.)

When a decision to expand the evaluation has been made, the following areas may be considered.

Additional sensory testing (VII.a): This may include further evaluation of:

- retinal correspondence with Bagolini striated lenses and after-image test;
- fusion potential with use of synoptophore testing;
- sensory fusion with prism adaption test;
- significance of torsion as a potential barrier to fusion;

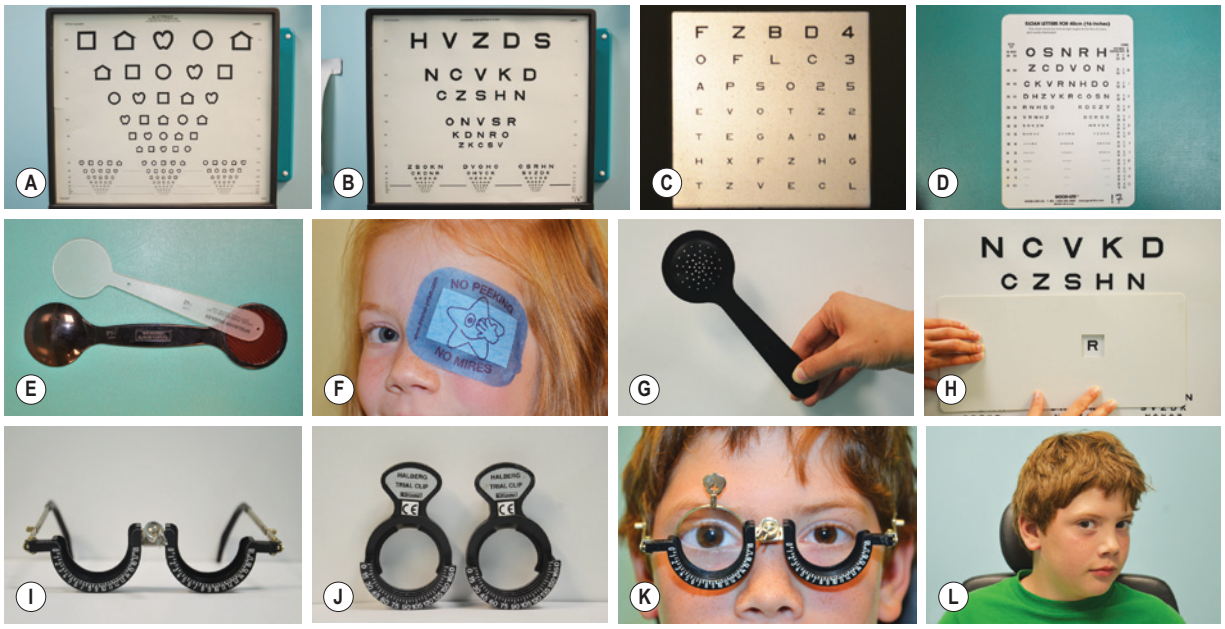

Fig. 75.8 Common vision tests and associated tools. (A) LH symbols, (B) EDTRS chart, (C) Snellen chart, (D) near Sloan chart, (E) eye occluder (opaque and translucent), (F) stick-on patch, (G) pinhole, (H) presentation of isolated optotype, (I) pediatric trial frame, (J) Halburg clips, (K) high plus lens (in a trial frame), (L) abnormal head posture. Images (A–D) are examples of standardized optotype charts with set testing distances. Images (E–L) are tools and techniques used to facilitate accurate assessment of vision.

Table 75.8 Vision evaluation: common tests and important concepts

Test/Concept	Comments
Pediatric	
Fix and follow	Assesses ability to pick up fixation and steadiness once fixation has been achieved
Heidi paddles	Fix and Follow method Permits crude quantification by using paddles of differing size Powerful stimulus for infants
Forced preferential looking	Fixation drawn toward a pattern stimulus rather than a plain background if detected Quantifiable but not comparable to other tests Examples: Teller acuity cards, Keeler cards, Cardiff cards, and Lea gratings
Binocular fixation pattern	Use in the presence of a manifest strabismus Assesses fixation preference between eyes under binocular conditions Crude quantification, not comparable to other methods
10-Diopter prism	Same principle as binocular fixation pattern but small vertical prism used to induce manifest deviation in a patient with straight eyes
OKN drum	Inducing optokinetic nystagmus indicates grating can be seen
Young children (optotype acuity)	
LH symbols (Lea symbols)	Various optotype presentations Naming or matching of optotypes by patient **Image A** shows distance LogMar method
Sheridan Gardiner letters	Various optotype presentations; naming or matching
HVOT	Various optotype presentations; naming or matching; standardized to Snellen principle
Allen pictures	Not standardized to Snellen principles
Tumbling E (Illiterate E)	Various optotype presentations Standardized to Snellen principles
Kay pictures	Various optotype presentations Naming or matching of optotypes by patient

Table 75.8 Vision evaluation: common tests and important concepts—cont'd

Test/Concept	Comments
Adult (optotype acuity)	
EDTRS	Standardized to LogMar principles **Image B**
Sloan near card	Standardized to LogMar principles **Image D**
Sloan low vision chart	Standardized to LogMar principles
Snellen chart	Standardized to Snellen principles
Important Concepts and Tools	
Standardized testing	Important to use standardized charts at the appropriate distances; patient should have the same test administered in the same way at each visit regardless of the room used; always use prescribed optical correction (can modify later if needed)
Age-appropriate methods	Selection of most appropriate test based on age and cognitive ability maximizes reliability of results
Maintain cooperation	Important to know when to coax a patient, when they are guessing, and even when to take a break
Be mindful of situations that can lead to loss of cooperation:	
Making patient wait	• A long wait in a noisy waiting room will fatigue a child. It also can frustrate the parent or care giver which will be sensed by the child further increasing his/her anxiety • Therefore be prepared for patients in advance (review notes in advance), book appointment times appropriately and try to stay on schedule as much as possible.
Testing good eye first	• Some children become distressed if good eye is tested first followed by the poorer seeing eye. Comprehension issues can be addressed by first practicing with both eyes. If clinician is confident optotypes are known then vision in the suspected poor eye can be tested next. Any lack of response at this time can be attributed to vision, not comprehension. This is further confirmed by the rapid identification of optotypes when the fellow eye is tested next (last).
Saying "no" or "that's wrong"	• Avoid negative responses to children. Most will stop "playing the game" if they feel they are doing poorly. Use alternative wording like "good try" or "I bet you can get this one"
Stick-on eye patch	Eliminates the need for patient to hold an occluder, thereby reducing chance of peeking; keeps hands free to hold matching card **Image F** shows complete occlusion of an eye with a sticky patch. This would still be placed on the eye behind the lens if patient was wearing glasses
Pinhole	To be used in any patient with reduced vision (~worse than 20/30; 6/7.5) that might be secondary to abnormal refractive status **Image G** shows a multi-holed pinhole
Optotype presentation	Full chart, line, or isolated optotype presentation to determine effect of crowding phenomenon **Image H** illustrates how to present an isolated optotype on a full chart
Testing vision with both eyes open	Important in setting of manifest-latent or latent nystagmus; or in patients over- or under-accommodating to control a deviation
Unilateral blur/fogging using high plus lens or translucent occluder	Use is indicated in any patient with latent or manifest-latent nystagmus **Image E** shows a translucent occluder that blocks form but still permits light to pass, **Image K** shows a high plus lens to reduce vision in the right eye without inducting or worsening nystagmus during left eye vision testing
Trial frames (pediatric or adult)	Used to hold specialized lenses (optical, prism, occluder, Bagolini, or Maddox rod) in front of an eye in a patient who does not wear glasses **Image I** is an example of a pediatric frame
Halberg clips	Same as above but used for patients wearing glasses These are clipped to the frame to hold a specialized lens in front of the spectacle lens **Image J**
AHP	May be adopted to utilize null zone in nystagmus, avoid ptosis, compensate for off-axis correction of astigmatism **Image L** represents a marked head turn left in a patient with a null zone in right gaze
Direct ophthalmoscope or muscle light	To evaluate pupillary responses to light

Images are seen in Figure 75.8.

Table 75.9 Motor evaluation: common tests and descriptions

Tests for basic evaluation	Remarks
Cover test	Repeated again during the formal motor evaluation Findings should be consistent with the initial cover test – changes could result if control decreases with testing fatigue Look for strabismus in all positions of gaze and document direction (eso, exo, hyper, hypo), control (phoria, tropia, or intermittent) and estimation of size (tiny, small, moderate, large) Used to predict strabismus classification (see below)
Document and Quantify Strabismus	
Prism cover test	Gold standard to quantify (measure) size of deviations • Positions to perform ◦ Distance (6 meters): • Straight ahead (primary position) • Right and Left gaze • Up and down gaze ◦ Near (1/3rd meter) • Additional positions ◦ Head tilt to either shoulder if vertical strabismus present ◦ Reading position (~25° down gaze at near) if near symptoms are present ◦ Fixing either eye if paretic strabismus suspected ◦ Supine position if skew deviation suspected • Information used to classification of strabismus ◦ Presence and amount of distance / near disparity, A/V patterns, other incomitance in lateral, vertical, or oblique positions of gaze. Methods • Alternate prism cover test (APCT) ◦ To measure full extend of deviation by maximizing the amount of dissociation between the eyes • Simultaneous prism cover test (SPCT) ◦ To measure minimum amount of manifest deviation (aka: the amount the patient typically walks around with under binocular viewing conditions) ◦ Important for sensory evaluation of monofixation syndrome
Synoptophore	Quantification of strabismus in any position of gaze Size of fusional amplitudes Detection and quantification of subjective torsion
Assessing and Quantifying Ocular Movement*	
Versions and ductions	Determine the extent of ocular excursion in all directions of gaze. Perform versions first then repeat with ductions if any anomaly of versions is suspected Underactions can be observed during both versions and ductions; however, ductions are usually quantified in this setting. Common grading systems include: • 0 to –4 scale: where 0 represents full movement and –4 represents no ductional movement into that particular field of action. In cases of severe restrictions or complete palsy with contraction of ipsilateral antagonist greater than –4 can be present • Percent of normal movement – clinician estimates what percent of normal movement is present • Percent of abnormal movement – generally avoided in lieu of estimating amount of movement possible. However, when documenting ocular movements it must be clear what the numbers represent Overaction can be graded only during versions
Tests for Expanded Evaluation	
Lees screen Hess screen Lancaster Red-Green test	Diagrammatical representation of eye movements in all positions of gaze • Sensitive to subtle limitations (and corresponding over actions) of ocular movement • Information on muscle sequelae
Field of binocular single vision	Quantifies area in which binocular single vision is present and where diplopia is appreciated
Specialized ocular motility assessment*	Suspected supranuclear involvement requires evaluation of other types of eye movements: • Saccades • Smooth pursuit • Vestibular ocular reflex • Optokinetic nystagmus • Bell's phenomenon Suspected paretic vs. restrictive etiology may include: • Saccadic velocities • Forced duction testing • Forced generation testing • Bell's phenomenon

Table 75.9 Motor evaluation: common tests and descriptions—cont'd

Tests for basic evaluation	Remarks
Double Maddox rod	Detection and quantification of subjective ocular torsion
Direct ophthalmoscopy	Detection and objective quantification of ocular torsion Can also be done with fundus photography
Tests for Modified Evaluation	
Hirschberg	Objective near test to detect and estimate size of a manifest strabismus Rarely indicated but useful in uncooperative patients
Krimsky test	Objective near test to estimate size of a manifest strabismus Useful in setting of poor vision in one eye where a standard prism cover test would not be reliable
Maddox rod	Detects direction of a heterophoria without the need for a cover test Does require subjective responses

*Assessment of eye movements includes both extent and quality of the movement.

Table 75.10 Additional testing in setting of reduced vision

Task	Remarks
Check vision at both near and distance	Equal reduction of vision at all distances is expected in the setting of amblyopia and organic disease. Differences between near (33 cm) and distance (6 m) may suggest refractive or accommodative anomalies and require further investigation
Check vision with and without identified anomalous head postures	Significant improvement in vision while using a head posture (outside primary position) is common in patients with nystagmus having a null zone
Repeat VA using a pinhole	Improvement suggests uncorrected or miscorrected refractive error
Use trial lenses	For VA assessment: • Add minus over a hyperopic correction to see if distance VA improves (overcorrected/not relaxed into correction) • Add plus lens (+1.00 to +3.00) to see if near VA improves (accommodative insufficiency) • Add 0.12 D lens to see if VA improves (element of functional visual loss) • Introduce high plus lens to fellow eye to test VA (in presence of latent or manifest-latent nystagmus) For ocular alignment assessment*: • Add minus (reduce plus) to determine if *control* improves in an exodeviation; or decreases control of an esodeviation • Add plus (reduce minus) to determine if control improves in an esodeviation; or decreases control of an exodeviation
Isolated optotypes	Assess influence of crowding phenomenon. More significant improvement in VA may be expected if due to amblyopia
Change optotypes or procedure	Careful selection of the vision test is important to ensure accurate quantification Be cognizant of patient not understanding what is required (e.g. always points to the same picture) or not absolutely sure about the names of letters or symbols Clinician should consider changing from letter chart to symbols or from asking for verbal responses to having patient "match" symbols
Other optic nerve function testing	Color vision and contrast sensitivity testing Look for RAPD

RAPD, Relative afferent pupillary defect; VA, visual acuity.
*Included here as the use of lenses to alter alignment in the clinic or as a management strategy may affect vision status.

- suppression scotomas and risk of inducing diplopia if strabismus surgery is performed (postoperative diplopia test);
- ability to eliminate diplopia by fitting a Fresnel prism (permitting fusion) or Bangerter occlusion foil (inducing blur to ignore).

Additional vision testing (VII.b): When vision is reduced (unilateral or bilateral), additional testing may be warranted. Table 75.10 outlines additional testing that should be performed when there is an unknown etiology. Other aspects of vision may also need to be evaluated such as visual evoked potential, contrast sensitivity, color vision, visual fields, dynamic visual acuity (vision during slight headshaking),[11] or tests for functional visual loss.

Additional motor testing (VII.c): This may include:

- further ocular motility testing by performing a tangent screen test (e.g. Hess screen, Less screen, or Lancaster red/green test), forced duction, and/or forced generation testing;
- additional prism cover test measurements:
  - fixing either eye;
  - other distances (e.g. past 20 feet);

  - other positions (e.g. oblique, head tilts, reading position, or even supine)[12];
  - with the use of additional lenses (e.g. more/less plus or minus power);
- investigation of torsion – detection and measurement (synoptophore, double Maddox rod, fundus photography).

Accommodation and other documentation (VII. d&e): Other testing may include formal investigations of accommodation (near vision, near point of accommodation, and dynamic retinoscopy), detection of nystagmus, red reflex assessment, measuring ptosis, or documenting improved visual functioning using an identified compensatory mechanism.

Diagnosis (VIII)

At completion of the evaluation there should be sufficient evidence to make a primary diagnosis and classify the strabismus type (e.g. incomitant intermittent exotropia). Multiple etiologies may be included e.g. partially accommodative esotropia with high accommodative convergence/accommodation (AC/A) ratio and amblyopia right eye.

Report (IX)

The final step in the process is to create a report. This succinct summary should provide the pertinent information that defines the orthoptic status of the patient. These details include:

- A summary of motor, sensory and vision findings used to support the diagnosis.
- A statement about the significance of these findings for the patient.

Examples:

New visit: "Patient's complaints of eye strain at near may be explained by his remote near point of convergence and reduced amplitude of accommodation."

Follow-up visit: "Vision in the right eye has improved 2 lines since last visit with full-time use of glasses and 6 hours/day patching of the left eye."

Follow-up visit: "Patient now has a manifest vertical strabismus in all positions of gaze. This fits with complaints of increasing awareness of double vision since last visit 1 week ago."

It should also include:

- A short list of differential diagnoses when a primary diagnosis is uncertain.
- Further description of any strabismus patterns that were found, particularly if strabismus surgery is being considered.
- Clearly highlight any red flags (e.g. worsening of symptoms, worsening of control of an intermittent deviation, increasing ptosis, or new fixation preferences, etc.).
- Identify specific items to be monitored (e.g. watch for amblyopia, changes in ductional deficits between visits, etc.). This is important when patients are shared between a team of clinicians.
- Re-state patient's/family's main concern. Frequently the formal orthoptic evaluation will be done by an orthoptist and later reviewed by a referring ophthalmologist. In these cases, it is useful to communicate the main concern or expectations of the patient, particularly when these are not in keeping with results of the exam or with planned management.

Including the following will be dependent on the institution from which the evaluation was performed:

- A suggested management plan (e.g. trial of a Fresnel prism, change in amblyopia management, etc.), a follow-up plan, and specific items to monitor between visits. Level of detail given will be institution-dependent.

Finish by signing your name and ensuring the report is directed to the appropriate members of the care team.

Designing a patient-specific orthoptic evaluation: factors to consider

The basic orthoptic evaluation involves three main components: sensory, motor, and vision. However, the procedure to conduct an evaluation is rarely static and should never be viewed as a check list of "tests" to complete. Rather, the approach frequently needs to be tailored for each patient to address their particular problem (see Fig. 75.1).

Figure 75.3A is an overview of factors to consider when designing the best approach for a particular patient. The following are brief descriptions for this flowchart.

Patient details (A1)

Important items to consider are: age of the patient, visit history, and co-existing morbidities.

Age at exam (A1.1)

This influences tests that can be performed, ability to get cooperation, and level of subjective feedback that may be possible. In general terms, the younger the child, the more limited the depth of the evaluation; however, age is not the only factor that dictates which tests should be performed:

Is the patient visually mature or immature?

Visually immature: Under the age of 7 years, patients are considered visually immature. Disruptions to normal binocular input below this age can permanently inhibit normal development. This group is liable to develop sensory adaptions.

Each visit for this age group must include:

- detection of amblyogenic mechanism(s);
- statement about presence of sensory adaption if amblyogenic mechanism is detected;
- statement about vision (and amblyopia), eye alignment, and eye movements;
- vigilance for any underlying mechanism to account for strabismus or poor vision when etiology is unclear (e.g. subtle duction deficit, and relative afferent pupillary defect).

Visually mature: Disruption of binocularity in this group should be accompanied by predictable visual symptoms. Be aware of the following:

- Motor system disruption – incomitant strabismus:
  - innervational, mechanical, neuromuscular, and myopathic.
- Sensory system disruption – comitant strabismus:
  - decompensating heterophoria in isolation or secondary to new monocular visual disruption (e.g. cataract or retinal anomaly);
  - disruption of pre-existing sensory adaption;
  - fusion disruption (e.g. correction of longstanding aphakia, etc.).

It is also important to identifying findings that do not fit the story (e.g. a patient who reports new strabismus but does not have double vision). You must think of possible explanations such as severe monocular visual loss, change in alignment of a childhood strabismus (e.g. previous suppression for childhood esotropia, with the eye now drifted into an exotropic position).

Visit history (A1.2)

Is this a new visit or follow-up visit?

New visit: Assessment at the first visit needs to create a baseline for future visits. Also pay careful attention to features that may be suggestive of neurologic or systemic disease. However, the time allotted must allow other testing at that visit such as the cycloplegic refraction and fundus exam.

Other key points:

- Visually immature: do not miss amblyogenic mechanisms or any sensory adaption that may already be present.
- Visually mature: detection and careful quantification of ocular misalignment and be able to correlate patient symptoms (or lack of) with results on the orthoptic evaluation.

Follow up visit: The follow-up visit depends on current management. Therefore, at each visit be sure the objective is clear in order to best tailor the evaluation. Questions would include:

What treatment is being considered?

- Is this a preoperative visit or does the patient need to be evaluated for the use of a prism? The evaluation of a surgical candidate will emphasize quantification of the strabismus while evaluation for use of a prism (Fresnel or incorporated) will be to identify an optimal amount of correction that permits comfortable binocular single vision in positions of gaze most appropriate to the patient's needs.

Is there ongoing treatment?

- Amblyopia therapy – is the visual acuity improving?
- Cessation of amblyopia therapy – has there been a reduction in the visual acuity?
- New glasses given for possible accommodative esotropia – what is the response to using hyperopic correction?
- Use of a prism – are the symptoms adequately reduced? Is there intolerance to prism suggesting a change in the size of the deviation?

Has management been observation only?

- Is there any change in symptoms?
- Is there any change in the orthoptic status?
  - Onset of amblyopia in an infant with previous alternating esotropia.
  - Difference in control of an intermittent deviation.
  - Resolution of a strabismus in a patient with a presumed microvascular cranial nerve palsy.
- Has anything changed from the first visit? Are things better, worse, or the same?

Has there been recent strabismus surgery?

- What change has occurred in the motor status?
- Has there been any change in the sensory status? Have symptoms been eliminated, has the procedure created new or unexpected symptoms?

Co-existing conditions (A1.3)

Co-existing neurologic or systemic conditions can influence testing and reliability. This may include cognitive and behavioral problems or motor issues such as cerebral palsy or even myasthenia gravis. Overall, the patient needs to be alert and physically able to participate in testing. This entails being able to move their head for measurements, to wear glasses for specific tests, and to be positioned appropriately (e.g. Hess screen, in front of a synoptophore).

Resource availability (A2)

To generate a basic orthoptic evaluation requires an in-depth understanding of several key components already discussed. However, it is also dictated by available resources. These resources include equipment and time.

Equipment

The level of the orthoptic evaluation will be determined by the equipment available in the clinic. An example of this is the major amblyoscope. Although it is an integral part of the orthoptic evaluation, not all centers have one. Reasons may involve cost of the equipment, lack of trained personnel, or a surgeon unfamiliar with the benefits of the data provided by the device. Other tests like Hess/Less/Lancaster may only exist in facilities dealing with complex strabismus that require detailed quantification of motility deficits. This information may not be required in centers that only conduct preliminary evaluations and refer management to other centers.

The following are minimum equipment requirements to conduct a basic evaluation:

- Basic sensory evaluation: near stereo test, red filter, and W4DT (or Bagolini lenses).
- Basic motor evaluation: occluder, prisms, accommodative targets.
- Basic vision evaluation: occluder/eye patch, fixation sticks, optotype chart.
- Bright light source, e.g. direct ophthalmoscope, muscle light.

Tables 75.7–75.9 list additional equipment (tests) involved in the basic and expanded orthoptic evaluation.

Time

The orthoptic evaluation will be dictated by time. A *modified* exam looking for strabismus, ocular motility anomalies, and gross deficits of vision can be performed in roughly

10 minutes by an experienced orthoptist. However, a *basic* evaluation is closer to 30–45 minutes (including a written report) and increases to 90 minutes or more for an *expanded* evaluation if the following additional testing is performed: field of binocular single vision, Hess screen, full synoptophore evaluation, formal testing of retinal correspondence, torsion, accommodation, quantifying complex forms of strabismus, and assessing (and fitting) a patient for a Fresnel prism. These times do not include patient factors that could further delay the work-up (e.g. developmental delay, autism, brain injury, etc.).

Summary

An orthoptic evaluation is dynamic. It must be flexible to address specific patient or care team needs while still generating useful and accurate information.

The evaluation is more than the sum of its parts. The paradigm discussed here separates the evaluation into three distinct components – a motor, a sensory, and a vision evaluation. The interaction between these components creates a synergy of information that ultimately defines the patient's orthoptic status.

The hope is that by understanding the concepts presented here, a better understanding of binocular vision will be elucidated. This will allow the clinician to better "visualize" the best approach for any patient in any situation, thereby maximizing the information gained from the orthoptic evaluation.

Fig. 75.2 The orthoptic paradigm pathway: main themes and determination of orthoptic status.

Defining the orthoptic status involves a series of steps that ensures efficiency and accuracy. The first step identifies factors to help determine the best approach for a given patient or situation. Next involves specialized clinical testing to assess major themes within each of the core components (A, B, and C). The interaction between each component is analyzed and interpreted. The outcome constitutes the orthoptic status of a patient. This information is used to determine best management approach. (Additional details provided in Table 75.1.)

Fig. 75.3 Pre-testing factors to consider when determining best approach to the orthoptic evaluation.

Section (A) and (B) expands step 1 in Figure 75.2. These are essential when designing the best approach to the orthoptic evaluation (C).

Fig. 75.4 Putting it all together – algorithm to determine the orthoptic status.

A flowchart to facilitate determination of the orthoptic status. Pathways are determined by the sensory responses for a given ocular alignment as determined by the cover test. It already takes into account underlying influences of vision. Table 75.4 provides full details of each arm of the flowchart.

Fig. 75.5 The orthoptic evaluation: pathway for clinical testing.

First, we must, I believe, firmly embed strabismus in the matrix where it belongs – an anomaly of neurodevelopment.
John T Flynn[1]

Infantile esotropia (IET) is a constant non-accommodative esotropia with onset before 6 months of age in a neurologically normal child (Fig. 76.1). The angle is generally greater than 30 prism diopters (PD), with mild or no amblyopia and low hypermetropia. "Congenital esotropia" is often used synonymously but the condition is rarely present from birth. There is accumulating evidence that these children have the potential for good binocularity if they are treated early, suggesting the underlying defect is not congenital. Animal studies support the idea that IET is caused by decorrelation of cortical inputs.[2]

IET is often accompanied by dissociated vertical deviation (DVD; 50–90%),[3,4] inferior oblique overaction (IOOA; 70%),[5] latent nystagmus (40%), and optokinetic asymmetry. IET and the secondary associations are often grouped under the term "infantile strabismus complex"; some components may exist in isolation even in the absence of strabismus.

History

The term "infantile esotropia" was initially introduced by Costenbader in 1961 to include age of onset <1 year.[6] He had previously defined "congenital" esotropia as having an onset <6 months.[7] The term "congenital esotropia" reflects Claud Worth's theory[8] that esotropia (ET) is caused by a congenital defect of fusion: "The essential cause of squint is a defect of the fusion faculty." Worth's theory implies that the "congenital defect" is irreparable and this has been taken to mean that surgery can be carried out at leisure, largely for cosmetic reasons. The opposing view, that the infant visual system is normal for a period of time until esotropia occurs as a result of extrinsic factors was taken by Chavasse.[9] Chavasse thought that "most infants with congenital squint are capable of developing fusion if the deviation is fully corrected before the age of two years." This view was accepted by Costenbader,[10] Parks and his fellows, and became widely accepted, particularly after the work of Ing.[11] It has not been widely accepted in Europe, where strabismus surgery is often carried out much later.[12] The evidence supporting Chavasse's view, that corrective surgery should be carried out quite early in infancy began to appear in the 1960s. During the 1980s there was an explosion of knowledge concerning development of vision in infancy[13–15], and a refinement of surgical techniques. Surgical case series have led to consolidation of clinical knowledge concerning IET.[16–18]

Epidemiology

There are few studies of the prevalence of IET as defined. The prevalence of any ET in a population of 38,000 children aged 1–2½ years was found to be 0.9% in 1980,[19] while the prevalence of IET over a 30-year period in one area of the US was found to be relatively constant at 0.25% of the population.[20] The overall rate of strabismus surgery in childhood has substantially declined in the UK in recent decades, possibly be due to the routine prescribing of the full cycloplegic refraction in strabismic children.[21] Despite the apparent overall decrease in strabismus surgery, Carney et al. stated that the rate of surgery in children under 1 year was unchanged.[22] Fewer ophthalmologists are now undertaking strabismus surgery, so the surgical work is being concentrated into fewer hands.[23]

Fig. 76.1 Large-angle infantile esotropia.

IET often runs in families and the hereditary component is reported in older literature. Primary monofixation syndrome occurs much more commonly in the parents and families of children with IET than in the general population.[24] Maumenee et al. concluded that the inheritance pattern was most likely Mendelian codominant.[25]

Natural history of the development of ocular alignment

In a study of normal neonates, Sondhi et al.[26] found that 55% had a constant deviation (66% of whom had an exodeviation) and only 30% were orthotropic. No neonatal esodeviations were seen after 2 months of age and 97.2% of their infants were orthotropic at age 6 months. In another study of neonates followed until 6 months of age[27] the same authors concluded that the time of onset of IET was between 2 and 4 months of age. Horwood described "neonatal misalignments" (NMs) as "fleeting, large angle, mainly convergent, ocular deviations"[28] occurring commonly in the first 2 months of life (73.2% of infants in the first month of life). The NMs declined to almost zero by 4 months of age except in those children who went on to develop IET, where the frequency of misalignment increased.[29] There was no relationship between frequent NMs in the first 2 months of life (which are probably due to early development of the vergence system) and the subsequent development of IET. Horwood's report of a high prevalence of convergent misalignments in (older) normal infants is apparently in direct contrast to the findings of Archer et al.,[27] of high prevalence of divergent deviations (especially in the immediate newborn period) in another healthy population. Sondhi and Archer[26,27] used a method that relied upon the infant fixating on the examiner's face. This may have had an artifact induced by the large positive angle kappa seen in early infancy and the particular fixation pattern of neonates when looking at a face.[30] Friedrich and de Decker[31] also found a high (50%) incidence of exotropia (XT) in neonates but only one of 1024 newborn infants developed an ET that was still present at 3 months of age. Children who develop IET begin to be different from normal infants at approximately 4 months of age. Transient misalignment of neonate eyes appears to be common, so parental reports of the age of onset of strabismus must be viewed with caution.

Birch et al. reported that none of 66 infants with misalignment ≥40 PD of ET and an onset between 2 and 4 months of age had spontaneous regression, suggesting that they were suitable candidates for early surgery.[32] The Congenital Esotropia Observation Study (CEOS)[33] reported that, before 12 weeks of age, the majority of esotropic infants had an intermittent or variable deviation, whereas after 12 weeks of age, the deviations were more likely to be constant. CEOS further concluded that normal infants over 10 weeks old with a constant ET of ≥40 PD (and ≤3.00 D of hypermetropia) had very little prospect of spontaneous regression (2%) and could be offered early surgery (Box 76.1).[34,35] However, if the deviation was <40 PD and intermittent or variable, it usually resolved.

Box 76.1

Clinical profile of infants who will benefit most from early surgery, i.e. unlikely to spontaneously resolve

1. Presence or persistence of ET between 10 weeks and 6 months of age
2. Constant ET 40 PD at near (⅓ m) on two examinations 2–4 weeks apart
3. Refractive error ≤+3.00 D
4. Absence of any of the following conditions:
   - Gestational age <34 weeks
   - Birth weight ≤1500 g
   - Ventilator treatment in the newborn period
   - History of meningitis or other major medical event
   - Developmental delay
   - Incomitant or paralytic strabismus
   - Manifest nystagmus or head bobbing
   - Prior eye muscle surgery
   - Presence of structural ocular anomalies

Adapted from Spontaneous resolution of early-onset esotropia: experience of the Congenital Esotropia Observational Study. Am J Ophthalmol 2002; 133: 109–18 by Wong AMF. Can J Ophthalmol 2008; 43: 643–51.

Clinical patterns

Dissociated vertical deviation

DVD (alternating sursumduction, occlusion hyperphoria) occurs in any ocular condition where there is disruption of early binocular development. DVD is not usually evident at presentation but is a later feature of IET (mean onset 2.8 years).[4] In DVD, the deviating eye elevates and extorts (Fig. 76.2) and is not associated with a corresponding downward movement of the other eye when fixation is resumed, i.e. DVD does not follow Hering's Law. In children with larger preoperative angles, surgery before 24 months resulted in a lower incidence of manifest DVD.[36] In any one patient, DVD can vary both in size and frequency of occurrence. It can occur spontaneously or only when the eye is occluded. Rarely, the patient adopts a head tilt to the same side. DVDs can

be quantified with base-down prism. The prism is placed in front of the eye with DVD until the upward and downward movements are identical on alternate cover testing.

Inferior oblique overaction

IOOA is visible in adduction only and is associated with fundus excyclotorsion (Fig. 76.3). DVD and IOOA are usually bilateral but can be asymmetric. If the eye elevates in adduction and there is a corresponding (equal in size) hypodeviation in the opposite eye on alternate cover testing, the deviation is due to IOOA. If there is no corresponding hypodeviation, then DVD is present. If the elevation of the adducted eye exceeds the hypodeviation in the fellow eye, then combined DVD and IOOA are present; the difference between the two vertical measurements is the extent of the DVD.

Dissociated horizontal deviation

Dissociated horizontal deviation (DHD) is defined as a change in horizontal ocular alignment, unrelated to accommodation, that is brought about solely by a change in the balance of visual input from the two eyes.[37] DHD occurs much less frequently than DVD. It is often asymmetric and can occur simultaneously with DVD. Indeed, DHD may merely be a DVD with a large horizontal component. It can be mistaken for consecutive (XT) and the two may co-exist. The two can be distinguished by a difference in horizontal measurements when measuring with the prism in front of each eye. The treatment is a supramaximal lateral rectus recession of the affected eye.[38]

Fig. 76.2 Right dissociated vertical deviation.

Fusion maldevelopment nystagmus syndrome

Fusion maldevelopment nystagmus syndrome (FMNS) was previously known as latent nystagmus.[39,40] FMN is a common accompaniment of IET and occurs on monocular occlusion. The fast phase is always toward the side of the uncovered eye. The nystagmus is lessened in adduction and worsened in abduction. Accurately measuring the visual acuity in the presence of latent nystagmus can be difficult because the nystagmus can dramatically lower the acuity in the uncovered eye. This can be obviated by fogging the eye not being tested with a +3.00 lens rather than occluding it. FMNS can become "manifest" (manifest latent nystagmus) when it is present in binocular viewing.

Optokinetic asymmetry

Infants under 2 months of age show greater sensitivity to objects moving from temporal to nasal than objects moving from nasal to temporal. This asymmetry disappears by 4–6 months of age in normal infants. This nasal-ward bias in infants persists when infants develop IET, and becomes permanent.

Differential diagnosis

The differential diagnosis and clinical forms of IET can be considered as either truly congenital or early in onset within first 6 months (Box 76.2). In most cases, a thorough history and ophthalmic examination helps to differentiate the subtypes (Fig. 76.4).

Pseudoesotropia is common. It can be confirmed by performing the Bruckner,[41] Hirschberg, and cover tests to determine that the eyes are orthotropic (Fig. 76.5). Note that the Bruckner test can have false positives in children younger than 8 months of age.[42] Flash photographs are useful to demonstrate pseudostrabismus to the parents. Infants initially diagnosed with pseudostrabismus showed a 12% rate of strabismus or amblyopia at 3 years of age,[43] but these findings were not replicated in another study.[44]

In type 1 Duane syndrome, the diagnosis is confirmed by limitation of abduction and globe retraction in adduction. Bilateral type 1 Duane syndrome can be difficult to distinguish from IET, particularly if the child is cross-fixating, as the globe retraction in adduction can be quite subtle in infants.

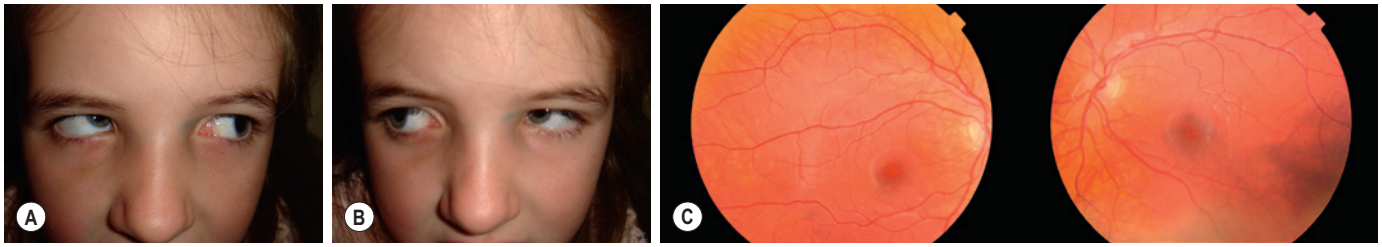

Fig. 76.3 Right inferior oblique overaction (IOOA) (A), left IOOA (B), and fundus excyclotorsion (C) in the same patient. Note the fovea now lies below a line passing through the inferior edge of the optic discs.

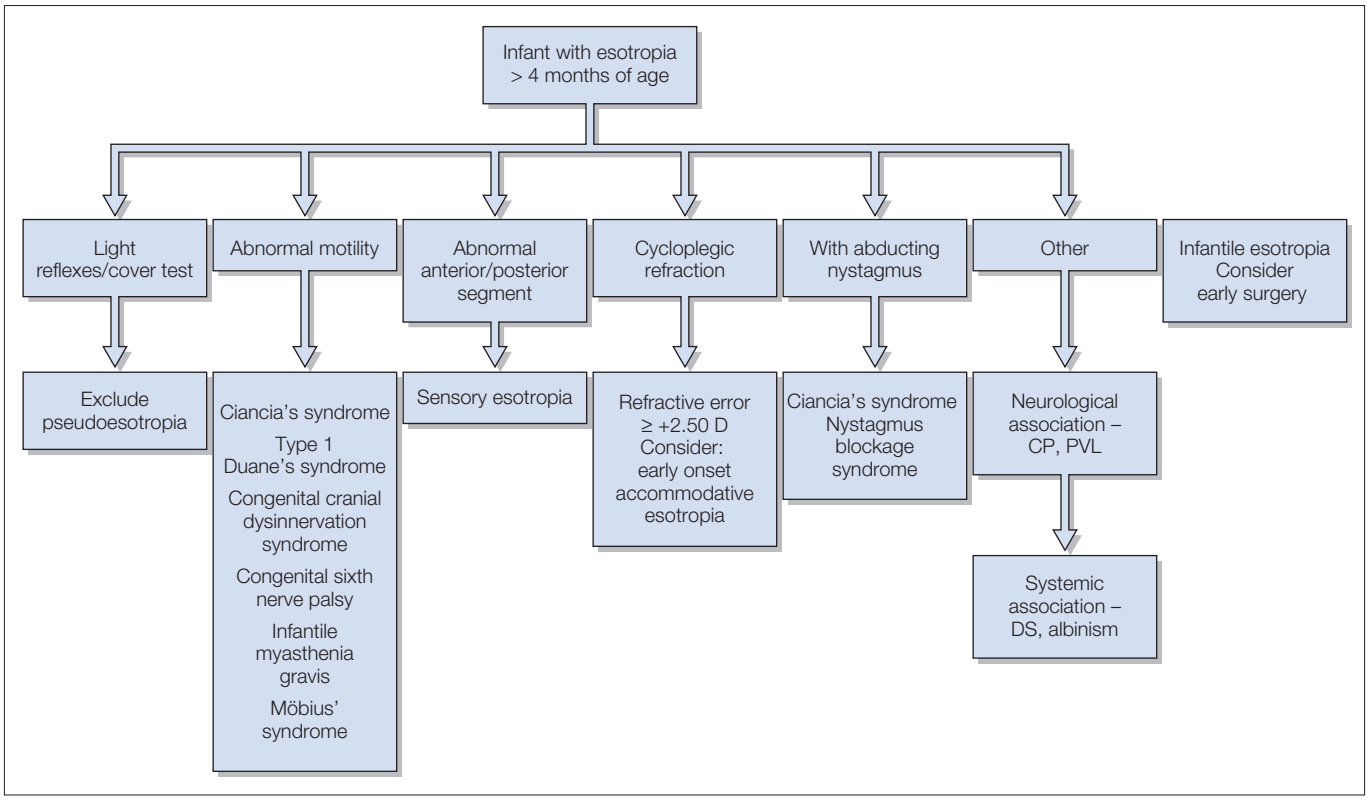

Fig. 76.4 Work-up of infant ≥4 months of age with esotropia. CP, Cerebral palsy; PVL, periventricular leukomalacia; DS, Down syndrome.

Box 76.2

Differential diagnosis of infantile esotropia (IET)

True congenital-onset ET	*Infantile-onset ET*
(True) congenital ET	Infantile ET
Pseudoesotropia	Early-onset accommodative sensory ET
Type 1 Duane syndrome	Ciancia syndrome
Congenital sixth nerve palsy	Associated neurologic – CP, PVL
Nystagmus blockage syndrome	Associated systemic – DS, albinism
Congenital fibrosis syndrome	
Infantile myasthenia gravis	
Möbius syndrome	

CP, Cerebral palsy; PVL, periventricular leukomalacia; DS, Down syndrome.

If the angle of misalignment is such that the child requires surgery, then bilateral medial rectus recessions (BMRc) are the treatment of choice for mild cases of IET or Duane syndrome. Performing a doll's eye maneuver demonstrating full abduction will exclude a Duane syndrome or congenital sixth nerve palsy (a generally benign condition that usually resolves by 6 weeks of age).[45] Other techniques to elucidate abduction include rotating the child or using monocular occlusion to force abduction in the non-occluded eye. A sixth and seventh nerve palsy occurring together may be due to Möbius syndrome, which is usually associated with a number of other orofacial and limb abnormalities (Fig. 76.6).

A full ophthalmic examination (including cycloplegic refraction) will exclude any anterior or posterior segment cause of a sensory ET.

Fig. 76.5 Pseudoesotropia. The child appears to have an esodeviation due to a prominent left epicanthic fold limiting the amount of visible nasal sclera; however, the light reflexes are symmetric and cover test was normal.

Ciancia described a subset of ET[46] that others describe as "cross-fixation congenital ET."[18,47] Ciancia syndrome has the following features:

1. esotropia of early onset;
2. a generally large angle of deviation;
3. bilateral limitation of abduction;
4. jerk nystagmus with the quick phase toward the side of the fixating eye, increasing with abduction and decreasing with adduction;
5. torticollis with face turn toward the side of the fixating eye;
6. head tilt toward the side of the fixating eye.[48,49]

Fig. 76.6 Möbius syndrome.

Nystagmus blockage syndrome (NBS) was first described in 1966 by Adelstein and Cuppers[50], with a reported prevalence of 4.8–10.3% of congenital esotropes.[51] The syndrome is characterized by:

1. nystagmus with early-onset large/variable-angle ET;
2. pseudoabducens paralysis;
3. head turn in direction of fixing eye;
4. absent nystagmus with the fixing eye in adduction;
5. increasing amplitude of manifest nystagmus with abduction.

NBS and Ciancia syndrome should be considered in any esotropic child with abducting nystagmus. However, the underlying pathophysiology is different. In Ciancia syndrome, the ET and nystagmus are coincidental,[16] whereas, in NBS the patient has congenital idiopathic nystagmus with the null point in adduction (causing ET). Accommodation/convergence innervation may play a role and pupillary constriction in adduction may assist in making the diagnosis of NBS.[52]

With alternating ET and cross-fixation, there is no nystagmus in the primary position or abduction. The fixating eye usually is in the primary position with the non-fixating eye adducted (unlike in NBS, where both eyes are in adduction) and there is often no amblyopia (unlike in NBS).[51] These features may assist in differentiating NBS from IET. Treatment in all these syndromes is often the same, with large BMRs producing good motor outcomes[53] in most cases.

The prevalence of strabismus in children with developmental delay is variably reported between 27% and 100%.[54,55] The population-based longitudinal study by Haugen et al. found that strabismus was present in 42% of patients with Down syndrome and was predominantly early-onset ET (84%) and associated with hypermetropia.[56] The prevalence of strabismus in patients with cerebral palsy is 44% on average (15–62%).[57]

Surgery for ET in developmentally delayed children has variable postoperative alignment outcomes. Some groups report high rates of overcorrection and unpredictable outcomes when using standard surgical tables.[58] Muen et al. reported suboptimal surgical results in seven patients who were subsequently diagnosed with periventricular leukomalacia after presenting with strabismus.[59] While some authors decrease the surgical dosage, Yahalom suggested that reduction of standard surgical dosages for ET in Down syndrome is unnecessary.[58] The authors follow this practice.

Does stability of preoperative alignment affect outcomes?

Ing showed that the majority of patients observed prior to surgery for IET showed an increase of at least 10 PD, with 50% showing an increase of at least 20 PD.[60] When surgery was based on the measurements taken 1 day before surgery, there was no difference in alignment between the group with an increase in angle and those with stable measurements. In a study of infants with IET grouped into "stable" (<10 PD difference in measurements between visits) or "unstable" (≥10 PD difference in measurements between groups), Birch et al. demonstrated that there was no difference in postoperative alignment, re-operation rates, rates of prescription of hyperopic or bifocal spectacle prescription, or stereoacuity.[61] In a further study, the motor outcomes (alignment) were the same regardless of the stability of measurements before surgery.[62] Of note, there does appear to be an improvement in measurement stability after 6 months of age.[63]

Measurement uncertainty

Schutte et al. identified the sources of human error in strabismus surgery.[64] They estimated that half of re-operations were due to inaccuracy in measurement of the angle of strabismus, variability in surgical strategy, or imprecise surgery.

In the Early vs. Late Infantile Strabismus Surgery Study (ELISS) pilot study, the three masked examiners found high inter-observer agreement with the Hirschberg test, but in 10% of cases it exceeded 10° (20 PD).[65] In another study, experienced strabismologists reviewed a series of photographs of patients with a variety of common strabismus entities (25Δ L ET, 25Δ R XT, 80 Δ ET, 75 Δ IET) and estimated the angle of squint using the Krimsky and Hirschberg tests with an expert examiner prism cover test (PCT) as the "gold standard."[66] The majority of examiners overestimated at least one patient by 10Δ with the Krimsky test and differences of 5Δ were difficult to distinguish. With the Hirschberg test, each patient was underestimated by 10Δ by at least one examiner, with more inaccuracy for larger angles. The authors concluded that the Krimsky test is more accurate than Hirschberg, especially for larger angles of strabismus, but both tests are substantially less accurate than PCT. Thompson and Guyton reported that it is impossible to accurately measure extremely large angles of strabismus with prisms.[67] A Pediatric Eye Disease Investigator Group (PEDIG) study[68] looked at inter-observer reliability of the prism and alternate cover tests. They concluded that in childhood ET of greater than 20Δ, differences of 12Δ or more are likely to indicate real change but smaller differences could be due to measurement error. We should, therefore, be skeptical about the accuracy of our measurements.

The PCT is the "gold standard" for strabismus measurement but can be limited by the child's cooperation. The Krimsky test is easy to perform in infants with the prism split between the two eyes for angles of squint ≥40 PD. When the child is

uncooperative, the authors have found it useful to combine the Krimsky and Bruckner tests[69] to confirm accuracy of the PCT. Loose plastic prisms are used for the PCT. Plastic right-angled prisms should be held in the frontal plane position and plastic isosceles prisms should be held close to the position of minimum deviation.[70] In practical terms, this means that for both types of prism, each prism is held with the base in the sagittal plane. The authors acknowledge that the prismatic effect of two split prisms is not the arithmetic sum of the two individual prisms, but for most angles of ET encountered in clinical practice, the difference is still within the observer's measurement error. What is absolutely crucial for any strabismologist is to use the same measurement technique consistently and adjust surgical doses according to results over time. The measurement of distance deviation is often problematic in small infants, but it is always possible to measure the near angle, so the authors usually base their surgical plan on the near angle, as is now common practice in acquired ET.[71,72]

Nonsurgical management

Refraction is crucial to the management of IET, especially, but not limited to, the follow-up period after surgery. Hypermetropia occurs in 15% of children with IET.[73,74] At presentation, we treat infants with ≥2.5 D hypermetropia with full spectacle prescription[73,75] to determine whether the ET is partially or fully accommodative. This resolves the ET completely in almost 50% of cases, so prevents unnecessary surgery.[73,74] However, 20% of infants initially controlled with glasses will decompensate and ultimately require surgery.[76] Spectacle correction can reduce a large-angle strabismus so that only two muscles need to be operated (for the corrected angle) rather than three. Correction of hypermetropia is essential for maintaining postoperative stability.

Amblyopia can be inferred by the child's fixation pattern. Fixation should be maintained through a blink in both eyes if the vision is equal.[77,78] Cross-fixation occurs when an infant fixes across their nose at the object of interest (Fig. 76.7). As an object of interest (e.g. a toy) is moved from one side to the other, fixation switches at the midline if the vision is equal. If fixation switches past the midline, amblyopia is present in the eye toward which the toy is being moved.[79] It would seem logical to treat amblyopia before surgery. However, in one series of surgery in (older) children with untreated amblyopia, there was no difference in postoperative outcomes compared to those children who were patched preoperatively. One-sixth of the amblyopic patients had spontaneous resolution of the amblyopia as a result of surgery alone.[80] In a larger series, operating for IET in the presence of mild amblyopia made no difference to outcome but the results were worse in infants with moderate amblyopia.[81] Preoperative alternate daily patching of each eye has been recommended to prevent the development of suppression,[82] but was argued against by Parks,[83] in particular because he felt that suppression rarely occurs until after the eyes are aligned and some binocularity develops. Ing reported no difference in alignment outcome[84] between alternate-day preoperative patching with unpatched controls, but the study was underpowered to detect less than a 25% difference in outcome.

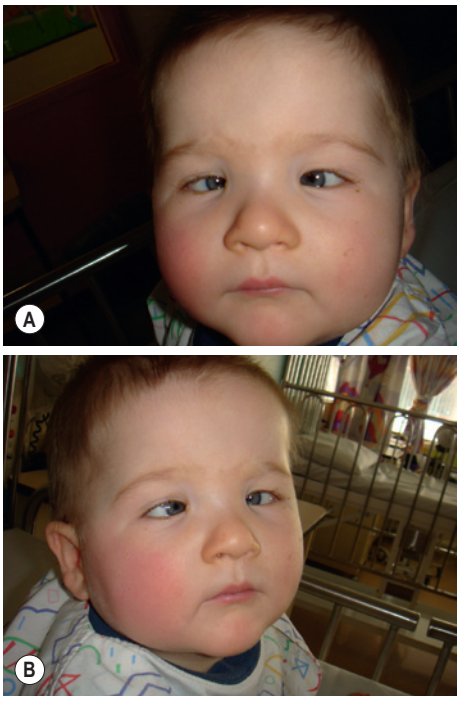

Fig. 76.7 Cross-fixation. Left gaze with right eye fixating (A), right gaze with left eye fixating (B).

Timing of surgery: why early surgery

Fusion and stereopsis are absent before 2 months of age but develop rapidly between 3 and 5 months of age.[14] Forced-choice preferential looking and visual evoked potential stereoacuity both reach adult levels by 6–7 months of age.[85] Infants with a recent onset of strabismus (within weeks) that had been corrected with prisms had similar stereoacuity to normal infants of the same age[86,87] (Fig. 76.8). The critical period for disruption of stereopsis in IET peaks at 4.3 months of age, so the time window for correction of IET with the aim of obtaining high-grade stereopsis may be very narrow.[88] Wong reviewed the evidence in favor of early surgery.[35] She showed there was a clear trend of declining stereopsis outcomes with increasing age at surgery (Fig. 76.9). Cerman et al. identified 16 months of age as a critical time point after which even an excellent motor outcome will not produce stereopsis.[89]

Chavasse argued that most infants with IET could develop fusion if the squint was fully corrected before the age of 2 years. This was confirmed by Ing,[11] who reported a significant difference in sensory outcome between infants surgically aligned before and after age 2 years. Zak and Morin demonstrated that the development of Worth 4-dot fusion was related to the age at time of surgery.[90] Surgery after age 12 months was related to the development of latent nystagmus, inferior oblique overaction, amblyopia, and reduced degrees of fusion.

Better sensory outcomes with surgery before age 2 years has been confirmed by a controlled prospective multicenter study (ELISS), but the study had a high dropout rate.[12]

Birch and Stager compared two groups of infants who had surgery before age 1 year.[91] The first group had surgery at or before 6 months of age and the second between 7 and 12 months of age, with a follow up of 4–17 years. Both cohorts were

Esotropic infants were aligned using prisms and tested before surgery. *(Adapted from Stager DR, Birch EE. Preferential-looking acuity and stereopsis in infantile esotropia. J Pediatr Ophthalmol Strabismus 1986; 23: 160–5 by Tychsen L. J AAPOS 2005; 9: 510–21. Reprinted by permission of Slack.)*

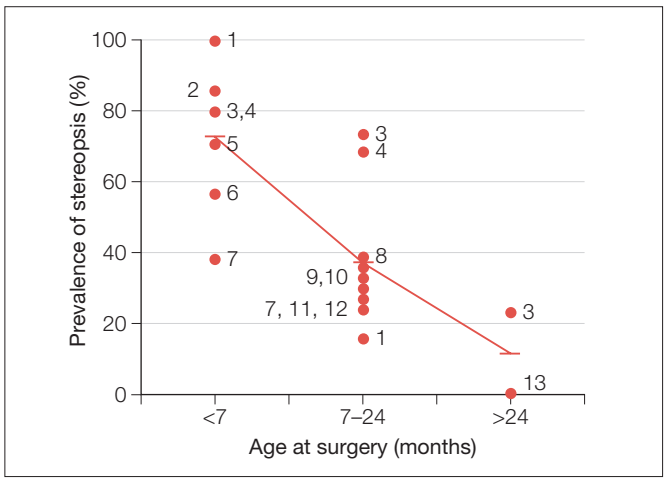

Fig. 76.9 Summary of prevalence of stereopsis by age at the time of surgery. Each circle indicates the prevalence of stereopsis from published studies. Short horizontal dashes represent mean prevalence of stereopsis for different age groups. *(From Wong AMF. Timing of surgery for infantile esotropia: sensory and motor outcomes. Can J Ophthalmol 2008; 43: 643–51. Reprinted by permission of Elsevier.)*

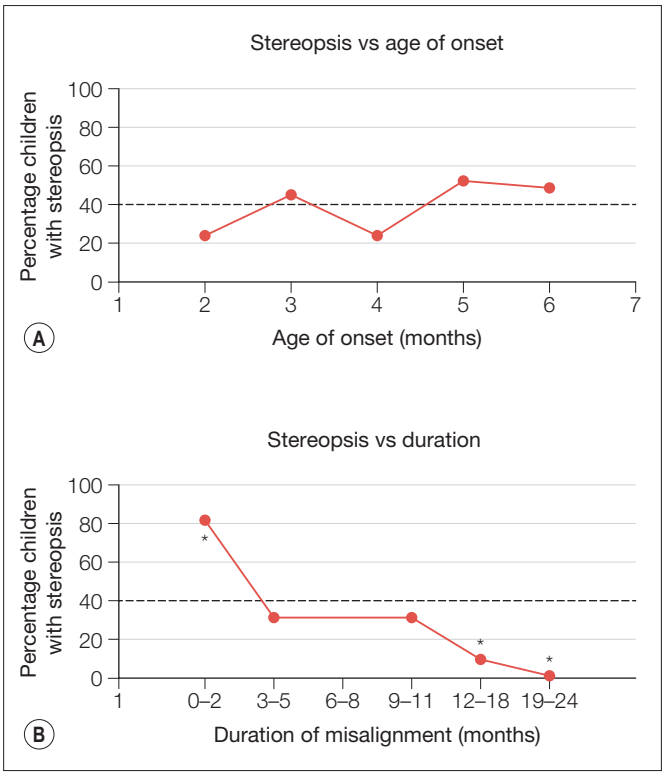

Fig. 76.10 (A) Stereopsis versus age of onset. (B) Stereopsis versus duration of misalignment. There is an inverse relationship between duration of misalignment and development of stereopsis. *(From Birch EE, Fawcett S, Stager DR. Why does early surgical alignment improve stereoacuity outcomes in infantile esotropia. J AAPOS 2000; 4: 10–14. Reprinted by permission of Elsevier.)*

similar at entry and had similar motor outcomes (83–94% had alignment within 6 PD) but the early group had significantly better peripheral and central fusion, Randot stereopsis, and Randot stereoacuity of ≥200 seconds of arc. Even with early surgery, only 38% of infants developed Randot stereopsis and only 20% developed Randot stereoacuity of ≥200 seconds of arc, indicating that even short periods of misalignment may be enough to disrupt binocular development.[91]

Birch et al.[92] concluded that the duration of misalignment (not age of onset or age at alignment) was the significant factor in determining stereopsis outcomes (Fig. 76.10). If the misalignment was longer than 2 months, then excellent stereopsis was not achieved, and after 12 months duration of misalignment, only 4% of patients had Randot stereopsis. Patients with Randot stereopsis had fewer re-operations, and a lower prevalence of DVD, but no difference in the prevalence of amblyopia or the need for vertical muscle surgery. Subsequently, they reported that patients with absent Randot stereopsis recorded immediately after surgery had 3.6 times more risk of surgery for recurrent ET or consecutive XT after surgery than those with measurable stereoacuity.[93] Ing and Okino[94] confirmed loss of stereopsis was related to the duration of misalignment. In a further paper, Ing and Rezentes[95] reported that there was no significant difference in fusion in subgroups of infantile esotropes who had up to 21 months of misalignment or who were surgically aligned by 6, 12 or 24 months of age. They concluded that the time window for the development of fusion was wider than that for the development of stereopsis.[21]

The importance of Birch and colleagues finding that duration of strabismus is the major determinant of sensory outcomes (less than 3 months of duration is the cut-off for good sensory outcomes) corresponds to the duration of misalignment in esotropic monkeys known to produce irreversible deficits in binocularity.[2,96] The authors believe, along with Tychsen,[87] that it has major implications for the rapidity with which referrals must be made and surgery carried out for children with IET if high grades of binocularity are a desired outcome.

The best functional outcome for most infants with IET after surgery is the monofixation syndrome[97]; a small residual tropic misalignment of 8 PD or less, peripheral fusion, and gross stereopsis. The vast majority of patients with the monofixation syndrome show good long-term stability, even over decades.[98]

However, Wright reported excellent motor alignment and high-grade stereopsis in two of seven patients operated on between 13 and 19 weeks of age.[99] Ing reported on a series of 16 patients aligned before 6 months of age[100]; only one achieved high-grade stereopsis. However, Helveston et al. cautioned that children operated on before 6 months of age had an average of one additional procedure later on, in order to retain a satisfactory alignment.[101]

There are several studies reporting delayed development in children with IET prior to surgery with improvement within months after surgery.[102–104] Drover et al. tested fine and gross motor development in infants with IET.[102] The pre-surgery group showed both delayed sensorimotor and gross motor milestones (Fig. 76.11). After surgery, the delays disappeared, suggesting that early surgery is beneficial to infant development (Fig. 76.12).

Using a decision analysis approach, Trikalinos et al. concluded that it is probably warranted to attempt surgery for IET "as early as possible."[105] In one series, parental satisfaction with their child's surgical outcome was reported as 85% and this correlated with a postoperative alignment in the microsquint range (≤8 PD.[97,106] Parents noted improved eye contact and appearance of their children. Patients with IET were reported to have a 2.6 times increased rate of mental illness when compared with controls; this did not occur with children with other types of strabismus and was not related to premature birth.[107] So, the psychosocial benefits of early surgery should not be underestimated.

Why delay primary surgery?

The usual reasons advanced for delaying surgery include:

1. difficulties with measuring the angle of misalignment;
2. the lack of stability of deviation in young infants;
3. the possibility of spontaneous resolution;
4. anesthetic risk;
5. technical difficulties of surgery on infants' eyes;
6. the difficulty of diagnosing amblyopia in infants with microtropia after successful surgery.

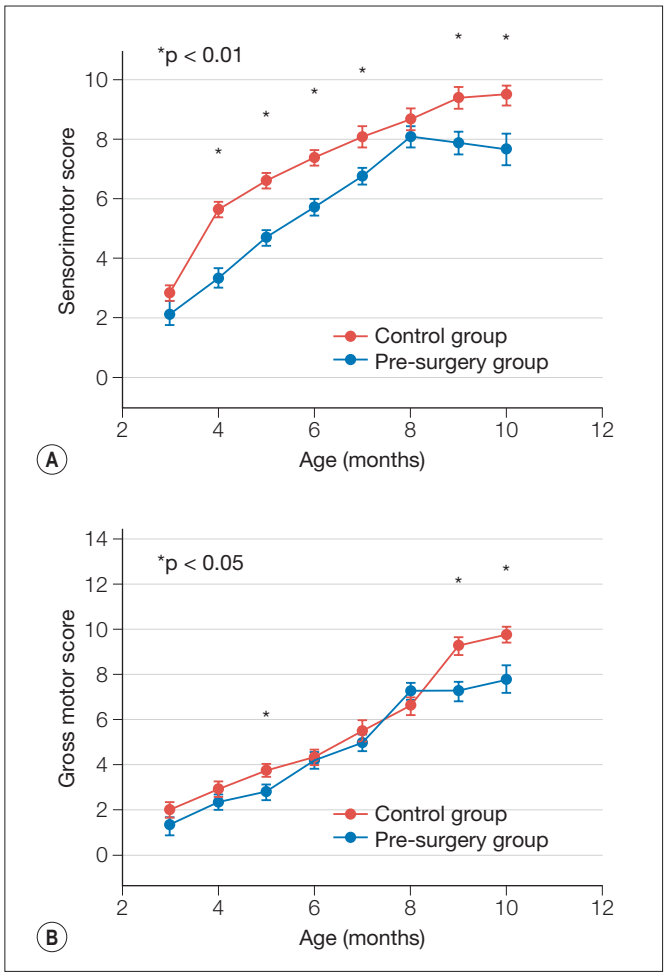

Fig. 76.11 Comparison of fine motor (A) and gross motor (B) score of presurgery and control groups. Bars represent 1 standard error. Asterisks represent significant differences. Planned comparisons indicated that the delay of sensorimotor milestones was significant at 4, 5, 6, 7, 9, and 10 months of age ($p < 0.01$). Delay of gross motor milestones was significant at 5, 9, and 10 months of age ($p < 0.05$). *(From Drover JR, Stager DR, Morale SE, et al. Improvement in motor development following surgery for infantile esotropia. J AAPOS 2008; 12: 136–40. Reprinted by permission of Elsevier.)*

Improvement in motor development following surgery for infantile esotropia. J AAPOS 2008; 12: 136–40. Reprinted by permission of Elsevier.)*

Spontaneous resolution has been reported in a small percentage of patients.[34] CEOS reported that spontaneous resolution usually occurs when the deviation is <40 PD in size and is intermittent or variable in infants <20 weeks of age.[34] In infants with a constant deviation >40 PD, only 2.4% of cases spontaneously resolved.

In infants <1 year of age with intermittent, small-angle ET, Fu et al.[108] reported a 46% likelihood of spontaneous resolution or control with spectacle correction alone. However, patients with a constant small- or variable-angle ET progressed to a constant large-angle ET requiring surgery.

Calcutt and Murray reported on a series of adult patients with unoperated IET. The prevalence of amblyopia was 14%, in whom two-thirds were anisometropic.[109] Later they reported an improvement in sensory status in 88% of IETs who were operated on aged >8 years, with a widening of the visual field in 76% patients.[110]

Posterior segment eye growth is rapid in the first few months of life[111] producing major alterations in the insertion sites of the muscles relative to the equator, so the determination of surgical dosage under the age of 6 months may be difficult. However, Helveston reported that this was not an issue when surgery was carried out at 4 months of age or later.[112]

Surgical management

The majority of patients with IET require surgical correction. Orthotropia or microesotropia gives better long-term results than microexotropia.[113] Surgery for IET can be technically demanding in children under 2 years of age. Surgical approaches include BMRc (measured from the insertion or the limbus), unilateral recess/resection, and, for larger angles, BMRc with added unilateral or bilateral lateral rectus resection.[114–118] The authors no longer perform four horizontal muscle surgery due to an unacceptable rate of overcorrections. For moderate angles of strabismus, amounts of surgery based on those reported by Helveston are used (Table 76.1). For larger angles of strabismus ≥60 PD, the authors have developed and validated a surgical table for three-muscle squint repair (Table 76.2).[119]

The authors perform BMRc rather than a unilateral recess/resect procedure because it is technically easier, quicker, and does not involve a loss of muscle tissue. A controlled randomized comparison of BMRc and unilateral recession/resection procedures reported no difference in outcome in children with IET.[120] The position of the muscle insertion varies from 3–6 mm from the limbus and can also vary according to the degree of traction exerted during surgery.[122] Kushner and Morton proposed that unreliable results may be minimized by measuring surgical recession from the limbus rather than the insertion.[123] They reported success in 84% of cases of mean preoperative deviation 53 PD after performing 10.5 mm BMRc from the limbus. This was significantly better than graded recession from the insertion. The authors prefer measuring from the limbus because this is a constant ocular landmark (Fig. 76.13). A table of numbers for recession amounts measured from the muscle insertion is listed elsewhere in this book.

Successful alignment with BMRc (measured from the insertion or the limbus) in children with IET (30–100 PD)

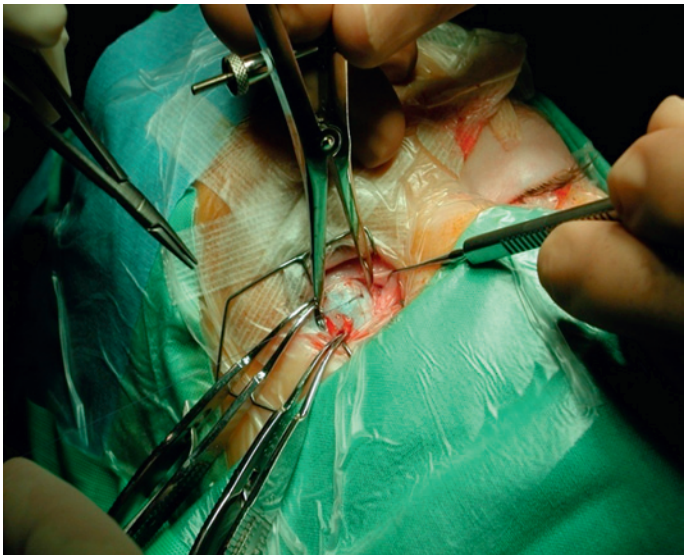

Fig. 76.13 Measurement of right medial rectus recession 11 mm from the limbus. Left arm of caliper at 3 o'clock position on limbus. Note infantile type insertion approximately 3 mm from limbus. *(Measurement technique is described in Camuglia JE, Walsh MJ, Gole GA. Three horizontal muscle surgery for large-angle infantile esotropia. Eye 2011; 25: 1435–41.)*

Table 76.2 Three horizontal muscle surgery dosage for large-angle infantile esotropia ≥60 PD*

Preoperative deviation (PD)	Bilateral medial rectus recessions (mm)		LLRs (mm)
	Age <1 year	Age >1 year	
60–65	10	10.5	4
70	10	10.5	5
75	10	10.5	6
80	10.5	11	6
85	10.5	11	8

LRR, Lateral rectus resection.
*Amount of recession is measured from the limbus and recession amounts for 3 muscle squint repair (3MSR) are reduced to lower the risk of consecutive exotropia.

has been variably reported to be between 30–90%[100,101,114,124–127] with a wide range of duration of follow-up. Many series report success rates of approximately 80% with one operation. The prevalence of larger angles >60 PD among children with IET is 18% and few studies have reported the results of surgery for this group in isolation. Undercorrection rates are still significant and have been proposed to be due to inadequate surgery amounts and/or the variability of the medial rectus insertion.[114,121] Scott retrospectively compared BMRc 5–6.5 mm from insertion with three horizontal muscle surgery (BMRc measured from the limbus with lateral rectus resection) in angles >50 PD.[114] Success to orthophoria was 37.3% for two horizontal muscle repair group with residual ET in 58%. Success in the three-muscle group was 64.5%.

We conducted a validation study of a table guiding surgical dosage for three horizontal muscle surgery for 51 patients with larger-angle IET and reported successful alignment to within 10 PD of orthotropia in 91.3% at 1 year, 77.8% at 4 years, and 73.6% at 8 years.[119] Chatzistefanou et al. reported similar results in patients with large-angle IET >50 PD from a single surgeon performing three horizontal muscle surgery.[118]

Inferior oblique surgery can be included at the time of initial surgery if the IOOA is significant, especially with a "V" pattern ≥20 PD. The options for inferior oblique weakening include recession, anterior transposition, and myectomy. Mims et al. reported that bilateral anterior transpositions also reduced the need for DVD surgery.[128] The authors do not perform inferior oblique myectomy in patients with IET because this prevents its use to treat DVD in the future. If IOOA exists in isolation, a graded IO recession is performed. If IOOA and DVD co-exist, the preferred operation is graded IO anterior transposition. For isolated DVD, the authors perform a large ipsilateral superior rectus recession.[128]

Review of botulinum and its theoretical rationale

The role of botulinum toxin A injections in children as the sole primary treatment, adjunct at the time of primary surgery or secondary treatment for failed surgery, is still under debate. Botulinum toxin as a primary treatment in IET has been studied in a number of prospective and retrospective studies,[129,130] and is discussed in Chapter 85 in more detail. Follow-up of children after botulinum toxin treatment is the same as that following surgery.[131] Despite the reasonable motor and sensory outcomes with multiple botulinum toxin injections, its use as the primary therapy in IET has not become widespread, so surgery remains the standard in most centers.

Postsurgical management

In the immediate postoperative period, the most important considerations are to exclude a lost muscle, conjunctival dehiscence, and to detect postoperative infection. The authors review patients on day 1, week 1, week 3 and week 6 postoperatively. The 6-week postoperative alignment correlates with the likelihood of long-term success.[132] Postoperatively, the authors prescribe antibiotic drops qid and steroid drops (bd only to reduce steroid-induced ocular hypertension)[133] for 2 weeks. At week 1, if the strabismus is undercorrected, cycloplegic refraction should be repeated and the full plus correction given. Miotic drops (e.g. phospholine iodide 0.06% bd) can also be used for undercorrections as a temporizing measure but phospholine iodide drops are no longer widely available. Pilocarpine 0.5% is an alternative.

If the alignment is ≥15 PD ET at the 6-week postoperative visit, further surgery needs to be considered. For residual ET the authors perform lateral rectus resections rather than medial rectus re-recessions due to a lower rate of consecutive XT.[134,135] A small-angle XT with normal ductions in the immediate postoperative period usually resolves spontaneously; however, an underacting medial rectus muscle in the immediate postoperative period is a predictor for consecutive XT. If there are no active issues, patients are reviewed 3-monthly for 2 years after surgery, then 6-monthly until age 6, then yearly until age 8. If the uncorrected alignment is satisfactory, the authors discharge after age 8. All parents should be warned of the long-term risk of their child developing consecutive XT even decades later.

Long-term follow up of IET is essential for the early detection of amblyopia, refractive errors, accommodative ET and secondary associations of DVD, and IOOA. Postoperative amblyopia rates vary due to the differences in definition but the reported prevalence is between 17% and 39%.[11,91,136–138] Risk factors for its development include preoperative amblyopia and uncorrected refractive errors (particularly anisometropia). Approximately 60% of patients with IET will develop accommodative ET within 2–3 years of their initial surgery.[139,140] Birch et al.[75] identified three risk factors for the development of accommodative ET after IET surgery:

1. delay from diagnosis to surgery >3 months;
2. a sustained increase in hypermetropia of as little as +0.5 D;
3. absent or poor stereopsis.

The usual decrease in hypermetropia seen in normal infants in the first 9 months of life does not occur in IETs, making it necessary to carry out long-term refraction follow-up until after 8 years of age.[141]

Follow-up studies have shown that despite early postoperative motor success, alignment to orthotropia can fail over time. Prieto Diaz et al. estimated that 75% patients still have successful alignment at 10 years in a long-term follow up of IETs[142] and 55% of patients maintain a satisfactory alignment after 18 years (Fig. 76.14). Helveston reported failed alignment in 70% after initial BMRc 8–10 mm from the limbus in children <6 months old (with true congenital ET) with mean preoperative angle of 50 PD (range 35–60 PD).[101] Over an 8–12-year follow-up period, there was a 52% reoperation rate. In the follow-up of 130 children, Louwagie et al. determined that repeat surgery was required in 51% by 10 years and 66% by 20 years.[143] Preoperative moderate amblyopia is a risk factor for loss of alignment.[144]

Conclusion

It is now well established that we should operate early to promote the development of binocular vision and some stereopsis. We recommend anytime from 6 months of age for children with a constant ET ≥40 PD. The onset of IET is often around 4 months of age. This produces profound deficits in

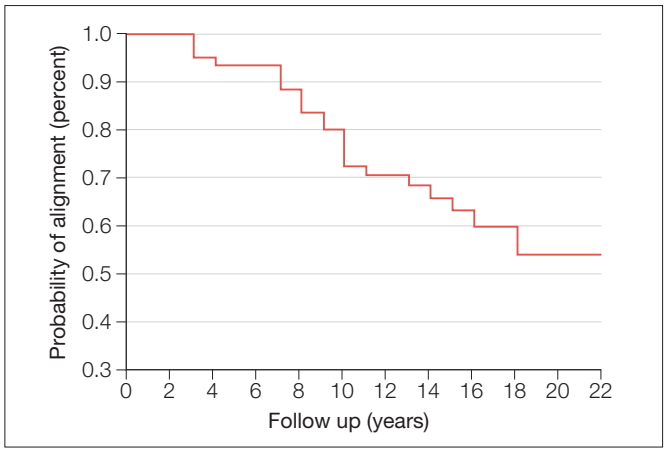

Fig. 76.14 Kaplan–Meier survival curve showing the percentage of patients with long-term success after two-muscle surgery for infantile esotropia. *(From Prieto-Diaz J, Prieto-Diaz I. Long term outcome of treated congenital/infantile esotropia: does early surgical binocular alignment restoring (subnormal) binocular vision guarantee stability? Binoc Vision Strab Q 1998; 13: 249–54. Reprinted by permission of Binoculus Publishing.)*

binocular vision if not corrected promptly. Early alignment appears to produce better functional results, particularly if good follow-up is maintained. Some measurement uncertainty and instability of alignment occurs but does not appear to affect results. Much of our clinical knowledge is still based on retrospective case series. The only new treatment for IET in recent decades has been botulinum toxin. A Cochrane review did not find any randomized controlled trials of surgical intervention for IET and concluded that while early surgery should be the standard we are not yet finally able to resolve the controversies regarding type of surgery, nonsurgical options, and specific age of intervention.[145]

Acknowledgments

Glen Gole would like to acknowledge the generosity and patience of his inspirational strabismus teachers, especially William E. Scott MD, G. Frank Judisch MD, and Graham Pittar, FRANZCO. They set a high standard to follow.

Characteristics

Accommodative esotropia describes an esotropia caused in whole, or in part, by the use of accommodation to clear vision in the presence of uncorrected hypermetropia. This association is widely attributed to Donders.[1] Accommodative esotropia is one of the most common forms of childhood strabismus accounting for about a third of all strabismus patients in most studies in Europe and North America.[2]

The typical age of onset ranges from 2 to 5 years old, but may present earlier ("infantile accommodative esotropia") or, less commonly, at a later age. Caregivers typically report crossing that is intermittent initially and most apparent when the child is fixing on a near object or when fatigued. With time, the crossing occurs more frequently and, without treatment, often becomes constant. Accommodative esotropia may manifest suddenly following a minor illness, trauma, or without any obvious precipitating event.

Classification

The most widely accepted classification of accommodative esotropia includes four distinct types:

1. Fully accommodative esotropia (refractive esotropia): those patients in whom the distance and near deviation are equal and the esotropia is caused entirely by uncorrected hypermetropic refractive error. In one study, these patients had a mean age of onset of 3½ years and a mean refractive error of +4.75 D.[3] They have a normal accommodative convergence to accommodation (AC/A) ratio and respond to correction of the full cycloplegic refractive error (Figs 77.1 and 77.2).
2. High AC/A ratio accommodative esotropia: those patients who have a significant near–distance disparity in the magnitude of the esotropia, with the deviation being at least 10 prism diopters (PD) more at near than at distance. They have a younger age at presentation (mean 2.7 years old),[4] and a lower degree of hypermetropia than patients with typical fully accommodative or refractive esotropia. They have a normal hyperopic refractive error for age and little or no esotropia in the distance.
3. Refractive esotropia with high AC/A: this, arguably the most common type, has elements of both of the preceding types. These patients have a significant hypermetropic refractive error and some level of high AC/A ratio that leads to a deviation that is greater at near than distance by at least 10 PD.
4. "Early-onset esotropia" or "infantile accommodative esotropia": these terms refer to patients with fully accommodative esotropia presenting at a very early age. They may present with esotropia as early as 6 months of age and typically have very high hypermetropia and are more likely to have inferior oblique overaction.

The accommodative convergence/accommodation ratio (AC/A)

The AC/A plays an important role in the development, treatment, and prognosis in accommodative esotropia. Patients with a high AC/A ratio present earlier, are more likely to require surgery, and have a poorer prognosis for long-term binocular vision.[5] There are different ways to calculate the AC/A ratio although in clinical practice this is not necessary. A clinical comparison of distance to near deviation is most commonly used to determine whether or not the AC/A ratio is high. Patients can be further classified based on the degree of near–distance disparity:

grade I: 10–19 PD more deviation at near;
grade II: 20–29 PD more deviation at near;
grade III: 30 PD or more deviation at near than distance.

To calculate the AC/A ratio, either the gradient or heterophoric method can be used. For the gradient method, measure the

Fig. 77.1
A 3-year-old girl presented with a new onset of left esotropia (with strong fixation preference for the right eye). The deviation was 35 PD at near and distance fixation. The cycloplegic refraction was +4.25 in the right eye and +4.50 in the left eye.

Fig. 77.2 The same girl as in Fig. 77.1, 4 weeks later, wearing her full hyperopic correction. She had a small left esotropia with fixation preference for her right eye. Part-time occlusion therapy of the right eye was begun.

deviation at a fixed distance while relaxing accommodation by introducing plus lenses as follows:

$$\mathbf{AC/A = (D1 - D0)/p}$$

where p is the power of the lens used; D0, the deviation without lenses; and D1, the deviation with lenses.

In the heterophoric method, near and distance deviations are compared while taking into account the interpupillary distance (IPD) as follows:

$$\mathbf{AC/A = IPD\,(cm) + (Dn - Dd)/D}$$

where D is the fixation distance at near, Dn is the deviation at near, and Dd is the deviation in the distance. The gradient method is more easily performed and more accurate. By this method, a normal AC/A ratio is between 3 : 1 and 5 : 1.

Risk factors for accommodative esotropia

The most commonly recognized risk factor for the development of accommodative esotropia is excess hypermetropia. Its prevalence increases with increasing levels of hypermetropia. Other factors including family history, subnormal binocularity, and the presence of anisometropia all increase the risk of developing accommodative esotropia.

The prevalence of affected first-degree relatives in patients with accommodative esotropia is 18–23%, with as many as 75% of patients having an affected sibling, parent, grandparent, aunt, or uncle. Subnormal stereopsis or fusion preceding the onset of accommodative esotropia is a contributing factor in its development. These patients may develop accommodative esotropia with lower levels of hypermetropia.[6] Anisometropia of >1 D and amblyopia, in patients with hypermetropia, increase the likelihood of developing accommodative esotropia, particularly in patients with lower levels of hypermetropia.[7]

Clinical evaluation

Evaluation of patients with presumed or suspected accommodative esotropia requires a systematic approach. First, determine if a family history is present and if the child has any developmental issues or recent illness. The caregivers should be questioned about duration, frequency, and constancy of the crossing. Triggering factors such as near viewing or fatigue should be ascertained. Though accommodative esotropia is typically intermittent in the early stages, delay in treatment will often result in deterioration of fusion and development of a constant deviation and amblyopia.

The examination should include age-appropriate acuity testing, extraocular motility evaluation with attention to other causes of acquired esotropia (decreased abduction in sixth nerve palsy, etc.), as well as measurement of the deviation at near and distance. Evaluation for oblique muscle dysfunction and the presence of "A" or "V" patterns should be assessed. Inferior oblique muscle overaction, though less common than in infantile esotropia, may occur, particularly in cases of infantile accommodative esotropia or in the presence of significant amblyopia.[8,9] As noted, the AC/A ratio need not be calculated but can be graded based on the near–distance disparity.

A cycloplegic refraction is essential. Though some believe atropine refractions are necessary, the additional hypermetropia detected with atropine compared to cyclopentolate is unlikely to be of clinical significance, especially if blue-eyed, because they dilate and cycloplege more readily. The authors feel adequate cycloplegia can be obtained using 0.5% cyclopentolate (Mydrilate, Cyclogyl, Pentolair) under 6 months of age, 1% cyclopentolate from 6 months up to age 2 years, and 2% cyclopentolate may be used in patients over 2 years of age. Typically, the authors use 2.5% neosynephrine (phenylephrine) to facilitate dilation. The drops may be repeated in 5 minutes if needed and 30–40 minutes should be allowed to pass before refracting the patient. Children who do not dilate or become cyclopleged with cyclopentolate should be atropinized.

A fundus examination is critical; attention should be directed to any structural lesions that could result in a sensory deviation,

as well as assessment of the optic disc to detect swelling that that could indicate increased intracranial pressure.

Nonsurgical treatment

Initial treatment of presumed accommodative esotropia is proper spectacle correction. In most cases, the full cycloplegic refraction should be prescribed (see Fig. 77.2). In a patient in whom the angle of deviation is small and the hypermetropia significant, an undercorrection of 1–2 D can be prescribed to facilitate initial compliance with spectacles. However, one should increase to the full cycloplegic refraction if the child is not well aligned at the first follow-up visit. The authors do not initially prescribe bifocals even if the AC/A is high. It is important to correct any anisometropia as well as astigmatic error even if the full spherical correction is not prescribed.

If significant amblyopia is present, treatment should be instituted initially, although in mild to moderate cases it may be preferable to wait until the child has been in the glasses for a few weeks before beginning amblyopia therapy. Spectacle correction alone improves acuity in amblyopic eyes even in the presence of strabismus.[10] Once the child has adapted to the spectacles, a more accurate baseline acuity can be determined to assess the response to amblyopia therapy. Atropine penalization or patching is effective (see Chapter 73), though decreasing the spectacle power of the sound eye when using atropine does not significantly improve its effectiveness.[11]

Alignment in spectacles should be assessed after about 6–8 weeks. If the eyes are well aligned at near and distance, the child can be seen in 6 to 12 months unless amblyopia therapy necessitates more frequent follow-up. If alignment is unsatisfactory, longer observation in spectacles is generally acceptable, particularly if compliance with glasses is in question. Administration of atropine 1% to both eyes each morning for 1 to 2 weeks often improves compliance. Repeat cycloplegic refraction can be performed if its accuracy is in question.

If distance alignment is good, but significant esotropia persists at near after 3 months of spectacle wear, +3.00 bifocals can be considered. The bifocals should be executive or flat topped and set at the level of lower edge of the pupil. Miotics, such as phospholine iodide, may be considered, though their potential side effects and difficulty of administration limit their usefulness.

Surgical treatment

Surgery is indicated when the eyes are not aligned adequately with glasses; the definition of what constitutes "adequate" differs among clinicians. The decision to proceed with surgery involves a number of factors in addition to alignment with glasses. These include the patient's age, family or patient desires, presence or absence of amblyopia, and previous experience and compliance with spectacle or contact lens correction.

In the visually formative years, alignment that allows for fusion and prevention of amblyopia is paramount. Surgery should not be delayed if alignment is unsatisfactory. Fusion disruption for as little as 4 months can risk permanent loss of binocularity.[5] Common situations in which surgery is indicated are:

1. Partially accommodative esotropia: patients who never achieve good alignment in glasses alone.
2. Deteriorated accommodative esotropia: patients with initially good response to spectacles who later lose it. Deterioration of previously controlled accommodative esotropia has been associated with early-onset, high AC/A ratio, and amblyopia.[7,12]
3. Surgery may be indicated in patients with marginal control, those with good distance alignment but residual esotropia at near who do not tolerate or desire bifocals.[13]
4. Older patients whose hypermetropia may have normalized but who cross without minimal correction.

Surgery need not be deferred until amblyopia therapy is complete. Amblyopia therapy may benefit from improved alignment.[14]

In general, bilateral medial rectus recessions are the preferred surgical approach. Undercorrection is common in patients with accommodative esotropia if standard surgical dosages are followed. This is particularly true in the presence of a clinically high AC/A ratio. Various approaches can improve results, including adding additional recession to standard surgical dosages,[15] operating for the near deviation,[16] or combining medial rectus recessions with traditional or "muscle pulley" posterior fixation sutures.[17]

Long-term prognosis

One of the most commonly asked questions by parents of children with accommodative esotropia is "Will my child always have to wear glasses?" While it is important to keep patients in their full hyperopic correction through the visually formative years, many clinicians "wean" patients out of their full correction (and bifocals, if worn) to decrease spectacle dependence over time.

Mohney et al. reported 20% of accommodative esotropes will be free of spectacles by 10 years after diagnosis (Fig. 77.3).[18] Patients with high hypermetropia,[19] high AC/A ratio (bifocal dependence), and anisometropia are more likely to need glasses long term. Those with low hypermetropia, normal AC/A ratio, and those that undergo surgery are more likely to be successfully weaned from spectacles.

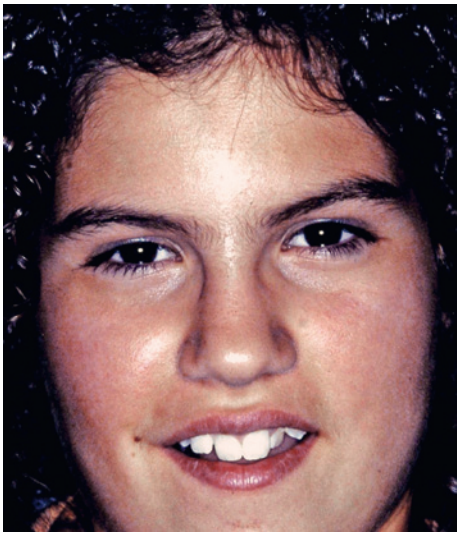

Fig. 77.3 The same girl as in Figs 77.1 and 77.2 at 15 years of age. She has been weaned from glasses. Her cycloplegic refraction is +1.50 in the right eye, +1.50 in the left eye. Visual acuity is 20/20 in each eye and she is orthotropic at near and distance fixation with high-grade stereoacuity.

For those patients that need correction beyond 10 years of age, contact lenses are a viable option and may improve compliance; additionally, refractive surgery has been used successfully in small series of older children and young adults.[20,21]

ACUTE COMITANT ESOTROPIA
SENSORY DEPRIVATION ESOTROPIA
MYOPIA-ASSOCIATED ESOTROPIA
MICROTROPIA
SYNTHESIS
REFERENCES

These esotropias mostly occur later in childhood when binocular fusion is stable. There is considerable overlap between some groups and all patients do not fit neatly into a category. They are best approached by trying to understand the pathophysiology of each individual case and attempting to identify the cause of the breakdown of fusion.

Acute comitant esotropia

In a child presenting with sudden-onset comitant esotropia, a reason needs to be sought for loss of fusion at an age when binocular function is usually stable. This is commonly a benign condition, but children with intracranial pathology, particularly posterior fossa tumors, can present in this way.[1,2]

Children with acute-onset comitant esotropia can be divided into three groups[3]:

1. Acute onset esotropia following artificial interruption of fusion (Swan-type esotropia): This can occur with patching for anisometropic amblyopia, but has also been described following patching for a corneal abrasion. Loss of fusion may be associated with uncorrected hypermetropia. It can also occur following visual loss in one eye (see below, sensory esotropia).
2. Comitant esotropia of the "Franceschetti" type: This is an acute-onset comitant esotropia with diplopia and good potential binocular cooperation. It may be intermittent at first. The accommodative element is usually minimal. In most patients no immediate cause can be found; in some, an illness or shock may precede the onset.[3]
3. Comitant esotropia of the "Bielschowsky" type: These patients have up to 5 diopters (D) of myopia. There is uncrossed diplopia for distance, with fusion for near. The mechanism of a causal relationship between the myopia and esotropia is debated.

In groups 1 and 3 there is generally a clear cause for loss of fusion and investigation is not indicated in the absence of any other abnormalities. In group 2, there is no clear cause for the breakdown of fusion and there is concern about underlying neurological disease.

The decision on neuroimaging depends on the features of each case.[4] The risk of underlying pathology must be balanced against the risks associated with the X-ray dose for a computed tomography (CT) scan and a general anesthetic for CT or magnetic resonance imaging if required.

History and examination should determine whether there is evidence of a pre-existing cause for the esotropia and whether there is evidence of any associated neurological disease. If there is a cause for the esotropia (significant uncorrected hypermetropia or myopia, a high accommodative convergence/accommodation [AC/A] ratio, or anisometropic amblyopia), without other suspicious features, imaging is not required. Untreated anisometropic amblyopia may result in decompensation. Patching can precipitate a manifest squint in a child with a pre-existing microtropia or esophoria.

Features suggesting neurological disease include age of onset after the age of 5 years and distance diplopia prior to the onset of the esotropia. Diplopia at presentation indicates esotropia of recent onset without pre-existing suppression and so higher risk. Suspicious features of the examination include a distance angle larger than the near angle, an increase in esotropia in lateral gaze, lateral rectus underaction, and nystagmus. Lack of fusion on testing with prisms or the synoptophore is more common when there is a brain lesion. An "A" pattern esotropia may be associated with hydrocephalus secondary to an Arnold–Chiari malformation, a tumor, or aqueduct obstruction. Papilledema or optic nerve dysfunction causing reduced acuity or color vision or abnormalities of pupil responses mandate imaging.[4] Visual fields and clinical electrophysiological testing may provide valuable information.

Headache, clumsiness, evidence of developmental regression, or abnormalities of other cranial nerves may indicate neurological disease.

Initial treatment consists of full correction of any refractive error and treatment of amblyopia. If re-alignment is not achieved with refractive correction alone, then early surgery is indicated to realign the eyes before the potential for fusion is lost. As an alternative treatment, botulinum toxin may result in the long-term re-establishment of high-grade stereoscopic function.[5]

Early re-alignment carries a good prognosis for re-establishing fusion. The failure to re-establish fusion may indicate an underlying neurological problem.[1] However, fusion following strabismus surgery has been reported in patients after a tumor has been treated.[2] Patients with treated intracranial tumors and *incomitant* strabismus have a better chance of re-establishing fusion.[6] In the absence of involvement of brainstem fusion centers, the duration of misalignment is generally considered a major prognostic factor for the re-establishment of binocular function. However, the timeframe for loss of fusion potential varies from child to child and some older children have regained fusion after several years[7] and more than one surgical procedure.[8] In younger children, fusion potential may be lost in a few months. Early surgery or botulinum toxin to re-establish alignment is likely to be beneficial even in children with (treated) intracranial tumors.

The children with Franceschetti-type acute-onset esotropia probably represent the end of a spectrum of children with acquired non-accomodative esotropia (ANAET) in whom the onset may not be acute (or recognized as acute by parents) but who are otherwise similar and have a good chance of re-establishing binocular function after strabismus surgery,[9–11] even after early onset between 6 months and 3 years of age.[10] Of well over 200 children in these studies, none developed any neurological problems, even with long-term follow-up.

Sensory deprivation esotropia

The visual cortex fuses the images from the two eyes into a single image. If the image from one eye is severely degraded or lost, fusion cannot occur. In adults, divergence is common, but in children an eye with poor vision and absent binocular function will commonly become convergent, perhaps because they are hyperopic. Sensory esotropia may occur with early-onset conditions (monocular congenital cataract or optic nerve anomalies; Fig. 78.1), or with later acquired visual loss (trauma; Fig. 78.2). Hypermetropia of the fixing eye should be corrected before surgery is considered, since doing so is likely to reduce the deviation.

Management must address whether vision can be restored in the affected eye and, if so, whether fusion can be re-established. A common cause of reversible monocular visual loss in an older child is a traumatic cataract. In the absence of other ocular damage, the visual prognosis is good. Amblyopia does not develop in older children, but fusion may be lost rapidly and restoration of vision following cataract surgery may result in intractable diplopia, even with straight eyes. For this reason, cataract surgery should be undertaken as promptly as possible.

In a child with no prospect of visual improvement, strabismus surgery can be undertaken if the appearance of the deviation is unacceptable. All hypermetropia of the fixing eye should be corrected. The author prefers medial rectus recession and lateral rectus resection of the deviating eye, with the goal of leaving a small convergent deviation with no adduction deficit to minimize consecutive exotropia.

Fig. 78.1 Left sensory esotropia in a 6-year-old boy with left optic nerve hypoplasia. The left acuity was LogMAR 1.1 (6/76, 20/250, 0.07). The esotropia is controlled to an acceptable appearance by his hypermetropic spectacle correction.

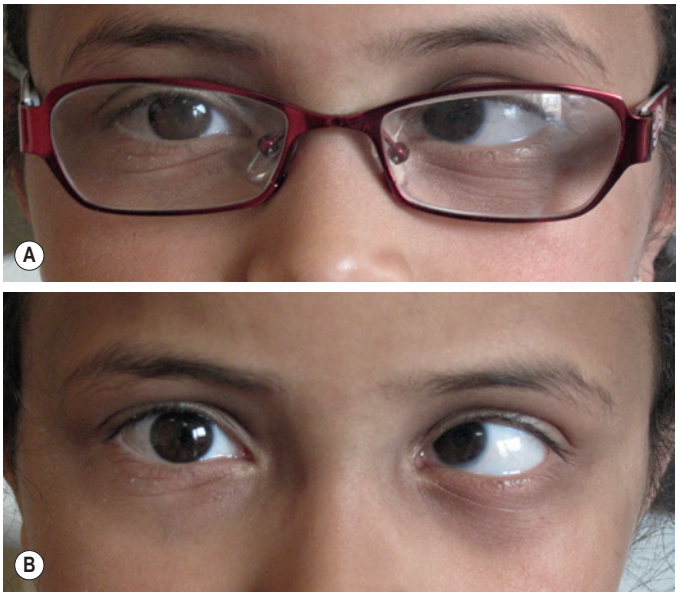

Fig. 78.2 Left sensory esotropia with left inferior oblique overaction in a 9-year-old girl following blunt trauma to her left eye as a baby. The left acuity is LogMAR 1.30 (6/120, 20/400, 0.05). The fundus was normal, but electrodiagnostic testing showed left optic neuropathy and maculopathy. Although the deviation is smaller with glasses (A) than without (B), surgery will be needed to improve the appearance.

Some children adopt a face turn toward the fixing eye because of manifest latent nystagmus in this eye that can substantially reduce their acuity. Acuity is maximized by adducting the fixing eye and turning the head. The abnormal head posture can be improved by recession of both medial recti or medial rectus recession and lateral rectus resection of the fixing eye, provided that parents and patient are comfortable with surgery to the only good eye. Inferior oblique overaction may also develop in both eyes. In the fixing eye this results in downdrift of the non-fixing eye on abduction ("the fallen eye syndrome"). This can be improved by weakening the inferior oblique in the fixing eye.

Myopia-associated esotropia

Esotropias have been described in association with different degrees of myopia. Bielschowsky[12] described distance esotropia

occurring in patients with myopia of up to −5.00 D. This can be of acute onset, but the time of onset can be difficult to determine because the diplopia is intermittent. This occurs mainly in adults, but also in older children.[3] Inadvertent optical overcorrection of the myopic error stimulates accommodation and convergence and must be avoided. There is typically a small distance esotropia with diplopia, and binocular fusion for near, although this may eventually break down.[13] Slight lateral rectus underactions may occur, potentially simulating sixth nerve palsy, a diagnosis that should be excluded in any patient with distance esotropia. Prisms give good symptomatic control. Most patients eventually undergo strabismus surgery, with good results.

Patients with high myopia develop esotropia by two overlapping mechanisms. With esotropia of high myopia, there is good corrected acuity in each eye and a purely convergent deviation with good motility and mild restriction of abduction. These patients do well with medial rectus recession and lateral rectus resection of the deviating eye. Histological examination of the resected lateral rectus may show fibrotic change. This may be an important etiological factor.[14]

Other patients have the eso-hypotropia of high myopia.[15] This is due to stretching and dehiscence of the connective tissue band running between the pulleys[16] of the superior and lateral recti in the super temporal quadrant. This results in downward slippage of the lateral rectus and nasal slippage of the superior rectus muscles.[17,18] There is superolateral dislocation of the posterior pole of the globe out of the muscle cone, with inferonasal displacement of the cornea resulting in an eso-hypotropia. This has been confirmed by high-resolution magnetic resonance imaging studies.[17,18] Significant secondary contracture of the medial rectus may occur. Motility may be very restricted and vision in one or both eyes is often poor from myopic macular change or amblyopia. Binocular function is commonly absent.

Horizontal recess–resect procedures are of limited value, but several forms of "muscle-path" surgery have been reported as successful. The lateral border of the superior rectus is sutured to the superior border of the lateral rectus at 15 mm behind the muscle insertions using a non-absorbable suture to appose the muscle borders and reposition the posterior pole of the globe into the muscle cone.[19,20] If the medial rectus is contractured, it is recessed. This improves both the deviation and ocular motility[19,20] and is valuable in patients with a wide range of myopia and eso-hypotropia, even those with good vision in both eyes and binocular function who present with intermittent diplopia.[21]

Microtropia

A microesotropia is a small angle convergent squint with anomalous binocular function. Microtropia is best considered as a description of the binocular status of the patient who may have any of a number of different types of squint. It represents the first stage in the breakdown of binocular function caused by abnormal visual experience during visual development. It is often seen with anisometropic amblyopia, but may be a primary abnormality.[22] It may be the result of reduced binocularity from intermittent misalignment of the eyes during visual development, e.g. Duane syndrome. In patients with accommodative esotropia, it may be the end result of treatment rather than bifoveal binocular fusion. A microtropia is often the outcome of early strabismus surgery,[23] particularly in younger children.

Patients with a microtropia demonstrate the monofixation syndrome, with peripheral fusion but a central area of suppression in the deviating eye.[24] However, not all patients with monofixation have a clinically demonstrable microtropia.[24] Anomalous binocular function can be maintained up to an angle of about 8 prism diopters.[24] Stereopsis is present, but reduced; smaller deviations are associated with better stereopsis.[25] Receptive fields of visual cortical neurons in the foveal part of the visual field representation are small and become progressively larger with increasing eccentricity. For a small angle of ocular misalignment, the fields no longer overlap centrally, but binocular correspondence can be maintained with the larger, more peripheral fields. Thus, there is central suppression of the deviating eye while peripheral binocular function is maintained.

Patients with a microtropia may demonstrate central monocular fixation with their deviating eye, in which case there is a small flick on cover–uncover testing. However, some children have eccentric monocular fixation with their deviating eye and fixate monocularly using the same eccentric retinal point that corresponds to the fovea of the non-deviating eye under binocular conditions. In this case, there is no movement on cover test.[26] Eccentric fixation can be demonstrated with the visuoscope. A few patients fix monocularly with an eccentric point that differs from that corresponding to the normal fovea and they show a flick on cover test.

The central suppression scotoma can be demonstrated by the 4-D base-out prism test. When a 4-D base-out prism is placed in front of one eye, a patient with bifoveal fixation makes a small conjugate movement of both eyes to re-establish fixation, followed by a small vergence movement to re-establish bifoveal alignment. In monofixation, this latter vergence movement will not occur if the prism is placed in front of the fixing eye, and no movement at all occurs if the prism is placed in front of the eye with the suppression scotoma. Testing with Bagolini glasses shows lateral displacement of the arm of the cross seen by the deviating eye, together with a break in the center of the line corresponding to the central suppression area.

A stable microtropia is not amenable to surgical or prismatic treatment. The microtropia, acuity, and stereopsis may improve with patching for anisometropic amblyopia.[27]

A microtropia occasionally decompensates to a large esotropia in childhood, particularly following patching or in hypermetropic children who do not wear their glasses. If this happens, full hypermetropic correction is required. If this is unsuccessful, then early re-alignment by surgery or botulinum toxin will likely lead to recovery of binocularity. Patients with a microtropia have good motor fusion and stable ocular alignment. Ing et al.[28] found 92% of patients with a microtropia had remained stable for a mean of 13.9 years and the few who decompensated recovered stereopsis following surgery. Arthur et al.[29] studied 80 early-onset esotropes surgically aligned to within 8 PD. Those achieving monofixation were aligned at a significantly earlier age than those without monofixation. Seventy-five percent of those with monofixation remained stable, whereas only 45% of non-monofixators maintained stability. Patients who have monofixation and subsequently lose alignment have a good prognosis for recovering monofixation with surgery.[28,30]

Synthesis

Different esotropias have been described. The distinction between them is not always clear-cut and there is considerable overlap. Patients are best approached by attempting to understand the underlying pathophysiology of each case. The common thread in many cases is the breakdown of binocular fusion relatively late in childhood. The reasons for this can be divided into three main categories:

1. sensory impairment;
2. motor imbalance;
3. impairment of central fusion centers.

Some cases may be multifactorial. Some patients show weak fusion easily disrupted by one of the other factors. In a child where there is no sensory or motor reason for the loss of fusion, symptoms or signs of neurological disease must be sought and neuroimaging considered.

In a child with previously normal binocular function, diplopia occurs until suppression develops and binocular potential will be retained for an unpredictable period of misalignment. Binocular function can often be recovered by early re-alignment. In an older child, fusion potential is likely to be retained for longer, but if it is lost and suppression does not develop, intractable diplopia results.

Definition

Intermittent exotropia (XT) is a strabismus condition with outward drifting of either eye interspersed with periods of good alignment or orthotropia (Fig. 79.1). Monocular eye closure may occur during exodeviation. Near stereoacuity is often normal during periods of alignment, though it may deteriorate if the condition progresses.

Cause

The causes of intermittent exotropia are not fully understood. The following have been suggested:

1. An imbalance between active convergence and divergence,[1] although it is not clear that divergence is active.[2]
2. Abnormal orbital anatomy.[3]
3. Abnormalities of extraocular muscle proprioception,[4] although the existence of active proprioceptors in extraocular muscles is disputed.[5]

It is tempting to speculate that X(T) relates to the ability to switch between a state of suppression and relatively normal binocular function seen in children with the condition. In macaque monkeys there is reduced metabolic activity in the ocular dominance columns that serve the ipsilateral eye's peripheral temporal retina. This is consistent with the topographic organization of suppression scotomas in humans with exotropia.[6]

Accommodative convergence may help to maintain alignment during near viewing.[7]

Epidemiology

X(T) is the most common form of divergent strabismus.[8,9] As divergent strabismus is much more common than convergent strabismus in Asia, it is now the most common form of strabismus worldwide.[10,11] The prevalence of exotropia in children less than 11 years of age was estimated as 1%.[12] X(T) accounted for approximately half of all cases of exotropia.[9] In Singaporean children aged between 6 and 72 months, the prevalence of strabismus was 0.8%, with an exotropia : esotropia ratio of 7 : 1. Sixty-three percent of cases of exotropia were intermittent.[11] In Japanese elementary school children, the incidence of X(T) was estimated as 0.12%.[13] By contrast, intermittent exotropia appears rare in South African black and mixed race children.[14] A female predominance has been found in some studies.[15]

Clinical features

The onset is typically in the second to third year of life,[16,17] when an intermittent outward drift of one eye or monocular eye closure in bright sunlight is noted (Fig. 79.2). Monocular eye closure in X(T) has been attributed to photophobia,[18] although it is difficult to explain why more light should enter exotropic than orthotropic eyes. Monocular eye closure may be due to diplopia or an abnormal visual percept, or reduction in threshold for bright lights, induced by divergence of the eyes.[19,20] It may resolve following surgery.[21,22]

It is usually not possible to measure stereoacuity accurately at presentation because the children are too young, but older children with X(T) have normal, or near normal (for age), near stereoacuity.[16] One study found reduced visual acuity in one or both eyes of 26% of children at presentation, although this reduction was generally just below age-related normal thresholds and due to anisometropia.[14]

X(T) is traditionally classified into three types:

1. *True divergence excess*: the deviation is more than 10 prism diopters (PD) larger when measured at distance fixation than at near.

Fig. 79.1 A 7-month-old child with intermittent exotropia that progressed to constant exotropia. (Top center) At age 7 months, note orthotropia in primary gaze; (top left) large angle exotropia with right eye fixing; (top right) large angle exotropia with left eye fixing. Patient was initially managed conservatively with patching and convergence exercises with good control of the deviation after only 3 months. Patient failed to follow-up regularly. (Bottom) At the time of last evaluation at age 2 years, she had a large angle constant exotropia with a left eye preference. Photos also show deviation with either eye fixing.

Fig. 79.2 Two brothers standing in Southern California sunshine. Boy on the left has no strabismus. Boy on the right has intermittent exotropia with monocular eye closure, a common sign of intermittent exotropia.

2. *Simulated divergence excess*: initially greater at distance fixation, but the misalignment at near fixation increases to within 10 diopters of the angle at distance following disruption of near binocular vision by monocular occlusion and/or +3 lenses.
3. *Basic*: the size of the misalignment is equal, to within 10 PD, whether the misalignment is measured at distance or near fixation.[23,24]

The measurements required may be difficult in young children but the distinction between the types helps to plan appropriate surgical treatment,[25] although this has been disputed.[26]

One of the most striking neurophysiologic features of X(T) is that children with the condition alternate between a state of apparently normal (or near normal) binocular vision, with normal stereoacuity when the eyes are aligned, and a state of suppression, and anomalous retinal correspondence, when the eyes are divergent.[27–29] However, when the eyes are straight, binocular function is not entirely normal in X(T). Children with X(T) have reduced positive fusional vergences (reduced convergence in response to a base-out prism).[30] Also, suppression can be demonstrated even during periods of normal ocular alignment, indicating that it can be triggered by purely retinal information.[31]

A subset of children with X(T) have subnormal binocular function even when the eyes are "straight" because when "straight" a small constant divergent deviation is present.[32] This may underlie the reduced stereoacuity seen following treatment of X(T) in some cases.[33]

While X(T) is not associated with neurodevelopmental abnormalities, it has been associated with later development of psychiatric disorders.[34,35] The reason for this is unknown, but it is unlikely to be due to the consequences of an abnormal appearance in childhood, as it is not seen in children with esotropia,[34] nor is it altered by eye muscle surgery.[36] X(T) has also been associated with attention-deficit hyperactivity disorder.[37]

Quality of life

The Pediatric Quality of Life Inventory was used for patients with X(T); no significant effect was observed.[38,39] Hatt et al.[40,41] developed a specific quality of life measure based on interviews with children with X(T). They identified concerns about the presence of exotropia relating to observers' awareness of the strabismus, but also the child's awareness of strategies they used to control exotropia, such as blinking. They identified parental anxiety about exotropia as the most significant concern.[42] Childhood concerns related both to anxiety about the social consequences of X(T) and monocular eye closure.[43] Reduced parental and proxy health-related quality of life are also associated with the decision to undertake surgery for X(T).[44]

Clinical evaluation

Possible measures of progression or outcome in X(T) are:

- angle (size) of misalignment;
- stereoacuity (for near and/or distance fixation);
- deterioration of convergence;

- control of misalignment;
- deterioration to constant exotropia (± development of strabismic amblyopia).

Measurements of stereoacuity and convergence are not consistent in children under the age of 4 years, and control, constancy, and angle (particularly at distance) are also challenging to measure in this group. Any therapy for children under the age of 4 years with X(T) is necessarily based on imperfect clinical measurements, making assessment of the effect of therapy difficult. Thus, many clinicians defer treatment until later, despite the theoretical benefits of early therapy.[16]

The traditional outcome measure for the effect of therapy on X(T) is the size of the angle of the misalignment, with successful outcomes following therapy often taken as angles of between ±10 PD of orthophoria.[45–47]

Ocular alignment (usually with a range of ±10 PD), is, however, an inadequate outcome measure for treatment of X(T). The measurement given usually includes latent and manifest (tropia and phoria) components of the misalignment. Thus, small constant misalignments, both esotropic and exotropic, with worse functional correlates than X(T)s, are included as treatment "successes."[48]

Assessing the control of intermittent exotropia

A more relevant measure of treatment of X(T) is the degree of control of the misalignment, as measured by the frequency with which a strabismus is manifest, and the ease with which an induced misalignment can be re-aligned. Diplopia is not a feature of X(T), and the mechanisms underlying control are obscure, but some children report awareness of their misalignment.[40]

Two scoring systems for the measurement of control of X(T) are in common usage: the Mayo office-based scale,[39] and the Newcastle Control Score.[49,50]

The Mayo scoring system is outlined in Box 79.1. The Mayo scale is based solely on timed observations. An average of three scores are recommended to provide a reliable measure.[51]

The second scoring system is the Newcastle Control Score for Intermittent Exotropia (NCS).[52] The criteria for assigning an NCS are given in Table 79.1. The NCS is based on the criteria for surgical intervention popularized by Rosenbaum.[53] These criteria consist of a parental report of the frequency with which a divergent misalignment of the eyes is observed (home control) and an objective assessment of the ease with which the eyes can be re-aligned following the induction of strabismus with a cover test (office control). Rosenbaum suggested that surgery should be considered if the strabismus was present more than 50% of the time and was poorly controlled on examination. The relationship between these two criteria requires further study, but correlations have been shown between home and office control.[54]

The home control element is potentially subject to observer bias but does have the merit of being a parent-reported outcome measure.

Measuring the deviation

For measurements to be reproducible, any significant refractive error must be corrected. This is usually the maximum tolerated plus or the least minus prescription. An accommodative fixation target slightly above threshold must be used; for example, a patient with 20/20 vision in both eyes needs to be presented with a 20/50 line. In preverbal children, videos or toys presented as targets should have sufficient detail to control accommodation.

Distance measurements should be made at more than 20 feet to eliminate accommodation. In some cases, distance deviation may have to be measured outside or beyond the confines of the standard visual lane. Breaking fusion by prolonged monocular occlusion for 30–60 minutes may be required to eliminate all fusional vergence.[55,56] The patch is removed by the examiner, and fusion, no matter how momentary, is not allowed.

Stereoacuity in intermittent exotropia

In X(T), the eyes usually remain aligned for near fixation, or are capable of re-alignment in response to a stereoscopic image.

Box 79.1

The Mayo scale for scoring control in intermittent exotropia[39]

5 = Constant exotropia
4 = Exotropia >50% of the exam before dissociation
3 = Exotropia <50% of the exam before dissociation
2 = No exotropia unless dissociated, recovers in >5 seconds
1 = No exotropia unless dissociated, recovers in 1–5 seconds
0 = No exotropia unless dissociated, recovers in <1 second (phoria)

Notes:
The score is measured at distance and near fixation, and so yields an overall control score ranging from 0 to 10.
Levels 5 to 3 are assessed during an initial 30-second period of observation at distance fixation and repeated at near fixation for another 30-second period.
Levels 2 to 0 are then graded as the worst of three rapidly successive trials; an occluder is placed over the right eye for 10 seconds and then removed, measuring the length of time it takes for fusion to be re-established. The left eye is then occluded for 10 seconds and the time to re-establish fusion is similarly measured.
A third trial of 10-second occlusion is performed, covering the eye that required the longest time to re-fuse.
The worst level of control observed following the three 10-second periods of occlusion should be recorded.
If the patient has a microesotropia by simultaneous prism and cover test, but exodeviation by alternate cover test, the scale applies to the exodeviation.

Table 79.1 The revised Newcastle Control Score for Intermittent Exotropia (NCS)[41]

NCS criteria	Score
HOME CONTROL (XT OR MONOCULAR EYE CLOSURE SEEN)	
Never	0
<50% of time fixing in distance	1
>50% of time fixing in distance	2
>50% of time fixing in distance + seen at near	3
CLINIC CONTROL (SCORED FOR NEAR AND DISTANCE FIXATION)	
Immediate re-alignment after dissociation	0
Re-alignment with aid of blink or re-fixation	1
Remains manifest after dissociation/prolonged fixation	2
Manifest spontaneously	3
Total score: n/9	

XT, Exotropia.

Values of near stereoacuity in X(T) are normal,[27] making near stereoacuity a poor measure of severity. Near stereoacuity may be lost completely if X(T) deteriorates to a constant exotropia, but it may be restored surgically in some cases.[57]

The initial abnormality in X(T) is misalignment at distance fixation. Measurement of stereoacuity at distance fixation is, therefore, a potential measure of X(T) severity. The tendency to diverge at larger viewing distances may introduce a "pedestal disparity" between the reference surface and the fixation point, thus lowering stereoacuity.[29]

Measurement of stereoacuity at distance fixation is technically challenging. Previous studies used a liquid crystal system (Binocular Visual Acuity Test)[58] requiring goggles during measurement, limiting its use in young children. This is no longer available. Subsequent studies have utilized the Frisby Davis Distance Stereotest[59,60] and the Distance Randot Test.

The effect of X(T) on distance stereoacuity is variable, depending on the characteristics of the test used. It has been reported as being either normal or absent.[61] Conversely, others have found distance stereoacuity to be degraded in X(T),[62] and to be improved by surgery.[63,64] This may be due to the way in which absent distance stereoacuity was recorded, as in some studies a nominal value was ascribed to absent stereoacuity. It is not clear if improvements in distance stereoacuity following surgery represent regression to the mean of a series of measurements, as surgery is more likely to be performed when a poor distance stereoacuity measurement is found.

Differential diagnosis

X(T) is not associated with neurologic pathology.[9,65] However, a constant exotropia with variable angle can mimic X(T), and constant exotropia is associated with neurological and ocular pathology[65] (see Chapters 43 and 57) as in optic nerve glioma or retinoblastoma reducing vision in one eye which may masquerade as cases of X(T).[66–68]

Children with craniofacial anomalies are frequently exotropic (see Chapter 28). Alphabet pattern deviations are common. "V" patterns mimic inferior oblique overaction; "A" patterns mimic superior oblique overaction. Dynamic magnetic resonance imaging (MRI) of the rectus muscles may suggest heterotopic rectus muscles (Fig. 79.3). These patients benefit from transposition surgeries correcting the muscle displacements to improve the pattern deviations. Inferior oblique surgery is usually unnecessary.

Management

The evidence underpinning the management of X(T) is poor, but this situation is improving.[69,70] Most outcome studies of treatment of X(T) consist of highly selected retrospective case series, which use multiple, often conflicting, outcome measures.[71] There is evidence that the long-term success of treatment in curing X(T) is poor.[72] Assessing the true effects of treatment must await the results of robust, prospective, long-term randomized studies.

One recent trial compared part-time patching with observation in children aged 3–10 years with intermittent exotropia.[73] This trial showed only a marginal benefit from patching over a 6-month period. A recent pilot trial comparing surgery to active monitoring for X(T) was hampered by low recruitment, and was not powered to meaningfully assess clinical outcomes; however, it showed no meaningful change in the condition of those children undergoing active monitoring, and improved alignment in those undergoing surgery, at the expense of a 10–20% overcorrection rate with deterioration of stereoacuity.[74]

The long-term outcome in a cohort of patients with X(T) is unknown; studies of untreated patients are biased by the drop-out of patients with more severe X(T) who go on to have treatment. However, a significant proportion of children with X(T) do not progress to constant exotropia. One study of 73 patients, with an average 10-year follow-up, showed a reduction in the angle of exotropia over time; however, 82% of the patients received some form of non-surgical treatment,[75] which the authors suggested might represent regression towards the mean of varying measurements. Many children with X(T) do not need active management[16,76]; prior to any intervention, parents should be counseled regarding the uncertainties of the evidence for treatment.

Overminus lenses

Minus lenses may have a beneficial effect on angle and control of X(T)[54,77] and be useful as a temporizing measure, allowing surgery to be deferred until an age when amblyopia is unlikely to develop in the event of a surgical overcorrection. The amount of overminus used should be assessed with trial frames. It commonly is around 2 diopters. Overminus lenses may have a particular application for children with X(T) and a high accommodative convergence/accommodation (AC/A) ratio. It is possible that the beneficial effect observed is due to spontaneous improvement since there has been no randomized controlled trial of this treatment in X(T).

Correction of hypermetropic refractive errors

Correction of significant hypermetropic refractive errors may improve control of X(T).[78]

Orthoptic/occlusion treatment

Occlusion for early-onset unilateral exotropia[79] for 4–6 hours per day for 3–6 weeks has been advocated to modify suppression. Orthoptic/occlusion treatment prior to surgery may improve surgical success rates.[80] The results of the recent randomized controlled trial, however, suggest that this treatment is of limited efficacy.[73] Its use is probably limited to those parents who wish to avoid surgery for a child too young to tolerate minus lenses.

Chemodenervation

There are few reports of the use of botulinum toxin in X(T)[81,82] and it is rarely used in X(T) except for surgical overcorrection of X(T).[83]

Surgical management

X(T) is commonly treated surgically. Some, with support from visual physiology data,[84] recommend surgery shortly after diagnosis because early restoration of normal ocular

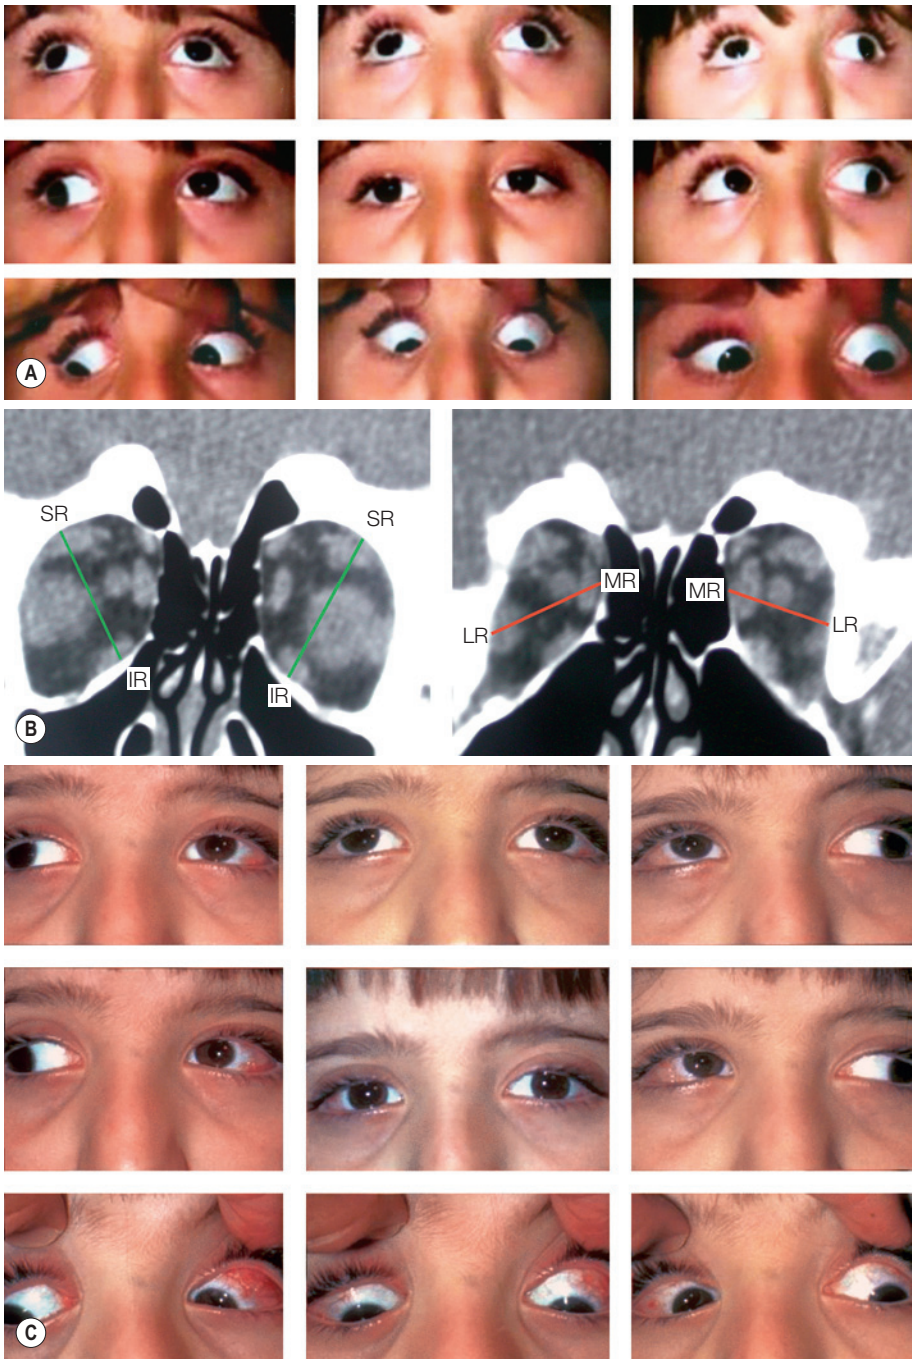

Fig. 79.3 (A) Patient with craniosynostosis showing a "V" pattern deviation with apparent pseudo-overaction of the inferior oblique. (B) Dynamic magnetic resonance imaging shows lateral displacement of the superior rectus muscles (SR), downward displacement of the lateral rectus muscles (LR), and medial displacement of the inferior rectus muscles (IR). (C) After repositioning of the lateral rectus muscle bellies superiorly, the "V" pattern deviation is improved.

alignment is desirable to promote normal visual development. Surgery in young children with X(T) may present practical challenges: Inaccurate and incomplete assessments mean that measurements are uncertain and the diagnosis can only be provisional. Also, surgical overcorrection may result in constant suppression and amblyopia in young children, a worsening of sensory status in a group of patients whose preoperative visual acuities and stereoacuity are usually normal.

Thus, many surgeons defer surgery until the age of 4 years or older, provided that there is no deterioration in the condition to a constant exotropia. These views are supported by retrospective case series, which suggest that age at surgery does not influence outcome.

Ekdawi et al.[85] reported 33% of X(T) patients had surgical treatment, with 19.7% undergoing a second procedure. Buck et al. reported a rate of surgery of only 7.6% in the first 12 months following diagnosis in a UK cohort,[16] rising to 17% after 2 years.[86] The continued observation of these children represents a significant use of health care resources. While recovery of stereopsis has been reported in cases of X(T) that have progressed to constant exotropia,[47] Wu et al. reported significantly better stereoacuity results in X(T) compared to constant exotropia and a history of previous X(T),[57] despite similar rates of motor alignment. Initial overcorrection of the deviation has been associated with improved long-term alignment[48,87]; however, others have challenged this view.[88]

Exotropias tend to recur following initially successful surgery; in one large study, orthotropia or mini-microtropia was achieved in 60.2% of patients 1 month after surgery, but half of these patients developed recurrent X(T) by 4 years after surgery.[26] Ekdawi et al. found the rate of developing greater than 10 diopters of misalignment at distance after the first surgery for X(T) was 54% by 5 years, 76% by 10 years, and 86% by 15 years.[85]

Surgical procedures

A weakening procedure on the lateral rectus muscle and/or a strengthening procedure on the medial rectus muscle may be used. Lateral rectus recession is believed to affect the distance deviation more than near; the reverse is thought to be true for the medial rectus muscle. The choice of surgery is suggested by the clinical pattern of the deviation.

If a patient has true or simulated divergence excess exotropia, bilateral lateral rectus recession is appropriate; patients with basic exotropia with equal near and distance deviation are treated with a recess–resect procedure.[89] A prospective, randomized clinical trial revealed only a 52% success rate in patients with basic exotropia if only lateral rectus recessions are performed. This increased to 82% if a recess–resect procedure was chosen.[25]

Desired early postoperative alignment

Within the first 2 weeks, the aim is to achieve a small angle (5–10 PD) esotropia. The eyes are brought beyond the temporal hemiretinal suppression scotoma to increase diplopia awareness. This may stimulate fusional vergences and stabilize postoperative alignment. Intentional overcorrection has risks in children with an immature visual system. In the immediate postoperative period, base-out prisms to neutralize residual deviation to maintain bifoveal fixation may be useful to prevent development of monofixation esotropia with foveal suppression.

In older children and adults who develop X(T) after the visual system has matured, diplopia and visual confusion occur with little or no suppression. The surgical goal in these cases should be orthotropia, even on the first postoperative day using adjustable sutures. Base-out prisms are used temporarily if overcorrection occurs. Non-surgical management of postoperative overcorrection should be tried for at least a month before reoperation is contemplated because of the high likelihood of spontaneous resolution. Botulinum toxin to the medial rectus is often used before considering repeat surgery.[83]

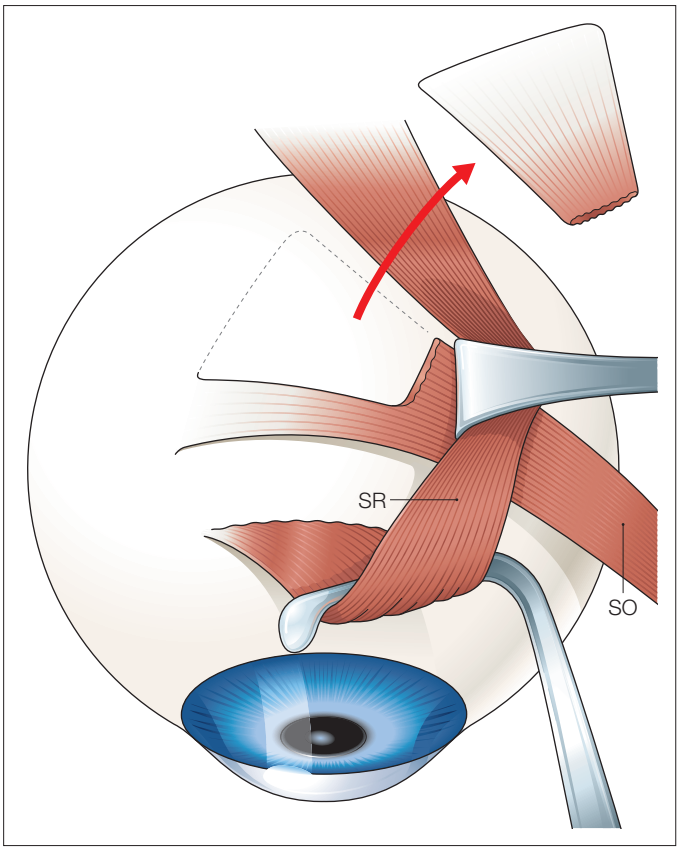

Fig. 79.4 Posterior three-quarters superior oblique tenectomy. A quadrilateral posterior tenectomy is performed on the superior oblique tendon (SO) where it fans out, leaving the anterior 1–2 mm of the tendon intact to preserve intorsion. *(From Shin GS, Elliott RL, Rosenbaum AL. Posterior superior oblique tenectomy at the scleral insertion for collapse of A-pattern strabismus. J Pediatr Ophthalmol Strabismus 1996; 33: 211–8. Reprinted with permission from Slack, Inc.)*

Fig. 79.5 Four-year-old patient with intermittent exotropia with "V" pattern and inferior oblique overaction. Photograph shows right exotropia that increased in upgaze and reduced in downgaze.

Other associations

Pattern deviations (see Chapter 82)

In patients without significant oblique muscle dysfunction, we perform vertical transposition of the horizontal recti. In "A" pattern exotropia with superior oblique overaction we prefer a posterior three-quarters tenectomy of the superior oblique tendon (Fig. 79.4). In "V" pattern deviations with inferior oblique overaction (Fig. 79.5), we weaken the inferior oblique muscle.

In patients with craniofacial syndromes, dynamic MRI may show that rectus muscles are excyclorotated and that the X(T) in upgaze is due to the lateral displacement of the superior rectus with downward displacement of the lateral rectus. Repositioning the muscle to its normal anatomic position may improve the pattern deviation (see Fig. 79.3).

In patients with longstanding exodeviations, a tight lateral rectus muscle may cause an "X" pattern deviation (Fig. 79.6). Both the inferior oblique and superior oblique muscles appear

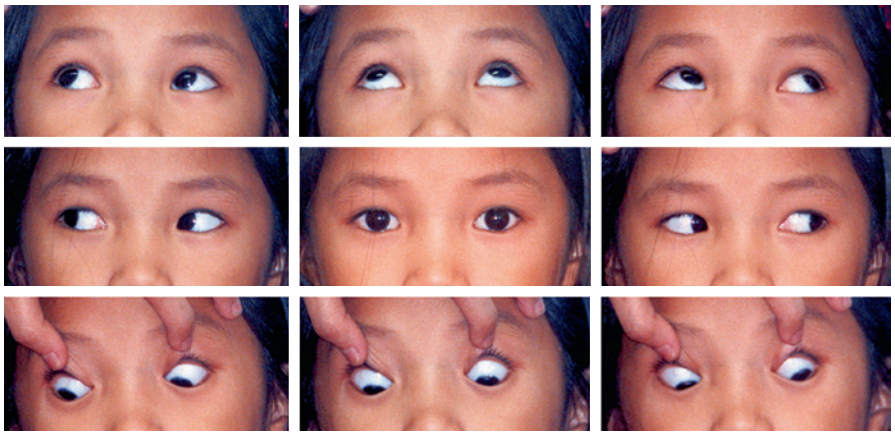

Fig. 79.6 Patient with "X" pattern deviation because of longstanding exotropia. Tight lateral rectus muscles act as a leash. Forced duction testing will show resistance to full adduction. Only weakening procedures on the lateral rectus are necessary to relieve the "X" pattern. No surgery is required on the oblique muscles. *(From Santiago AP, et al. Intermittent exotropia. In: Rosenbaum AL, Santiago AP, editors. Clinical Strabismus Management: Principles and Surgical Techniques. 1st ed. Philadelphia: Saunders; 1999. With permission from Elsevier.)*

to overact. The tight lateral rectus muscles cause a leash effect, creating pseudo-overaction of the oblique muscles. The apparent oblique muscle dysfunction disappears after lateral rectus weakening. The tight lateral rectus syndrome is uncommon and probably found only in a very large poorly controlled decompensated X(T). It is more common with longstanding constant exotropia.

Lateral or horizontal incomitance

Patients whose primary deviation exceeds right and left lateral gazes by 20% or at least 10 PD have significant horizontal incomitance, which is associated with postoperative overcorrection and reoperation.[90] They may benefit from reducing the intended surgical weakening procedure on the lateral rectus muscle. This modification prevents overcorrection on lateral gazes but risks undercorrection in primary position. When lateral incomitance is due to a tight medial rectus muscle, resection procedures on this muscle worsens the incomitance. We recommend preoperative forced duction testing and recession of the tight medial rectus with enhanced lateral rectus recession to compensate for the effect of the medial rectus recession. Adjustable sutures improve results, but are challenging to perform in young children.

High AC/A ratio

Patients with X(T) and a high AC/A ratio are at risk of postoperative overcorrection,[91] and may be better managed with overminus lenses. There is significant test/test variability in the measurement of AC/A ratio, particularly in the young.

Concomitant vertical deviations

Small vertical deviations may occur with X(T), and may resolve after surgical treatment.[92] Vertical deviations of less than 10 PD can be corrected by vertical transposition of the horizontal rectus muscles. For example, the recessed lateral rectus and the resected medial rectus muscle may be displaced superiorly one-half to a whole tendon width in the hypotropic eye (directions are reversed for a hyperdeviation). This adds an additional upward vector assisting in the control of the vertical deviation. Large vertical deviations should be addressed by appropriate surgery on the vertical muscle at the time of exotropia surgery.

Postoperative undercorrection

Severe early postoperative undercorrection may arise because of a slipped resected medial rectus muscle. Adduction is usually limited; there is widening of the palpebral fissure on attempted adduction. Early surgical exploration and repair is indicated. More commonly, X(T) persists or recurs following surgery. Further treatment including surgery should be considered and discussed with the parents.

Postoperative overcorrection

Overcorrection that persists beyond the immediate postoperative period is less common than undercorrection, even when surgery for the largest recorded angle of exodeviation is the target; however, rates of postoperative overcorrection are probably around 15%.[93] Transient esotropia for near targets is common in the first few postoperative weeks. A small angle esotropia that persists at distance, with only exophoria or orthotropia at near, is usually stable and best left untreated, provided diplopia is not problematic. Rarely, a large overcorrection following an over-recessed, slipped, or lost lateral rectus muscle may occur. It is most bothersome in the field of gaze of the weakened lateral rectus (Fig. 79.7).

In the early postoperative period, a rather large esotropia may not necessarily mean a poor response to surgery. Long-term stability of alignment after bilateral lateral rectus recession was achieved in patients who demonstrated up to 20 PD of esotropia in the first 10 days after surgery.[46,48]

Esotropia at near that persists beyond 3 weeks is worrisome, especially in children susceptible to suppression and deterioration of fusional status. Children can develop monofixational esotropia even if aligned to within 8 PD of orthotropia. Older children and adults, on the other hand, tolerate overcorrection poorly because of diplopia.

Further treatment with occlusion, prisms, and botulinum toxin injection to the medial rectus and further surgery (usually medial rectus recession) should be considered if the overcorrection does not settle within an acceptable time period.

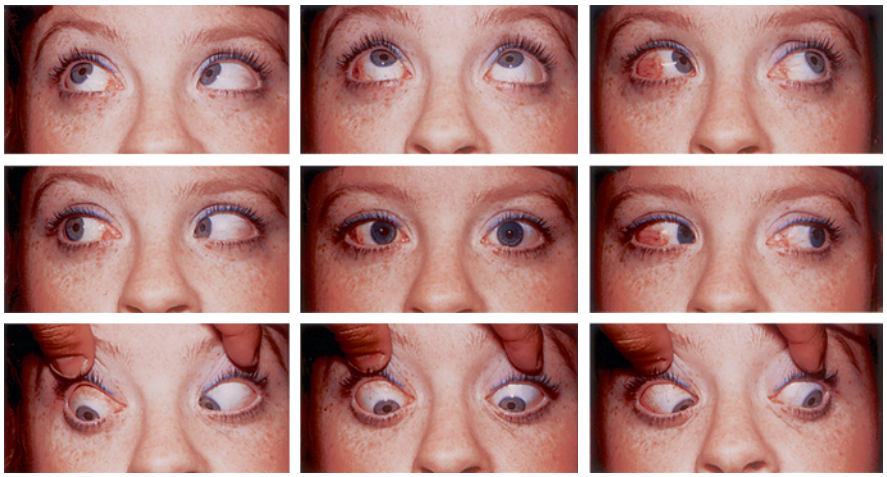

Fig. 79.7 Overcorrection after bilateral rectus recession for intermittent exotropia. Patient developed 25 PD of right esotropia with abduction deficit in right gaze. Differential diagnosis should include slipped or lost lateral rectus muscle. A lost muscle, however, seems less likely because of relatively good right lateral rectus rotation despite the observed deficit. *(From Santiago AP, et al. Intermittent exotropia. In: Rosenbaum AL, Santiago AP, editors. Clinical Strabismus Management: Principles and Surgical Techniques, 1st ed. Philadelphia: Saunders; 1999. With permission from Elsevier.)*

INTRODUCTION
INFANTILE EXOTROPIA
MONOFIXATIONAL EXOTROPIA
EXOTROPIA WITH HEMIANOPIC VISUAL FIELD DEFECTS
SENSORY EXOTROPIA
REFERENCES

Introduction

Exodeviations in children can be comitant or non-comitant. Non-comitant exodeviations result from either innervational causes, i.e. third nerve paresis and Duane syndrome, or mechanical causes, such as tumors or trauma (see Chapters 83 and 84).

The most common comitant type in children is intermittent exotropia, and there are other comitant exodeviations whose management can be challenging. This chapter deals with infantile exotropia, monofixational exotropia, exotropia associated with hemianopic visual field defects, and sensory exotropia. Although they are considered as comitant deviations, they may develop incomitance from secondary changes in the lateral rectus muscles in longstanding cases, especially in sensory exotropia or infantile exotropia with a large deviation.

Infantile exotropia

Introduction

Infantile exotropia is an exodeviation that develops within the first few months of life and persists. While infantile esotropia is generally defined as having its onset by age 6 months, the term infantile exotropia is used for exodeviations that first manifest up to 1 year of age.[1–4] It can be a primary disorder or secondary to an ocular or systemic problem.

Primary infantile exotropia, unrelated to a systemic or ocular disorder, is rare, occurring in approximately 1 per 30,000 births.[1] In primary strabismus in infancy, for every case with exotropia, there are between 150 and 300 cases with esotropia.[1] Intermittent exotropia can manifest by age 12 months, and it may represent a large proportion of cases of exotropia seen before age 1 year (see Chapter 79).[2–4] Infantile exotropia is often associated with ocular or systemic disorders. It is seen with ptosis, albinism, ocular motor apraxia (saccadic initiation failure), optic nerve anomalies, and with diseases that lead to vision loss, including retinoblastoma, retinoschisis, iridolenticular abnormalities, and cataracts.[1,5] Exotropia can be a feature of several congenital strabismus syndromes, including third nerve palsies, Duane syndrome, congenital fibrosis of the extraocular muscles, and strabismus fixus[1,5] (see Chapter 83). It is described in association with many systemic disorders including prematurity, cerebral palsy, seizure disorders, hydrocephalus, craniofacial syndromes, and various chromosomal anomalies.[1]

Ocular or systemic disorders are more common in infantile exotropias than in esotropias, and infants with constant exotropia have a much stronger chance than those with intermittent exotropia of having a co-existing problem.[5] The incidence of systemic anomalies may also be positively correlated with the size of the angle of deviation[1]: it is prudent to consider a neurodevelopmental assessment of a child with infantile exotropia.[5]

Etiology

Vergence abnormalities

Exodeviations appear in over one-third of healthy neonates, while esodeviations are rare.[1] Mostly, they are transient and resolve by 6 months of age as the vergence system matures.[1] Therefore, primary infantile exotropia may be an arrested development of the convergence system.

Abnormal convergence may be a primary or secondary phenomenon. There may be a primary deficit in the convergence system, or it may arise from defective cortical binocular development.[2] Disruption of binocular connections in the immature visual cortex can hinder the normal development of vergence, leading to strabismus and to functional deficits, loss of fusion, asymmetric monocular smooth pursuit, and asymmetric monocular motion perception.[2] The asymmetries are characterized by better tracking and detection of targets when they are followed from the temporal to the nasal visual field than when they are tracked in the reverse direction. This directional asymmetry should lead to infantile esotropia, rather than exotropia. Therefore, the severity of a primary or secondary convergence system deficit must override the other abnormal processes so that divergence is predominant. The

identical pursuit asymmetry seen in infantile esotropia also occurs in infantile exotropia.[6]

Anatomic factors

The structure of the lateral and medial rectus muscles is asymmetric; length–tension curve studies show the lateral rectus muscle to be stiffer than the medial rectus. The diameter of the lateral rectus may be congenitally larger than normal, allowing it to "overpower" the medial rectus.[1] Finally, orbital dysmorphism, as in craniofacial syndromes, can produce a divergent positioning of the eyes.

Genetic factors

Infantile exotropia occurred in three consecutive generations of one family, suggesting autosomal dominant inheritance. It may be more common in Asians and Africans than in Caucasians.[1]

Clinical features
