Infantile exotropia occurs by 12 months of age.[2–4] The deviation may vary from 20 to 90 prism diopters (PD), and is greater than 35 PD[2,5] in most cases (Fig. 80.1). The angle is usually stable initially but increases slowly. Amblyopia occurs in up to 25%, usually caused by strabismus rather than anisometropia.[1] It responds to the usual treatments (see Chapter 73). There is a normal distribution of refractive errors.[2] If the deviation is large, an "X" pattern strabismus is common, as also seen in adults with large angle exotropia who have a tight lateral rectus syndrome. The deviation is larger in upgaze and downgaze than in the primary position with mild limitation of adduction in one or both eyes and upshoots and downshoots in adduction (see Fig. 80.1) that has been ascribed to overaction of the oblique muscles, to sideslip of the lateral rectus around the globe (a "leash effect"), or to the globe having more room to elevate and depress when it is not fully adducted.[1] Alternatively, there may be "A" or, more commonly, "V" patterns.[2] Latent nystagmus, dissociated vertical deviations (DVD), and inferior oblique overaction are frequent associations, similar to infantile esotropia.[2] The reported frequencies of DVD and inferior oblique overactions in primary infantile exotropia are as high as 60% for both features.[3] In fact, these vertical anomalies are rarely seen in early-onset intermittent exotropia, and their presence would confirm that the exotropia is, in fact, an infantile form rather than an acquired intermittent form.[3]

Examination

Some pertinent points must be noted in the evaluation of infantile exotropia.

1. The general behavior and physical features of the child may suggest a systemic or orbital association.
2. Anterior and posterior segment disorders can be associated with infantile exotropia. Cycloplegic refraction and fundus examination are vital.
3. The examiner must observe the corneal light reflexes to rule out a positive angle kappa that gives a false appearance of exotropia[2]: the cover test will confirm a true exodeviation rather than a pseudo-exotropia (see Chapters 7 and 75).
4. When the angle is large, the examiner needs to use two prisms oriented base-in and split between the two eyes to get an approximation of the total angle, whether the angle is measured by the Krimsky or prism and alternating cover methods (see Chapter 75).
5. The examiner should search for features of the infantile strabismus complex including dissociated vertical deviations and oblique muscle overactions. Optokinetic testing may detect monocular nasal–temporal motion asymmetries.

Fig. 80.1 Photos of nine diagnostic gaze positions of a child with infantile exotropia. Note the large angle of exotropia in the primary position (central photo). There is limited adduction of each eye and an "X" pattern. Each eye shows an upshoot and downshoot in the adducted position. *(From Kraft SP. Selected exotropia entities and principles of management. Management

Non-surgical therapy

Infantile exotropia usually requires surgery after any refractive errors and amblyopia have been treated. Although the angle of the deviation is generally stable, it may reduce with occlusion.

Botulinum toxin has been used for infantile esotropia, but there is no reported series of this for the rarer infantile exotropia. Success rates for treating childhood exotropia with botulinum toxin range from 50% to 70%, with bilateral, not unilateral, lateral rectus injections.[1] Most had intermittent exotropia: the success rates for exotropia over 35–40 PD was much lower, and, since most infantile exotropias are larger than this, surgery is the preferred treatment.

Surgery

Timing

Patients with primary infantile exotropia should be approached in the same manner as those with infantile esotropia where the general consensus among pediatric ophthalmologists for many years was to align the eyes before the age of 24 months to achieve optimal motor and sensory outcomes.[1] In recent years, earlier surgery for infantile strabismus has been favored in the belief that it is more effective in reversing the binocular vision and vergence deficits. Evidence suggests that the optimal "window" for treating infantile esotropia may be the first 8–10 months of life,[2] but whether it is applicable to infantile exotropia is not known. The consensus still favors re-aligning the eyes before 24 months of age, although one study showed that the likelihood of surgical success may be greater if the eyes are re-aligned within 24 months of onset of the exotropia rather than by a specific age.[7] Once the diagnosis of infantile exotropia is confirmed and any refractive error or amblyopia corrected, the child should be followed for a few weeks to document that the angle of the strabismus is stable.

Surgical planning

Strabismus surgery techniques for exotropia are described in Chapter 86, but there are some specific recommendations for surgical treatment of infantile exotropia:

1. The aim in primary infantile exotropia is to create an esotropia in the immediate postoperative period, as in most exotropias in older children and adults.[1,2] This principle also applies to children with infantile exotropia and developmental delay or cerebral palsy, as the postoperative drift is usually in the divergent direction whether they originally had esotropia or exotropia immediately after surgery.[1,2] For either category, the best result from a single operation is with an immediate postoperative angle in the range of 10–14 PD, slightly larger than the desired postoperative angle in later-onset intermittent exotropia. In a recent study, the average exotropia drift rate was 10.4 PD over 3 years after surgery, and the success rate was best when surgery achieved a mean esotropia of 10 PD immediately after surgery.[8]
2. The strategy generally involves weakening (usually recession) of one or both lateral rectus muscles, as they are often tight.[8] If the deviation is larger at near than that at distance, then a strengthening procedure of a medial rectus muscle should be included.[1,2]
3. Strabismus angles under 40 PD can usually be successfully treated with surgery on two horizontal muscles, either bilateral lateral rectus recessions or a unilateral lateral rectus recession with a medial rectus resection.[2] Treatment of angles over 40 PD may require "supramaximal" amounts of recessions or resections if surgery is limited to two muscles. Alternatively, surgery of more "regular" dosages can be planned on three or four horizontal muscles.[1,2] Another strategy involves large recessions of both lateral rectus muscles combined with simultaneous injections of botulinum toxin into the two muscles.
4. Surgery for any co-existing dissociated vertical deviations or oblique overactions can be planned for the same sitting or at a later date, as in infantile esotropia.

Results

The overall success rates for infantile exotropia surgery, defined as a microtropia angle under 10 PD, are not high, with one study reporting 40% at 3 years after the first surgery.[8] Reoperation rates are as high as 50% of patients: Undercorrections are much more common than overcorrections.[1] The size of the preoperative angle is an important factor in the eventual success rate, as the results for exotropia under 40 PD are better than those for larger deviations.[3,9] A recent study on early-onset exotropia with deviations 40 PD or less reported a success rate of 67% up to 3 years after surgery.[4]

Up to 50% of children whose exotropia is corrected before age 24 months develop peripheral fusion. Some may show gross stereopsis.[2,4] The best binocular outcomes reported are monofixation syndromes.[1,2] Re-aligning patients with infantile exotropia after the age of 2 years can still lead to stable long-term results, and sensory fusion may be achieved in some patients after this age.[1,4]

Monofixational exotropia

Introduction

The monofixation syndrome is characterized by fixation with the fovea of only one eye under binocular conditions.[1] Sensory features include intact peripheral fusion, preserved gross stereopsis, and, frequently, amblyopia of the non-foveating eye. The motor features include manifest heterotropia, <8 PD, a larger heterophoria, and preserved convergence and divergence fusional amplitudes (see Chapter 75).[1,2] When there is no heterotropia on cover test but with sensory findings of monofixation, these are termed monofixational phorias. Some show a heterotropia without a superimposed heterophoria: these are sometimes termed microtropias (see Chapter 78).[1,2]

In most patients with monofixation syndrome who have a manifest deviation, this is an esotropia and any associated heterophoria is an esophoria. However, between 5% and 20% have an exotropic orientation for the tropia and the phoria.[1,10] Most cases of monofixational exotropia are secondary, either associated with anisometropia or following surgery for exotropia. However, a monofixation syndrome may underlie some cases of intermittent exotropia and its true nature may only become evident after surgery for the total exodeviation.[11,12]

Most cases of monofixational exotropia retain a stable long-term small exotropia under binocular conditions by virtue

of intact vergence amplitudes. In a minority, fusion control is disrupted and the exophoria becomes predominant: this is termed a decompensated monofixational exotropia.[1,10,13,14] It has been suggested that sensory changes along with decreasing horizontal and/or vertical fusion amplitudes may be important factors in leading to decompensation.[13] The risk of decompensation does not seem to be related to the depth of amblyopia.[13]

The reported rates of decompensation in monofixation exotropia vary, ranging from zero to 25% with up to 20 years or more follow-up.[10,13,14] The risk of decompensation is less the better the binocular function (motor amplitudes and depth of stereopsis) and the smaller the initial angle of the heterotropia when the monofixation adaptation is established, whether it is a primary disorder or it develops after eye muscle surgery.[13,15]

Etiology

The monofixation syndrome can be primary or secondary to anisometropia, a macular lesion, or previous surgery for infantile or acquired strabismus.

Primary monofixation exotropia

Patients with the primary form have a deficit in fovea-to-fovea correspondence: they cannot attain bifoveal fusion.[1,2] This may be a hereditary error in foveal correspondence that may exceed the capability of Panum's fusional space to compensate for it, leading to suppression of the less dominant fovea.[1,2] Alternatively, there may be a reversal of the normal dominance of the nasal over the temporal hemifield. As a result, any degree of foveal disparity can lead to a facultative scotoma on the temporal side of the fovea rather than in its usual location on the nasal side.[1]

A primary monofixational exotropia can decompensate because of an acute illness or chronic fatigue as the "all-or-none" suppression in exodeviations is less flexible than that of esodeviations.[1] If the latent heterophoria begins to manifest, then the strong hemiretinal suppression mechanism may increase the propensity for the exodeviation to decompensate.[1]

Secondary monofixational exotropia

The majority of secondary forms in children result from surgery for constant or intermittent exotropia.[11,12] Monofixation after surgery suggests a pre-existing defect in bifoveal fusion, and this may underlie a minority of cases of seemingly typical intermittent exotropia.[2,11] Anisometropia is a less common cause but, as an obstacle to bifoveal fusion, it may lead to suppression of the less dominant fovea. Finally, a unilateral macular lesion can lead to a progressive manifest exotropia; small lesions can result in a small scotoma with the attributes of a monofixation syndrome.[1]

Secondary monofixation exotropia has the same propensity for deterioration as the primary form. There is an abnormal binocular state, and any loss of the "peripheral fusion lock" allows the heterophoria to manifest. If the control deteriorates then the hemiretinal suppression adaptation may take over and increase the likelihood that the exotropia becomes constant.[1]

Clinical features

Motor features

Most patients with a monofixation syndrome show a heterotropia of 2–8 PD under binocular conditions (see Chapter 75). Up to one-third of cases will show no shift on cover test – most commonly in the form secondary to anisometropia.[1,2]

The exophoria uncovered on alternating prism and cover test tends to be larger than that seen in bifoveal patients who have exophoria, although it rarely exceeds 25 PD[1] and the fusional amplitudes are nearly normal.[1] When exotropia and exophoria co-exist, the simultaneous prism and cover test should be performed initially to measure the static heterotropia. Then the prism and alternating cover test measures the superimposed heterophoria[1] (see Chapter 75).

Cases of decompensated monofixational exotropia can appear as intermittent exotropia while chronic cases may show a constant exotropia.[11,12] Children whose monofixation exotropias decompensate may complain of asthenopia as their deviations stress their fusional amplitudes, or give them diplopia if the separation of the perceived images exceeds the size of their suppression scotoma. These symptoms are more common with decompensating monofixation exotropia than for esotropia, but asthenopia in monofixation exotropia is less frequent than in bifoveal patients with exophoria.[1]

Sensory features

Binocular sensory testing in monofixation confirms a foveal scotoma in the non-dominant eye with preservation of peripheral fusion. In monofixation exotropia, there may be a suppression scotoma extending temporally from the fovea. Depending on the test, the size of targets, the patient's age, and the size of the deviation, they can indicate either normal retinal correspondence or anomalous correspondence, even in the same patient.[1,2] Eccentric fixation may also be demonstrated in the non-dominant eye, especially if amblyopia is severe. In fact, scanning laser ophthalmoscopy microperimetry has shown that the preferred eccentric fixation points in monofixation syndrome are more than 2° from the fovea in 40% of eyes.[16]

Stereopsis is often present but subnormal in monofixational exotropia.[1,2] Stereoacuity is higher in the primary than in the secondary form, in both monofixational esotropia and exotropia.[1]

Where the exodeviation has decompensated and is almost constantly manifest, sensory testing with the angle corrected with prisms may show subnormal binocular vision, suggesting an underlying monofixation syndrome.[1,11,15]

Amblyopia (see Chapter 73)

The incidence of amblyopia in monofixation exotropia ranges from 30% to 65%, slightly less than in monofixational esotropia.[1] It occurs most commonly with anisometropia and least often with the postsurgical form.[2] Up to 50% of patients with monofixation and moderate-to-severe amblyopia may also show eccentric fixation on monocular testing.[16]

Treatment

Once a primary or secondary monofixation syndrome develops, it is difficult to restore bifoveal fixation.[1] Aggressive attempts to break down the facultative macular scotoma to achieve this may risk diplopia.[2] There are anecdotal cases of conversion of monofixation to bifoveal fixation with aggressive therapy in children.[2]

In children there are two clear indications for treatment in monofixation exotropia: the reversal of amblyopia and the restoration of alignment in a decompensated exotropia.

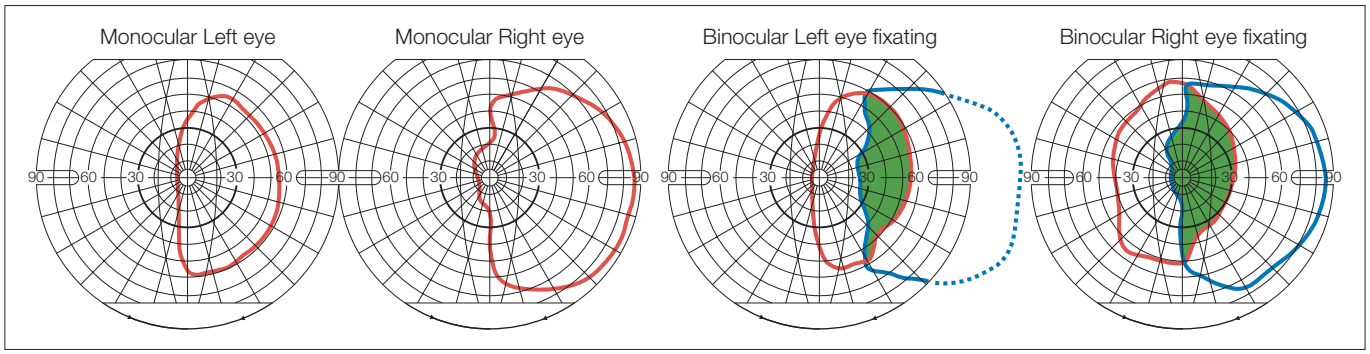

Fig. 80.2 Monocular and binocular visual fields in a patient with congenital complete left homonymous hemianopia and exotropia. The first two plots show the monocular visual fields of the left and right eyes. The third plot shows the binocular field with the left eye fixating, and the fourth plot shows the binocular field with the right eye fixating. The shaded area is the overlap of the monocular fields. Note that the panorama of the binocular field is greater when the right eye is used for fixation than when the left eye takes up fixation. *(From Kraft SP. Selected exotropia entities and principles of management. In: Rosenbaum AL, Santiago AP, editors. Clinical Strabismus Management. Philadelphia, PA: Saunders; 1999: 176–201. Copyright Elsevier 1999; after Gote H, Gregersen E, Rindziunski E. Exotropia and panoramic vision compensating for an occult congenital homonymous hemianopia: a case report. Binocul Vis Eye Muscle Surg Q 1993; 8: 129–32, with permission of Binoculus Publishing.)*

Amblyopia

6/9	20/30	0.63	0.18

Amblyopia of worse than LogMAR 0.40 (6/15, 20/50, 0.40) should be treated, even in a monofixation syndrome, by correcting the refractive errors and anisometropia with glasses, and patching or penalization.[2] In decompensated monofixational exotropia, treatment of the amblyopia can improve control of the exotropia and reduce symptoms such as asthenopia. The aim is to improve the visual acuity to LogMAR 0.18 (6/9, 20/30, 0.63) or better and achieve a stable monofixation – a small angle exotropia with peripheral fusion.[1,2]

Alignment

No treatment is indicated for asymptomatic patients with small, infrequently manifest exodeviations, but those with frequent exotropia who complain of asthenopia or diplopia warrant intervention. The goal is comfortable single vision, usually by achieving monofixation exotropia rather than bifoveal fixation.[1,11]

Non-surgical options include part-time occlusion, prisms, and minus lens overcorrection (see Chapter 85). Orthoptic exercises are not usually indicated for decompensated monofixation exotropia as the fusional amplitudes are good. Anti-suppression therapy is contraindicated, as in decompensated monofixational esotropia, to avoid breaking down suppression.[1,2] Botulinum toxin and surgery are used to treat children whose exodeviation has decompensated or is not corrected by amblyopia treatment or non-surgical interventions discussed above (see Chapters 86 and 87). Botulinum toxin has a good success rate for children with deviations of less than 20–25 PD.[1] Surgery has about the same rate of success as for the common forms of intermittent exotropia. However, the result is a monofixation syndrome rather than bifoveal fixation.[1,2,11]

Exotropia with hemianopic visual field defects

Introduction

Exotropia occurs with both homonymous and bitemporal hemianopias. The field loss is usually extensive when an exotropia develops in association with one of these disorders. Binasal hemianopias are very rare and will not be discussed in this chapter.

Homonymous hemianopias

Etiology

Exotropia can occur with homonymous hemianopias caused by congenital or acquired intracranial disorders. It is mostly acquired before the age of 2 years, but it can be an adaptation with hemianopia onset as late as 7 years.[1,17,18] The divergent strabismus is likely an adaptive compensation to enlarge the binocular field[1,18–20] (Fig. 80.2), although some argue that the exodeviation is an epiphenomenon and not adaptive.[1]

Clinical features

In contrast to patients who develop homonymous hemianopias later, children with congenital or early-acquired brain lesions adapt well. They are often unaware of their field loss[1] and develop eye movement strategies that include large saccadic movements into the blind field followed by smooth pursuit into the intact field to fixate a target.[19] They may develop a face turn to the side of the hemianopia in order to better center their remaining hemifield.[2,18,19]

Children who later develop a homonymous hemianopia do not adapt as well: they often bump into objects on the side of the hemianopia, and reading is difficult (see Chapter 102).[19]

Motor features

Exotropia mostly occurs as an adaptation if visual field is lost congenitally or early in life, although this has also been described in a teenager.[17] The compensatory exotropia can be seen either in childhood or later.[17,19] In early-acquired cases, the onset of exotropia can be as soon as 8 weeks after the cause of the hemianopia. One study reported that among 45 children with early-onset total homonymous hemianopia due to hemispherectomy, 40% developed a compensatory exotropia contralateral to the side of the surgery.[17] The deviation is usually constant but intermittent deviations can be seen.[17] This contrasts with the intermittent exodeviations that are more frequently reported with later-acquired hemianopias. The angle in early-onset cases ranges from 20 to 70 PD and it is often larger for distance fixation than for near.[1,19] It may be associated with a vertical heterotropia or a pattern strabismus.[1]

Children with later-acquired hemianopia and exotropia usually have deviations less than 20 PD.[1] They can be an exophoria or an intermittent or constant exotropia. Exotropias in such cases may not be adaptive.[1,21]

Sensory features

Young children adapt better to homonymous hemianopia than do older children; those who develop exotropia have complete defects.[1] With the exotropia, the expansion of the visual field to the side of the missing field ranges from 20° to 45°. This strategy is only relevant if the exotropia develops in the eye ipsilateral to the field loss (that is, contralateral to the cerebral damage), while the child fixates with the eye on the side of the intact field (see Fig. 80.2). The amount of expansion is proportional to the size of the exotropia.[1]

Children with exotropia with congenital or early-onset hemianopia rarely complain of diplopia or asthenopia because they may develop anomalous retinal correspondence (ARC).[1,21] They suppress within the overlapping portions of the monocular fields, and elsewhere they show ARC. This can be tested by the synoptophore or with sensory tests performed while the angle of exotropia is corrected with base-in prisms.[1,21]

Patients with later-acquired hemianopias generally complain of diplopia since they retain normal correspondence, cannot develop ARC, and cannot develop suppression.[1,21]

Treatment

Surgery for exotropia with congenital or early-onset homonymous hemianopia should be undertaken with caution. First, the re-alignment of the eyes reduces the total binocular visual field.[1,19] Second, patients who develop ARC in response to the exodeviation may experience paradoxical diplopia if the eye is re-aligned once the adaptation is complete.[2,20] Patients should be tested before surgery with a monocular patch to see whether they can adapt to the smaller binocular field and then with a prism to see whether they develop diplopia.[21] Some patients with large angle exodeviations may elect to undergo surgery for cosmetic reasons.[20] These patients require detailed discussion and education prior to surgery.[20]

Patients with later-onset hemianopia who develop diplopia or asthenopia because of an exodeviation may be treated initially with a prism or a patch, or they may require surgery or botulinum toxin injections.[21]

Bitemporal visual field defects

Clinical features

The disruption of the vergence reflex may lead to exodeviation, which can cause several sensory phenomena, especially if the field loss in each eye is extensive enough to involve the two maculae.

Motor features

The exodeviation measures a few PDs, often variable because of poor fusional vergences. The endpoints can be difficult to measure.[1] Patients may have an exophoria or exotropia. With complete hemianopia, an exophoria can decompensate due to the loss of vergence reserves and the loss of correspondence between the intact nasal fields of the two eyes.[22] The extraocular movements are usually normal.

Sensory features

Patients with bitemporal hemianopia may have two unusual and often missed symptoms. First, the loss of overlapping visual fields can lead to "hemiretinal slide" as the intact nasal visual fields of the two eyes cannot be juxtaposed.[22–24] In the presence of an exodeviation (either an exotropia or exophoria), there is a reduction of the binocular field and overlap of the partial images seen by the intact, but non-corresponding, nasal fields.[1,22] Any target can appear elongated, and there is duplication of features within the target leading to diplopia[1,21,23] (Fig. 80.3). This leads to reading difficulties.

Second, complete bitemporal hemianopia produces "postfixation blindness" from stimulation of non-seeing nasal retina by objects that lie behind the fixation target[1] (Fig. 80.4). An exotropia places the area of postfixation blindness further from the eyes and any proximal object, including the fixation target, may be double, as most patients have normal retinal correspondence (NRC)[1,21,22] (see Fig. 80.4). This leads to difficulty with daily tasks such as reaching accurately, pouring, or picking things up off a flat surface.

Very young children with bitemporal hemianopia and exotropia may not have symptoms. They may be able to develop suppression as an adaptation to diplopia.[23] Others may adapt to their abnormal binocular vision in the same way that children can learn strategies to overcome symptoms of bilateral homonymous hemianopia.[1]

Treatment

Exotropia with total or almost complete bitemporal hemianopia can be difficult to treat, whether it appears in young or older children. Prisms can be tried to alleviate diplopia, but they are not always helpful due to the variability of the exodeviation.[23] Prisms can be helpful if the hemianopia is not complete.[22] One study showed some benefit of midline stereopsis training in two patients with total bitemporal hemianopia.[22] Patching one eye reduces the visual field. Surgery to eliminate diplopia and exotropia can help if the misalignment is eliminated. However, the result is rarely stable with complete hemianopia due to lack of adequate fusional vergences.[23,24] In cases of almost complete hemianopia, strabismus surgery can be successful, especially if adjustable sutures are used for optimal alignment.[24] Pre-operative testing with prisms is helpful to assess the potential stability of the result and to give the patient a sense of the reduced binocular field that will be generated by the surgery.[21,24]

Sensory exotropia

Sensory exotropia – a unilateral exodeviation – develops as a result of loss of vision or chronic poor vision in one eye.[1] Children under age 5 or 6 years who develop strabismus due to vision loss in one eye tend to develop esotropia more often than exotropia, especially if the child's sound eye has a hyperopic refractive error.[2,25–27] After 6 years of age, exotropia develops much more often.[25–27]

Etiology

Sensory exotropia occurs in children as a result of congenital and acquired ocular disorders. Congenital disorders compromise vision development; normal binocular vergence reflexes cannot develop and strabismus is a frequent result. Acquired causes include traumatic and non-traumatic diseases, such as cataracts, that disrupt the fusion reflex[1] (Fig. 80.5). One specific

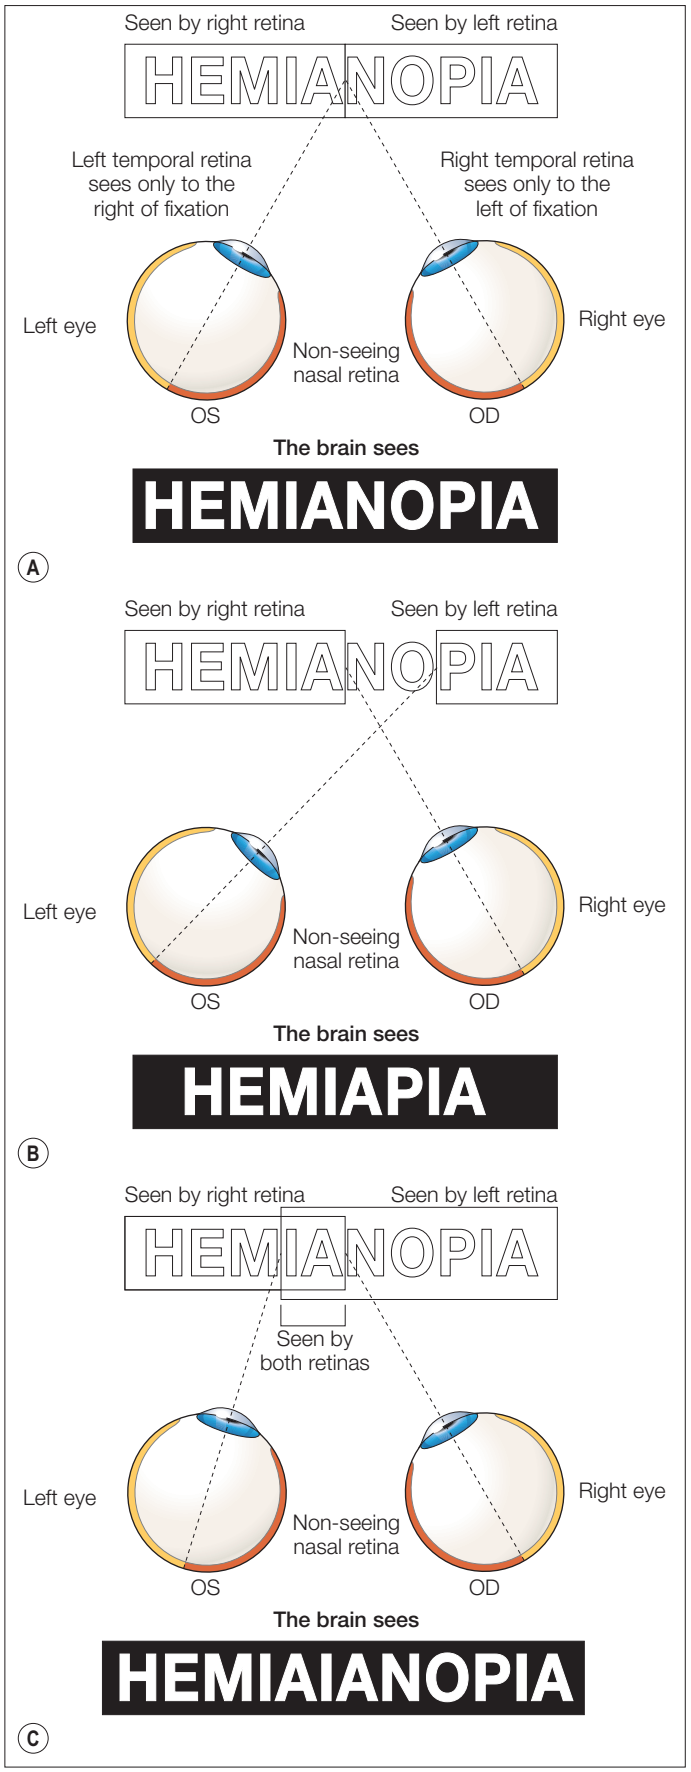

Fig. 80.3 Hemifield sliding and abnormal binocular phenomena in a patient with complete bitemporal hemianopia. (A) Straight eyes: the two separate monocular visual fields juxtapose to form a complete image of the target. (B) Left esotropia: central portions of the target are missing. (C) Left exotropia: central portions of the target are duplicated as a result of redundant reception by the functioning temporal retinas of both eyes. *(From Kraft SP. Selected exotropia entities and principles of management. In: Rosenbaum AL, Santiago AP, editors. Clinical Strabismus Management. Philadelphia, PA: Saunders; 1999: 176–201. Copyright Elsevier 1999; after Fritz KJ, Brodsky MC. Elusive neuro-ophthalmic reading impairment. Am Orthoptic J 1992; 42: 159–64, with permission of University of Wisconsin Press.)*

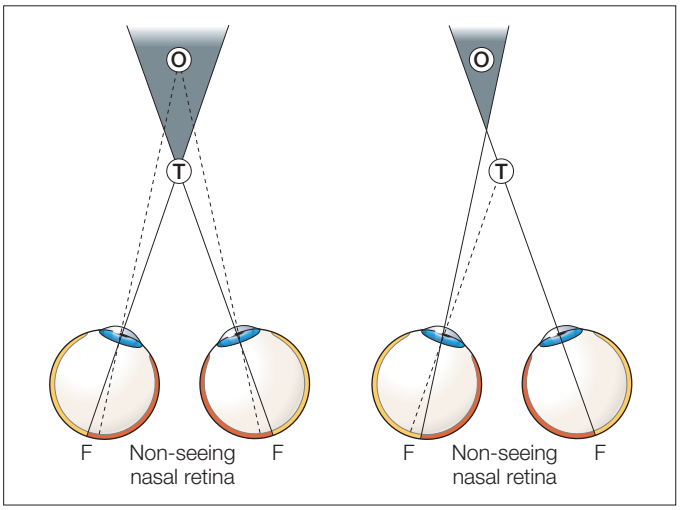

Fig. 80.4 Postfixation blind area in a patient with complete bitemporal hemianopia. (Left) The diagram shows the situation when the eyes are straight. When both foveae (F) fixate on a target (T), the retinal image of any second object (O) located within the shaded area would fall on the non-functioning nasal retinas of both eyes and not be seen. (Right) The diagram shows the situation in the presence of a left exotropia with the right eye fixating. The target (T) may be seen as diplopic because the image falls on the fovea of the right eye and on the functioning temporal retina in the left eye. A second object (O) is not visualized as it is located in the postfixation blind area, which is more remote from the patient compared to the orthotropic state. *(From Kraft SP. Selected exotropia entities and principles of management. In: Rosenbaum AL, Santiago AP, editors. Clinical Strabismus Management. Philadelphia, PA: Saunders; 1999: 176–201. Copyright Elsevier 1999; after Roper-Hall G. Effect of visual field defects on binocular single vision. Am Orthoptic J 1976; 26: 74–82, with permission of University of Wisconsin Press.)*

In: Rosenbaum AL, Santiago AP, editors. Clinical Strabismus Management. Philadelphia, PA: Saunders; 1999: 176–201. Copyright Elsevier 1999.)*

cause is anisometropic amblyopia, especially anisohyperopia. Older children whose vision remains reduced are at particular risk of developing exotropia, although esotropia is common among children with vision loss in one eye and hyperopic refractive errors in the sound eye.[2,26]

The mechanisms for the development of exotropia when vision is lost in one eye are the following:

1. *Binocular rivalry*: When the retinal image of one eye is degraded, it sets up a rivalry between that and the fellow eye. Normal visual signals become inhibitory to the disadvantaged eye; this is even more powerful with partial than with total loss.[1] Also, there is a superiority of the nasal retina over the temporal retina in response to bright and formed stimuli, and this becomes exaggerated when an eye loses vision. These factors lead to disruption of the vergence system, and an active retinomotor divergence takes hold with a progressive exodeviation, especially in older children.[1]
2. *Decompensation of exophoria*: A well-controlled exophoria can decompensate from loss of fusion if one eye loses vision. This appears to be a settling of the poorer eye into its "elastic" rest position, not an active divergence reflex. The divergent position results from an imbalance of muscle tone between the lateral and medial rectus muscles.[1]
3. *Mechanical factors*: Orbital dysmorphism or muscle anomalies predispose to an exotropia if one eye suffers a loss of vision. Strabismus in which there is congenital tightness or restriction of the lateral rectus, such as in Duane syndrome, can show progressive exotropia if vision deteriorates in the affected eye.

Clinical features

Motor features

Sensory exotropia is usually over 30 PD, and the angles can be very large in some patients,[1] although one paper reported a large series of patients with sensory exotropia whose angles were less than 30 PD.[28] If the cause of the vision deficit persists, then the angle can increase progressively,[28] although this is not always the case.[27] There is a positive correlation between age of the patient and size of the exotropia.[26] A longstanding large exotropia leads to secondary muscle changes. The lateral rectus contracts and the overlying soft tissues shorten, creating a tight lateral rectus syndrome (see the "Clinical features" subsection of Infantile Exotropia, above): an updrift and downdrift in the adducted position, and possibly an "X" (see Fig. 80.1), "A," or, less commonly, a "V" pattern.[1] The exotropic eye may exhibit a small hypertropia.

Measuring the angle of the exotropia can be tricky when the vision is poor in one eye. The prism and alternating cover test may not be accurate since the poor fixation in the eye does not allow the examiner to see a stable endpoint during the measurement; thus, the angle is better measured with the modified prism and light reflex (Krimsky) test: After the angle kappa is noted for the fixating eye, progressive base-in prism power is placed over that eye until the exotropic eye is drawn over sufficiently in the nasal direction to create a matching angle kappa in that eye.[2]

Sensory features

Several adaptations can occur in sensory exotropias. If the vision is very poor, there may be deep suppression and no binocular responses. Children whose vision is not severely reduced and who have exotropia not exceeding 40 PD may develop ARC.[1] Children with anisometropic amblyopia and exotropia may retain NRC.[1] Young children can avoid diplopia by suppressing the displaced image. Older children with sensory exotropia may experience diplopia because they cannot develop ARC.

Sensory tests in a patient can vary, ARC or NRC, depending on the depth of suppression and the dissociating ability of the tests, the brightness of ambient lighting, the distance of the testing apparatus from the patient, and the size of the exotropia.[1]

Management

Treating the underlying cause of the vision loss is paramount: cataracts, corneal opacities, anisometropic amblyopia, ptosis, eyelid hemangioma, retinoblastoma, and retinal detachments are potentially reversible examples. If the problem is present early, then the exotropia can be prevented if vision can be restored by treatment, especially of amblyopia. If exotropia has already developed, it may still reduce if vision can be recovered.[1] If exotropia persists despite correction of the underlying disorder, or if the vision loss is chronic and irreversible, it can be treated with either non-surgical or surgical options.

Non-surgical therapy and safety precautions

Prescription of safety lenses for patients with unilateral vision loss is important: those who already wear glasses should be sure that their lens and frame designs meet safety specifications.

Patients with diplopia or asthenopia can be helped with prisms if the angle of the exotropia is not over 30 PD.[29] In some patients, the prism can be weaned with the restoration of stable single binocular vision.[29] Children who are aware of the second image but are not helped by base-in prisms may be helped by base-out prisms to further separate the two images. Patients with intractable diplopia may be helped by Bangerter or MIN occlusion foils to reduce the clarity, and therefore awareness, of the displaced image in the exotropic eye.

Botulinum toxin injections are successful in re-aligning angles of exotropia under 35 PD.[1] However, the angles in sensory exotropia tend to be larger, with a lower long-term success rate. Patients with a large exotropia angle who choose botulinum injections rather than surgery must understand that periodic re-injections may be needed.[1]

Surgery

Surgical planning

Children with sensory exotropia should undergo preoperative prism testing to see whether they can be re-aligned without inducing intractable diplopia.[29] If a prism, placed base-in and matching the strabismus angle, is introduced before the misaligned eye and the child does not complain of diplopia, then the surgeon can plan to align the eyes close to orthotropia. If the child complains of diplopia when the prism used corrects the whole deviation, a reduced amount of prism for partial correction can be tried. However, a diplopia response to correction of the whole angle does not necessarily predict postoperative diplopia. In such a case, a trial with a Fresnel prism correction of the whole angle for several days should be used to determine if the child can adapt to perfect alignment.[1]

A complete eye examination is mandatory prior to surgery. The surgeon must be sure that the eye is healthy enough to

undergo strabismus surgery. Problems such as phthisis, corneal compromise, and orbital factors may make it risky to perform muscle surgery. Older children may allow a forced duction test on their eye to detect a contracture of the lateral rectus or any other restrictive phenomena that will help in the planning of surgery.

Most cases of sensory exotropia require surgery on two muscles due to the large angles typically seen in these patients.[30] Sensory exotropia of 25 PD or less can be successfully treated with unilateral lateral rectus recession alone.[28] Weakening of the lateral rectus is almost always a component of the surgery plan, and, if the overlying conjunctiva is also tight, it should be recessed as well.[1] The medial rectus can be lax and may be strengthened. The surgeon should perform several forced ductions at surgery as each layer is dealt with, to be sure that restrictions are released. For large angles, from 55 to 90 PD, supramaximal lateral rectus recession (10 mm or more) along with medial rectus resection or plication (9 mm or more) have been reported to lead to successful long-term alignment.[30] Alternatively, the addition of ipsilateral inferior oblique and superior oblique weakening to more traditional dosages of horizontal rectus surgery can increase the success of surgery for these large angles.[1]

If the surgical goal is orthotropia, then the immediate postoperative alignment should be a small angle esotropia, as there is typically a drift toward exotropia of several degrees in the first few weeks.[1,31] Adjustable sutures may be help to achieve the desired target angle, although one study showed no difference in success rates for long-term alignment with or without the use of adjustable sutures.[31] In general, the postoperative target angle should be slightly larger than that recommended for routine cases of intermittent exotropia, of the order of 10–14 PD, similar to that recommended above for infantile exotropia. To achieve this and to improve the long-term stability, the forced duction at the conclusion of surgery should be mild-to-moderately limited to abduction and the spring-back balance test should be biased in the esotropic direction. Some authors caution against aligning to orthotropia any older patient with sensory exotropia caused by anisometropia, and they recommend leaving such patients undercorrected.[1]

Results

Patients with preoperative exotropia angles under 40 PD have at least 75% chance of a stable small angle heterotropia. Over 45 PD, the results decrease dramatically to 40–50% long-term success.[26] Once the eye is re-aligned, the secondary muscle phenomena such as upshoots and downshoots and "X" patterns often resolve within weeks.[1]

Overview and definitions

For a patient with vertical strabismus, one should first determine whether the deviation is comitant or incomitant. If the latter, one next determines if the problem is paretic, restrictive, or a manifestation of primary oblique muscle dysfunction. Finally, one determines if the deviation is dissociated (e.g. does not appear to follow Hering's Law with respect to the vertical component).

It is best to describe the deviation as it is actually manifested. Thus, if a patient fixes with the left eye and has a restrictive right hypotropia, you should call it a right hypotropia rather than using the old convention of describing it in terms of a hypertopia – in this example a left hypertropia. If the patient freely alternates fixation, you should then use the old convention. There has also been confusion about the terminology for describing dissociated vertical divergence (DVD). Terminology should be descriptive by addressing three issues; indicate if the deviation is:

1. constant or intermittent;
2. latent of manifest (e.g. a phoria or tropia);
3. dissociated or not dissociated.

The most common presentation for DVD is for one eye to have a hypertropia that is intermittently manifest and for the other to have a hypertropia that is latent (only present in the dissociated state, e.g. under cover). Appropriate terminology for describing such a patient would be "intermittent manifest DVD in one eye and latent DVD in the other." An alternative would be "an intermittent dissociated hypertropia in one eye and a dissociated hyperphoria in the other."

Physiology

The cyclovertical muscles have a triple function that includes a vertical, torsional, and, to a lesser degree, horizontal action. With head tilt right or left, there is a small partial compensatory torsional rotation of each eye, which corrects for about 5–10% of the head tilt.[1] This comes from stimulation of the intorters (superior oblique and superior rectus) in the eye on the side to which the head is tilted, and the extorters (inferior oblique and inferior rectus) in the fellow eye, and forms the basis for the Bielschowksy head tilt test and the Parks' three-step test.[2] Although the vertical rectus muscles have their main vertical action in adduction, they are still the primary elevators and depressors across the horizontal gaze fields. Oblique muscles have a relatively weak vertical action. If the superior rectus is detached from the globe, the inferior oblique alone cannot elevate the eye above the midline.[1] The superior oblique, however, has a stronger vertical action than the inferior oblique.

Patient evaluation

History

Before measuring the deviation, observe whether the patient has a spontaneous compensatory head posture (CHP) with visual effort. Although there are many causes for CHPs, this author finds they mostly serve to place the eyes in a gaze field in which the deviation is less, or to damp nystagmus (see Chapters 82, 84, and 89). The presence of facial asymmetry typically identifies the CHP as dating back to early childhood. There is a shortening of the midface between the horizontal canthus laterally and the corner of the child's mouth on the side to which the head is habitually tilted[3] (Fig. 81.1). Measure the deviation with the head posture using the prism and alternative cover test, and then in the head-erect position. Although a diagnosis can often be made by just measuring a patient in seven fields of gaze (primary, up, down, right, and left) and on head tilt right and left, an optimum treatment plan often requires additional measurements in the four oblique fields. Ductions and versions should be assessed with particular attention to the presence of overelevation or overdepression in the oblique fields. If there is overelevation of the adducting eye on side gaze, do a cover test in that gaze field to ascertain if the vertical deviation is

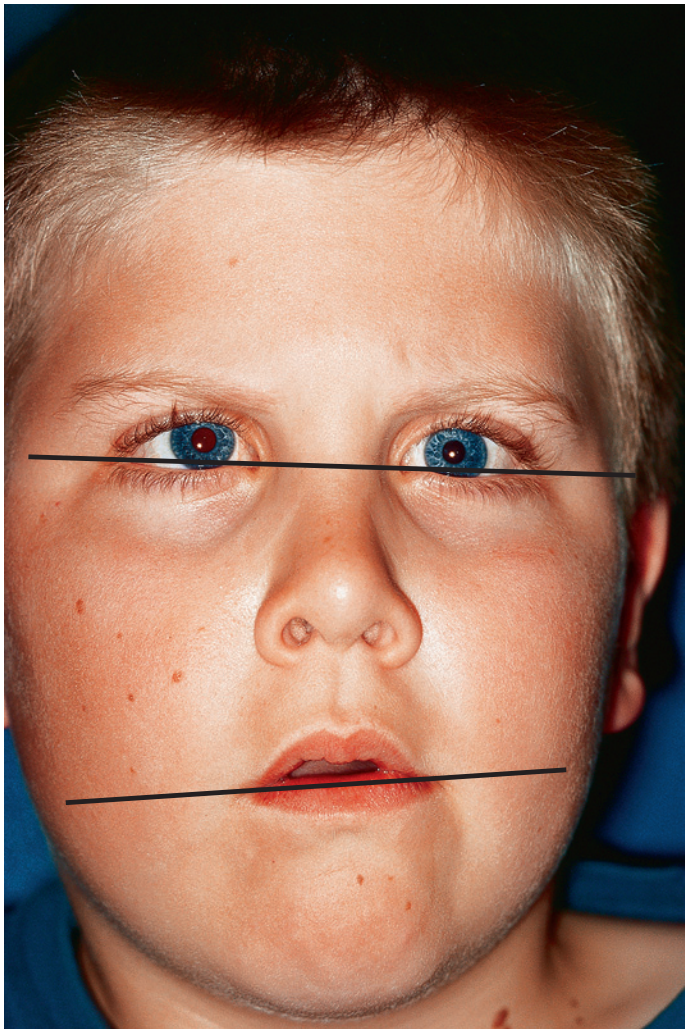

Fig. 81.1 Facial asymmetry. There is shortening of the left side of the face in this boy with a longstanding head tilt to the left for control of a right superior oblique palsy.

a manifestation of DVD or true inferior oblique overaction. In Video 81.1, both boys show overelevation of either eye in adduction. The first boy does not have a hypotropia of the abducting eye when cover testing is done in side gaze. His overelevation in adduction is solely due to DVD. The second boy does have a significant hypotropia of the abducting eye when cover testing is done in side gaze. He has DVD coexisting with true inferior oblique overaction.

Determine if the deviation is dissociated or not. With a non-dissociated deviation, a hypotropia is present in the contralateral eye when fixation is with the higher eye. Unless a secondary deviation is present due to paresis or restriction, the hypotropia in one eye will be of equal size to the hypertropia of the other eye. With DVD, the hypotropia of the fellow eye is either smaller or absent when fixation is with the eye with the DVD (see section "Dissociated vertical divergence").

The Parks' three-step test will tell, in theory, which of the eight cyclovertical muscles is paretic; however, in practice it works best for confirming the diagnosis of unilateral superior oblique palsy.[2,4] Even in cases of isolated superior or inferior rectus palsy, it may be misleading. Most importantly, it does not tell whether a vertical strabismus is due to a palsy of one of the cyclovertical muscles, but is based on the assumption that it

Box 81.1

Situations in which the Parks' three-step test may be misleading[4]

Dissociated vertical divergence
Multiple muscle involvement
  Bilateral fourth nerve palsy
  Multiple other muscle weakness
Pulley heterotopia
Superior rectus overaction/contracture
Inferior rectus restriction
Superior rectus palsy
Inferior rectus palsy
Skew deviation
Prior extraocular muscle surgery

is. Box 81.1 lists some of the common situations in which the three-step test leads to an incorrect diagnosis. The man in Video 81.2 developed vertical diplopia immediately after closed head trauma from a motor vehicle accident. He had a left hypertropia that increased in right gaze and on left head tilt, thus meeting the three-step test criteria for a left superior oblique palsy. In fact, he had an orbital floor fracture in his right eye. He consistently fixed with his right eye due to mild amblyopia in his left eye. His diplopia resolved when the fracture was repaired.

You should test for the presence of torsion, both objectively and subjectively. The latter is accomplished with the double Maddox rod test using two red lenses, because the use of one red and one white lens frequently leads to a localization artifact; if the eye behind the white lens is the one that is torted, the patient will frequently perceive the torsion as being in the eye behind the red lens.[5] However, even when this author uses two red lenses, he sometimes finds that the double Maddox rod test just reveals the total amount of torsion between the two eyes, and may be misleading with respect to localizing to the specific eye affected. Objective torsion is determined with the indirect ophthalmoscope and may be more useful in determining which eye actually is torted.[6] Normally the position of the fovea should be level with the lower one-third of the optic disc (Fig. 81.2). The absence of subjective torsion in the presence of objective fundus torsion usually means the deviation is longstanding and sensory adaptations have occurred. If a patient describes torsion, determine if the patient can fuse when the vertical and horizontal deviations are offset with prisms. If the patient can fuse comfortably despite the presence of torsion, it may be possible to ignore the torsion when designing a surgical strategy. If they cannot fuse, there may be a central disruption of fusion. Testing on the synoptophore, which can offset the torsion, may determine whether one can expect fusion if the strabismus is successfully treated.

General diagnostic pointers

1. Are history and symptoms helpful in determining etiology? Is there diplopia, childhood strabismus (if the patient is an adult), and is there DVD?
2. Is incomitance greater vertically or horizontally? If it is greater vertically, consider a restriction or palsy of a vertical rectus. If the largest difference is horizontal, consider an oblique problem.

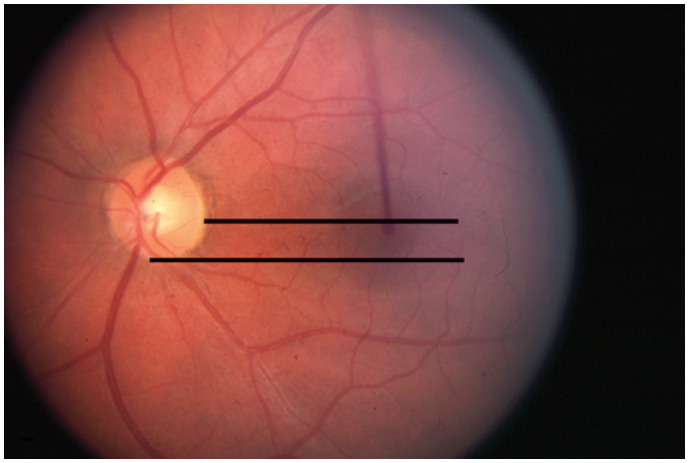

Fig. 81.2 Normal relationship of fovea to disc with respect to torsion. The fovea is normally positioned level with the lower third of the optic disc. The borders of normal lie between the two black lines in the figure. This photograph indicates an absence of objective torsion but is near the border for intorsion.

3. Is there a limitation of rotation? Differentiate restriction from paresis with forced duction and active force generation testing.
4. Is there substantial torsion? If so, consider oblique problems or a vertical restriction.
5. Might the patient be fixing with the involved eye? Always consider this if there is asymmetric best-corrected visual acuity. Check for a secondary deviation.

General treatment principles

You should choose a treatment plan that will give the maximum correction in the field of gaze in which the deviation is greatest. Thus, you need to pay attention to the pattern of incomitance and the presence of torsion. Keep in mind that the primary position and downgaze (for reading) are the two most important fields of gaze and should not be sacrificed for the benefit of eccentric gazes. Oblique muscle surgery will give much more correction in adduction than abduction, but with vertical rectus surgery the difference in correction between abduction and adduction is less dramatic. Also, oblique muscle surgery causes more torsional change than rectus muscle surgery. An exception is with vertical rectus restrictions in which releasing the restriction may correct substantial torsion.

In general, surgery on the superior oblique is least "forgiving," with surgery on the inferior rectus running a close second. Inferior rectus recessions of 5 mm or more may cause a lag of that eye in downgaze unless there was a hypotropia that increased in downgaze prior to surgery. Also, large recessions of the inferior rectus may cause lower eyelid retraction postoperatively, which can be minimized by advancement of the capsulopalpebral head at surgery.[7] Large resections of the inferior rectus muscle may cause narrowing of the palpebral fissure, and large recessions of the inferior rectus using a suspension technique (hangback adjustable suture) have a higher incidence of muscle slippage or non-adherance. This is probably caused by the shorter arc of contact of that muscle, which can cause the muscle to lose apposition with the globe in downgaze after surgery if the muscle is not fixed to the sclera.[8] Slippage can be prevented by using the semi-adjustable suture technique,[9] or a non-absorbable suture.

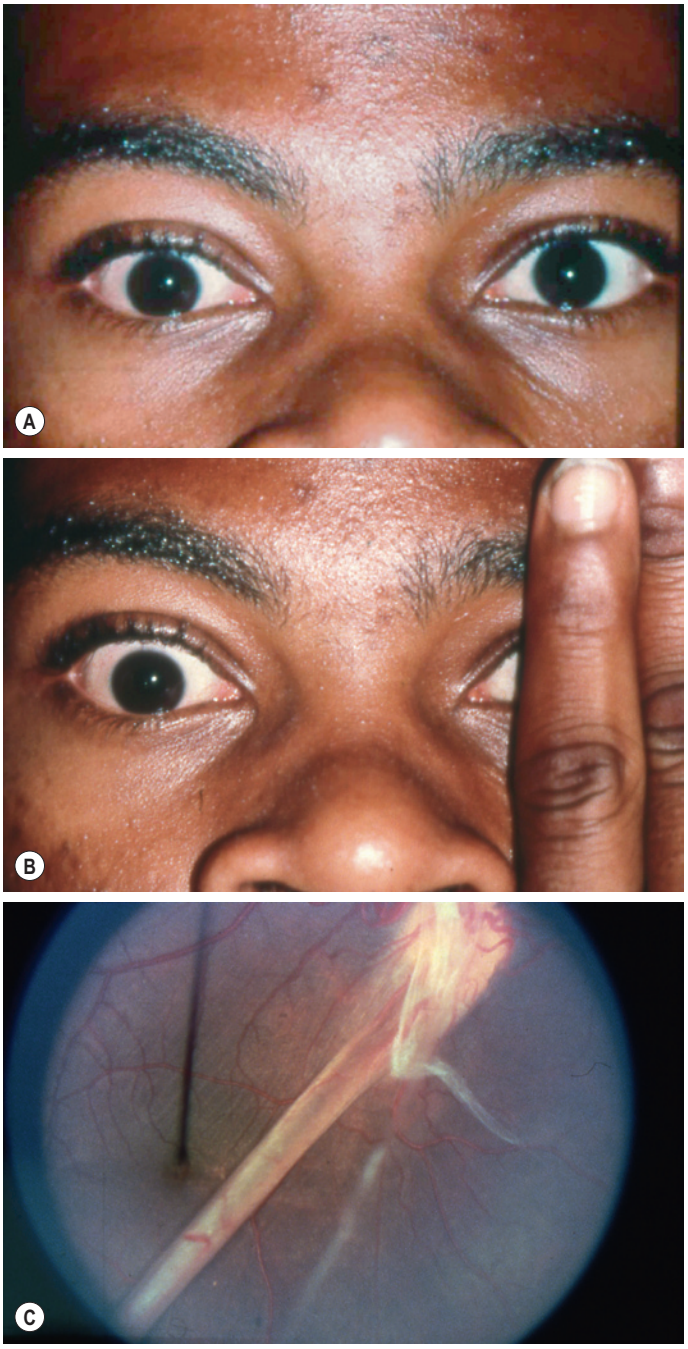

Fig. 81.3 Pseudohypotropia. (A) Patient with what appears to be a right hypotropia. (B) Cover test shows he is actually fixating with the eye when it appears to be infraducted. (C) His right fovea is dragged inferiorly due to traction secondary to retinopathy of prematurity, resulting in a large vertical angle kappa.

Specific clinical entities

Pseudohypertropia

Some patients may appear to have a hypertropia when in fact they do not. These include cases of orbital dystopia, anterior segment anomalies, or vertical angle kappa (Fig. 81.3). This latter

may be due to a displaced fovea secondary to retinopathy of prematurity (see Chapter 44) or other causes of retinal dragging.

Comitant deviations

Small comitant hypertropias, unrelated to prior strabismus surgery, are common. If they are more than several prism diopters (PD), they may cause symptoms of asthenopia or diplopia, which are often managed successfully with prisms. Large comitant vertical deviations not associated with horizontal strabismus are relatively uncommon. When present, they most likely represent a spread of comitance in a patient that initially had paralytic strabismus. If the deviation is large but comitant, vertical rectus muscle surgery is usually appropriate.

Incomitant deviations: non-restrictive non-paretic

Primary oblique dysfunction

Primary overaction of the inferior oblique muscles, and to a lesser degree the superior oblique muscles, is a common accompaniment of primary horizontal strabismus. Oblique muscle overaction is not usually present at birth but after 1 year of age. Inferior oblique overaction is characterized by an overelevation in adduction and is associated with a "V" pattern. Superior oblique overaction is associated with overdepression in adduction and is associated with an "A" pattern (see Chapter 82). Typically objective extorsion is present with inferior oblique overaction and intorsion with superior oblique overaction. Subjective torsion may not be present as the patient develops sensory adaptations. The main differential diagnosis between primary oblique overaction and palsy of the antagonist oblique muscle is settled with the head tilt test. With bilateral superior oblique palsy, the Bielschowsky head tilt test should reveal alternating hypertropias (right hypertropia on right head tilt and left hypertropia on left head tilt) for the reasons above. With primary oblique dysfunction, the difference in the vertical deviation with head tilting is minimal.[10] The boy in Video 81.3 has marked inferior oblique overaction, superior oblique underaction, and a large "V" pattern. On head tilt right and left, there is a negligible hypertopia, thus distinguishing primary inferior oblique overaction from bilateral superior oblique palsy. He had a history of previously undergoing medial rectus recessions for infantile esotropia (IED). Subsequently, a computed tomography scan for unrelated reasons showed the superior obliques were of normal size. I believe primary inferior oblique overaction is primarily due to inferior oblique muscle contracture,[10] possibly due to a chronic excyclorotation of the eye. It can be treated with inferior oblique muscle weakening.

It is rare for bilateral superior oblique overaction to be secondary to inferior oblique palsy. If superior oblique overaction is bilateral and symmetric, there will be no hypertropia in the primary position, but an "A" pattern is typically present. If the superior oblique overaction is unilateral, there may be a small hypertropia in the primary position. For mild superior oblique overaction, this author prefers a posterior 7/8 tenectomy performed at the insertion of the superior oblique. For greater amounts of superior oblique overaction, the split tendon lengthening procedure[11] allows titration of the effect, is potentially reversible, and unlike the silicone expander, does not place a foreign body in the orbit.

Paralytic strabismus (see Chapter 84)

Fourth cranial nerve palsy

Fourth nerve palsy is the most common form of paralytic vertical strabismus. The diagnostic criteria include a hypertropia of the affected eye that increases on adduction and ipsilateral head tilt (Fig. 81.4). A useful test for differentiating fourth cranial nerve palsy from skew deviation is to measure the deviation in the head erect and supine position. A decrease in the hypertropia by 50% or more is strongly suggestive of skew deviation.[12]

When treating fourth nerve palsy, slightly undercorrect the deviation or the patient may have bothersome diplopia. The primary position measurement determines how many muscles need surgery, and the pattern determines which muscles. Although Knapp's classification of superior oblique palsy is sound, it does not take into account the use of adjustable sutures and some newer observations about superior oblique anatomy and function.[13] The author follows this approach:

1. If the deviation is 15 PD or less, do one muscle. That threshold may be lowered to 10 PD if adjustable sutures are used.
2. If the deviation is greater in the inferior oblique field, recess the ipsilateral inferior oblique. If it is greater in the superior oblique field, tuck the superior oblique. An alternative to tucking the superior oblique in this setting is to recess the contralateral inferior rectus muscle for the vertical deviation, and transpose the ipsilateral inferior rectus nasally for the torsion.[14] This is useful for surgeons who are not comfortable tucking the superior oblique; however, it should not be done if there is anything more than a few prism diopters of esodeviation in downgaze, as it may exacerbate a downgaze esodeviation.[15]
3. If the deviation in primary mandates more than a one-muscle procedure, recess the ipsilateral inferior oblique and the contralateral inferior rectus. The author finds the semi-adjustable suture technique useful in this setting.[9]
4. If there is 10 PD or more of hypertropia in the horizontal abducted field, there is most likely some degree of superior rectus overaction/contracture. Often this is more a manifestation of overaction than contracture, and may not be detectable by forced ductions.[10] Then recess the ipsilateral superior rectus a small amount along with the ipsilateral inferior oblique. Small superior rectus recessions are indicated to avoid crippling upgaze.

Many patients with congenital superior oblique palsy have lax superior oblique tendons.[16] The dogma is that, if a lax tendon is found, it should be tucked and, if it is not lax, a tuck is to be avoided. This is based on the belief that the primary problem is a tendon anomaly. The author feels this philosophy has never been validated clinically and may not be sound. Lax tendons are associated with atrophy of the superior oblique muscle,[17] so trying to strengthen a paralyzed superior oblique would be comparable to resecting a paralyzed and flaccid lateral rectus muscle, for which a transposition of the vertical rectus muscles would be a better choice. Tucking a non-lax superior oblique would be akin to resecting a mildly paretic lateral rectus, which is often successful. Perhaps the wisest approach is to tuck tendons that are not lax if the incomitance pattern justifies it, but do a small tuck.

Fig. 81.4 Three-step test for left superior oblique palsy. This girl has a left hypertropia that increases on right gaze and left head tilt, meeting the three-step test criteria for a left superior oblique palsy. There is overaction of the left inferior oblique muscle and mild underaction of the left superior oblique muscle.

Fourth nerve palsy, particularly if acquired, is often bilateral. If the degree of paresis is very asymmetric, the palsy in the lesser-affected eye may not be evident on routine testing, and only becomes apparent after surgery is performed on the more paretic eye. This is called a bilateral masked superior oblique palsy. Diagnostic signs of a bilateral problem include a large "V" pattern, more than 10 degrees of excyclotropia, bilateral objective fundus torsion, a relatively small Bielschowsky head tilt difference, and reversal of the hypertropia in any field of gaze (particularly the contralateral superior or inferior oblique field) or on forced head tilt.[18] This is one of the reasons that proper surgical planning necessitates measuring in all nine diagnostic fields of gaze plus on head tilt right and left. If there are findings that suggest a bilateral masked palsy, the author does bilateral surgery even without reversal of the hypertropia in the routinely measured gaze fields. Surgery depends on the specific pattern of incomitance, but usually involves bilateral oblique muscle surgery. This may be bilateral but asymmetric inferior oblique recessions, a Harada-Ito procedure in one eye, and a superior oblique tuck in the other, or symmetric oblique surgery to treat torsion and a vertical rectus recession to treat primary position hypertropia.

Inferior oblique palsy

Inferior oblique palsy is relatively rare and can be treated with ipsilateral superior oblique weakening. It must be differentiated from Brown syndrome, which has a similar appearance on versions in the inferior oblique field. A diagnostic criterion is an "A" pattern, which is typically present with inferior oblique palsy, whereas a "V" pattern is typical of Brown syndrome (Fig. 81.5).

Vertical rectus palsy

Vertical rectus palsy is usually treated with recession of the antagonist vertical rectus if mild, the same combined with a resection of the paretic muscle if moderate, or a transposition procedure of the horizontal rectus muscles if severe. In mild

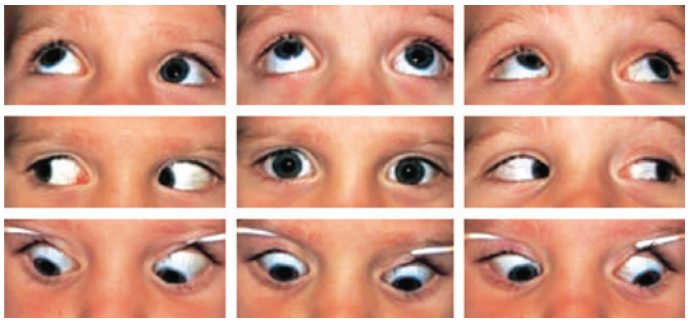

Fig. 81.5 Brown syndrome. This boy has marked limitation of elevation of the left eye in adduction. Although the appearance in that gaze field alone suggests a left inferior oblique palsy, there is a "V" pattern as opposed to an "A" pattern suggesting Brown syndrome.

cases, recession of the same vertical rectus muscle in the other eye to match the deficit can give good results. The head tilt test is inconsistent with vertical rectus palsy.[4]

Dissociated vertical divergence

DVD is a marker for early-onset strabismus, but it is unusual at birth. Most commonly it appears after 1 year of age, and may not be evident until after surgery for IET. It may present as a subtle deviation, which may be small and only present on cover testing. Or it may be associated with a large and frequently manifest vertical deviation that can be as cosmetically disfiguring as the initial horizontal strabismus. Although DVD is a bilateral disease, it may appear to be unilateral because the preferred eye only has a latent deviation. This is particularly the case with amblyopia: fixation always occurs with the non-amblyopic eye. However, this can also occur in patients with equal vision.

DVD is characterized by a slow upward drifting of the eye; the eye extorts when it elevates, simultaneously, intorsion occurs in the fixing eye. It is typically associated with latent or manifest latent nystagmus. The hallmark is that, when the fixing eye is covered and the patient regains fixation with the deviating eye, the previously fixing eye does not have a commensurate hypotropia. If the DVD is significant in both eyes, the formerly fixing eye will elevate under cover. Thus, it appears that DVD is characterized by an uncoupling of Hering's Law. Often DVD appears worse in adduction, simulating inferior oblique overaction. Differentiating the two conditions includes performing a cover test on side gaze to see whether there is hypotropia of the abducting eye when it is occluded. With DVD the abducting eye will not show a hypotropia and may be hypertropic if the DVD is bilateral (Fig. 81.6; Video 81.1). Because of the nature of DVD, and that there is not an equal hypotropia of the contralateral eye, one cannot neutralize this deviation with the alternate prism and cover test. To accurately measure DVD, one must use the prism under cover test. This test is carried out by first estimating the size of the DVD. Then a prism equal to the estimated size of the deviation is placed base down in front of the affected eye, while the eye is dissociated behind a cover. The cover should then be rapidly switched to the other eye. If the estimated amount of prism was correct, no movement of the eye being tested should occur. If there is still a downward movement, the test should be repeated with a larger prism; if an upward movement occurs, it should be repeated with a smaller prism. However, many patients with DVD have a marked redress movement and an accurate endpoint cannot be obtained, even with the prism under cover test. In that case, the deviation must be estimated by determining whether the upward and downward components of the redress movement were of equal magnitude, or by using a light reflex test.[19]

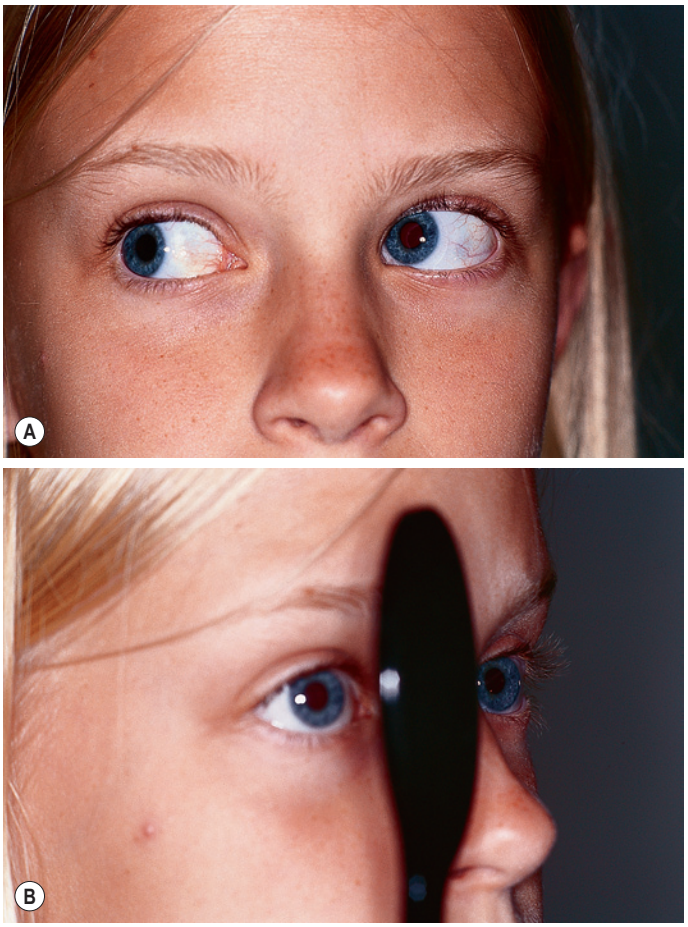

Fig. 81.6 Dissociated vertical divergence (DVD) mimicking inferior oblique overaction. (A) This girl shows overelevation of the left eye in adduction, which is consistent with left inferior oblique overaction. (B) Under cover, however, a hypertropia is seen in the right eye, confirming that this child, in fact, has DVD.

Approximately one-third of patients with DVD have a spontaneous abnormal head posture.[19] Most patients with DVD show an increase in the size of the DVD on contralateral head tilt (e.g. right DVD increases with left head tilt); however, some show the converse (Fig. 81.7).

Similar, but somewhat different, theories by Guyton and Brodsky have shed light on the etiology and pathophysiology of DVD. They suggest that DVD is a result of damping of nystagmus by complex interactions of the cyclovertical muscles,[20] possibly via a vestigial remnant of the dorsal light reflex of lower animals.[21]

Surgical management of DVD depends on whether inferior oblique overaction is present, the size of the deviation, and if it is bilateral or unilateral. If it is unilaterally manifest, the possibility that the patient may shift fixation after surgery should be taken into account. If amblyopia is present, a shift in fixation is unlikely. If inferior oblique overaction is present

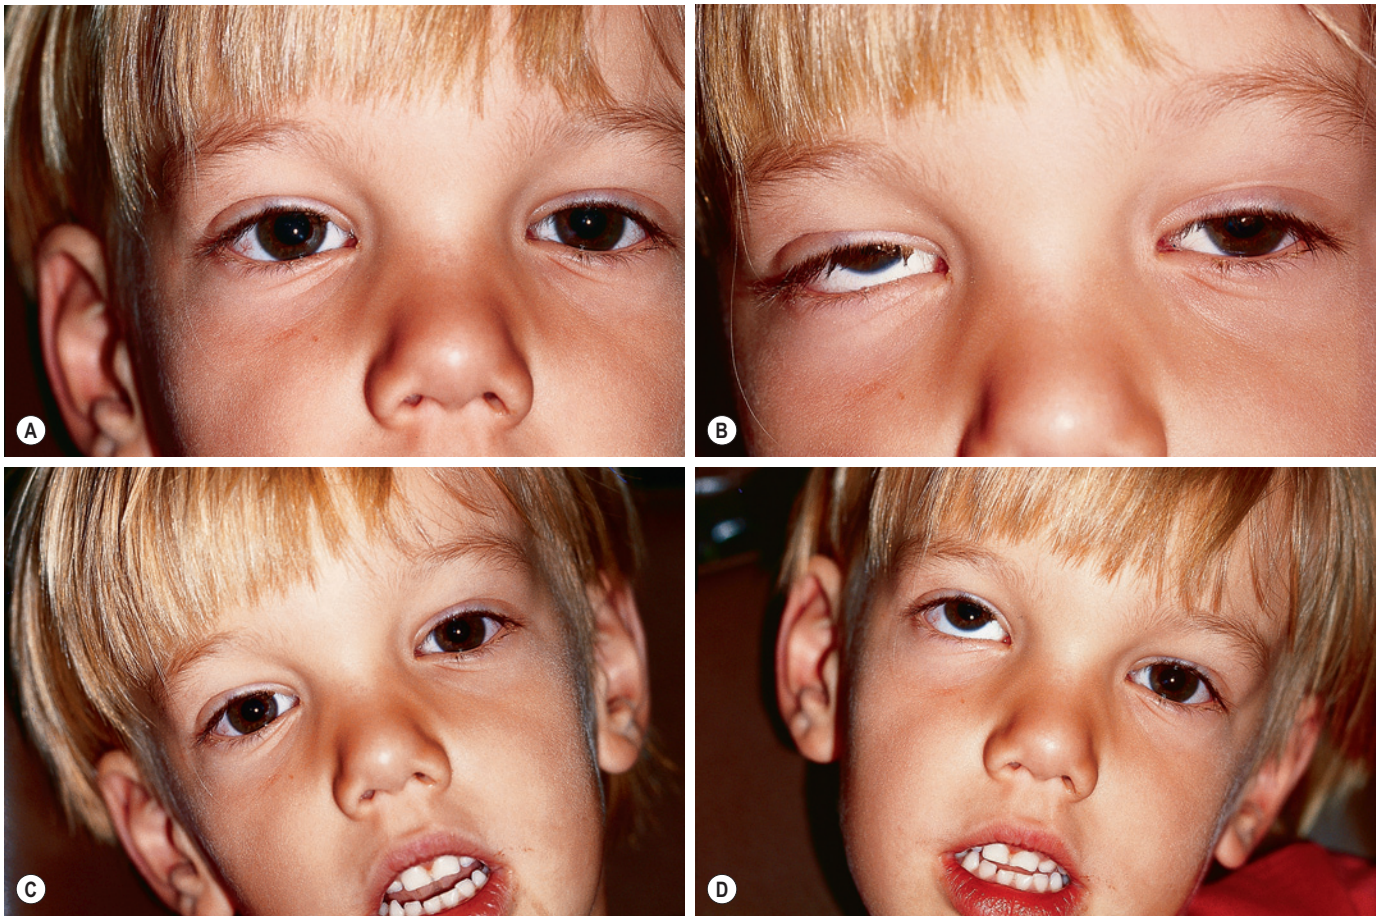

Fig. 81.7 Head tilt test with dissociated vertical divergence (DVD).This boy has the typical head tilt response for DVD. (A) His DVD is latent and his eyes are often well aligned. (B) A right DVD is intermittently manifest. (C) The deviation is absent on head tilt to the right. (D) The deviation increases on head tilt to the left, which is common for a right DVD.

concurrently with DVD, this author prefers to anteriorly transpose the inferior oblique muscle to a point level with the inferior rectus insertion.[22] Weakening the inferior oblique without anterior transposition may not adequately treat DVD. If anterior transposition of the inferior oblique is planned, it should be done bilaterally or there will be a resultant hypotropia of the operated eye in upgaze. It should not be performed if the inferior obliques are not overacting, or if there is substantial superior oblique overaction.

If DVD is significant and there is no overaction of the inferior obliques, recession of the superior rectus muscles is the treatment of choice. Even if DVD is unilaterally manifest, bilateral surgery is advisable if the dominant eye shows latent DVD under cover and if equal vision is present. Then, if unilateral surgery is performed, it is likely that the patient will shift fixation postoperatively and manifest a DVD in the previously preferred eye. For guidelines for the magnitude of superior rectus recession for DVD see Table 81.1. As is depicted in the table, with unilateral surgery (which is desirable if amblyopia is present), the amount of superior rectus recession for a given amount of DVD should be less.

Symmetric inferior rectus resections in the range of 4–7 mm can be used to treat DVD. This procedure is generally reserved for use as a secondary procedure after other treatments have failed. This magnitude of inferior rectus resection will often cause narrowing of the palpebral fissure by raising the height of the lower eyelid.

Special forms of vertical strabismus

Brown syndrome

Brown syndrome is caused by a mechanical restriction of the superior oblique tendon moving through the trochlea, which results in a restriction of elevation in adduction. On version

testing, it mimics an inferior oblique palsy, except that a "V" pattern is present; an "A" pattern is expected with inferior oblique palsy. Most cases of Brown syndrome are congenital, but can be acquired due to either trauma or inflammation. If an inflammatory etiology is suspected, a systemic work-up for autoimmune disease is appropriate. Inflammatory Brown syndrome may resolve spontaneously. If not, it can be treated with steroid injection in the region of the trochlea. Systemic anti-inflammatory medications may play a role, but this author has found the results disappointing.

Some cases of congenital Brown syndrome resolve spontaneously. Treatment may be indicated if a child needs to assume an unacceptable head posture for fusion. At surgery, forced ductions with attention to elevation in adduction should be performed. They will be positive if Brown syndrome is present and negative if there is an inferior oblique palsy. The surgical treatment of Brown syndrome consists of one of many procedures to weaken or lengthen the superior oblique tendon.

Duane syndrome (see Chapter 83)

Patients with Duane syndrome frequently have an upshoot or downshoot of the affected eye on adduction (Fig. 81.8). Although this appears to be caused by overaction of an oblique muscle, it is in fact caused by co-contraction of the lateral rectus muscle. This causes the lateral rectus to slip above or below the midline on adduction, creating the vertical deviation. Treatment in the form of oblique muscle weakening is usually not helpful. Successful treatment involves releasing the lateral rectus muscle in the form of either recession or Y splitting with recession. In severe cases, it should be disabled by suturing it to the lateral orbital periosteum.

Restrictive strabismus

Common forms of restrictions that cause vertical strabismus include orbital floor fracture, primary ocular muscle fibrosis, Graves orbitopathy, myotoxicity from local anesthetic, and scarring after prior strabismus surgery. In these cases, there will be a limitation of rotation of the eye in the field opposite the affected muscle. Treatment involves recession of the affected muscle and freeing of any scar tissue (Fig. 81.9).

Oblique muscle incarceration

Surgery on one of the vertical rectus muscles and/or the adjacent oblique muscle may result in the oblique muscle becoming incarcerated in the insertion of the rectus muscle. When this occurs with the superior oblique tendon, a restrictive hypertropia and incyclotropia results[23] (Fig. 81.10).

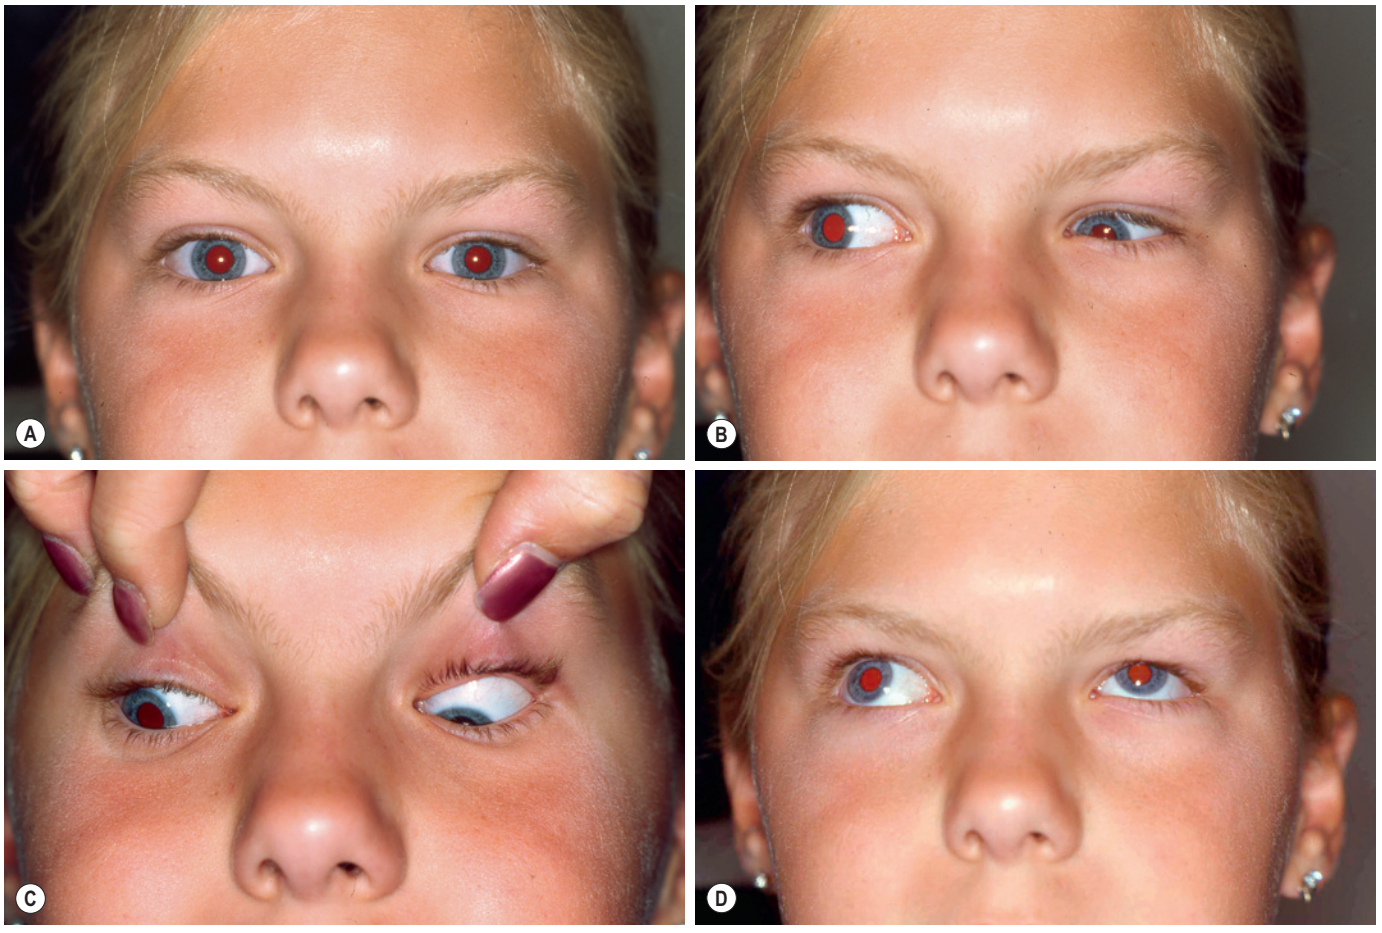

Fig. 81.8 Exotropic Duane syndrome with upshoot. (A) This girl has a small left exotropia (B) associated with limited adduction in her left eye secondary to Duane syndrome. (C) There is a marked downshoot of the left eye with adduction and (D) a large upshoot of the left eye with adduction above the midline. Narrowing of the left palpebral fissure and globe retraction are seen in the left eye on adduction. Although this resembles oblique muscle overaction, weakening of the apparent overacting oblique muscle is ineffective but weakening the lateral rectus may be effective.

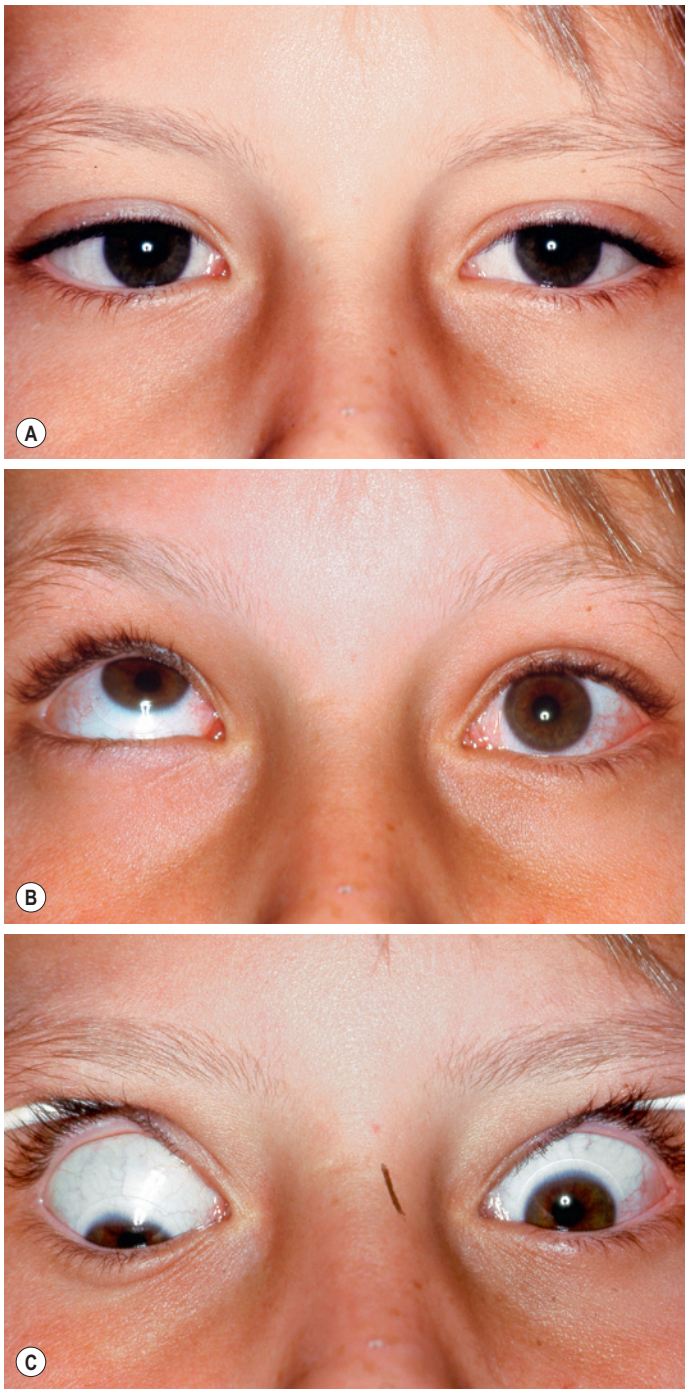

Fig. 81.9 Orbital floor fracture. This boy was struck in his left eye with a baseball, resulting in a large posterior orbital floor fracture. (A) He is straight in the primary position. (B) There is limitation of elevation of the left eye with positive forced ductions, and (C) a pseudo-paresis of the left inferior rectus resulting in a limitation of depression.

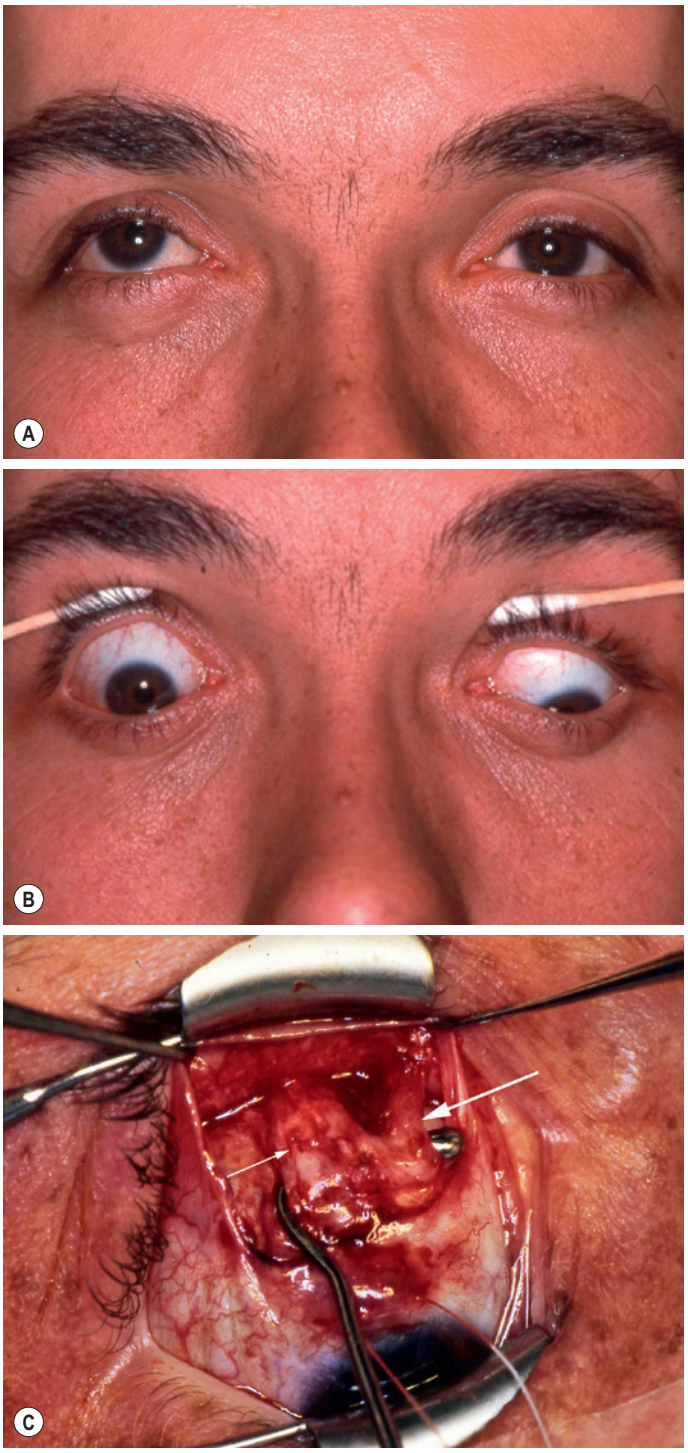

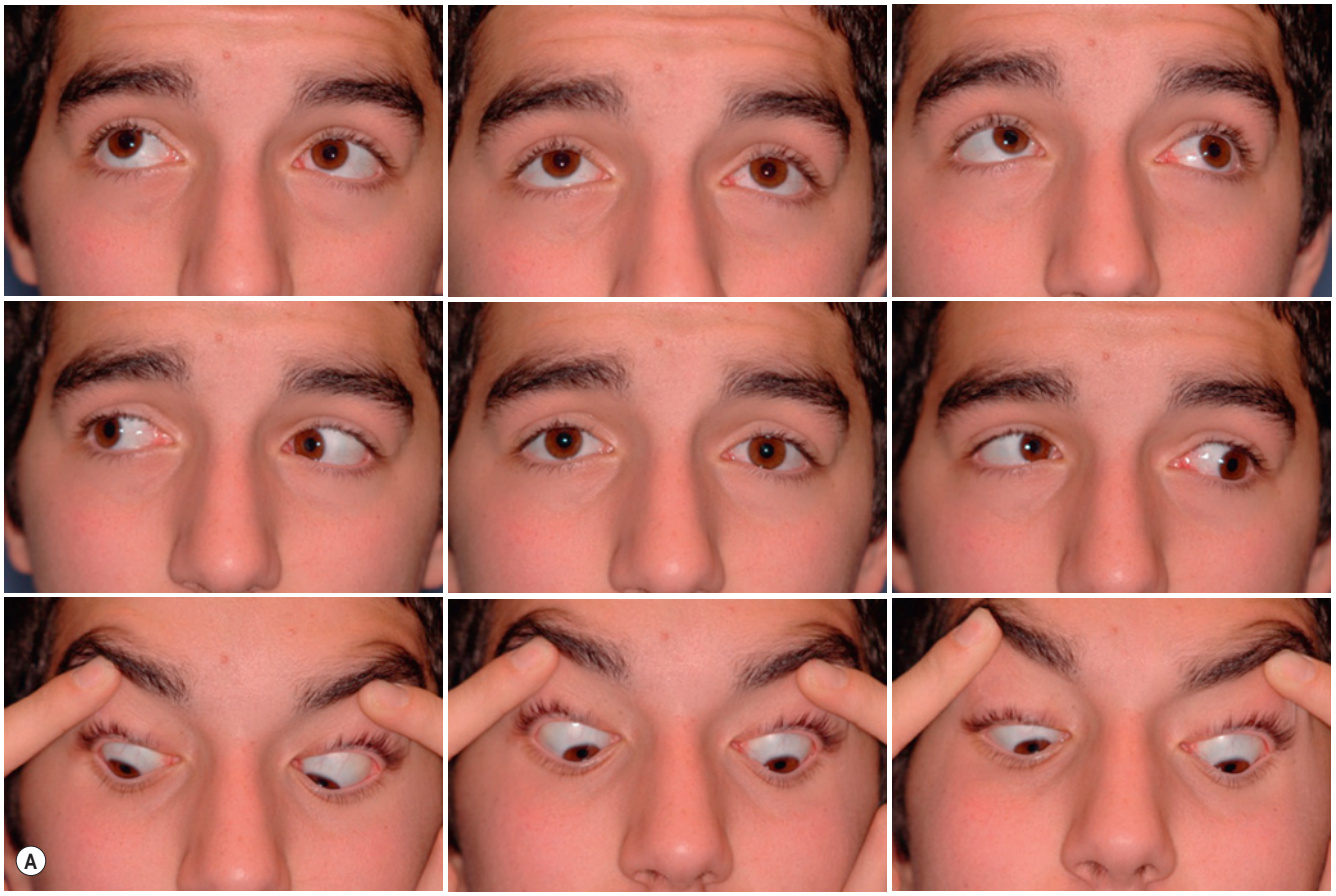

Fig. 81.10 Superior oblique incarceration. (A) This man developed a restrictive right hypertropia and large right incyclotropia after undergoing a small right superior rectus muscle resection. (B) There is limitation of depression of the right eye. (C) At subsequent surgery, the right superior oblique tendon (large arrow) was found scarred into the right superior rectus insertion (small arrow) causing the restriction.

With the inferior oblique muscle, a restrictive hypotropia is found.[24] Treatment can be difficult and consists of freeing the incarcerated oblique muscle or tendon, and often recessing the adjacent vertical rectus muscle.

Altered rectus muscle path

Alteration of the normal path of the rectus muscles due to pulley heterotopia or pulley laxity may result in a vertical strabismus that may mimic other more common forms of vertical strabismus.[25] Inferior slippage of the lateral rectus muscle can mimic Brown syndrome, and high-quality imaging is needed to make the diagnosis. It can be treated by using posterior fixation sutures to reposition the muscle in the proper position (Fig. 81.11). The 14-year-old boy in Video 81.4

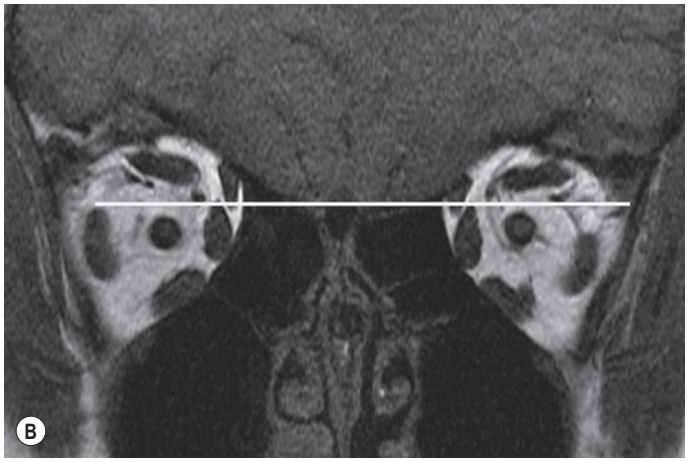

Fig. 81.11 Pulley heterotopia. (A) This 14-year-old boy has a left hypotropia with diplopia to the right and left of the primary position. There is a downshoot of the left eye on adduction and a mild limitation of elevation in adduction. (B) Orbital imaging shows inferior displacement of the left lateral rectus muscle.

has diplopia to the left and right of the primary position. His left eye has a downshoot on abduction and is mildly limited in adduction. Orbital imaging shows the left lateral rectus is to be slipped inferiorly.

Overview and definitions

The terms "A" and "V" pattern describe horizontal strabismus that is vertically incomitant. It is characterized by a substantial difference in the horizontal deviation between the midline upgaze and downgaze positions. A patient with a "V" pattern is more esotropic or less exotropic in downgaze than upgaze (Fig. 82.1); an "A" pattern is characterized by the converse (Fig. 82.2). By convention, the difference between upgaze and downgaze must be 15 prism diopters (PD) or greater to diagnose a clinically significant "V" pattern, and 10 PD to diagnose an "A" pattern. Less commonly, there are variations of pattern strabismus in which there is minimal change from downgaze to the primary position, but the eyes diverge in upgaze resulting in a "Y" pattern. The girl shown in Figure 82.3 and Video 82.1 was first diagnosed with this motility pattern at 3 years of age. This author has continued to care for her for 37 years and her motility is unchanged. She is symptom free without treatment.

Converse to a "Y" pattern, the main exo shift may be between the primary position and downgaze to form a "λ" (lambda) pattern.

History

Duane first described a "V" pattern in 1897 in a patient with bilateral superior oblique palsy.[1] Subsequently, little attention was given to the importance of measuring the angle of strabismus in upgaze and downgaze until Urrets-Zavalia described vertically incomitant horizontal strabismus in 1948.[2,3] Urist brought the "A" and "V" patterns into the English literature in 1951.[4]

Occurrence

Estimates of patients with strabismus having an "A" or "V" pattern range from 12% to 50%.[5–8] The wide range is because ethnic and systemic factors influence the incidence of pattern strabismus and the make-up of each series. In one series of 421 patients with "A" or "V" patterns, 58% had an onset of strabismus prior to 12 months of age.[6] "A" or "V" pattern strabismus occurs much more frequently in congenital or paralytic strabismus than in non-paralytic acquired strabismus. Brown syndrome (see Chapter 81, Fig. 81.5) characteristically has a "V" pattern, differentiating it from inferior oblique palsy, in which an "A" pattern is found. Duane syndrome often presents with a "V" or "Y" pattern, and less commonly an "A" or "λ" pattern (see Chapter 81, Fig. 81.8). "A" patterns with overdepression in adduction are frequently seen in patients with spina bifida and/or hydrocephalus with a 31% incidence having been reported.[9,10] Frontal bossing in children with hydrocephalus (see Chapter 59) may result in anterior displacement of the trochlea, mechanically enhancing the vertical vector of the superior oblique tendon with strengthening of the depressing action of the superior oblique, and this may be the cause of. However, the exact mechanism that causes "A" patterns to occur with hydrocephalus is unclear.

Etiology

There are differing theories as to the etiology of "A" and "V" patterns, in part because different mechanisms may be responsible in different patients.

Oblique muscle dysfunction

The most popular theory, suggested by Knapp in 1959,[11] attributes most cases of "A" and "V" pattern to oblique muscle dysfunction. Abduction is a tertiary action of the oblique muscles. Thus, if the inferior obliques are overacting and

Fig. 82.1 "V" pattern esotropia. This girl has a "V" pattern esotropia with associated inferior oblique muscle overaction and superior oblique muscle underaction.

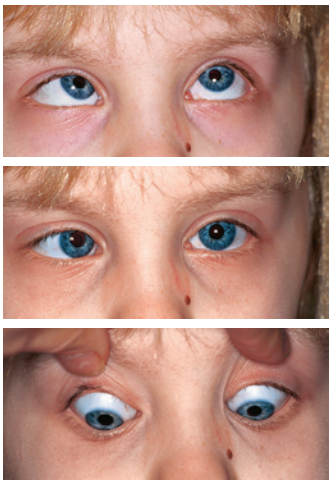

Fig. 82.2 "A" pattern esotropia. This girl has an "A" pattern esotropia showing an increase in the deviation in upgaze and orthophoria in downgaze.

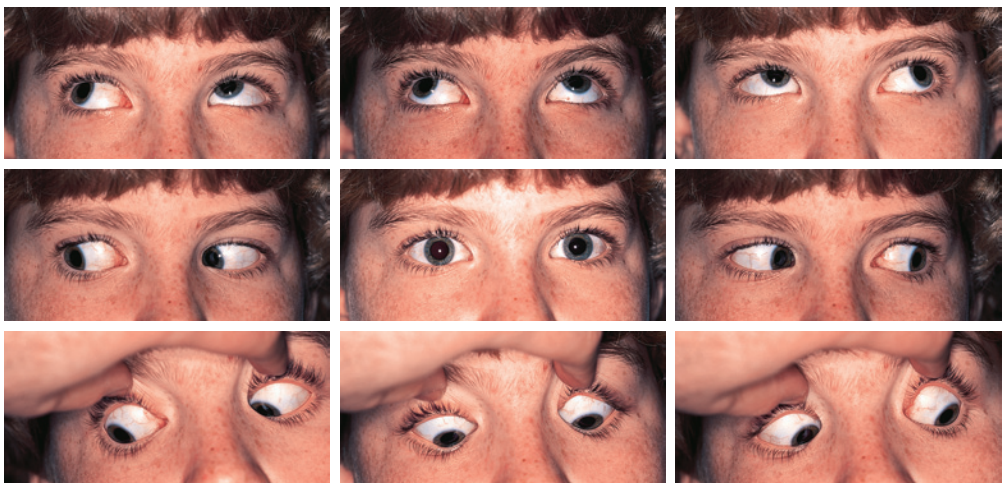

Fig. 82.3 "Y" pattern exotropia. This girl has a "Y" pattern exotropia with pseudo inferior oblique overaction. She is orthophoric in the primary position, horizontal sidegaze, and all downgaze fields. In all upgaze fields she has a large exotropia.

the antagonist superior obliques are underacting, one would expect a relative convergence in downgaze and divergence in upgaze, resulting in a "V" pattern. The converse occurs if the superior obliques are overacting and the inferior obliques are underacting, resulting in an "A" pattern. One typically finds the oblique muscles to be dysfunctional in this manner in most patients with pattern strabismus. This clinical observation, combined with the theoretical construct, has led to the justified implication of oblique muscle dysfunction as a cause of many "A" and "V" patterns.

Torsion as a cause of "A" and "V" patterns

The torsion that accompanies oblique muscle dysfunction should theoretically cause or contribute to "A" and "V" patterns.[12] Patients with a "V" pattern typically have excyclotropia, which is most likely secondary to the accompanying inferior oblique overaction. This excyclotropia results in rotation of the rectus muscles (Fig. 82.4). The superior rectus muscles would become partial abductors and the inferior rectus muscles partial adductors, which will contribute to a "V" pattern. The medial

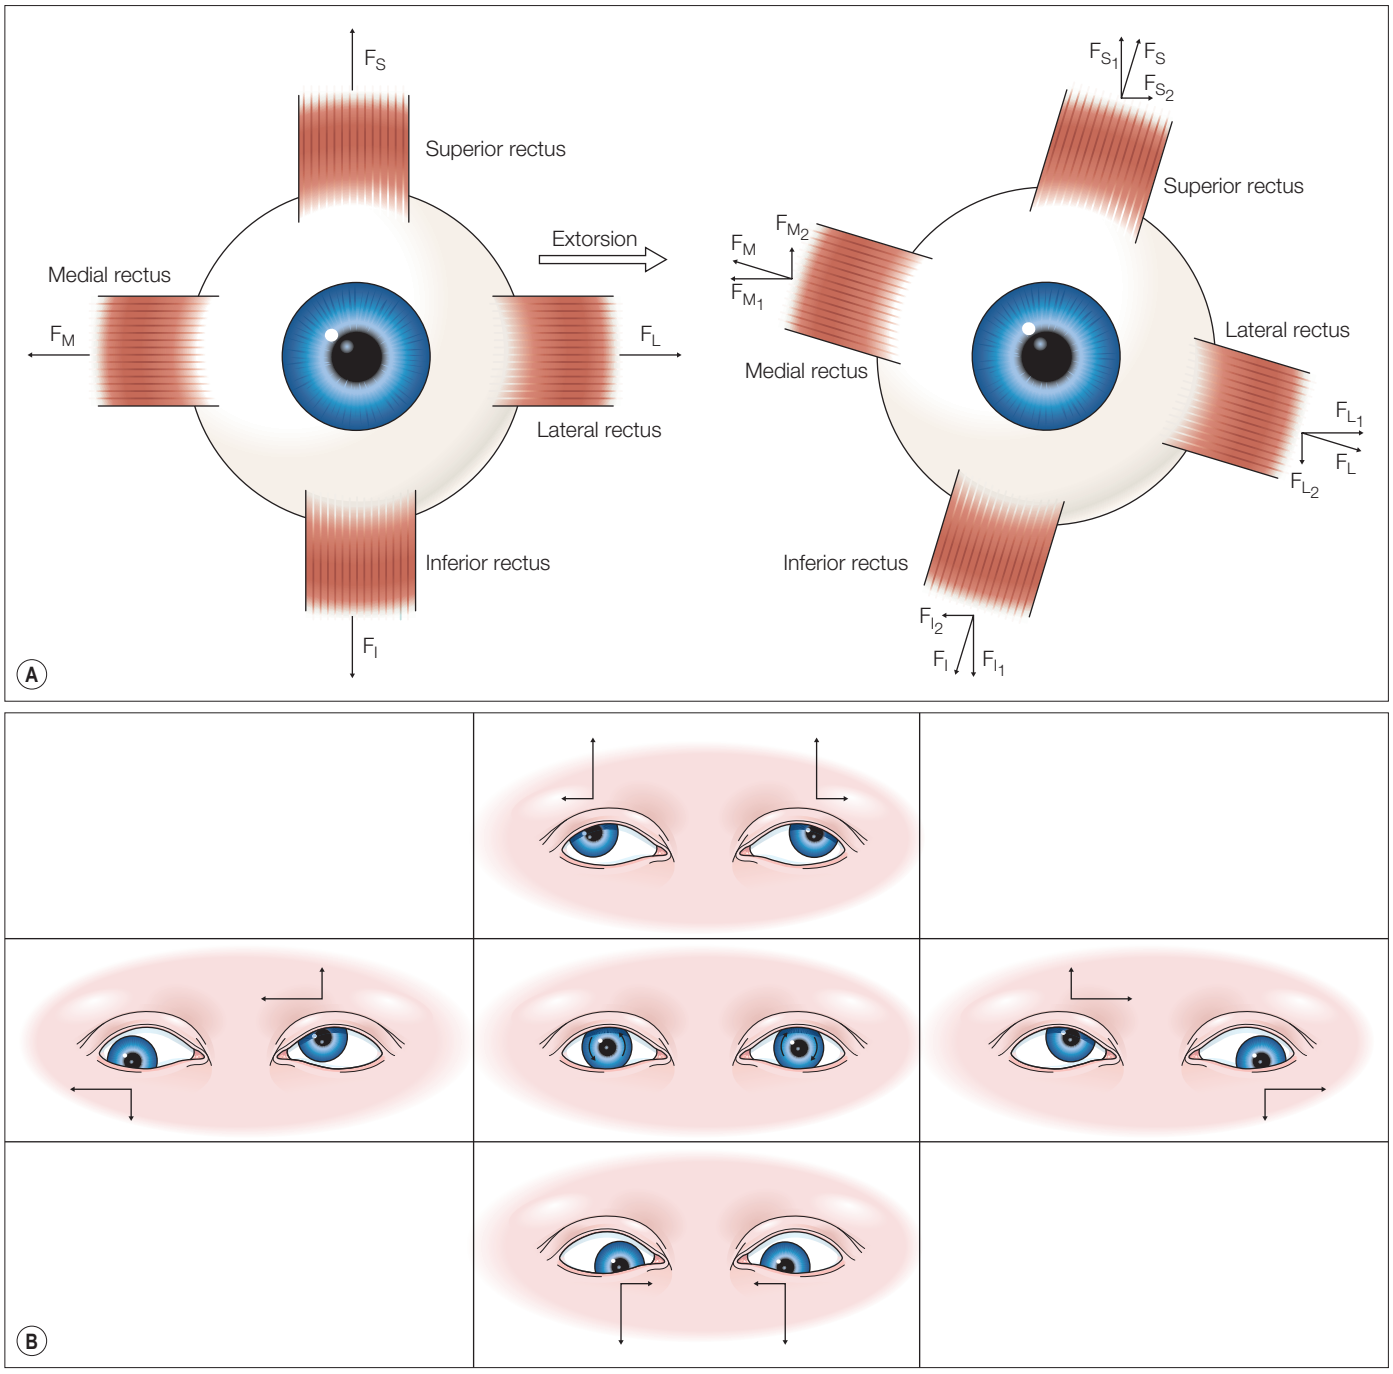

Fig. 82.4 (A) Effect of torsion on individual muscle function. An excyclorotation of the left eye will result in a clockwise rotation of the insertion of the muscles. This will create a vector for elevation for the medial rectus muscle, abduction for the superior rectus, depression for the lateral rectus, and adduction for the inferior rectus. (B) Effect of torsion on motility pattern. If the torsional changes that are depicted in (A) occurred in both eyes, the new force vectors would cause divergence in upgaze and convergence in downgaze. In addition, there would be an elevation of the adducting eye and depression of the abducting eye. Thus, these torsional changes that occurred as a result of extorsion contribute to both the "V" pattern and the elevation seen in adduction.

rectus muscles also have elevating force vectors and the lateral rectus muscles depressing force vectors, contributing to the elevation seen in adduction with overacting inferior obliques. I believe, however, that torsion is only a minor contributing cause of pattern strabismus rather than the main cause. Several observations support this belief.[13] First, the rise or fall of an eye with oblique muscle overaction, as it moves into adduction, is curvilinear. The boy seen in Video 82.2 has primary inferior oblique overaction. The rise of each eye on adduction appears to increase exponentially, rather than linearly. If the rise or fall were primarily caused by the change in force vectors of the rectus muscles as seen in Figure 82.4, one would expect a linear trajectory. Secondly, surgery like the Harada–Ito procedure that mainly corrects torsion has a negligible effect on the overelevation in adduction in patients with fourth cranial nerve palsy, even when it eliminates the excyclotropia. In addition, it has been shown that objective extorsion may precede the development of overelevation in adduction and a "V" pattern

in patients with infantile esotropia (see Chapter 76), by as much as several years. If the torsion caused the overelevation in adduction and the pattern, they should occur concurrently. Finally, surgery in the form of vertical transposition of the horizontal rectus muscles that successfully eliminates an "A" or "V" pattern will predictably worsen the underlying torsion (see section "Horizontal transposition of vertical rectus muscles" below).

Orbital structural anomalies

Orbital anomalies are often associated with "A" and "V" patterns. There is a frequent occurrence of "A" pattern esotropia accompanied by inferior oblique underaction in patients with upslanting palpebral fissures and an association of "V" pattern exotropia with inferior oblique muscle overaction.[14] In patients with downslanting palpebral fissures the opposite occurs. There is also a very high incidence of "A" and "V" patterns in patients with craniofacial syndromes[15,16] (Fig. 82.5). Clark et al. and Demer have attributed some cases of "A" and "V" patterns to orbital pulley heterotopia or laxity.[17,18] This is an evolving concept with no good data as to the frequency that pulley issues are causative of pattern strabismus.

Iatrogenic

An "A" or "V" pattern may develop as a result of prior strabismus surgery. This can result from an overcorrection from prior treatment of "A" or "V pattern strabismus. On occasion, a marked "Y" pattern can occur in the form of the anti-elevation syndrome after anterior transposition of the inferior oblique muscles[19] (Fig. 82.6). The girl in Video 82.3 had undergone

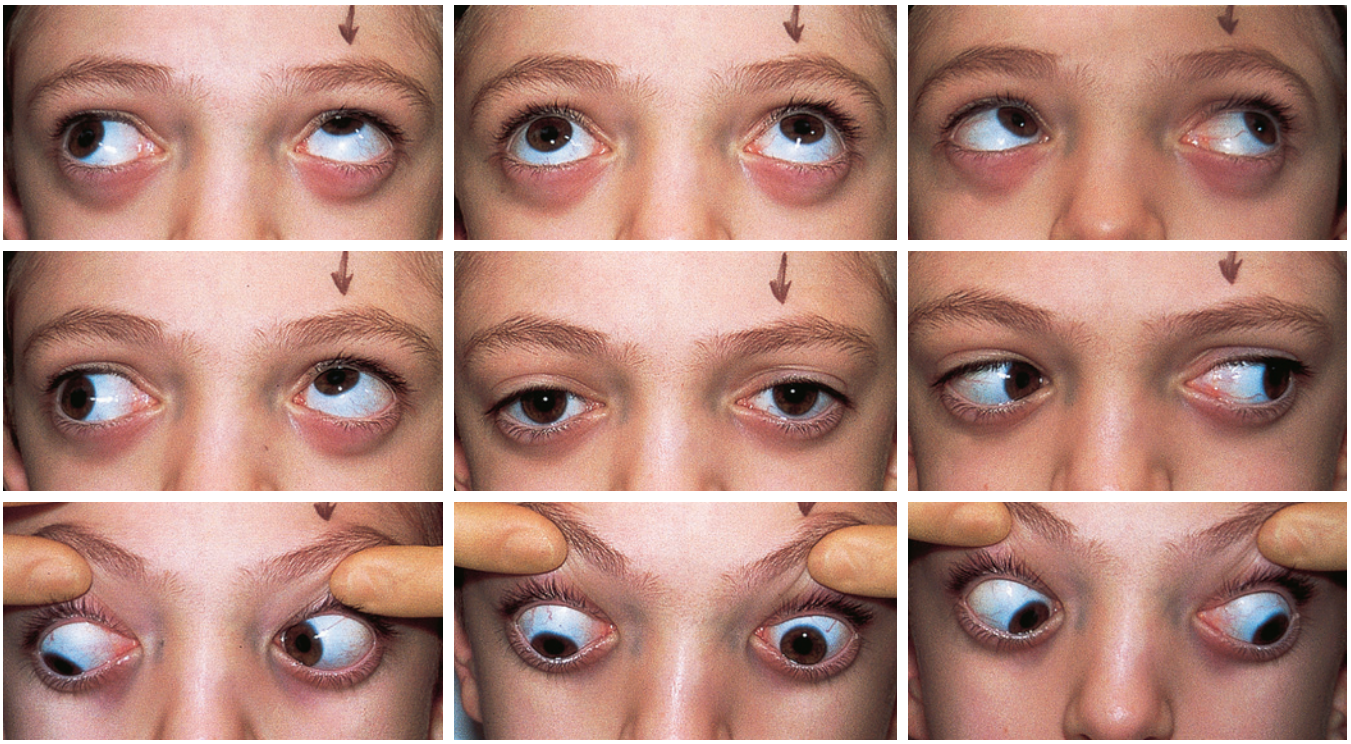

Fig. 82.5 Craniofacial anomaly with associated pattern: Crouzon syndrome. This boy shows the classic "V" pattern seen in Crouzon syndrome (see Chapter 28). There is overelevation and underdepression of each eye in adduction. *(Photo courtesy of Ken K. Nischal, FRCOphth.)*

Fig. 82.6 The anti-elevation syndrome. This boy has a large "V" pattern after previously undergoing inferior oblique anterior transposition bilaterally to treat dissociated vertical divergence. What looks like residual inferior oblique overaction is actually a result of fixation duress to the abducting eye on attempted elevation, due to the anti-elevating property of the transposed inferior oblique muscle. This drives the adducting eye superiorly and mimics contralateral inferior oblique overaction.

bilateral anterior transpositions of the inferior oblique muscles with both muscles placed 2 mm anterior to the inferior rectus muscle insertions. The overelevation she now shows on attempted elevation in adduction is due to fixation duress secondary to a limitation of elevation of the abducted eye. Also, an "A" pattern frequently occurs following large bilateral recessions of the inferior rectus muscles, commonly in thyroid eye disease. This occurs from a loss of the adducting effect of the inferior rectus muscles in downgaze secondary to surgical weakening, and by an increase in innervation to the yoke superior oblique muscles.[20]

Horizontal rectus muscles

Urist felt overaction or underaction of the horizontal rectus muscles were responsible for "A" and "V" patterns[4,5] and that the medial rectus muscles were more active in downgaze and the lateral rectus muscles were more active in upgaze. His surgical recommendations involved weakening the offending muscles. Although this theory is less compelling than others, it may explain the occurrence of some cases of "A" or "V" pattern where there is no other apparent cause. It can also explain the small decrease in "V" pattern observed after bilateral medial rectus recessions. Recent work by Demer and coworkers has described distinct and separate innervation to the superior and inferior compartments of the horizontal rectus muscles.[21,22,23] In theory, this could give rise to "A" or "V" patterns if the superior and inferior compartments are recruited separately on upgaze or downgaze. At this point, the role of this compartmental innervation on "A" or "V" patterns is not clear and is still evolving.

Other less popular theories

Brown felt that "A" and "V" patterns were caused by a weakness of the inferior and superior oblique muscles respectively, resulting in apparent overaction of the yoke oblique muscles due to fixation "duress."[24] This theory is not widely accepted.

Gobin suggested that the primary event that causes a "V" pattern is an abnormal sagittalization of the inferior oblique muscles, which decreases its vector for torsion, resulting in an incyclotropia. Subsequently, to correct this abnormal incyclotropia, there is increased innervation to the excyclorotary muscles, resulting in inferior oblique overaction.[25] In the author's opinion, this theory is inconsistent with the clinical findings of torsion in patients with pattern strabismus. According to the sagittalization theory, a patient with a "V" pattern should have no fundus torsion as the inferior oblique overaction served the purpose of eliminating an abnormal intorsion. In fact, these patients typically have objective extorsion.

Presentation

The manner of presentation of a patient with an "A" or "V" pattern depends on the underlying strabismus and the size of the deviation. If there is a sufficiently large deviation in the primary position such that, despite the presence of an "A" or "V" pattern, there is no head position in which fusion is possible, the pattern may not affect the presentation. If the deviation is small enough that fusion is possible in upgaze or downgaze, the patient may assume a chin-down or chin-up head posture in order to fuse. Some adults with an "A" or "V" pattern may not become symptomatic until they become presbyopic. Their symptoms may not become manifest until they need to get their eyes into downgaze to read through a bifocal segment. Prior to becoming presbyopic, they may have unconsciously held reading material closer to the primary position. Similarly, some presbyopic patients with strabismus that is only significant in downgaze may become symptomatic if they switch from a flat-top to a progressive bifocal, which has a wide transition zone that requires the eyes to move further into downgaze in order to permit vision through the prescribed add.

Examination

Motor exam

The diagnosis of an "A" or "V" pattern must be made by measuring with the prism and alternate cover test 25–30° above and below the midline. Testing should be done at 6 m to eliminate the near reflex. You can be misled by assessing the size of the deviation on version testing using a light reflex, as this will not bring out the latent deviation. Particularly in patients with intermittent exotropia, the deviation may be controlled in the primary position; however, fusion may break down when the eyes are rotated into extreme fields of gaze giving the false appearance of a "Y," "λ," or "X" pattern. Testing should be done with full optical correction in place *and* while fixation is maintained on an accommodative target: if not, a pseudo "A" or "V" pattern may be observed.

Special care should be taken to assess any relative overelevation or overdepression in adduction, and the presence or absence of fundus torsion should be assessed with indirect ophthalmoscopy.

Sensory findings

Sensory findings depend on whether the patient is orthotropic in any field of gaze. Patients who are well aligned in the primary position may have surprisingly good fusion. If the patient is tropic in all fields of gaze, suppression and varying depths of anomalous retinal correspondence (ARC) may be found. In many patients with ARC and pattern strabismus, the angle of anomaly varies with the angle of deviation, thus resulting in ARC that is harmonious in all fields of gaze. This speaks to the fluidity of ARC.

Surgical treatment of "A" and "V" patterns

If a pattern needs to be eliminated, the treatment is surgery. However, first you need to determine whether the pattern itself needs to be addressed. If the patient has a significant chin-up or chin-down head posture in order to fuse, surgery is appropriate. A continuous change in the size of the deviation that varies with change in gaze direction is destabilizing for binocular fusion. Thus if an "A" or "V" pattern is clinically significant, it should be addressed in any child undergoing horizontal strabismus surgery, in whom there is any likelihood of some degree of binocularity being gained. This is probably the case in all children unless there is dense amblyopia. You

should also pay attention to the location of the pattern. The primary position and downgaze are the two most important fields of gaze. You might ignore the pattern completely in an asymptomatic patient with a "Y" pattern who only manifests a deviation in upgaze. This is particularly true if treating a pattern might be at the expense of the good alignment in the primary position and downgaze. If the strabismus is cosmetically unacceptable because of an "A" or "V" pattern, surgery for the pattern is appropriate. For most adults undergoing surgery for other reasons, a pattern should be treated if also present. Exceptions include patients in whom treating the pattern might adversely affect the outcome in the primary position or downgaze, and if dense amblyopia is present, one may decide to ignore the pattern.

Oblique muscle surgery

If you decide to treat a pattern in a patient in whom there is substantial oblique muscle overaction, the overacting oblique muscles should be weakened because doing so:

1. decreases the excessive abducting force in the gaze direction in which the eyes diverge (upgaze for a "V" pattern, downgaze for an "A" pattern);
2. decreases the torsion that contributes to the pattern and may be an obstacle to fusion;
3. corrects any cosmetically unacceptable upshoot or downshoot occurring in adduction.

Oblique muscle surgery should be combined with any necessary horizontal surgery, the latter based on the angle of misalignment in the primary position. No allowance is necessary for the loss of abducting force of the oblique muscles, because it is negligible in the primary position. Weakening both inferior oblique muscles will result in 15–25 PD of esotropic shift in upgaze, depending on the degree of overaction of the inferior oblique muscles; the greater the degree of overaction, the more effect is obtained. There will be little or no effect on the horizontal deviation in the primary position. Initially, there will also be no horizontal effect in downgaze from weakening the inferior oblique muscles. Later, however, there may be some increased divergence in downgaze because the previously underacting superior obliques may recover function after the antagonist inferior obliques have been weakened.

The effect of weakening the superior obliques depends on the technique. Weakening the superior obliques nasally, by any technique, has a large effect and can correct up to 40 PD of exotropia in downgaze. Weakening the superior obliques temporally is a less powerful operation, but is also less likely to cause complications. A posterior 7/8 tenectomy will cause a reduction of approximately 15–20 PD of exotropia in downgaze.[26,27] A somewhat more powerful operation than a posterior tenectomy is a complete disinsertion of the superior oblique tendon. A still greater effect can be obtained with a tenectomy of the superior oblique tendon at the insertion or a graded recession. Weakening the superior oblique has no effect on the horizontal deviation in upgaze. In the primary position, it will only correct between 0 and 3 PD of exotropia.[28,29] You need little or no adjustment in your horizontal surgery if you do bilateral superior oblique weakening.

When treating a pattern by weakening oblique muscles, it is important to perform the surgery symmetrically unless you are also trying to correct a vertical deviation in the primary position. Otherwise you will create an unwanted vertical strabismus. Complete weakening procedures of the superior obliques, such as nasal tenectomy or tendon expansion, have a powerful effect on torsion. They may lead to a disruption of fusion in a patient with bifoveal fusion and can create postoperative torsional diplopia in a fusing patient. Exercise extreme caution when weakening the superior obliques in such patients! A posterior tenectomy procedure may be adequate for addressing the pattern and is safer than doing a complete superior oblique tenectomy or tendon expansion. Alternatively, it might be prudent to address the pattern with vertical transpositions of the horizontal rectus muscles, and just decrease, rather than eliminate, the pattern, if it is large.

If oblique muscles are not overacting, they should not be weakened when treating an "A" or "V" pattern. Finally, "V" patterns with superior oblique underaction can be treated with superior oblique tucks.

Vertical transpositions of the horizontal rectus muscles

Many patients with "A" or "V" patterns can be treated effectively with transpositions of the horizontal rectus muscles, combined with the usual recession or resection you would perform based on the primary position deviation. You should not make any adjustment in your standard surgical formula because of the transposition.

Horizontal rectus transpositions are based on the principal that, when a rectus muscle is transposed, its primary action is decreased when the eye rotates into the field of gaze toward which the muscle was moved, and its action increases when the eye moves in the opposite direction (Fig. 82.7). For example, if a medial rectus muscle is transposed inferiorly, it becomes a weaker adductor when the eye is in downgaze and a greater adductor when the eye is in upgaze. This occurs because the insertion of the transposed muscle has a new relationship to the center of rotation of the globe, as seen in Figure 82.7. Thus, for treating a "V" pattern esotropia, you can recess and infraplace the medial rectus muscles, because downgaze is the field in which you want them to have less adducting action. However, when transposing rectus muscles, it is important to consider that two additional changes in their function occur simultaneously (Fig. 82.8). One effect is the creation of a force

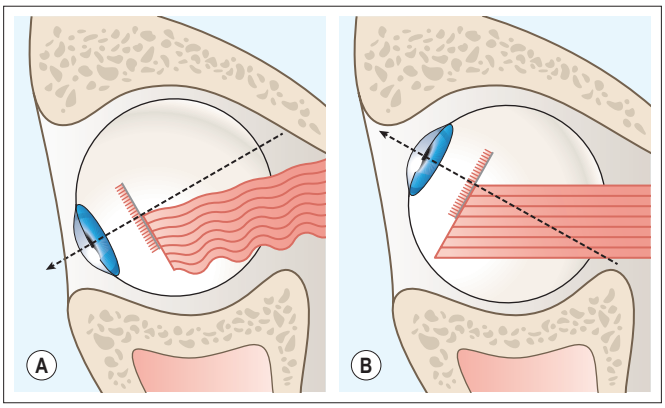

Fig. 82.7 Effect of vertical transposition of rectus muscle on its primary action. If a muscle is infraplaced, there will be more slack in the muscle when the eye is in downgaze (A) than in upgaze (B). This weakens the primary action of the muscle more in downgaze than in upgaze.

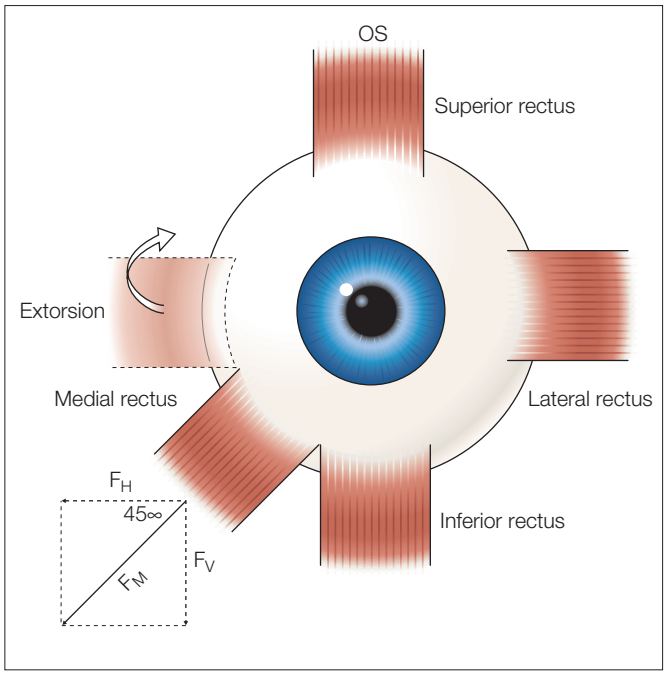

Fig. 82.8 Multiple effects of transposition of rectus muscle. If a medial rectus muscle is infraplaced, a new force vector for depression will be created. In addition, a torsional force vector will be created in the direction toward the original insertion. With infraplacement of the medial rectus, a vector for extorsion is created.

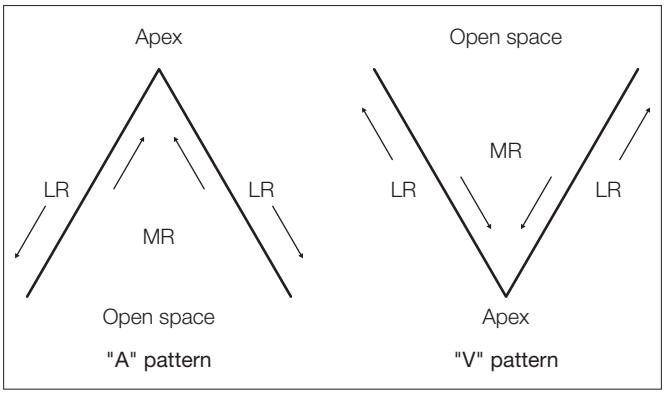

Fig. 82.9 Mnemonic for transposing horizontal rectus muscles. This diagram depicts the directions to move the horizontal rectus muscles for the treatment of an "A" pattern (left) and a "V" pattern (right). The lateral rectus muscles (LR) are always moved toward the open space and the medial rectus muscles (MR) always move toward the apex of the pattern.

vector in the direction in which the muscle is moved. Thus, if a medial rectus muscle is infraplaced, an additional force vector for depression is established. For this reason, it is important to always use this treatment symmetrically; otherwise an unwanted vertical deviation in the primary position will be induced. The exception might be those circumstances in which you want to treat a pre-existing primary position vertical deviation, in which case you might perform a unilateral transposition or a bilateral transposition that is asymmetric.

The other effect of transposition of rectus muscles relates to torsion. When a muscle is transposed, a torsional vector is created in the direction from which the muscle is moved. For example, moving a medial rectus inferiorly creates a force vector that results in extorsion as shown in Figure 82.8. Importantly, this torsional rotation is in the opposite direction to the torsional correction one desires when treating most "A" or "V" patterns. A "V" pattern esotropia is typically associated with inferior oblique overaction and excyclotropia. Transposing the medial rectus muscles inferiorly successfully treats a "V" pattern but makes excyclotropia worse.[13,30] This rarely results in adverse symptoms, probably because most patients with "A" and "V" patterns do not have bifoveal fusion, and also because the amount of torsional change is small.

A simple mnemonic for remembering the direction in which to transpose the horizontal muscles for treating pattern strabismus is presented in Figure 82.9. The medial rectus muscles are always transposed toward the apex of the pattern (down for a "V" pattern and up for an "A" pattern) and the lateral rectus muscles are always transposed toward the open space of the pattern (up for a V" pattern and down for an "A" pattern). This holds true whether the muscles are recessed or resected, and if the patient is esotropic or exotropic. Vertical transposition of the horizontal rectus muscles is generally effective for treating pattern strabismus if there is no significant oblique dysfunction, but is less effective if the obliques are significantly overacting. This is understandable in light of the fact that transpositions worsen the torsion that is already present if there is oblique dysfunction and because torsion contributes to the pattern.

The author finds that, in most cases of "A" or "V" pattern without oblique muscle dysfunction, a symmetric vertical transposition of the appropriate horizontal rectus muscles by one-half tendon width (5 mm) is effective in reducing an average of 15–20 PD of pattern. In most cases in which the pattern is more than 20 PD, there is usually significant oblique muscle dysfunction, and the author usually addresses the pattern with oblique muscle surgery. If oblique muscle surgery is not indicated in a patient with a large pattern (perhaps it has already been performed but a pattern persists), transposition of the appropriate horizontal rectus muscles three-quarters or a full tendon width can be effective for patterns that are greater than 20 PD. Also, transpositions of the horizontal rectus muscles can be combined with oblique muscle surgery. For example, a patient with a very large "V" pattern (perhaps 40 PD or more), and inferior oblique overaction plus superior oblique underaction, might benefit from bilateral medial rectus recessions with infraplacement and bilateral inferior oblique weakening.

One can also apply the principles of transposition when doing unilateral surgery in the form of a recess–resect procedure. One muscle can be raised and the other lowered. Keep in mind, however, that doing so does not create an equal balance of forces. If you raise a weakened (recessed) muscle the same amount as you lower a tightened (resected) muscle, you are creating an increased force vector in the direction the resected muscle was moved. Unwanted vertical deviations can be created from this surgical approach. Although unilateral transposition is often successful, the author prefers symmetric surgery when performing transpositions.

Horizontal transposition of vertical rectus muscles

Horizontal transposition of the vertical rectus muscles can treat "A" and "V" patterns.[31,32] The theoretical efficacy of this

Table 82.1 Summary of directions in which to transpose vertical rectus muscles

Strabismus	Transposition
"V" esotropia	IR OU temporally
"V" exotropia	SR OU nasally
"A" esotropia	SR OU temporally
"A" exotropia	IR OU nasally

IR, inferior rectus; OU, both eyes; SR, superior rectus.

approach is based on a different principle than that of vertical transposition of the horizontal rectus muscles. It is predicated on one of the effects depicted in Figure 82.8 – specifically that a force vector is created in the direction a muscle is moved. This same principle is the basis for transposition procedures to treat paralytic strabismus. Thus a "V" pattern esotropia can be treated by temporal transposition of the inferior rectus muscles along with appropriate recessions of the medial rectus muscles; typically the vertical rectus transpositions are 7 mm. A summary of the directions to transpose the vertical rectus muscles for treating "A" and "V" patterns is presented in Table 82.1.

Notably, horizontal transposition of the vertical rectus muscles may create a torsional shift that exacerbates a pre-existing cyclotropia for the reasons depicted in Figure 82.8. This is particularly relevant in treating patients with Graves orbitopathy with large bilateral inferior rectus recessions, which often results in a postoperative "A" pattern with intorsion. The author has seen such patients in whom the inferior rectus muscles were transposed nasally at the time of recession in hopes of preventing the occurrence of an "A" pattern, and an unexpectedly large and symptomatic incyclotropia was created.[30] The author prefers to combine large inferior rectus recessions with posterior tenectomy of the superior oblique tendon to prevent an "A" pattern in this setting.

Horizontal transposition of the vertical rectus muscles never gained popularity for treating routine cases of "A" or "V" pattern strabismus. In the author's opinion, this is largely because it involves operating on an additional rectus muscle in each eye, which is not necessary when oblique muscle surgery or vertical transposition of the horizontal rectus muscles can be performed.

Surgery to correct pulley abnormalities

If pulley heterotopia or laxity is the cause of an "A" pattern, surgery could be performed to stabilize or reposition the orbital pulleys. Diagnosis of pulley abnormalities requires orbital imaging.[17,18]

Insertion slanting surgical procedures

Mathematical modeling of extraocular muscle mechanics indicates that one can theoretically consider an extraocular muscle as inserting at a point in the middle of its insertion[33] (Fig. 82.10A). If there is unequal tension along the edges of the muscle, one can still consider the muscle as inserting at a point that is then shifted toward the edge with greater tension (Fig. 82.10B). In theory, this principle can be used to treat

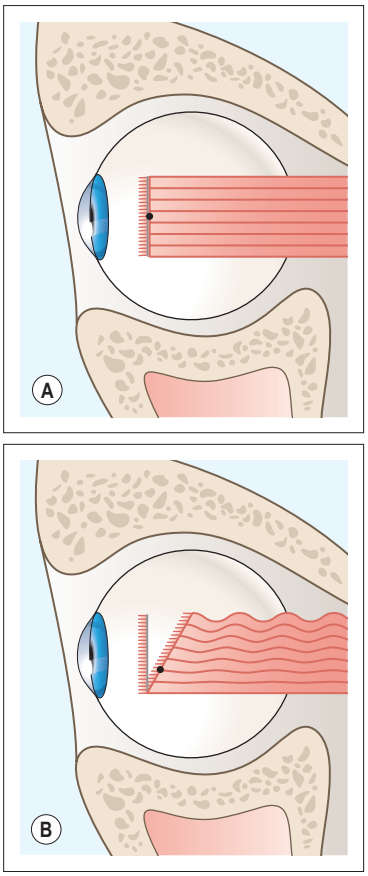

Fig. 82.10 (A) Mathematically one can consider a rectus muscle to insert at a point (black dot) at the middle of its insertion. (B) If there is unequal tension along the edges of a muscle as occurs with a slanting procedure, the muscle still can be thought of as inserting at a point (black dot). However, the point shifts toward the edge under greater tension. If the superior pole of a horizontal rectus muscle is slanted back, the point shifts toward the inferior edge, which is akin to infraplacing the muscle.

pattern strabismus by selectively slanting the superior or inferior pole of the recessed muscles to simulate transposition. For example, for a "V" pattern esotropia, the superior poles of the medial rectus muscles are recessed more than the inferior poles, which simulates the effect of an infraplacement. This approach has been used successfully to treat pattern strabismus.[34] Paradoxically, good results have been reported with slanting the muscles in an opposite manner by numerous authors.[33,35] For a "V" pattern esotropia, these authors would recess the inferior pole of the medial rectus muscles more than the superior poles. The rationale for this approach is based on the thought that the inferior edge of a horizontal rectus muscle is more taut in downgaze and the superior edge more taut in upgaze. The authors arrived at this conclusion through a misinterpretation of known facts about extraocular muscle mechanics. In fact, the opposite is true. This leads to a conundrum: How can opposite methods of slanting both produce good results (Fig. 82.11)? For the same "V" pattern esotropia, some investigators would slant in the manner depicted in Figure 82.11A and others would use the configuration shown in Figure 82.11B. I believe that, despite their popularity, insertion-slanting procedures in either manner should have a negligible effect on pattern strabismus. Sarcomere remodeling should rapidly occur and even out the edge tension after an insertion-slanting procedure (Fig. 82.12). This should occur even if the aforementioned investigations on the compartmental innervation of the horizontal rectus muscles proves that there is selectively different innervation to the superior and inferior compartments on upgaze and downgaze.[21,22,23] Probably the good outcomes reported with

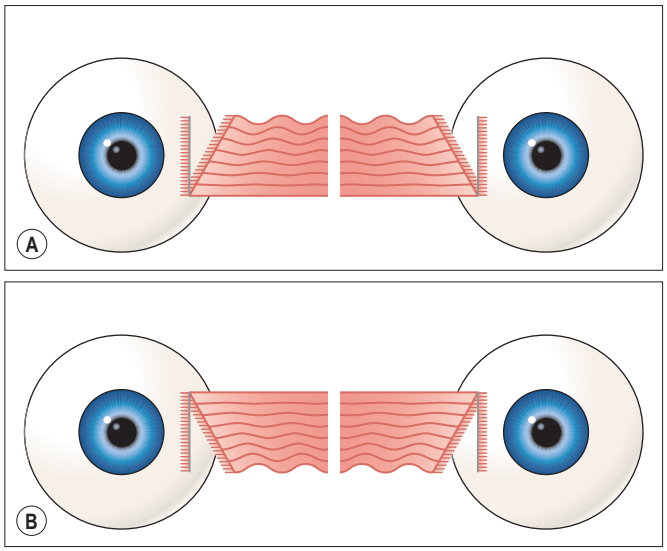

Fig. 82.11 (A) The treatment of a "V" pattern esotropia with insertion slanting according to the principles shown in Fig. 82.10. The superior poles of the medial rectus insertions are slanted back, which simulates infraplacement. (B) The treatment of a "V" pattern esotropia according to the concept that the inferior fibers are more taut in downgaze.

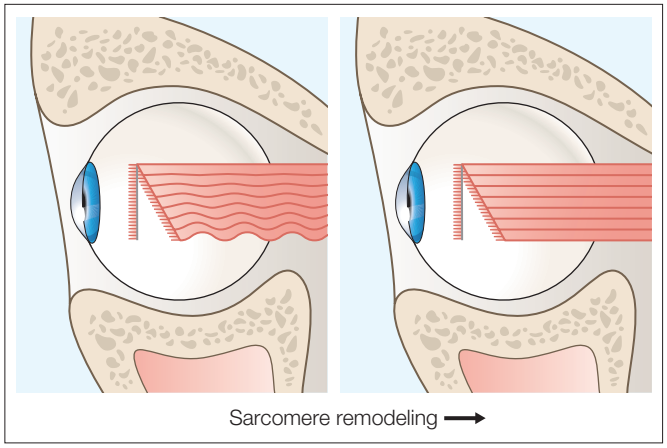

Fig. 82.12 Initially after slanting back the inferior pole of a rectus muscle, there is substantial slack induced in the inferior muscle fibers (A). After a period of several weeks, sarcomere remodeling should even out the differential edge tension and largely negate the effect of the slanting procedure (B).

these procedures were the result of the recession or resection performed.

Summary of surgical planning

In all cases, the author does the standard horizontal surgery based on the primary position measurement except perhaps allowing for up to 3 PD of eso shift in the primary position with superior oblique weakening. Table 82.2 summarizes recommendations for the surgical management of "A" and "V" patterns.

Optical management

Some patients with "A" or "V" patterns may have good alignment in the primary position but have an esotropia or exotropia in downgaze. As stated earlier, such patients may first become symptomatic as they become presbyopic. Some patients of this type can be managed by either using single vision reading glasses, or having a separate bifocal for prolonged reading with a segment that is higher than is typically prescribed.[36]

Table 82.2 Summary of surgical recommendations

If oblique dysfunction is present[a]	
"V" eso with IO OA	Recess MR or resect LR and weaken IO OU
"V" exo with IO OA	Recess LR or resect MR and weaken IO OU
"A" eso with SO OA	Recess MR or resect LR and weaken SO OU[b]
"A" exo with SO OA	Recess LR or resect MR and weaken SO OU[b]
Without oblique dysfunction[a]	
"V" eso	Recess MR and infraplace or resect LR and supraplace OU
"V" exo	Recess LR and supraplace or resect MR and infraplace OU
"A" eso	Recess MR and supraplace or resect LR and infraplace OU
"A" exo	Recess LR and infraplace or resect MR and supraplace OU

[a]Perform the usual amount of recession or resection of the horizontal rectus muscles based on the deviation in the primary position.
[b]Avoid a powerful superior oblique weakening procedure in patients with bifoveal fusion.
IO, Inferior oblique; LR, lateral rectus; MR, medial rectus; OA, overaction; OU, both eyes; SO, superior oblique.

The term "congenital cranial dysinnervation disorders" (CCDDs) denotes a group of congenital, non-progressive disorders resulting from developmental abnormalities of one or more cranial nerves or their nuclei and primary/secondary dysinnervation.

They may be sporadic or familial, but most are either proven or suspected to have a genetic basis[1,2] (Box 83.1). Ophthalmologists are frequently consulted about these conditions because of the involvement of the extraocular muscles. Although many of these conditions are characterized only by abnormal extraocular muscle innervation, facial innervation, or both, some have associated systemic and/or neurologic abnormalities, such as cerebrovascular, cardiovascular, and skeletal malformations that also are attributable to the underlying genetic defect.[2] At present, a total of seven disease genes and ten phenotypes have been identified.[2]

This chapter focuses on CCDDs characterized wholly or in part by abnormalities of eye movements. These include the three main types of congenital fibrosis of the extraocular muscles (CFEOM), Duane retraction syndrome (DRS), homeobox A1 (*HOXA1*) spectrum, horizontal gaze palsy with progressive scoliosis (HGPPS), and Möbius syndrome. For the ease of understanding, these can be subclassified into those that affect the vertical movements (CFEOMS [oculomotor and trochlear nerve]) or the horizontal movements (DRS, Möbius syndrome, HGPPS, and HOAX1 spectrum [abducens nerve and supranuclear pathways]).

Congenital fibrosis of extraocular muscles

This group of disorders is characterized by congenital ocular motility abnormalities, congenital ptosis, and fibrotic extraocular muscles. Most of these patients present first to ophthalmologists because of ptosis or deviation of the eyes. Although previously thought to be secondary to muscle fibrosis (myopathy), clinical and pathological evidence suggest absence of the oculomotor/trochlear/abducens nerve or nuclei (neuropathy). To date, three primary CFEOM phenotypes have been described – CFEOM1, CFEOM2, and CFEOM3. CFEOM3 has three phenotypic variants: CFEOM3A, CFEOM3B, and CFEOM3C.[2,3]

Congenital fibrosis of the extraocular muscles type 1 (MIM #135700)

CFEOM1 is the most common of the CFEOM phenotypes. It is autosomal dominantly inherited with full penetrance.[4] It is characterized by congenital bilateral ptosis, bilateral infraducted globes, restricted upgaze, variably restricted horizontal gaze, and a compensatory chin-up head posture (Fig. 83.1). These patients have positive forced duction testing and misdirected eye movements such as a marked synergistic convergence on attempted upgaze. Neuropathologic studies reveal significant atrophy and fibrosis of the superior rectus and levator palpebrae muscles, with variable reduction in the size of the other extraocular muscles. Histopathologic studies have shown that the oculomotor nerves may be absent or hypoplastic. The diameter of the optic nerves is reduced by 30–40%.[5] CFEOM1 is caused by a heterozygous missense mutation in *KIF21A*, chromosome 12 (12q12)[3] that encodes a kinesin microtubule-associated protein associated with anterograde organelle transport in neurons.[6]

Congenital fibrosis of the extraocular muscles type 2 (MIM #602078)

CFEOM2 is an autosomal recessive disorder characterized by bilateral ptosis, bilaterally absent adduction, upgaze, and downgaze (Fig. 83.2A,B).[7] Although abduction is present, it is limited and the pupils are often irregularly shaped, unequal in size, and non-reactive to both light and near stimulation. The appearance is that of bilateral oculomotor (third) nerve palsies and neuroimaging shows a bilateral absence of the third nerves.[8] This condition is caused by homozygous mutations in the *PHOX2A* gene located on chromosome 11 (11q13.3–q13.4)[7] that codes for a homeodomain transcription factor expressed predominantly in developing oculomotor and trochlear neurons that is essential for their survival. Mutations alter the factor sufficiently that the oculomotor (and probably trochlear) nerves never develop.

Fig. 83.2 Congenital fibrosis syndrome type 2 (CFEOM2). (A) This patient with the typical congenital exotropia and bilateral ptosis (note furrowed brow to elevate the lids) associated with CFEOM2.

Box 83.1

Common features of congenital cranial dysinnervation disorders

- Onset from birth
- Non-progressive
- Sporadic or familial
- Developmental abnormalities of one or more cranial nerves/nuclei
- Dysinnervation:
  - Primary – due to absence of the nuclei/neurons, or
  - Secondary – from branches of another nerve during development

Fig. 83.1 Congenital fibrosis syndrome type I (CFEOM1) in a father and son. Because of their bilateral ptosis and deficient upgaze, both have adopted a head posture with the chin elevated.

Congenital fibrosis of the extraocular muscles type 3

CFEOM3 is an autosomal dominantly inherited disorder that has clinical features similar to those of CFEOM1 except that they are more variable and sometimes associated with the ability to elevate the eyes above the midline[9] (Fig. 83.3A,B). The phenotypic variability results at least partly from heterozygous mutations in at least two genes: *TUBB3* (CFEOM3A; MIM #600638) and, rarely, *KIF21A* (CFEOM3B).[10,11]

In addition, several different missense mutations may occur in the *TUBB3* gene, which codes for a component of microtubules. Thus, some patients with CFEOM3A have isolated ocular motor deficits (some even have isolated absence of upgaze), whereas others have bilateral facial weakness, peripheral sensory or sensorimotor neuropathies, wrist and finger contractures, cognitive dysfunction, or a combination of these features. Magnetic resonance imaging (MRI) may show dysgenesis of the corpus callosum and anterior commissure in some cases.[11] Patients have been described who have a phenotype similar to CFEOM1, except for the presence of some upgaze, and who have a mutation in *KIF21A*. They are said to have CFEOM3B.[2] A single family has been described in which three generations have what appears to be CFEOM3 but who carry a reciprocal translocation involving chromosomes 2q and 13q,[12] termed CFEOM3C (MIM #609384).

Management of CFEOM patients

CFEOM patients pose a significant challenge, as there is a problem of dysinnervation of multiple muscles, often associated with large angle deviation, ptosis, and abnormal head posture. They may have complex and unremitting ocular motor deficits and ptosis, but also systemic and/or neurologic deficits. Even though the outlook is guarded, there are some options and the following steps may help these patients:

a. Appropriate refractive correction/amblyopia therapy: A study of 40 patients with CFEOM by Chen et al.[13] reported an incidence of amblyopia of about 95%. In addition, they found that 85% of the patients had astigmatism, and 11.7% had simple hyperopia. Thus, all patients with CFEOM should undergo a cycloplegic refraction, part-time occlusion therapy or atropinization as appropriate (see Chapter 73), and regular follow-up throughout their period of visual development.

b. Management of strabismus:
   - Often these patients have a large hypotropia and chin elevation or moderate to large angle exotropia or esotropia due to tight inferior and lateral/medial rectus muscles. In some patients with trochlear nerve dysfunction, there may also be fibrosis and tightness of superior oblique muscles.
   - These patients usually benefit from large recessions/tenotomy of the inferior and lateral rectus muscles, thereby reducing the hypotropia.
   - Intraoperatively, the duction tests can be repeated for both inferior rectus and superior oblique muscles. Following inferior rectus weakening, patients with residual superior oblique tightness might benefit additionally from weakening of these muscles.
   - *Small recessions are often ineffective and may necessitate a repeat procedure.*
   - In addition, resections tend to be ineffective against tight antagonists.
   - Strabismus management requires an individualized approach based on the clinical presentation.

c. Management of ptosis:
   - Significant ptosis is frequently observed and may alone contribute to chin elevation.

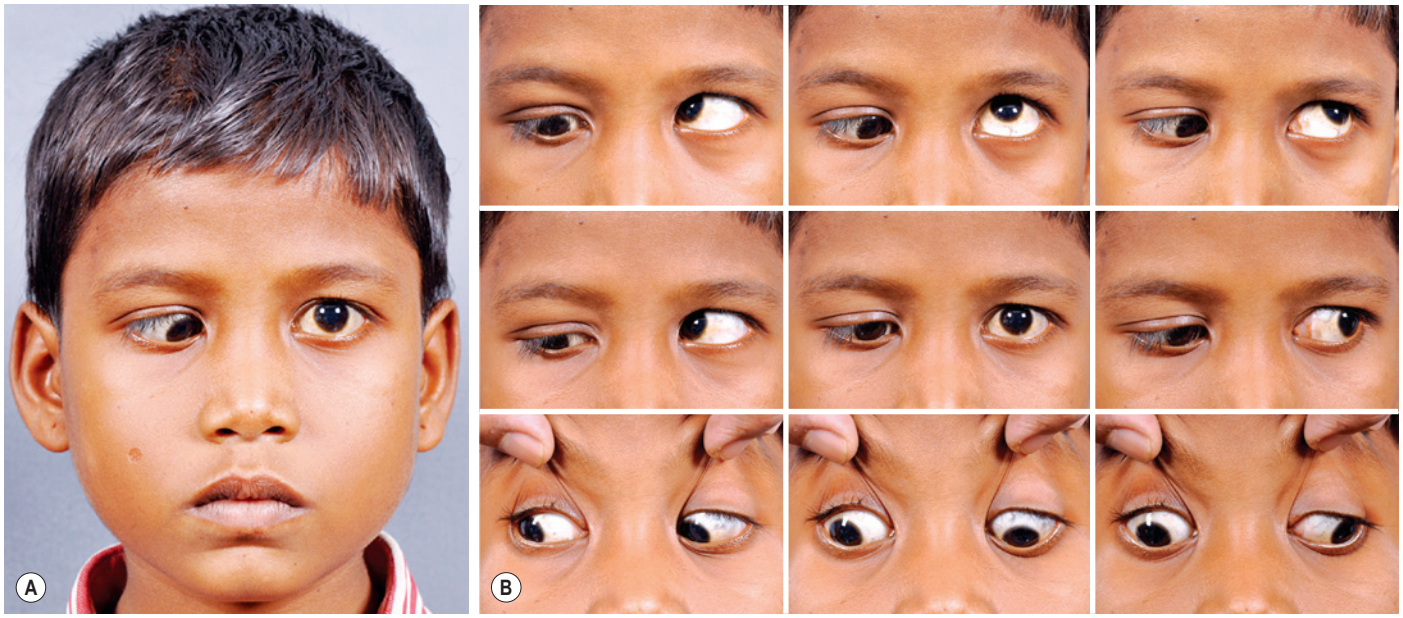

Fig. 83.3 This patient has: (A) unilateral ptosis with esotropia; (B) significant elevation deficit and normal horizontal movements.

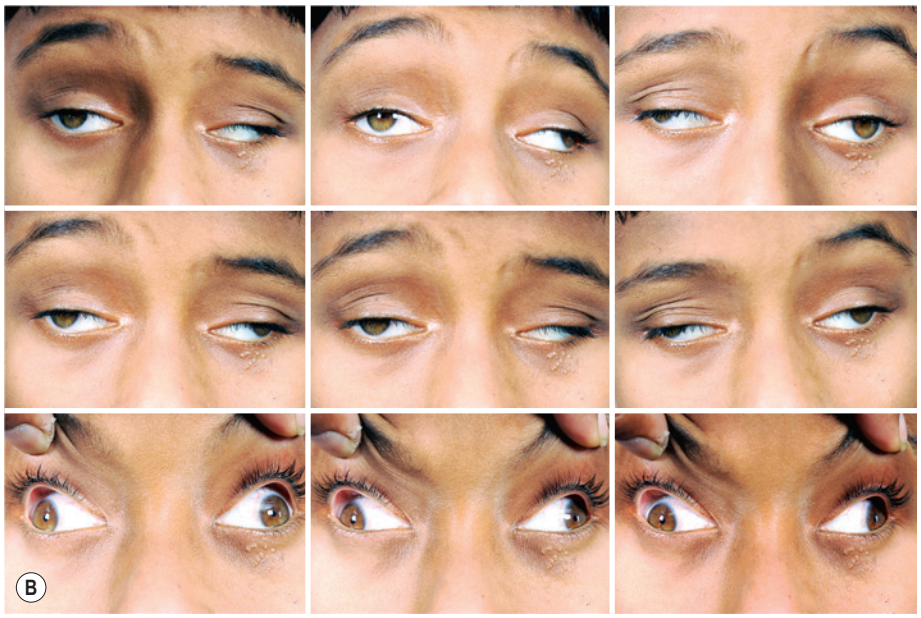

Fig. 83.2 Congenital fibrosis syndrome type 2 (CFEOM2). (A) Available online. (B) He had no upgaze or downgaze of either eye and no adduction of either eye.

- Ptosis should be reassessed and surgical correction considered after strabismus surgery.
- *Surgical overcorrection is hazardous*: this may result in exposure keratopathy because of the restricted eye movements and lack of a Bell's phenomenon.
- Frontalis sling procedure is usually more effective than levator resection. It can be managed relatively easily in case of overcorrection. If a levator resection is performed, the eyelids should be raised to a level just above the visual axis in the primary position.
- In patients with a poor Bell's phenomenon, surgery may not be possible. Conservative management with ptosis crutch glasses may be helpful.

The strabismus associated with CFEOM is not particularly amenable to surgery. Limited improvement can be attained in the ocular motility and alignment in the primary position by performing very large recessions and occasionally resections.[14] Recent work by Sener et al.[15] has suggested following an individualized approach. Satisfactory alignment may be achieved in a fair number of patients with CFEOMS; however, multiple procedures may be needed. Thus, the patient's parents should be counseled accordingly so that they have realistic expectations from the surgery.

Duane retraction syndrome

Duane retraction syndrome (DRS) is the most common CCDD resulting from abnormalities of the abducens nerve and its nucleus.[2] It is associated with the absence of normal innervation of the lateral rectus muscle by the abducens nerve, with paradoxical innervation of this muscle by the division of the oculomotor nerve innervating the medial rectus muscle. Hence, the characteristic feature is a co-contraction of the globe when the patient attempts adduction with globe retraction. There are several variants[16]: type I (limited abduction with normal to near normal adduction), type II (limited adduction with normal to near normal abduction), type III (limited abduction and adduction), and type IV (synergistic divergence). The most common presentation is type I characterized by marked limitation or absence of abduction, variable limitation of adduction, and palpebral fissure narrowing with globe retraction on attempted adduction (Fig. 83.4).

Most cases are unilateral (see Fig. 83.4), but bilateral DRS occurs in 15–20% of affected patients (see Fig. 83.7A).[17,18] In unilateral cases, females are more commonly affected than males, and the left eye is more frequently affected than the right. A face turn towards the affected side is observed in 40–60% of patients to avoid diplopia and maintain binocular vision. Upshoots or downshoots may be seen in about 40–45% of patients, especially those with unilateral disease and type III DRS.[18]

Most commonly patients are esotropic, followed by orthotropia, and least commonly exotropia. Up to 66% of the patients with DRS may have refractive error – most commonly hypermetropia or hypermetropic astigmatism (31.5%) followed by myopia or myopic astigmatism (22%).[18] An associated strabismic, ammetropic, or combined mechanism amblyopia may exist. Thus, all patients with DRS should undergo cycloplegic refraction and amblyopia therapy.

In addition, patients with DRS may have significant ocular associations such as cataract, nasolacrimal duct block, retinal degenerations, epibulbar dermoid, crocodile tears, and systemic associations such as hearing impairment, cleft lip, club foot, and Goldenhaar syndrome (Fig. 83.5).[18]

A myogenic vs. neurogenic phenomenon?

Although initially believed to occur secondary to pathology in the extraocular muscles (fibrosis) or orbital bands, recent electromyographical studies, MRI, and histological studies have established the neural basis of the disorder that is often associated with absence of the abducens nerve/nucleus.[16,19,20,21,22]

Fig. 83.5 Unilateral (right) Duane retraction syndrome type I in a 6-year-old girl. Note the presence of preauricular tag and limbal dermoid.

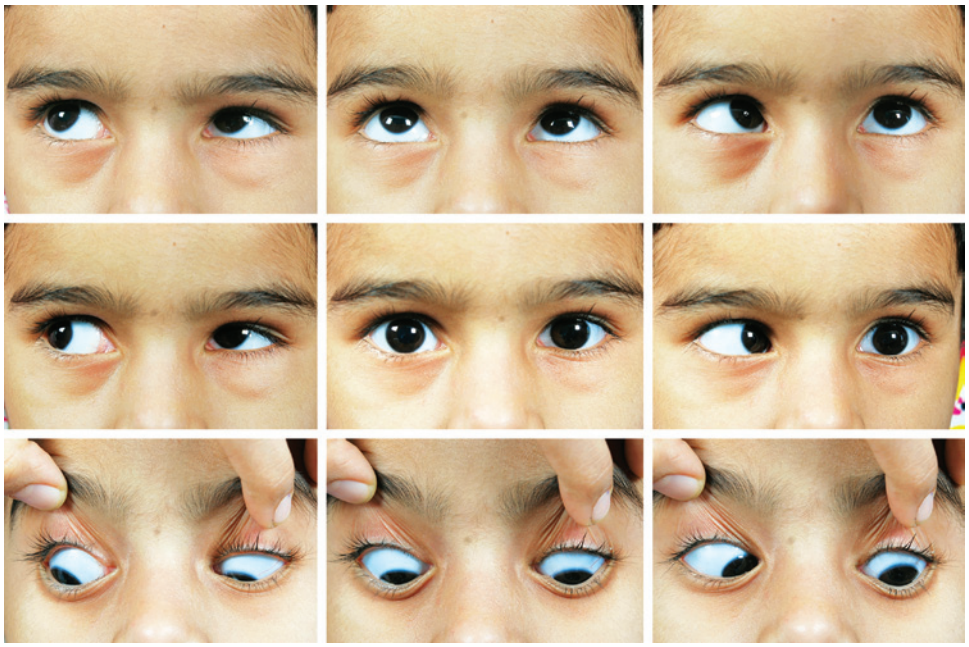

Fig. 83.4 Unilateral (left) Duane retraction syndrome type I in a 4-year-old girl. Note limitation of abduction of left eye and widening of left palpebral fissure on attempted left gaze.

Inheritance

Most cases of DRS are sporadic, but familial unilateral and bilateral cases occur.[23] Familial DRS usually is transmitted in an autosomal dominant pattern. Affected individuals in such families show substantial clinical variability.

Duane retraction syndrome 1 (MIM #126800)

In the Duane retraction syndrome 1 (DURS1) phenotype, the syndrome may be unilateral (see Fig. 83.4) or bilateral (see Fig. 83.7A) and, depending on the size of the deletion, it may be associated with other features including mental retardation, branchio-oto-renal syndrome, genital tract anomalies, and other somatic mutations. The gene disrupted by overlapping cytogenic abnormalities at the DURS1 locus located on chromosome 8 (8q13) may be CPAH, a carboxypeptidase gene with eight exons.[24,25]

Duane retraction syndrome 2 (MIM #604356)

The DURS2 phenotype is almost always bilateral. Associated findings include a variety of vertical deviations such as apparent superior oblique underaction and dissociated vertical deviation. Patients may have decreased abduction with or without decreased adduction. Amblyopia is common. It is autosomal dominantly inherited. The responsible gene, *CHN1*, is located on chromosome 2 (2q31).[26–28] It is involved with neuronal path finding during the development of the abducens nerve and, to a lesser extent, the oculomotor nerve.[29,30]

Duane radial ray syndrome (Okihiro syndrome, MIM #607323)

In this condition, unilateral or bilateral Duane syndrome is associated with unilateral or bilateral radial dysplasia. Thumb hypoplasia is most common, but the defect may range from hypoplasia of the thenar eminence to phocomelic limbs. Patients often have deafness and somatic malformations. Inheritance is autosomal dominant and is caused by truncating *SALL4* mutations on chromosome 20 (20q13),[31,32] which encode putative zinc finger transcription factors.

Box 83.2

Indications for surgery in Duane retraction syndrome

- Significant deviation in the primary position
- Abnormal head posture
- Significant overshoots (uphsoot or downshoot)
- Significant globe retraction
- To increase the field of binocular vision

Wildervanck cervico-oculo-acoustic syndrome (MIM #314600)

This syndrome of congenital deafness, Klippel–Feil anomaly (fusion of cervical vertebrae giving a short neck), and bilateral abduction palsy with retraction on adduction (Duane phenomenon) is almost completely limited to females, suggesting X-linked dominance with lethality in the hemizygous male.

Management of Duane retraction syndrome

Indications for surgical treatment of Duane syndrome are summarized in Box 83.2. A significant deviation in primary gaze is the most common indication.

Although many clinicians rely upon Huber's classification of DRS into types 1, 2, and 3,[16] classifying patients as esotropic, exotropic, or orthotropic[33,34] may be more useful for surgical

planning and treatment. Treatment depends on the amount of deviation in primary position, severity of the head turn, the degree of limitation of add- and abduction, the amount of retraction, up- and downshoots, and the results of forced duction testing (FDT). Although recessions of the medial and lateral rectus muscles have been the mainstay of management in DRS, in the last decade there have been significant advances in the efficacy of transposition procedures (i.e. vertical rectus transposition [VRT] and superior rectus transposition [SRT]).

General guidelines for the management of strabismus in DRS

Unilateral esotropic DRS

Unilateral esotropic DRS is the most common subtype of DRS (especially DRS type I). Depending on the amount of esotropia, these patients may be managed by unilateral or bilateral medial rectus recessions. While many strabismologists prefer unilateral or bilateral medial rectus recessions for esotropic DRS,[35] some recommend transposition procedures[36,37] to improve ocular alignment and abduction. While both medial rectus recessions and transposition procedures may lead to similar success in achieving alignment in primary position, vertical rectus transpositions may result in greater expansion of the binocular visual field.[36–39] In addition to VRT to the lateral rectus, Mehendale et al.[37] and Yang et al.[38] reported good success with SRT and medial rectus muscle recession (Fig. 83.6A,B). The authors have also reported greater improvement in abduction with SRT (1.5 units) compared to none in the medial rectus recession alone.[38] However, patients should be carefully selected: Transposition procedures should not be performed on patients with severe retraction/

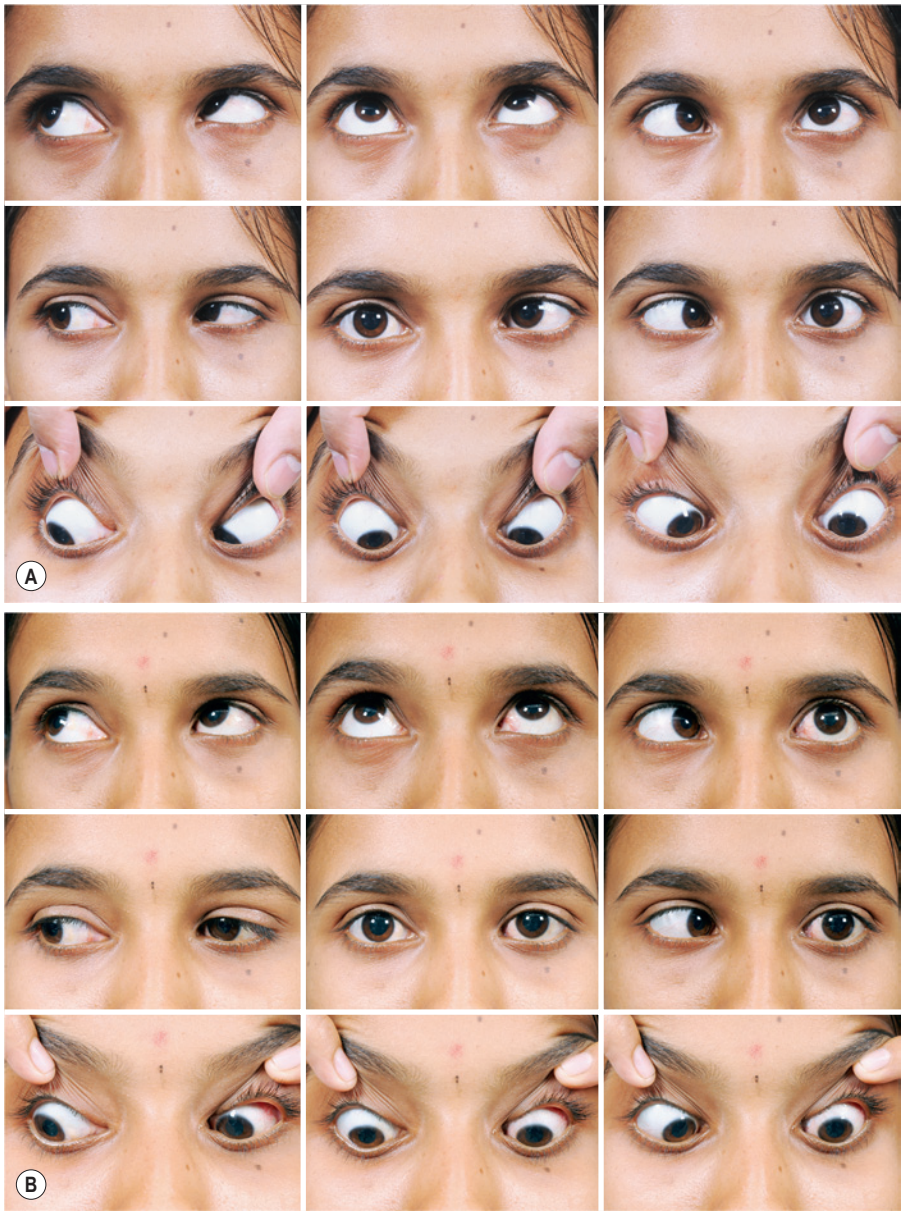

Fig. 83.6 Unilateral esotropic (right) Duane retraction syndrome type I. Preoperative (A) and postoperative (B) nine gaze picture. Please note the improvement in abduction.

co-contraction/exotropia in adduction. Table 83.1 summarizes the management of patients with esotropic DRS.

Bilateral esotropic DRS

This pattern is present in up to 15% of the patients with DRS. It is more common in males. They need to be distinguished from patients with infantile esotropia, Ciancia syndrome, and Möbius syndrome. The amount of esotropia may vary from small to large (reported up to 70 PD).[40] In general, similar principles may be applied to their management as in unilateral DRS. Bilateral medial rectus recession is the surgical procedure of choice. The amount of the surgery is dependent on the angle of the deviation and good success may be achieved in up to 86% of patients. Other options include bilateral medial rectus recessions with SRT/VRT (Fig. 83.7A,B); however, transposition procedures have been reported to have a similar success as bilateral medial recti recessions.[41]

Table 83.1 Surgical procedures and possible indications for patients with unilateral Duane retraction syndrome

No.	Clinical feature	Indicated procedure
1	Esotropia <20 PD	Unilateral medial rectus recession alone (MRc) If deviation <14 PD without significant retraction: superior rectus transposition (SRT) alone
2	Esotropia: 20–45 PD	Bilateral medial rectus transpositions: preferable if tight medial rectus and severe globe retraction Unilateral MRc + SRT* Unilateral MRc + vertical rectus transpositions*

*Preferable if not much globe retraction/overshoots.

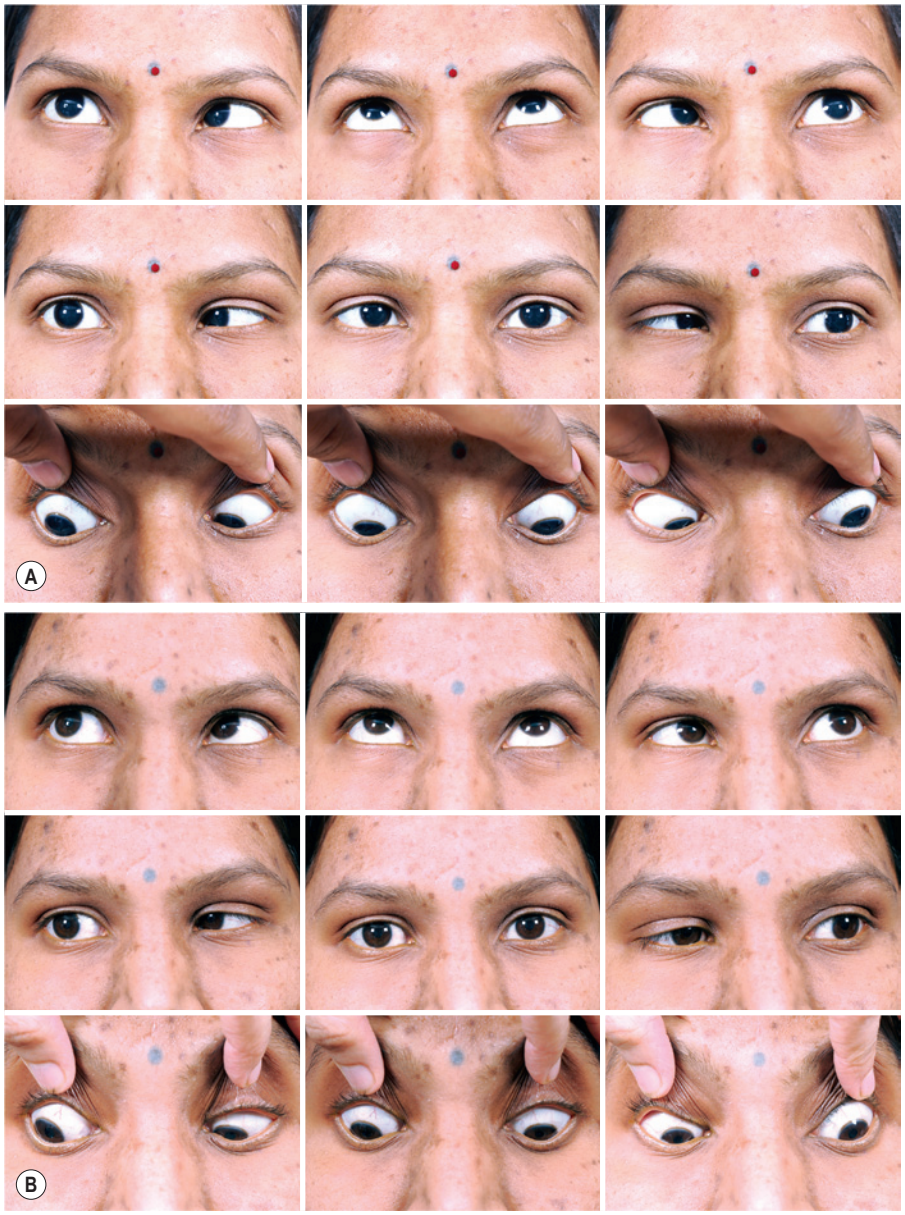

Fig. 83.7 Bilateral esotropic Duane retraction syndrome type I. Preoperative (A) and postoperative (B) pictures. Notice the improvement in the primary position deviation and globe retraction. However, the limitation of abduction still persists.

Exotropic DRS

Exotropic DRS accounts for 10–15% of all DRS cases and is most commonly associated with type II DRS. In these patients, the lateral rectus muscle is usually tight and there may also be globe retraction and overshoots. They may be managed by lateral rectus recession alone (unilateral if deviation <20 PD; bilateral if >20 PD; and lateral rectus recession with Y-split if associated with overshoot [Fig. 83.8A,B]). In patients with severe retraction and overshoots, fixation of the lateral rectus to the periosteum, with partial tendon vertical rectus transpositions to the lateral rectus insertion, may improve the retraction as well as the ductions.

DRS with overshoots (upshoot or downshoot)

Overshoots, defined as overelevation or overdepression, are usually caused by co-contraction of the horizontal rectus muscles, most commonly with type II and III DRS (see Fig. 83.8A). They are believed to be secondary to mechanical factors (leash effect of the tight lateral rectus muscle causing a slippage of the globe). Alternatively they may be due to dysinnervation of the vertical rectus or oblique muscles. While patients with "mechanical overshoots" tend to have an abrupt overshoot on attempted adduction, patients with "innervational overshoots" tend to have a more gradual overshoot with a primary position hyperdeviation. These patients may also have an associated inferior oblique overaction. Various surgical approaches have been proposed; however, a detailed discussion of each is beyond the scope of this chapter. In patients with mechanical overshoots, good results may be obtained with Y-splitting of the lateral rectus muscles (see Fig. 83.8A,B). This procedure may be combined with lateral rectus recession if there is a concurrent exotropia. In a study of 10 patients with a significant upshoot, with or without exotropia, Rao et al.[42] reported elimination of overshoots with improvements

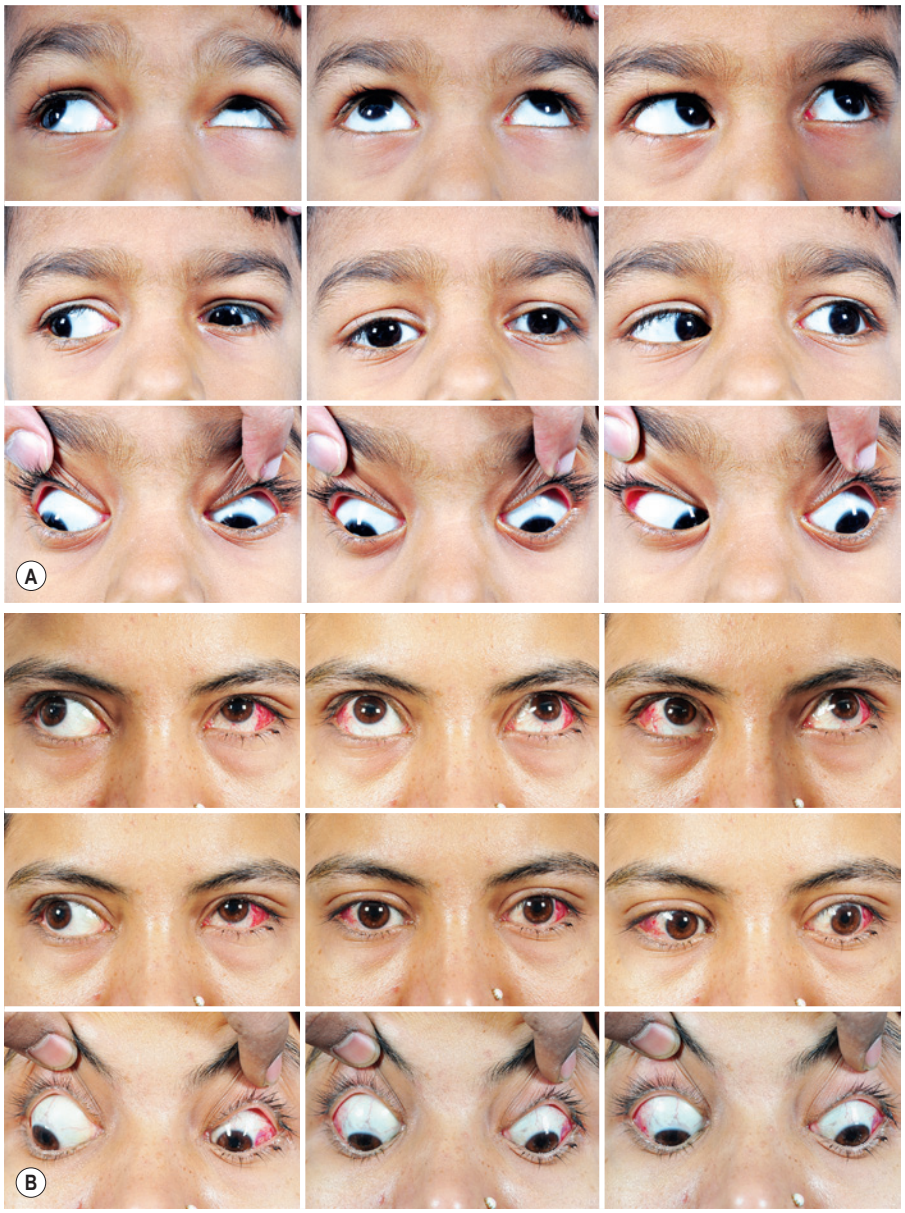

Fig. 83.8 Exotropic Duane retraction syndrome. Preoperative (A) and postoperative (B) pictures. Note the improvement in deviation in primary gaze and downshoot in the left eye.

in head turn, primary gaze deviation, and globe retraction (when present). Conversely, in patients with innvervational overshoots, recessions of the superior rectus or inferior oblique muscles may give good alignment.

Orthotropic DRS

Patient with orthotropic DRS may rarely need surgical procedures for associated severe retraction or overshoots. The management of the overshoots is discussed above. In patients with significant globe retraction as the primary indication, asymmetrical recessions of both medial and lateral rectus muscles may be beneficial. In general, the lateral rectus muscle should be recessed about 1 mm more than the medial rectus muscle. (and an adjustable suture used where possible to avoid inducing any new deviation in the primary position).

Human homeobox A1 spectrum (MIM #601536)

The *HOXA1* spectrum is autosomal recessive and characterized by bilateral DRS with absent abduction and reduced adduction (Fig. 83.9) associated with deafness, cerebrovascular and cardiovascular malformations, and, in some cases, autism that may be profound.[43–45] Some affected persons, particularly those with the Native American variant, have associated facial weakness, cognitive dysfunction, central hypoventilation, or a combination of these features.[46] MRI has demonstrated absence of both abducens nerves and almost completely absent development of the acoustic and vestibular structures in the petrous bone of many patients.[43–45]

The *HOXA1* spectrum is caused by homozygous mutations in the *HOXA1* gene on chromosome 7 (7p15.3), a gene that has been shown in animal models to be critical for hindbrain development.[3]

Practical management of the *HOXA1* spectrum

Patients with this condition may be quite impaired by their systemic disease. Ophthalmologists should focus on prescribing appropriate refractive correction, amblyopia therapy and, based on primary position ocular deviation, appropriate and timely strabismus surgery. However, more importantly, ophthalmologists should be aware of this entity while examining patients with bilateral DRS and be ready to involve their colleagues for multidisciplinary care of the child.

Horizontal gaze palsy and progressive scoliosis (MIM #607313)

HGPPS is an autosomal recessive syndrome characterized by complete or near complete bilateral horizontal gaze limitation (Figs 83.10 and 83.11), normal vertical gaze, variable convergence, variable congenital nystagmus, and asynchronous blinking.[47] Scoliosis begins in early childhood and may be both rapidly progressive and severe. MRI shows intact abducens nerves but deep anterior and posterior clefts in the medulla and lower pons, a large fourth ventricle, and no decussation of the axons of the corticospinal tract, medial lemniscus, or superior cerebellar peduncle.[48,49]

The mutations responsible for this disorder are in the gene *ROBO3* located on chromosome 11 (11q23–q25), a gene responsible for producing a transmembrane cell adhesion molecule that is a receptor for axon guidance during development of the hindbrain.[3,50]

The explanation for absence of horizontal gaze in patients with HGPPS is unclear; however, it may be due to aberrant supranuclear input onto the abducens motor neurons by axons from the paramedianpontine reticular formation that cannot

Fig. 83.9 Human homeobox A1 (HOXA1) spectrum. This patient with homozygous mutations in *HOXA1* has the classic triad of congenital bilateral type III Duane retraction syndrome, deafness due to almost complete absence of inner ear development bilaterally, and cerebrovascular malformations. She has a moderate esotropia in primary gaze, no abduction of either eye, and limited adduction of both eyes associated with obvious globe retraction and narrowing of the palpebral fissure; however, she has full upgaze and downgaze bilaterally.

Fig. 83.10 Horizontal gaze palsy with progressive scoliosis. This young man with homozygous mutations in *ROBO3* has a horizontal gaze palsy and a severe progressive scoliosis. His eyes are orthophoric in primary gaze, and he has excellent visual acuity in both eyes, binocular fusion, and no diplopia. He has essentially no conjugate gaze to the right, and can only move both eyes minimally to the left; however, he has full upgaze and downgaze. He also has small-amplitude horizontal pendular nystagmus. The disturbance of ocular motility was present at birth.

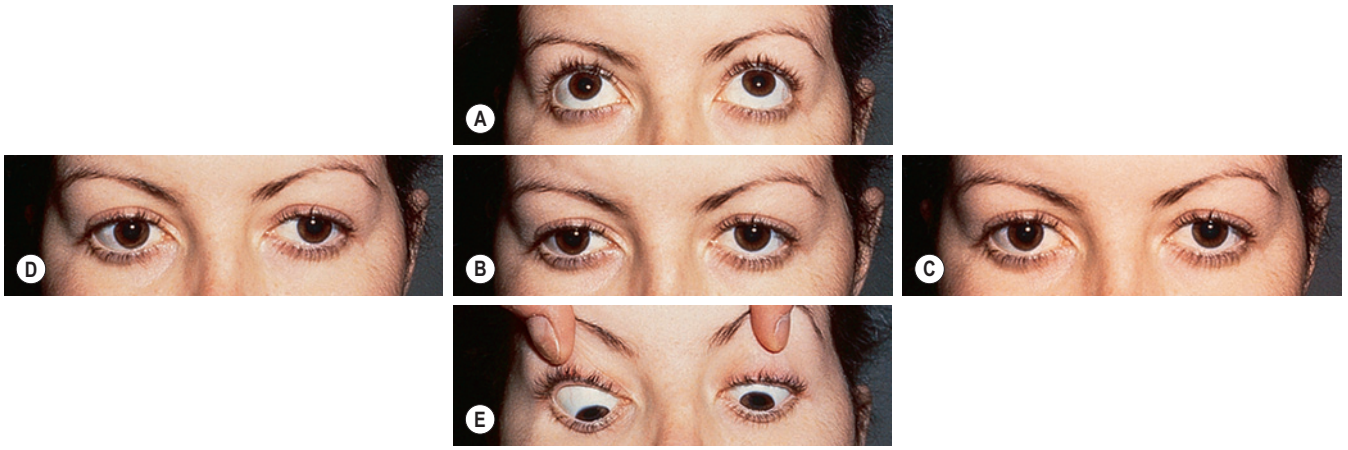

Fig. 83.11 Horizontal gaze palsy with progressive scoliosis. Note intact vertical movements. (A) Patient looking up. (B) Patient in primary gaze. (C) Patient attempting to look right. (D) Patient attempting to look left. (E) Patient looking down.

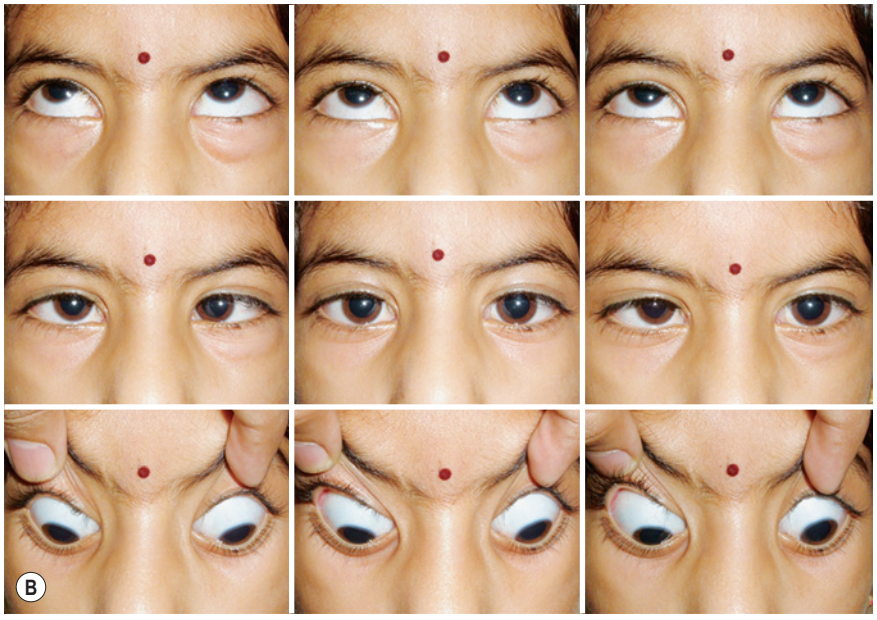

Fig. 83.12 Möbius syndrome in a 9-year-old girl. (A) Available online. (B) Nine gaze picture. Note the presence of a bilateral limitation of abduction in both eyes with intact vertical movements in both eyes.

cross the midline and/or to inability of developing axons in the medial longitudinal fasciculus to cross the midline.[51]

Practical management of horizontal gaze palsy and progressive scoliosis

Because the horizontal gaze deficit in patients with HGPPS is always bilateral and symmetric, such patients almost never have diplopia and, thus, do not require treatment for their ocular motility disturbance; however, they often benefit from surgery to correct their scoliosis.

Möbius syndrome (MIM #157900) and its variants

The eponym "Möbius syndrome" is reserved for the congenital combination of non-progressive facial weakness and at least an abduction deficit in one or both eyes. Möbius syndrome is usually a sporadic disorder, frequently accompanied by lingual or pharyngeal dysfunction, craniofacial dysmorphisms, and limb malformations. Several associated cytogenetic abnormalities have been reported.

Characteristically, affected children have mask-like faces. The mouth may be constantly held open preventing adequate nursing. The appearance may interfere with normal bonding and attachment. The eyelids often cannot be closed completely. There may be excess lacrimation with epiphora. Usually there is an associated esotropia (Fig. 83.12) with or without unilateral or bilateral limitation of abduction. However, the eyes may be orthotropic in many patients, despite limitation of horizontal movements. Henderson reviewed 61 cases of Möbius syndrome in the literature.[52] He found that bilateral abducens palsy was present in 43 cases, unilateral abducens nerve palsy in two cases, and horizontal gaze palsy in the rest. In rare cases, vertical eye movements are also abnormal.

Fig. 83.12 (A) Note esotropia and bilateral facial weakness.

Patients with Möbius syndrome may have deafness, webbed fingers or toes, congenital "amputations," supernumerary digits, defects of the muscles of the chest, neck, and tongue, and even absence of the hands, feet, fingers, or toes. Abnormalities of lower cranial nerves, with speech and swallowing difficulties, are extremely common. Less commonly, it may be associated with low-set ears, a small mouth opening, micrognathia, epicanthal folds, congenital heart defects, or a combination of these abnormalities. Some patients may have respiratory difficulty and tachypnea. Others have a combination of anosmia and hypogonadotrophic hypogonadism (Kallmann syndrome). Many patients with Möbius syndrome have some degree of mental retardation and autism. Patients with Möbius syndrome who undergo neuroimaging show heterogeneity of findings ranging from normal imaging to intracranial calcifications, brainstem hypoplasia, or changes consistent with ischemia.

The inheritance is usually sporadic, although some patients with Möbius-like phenotypes have mutations in *TUBB3* or *HOXA1*.[2] Baraitser concluded that the risk of another affected sibling is no greater than 2% in pedigrees in which the syndrome includes limb abnormalities.[53]

Towfighi et al. divided neuropathologic findings in Möbius syndrome into four groups as follows.[54] Group I: hypoplasia or atrophy of cranial nerve nuclei (4 cases). Group II: neuronal loss with evidence of active neuronal degeneration in the affected facial nerve nuclei (2 cases). It was postulated that these neuronal changes were caused by physical injury to the facial nerve, arising from a malformed temporal bone or from application of forceps during delivery. Group III: reduction in the number of neurons and reactive changes in the affected cranial nerve nuclei *along with* frank necrosis of the tegmentum of the lower pons (6 cases). These lesions are probably acquired later during fetal life rather than during early embryonic development, and both hypoxia and viral infections are implicated in their etiology. The final group, Group IV, consisted of three cases in which no lesions were found in the brainstem or cranial nerves. A primary myopathy may have been responsible for these cases.

The diversity of pathologic findings in patients with Möbius syndrome suggests that the syndrome is a heterogeneous group of congenital disorders caused by genetic and/or developmental defects related to a variety of insults, such as ischemia or toxic effects of prenatal prescribed drugs including misoprostol, a synthetic prostaglandin, or one of the benzodiazepines.

Practical management of Möbius syndrome

Most patients with Möbius syndrome do not require strabismus surgery because they have bilateral and symmetric horizontal gaze paresis; however, children with severe esotropia in primary gaze may benefit from surgical treatment. Surgical options include bilateral medial rectus recessions, medial rectus recession combined with lateral rectus resection, and, in severe cases, muscle transposition. A reasonable cosmetic appearance can be achieved in most cases, although more than one operation may be required.

Patients with Möbius syndrome and associated corneal anesthesia are at risk of developing exposure keratopathy in the setting of incomplete lid closure. This complication is of particular concern in young children, who may require tarsorrhaphy when simple corneal lubrication is not sufficient to provide adequate corneal lubrication.

Summary

Based on both neuropathologic and genetic evidence, it is clear that there exists a group of disorders for which absent or anomalous innervation of the extraocular and/or facial muscles is the most likely pathophysiology. These disorders are appropriately referred to as "congenital cranial dysinnervation disorders" and include CFEOM types 1, 2, and 3, Duane retraction syndromes 1 and 2, the Duane radial ray syndrome, the *HOXA1* spectrum, congenital horizontal gaze palsy with progressive scoliosis, and Möbius syndrome. The above list of clinical phenotypes and genetic loci is almost certainly incomplete and will undoubtedly increase with time. Since many of these affect extraocular muscles, patients may present first to ophthalmologists. The management of these conditions involves refractive correction, treatment of amblyopia, and strabismus surgery if indicated. The child should be assessed for systemic associations where appropriate, and referral to a specialist, since a multidisciplinary approach may improve the condition of these patients significantly.

Introduction

Cranial nerve palsies in childhood represent one of the more difficult evaluation and management challenges in pediatric ophthalmology. Severity and acuity of pediatric cranial nerve palsies can range from those that simply can be observed, to those that could represent life-threatening emergencies. Determining onset of ocular motor nerve palsies and dividing them into congenital and acquired forms aids in determining etiologies for these disorders, and therefore directs the approach to evaluation, treatment modalities employed, and subsequent outcomes – not only for the ocular alignment, but for morbidity and mortality. A multidisciplinary approach may be necessary in the evaluation and management of these children, dependent upon the acuity of the underlying causative disorder and its treatment. All children with ocular motor nerve palsies in the amblyogenic age range should be monitored for the development of amblyopia, with treatment initiated when necessary (see Chapter 73).

Examination techniques

When examining a child with ocular misalignment, determination of the presence of a cranial nerve palsy may be difficult with a non-cooperative child. Observing the ductions and versions of a young child in the office may reveal a gross limitation of ocular motility in a certain direction in complete cranial nerve palsies. However, partial nerve palsies leading to strabismus may be discovered by closely observing saccadic velocities, with a slowed, or "floating" saccade, suggestive of paresis of the muscle. Restrictive etiologies are possible causes for incomitant strabismus, and this should be accounted for when taking a history and examining the child. Forced duction and force generation tests may be performed in the office on adults, but are impossible on most children. Restriction to forced duction testing may only be uncovered in a child in the operating room. The surgeon should be ready to alter their plan based upon forced duction testing should paralytic strabismus be in question, keeping in mind the possibility of antagonist contracture following longstanding paresis.

Epidemiology

The combined annual population-based incidence of all ocular motor nerve palsies is 7.6 per 100,000, with fourth nerve palsies being the most common, followed by sixth nerve palsies, and third nerve palsies.[1] In this population-based incidence study, the most common etiology for fourth and third nerve palsies was congenital, while indeterminate origins were most common for sixth nerve palsies.[1] In an analysis of acquired cases seen at a tertiary referral center, the most common etiology was trauma.[2] Among cases presenting to tertiary referral centers, third nerve palsies are most frequently congenital or traumatic, fourth nerve palsies are most frequently congenital, and sixth nerve palsies are often associated with underlying neoplasms (Table 84.1).

Congenital third nerve palsy

Isolated oculomotor nerve palsies noted at birth are presumed to be the result of a prenatal or perinatal insult (Figs 84.1 and 84.2). High-resolution magnetic resonance imaging (MRI) may reveal a hypoplastic third nerve.[3] Many patients with a congenital third nerve palsy will exhibit aberrant regeneration, leading to complex motility dysfunction. Patients who have other neurologic deficits in association with an oculomotor palsy should undergo neuroimaging, as these children are likely to have more abnormalities of neuroanatomy. Bilateral

Table 84.1 Etiology of cranial nerve palsies presenting to tertiary care centers[5,14,26]

	Congenital	Trauma	Neoplastic	Inflammatory or Infectious	Craniofacial anomalies	Vascular	Idiopathic	Elevated intracranial pressure	Other
Third nerve palsy	34%	31%	13%	8%	X	11%	2%	X	X
Fourth nerve palsy	61%	5%	3%	1%	13%	X	15%	X	X
Sixth nerve palsy	11%	12%	45%	7%	X	X	5%	15%	5%

third nerve palsies should also undergo neuroimaging, which may reveal abnormal development of the third nerve nuclei, fourth nerve nuclei, and fibrosis of the extraocular muscles as part of the congenital cranial dysinnervation disorders[4] (see Chapter 83). Congenital third nerve palsies have been reported in association with PHACE syndrome, neurofibromatosis type II, neuroenteric cyst, agenesis of the internal carotid artery, and septo-optic dysplasia.

Patients with congenital third nerve palsies are likely to have visual impairment as a result of amblyogenic risk factors, including strabismus and ptosis. Treatment of the ptosis and strabismus may improve cosmesis, but restoration of binocular function is uncommon even after surgical and medical treatment.[5,6] Amblyopia treatment may be necessary, not only to attempt to improve vision in the amblyopic eye, but also to maintain visual acuity.

Acquired third nerve palsy

Approaching the child with a third nerve palsy starts with a good history and examination. A history of trauma or infection makes the diagnosis obvious, and many of these patients will come to see the ophthalmologist after undergoing neuroimaging. A history of remission and recurrence or headache also helps to direct the evaluation. However, any case of new-onset oculomotor nerve palsy should undergo neuroimaging.

The most common cause of an acquired third nerve palsy in childhood is trauma.[2,6] In closed head injuries, the entire length of the nerve, from nucleus to orbit, may be susceptible to injury. Shearing forces, skull fractures, brainstem herniation, and orbital fractures can all cause damage to the oculomotor nerve. Recovery of function altered by aberrant regeneration may be seen following the initial injury, particularly in complete third nerve palsies. Neoplasms of any type may cause third nerve palsies by compression at any point in the course of the third nerve. The presence of a slow-growing tumor such as a schwannoma or meningioma should be suspected if primary progressive signs of third nerve palsy are noted with evidence of aberrant regeneration. Tumors are the second most common cause of an acquired oculomotor nerve palsy.[2,6] Third nerve palsies may be seen in patients with meningitis from any organism. Direct inflammation and infection of the oculomotor nerve may lead to its dysfunction, or it can be affected by cavernous sinus thrombosis. Post-infectious or post-viral third nerve palsies usually resolve completely without recurrence, and are associated with normal neuroimaging. Aneurysms, in contrast to adults, are a rare cause of third nerve palsy in children. However, they do remain a possible etiology, with case reports in the literature.[7] For a patient with a painful third nerve palsy, angiography should be performed to rule out the possibility of an aneurysm. Vascular malformations can also lead to a third nerve palsy (Fig. 84.3). An interesting cause of third nerve palsy is the ophthalmoplegic migraine, now called "recurrent painful ophthalmoplegic neuropathy." Diagnosis is based upon fulfilling the criteria from the International Headache Committee of at least two attacks of unilateral headache accompanied by ipsilateral paresis of at least one ocular motor nerve, with absence of a causative lesion, and not consistent with another headache syndrome.[8] Enhancement of the third nerve may be present on MRI (Fig. 84.4). Resolution of the palsy may help to distinguish this entity from a schwannoma involving the oculomotor nerve, although schwannomas have been reported to mimic recurrent painful ophthalmoplegic neuropathy.[9] Treatment with steroids may be of some benefit. However, with recurrent attacks, a permanent deficit may develop.

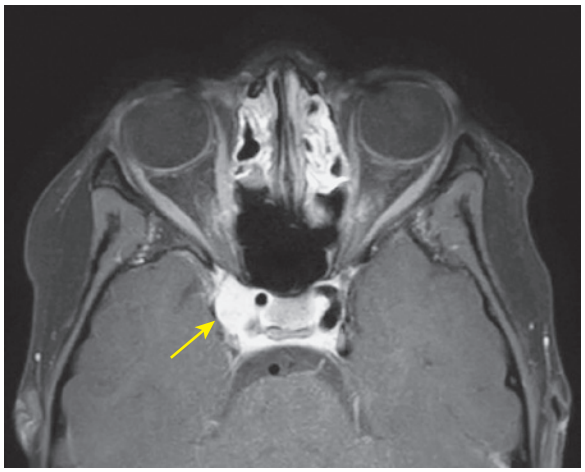

Fig. 84.3 Acquired partial right third nerve palsy. Axial T1-weighted fat-suppressed magnetic resonance imaging scan revealing a right cavernous sinus hemangioma (yellow arrow) in a patient with a partial right third nerve palsy.

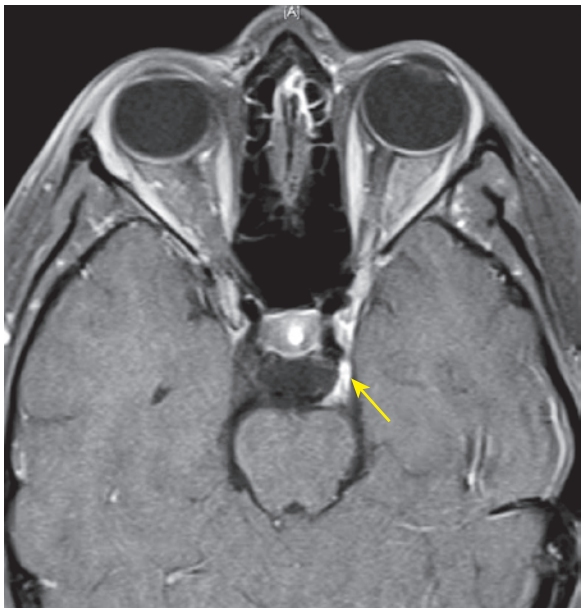

Fig. 84.4 Recurrent left third nerve palsy. Axial T1-weighted fat-suppressed magnetic resonance imaging scan revealing enhancement of the left third nerve (yellow arrow) in a patient with recurrent painful left third nerve palsy.

Treatment

Patients in the amblyogenic period should be pre-emptively treated to prevent the development of amblyopia while awaiting surgery or recovery of function. Recovery may take up to 6–12 months. Resolution of the third nerve palsy is associated with better visual outcomes in terms of visual acuity and binocularity. Strabismus from oculomotor nerve palsies is among the most complex and difficult disorders to treat. A complete third nerve palsy leaves only two functioning muscles: the superior oblique muscle and lateral rectus muscle. The eye is in a "down and out" position. Although the goal of surgery is to restore binocular single vision in primary position, this is difficult to achieve, and in children, binocularity is rarely restored.[5,6] Adoption of a head position may maintain binocularity in some children.[10] Strabismus surgery may be complicated by bizarre motility patterns caused by aberrant regeneration and misinnervation of the extraocular muscles. Many surgical procedures have been developed to treat complete oculomotor nerve palsies. These include large recess/resect procedures, transposition of the superior oblique tendon nasally,[11] disinsertion of the lateral rectus muscle with attachment to the periosteum of the orbit,[12] suture fixation of the globe to the periosteum, extirpation of the lateral rectus muscle, and nasally transposing the split halves of the lateral rectus muscle. Partial oculomotor nerve palsies are easier to treat as there are either fewer muscles involved, or the muscles involved are not completely paralyzed. This allows for more conventional surgery involving recession and resections of the appropriate muscles to expand the field of binocular single vision. Visual outcomes in patients with amblyopia are best in congenital cases, and traumatic and neoplastic etiologies for third nerve palsies have worse outcomes.[6] If the eyelid is malpositioned, strabismus surgery should precede ptosis repair. The eyelid position may change with strabismus surgery, and a ptotic eyelid will prevent diplopia, should strabismus surgery be unsuccessful.

Congenital fourth nerve palsy

Trochlear nerve palsies are the most common ocular motor nerve palsy in children, and the most common cause of hypertropia in childhood.[13] The majority of fourth nerve palsies were congenital in origin among patients under 8 years old presenting to a tertiary referral center, and none had previously unidentified underlying intracranial pathology.[14] Congenital fourth nerve palsies are the most common cause of pediatric fourth nerve palsies overall. Routine examination in asymptomatic patients may reveal an incidentally found head tilt or hyperphoria without diplopia that is consistent with a fourth nerve palsy.[1] The underlying cause of most congenital trochlear palsies is unknown, but some cases of nerve aplasia exist, which could possibly be on the spectrum of congenital cranial dysinnervation disorders[15] (see Chapter 83). The motility findings suggestive of a fourth nerve palsy include an ipsilateral hypertropia greater on contralateral gaze and ipsilateral head tilt. The Parks–Bielschowsky three-step test is classically used to identify a paretic muscle; however, its use in fourth nerve palsies associated with superior oblique atrophy demonstrated that the three-step test failed to identify 30% of cases.[16]

The finding of a head tilt is common in children who have a fourth nerve palsy. The head tilt is usually directed to the contralateral side of the palsy as a compensatory mechanism. In cases of longstanding and congenital fourth nerve palsies, the head tilt can be identified on previous photographs.[17] The patient may additionally have midface hypoplasia on the side of the head tilt. On MRI, the superior oblique tendon may be hypoplastic or absent in congenital cases. The belly of the superior oblique muscle atrophies in superior oblique palsy, and differential degrees of atrophy affect the clinical features observed.[18] The trochlear nerve itself may be congenitally absent, as has been revealed in MRI investigations.[19] Upon performing alternate cover testing, the examiner may find that the existing hypertropia increases in amplitude with prolonged

testing. Patients with congenital fourth nerve palsies tend to have larger than normal vertical fusional amplitudes, normal being about 2–3 primsm diopters (PD). Over time, young patients who were able to fuse large vertical amplitudes may experience a reduction in their fusional abilities and begin to experience diplopia despite being able to compensate earlier in their lives.

In patients who have congenital trochlear palsy, some demonstrate extreme laxity of the tendon on the exaggerated forced duction test.[20] Subjective and objective torsion should be measured, when possible, with double Maddox rod testing, synoptophore and fundus photography. The presence of excyclotorsion increases the likelihood of a superior oblique palsy, even if patients do not complain of torsion. Care should be taken to consider bilateral fourth nerve palsies, especially in cases in which excyclotorsion measures >10° in the primary position, a "V" pattern is present, and there is a hypertropia that reverses between right and left gazes.[21]

Many children with congenital fourth nerve palsies do not develop amblyopia or decreased binocular vision, likely because of the compensatory mechanisms of increased fusional amplitudes and head tilt. However, some children have very large manifest hypertropias. These children should be treated aggressively for amblyopia, and require strabismus surgery to improve alignment and promote binocularity. Patients with synostotic plagiocephaly may have abnormal eye movements due to abnormal anatomy that simulates superior oblique palsy due to excyclorotation of the entire orbital contents, altering the forces upon the globe during muscle contraction. This finding may also be present in patients without craniofacial disorders.[22]

Treatment

Initial management of small comitant deviations can be successfully achieved with prisms.[23] However, many children with a congenital fourth nerve palsy have torticollis, which can be corrected with strabismus surgery. In general, the surgical procedure of choice for isolated unilateral congenital fourth nerve palsy with a small hypertropia (<15 PD) and inferior oblique overaction is inferior oblique weakening, such as recession. If there appears to be restriction of the ipsilateral superior rectus, then this muscle should be recessed. If there is a larger deviation, an inferior oblique recession can be combined with an ipsilateral superior rectus recession in cases of superior rectus restriction, or the contralateral inferior rectus muscle can be recessed. In patients with a larger hypertopia in downgaze and no ipsilateral inferior oblique overaction, a contralateral inferior rectus recession may be the surgical procedure of choice. Laxity of the superior oblique tendon makes superior oblique tendon tucking an alternative procedure. Motor outcomes tend to be good in children, but sensory outcomes are poorer in younger patients.[14]

Acquired fourth nerve palsy

Unlike patients with congenital fourth nerve palsies, patients with acquired etiologies are much more commonly diplopic, unless they are very young and are easily able to suppress one eye. These patients do not have the large fusional amplitudes that patients with congenital fourth nerve palsies have. The trochlear nerve has the longest course of all the cranial nerves, and is particularly sensitive to trauma. The nerve can be damaged as it exits the brainstem dorsally. It can also be damaged by contrecoup injuries as it enters the tentorium, where it is particularly sensitive to shear forces. Bilateral fourth nerve palsies should be suspected in traumatic cases. Patients who present with new-onset non-traumatic fourth nerve palsy should undergo neuroimaging studies. Although rare, these patients may have more serious causes of their fourth nerve palsy. Hydrocephalus may be a cause of acquired unilateral or bilateral fourth nerve palsies. Idiopathic intracranial hypertension can also lead to fourth nerve palsies.[24] Neuroimaging is higher resolution and easier to obtain than in the past, and so abnormalities such as trochlear schwannomas are more frequently recognized as a cause of fourth nerve palsy. These lesions are benign, and can be serially monitored for the development of brainstem compression, and the underlying strabismus can be treated if stable.[25] However, rarely, an isolated new-onset fourth nerve palsy can be the harbinger of another compressive lesion such as a brain tumor. When evaluating children who are suspected of having a fourth nerve palsy, care should be taken to exclude other etiologies of a hypertropia such as skew deviations and dissociated vertical deviations.

Treatment

Similar to congenital superior oblique palsies, acquired superior oblique palsies can be treated with prisms alone if the deviation is small and comitant. The treatment algorithm is similar, with inferior oblique-weakening procedures the operation of choice for small incomitant hypertropias, with or without an inferior rectus recession if the deviation is greatest in downgaze, or combined with a superior rectus recession if there is superior rectus restriction and a large deviation. Torsion tends to play a larger role in diplopia complaints for patients with an acquired fourth nerve palsy. In cases where torsion is the main complaint and there is a very small or absent vertical diplopia component, a surgery should be performed to address torsion alone. The Harada–Ito procedure (as described in Chapter 86) allows for selective transposition of the anterior superior oblique tendon fibers involved in incylorotation of the globe. Various modifications of the Harada–Ito procedure have also been described, such as the Fells modification that involves disinserting the anterior fibers of the superior oblique tendon and transposing them 8 mm posterior to the superior insertion of the lateral rectus muscle. Bilateral Harada–Ito procedures are indicated in some cases of bilateral fourth nerve palsy (Fig. 84.5). Intraoperative adjustment of a Harada–Ito procedure is possible by visualizing objective torsion of the fundus using indirect ophthalmoscopy. Postoperative adjustment of a Harada–Ito procedure has also been described using adjustable sutures.

Congenital sixth nerve palsy

Sixth nerve palsies are most often acquired, in contrast to fourth nerve palsies. At a tertiary referral center, only 11% of pediatric sixth nerve palsies were determined to be congenital in origin.[26] There are cases of true congenital sixth nerve palsy

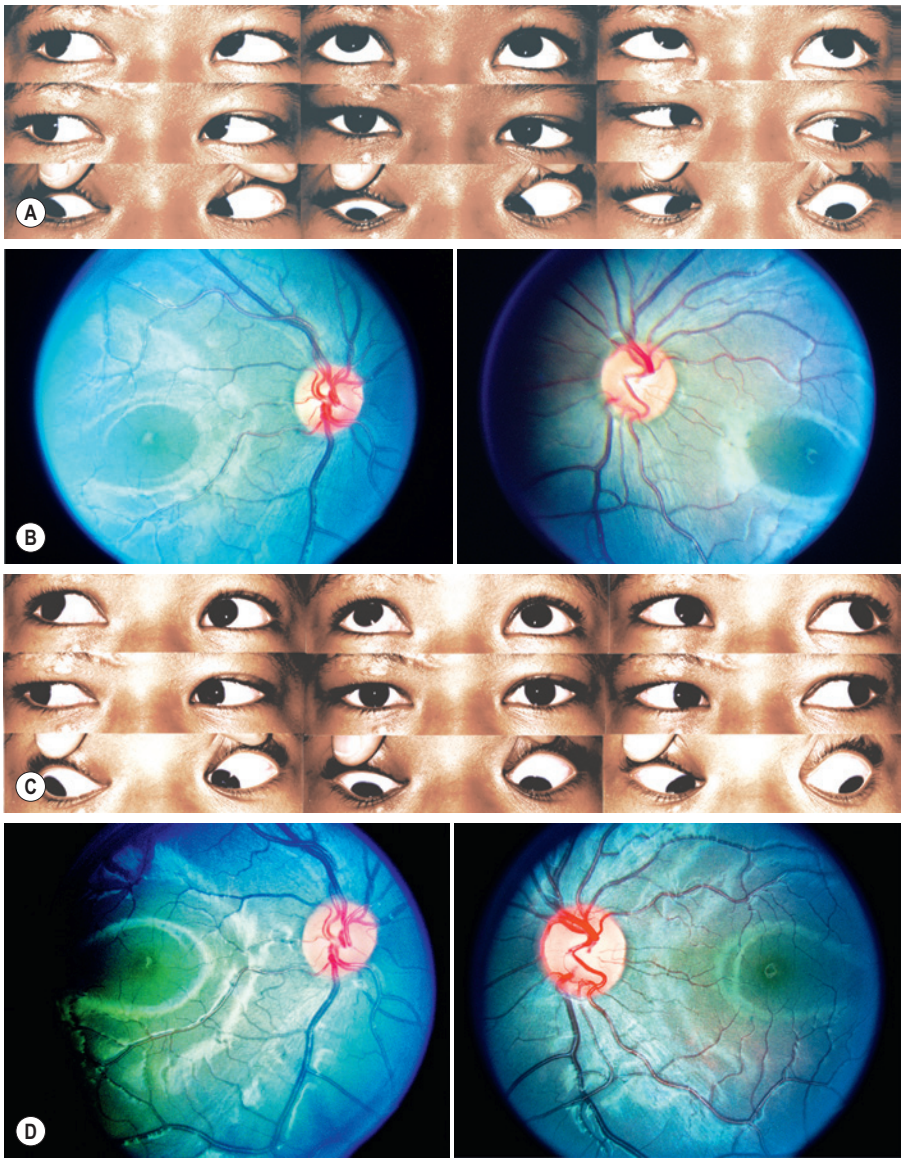

Fig. 84.5 Traumatic bilateral fourth nerve palsies. (A) Preoperative motility photographs in a patient with bilateral traumatic fourth nerve palsies. Note the "V" pattern esotropia and alternating hypertropia. (B) Preoperative fundus photographs demonstrating bilateral excyclotorsion. (C) Postoperative motility photographs demonstrating resolution of esotropia and alternating hypertropia following bilateral Harada–Ito procedures. (D) Postoperative fundus photographs demonstrating improvement in bilateral excyclotorsion following bilateral Harada–Ito procedures.

without misinnervation that present at or shortly after birth. These usually spontaneously resolve and are presumably secondary to birth trauma. Duane syndrome, a member of the congenital cranial dysinnervation disorders, is associated with absence of the sixth nerve nucleus and aplasia of the nerve[27] (Fig. 84.6 and see Chapter 83). Congenital bilateral sixth nerve palsies and seventh nerve palsies are the hallmarks of Möbius sequence (Fig. 84.7). Horizontal gaze palsy may be present as well due to involvement of the horizontal gaze centers. In the absence of classical findings of Duane syndrome, neuroimaging is required to eliminate the possibility of a more sinister cause of sixth nerve palsy in a neonate. Examination of the neonate or infant suspected of having a sixth nerve palsy can be difficult, and differentiating Duane syndrome from a sixth nerve palsy and infantile esotropia with cross-fixation may be challenging. Limited abduction or adduction, and narrowing of the palpebral fissure an attempted adduction and globe retraction are the hallmarks of Duane syndrome. Attempts can be made to have the child perform saccadic maneuvers with toys, to evaluate for a "floating" saccade suggestive of lateral

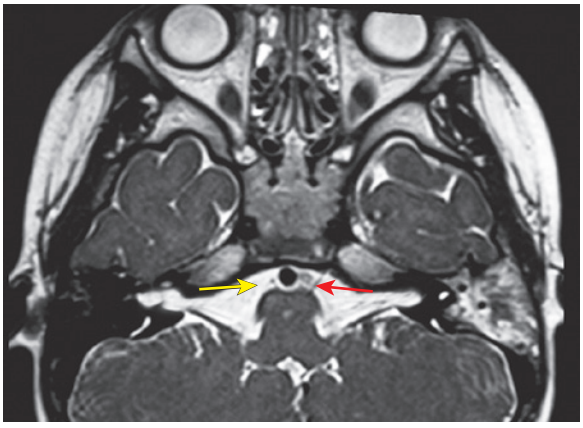

Fig. 84.6 Duane retraction syndrome. Axial oblique high-resolution reformatted volumetric T2-weighted magnetic resonance imaging scan demonstrating congenital absence of the right sixth nerve (yellow arrow) in comparison to a normal left sixth nerve (red arrow).

rectus palsy. Another technique is to hold an infant in one's arms and spin in the direction of the presumed paresis. The re-fixation movement will be in the direction of the suspect muscle, and a slowed re-fixation saccade indicates lateral rectus muscle weakness. As many patients with true congenital sixth nerve palsies experience spontaneous resolution within a few weeks to months, they may be observed without further treatment. Should surgery be necessary, it can be performed as described below for acquired sixth nerve palsies.

Acquired sixth nerve palsy

The majority of sixth nerve palsies in childhood are acquired. At a tertiary referral center, 45% of the patients seen with sixth nerve palsies had neoplasms or their treatment as the underlying etiology, while a population-based study found 17% were due to brain tumors.[1,26] Etiologies in descending order of frequency following tumor were: elevated intracranial pressure (such as from idiopathic intracranial hypertension or hydrocephalus), trauma, inflammatory, and idiopathic.[26] Due to the association of sixth nerve palsies with conditions of high morbidity, early neuroimaging is warranted. Younger patients may be capable of suppressing one eye, and do not complain of diplopia. A recent history of significant head trauma makes the diagnosis clearer, and these children often will already have had neuroimaging performed (Figs 84.8 and 84.9). The sixth nerve is particularly sensitive to traumatic injury where it passes under the petroclinoid ligament into Dorello's canal. Increased intracranial pressure is an important cause of unilateral and bilateral sixth nerve palsies and is usually accompanied by papilledema. Elevated intracranial pressure causes descent of the brainstem, leading to stretching of the sixth nerves at the skull base, leading to sixth nerve palsies. Any cause of elevated intracranial pressure can cause sixth nerve palsies, such as idiopathic intracranial hypertension, meningitis, venous sinus thrombosis, dural fistula, obstructive hydrocephalus, or tumor. The sixth nerve palsies, after treatment of the underlying cause of elevated intracranial pressure, usually spontaneously resolve. Brainstem and posterior fossa tumors are the most feared cause of a sixth nerve palsy in a child. It should be noted that a recent review of patients diagnosed in the emergency department with a brain tumor found that patients presented with symptoms and signs of sixth nerve palsies 6.9% of the time.[28] Brainstem and posterior fossa tumors, such as pontine gliomas, ependymomas, clival chordomas, and medulloblastomas, may lead to compression of the sixth nerve nuclei, nerves, or elevated intracranial pressure (Figs 84.10 and 84.11). Treatment of the underlying tumor and elevated intracranial pressure may lead to improvement of the sixth nerve palsy, or may worsen it through iatrogenic trauma. Cavernous malformations of the pons may spontaneously hemorrhage, leading to a sixth nerve palsy (Fig. 84.12). Cavernous sinus lesions may cause sixth nerve palsies, although it is unusual to be clinically isolated (Fig. 84.13). The finding of a sixth nerve palsy with an ipsilateral Horner syndrome should prompt neuroimaging to evaluate for a lesion in the cavernous sinus. Pituitary tumors may invade the cavernous sinus and cause a sixth nerve palsy. Sixth nerve palsies with retro-orbital pain (from involvement of the ophthalmic branch of the trigeminal nerve) following middle ear infections should prompt an evaluation for Gradenigo syndrome (infection involves the petrous apex) (Fig. 84.14). Multiple sclerosis may cause sixth nerve palsies, which usually recover. Following a viral infection or vaccination, patients may develop a post-viral sixth nerve

palsy, which usually resolves spontaneously. Sixth nerve palsies may also occur on an idiopathic basis and are referred to as benign recurrent sixth nerve palsy. These children experience the sudden onset of an isolated complete sixth nerve palsy, which recovers, with no known etiology.[29] Older patients with benign or idiopathic sixth nerve palsies tend to experience recurrence less frequently.[30]

Treatment

Patients in the amblyogenic age range should be examined for the development of amblyopia when a sixth nerve palsy is discovered. Close follow-up for amblyopia is recommended, and preventative patching can be performed if one eye is noted to be dominant. Spontaneous recovery may occur, although recovery rates in children with traumatic sixth nerve palsies may be lower than that for adults. Small deviations may be treated with prism spectacles. However, patients who have incomitant strabismus may be best served by surgical intervention. Careful examination should be performed to evaluate the saccadic velocity of a child who had a sixth nerve palsy and a residual esotropia, to look for contracture of the medial rectus muscle following recovery of function of the lateral rectus muscle. Intraoperative forced duction testing will help with this diagnosis as well. Patients who have a partial sixth nerve palsy are best served by horizontal rectus recess/resect procedures to strengthen the abducting effect while treating any contracture of the ipsilateral medial rectus muscle. Patients who have a complete abduction deficit require a transposition operation to restore an abducting force. Surgical procedures that have been described to treat a sixth nerve palsy with a complete abduction deficit include: full vertical rectus muscle transposition, a Hummelsheim procedure (transposition of the lateral half of the superior and inferior rectus muscles), a Jensen procedure (suture fixation of the superior and inferior rectus muscles to the lateral rectus muscle), vertical rectus muscle transposition without tenotomy, and a superior rectus muscle transposition coupled with medial rectus muscle recession.[31]

These operations can be combined with an ipsilateral medial rectus muscle recession for medial rectus muscle contracture, either concurrently or at a later date, depending upon the vascular supply to the anterior segment. Pre- or intraoperative botulinum toxin injection to the medial rectus is a helpful non-surgical alternative. A contralateral medial rectus muscle recession with or without Faden operation can also be performed to match any residual lateral rectus abduction deficit and/or residual esotropia.

Multiple cranial nerve palsies

Clinical examination aids the neuroanatomic localization of a lesion in cases of multiple cranial nerve palsies. For instance a sixth nerve palsy associated with ipsilateal decreased corneal sensation (fifth nerve palsy) points to a cavernous sinus lesion, whereas sixth nerve palsy with ipsilateral facial nerve palsy suggests pontine pathology. Multiple ocular motor nerve palsies associated with pain on the same side can be localized to the cavernous sinus. Multiple ocular motor nerve palsies and an optic neuropathy can be localized to the orbital apex. Localization of the lesion is of utmost importance to assist the neuroradiologist in interpreting the study. Without the appropriate clinical information, the neuroradiologist may identify a small lesion if they knew where to focus their attention. Review of the actual images from neuroimaging studies by the ordering physician should be routine practice. Causative lesions of multiple cranial nerve palsy include cavernous sinus thrombosis, orbital apex tumors, Tolosa–Hunt syndrome, trauma, leukemia, and any brainstem neoplasm. Following viral illnesses, a patient may develop multiple cranial nerve palsies due to Miller–Fisher syndrome, a form of Guillain–Barré syndrome. Surgical correction of strabismus from multiple cranial nerve palsies surgically can be very difficult, especially when the palsies are complete.

Role of botulinum toxin

Botulinum toxin can be used as a temporizing method of improving binocular vision while awaiting possible spontaneous recovery in sixth nerve palsies. The botulinum toxin is injected into the antagonist medial rectus muscle. However, botulinum toxin for acute sixth nerve palsies has been reported to have no long-term effect on the outcome.[32]

Mimickers of paralytic strabismus

Restrictive etiologies of strabismus may be obvious by history, such as post-traumatic orbital fracture with muscle entrapment and fibrosis, or may be shown on neuroimaging of the orbits. Myasthenia gravis is the great mimicker of cranial nerve palsies. Fluctuating ptosis, variable measurements, a Cogan's lid twitch, fatiguability, are all suggestive of myasthenia gravis. Children with ocular myasthenia gravis may be treated with pyrodistigmine alone and the ocular findings may resolve or stabilize over time.[33] The development of generalized myasthenia gravis in patients who present with ocular findings alone occur in 23% of patients.[34] Amblyopia may develop from ptosis or strabismus and should be treated aggressively. Finally, forced duction testing should be performed on every patient intraoperatively to determine if there is a restrictive component to their strabismus. The results may influence the surgical plan.

Acknowledgments

This study was supported in part by a departmental grant (Department of Ophthalmology) from Research to Prevent Blindness, Inc., New York, NY, and by Core Grant P30-EY006360 (Department of Ophthalmology) from the National Institutes of Health, Bethesda, MD. Reformatting of source information for Fig. 84.6 was performed by Dr. Bruno Soares.

Many treatments used to manage children and adults with strabismus are nonsurgical. Even in patients who require surgery to restore normal alignment and/or binocular function, our surgical approaches are usually complemented by nonsurgical treatments ranging from altering the refractive correction to using pharmacological chemodenervation with botulinum toxin. The treatment of some forms of strabismus is entirely nonsurgical. For example, the treatment of convergence insufficiency includes vergence-accommodative exercises, or passive treatment with base-in prisms, but surgery is rarely required. This chapter reviews some of the most common nonsurgical treatments used in the management of strabismus, concentrating, when possible, on the best available evidence that supports their use.

Optical correction

Refractive errors, whether corrected or uncorrected, have a major impact on strabismus and its management. Correcting a refractive error may result in better control of a misalignment solely by gaining optimal visual acuity. Conversely, previously uncorrected non-alternating strabismus patients can be made symptomatic if correcting their refractive error results in spontaneous alternation or switch of fixation to their non-dominant eye.[1]

All children and young adults with strabismus or suspected strabismus require a cycloplegic refraction to determine the basic refractive state without the influence of accommodation. This can be done with 0.5% to 2% cyclopentolate (plus 1% tropicamide in dark irides), or 1% atropine. Cyclopentolate is commonly preferred over atropine due to its shorter onset and duration of action. The mean residual accommodation of these agents is less than 0.1 D for a 3-day administration of 1% atropine, and between 0.4 and 0.6 D for 1% cyclopentolate with 1% tropicamide.[2] The difference between atropine and cyclopentolate cycloplegia has consistently been measured to be between 0.4 and 0.7 D,[2–5] but it is important to recognize that 15–20% of children who have a cycloplegic refraction with 1% cyclopentolate alone will have a hyperopic undercorrection of 1 D or more.[2,3] Therefore, in accommodative esotropia with a residual deviation, an atropine refraction is still essential to uncover the maximal amount of hyperopia that needs to be corrected. The pupillary dilation achieved with any of these agents allows for an adequate funduscopic exam, which is mandatory during the initial evaluation of a strabismus patient to exclude visual axis opacification or abnormalities of the posterior segment.

Considering the optimal optical correction for each patient is essential in the management of their strabismus. In acquired esotropia, particularly accommodative esotropia, all degrees of hypermetropia may be significant, and should be fully corrected with spectacles. The full hyperopic correction should be prescribed in order to remove all accommodative convergence. In most forms of esotropia (including essential infantile esotropia), following surgical alignment, spectacle correction may be of considerable value in improving a small residual deviation. However, in patients with surgical overcorrections of partially accommodative esotropia, reduction of the hypermetropic correction of more than +2.50 D may be associated with long-term instability of the alignment: such overcorrections should be avoided.[6,7]

Bifocals may be indicated in children with a high accommodative convergence to accommodation ratio (AC/A) accommodative esotropia (convergence excess esotropia), if the full hypermetropic spectacle correction aligns the eyes for distance fixation, but a residual esotropia is seen at near.[8,9] Bifocals can be prescribed either as +3.00 D add or with the minimum near addition, which controls the near esotropia.[8] The recommended strategy is then to gradually and incrementally reduce the bifocal correction once the patient has demonstrated stable alignment and fusional amplitudes. It is important to make sure that when the child looks down, as when reading, the line of sight will be through the bifocal segment (executive style or large flat-top segment bisecting the pupil) and that the glasses are properly fitted to prevent slippage on the nose. It is surprising how often these details are neglected.

In patients with intermittent exotropia (IXT), it may seem logical not to correct moderate to high hypermetropia since accommodative convergence has a beneficial effect on the

control of the exodeviation. However, patients with high hyperopia and IXT may not be accommodating fully and may be experiencing blur, resulting in poor control of the deviation. In fact, a small study of children with moderate to high hyperopia (3–7 D) and IXT showed that full hyperopic prescription corrected the manifest deviation and improved the binocular status in all the patients.[10] In contrast, a different study showed that partial spectacle correction of hyperopia increased the exodeviation by an average of 10 prism diopters (PD) in one-third of patients with moderate hyperopia and IXT. This was not observed in patients with fully corrected hyperopia, emmetropia, or myopia.[11] High hyperopia, anisometropia, significant astigmatism, and myopia should always be corrected in patients with IXT. It is unclear if moderate hyperopia needs to be corrected unless the patient has decreased vision, or if surgical planning should be done wearing moderate hyperopic corrections to improve long-term surgical outcomes.[11]

For the treatment of IXT, much controversy still exists regarding what is the optimal nonsurgical treatment and its timing. Ideally, nonsurgical interventions improve the ability to control the deviation, preserve stereoacuity, and eliminate, or at least delay, surgical treatment. Most of these interventions have not been rigorously studied and their efficacy remains unclear.[12,13] Over-minus lens therapy (1.5–4 D additional minus) has been proposed to stimulate accommodative convergence and improve control of the exodeviation. In three prospective studies of children treated with over-minus glasses, some form of improvement (depending on the outcome measure used) was seen in 45–70% of patients.[14–16] This improvement was seen irrespective of the initial angle of deviation and, in some patients, was maintained after discontinuation of therapy. Over-minus therapy does not appear to increase myopia.[16,17]

In children with IXT, part-time occlusion of either the preferred eye or alternate patching has been reported to aid in eliminating suppression, improving the frequency or decreasing the magnitude of the deviation. Published studies have varied in terms of patching dosage, duration, and outcome measures, and have reported varying success rates.

The Pediatric Eye Disease Investigator Group (PEDIG) conducted a multicenter randomized controlled trial to determine the effectiveness of part-time patching (3 hours per day) compared with observation alone for reducing the risk of IXT deterioration over 6 months among 324 previously untreated children 3 to <11 years of age. This study is the first phase of a 3-year natural history study of IXT. The primary outcome measure of deterioration was the loss of motor control (IXT changing to a constant exotropia) or worsening of sensory fusion (decrease in stereoacuity). The effects were evaluated after 1 month of discontinuing patching.

The study found a small treatment effect of patching over observation but the proportion of patients who deteriorated in both groups was very small. At 6 months, deterioration occurred in only 6% of the patients in the observation group and 0.6% in the patching group (95% confidence interval [CI], 1.6–10.3%). Additionally, there were no statistically significant differences in rates of improvement in deviation magnitude, motor control, or stereoacuity in either group. The authors calculated the number of children who would need to be patched to prevent a single deterioration (number needed to treat) to be between 19–33 (depending on what definition of deterioration was used).[18] Similar findings were reported for the 12–35 months of age cohort,[19] where the rate of deterioration at 6 months was 2.2% for the patching group and between 2.3% and 4.6% for the observation group, making it unlikely that part-time patching provides a meaningful short-term benefit for young children with IXT. However, it also seems evident that immediate surgical intervention is not necessary to prevent IXT from deteriorating. Parental concern appears to be one of the more important drivers for immediate treatment of IXT[18,19] and patching did not have a deleterious effect on subjects with IXT. When deciding whether or not to initiate occlusion treatment in patients with IXT, one must consider several factors: age, compliance, psychosocial impact of patching on patient and caregiver, potential to delay surgery, presence of amblyopia, parental concern, and unknown effect over longer treatment periods.

Occlusion therapy

Some practitioners recommend treating amblyopia fully before strabismus surgery, even though in some cases this means delaying strabismus surgery. Two prospective studies evaluated the need for completion of amblyopia therapy versus early operation with continuation of occlusion postoperatively. Neither study detected a significant difference in motor or sensory outcome whether amblyopia was fully or only partially treated before surgery, provided that amblyopia treatment continued after surgery.[20,21] A recent study reported that, in patients with partially accommodative esotropia, the mean angle of deviation decreased significantly after occlusion treatment for amblyopia and noted that occlusion may resolve the non-accommodative component of the deviation, obviating the need for surgery. In that study, surgery would have been performed in 81% of patients if performed before the termination of amblyopia treatment, compared to 38% of patients that ultimately required surgery.[22] Another study showed that 61% of 46 small-angle strabismic children 1½–9 years of age, undergoing part-time treatment with Bangerter foils for amblyopia, developed motor fusion with no additional interventions.[23]

Prisms

Prisms have limited value in the management of early childhood strabismus. If a child has a temporary deviation that is expected to improve, as in consecutive esotropia after surgery for exotropia or in a post-viral sixth nerve palsy, temporary Fresnel prisms may be used to maintain binocularity while the deviation resolves. Prisms can be used for preoperative evaluation and calculation of surgical dosages (prism adaptation test) in patients with strabismus.

A recent case report documented the use of Fresnel prism to treat cyclic esotropia in a 6-year-old female with anisometropic amblyopia and esophoria who then developed cyclic esotropia. The authors report long-term resolution of the strabismus after 1 month of treatment with prisms, breaking the cyclic rhythm, perhaps, by restoring binocular function immediately.[24] Base-in prisms for reading can be used in patients with symptomatic convergence insufficiency.

Orthoptic exercises/vision therapy

Orthoptic exercises are sometimes used to teach patients how to use their fusion ability more efficiently. Orthoptic exercises may help in establishing control of strabismus in a small group of patients with good fusion potential. The effectiveness of orthoptic exercises (and the broader practice of "vision therapy" supported by some branches of optometry) in treating most forms of strabismus is debated. A comprehensive review of the evidence supporting orthoptic exercises/vision therapy from the UK concluded that there was little evidence-based research to support these practices.[25] A notable exception is the management of convergence insufficiency.[26,27] The Convergence Insufficiency Treatment Trial, a placebo-controlled randomized clinical trial, demonstrated that a 12-week office-based program of vergence and accommodative exercises (the patient is asked to converge on targets placed on a string or on a handheld card) with home reinforcement was more effective in reducing convergence insufficiency *symptoms* than home-based "pencil push-ups," home-based computer therapy plus "pencil push-ups," or office-based placebo therapy in children.[28] A similar conclusion was reached by the same researchers investigating convergence insufficiency treatment in young adults.[29] Symptomatic relief versus objective changes in accommodation and convergence, and the question of the true intrinsic treatment effects of office-based therapy versus the effects of motivation, effort, practice, and placebo due to therapist encouragement, continue to be debated.[30]

Drugs

Irreversible cholinesterase inhibitors, such as echothiopate (Phospholine Iodide® 0.125%, 0.0625% and 0.0325%) drops, can be used to control accommodation and, thereby, accommodative convergence. Pilocarpine, a muscarinic receptor agonist, can be used to decrease the synkinetic convergence response. Contraction of the ciliary body produces increased convexity and forward shifting of the lens, resulting in a myopic shift and reduction in the active accommodation effort made. The most common indications for these medications include persistent consecutive esotropia after surgical overcorrection of exotropia, small residual postoperative esotropia, and as a supplement to glasses in patients with high AC/A accommodative esotropia with residual esodeviation at near.

Phospholine iodide is rarely used now due to its limited commercial availability and side effects (supraorbital pain, poor vision [especially at night], and iris cysts and lens opacities with long-term use). Systemic absorption of the drops causes a depletion of plasma cholinesterase, making the patient susceptible to depolarizing muscle relaxants. If a child treated with cholinesterase inhibitors requires general anesthesia, a depolarizing relaxing agent such as succinylcholine should be avoided, as prolonged respiratory paralysis may result. The depletion may last up to 6 weeks and parents should be advised appropriately. To reduce the risk of iris cyst formation, phenylephrine eye drops can be prescribed concurrently.

In hypermetropic esotropic children who do not tolerate their newly prescribed spectacles, atropine 1% once daily for 5 days can be used to blur the vision and give the child an incentive to wear glasses (pharmacological encouragement).

In contrast to strabismus surgery, the treatment of strabismus with pharmacologic agents has the advantage of changing the functional qualities of the extraocular muscles (contractile strength, elastic stiffness, muscle length) without resecting tissue or compromising orbital mechanics.[31] Pharmacologic agents that have been used with success in the treatment of strabismus include botulinum toxin and the amino amide anesthetic, bupivacaine.

Botulinum toxin

The pharmacologic treatment of strabismus was pioneered by Scott, who experimented with the direct injection of various substances into the extraocular muscles. In 1990, botulinum toxin type A was granted Food and Drug Administration (FDA) approval. Botulinum toxin type A (BTX-A) is a large protein molecule of 150,000 daltons. After intramuscular injection, the toxin enters and remains at the nerve terminal for several days to weeks, inhibiting the release of acetylcholine by cleaving SNAP-25, a protein integral to the successful docking and release of the neurotransmitter in vesicles within the nerve endings, resulting in muscle weakness or paralysis maximal within 3–5 days after the injection. Although an irreversible binding occurs, extrajunctional acetylcholine receptors may develop. The nerve reinnervates the muscle with a reversal of the paralysis and eventual recovery. Extraocular muscle paralysis usually lasts from 2 to 8 weeks.

The mechanism by which permanent alignment can occur after the paralyzing effect of botulinum toxin is gone is not completely understood. One theory is that if the antagonist muscle remains contracted for a certain time because of reduced force in treated muscle, it will develop structural alterations that shorten it[32,33] and decrease its elasticity (contracture). Conversely, the chemodenervated muscle will undergo lengthening as its antagonist contracts. This length adaptation is believed to occur through the addition and deletion of sarcomeres.[32] The alterations induced in extraocular muscles by botulinum treatment have been shown to be specific to the orbital singly innervated muscle fibers.[33,34] This fiber-type specificity is thought to explain the permanent effect on static alignment but sparing the saccade kinematics after BTX-A injection.[34,35] Sensory mechanisms must also play a role in the permanent re-alignment after treatment with BTX-A in selected types of strabismus.[36] The structural theory (selective fiber-type atrophy) is clearly an insufficient explanation, as permanent double vision is rarely seen in patients who have diplopia immediately after periorbital BTX-A injections.[34]

The lyophilized drug is supplied in 100-IU vials and is reconstituted with non-preserved saline solution (0.9% sodium chloride injection), resulting in doses from 1 IU/0.1 mL to 12 IU/0.1 mL. One unit is equivalent to one-fiftieth of a lethal dose in a rat, or 4 ng. The estimated systemic toxic dose is 40 IU/kg body weight. Botulinum toxin is now commercially available as BOTOX™ (OnabotulinumtoxinA), Dysport™ (AbobotulinumtoxinA), Xiomin™ (IncobotulinumtoxinA), and Myobloc™ (RimabotulinumtoxinB).

Injection technique

Transconjunctival injection of botulinum toxin can be done with or without electromyography (EMG) guidance (Fig. 85.1). Adult patients can have the procedure with topical anesthesia; in younger patients, injections should be administered under

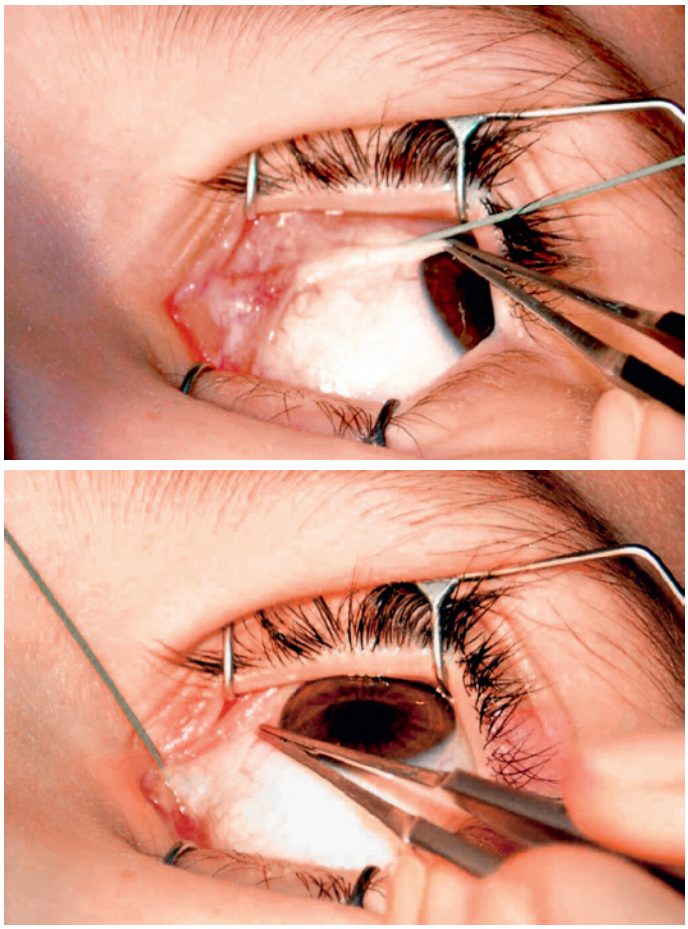

Fig. 85.1 Botulinum toxin A injection with electromyography. *(Courtesy of Pilar Gómez de Liaño, Madrid, Spain.)*

sedation using very low doses of ketamine if EMG is used. Ketamine produces unpleasant dreams or hallucinations when emerging from the dissociative state in about 5% of patients. To curb this reaction, some surgeons add a benzodiazepine, such as midazolam, at the end of the procedure, but the effectiveness is controversial.[37] The incidence of this unpleasant emergence reaction increases with age and with psychiatric comorbidities. It is contraindicated in patients with psychosis or those younger than 3 months of age.[37] When the injection is done without EMG assistance, sevofluorane, propofol, ketamine, or nitrous oxide can be used.[38] The efficacy and complication rates with and without EMG control appear comparable.[39–41]

This author performs most of the injections using a closed conjunctival technique without EMG (Fig. 85.2). Others prefer to inject under direct visualization using an "open sky" technique,[36] but this negates some of the advantages of BTX-A treatment over surgery (shorter anesthesia time, reduced scarring, etc.) We reserve the open sky technique for patients with previous large muscle recessions (Fig. 85.3). After placing a lid speculum, the eye is rotated into the opposite direction of the muscle being injected using conjunctival forceps. The insertion is identified and firmly grasped using toothed forceps such as Elschnig or Mendonça forceps[41] (Fig. 85.4) and a 25- to 27-gauge needle, with the bevel toward the sclera, on an insulin syringe is passed through the grasped tendon. The eye is then rotated to the straight position and the needle is introduced into the muscle belly. The desired dose of

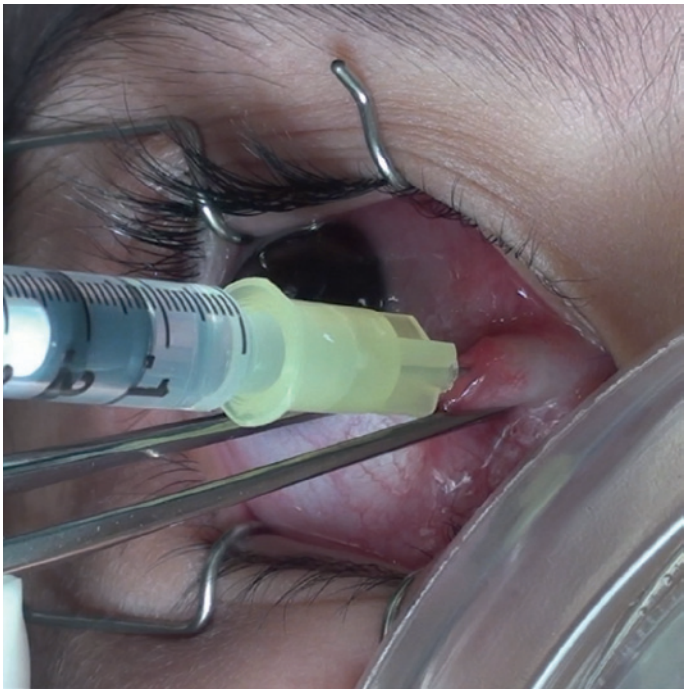

Fig. 85.2 Botulinum toxin A injection with closed conjunctiva technique.

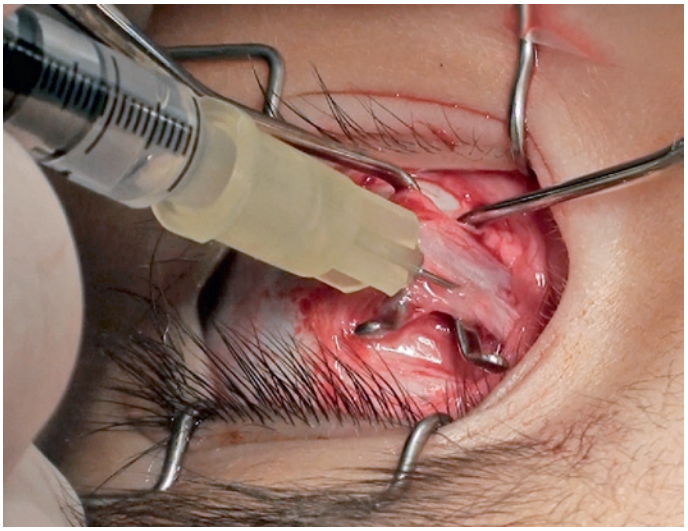

Fig. 85.3 Botulinum toxin A injection with open sky technique.

the drug is injected and the needle is retrieved; care is taken not to retract the needle too fast to avoid having the drug track back with the needle and diffuse out of the muscle.

Under EMG guidance, a special needle acts also as an EMG electrode connected to an amplifier that converts the electrical signal from the muscle to sound. The needle is introduced through the conjunctiva and conducted to the muscle until a characteristic cracking sound is heard, confirming that the tip is in the muscle body. The needle must penetrate the muscle posteriorly, close to the nerve insertion.

The doses used vary, most authors recommending 1.25–7.5 IU per muscle[42–44] in a volume of 0.05–0.15 mL per muscle (Table 85.1).

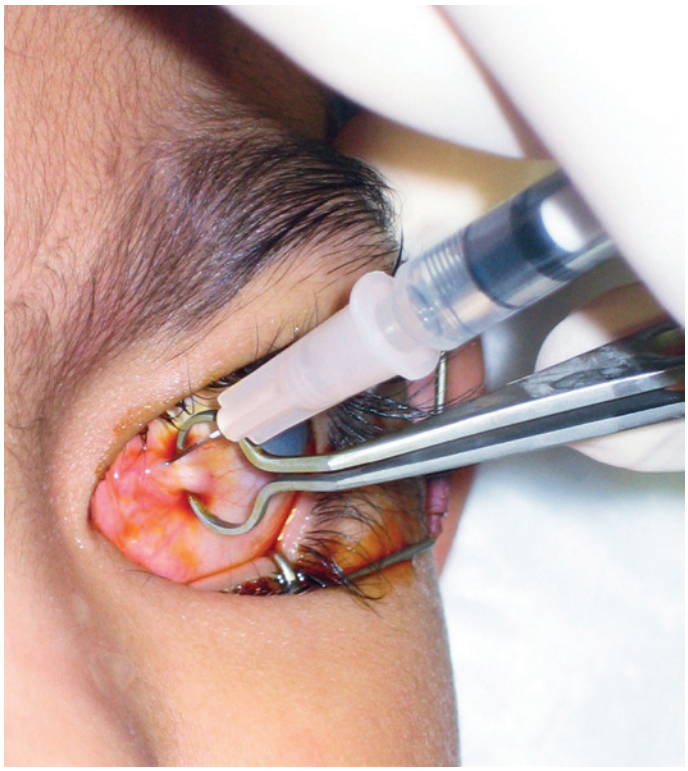

Fig. 85.4 Botulinum toxin A injection using Mendonça forceps.

Table 85.1 Examples of botulinum toxin type A doses

Indication	Dose
STRABISMUS	
Horizontal/vertical strabismus <20 PD	1.25–2.5 IU
Horizontal/vertical strabismus 20–50 PD	2.5–5.0 IU
Re-injection	1.5–2× original dose
CHILDHOOD ESOTROPIA	
Initial	2.5–5 IU
Re-injection	5–7.5 IU
SIXTH NERVE PALSY	
Initial LR weakness	1.5–2.5 IU
Recovered LR function, persistent small ET	2.5 IU
Large ET, paretic LR	5 IU
With transposition	2.5–5 IU

ET, Esotropia; LR, lateral rectus muscle.

Indications

The conditions that are most amenable to treatment with BTX-A are summarized in Box 85.1. The most common indications include small-to-moderate angle infantile and acquired childhood esotropia, postsurgical residual esotropia, and sixth nerve palsy in the acute phase. Unfortunately, most studies supporting or rejecting the efficacy of BTX-A as an alternative to surgery have lacked the methodological rigor of evidence-based medicine.[45]

Box 85.1

Common current indications of botulinum toxin type A

- Infantile esotropia without vertical deviations, little or no contraction, and moderate to small angle in patients less than 2–3 years old
- Acquired esotropia of less than 30 PD
- Residual esotropia of <30 PD (after surgery)
- Esotropia in patients with developmental delay (especially with angle variability)
- Consecutive exotropia if no duction deficit
- Acute sixth nerve palsy
- Diagnostically for the investigation of sensory or motor status in complex strabismus cases
- Treatment of oscillopsia in acquired nystagmus (retrobulbar or 4 muscle injection)

In two randomized controlled trials, BTX-A injection was as effective as re-operation in the treatment of residual esotropia after surgery for acquired[46] or infantile[47] esotropia, in terms of both motor and sensory outcomes. For acquired esotropia in children, the same authors reported that 1–3 injections of BTX-A as primary treatment was effective in 88% of patients.[44]

The success rate of BTX-A for the treatment of infantile esotropia (alignment within 10 PD of orthotropia) varies between 33% and 89%.[36,42,43,48–51] McNeer reported a high success rate of alignment (89%) in selected patients with infantile esotropia and a small to moderate angle of deviation.[49] Campos reported similar findings with a single injection in patients younger than 8 months old and small-to-moderate deviations.[36] Other studies have found an unacceptable rate of treatment failure, concluding that the prolonged period of misalignment and the need for multiple injections could interfere with early alignment and establishment of binocular vision.[52,53] The validity of these studies is limited due to no randomization and masking, small sample sizes, short follow-up, or ill-defined patient populations.

The author's group conducted a prospective, single center, non-randomized comparison between BTX-A and surgery as primary treatment in infantile esotropia before the age of 36 months. The primary outcome was alignment within 10 PD of orthotropia after one surgery or 1–3 bilateral botulinum injections.[42] BTX-A was injected in 322 patients and 120 patients underwent surgery. The odds of achieving a successful outcome at the average angle of deviation pretreatment (38.6 PD) was 2.3 times higher in the surgical group than in the patients receiving BTX-A. However, there was a significant interaction between treatment group and pretreatment angle of deviation. A *post hoc* subgroup analysis was conducted using stratification by angle of deviation. This revealed that in subjects with deviations ≤30 PD, there was no statistical difference between groups, with 60% success rate in the surgery group and 59% in the botulinum toxin group (relative risk [RR], 1.03; 95% CI, 0.78–1.35). At deviation >30 PD, surgery achieved 69% success versus 36% with botulinum toxin (RR, 1.95; 95% CI, 1.53–2.49) (Fig. 85.5).

The relationship between the size of the strabismus angle and BTX-A effectiveness is well documented.[42,44,51] Studies that do not include appropriate stratification and effect modification analysis by different predictors, especially

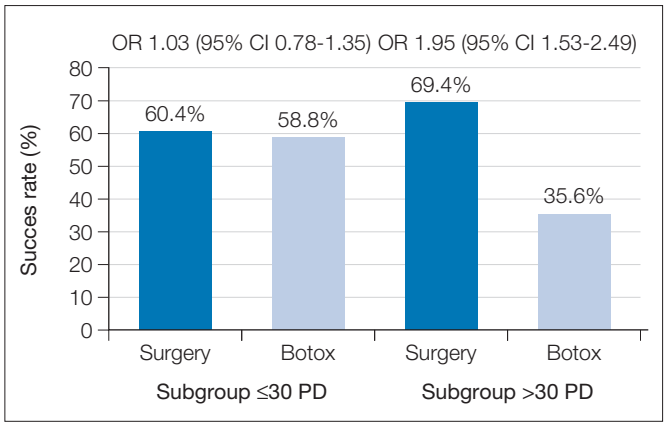

Fig. 85.5 Effectiveness of surgery versus botulinum toxin A (BTX-A) by angle of deviation. The pretreatment angle of deviation was statistically associated with a successful outcome in the BTX-A group only (the mean angle in the success group was 35.2 PD compared to 41.6 PD in the group with an unsuccessful outcome, $p<0.0001$). The magnitude of deviation did not predict a successful outcome in the surgical group ($p=0.17$). A *post hoc* subgroup analysis of those deviations classified as "small-angle esotropias" (≤30 PD) was performed. Stratification by this angle of deviation revealed that among subjects with deviations ≤30 PD, there was no statistical difference between groups (surgery 60%, botulinum toxin 59%; odds ratio [OR], 1.03; 95% confidence interval [CI], 0.78–1.35). At deviation >30 PD, surgery achieved 69% success versus 36% with botulinum toxin (OR, 1.95; 95% CI, 1.53–2.49).

magnitude of the deviation, will fail to demonstrate BTX-A true efficacy compared to surgery. Other possible interactions and confounders such as sensory status,[54] age,[36,49] and duration of misalignment may also play an important role in predicting which patients will have a favorable response to this treatment. The paucity of randomized clinical trials and well-conducted prospective studies have limited our understanding of which patients will obtain the greatest benefit from BTX-A.

BTX-A is less frequently used for exotropia and vertical deviations. Some use it in residual XT <15 PD or in young children (less than 3 years of age) with poorly controlled IXT, with the objective of delaying surgery until the age of 5–6 years. It has also been used successfully in patients with overcorrected exotropia and fusion potential.[55]

For cranial nerve palsies, the most common application of BTX-A is in the acute phase of a sixth nerve palsy to prevent contracture of the unopposed ipsilateral medial rectus muscle. Such contracture may lead to persistent esotropia even when there is recovery of the lateral rectus function. Reports of cases successfully treated with BTX-A injection, even after years of the onset of the esotropia, supports this concept, but whether this secondary contracture can be prevented is controversial. If truly effective, botulinum toxin injection into the medial rectus soon after the onset of the esotropia would improve the spontaneous recovery rate of sixth nerve palsies and decrease the rates of surgery.

Lee et al. reported their experience with non-traumatic acute sixth nerve palsy randomized to observation versus BTX-A injection to the ipsilateral medial rectus muscle.[56] At 6 months, no statistically significant difference was observed. Control of the deviation (within 10 PD of ortho) and single vision was achieved in 86% of the patients treated with BTX-A, and in 80% of the control patients. Despite randomizations, the two groups were different with respect to their initial angle of deviation (10 PD larger on average in the BTX-A group) and duration. Multivariate analysis adjusting for these differences (re-analyzed from published data) suggests that there may be an advantage to using BTX-A (odds ratio, 5.9; 95% CI, 0.6–57.8), although the power was insufficient to reach statistical significance. A non-randomized study conducted by the PEDIG reported that in 84 patients, age 2–79 years, with acute traumatic sixth nerve palsy, the adjusted relative risk of recovery in patients that received BTX-A within 3 months of injury was only 14% higher than in patients managed with observation alone (RR, 1.14; 95% CI, 0.70–1.35).[57]

The same investigators prospectively studied 56 patients with sixth nerve palsies of more than 6 months duration non-randomly allocated to observation, BTX-A alone, surgery alone, or a combination of surgery plus BTX-A. The success rates (absence of diplopia and ET <10 PD in primary gaze) were 10% (95% CI, 0–45%) in the BTX-A and 39% (95% CI, 17–64%) in the surgical groups. However, the authors warned that the different success rates might be due to selection bias and confounding by indication. For example, patients that received BTX-A were on average 27 years older than those who received surgery; 40% of patients that received BTX-A had complete paresis of the sixth nerve compared to 27% in the surgical group and most of the cases with a neoplastic etiology were treated with BTX-A alone. This study is also limited by its small sample size; the 95% confidence interval for the success rates in these two groups overlap significantly. Additional care should be taken when interpreting these results since these patients had a chronic longstanding deviation (median 270 days from onset to injection) and prevention of secondary contracture would not be expected.[58]

Medial rectus muscle injection of BTX-A prior to or during vertical muscle transposition can be used as an alternative to medial rectus recession, especially when anterior segment ischemia is of concern.

Complications

The complications of BTX-A treatment include subconjunctival hemorrhage, transient ptosis (Fig. 85.6) and hyperdeviations that usually resolve within 6 months (most resolving within several weeks of the injection). Transient vertical deviations occur in 5–30% of patients and ptosis in 15–35%. It is usually unilateral, and the risk increases with higher doses.[59] The amblyogenic potential of ptosis must be considered in young children, but most authors report only partial reversible ptosis with no amblyogenic effects observed. Pupillary abnormalities have also been reported after BTX injection; this has been described as a tonic pupil in the first week after the injection with delayed denervation hypersensitivity to pilocarpine.[60–63] It is unclear if this is due to direct trauma to the ciliary ganglion, anticholinergic toxicity from intraconal diffusion of BTX-A affecting the ciliary ganglion, and/or intraocular diffusion affecting the pupillary sphincter.[61,64] Rare, but severe, complications include globe perforation and retrobulbar hemorrhage. No systemic paralytic effect has been observed or suspected in any patient treated with the small doses of BTX-A used for strabismus. Antibodies to the toxin have not been detected in patients given small doses for ocular use. Therefore, repeat injections can be given when necessary.

In infantile esotropia, a temporary exotropia is not considered a complication of treatment; it is not only expected, but considered a sign of good prognosis.[36] It usually resolves by 6 weeks (4–10 weeks). Re-injection is recommended

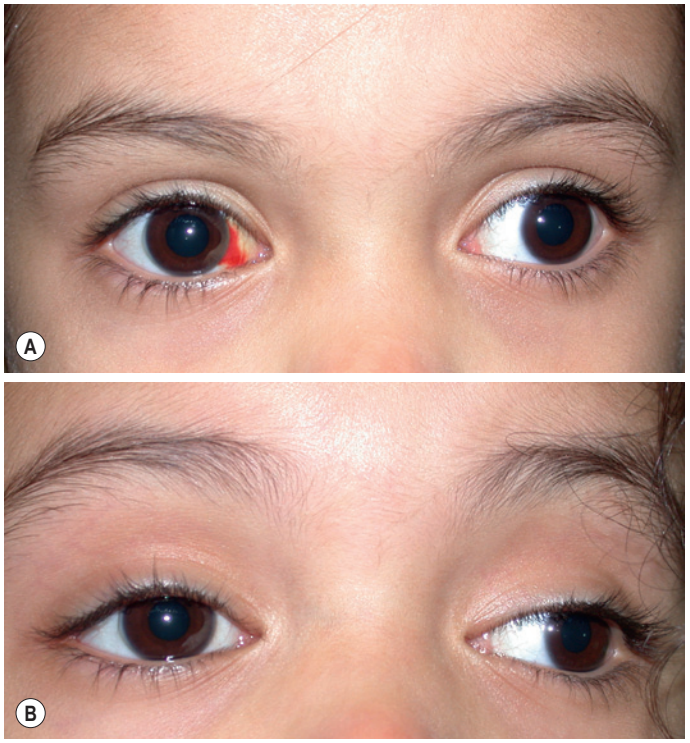

Fig. 85.6 Exotropia, ptosis (A) and subconjunctival hemorrhage (B) are commonly seen after botulinum toxin A injection.

after 4 months if the angle of esodeviation is more than 10 PD although, in many cases, we would consider earlier re-injection, especially in those cases in which an initial exodeviation was not obtained. Permanent exotropias are rare but patients with developmental delay or central nervous system abnormalities appear to be at higher risk of developing persistent overcorrections.[36,42,44,65]

Bupivacaine

The intramuscular injection of bupivacaine was first proposed as an alternative to muscle resection by Scott et al.[66] The recovery from the myotoxic effect of the anesthetic on the myofibrillar system of the extraocular muscles results in shorter, hypertrophic muscles with increased contractile strength and elastic force (stiffness).

The injection is done under topical anesthesia and EMG guidance using a volume of 1.5–3.0 mL (0.75–3%). Bupivacaine does not diffuse freely throughout the extraocular muscle so it is important to inject most of volume in the posterior third of the muscle, withdrawing the needle slowly while injecting the rest into the middle of the muscle to allow anterior spread. Low dose BTX-A (1–3 IU) can be injected simultaneously into the antagonist muscle to prevent the initial stretching of the bupivacaine-injected muscle, as the length at which the muscle is rebuilt is influenced by the position of the muscle during this process. At larger doses, significant orbital inflammation and edema can be observed and it is recommended to pretreat with oral prednisone for a few days. The paralysis caused by the anesthetic initially increases the strabismic deviation; 6–10 days later the improvement in alignment starts to occur.

In patients with small comitant non-paralytic horizontal strabismus (esotropia <25 PD and exotropia <35 PD) improvement (10–20 PD) and stability of alignment has been demonstrated for up to 5 years with 1–2 injections of bupivacaine (alone or together with BTX-A).[31]

Introduction

The management of patients with strabismus begins like any other patient. A careful history and examination is undertaken to understand current patient concerns, past treatments, and optimal treatments for the patient's current concerns. Treatment of strabismus may involve one or more of the following: correction of refractive error, orthoptics, patching, botulinum toxin injection, and surgery. This chapter will provide an overview of the surgical treatment of strabismus.

The indications, goals and risks of surgery should be clearly explained to the parents and the child, or, in the case of adults with strabismus, the patient. Parents and patients should understand the importance of ongoing follow-up, particularly during the period of visual development that extends through roughly the first decade of life.

Traditionally, the goal of strabismus treatment has been to re-align the visual axes in order to eliminate diplopia, or to maintain, or restore, binocular vision. Other functional indications for surgery might include the need to improve an abnormal head posture, eliminate abnormal eye movements, increase the area of single binocular vision in a patient with an incomitant deviation, or increase the functional visual field of a patient with esotropia. Restoring the normal anatomical position of the eyes without any other potential benefit is also a well-accepted indication for surgery. The psychosocial benefit of surgery for patients with strabismus has now been well documented, even in patients who may not achieve any other functional visual benefit.[1]

Surgically important anatomy

An understanding of the relevant anatomy and anatomical variations is an important prerequisite to performing strabismus surgery. The strabismus surgeon must not only be familiar with the anatomy of the extraocular muscles, but must also be cognizant of adjacent structures in the orbit and the ocular adnexa.

The conjunctiva

The conjunctiva is often inappropriately considered to be little more than a structure that must be incised to gain surgical access to the extraocular muscles. An understanding and recognition of key features of the conjunctival anatomy, especially medially, is necessary to perform appropriate conjunctival incisions to optimize access to the extraocular muscles. It also helps to ensure proper conjunctival closure and good cosmesis following surgery, and to avoid scarring and contracture of the conjunctiva, which can produce restrictive strabismus postoperatively.

The conjunctiva is a mucous membrane that covers the posterior surface of the eyelids and the anterior surface of the globe with the exception of the cornea (Fig. 86.1). The bulbar conjunctiva merges with the stroma and epithelium of the cornea. The palpebral conjunctiva begins on the lid margin at the mucocutaneous junction. The conjunctiva is tightly adherent to the underlying tarsus. The conjunctiva in the fornices is loose and is reflected into several folds, allowing movements of the globe not to be limited by connections between the palpebral and bulbar conjunctiva.

There is some redundancy of the conjunctiva so that excision of small portions of the conjunctiva is well tolerated without significantly altering its appearance or function. Only the bulbar conjunctiva is routinely incised during strabismus surgery. A fold of conjunctiva, known as the plica semilunaris conjunctivae (referred to simply as *plica* here), is present in the medial angle of the conjunctiva and represents a fold in the bulbar conjunctiva. When malpositioned or accidentally incised during strabismus surgery, it can result in serious cosmetic and/or functional problems.

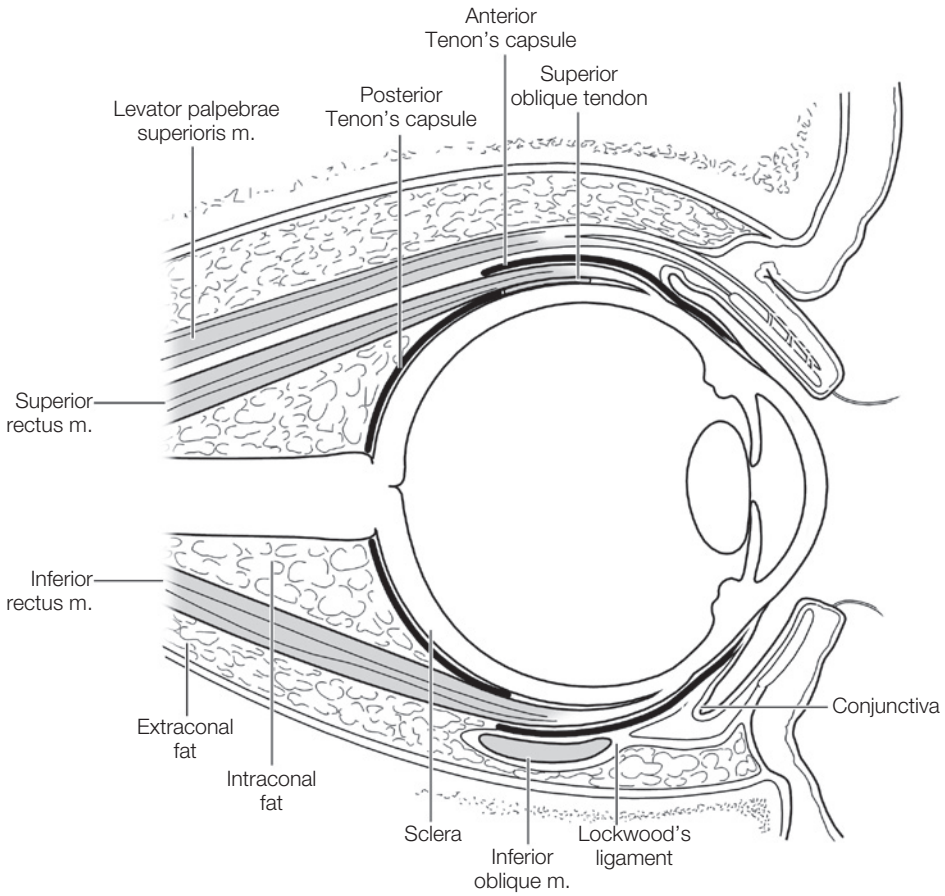

Fig. 86.1 Relationship of orbit fat to Tenon's capsule and other structures. Violation of the posterior portions of Tenon's capsule can result in protrusion of orbital fat into the surgical space. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/ Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

The sclera

The sclera is composed of densely packed collagen lamella. It is continuous with the dura mater of the optic nerve. It is continuous across the optic nerve head, forming the lamina cribrosa. The sclera is penetrated by a variety of vascular and neural structures anteriorly and posteriorly. The thickness of the sclera varies with age. It is typically thinnest in a newborn. The thickness of the sclera varies depending on its location on the globe. The sclera is thinnest behind the insertions of the rectus muscles, where its thickness is approximately 0.45 mm, a fact that is important to the strabismus surgeon since sutures may need to be passed into this thin area of the sclera to recess a rectus muscle. The sclera is approximately 0.6–0.7 mm thick at the corneal limbus and 1.1–1.3 mm thick at the posterior pole.

Tenon's fascia

The globe is suspended within the bony orbit by a fascial system, the bulk of which is known as Tenon's capsule. Tenon's capsule is a condensation of fibrous tissue that covers the globe from the entrance of the optic nerve at the posterior aspect of the globe extending to within 1 mm of the corneal limbus, where it fuses with the overlying conjunctiva. Tenon's capsule is thick and readily manipulated surgically in young patients, but becomes thin and fragile in older patients. A potential space exists both deep and external to Tenon's capsule known as the episcleral space (also known as sub-Tenon's space) and the subconjunctival space, respectively. These spaces are important during strabismus surgery, as they must be entered in order to gain access to the extraocular muscles. Several large and small structures penetrate Tenon's capsule including the optic nerve, the extraocular muscles, the vortex veins, and numerous other neurovascular structures.

The extraocular muscles penetrate Tenon's capsule to enter the episcleral space, coursing toward their insertions into the sclera (Fig. 86.2). Thus it is in the episcleral space, containing a length of about 7–10 mm of the rectus muscles, that the majority of extraocular muscle surgery is performed. After entering the episcleral space, the muscles have no sheath, but instead are covered by episcleral connective tissues that are loosely fused with the muscle. This tissue expands laterally along the edges of the muscles to form the intermuscular membrane and is present all the way to the muscle insertion. These tissues fuse with Tenon's capsule posteriorly where the muscles penetrate Tenon's capsule.

Tenon's capsule, as with all orbital tissues, should be handled with care. Tenon's capsule acts a barrier to orbital fat, and violation of the posterior aspects of the capsule can result in unwanted protrusion of orbital fat into the surgical space. This surgical complication can cause significant difficulties in completing planned surgery and can also lead to fat adherence and restrictive strabismus postoperatively.

The orbital aspect of the sheath of the superior rectus muscle is adherent to the internal surface of the sheath of the

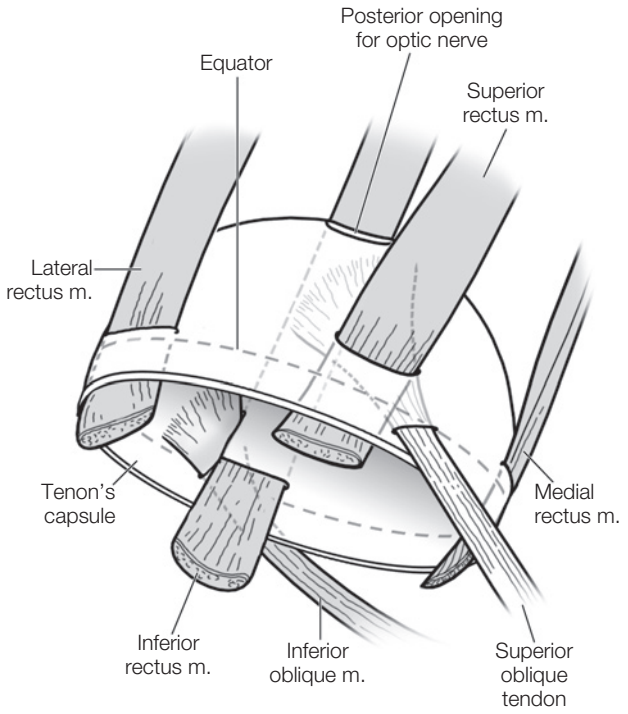

Fig. 86.2 Diagrammatic representation of Tenon's capsule and relationship to the extraocular muscles. Note that the rectus muscles are located external to Tenon's capsule posteriorly. They penetrate Tenon's capsule to enter the episcleral space, then course anteriorly to insert on the sclera. The inferior oblique muscle and superior oblique tendon enter the episcleral space anteriorly and course posteriorly to insert on the sclera. The rectus muscle pulleys, muscle capsule, and intermuscular capsule are not represented in this diagram. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

levator palpebral superioris muscle of the upper eyelid. The close association of these two muscles through their fascial sheaths accounts, in part, for the cooperative action seen during contraction of these two muscles, such as depression of the upper eyelid with downgaze. The surgeon must be aware of these connections because they can have important implications for the patient following strabismus surgery on the vertical rectus muscles, with resulting asymmetry of the eyelids postoperatively. The global portion of the sheath is tenuously associated with the sheath of the superior oblique tendon.

The fascial sheath surrounding the inferior rectus muscle is complex. It tends to be thicker than the fascial sheath surrounding the other rectus muscle, and this is readily apparent during surgery. The global portion of this sheath fuses with and becomes continuous with Tenon's capsule, while the orbital portion contributes to the formation of Lockwood's ligament of the lower eyelid, helping to explain why surgery on the inferior rectus muscle can alter the position of the lower eyelid.

The fascial sheath surrounding the portion of the superior oblique tendon distal to the trochlea is both strong and thick. The potential space inside of the superior oblique tendon sheath is continuous with the episcleral space. Numerous attachments extend from the sheath to adjacent structures including attachments to the global aspect of the sheath of the superior rectus muscle and attachments to the sheath of the levator palpebral superioris muscle of the upper eyelid. Abnormalities involving this sheath may play a role in the etiology of Brown syndrome.

The fascial sheath of the inferior oblique muscle surrounds the muscle from origin to insertion. It becomes thicker as the muscle approaches its insertion and it is usually tightly adherent to the orbital aspect of the sheath of the inferior rectus muscle. Small extensions of the sheath near the inferior oblique muscle insertion are directed to the sheath of the lateral rectus muscle and to the sheath surrounding the optic nerve posteriorly.

The rectus muscle pulley system

A reflection extending from Tenon's capsule envelops the posterior portion of the extraocular muscles that are extrinsic to the capsule at this position in the orbit. Fibroelastic sleeves consisting of dense bands of collagen, elastin, and smooth muscle surround the rectus muscles. These sleeves are suspended from the orbit and adjacent extraocular muscle sleeves by bands of tissue having similar composition. Often referred to as check ligaments, the function of these sleeves and their connections to the orbital walls is significantly more complex than simply to "check" movement of the globe. The term "check ligaments" should be discarded. Condensations and extensions from these muscle sheaths ultimately are also associated with anterior connections. Collectively, these structures form the rectus muscle pulley system and perform a specialized function within the orbit.

High-resolution computed tomography and magnetic resonance imaging have demonstrated that the paths of the rectus muscles remain stable relative to their adjacent orbital walls throughout most of their course in the orbit, even during eye movements and following large transposition procedures. Only the anterior aspect of the muscles actually move during normal eye movements into secondary gaze positions, while the posterior aspects of the rectus muscles are relatively fixed in position by rectus muscle pulleys, which are, in part, located near the equator of the globe. These rectus muscle pulleys essentially function as the effective origins of the rectus muscles. The pulleys are important for altering both the paths of the rectus muscles through the orbit and altering their function.[2]

Innervation of the extraocular muscles

The third cranial nerve (oculomotor nerve) is the most complex of the cranial nerves supplying innervation to the extraocular muscles. It provides innervation to four of the six extraocular muscles and to the levator palpebral superioris muscle. The inferior division of the third nerve innervates the medial and inferior rectus muscles as well as the inferior oblique muscle. The superior division innervates the superior rectus muscle and levator palpebral superioris muscle. The neurovascular bundle supplying the inferior oblique muscle enters the muscle from its posterior surface near the lateral border of the inferior rectus muscle.

The superior oblique muscle is innervated by the fourth cranial nerve (trochlear nerve). It is the only extraocular muscle that receives its innervation from the external or orbital surface of the muscle. The nerve passes superiorly from the medial side of the superior oblique muscle to the orbital side of the muscle prior to entering the muscle as several small branches.

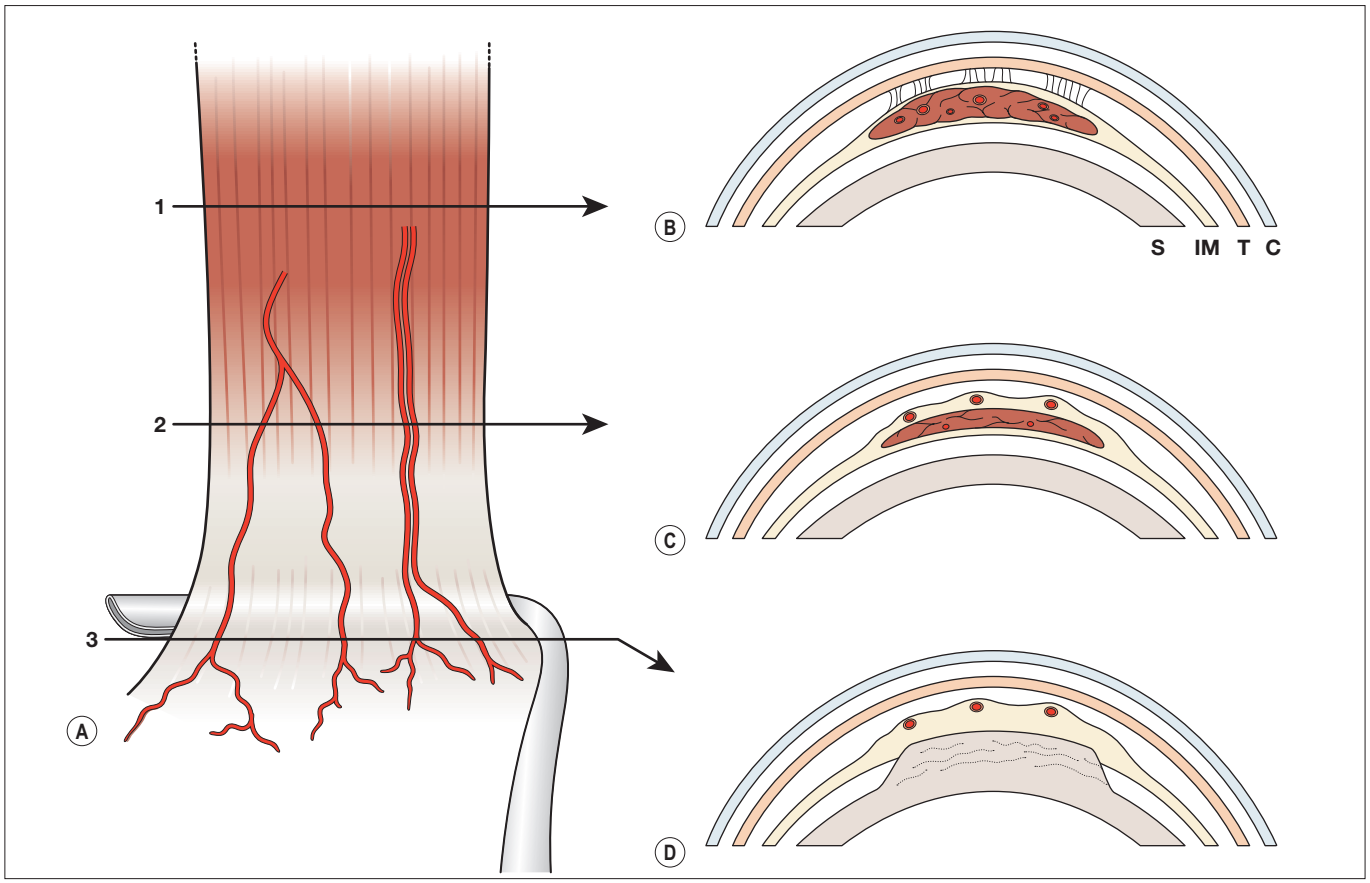

Fig. 86.3 Diagram of typical rectus muscle showing position of anterior ciliary vessels (ACVs). (A) Surgeon's view of inferior rectus. The ACVs emerge from the substance of the muscle, posterior to the transition from muscle to tendon. Anterior to this point, the ACVs travel on the surface of the muscle and tendon, following a somewhat serpentine course in a plane that is continuous with the muscle capsule, continuing onto the surface of the sclera. (B) Transverse section of rectus muscle at position A-1, posterior to the point of emergence of the ACVs. The vessels are deep in the muscle, not visible to the surgeon. (C, conjunctiva; IM, intermuscular septum (continuous with the muscle capsule); S, sclera; T, Tenon's capsule.) (C) Transverse section at position A-2 showing three ACV "groups" on the surface of the tendon, in a plane that is continuous with the capsule of the muscle and tendon. Each anterior ciliary vessel group can contain more than one anterior ciliary vessel. (D) Transverse section at position A-3: the tendon insertion site. The ACVs remain on the surface and continue onto the sclera, anterior to the tendon insertion.

The lateral rectus muscle is innervated by the sixth cranial nerve (abducens nerve). The muscle is innervated from the internal or bulbar surface of the muscle near the junction of the anterior two-thirds and posterior one-third of the muscle.

Blood supply to extraocular muscles

Each of the extraocular muscles receives its blood supply from the medial and lateral muscular branches of the ophthalmic artery. The medial branch supplies the inferior and medial rectus muscles as well as the inferior oblique muscle, while the lateral branch supplies the lateral and superior rectus muscles, the superior oblique muscle, and the levator muscle. The inferior rectus and inferior oblique muscles also receive a small contribution of blood supply from other sources.

The muscular arteries of the four rectus muscles enter the muscles on their global surfaces at approximately the junction between the anterior two-thirds and posterior third of the muscle. They course anteriorly, emerging onto the orbital surface of the muscle/tendon approximately 10–12 mm from the insertions of the tendons into the sclera, where they are known as the anterior ciliary arteries (Fig. 86.3). Each rectus muscle characteristically has two anterior ciliary arteries, except for the lateral rectus muscle, which characteristically has only one, though there is much variation. The course of the anterior ciliary arteries along the muscles and their tendons is highly variable. It is important to recognize this variation when planning surgery on patients who are at risk for anterior segment ischemia. The anterior ciliary vessels course forward to the episclera, where they supply branches to the sclera, limbus, and the conjunctiva. They enter the sclera near the limbus where they ultimately anastomose with the long ciliary arteries to form the major arterial circle of the iris. Veins corresponding to the muscular arteries drain into the superior and inferior orbital veins.

Gross anatomy of the extraocular muscles

Rectus muscles

There are four striated rectus muscles arising from the annulus of Zinn in the apex of the orbit. Each is 40 mm in length and inserts on the sclera anterior to the equator of the globe. Following the "spiral of Tillaux," the medial rectus inserts

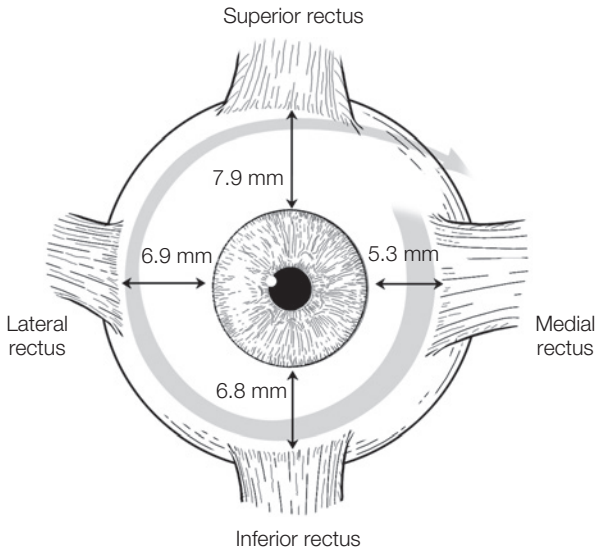

Fig. 86.4 The spiral of Tillaux. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

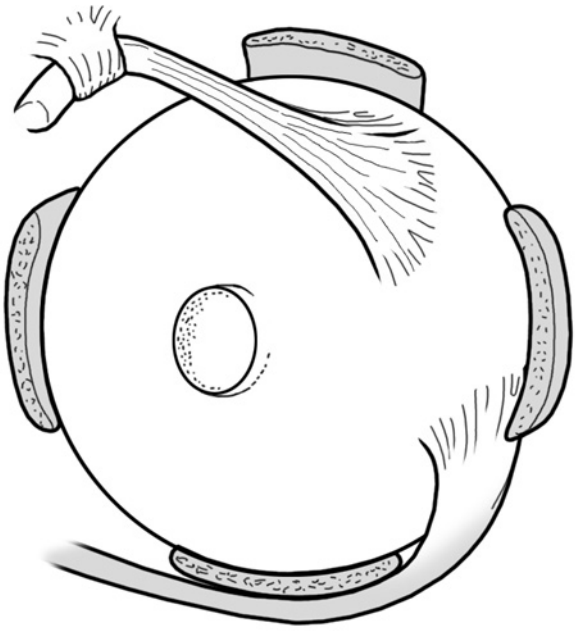

Fig. 86.5 Insertion of the inferior oblique muscle under the lateral rectus muscle. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

5.5 mm from the limbus, the inferior rectus 6.5 mm, the lateral rectus 6.9 mm, and the superior rectus inserts 7.7 mm from the limbus (Fig. 86.4). However, in actuality, the location of their insertions is somewhat variable. The insertions of the rectus muscles are curvilinear, particularly the vertical rectus muscles, whose temporal border insert further from the limbus than their nasal border.

The medial rectus muscle courses anteriorly along the medial wall of the orbit, inserting on the sclera without fascial attachments to an oblique muscle. Given its innate tension and relatively short arc of contact, the medial rectus muscle is at the greatest risk of inadvertent loss during surgery.

The lateral rectus muscle courses anteriorly along the lateral orbit, inserting on the sclera with a 10 mm arc of contact with the globe. The insertion of the inferior oblique muscle is in close proximity to the lower border of the lateral rectus muscle, 8–10 mm posterior to the lower pole of the lateral rectus muscle insertion (Fig. 86.5). Because of the close proximity of its insertion to the lateral rectus muscle, the inferior oblique muscle is often inadvertently hooked along with the lateral rectus muscle when isolation of the lateral rectus muscle is attempted during surgery. This complication is more likely to occur when the lateral rectus muscle has been previously recessed. Failure to recognize that the inferior oblique muscle has been inadvertently hooked can result in a significant postoperative motility disturbance that is restrictive in nature. The fascial attachments between the lateral rectus and the inferior oblique muscle help to locate the lateral rectus muscle if it becomes detached during surgery or trauma.

The inferior rectus muscle courses anteriorly, laterally, and inferiorly to insert on the sclera. It inserts an average of 6.8 mm posterior to the limbus. The temporal border of the tendon inserts approximately 2 mm more posteriorly than the nasal border of the insertion, a fact that should be considered when recessing or resecting the muscle. When hooking the inferior rectus muscle, the surgeon should avoid passing the hook too deeply into the orbit. A vortex vein can typically be seen posteriorly near both the medial and lateral borders of the

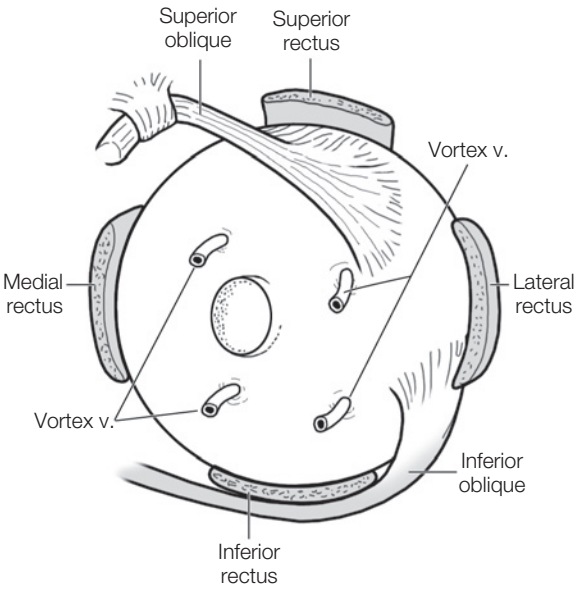

Fig. 86.6 Vortex veins as seen from the posterior aspect of the globe. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

inferior rectus muscle (Fig. 86.6). Disturbance of a vortex vein can result in considerable bleeding; continuation of surgery in this situation may be hazardous. The inferior rectus muscle forms a 23° angle with the visual axis when the globe in the primary gaze position. It has fascial attachments to the inferior oblique muscle and the lower eyelid retractors. If these attachments are not severed during significant recession or resection of the inferior rectus muscle, eyelid fissure changes may occur. Connective tissue attachments between the superior

rectus and the superior oblique muscles may assist the surgeon in locating a "lost" superior rectus muscle.

The superior rectus muscle courses anteriorly, laterally, and superiorly to insert on the sclera. The temporal border of the tendon inserts almost 3 mm more posteriorly then the nasal border. It is the only rectus muscle that inserts posterior to the ora serrata. As such, perforation of the eye wall near the insertion of the superior rectus muscle may involve the retina. A vortex vein can usually be found posteriorly near the border of the superior rectus muscle nasally and temporally (see Fig. 86.6). Vortex veins are infrequently damaged during surgery on the superior rectus muscle. Compared to the inferiorly located vortex veins, it is more difficult to inadvertently hook or otherwise manipulate when attempting to isolate the superior rectus muscle because it is somewhat protected by the superior oblique tendon. The superior rectus muscle forms a 23° angle with the visual axis when the globe is in the primary gaze position. The global aspect of the superior rectus muscle sheath is attached to the superior oblique tendon through relatively tenuous connections (Fig. 86.7). If the close relationship between these two structures is not recognized, the superior oblique tendon can sometimes be inadvertently hooked, along with superior rectus muscle tendon. If unrecognized, the superior oblique tendon may be recessed or resected along with the superior rectus muscle, producing unexpected torsional and vertical misalignment. The superior rectus muscle also has fascial attachments to the levator palpebrae muscle. If the attachments to the levator palpebrae muscle are not divided during recession or resection of the superior rectus muscle, eyelid fissure changes may occur.

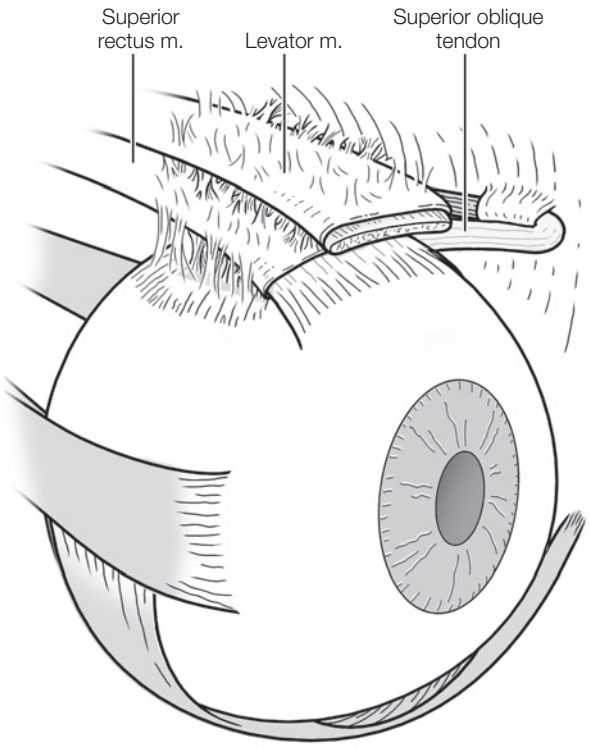

Fig. 86.7 Complex sheath of the superior oblique tendon. Note tenuous attachments to the sheath of the superior rectus muscle and to the levator muscle. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

Superior oblique muscle

The actions of the superior oblique muscle are incyclotorsion, depression, and abduction. The superior oblique muscle arises from the periosteum in the orbital apex above the annulus of Zinn and travels anteriorly along the superomedial orbital wall. It becomes a cord-like tendon, passing through the trochlea to run in a posterolateral direction at an angle of approximately 51° to 54° with the sagittal plane. The tendon passes under the superior rectus and fans out, inserting on the sclera in the superotemporal quadrant. The anterior pole of its insertion is located close to the lateral border of the superior rectus muscle, beginning 4–6 mm posterior to the superior rectus insertion. Its tendon is thin and broad, extending posteriorly for about 11 mm, but with considerable variability. The posterior end of the insertion lies 6–7 mm from the optic nerve. The superior temporal vortex vein can exit the sclera temporal to the superior oblique insertion, under the insertion or sometimes split the fibers of the insertion and pass through them (see Fig. 86.6).

Inferior oblique muscle

The actions of the inferior oblique muscle are excyclotorsion, elevation, and abduction. The inferior oblique muscle forms an antagonist pair with the superior oblique muscle with respect to torsion. The additional actions of the inferior oblique are not strictly antagonistic with the superior oblique.

The inferior oblique muscle originates from the maxillary bone adjacent to the lacrimal fossa. It passes posteriorly and laterally, forming approximately a 51° angle with the sagittal plane. After passing beneath the inferior rectus muscle, the inferior oblique muscle travels upward, inserting on the sclera, close to the macula. The tendon of the inferior oblique muscle is 1–2 mm long, the shortest of the extraocular muscle tendons. The anterior aspect of the inferior oblique muscle insertion is 8–12 mm posterior to the lateral rectus insertion, adjacent to its lower border. There is considerable variability in the location and configuration of the inferior oblique muscle insertion.

The inferior temporal vortex vein lies close to the posterior border of the inferior oblique muscle (see Fig. 86.6). It can be damaged when the surgeon isolates the inferior oblique muscle, or when repositioning an inferior oblique muscle near the sclera exit of the vortex vein exits during the process of recession.

The neurovascular bundle enters the inferior oblique muscle as it passes beneath the inferior rectus muscle. The neurovascular bundle may serve as the effective origin of the inferior oblique muscle, particularly after anterior transposition of the muscle.

General surgical considerations

Anesthesia

Most strabismus surgery is performed in an outpatient setting. The type of anesthesia depends upon one or more of the following factors: patient preference, surgeon preferences, nature of the operation planned, health of the patient,

and the recommendations of the anesthesiologist. No single anesthesia modality universally applies to all patients in all situations. Options include general, local, and even topical anesthesia. Children, and even most young adults, require general anesthesia because they usually are unable to tolerate surgical manipulation under local anesthesia.

Preoperative patient preparation

Safe and effective strabismus surgery begins even before the patient enters the operating room. The patient, and/or parents, should understand the risks, benefits, and alternatives of the proposed operation as well as have realistic expectations for the surgery. Ideally, this conversation will have occurred before the day of surgery and will be documented in the medical record. A surgical consent that properly documents these issues should also be signed and placed into the record. The laterality of the procedure should be recorded and the patient marked when indicated. Once the patient is brought into the operating suite, all parties in the room should perform a "time-out" and agree upon the procedure and other important details. The patient is then prepared for the operation.

The patient is properly positioned, and many strabismus surgeons instill one drop of 2.5% phenylephrine in the operated eye(s) prior to the surgical preparation to provide vasoconstriction and dilate the pupil should postoperative fundoscopy be needed. Alternatively, brimonidine 0.1% may be used. This causes effective conjunctival vasoconstriction without pupillary dilatation. The patient's skin, lid margins, and conjunctiva are the most common source of bacterial contamination, potentially causing serious postoperative infection following eye surgery. Thus cleansing these structures with an antimicrobial solution prior to surgery is among the most important ways the risk of postoperative infection can be reduced. Skin preparation can be accomplished with 5–10% povidone-iodine solution. Irrigation of the conjunctiva with half strength (5%) povidone-iodine solution prior to surgery has been shown to be effective in reducing conjuctival bacterial flora. Draping should sufficiently overlap the cleansed area of the skin, while allowing easy access to the operative site. The eyelashes can be covered with an adhesive drape if desired. Markings made on the skin preoperatively to identify the surgical site should be visible after the drapes have been placed (Fig. 86.8).

Surgical instruments and equipment

While there is a wide variety of instruments of various shapes and sizes available for strabismus surgery, the reality is that strabismus surgery can usually be performed very well with a set of basic instruments as shown in Figure 86.9. Many surgeons find 0.5 locking forceps and grooved muscle hooks to be particularly valuable in facilitating strabismus surgery.

Sutures used for strabismus surgery should generally be bioabsorbable, though not all surgeons agree. Polyglactin 910 (Vicryl®, Ethicon, Somerville, NJ) is one commonly used bioabsorbable synthetic suture. Two polyglycolic-based sutures that have been used for strabismus surgery are Biosorb™ C (Alcon, Fort Worth, TX) and Dexon™ S (Covidien/Medtronic, Dublin, Ireland). Non-absorbable suture, such as polyester fiber suture (Mersilene®; Ethicon, Somerville, NJ) is often used for procedures where a permanent suture is desired.

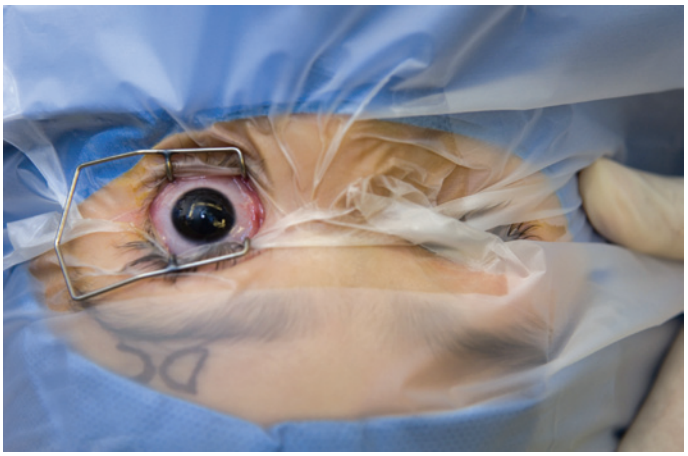

Fig. 86.8 Isolation of the lashes preoperatively with an adhesive drape. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

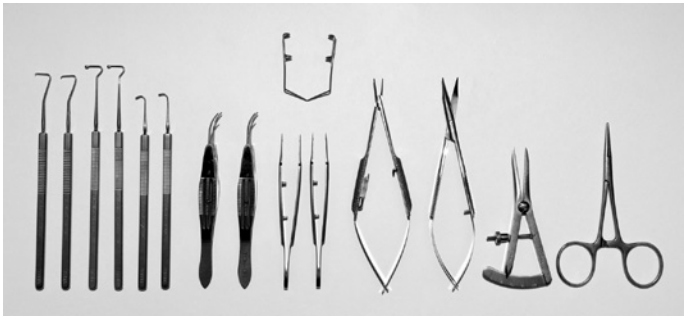

Fig. 86.9 A-List instruments that should be available for every case on the instrument stand. This list will vary depending on the personal preferences of the surgeon. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

Table 86.1 Characteristics of several available and commonly used spatula needles for strabismus surgery

Type of needle	S14	S24	S28	TG 100
Cross section				
Point of needle	Top	Top	Bottom	Top
Curvature (degrees)	112	90	164	97
Chord length (mm)	7.23	7.31	5.28	5.94
Radius (mm)	4.37	5.16	2.67	3.96
Thickness (mm)	0.33	0.33	0.2	0.2

Spatulated needles are preferred for making scleral passes during strabismus surgery because they facilitate keeping the needle in the surgical plane, thereby reducing the risk of scleral perforation. The features of four commonly used spatulated needles are highlighted in Table 86.1. A collagen suture, such as 6.0 plain gut suture is a good choice for closing the conjunctiva. These come on a variety of needles, the choice of which is based on surgeon preference.

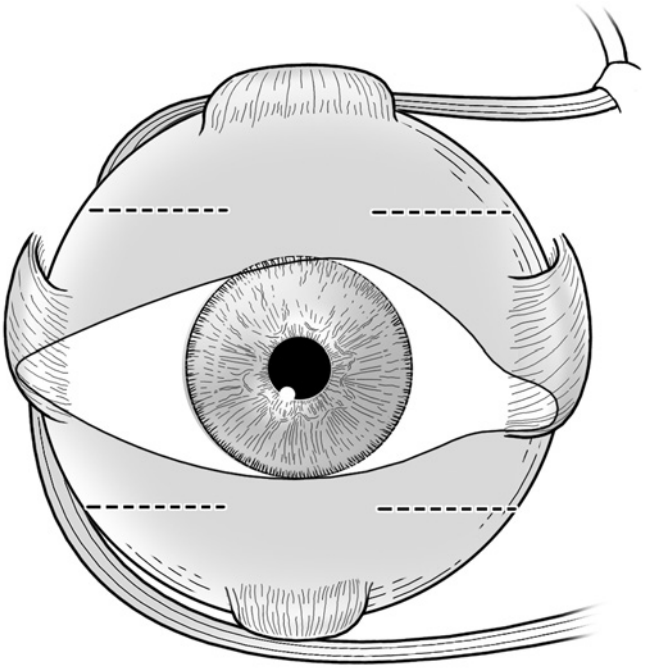

Fig. 86.10 Potential locations for placement of a fornix incision for rectus muscle surgery. Incisions placed in the lower quadrants are preferred, when possible. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

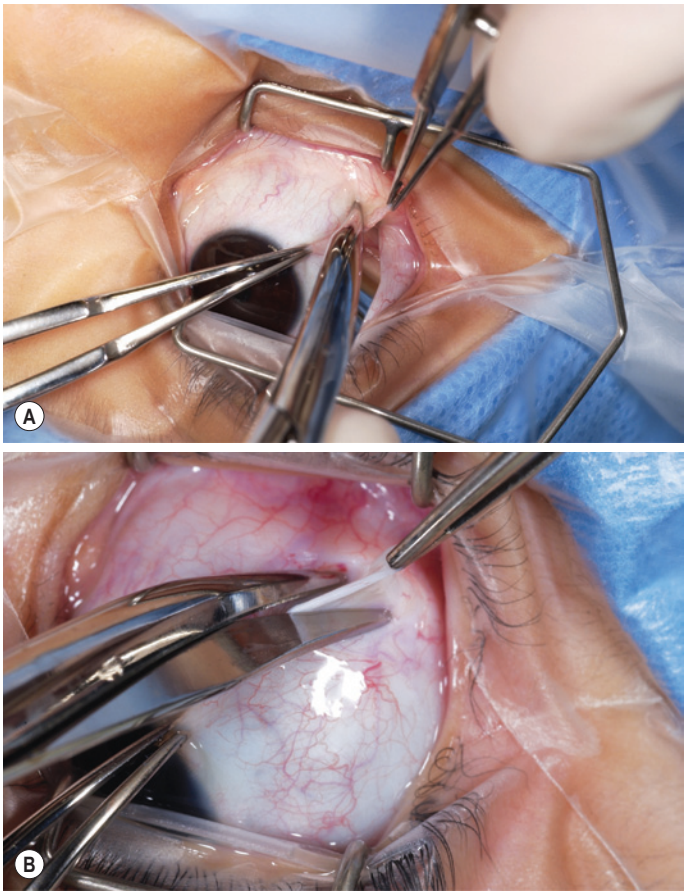

Fig. 86.11 Initiation of a fornix incision using one of two approaches. (A) Placing the adjacent conjunctiva under traction followed by incision; (B) Tenon's fascia is then incised to gain access to the episcleral space. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

The type of magnification, and even the choice of using or not using magnification during strabismus surgery, is based upon the personal preference of the surgeon. When magnification is desired, it can be accomplished through the use of a surgical microscope or through the use of surgical loupes.

Conjunctival incisions for rectus muscle surgery

All strabismus surgery requires an incision through the conjunctiva and through Tenon's fascia to gain access to the episcleral space, and all standard surgical manipulation of the extraocular muscles and associated structures occur in this space. The fornix and the limbal approaches represent the two most commonly utilized surgical approaches for strabismus surgery. Each has a set of advantages and disadvantages.

Fornix (cul-de-sac) approach

The fornix conjunctival incision approach to strabismus surgery was popularized by Parks and has undergone modifications by several surgeons.[3] A fornix conjunctival incision can be made in any of the oblique quadrants between adjacent rectus muscles (Fig. 86.10). Incisions in the inferior quadrants are preferable, when possible. The incision is made approximately parallel to the lid margins, 8–10 mm posterior to the limbus. The precise location and orientation of a fornix incision depends on a number of factors, including which muscle(s) is to be operated on, surgeon preference, the type of surgery (recession vs. resection), size of the recession, presence of other ocular pathology, and previous surgery.

The globe is rotated to expose the incision site. The conjunctiva is grasped with a fine-tipped forcep, placed under mild anterior traction, and a 6–8 mm incision is made (Fig. 86.11A). Tenon's fascia is then incised to gain access to the episcleral space (Fig. 86.11B). A hook is passed through the incision into the episcleral space and is advanced to isolate the rectus muscle insertion (Fig. 86.12). Many surgeons pass a second hook to assure that the entire width of the muscle has been isolated. A small muscle hook is used to retract the conjunctiva over the muscle insertion (Fig. 86.13A). The intermuscular septum, now visible, is placed under tension and incised to expose the toe of the muscle hook and underlying bare sclera (Fig. 86.13B). The toe of small hook is placed on bare sclera located behind the muscle insertion. While maintaining contact on the globe, the hook is slowly moved around the muscle insertion to assure that the full width of the muscle insertion has been isolated. The muscle insertion is then exposed by dissection of the muscle capsule and intramuscular septum. The amount of dissection required is dependent upon the procedure planned and the personal preference of the surgeon (Fig. 86.14). After completion of surgery, the incision can be closed with bioabsorbable suture, or the edges of the incision can be re-approximated without suture closure. This is largely a matter of surgeon preference.

Limbal approach

The limbal approach to strabismus surgery was popularized by von Noorden.[4] Many surgeons prefer limbal incisions because they are universally applicable to any and all rectus muscle operations. The limbal approach to strabismus surgery involves creation of a conjunctival flap that is initiated at the limbus and has its base in the fornix. The incision typically involves 2–3 clock hours of conjunctiva adjacent to the corneal limbus, with radial incisions that are 8–10 mm in length into adjacent oblique conjunctival quadrants between adjacent rectus muscles. Placement of limbal incisions for surgery on each of the rectus muscles is shown in Figure 86.15.

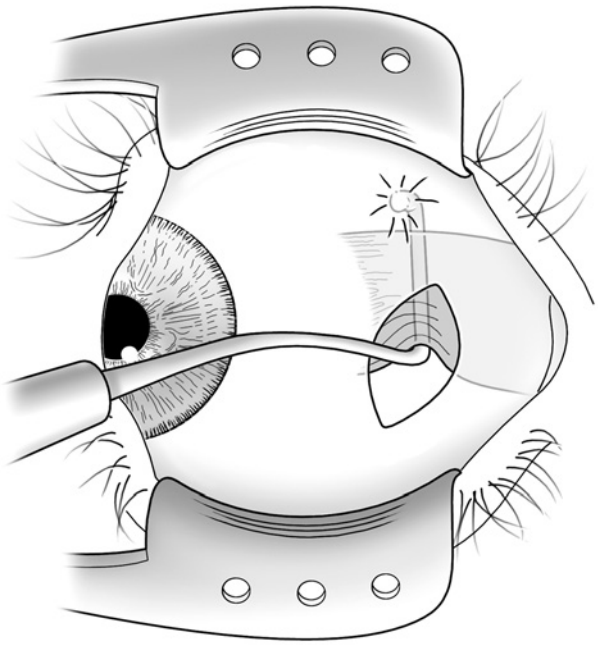

Fig. 86.12 Isolation of a rectus muscle insertion. The small hook is replaced by a larger hook to engage the entire muscle insertion. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

The conjunctiva incision is created using sharp dissection (Fig. 86.16A,B). The intermuscular septum is opened with blunt dissection on one or both sides of the muscle, adjacent to the muscle border (Fig. 86.17A). The muscle insertion is then isolated on a muscle hook, under direct visualization (Fig. 86.17B). The muscle capsule and intermuscular septum are then dissected to expose the rectus muscle (Fig. 86.17C). The amount of dissection of these structures depends on the preference of the surgeon and the procedure being performed. The incision is closed at the conclusion of surgery by placing a bioabsorbable suture at each edge of the conjunctival flap and suturing it to the adjacent intact conjunctiva. Additional sutures to close the radial relaxing incisions are permissible, but not required.

Conjunctival incisions for oblique muscle surgery

Surgery on the oblique muscles is generally performed through a fornix incision. The incision is created in a manner similar or identical to that described above. Oblique muscles can also be

Fig. 86.14 Dissection of the rectus muscle fascia. A sharp dissection of the intermuscular septum is done to expose the muscle border. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. approached through a limbal incision. Techniques to isolate the oblique muscles will be described in later sections.

Recession of the rectus muscles

General principles for recession of the rectus muscles

By moving a rectus muscle posterior to its original insertion site and re-attaching it to the sclera, the length/tension curve of the muscle is altered. This has the effect of "weakening" the muscle's effect on the globe. For most recessions, this effect is seen clinically only as a change in the alignment of the eye. Ocular ductions are not clinically limited unless a very large recession is performed, typically involving placement of the muscle posterior to the equator. This weakening effect probably occurs both because of a reduction in the distance between the origin and new insertion of the muscle, and because of changes in the relationship between Tenon's capsule, the intermuscular septum, and the rectus muscle pulley system. The relationship between the amount of recession required and the size of the deviation treated is not linear. As can be seen in Table 86.2, the effect obtained from recessing the medial rectus muscle is initially linear, but as the size of the recession increases, the relative effect of the procedure increases. Once the muscle is placed behind the equator, the incremental effect of further recession will then be reduced.

The "safe" limit for a recession depends on the condition being treated. In the mid-20th century, it was believed that the medial rectus muscle could not be recessed more than 5.0 mm without significantly interfering with movement of the eye. This belief resulted in many cases of congenital esotropia being undertreated. In an effort to improve the success rate of surgery, three or four muscles often were operated on at one time. It was later recognized that medial rectus recession of at least 7 mm could be performed without producing an adduction deficit. This led to a higher surgical success rate, particularly for larger deviations, while avoiding the need to operate on additional muscles. Some studies have shown that even larger recessions can be performed on the medial rectus muscle without creating a duction deficit. It may be necessary to accept a postoperative duction limitation for treatment of some conditions. For example, a patient with a large exotropia in a poorly seeing eye will usually gladly tolerate the requisite abduction deficit that will occur after a large recess-and-resect operation in order to avoid the need to operate on the "sound eye." The notion that there is a "maximum" amount of rectus muscle recession, should be avoided.

Recessions can be performed by attaching the muscle to the sclera at the desired position or by employing "hang-back," "hemi hang-back" recession, or various modifications of these techniques. Direct fixation of the recessed muscle to

the sclera is widely used. The muscle is sutured at the desired new location of the muscle and, unless intentionally offsetting the muscle, the muscle should be placed directly posterior to the original insertion site. The muscle is typically spaced to maintain the width of the recessed muscle in order to avoid "central sag." If sagging occurs, the center of the muscle can be sutured to the sclera. Because the muscle is sutured directly to the sclera, it allows accurate supra- and infraplacement and "slanting" of the recession, if desired, in "A" and "V" patterns.

Both experienced and occasional strabismus surgeons may use the hang-back and hemi hang-back techniques. The hang-back procedure can be used with recession of any of the rectus muscles. The muscle can be approached using either a limbal or fornix incision. The techniques have several potential advantages. The procedure is conducted at the original insertion site (hang-back) or more anterior then a conventional recession (hemi hang-back). Because of this, surgical exposure is typically excellent regardless of the amount of recession being performed. This makes the surgeon much less dependent on the skills of a surgical assistant, especially for large recessions. Improved exposure, and the more anterior location of the area to be manipulated during surgery, may result in less risk for deep needle passes, thus reducing the risk of scleral perforations. This may be especially true for less experienced strabismus surgeons. In the event that a perforation does occur when using a hang-back approach, it unlikely to result in damage to the retina because the rectus muscle insertions, with the exception of the superior rectus muscle insertion, are located anterior to the ora serrata.

In some animal experiments, very large rectus muscle recessions performed with the hang-back technique have been demonstrated to migrate anteriorly following the procedure.[5] If this occurred following hang-back surgery in patients, a surgical undercorrection would be predicted. To mitigate this potential problem, some surgeons prefer to use the hemi hang-back recession technique for recessions larger than 8 mm. In this method, the suture needles are passed through the sclera approximately half the distance between the original insertion site and the desired new recession position.

Measurement of recession

The distance a muscle is moved during a recession procedure can be measured from either its original insertion site or its distance from the limbus. There are a number of articles in the literature demonstrating variability of rectus muscle insertion sites as referenced to the limbus. The relationship between the muscle insertion site and the limbus has been shown to be particularly variable in young patients before the anterior segment is fully developed.

The distance the muscle is moved along the globe can be measured using a cord length or arc measurement. Most strabismus surgeons use a caliper. For larger recessions where the use of a caliper can be cumbersome, the measurements can be made in two steps. The amount of recession to be performed is divided in half. The caliper is then used to mark the sclera for one half the distance of the recession. This mark is then used to perform a second measurement of equal magnitude to mark the final position for suture placement. Alternatively, a curved Scott ruler may be applied to the globe. Graduated in millimeters, it avoids the error introduced by calipers, which becomes significant for larger recessions.

General recession technique

The general technique for rectus muscle recession is similar for each of the four rectus muscles. Specific concerns regarding each individual rectus muscle are discussed later. Each of the rectus muscles may be exposed using either a limbal or a fornix incision. In most situations, the choice of surgical approach depends entirely on the preference of the surgeon. There are

a few isolated situations in which one surgical approach may be preferred over the other. Re-operations and patients with thin or friable conjunctiva are sometimes operated through a limbal incision since it requires minimal stretching of the conjunctiva, reducing the risk of tearing the conjunctiva, a complication that may make conjunctival closure more difficult. However, even most re-operations and surgery on elderly patients with thin sclera can be conducted through a fornix incision.

Placing suture near the muscle insertion

After the rectus muscle is isolated on a muscle hook, a suture is placed in the muscle near its insertion into the sclera. The suture should generally be placed no closer than 1 mm from the muscle's insertion into the sclera. Most surgeons prefer the use of a single double-armed suture. A suture pass is started in the center of the muscle and passed half thickness through each edge of the muscle (Fig. 86.18). This is referred to as the transverse pass.

Following completion of the transverse pass, locking suture passes are made at the borders of the muscle near the insertion. The needle is passed full thickness through the muscle from the posterior to the anterior aspect of the muscle and behind the transverse suture pass (Fig. 86.19A). The needle should not be passed through the anterior ciliary vessels, as this may result in significant bleeding. It is sometimes helpful to pass the needle around these vessels in order to ligate them and prevent bleeding when the muscle is detached from the globe. Care should be taken to pass the needle directly through the muscle. After the suture is passed full thickness through the muscle, the needle holder is passed through the suture loop, grasping the needle and pulling it through the suture loop to create a locking bite (Fig. 86.19B). It is preferable to grasp the suture rather than the needle during this step to prevent damage to the needle.

Detachment of the muscle from the globe

The muscle sutures are placed between the index finger and thumb of the hand holding the muscle hook. Independent control of the sutures is helpful. If the surgeon grasps the muscle hook in his hand and is able to pull the sutures with his fingers independently of the hook, more space can be created between the insertion site of the muscle and the sutures, facilitating detachment of the muscle and reducing the risk of cutting the suture in the muscle (Fig. 86.20).

Securing the muscle to the sclera at its new location

Locking forceps are placed on the edges of the muscle stump after the muscle has been detached from the sclera, or at the edges of the muscle insertion prior to disinserting the muscle from the sclera. The sclera is marked to identify the entrance site for the upcoming needle pass where the new insertion site of the muscle will be placed. The mark on the sclera is made

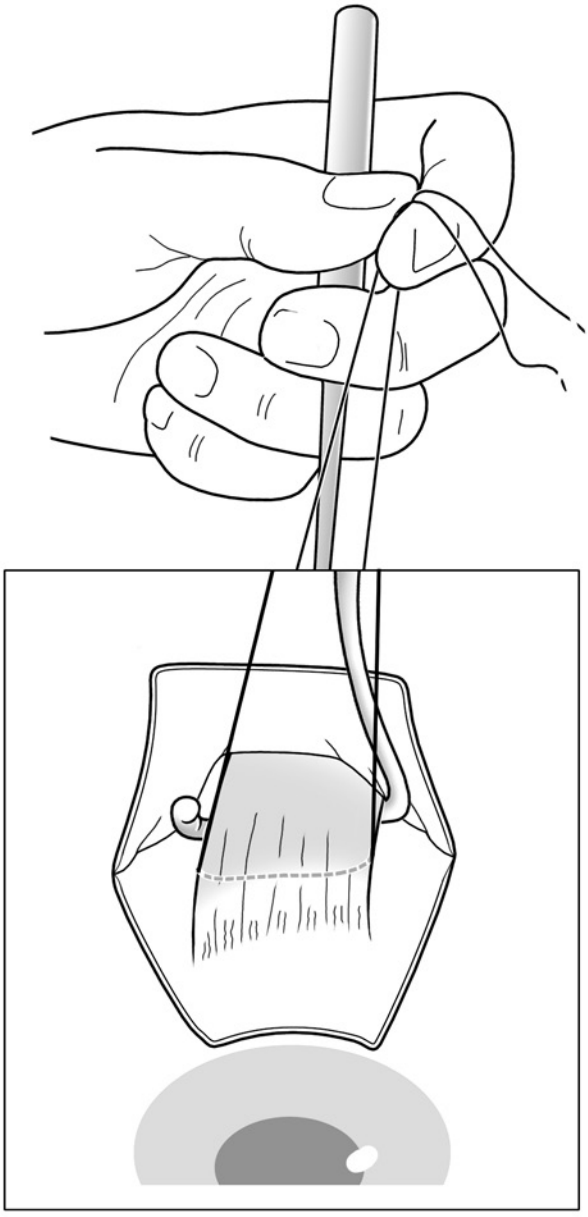

Fig. 86.20 Independent control of the muscle hook and the sutures while detaching the muscle from the sclera. Note that the surgeon is able to independently lift the sutures and provide more space to safely cut the muscle from its insertion site. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

by indenting the sclera at the desired recession site using a caliper (Fig. 86.21). This displaces fluid from the sclera and allows visualization of the underlying choroid which appears as a blue spot on the sclera.

The needle is then placed into the sclera at the previously marked positions. The sutures are then pulled through the sclera, tied and cut, making certain that the muscle remains in place in its new insertion site by maintaining anterior traction on the sutures when they are being tied (Fig. 86.22). If the needle passes are made too close to each other, the central portion of the muscle may sag posteriorly. This can be corrected by passing the needle back through the mid-portion of the muscle and behind the original suture, prior to cutting the muscle sutures. The suture is then tied to bring the central portion of the muscle up to its intended attachment site (Fig. 86.23).

Hang-back recession techniques

Securing the muscle to the sclera

The muscle is isolated and disinserted as previously described, and locking forceps are placed on the borders of the original insertion site. The suture needles are passed through the original insertion site. The needles are passed at an angle that allows both to emerge anterior to the insertion and as close together as possible (Fig. 86.24).

Measuring the recession

The sutures are advanced anteriorly through the sclera until the muscle rests firmly against the posterior aspect of the insertion. Unexpected, additional recession will occur if the muscle is not brought fully anteriorly in this step. This is especially likely to occur when the muscle is tight, where there is an increased tendency to retract away from the insertion site during this step of the procedure.

Calipers are placed perpendicular to the globe at the insertion site and a locking needle holder placed across the sutures as directed by the caliper measurements (Fig. 86.25). During this step, the caliper should rest gently on the insertion site. A smaller than intended recession will result if the caliper is pressed too firmly into the sclera during this step.

The suture is then tied and trimmed with the needle holder in place. The needle holder is removed and the globe is rotated away from the muscle, which causes the muscle to retract posteriorly. Alternatively, the muscle can also be placed into its new position by gently pulling the suture through the suture tract with a needle holder until the suture knots restrict further movement. If desired, the final position of the muscle can be confirmed by caliper measurement (Fig. 86.26).

Specific considerations for surgery on individual rectus muscles

There are unique considerations for performing surgery on each of the rectus muscles.

Medial rectus muscle

The medial rectus muscle does not have any direct attachments to adjacent oblique muscles, unlike the other rectus muscles. Because of this, the medial rectus muscle is more difficult to retrieve should it be lost at the time of surgery. Excessive dissection of the intermuscular membrane and muscle capsule is discouraged, in part for this reason. In addition to being unnecessary, it may alter the muscle pulleys and cause inadvertent muscle damage.

Inferior rectus muscle

The inferior rectus muscle has fascial attachments to Lockwood's ligament, the inferior orbital septum, and the tarsus of the lower eyelid. Because of these attachments, recession of the inferior rectus may produce retraction of the lower eyelid. Lid retraction may be seen with even moderate inferior rectus muscle recessions. Therefore, techniques designed to minimize the risk of lid retraction when performing a recession on an inferior rectus muscle are recommended, especially when large

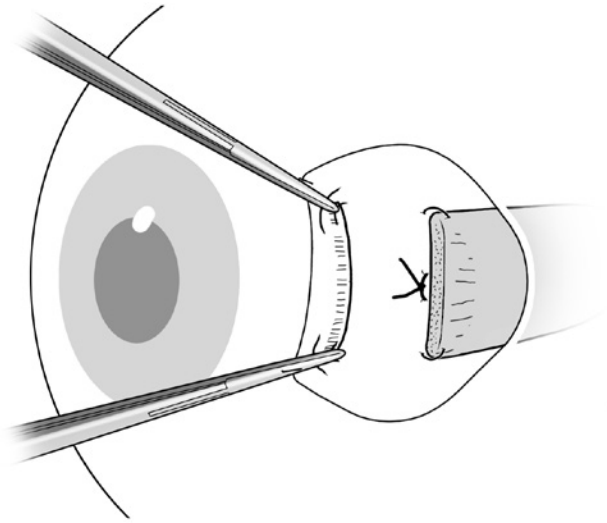

Fig. 86.22 The muscle has been pulled up to its new insertion and the sutures have been tied and cut. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

recessions are performed.[6,7] These may include advancement of the capsulopalpebral head after the recession is performed, or generous dissection of the attachments between the inferior rectus muscle and the lower eyelid prior to the recession.

Lateral rectus muscle

The insertion site of the inferior oblique muscle lies posterior to the insertion of the lateral rectus muscle. Therefore, the strabismus surgeon should exercise caution when attempting to isolate the lateral rectus muscle insertion on a muscle hook, to avoid inadvertently incorporating the inferior oblique on the muscle hook. This risk can be minimized by either passing the muscle from the superior side of the lateral rectus muscle insertion or by avoiding the tendency to pass the hook too deeply into the orbit during attempts to hook the lateral rectus muscle.

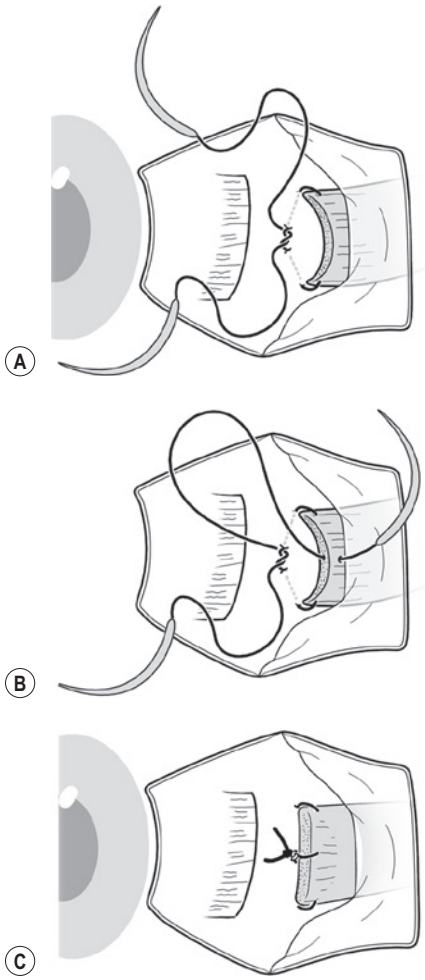

Fig. 86.23 Correcting malposition of the new muscle insertion. (A) The scleral sutures have been placed too close together causing the central aspect of the muscle to sag posteriorly. This can be corrected by (B) passing the needle through the central portion of the muscle, behind the original suture line, and (C) tying the suture to bringing the center of the muscle forward. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

Superior rectus muscle

The superior oblique tendon passes inferior to the superior rectus muscle starting approximately 5 mm posterior to the nasal border of the superior rectus muscle insertion. As with the lateral rectus muscle, it is important to avoid inadvertently hooking the superior oblique tendon when the superior rectus muscle is initially hooked. If the superior oblique tendon is unknowingly hooked along with the superior rectus muscle insertion, it is possible to perform an unintentional tenotomy on the superior oblique tendon when the superior rectus muscle is detached from the globe, potentially producing a significant iatrogenic motility disturbance. Once the insertion of the superior rectus muscle is isolated on a muscle hook, it should be inspected to ensure that the superior oblique tendon has not been inadvertently hooked. If this has occurred, the superior oblique tendon can be gently lifted off the surface of the globe while a new muscle hook is placed under the superior rectus muscle insertion, excluding the superior oblique tendon (Fig. 86.27).

Similar to the relationship between the inferior rectus muscle and the lower eyelid retractors, the superior rectus muscle has significant attachments to the levator muscle of the upper eyelid through the fascial sheaths of these two muscles. Moderate to large recessions of the superior rectus muscle may also cause eyelid retraction. Dissecting these attachments at least 12 mm posterior to the insertion site of the muscle at the time of superior rectus muscle recession will help to minimize this postoperative complication.

Strengthening procedures of the rectus muscles

Though rectus muscle resection and plication are commonly referred to as strengthening procedures, this characterization is technically inaccurate. In reality, these surgeries alter the relationship of the rectus muscle to the globe, changing its length–tension curve. Like the clinical effect of recession, the "strengthening" of a muscle is generally seen only in the change that occurs in the alignment of the eye(s) upon which the resection is performed. A change in the movement of the eye is not clinically obvious following surgery.

Resection

General resection principles

Compared to rectus muscle recession, a resection procedure generally produces more postoperative discomfort and redness

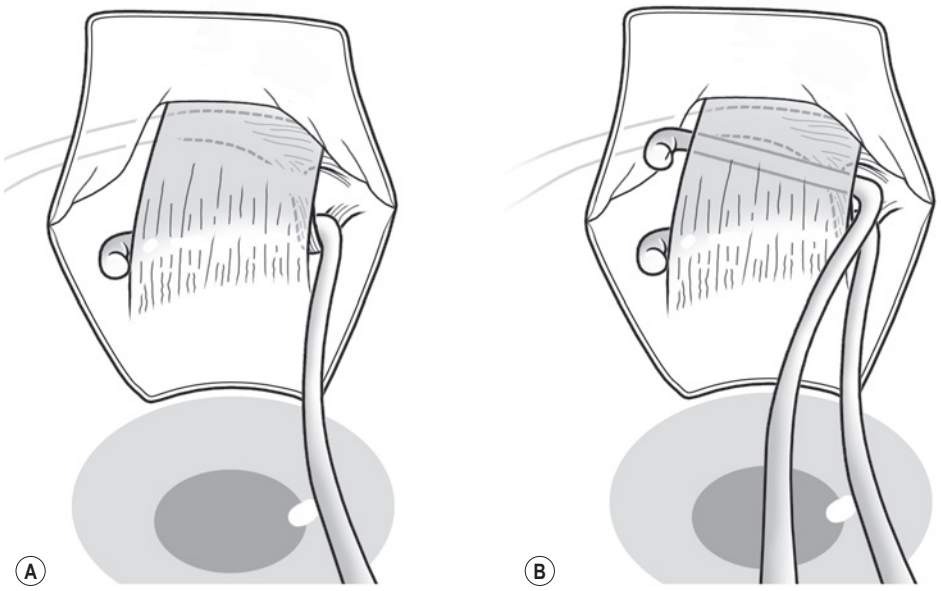

Fig. 86.27 Isolation of the superior rectus. (A) The tendon of the superior oblique has been unintentionally isolated in the hook along with the superior rectus muscle. (B) The superior rectus muscle and superior oblique tendon are lifted off the surface of the globe to allow passage of a second muscle hook to isolate the insertion of the superior rectus muscle only. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

of the conjunctiva. Additionally, the muscle that is sutured to the original insertion site after the resection has taken place is thicker than the tendon, and may become visible beneath the conjunctiva postoperatively. This is especially true for the medial rectus muscle, a finding that can be cosmetically distressing to some patients. Dellen formation is more likely to occur due to greater edema of the conjunctiva adjacent to the limbus following resection surgery. Large resections of the medial rectus may result in mild to moderate anterior displacement of the plica semilunaris, which can be a cosmetic concern. For these reasons and others, many surgeons prefer to perform recession procedures when possible. Despite these drawbacks, rectus muscle resection procedures are effective and they do play an important role in the treatment of strabismus. Common indications in which a resection may be preferred include the desire to limit surgery to only one eye, and treatment of a consecutive deviation in a patient who has previously undergone recession surgery.

General resection technique

Preparation of the muscle for resection

Once the rectus muscle has been isolated, the intermuscular membrane, muscle capsule, and other fascial tissues are dissected to allow for suture placement posterior to the insertion site of the muscle. During dissection, the surgeon should be careful to avoid penetrating Tenon's capsule, which can promote intrusion of extraconal fat into the operative site; this can produce restrictive strabismus that is difficult to repair.

Resection of the muscle

A second hook is placed between the muscle and the sclera, posterior to the hook that has been used to isolate the muscle insertion. A caliper is used to mark the position of the posterior limit of the resection. Coating the tip of the caliper with a sterile gentian violet skin-marking pen prior to this step may be helpful (Fig. 86.28A). When the caliper makes contact with the muscle, the ink will be transferred to the muscle surface, facilitating later steps of the procedure. Some surgeons place a central safety knot in the muscle at the caliper mark while others do not (Fig. 86.28B). Transverse passes are made, followed by locking bites at the borders of the muscle. A small straight hemostat is placed anterior to the suture and the posterior muscle hook removed (Fig. 86.28C).

The muscle is then detached from its insertion on the globe (Fig. 86.29) and the distal portion of the muscle is excised. During this step, the surgical assistant should assure that the sutures are retracted from the surgical site, to avoid inadvertently cutting them. Some surgeons prefer to cauterize the distal edge of the muscle prior to removal of the hemostat, though this step is not universally necessary. The hemostat can be left in place and used to help hold the muscle in position at the insertion while suturing, if desired.

Re-attaching the muscle to the sclera

The sutures are then passed through the original insertion site of the muscle and the now-shortened muscle pulled up to the original insertion site. The surgical assistant may facilitate this process by retracting the globe toward the muscle using locking forceps attached to the insertion site, to reduce the amount of tension placed on the muscle during this step of the procedure, or the hemostat may be used to hold the muscle in position if it has not yet been removed. The sutures are then tied and trimmed. Occasionally, the muscle is noted to have retracted posteriorly during the process of tying the sutures. In the event that the muscle does move posteriorly and this is noted after the sutures have been tied, a suture may be passed through each pole of the muscle and brought through the insertion site. The sutures are then tied and cut to bring the muscle back to its proper position (Fig. 86.30).

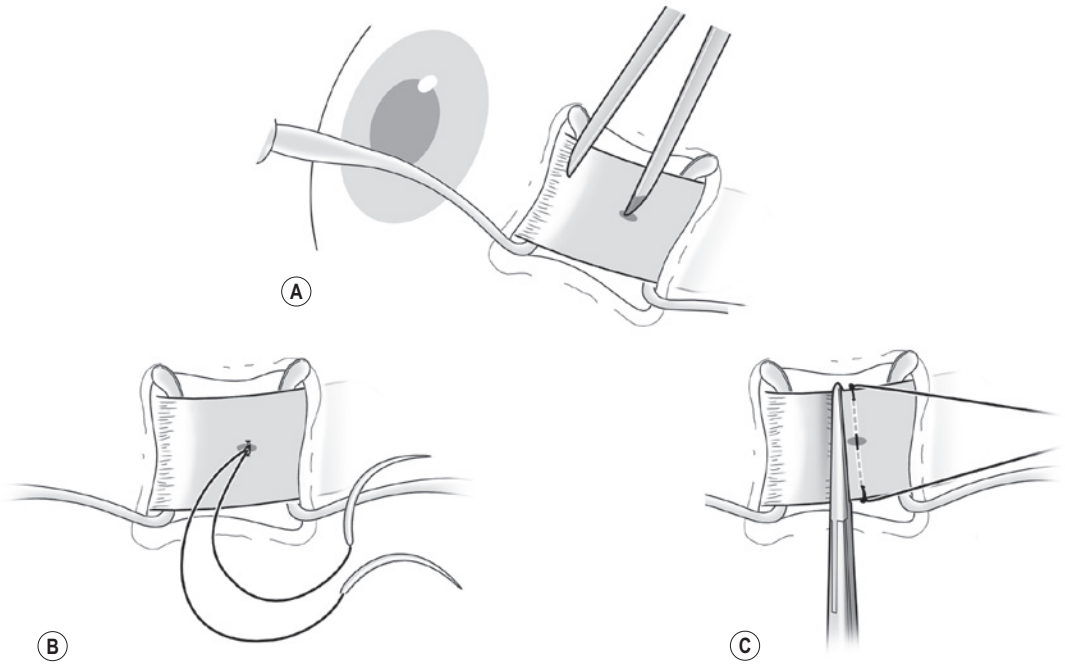

Fig. 86.28 Measuring and marking the resection. (A) After coating the tip of the caliper with ink from a sterile gentian violet skin-marking pen, the caliper is used to mark the resection position on the muscle. Rectus muscle plication

A rectus muscle plication can be used in lieu of a resection. Plication has the potential advantage of preserving the anterior ciliary circulation, thereby reducing the risk of anterior segment ischemia in susceptible patients. It also eliminates the potential loss of a muscle. In addition, the surgery tends to be less traumatic than a standard resection. In one version of this technique, two single-armed sutures are placed at each edge of the muscle. The needles are then passed just anterior to the insertion of the muscle and the sutures are used to pull the posterior portion of the muscle forward and fold it on itself.[8]

Surgery on the inferior oblique muscle

The most common indications for surgery on inferior oblique muscles include superior oblique palsy, primary inferior oblique overaction, "V" pattern horizontal strabismus with inferior oblique overaction, and dissociated vertical deviation associated with inferior oblique overaction. Most surgical procedures done on the inferior oblique muscle are designed to weaken its function, and will be the focus of this section.

Identification and isolation of the inferior oblique muscle

Most surgical procedures performed on the inferior oblique muscle are performed on its distal end. A discussion of the full scope of procedures that can be performed on the inferior oblique muscle is beyond the scope of this chapter, which will highlight the most important procedures performed on this muscle. Surgical access is generally gained through a standard fornix conjunctival incision, followed by incision of Tenon's capsule to gain access to the episcleral space. Excellent visualization of the inferior oblique muscle can usually be obtained by retracting the globe superiorly and nasally. The posterior border of the muscle can usually be identified

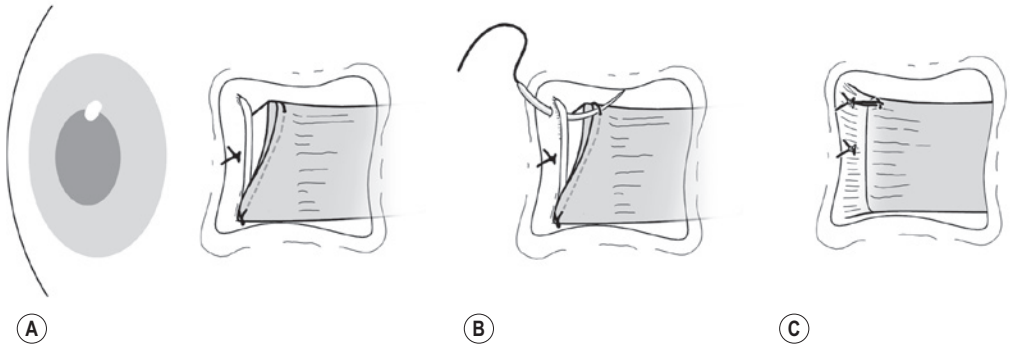

Fig. 86.30 Correcting posterior movement of the muscle during resection. (A) The suture has been tied and the muscle is not in direct contact with the original insertion site. (B) To correct this, a suture is passed through the insertion site and behind the muscle suture at each pole of the muscle, and (C) the newly placed sutures are tied and cut, bringing the muscle to the desired location. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Fig. 86.31 Surgical exposure of the surgical site for inferior oblique surgery using a lateral rectus muscle bridle suture. One or two hooks are placed into the incision and retracted inferiorly. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

approximately 10–12 mm from the limbus in Tenon's fascia as it is retracted from the globe (Fig. 86.31).

The posterior border of the inferior oblique muscle can be easily identified if good exposure has been obtained. Important landmarks that can aid the surgeon in confirming that the posterior border of the inferior oblique muscle has been identified include visualization of the posterior border of the inferior oblique muscle, the sclera, and the adjacent vortex vein simultaneously (see Figs 86.31 and 11.2C). A muscle hook is passed under the posterior border of the inferior oblique muscle, directed first toward the floor of the orbit and then drawn anteriorly (Fig. 86.32). The surgeon then sharply dissects the capsule to expose the inferior oblique muscle insertion on the sclera temporally (Fig. 86.33).

Inferior oblique muscle recession

The inferior oblique muscle is detached from the sclera at its insertion. This process can be facilitated by placement of a hemostat across the inferior oblique muscle several millimeters proximal to its insertion into the sclera, if desired (Fig. 86.34A). Cautery may be applied to the proximal muscle edge to prevent bleeding when the hemostat is removed. An absorbable suture such as 6-0 polyglactin is then placed in the muscle near its distal end (Fig. 86.34B). The muscle is then sutured to the sclera along the normal course of the inferior oblique muscle. The authors most commonly place the anterior muscle suture 2–4 mm posterior to the temporal border of the inferior rectus muscle insertion, and near the temporal border of the inferior rectus muscle (Fig. 86.34C). Some surgeons prefer graded recession of the inferior oblique muscle based on the degree of inferior oblique overaction.

Inferior oblique myectomy

After isolation and dissection of the inferior oblique muscle, two hemostats are placed across the inferior oblique muscle (Fig. 86.35A). This is followed by myectomy of the tissue between the hemostats. Cautery is applied to the cut edges of the muscle (Fig. 86.35B) prior to releasing them from the hemostats.

Denervation and extirpation

Denervation and extirpation of the inferior oblique muscle is an infrequently used procedure. It is reserved for pronounced overaction of the inferior oblique muscle and many surgeons reserve the procedure for recurrent inferior oblique overaction, despite previous weakening procedures on the inferior oblique muscle. The procedure involves identification and transection of the neurovascular bundle combined with removal of a large distal segment of inferior oblique muscle.

Inferior oblique anterior transposition

The most common indications for the inferior oblique anterior transposition procedure is dissociated vertical deviation coupled with inferior oblique overaction in the same eye. The procedure is usually performed bilaterally because asymmetry of the eyelids can occur after unilateral inferior oblique anterior transposition.[9] Anterior transposition of the inferior oblique muscle is virtually identical to inferior oblique recession except that the new muscle insertion is placed at or near the insertion

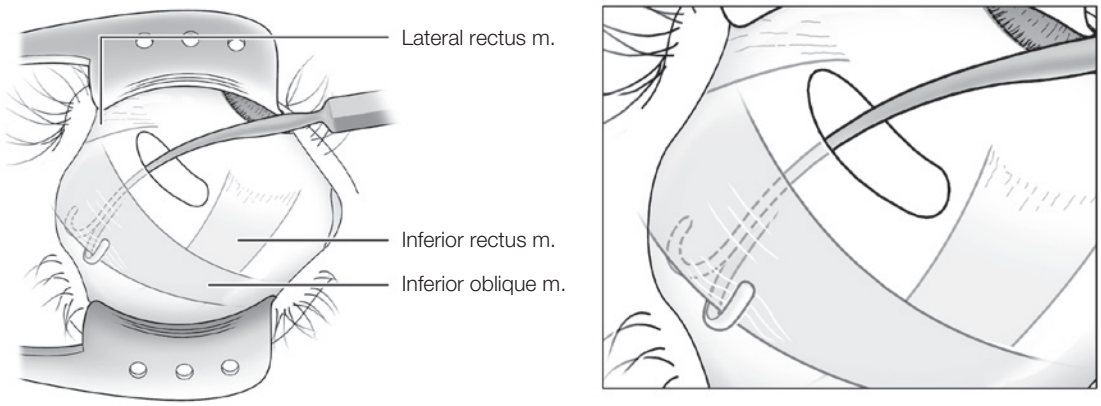

Fig. 86.32 Isolating the inferior oblique muscle on a muscle hook. A Scobee muscle hook is placed at the posterior border of the inferior oblique muscle. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

of the inferior rectus muscle. It is generally placed no more than 1 mm anterior or posterior to the insertion, and is most commonly placed at the level of the insertion, at its lateral edge (Fig. 86.36).

Surgery on the superior oblique tendon

Surgical procedures involving the superior oblique tendon are among the most intricate surgical procedures performed by a strabismus surgeon. Both the complex functions of the superior oblique muscle and its complex anatomical configuration make surgery on the superior oblique tendon unforgiving when proper indications and techniques are not followed. Postoperative problems are often difficult to remedy satisfactorily.

The function of the superior oblique muscle/tendon can be enhanced or reduced. The broad insertion of the superior oblique tendon into the sclera, as well as the anatomy of the insertion relative to the equator of the globe and the functional origin of the muscle in the superonasal aspect of the orbit, allow the surgeon to alter specific functions of the superior oblique muscle/tendon by manipulation of different portions of the superior oblique tendon and its insertion. The anterior fibers of the superior oblique tendon, insert anterior to the equator of the globe. They are thought to be primarily responsible for incyclotorsion of the globe. The posterior fibers course behind the equator and are primarily responsible for abduction and depression.

Forced traction testing of the superior oblique tendon

Both forced traction testing and exaggerated forced traction testing are useful adjuncts during surgery on the superior oblique tendon (Figs 86.37 and 86.38). They can be very useful in identifying a lax superior oblique tendon that is commonly found in patients with a congenital superior oblique palsy. They are also useful to confirm that the entire tendon has been transected when performing a tenotomy or tenectomy.[10]

Superior oblique strengthening procedures

Superior oblique strengthening procedures can be performed on the anterior portion of the tendon or on the full thickness

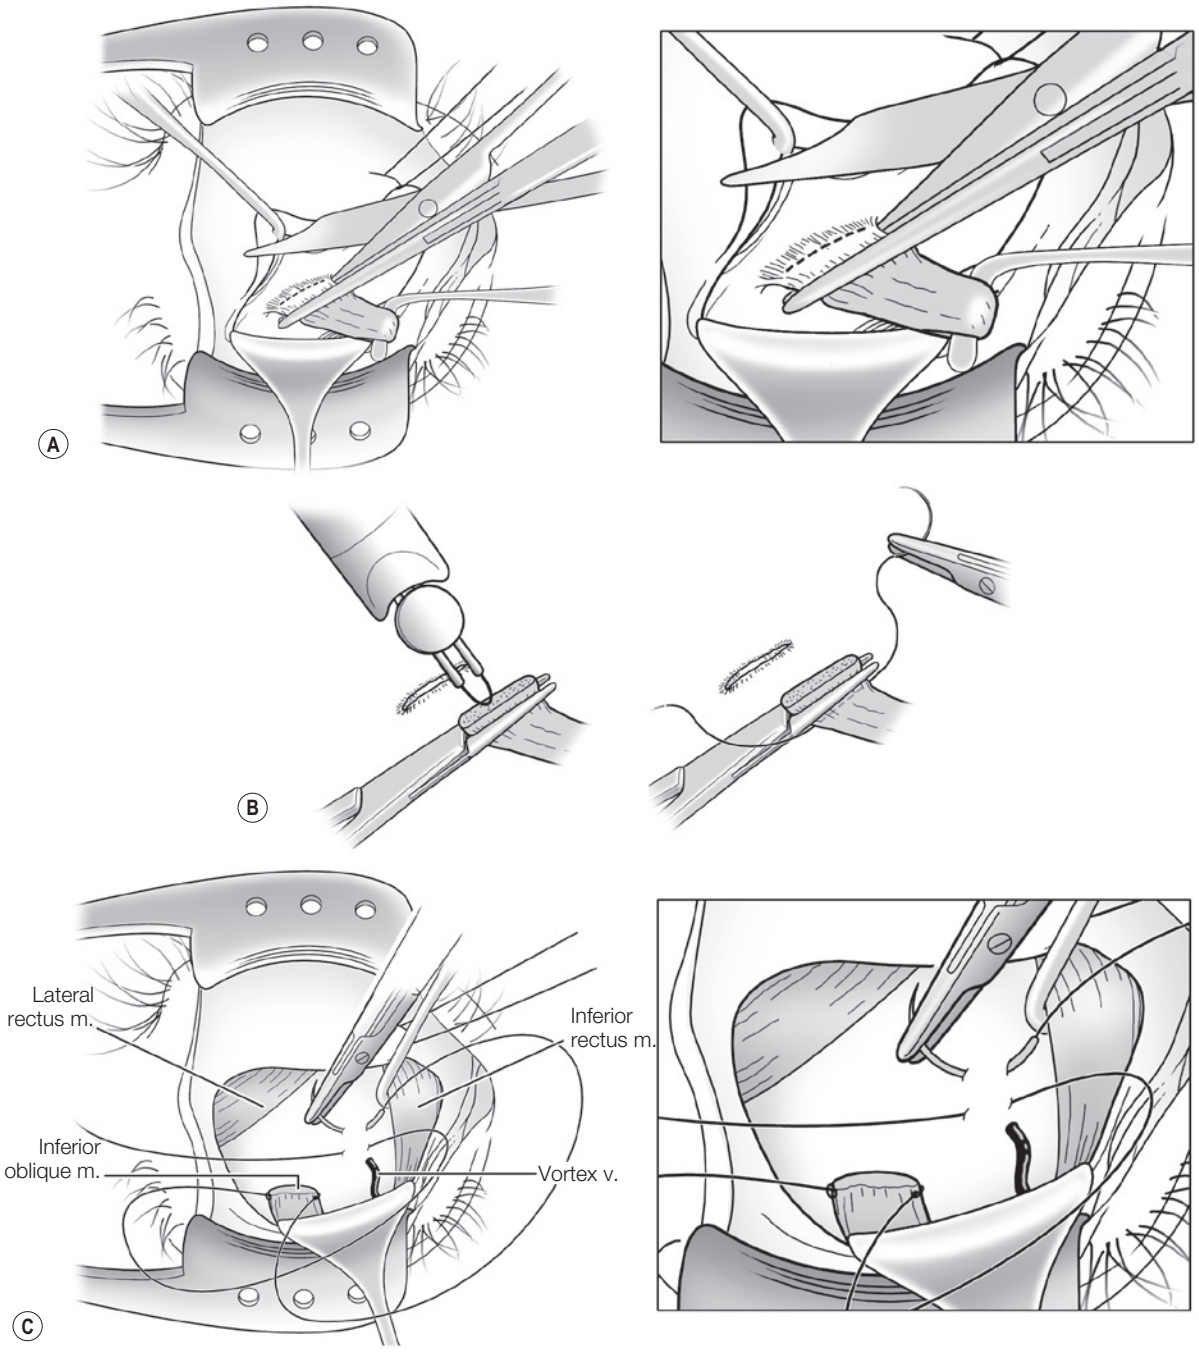

Fig. 86.34 Inferior oblique recession. (A) The muscle is transected distal to a hemostat placed across the muscle near the insertion. (B) Cautery is applied to the proximal muscle edge and absorbable sutures placed in the muscle posterior to the hemostat. (C) The muscle is sutured to the sclera; the anterior suture is most commonly placed 2–4 mm posterior to the temporal border of the inferior rectus muscle. Note the vortex vein just behind this location. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Fig. 86.35 Inferior oblique myectomy. (A) Two hemostats are placed across the muscle, separated by 5–10 mm. (B) The myectomy is performed, the muscle edges cauterized. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

of the tendon through tucking procedures. Tucking the full width of the tendon tightens both the anterior and posterior tendon fibers and therefore increases all three functions of the superior oblique muscle including incyclotorsion, depression, and abduction. Tucking of only the anterior fibers of the tendon selectively increases the incyclotorsion function of the superior oblique muscle and is used when excyclotorsion is the primary problem.

Superior oblique tucking procedure

A tuck of the superior oblique tendon may be performed for the treatment of superior oblique palsy as an isolated procedure, or combined with a weakening procedure of another cyclovertical muscle such as the ipsilateral inferior oblique muscle, ipsilateral superior rectus muscle, or contralateral inferior rectus muscle. Following a tuck of the superior oblique tendon, some degree of iatrogenic limitation of elevation in adduction can be anticipated. This is most likely to occur when a superior oblique tendon tuck is performed in conjunction with a weakening procedure of the ipsilateral inferior oblique muscle.

Identifying the superior oblique tendon

The superior rectus muscle is isolated and a small muscle hook is used to retract conjunctiva and Tenon's fascia posteriorly along the lateral border of the superior rectus muscle. A small dissection of the check ligaments above the superior rectus muscle may facilitate its exposure. A Desmarres or other retractor can be placed in the posterior aspect of the incision, to improve exposure of the temporal border of the superior rectus muscle as well as the superior oblique tendon. The insertional fibers of the superior oblique tendon can usually be easily identified traveling underneath the superior rectus

muscle and fanning out to insert into the sclera posteriorly on the temporal side of the superior rectus muscle (Fig. 86.39).

Isolation of the superior oblique tendon

A small hook is placed on the sclera adjacent to the temporal border of the superior rectus muscle and anterior to the superior oblique tendon. The small hook is moved posteriorly as it is held against the sclera. It is then turned superiorly and withdrawn anteriorly, resulting in isolation of the superior oblique tendon (Fig. 86.40). The small hook can be exchanged for a larger hook that will more securely maintain control of the tendon. Attachments between the superior oblique tendon and superior rectus muscle can bluntly be dissected if needed.

Tucking of the superior oblique tendon

The tendon is engaged on a tendon tucker or hook and the desired size of the tuck is measured (Fig. 86.41A). A non-absorbable suture is passed through the mid-portion of the tendon at the desired level and tied around the tendon (Fig. 86.41B). The tucked portion of the tendon is then allowed to retract back into the episcleral space.

Fells modification of the Harada–Ito procedure

The Fells modification of the Harada–Ito procedure is used to correct excyclotorsion, typically in the setting of a bilateral superior oblique palsy with minimal vertical deviation in primary position.[11] The procedure involves advancement of the anterior portion of the superior oblique tendon. After isolation of the superior oblique tendon on the temporal side of the superior rectus muscle, two small muscle hooks are used to divide the superior oblique tendon longitudinally extending from its insertion into the sclera for approximately 8–10 mm. The anterior 3 mm portion of the tendon fibers is separated from the remainder of the tendon. An absorbable suture is secured in the anterior tendon fibers (Fig. 86.42A). The fibers are then detached from the sclera at the insertion and advanced temporally. This portion of the tendon is sutured to the sclera approximately 8 mm posterior and 2 mm superior to the superior edge of the lateral rectus muscle insertion (Fig. 86.42B).

Superior oblique weakening procedures

Techniques to weaken the superior oblique include both graded and non-graded procedures. Graded procedures include silicone expander insertion and recession of the superior oblique tendon. Non-graded techniques include tenotomy and tenectomy. Posterior tenectomy combines some degree of both graded and non-graded weakening procedures. The advantages of a graded weakening procedure include the ability to titrate the surgical effect, perform asymmetric bilateral surgery, reversibility, and improved access to the operated tendon should further surgery be needed in the future.

Superior oblique tenotomy and tenectomy

A superior oblique tenotomy or tenectomy may be performed on the tendon, either nasal or temporal to the superior rectus muscle. During isolation of the tendon, the surgeon should minimize disturbance of the fascial tissues surrounding the tendon, which will minimize the risk of scarring between the cut ends of the tendon and the sclera.

The superior rectus muscle is isolated on a large muscle hook. A small muscle hook is used to retract the conjunctiva and Tenon's fascia nasally. The toe of the large muscle hook

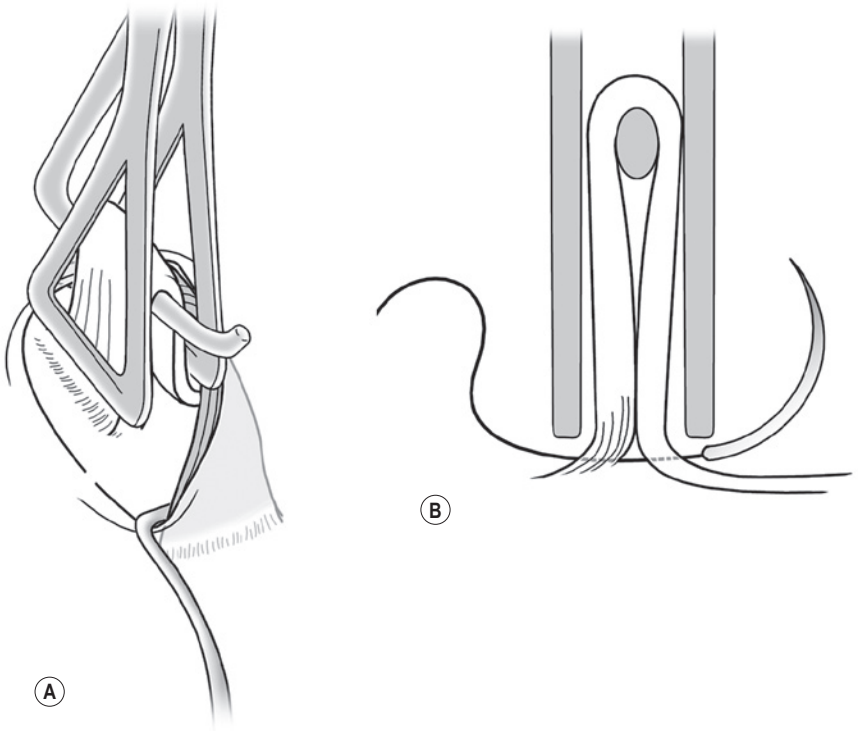

Fig. 86.41 Tucking the superior oblique tendon with a tucking device. (A) The tendon is engaged on a tendon tucker and the desired size of the tuck dialed into the tucker. (B) A non-absorbable suture is passed through the tendon to plicate the base of the tuck. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Fig. 86.42 Fells modification of the Harada–Ito procedure. (A) The superior oblique tendon is split longitudinally, separating the anterior 25% of the tendon from the remainder of the tendon. (B) An absorbable suture is secured in the anterior tendon fibers, which is then detached from the sclera. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

securing the superior rectus muscle will be covered by the intermuscular septum, which should not be disturbed. A retractor is placed along the nasal border of the superior rectus muscle and retracted posteriorly. The superior oblique tendon can be visualized through its surrounding fascia as white fibers running perpendicular to the superior rectus muscle against the sclera. Once the superior oblique tendon is visualized, a small incision is made through Tenon's fascia directly over the tendon. The tendon is then hooked with a small muscle hook and brought through the incision and the exposed tendon is then transected (tenotomy) or a portion of the tendon excised (tenectomy).

A superior oblique tenotomy/tenectomy can also be performed from the nasal side of the superior rectus muscle (Fig. 86.43A). Once the superior oblique tendon has been isolated on a muscle hook, temporal traction is placed on the tendon to expose as much of the nasal portion of the tendon as possible. Once the nasal portion of the tendon is adequately exposed, a tenotomy or tenectomy is performed (Fig. 86.43B). The weakening effect of surgery is greater when surgery is performed on the nasal aspect of the tendon.

Superior oblique tendon expander

The placement of an expander to lengthen the superior oblique tendon offers several potential advantages. A graded weakening procedure can be performed, the risk of creating an iatrogenic superior oblique palsy can be minimized, and the technique facilitates re-operation, if needed.[12]

The superior oblique tendon is isolated nasal to the superior rectus muscle as previously described for a nasal

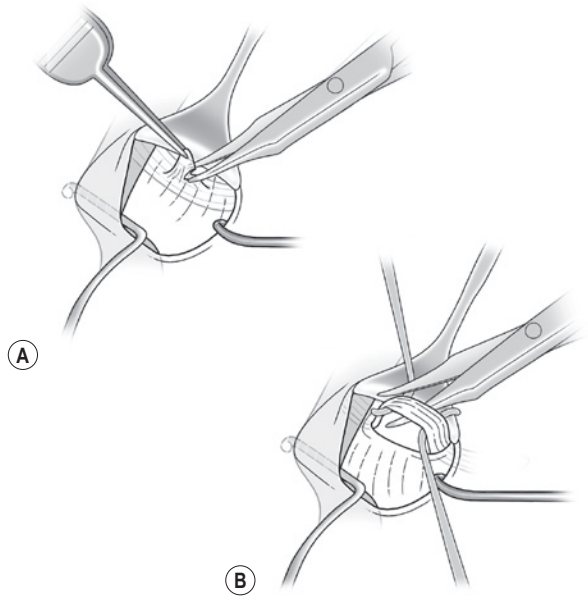

Fig. 86.43 Superior oblique nasal tenotomy and tenectomy. (A) A small incision is made through Tenon's fascia directly over the tendon, (B) transected (tenotomy) or a portion of the tendon is excised (tenectomy). *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

tenotomy/tenectomy procedure. Two double-armed 5-0 or 6-0 Mersilene® sutures are placed in the tendon (Fig. 86.44A). The first suture is placed approximately 3 mm nasal to the border of the superior rectus muscle and the second suture is placed approximately 2 mm nasal to the initial suture. The tendon is then transected between these two sutures and a silicone retinal band that has been cut to the desired length is sutured between the cut ends of the superior oblique tendon (Fig. 86.44B). Tenon's capsule overlying the tendon and expander is then closed with absorbable suture.

Superior oblique posterior tenotomy/tenectomy

Posterior tenotomy/tenectomy of the superior oblique is performed at its insertion site into the sclera. The procedure provides a predictable weakening of the function of the superior oblique muscle for the treatment of "A" pattern strabismus, primarily weakening its depression and abduction functions.[13] The insertion of the superior oblique tendon is isolated temporal to the superior rectus muscle. The posterior 7/8 of the insertion is detached and a small wedge of the posterior tendon is excised (Fig. 86.45).

Transposition procedures

Rectus muscle transposition procedures

Transposition procedures are used almost exclusively in cases of muscle paralysis or near paralysis. Common indications for rectus muscle transposition surgery include treatment of isolated rectus muscle paralysis, such as a sixth nerve palsy. Rectus muscle transposition procedures are most effective when the function of only one rectus muscle is severely compromised.

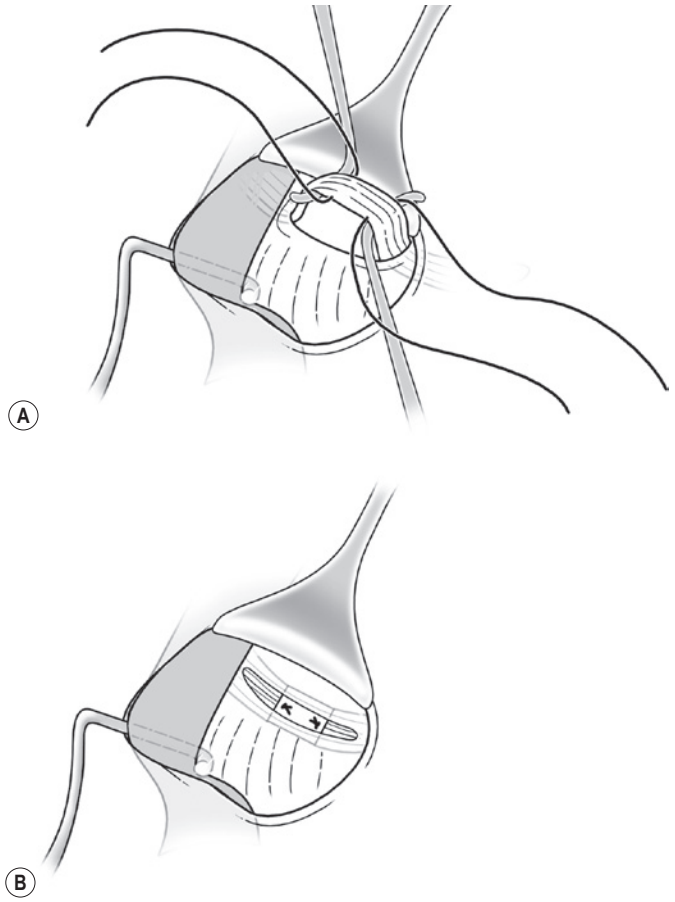

Fig. 86.44 Superior oblique tendon silicone expander. (A) Two double-armed 5-0 or 6-0 Mersilene® sutures are placed in the tendon, and (B) a silicone retinal band is sutured between the cut ends of the tendon using a horizontal mattress technique. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

The goal of transposition surgery is primarily to re-align the deviating eye as close to the primary position as possible, usually also attempting to achieve single vision for patients with diplopia. The results of transposition surgery are often good, but never perfect. Ocular alignment outcome from a transposition procedure can be enhanced by weakening the antagonist of the paralyzed muscle, either through recession or through injection of botulinum toxin, in selected cases. Weakening of the yoke muscle in the sound eye may be of value in some cases. This section will concentrate on the most important transposition procedures among a large number of potential options.

Transposition procedure can be performed through a large limbal incision or through two fornix incisions in adjacent quadrants. The incisions are placed as shown in Figure 86.46. The approach chosen is largely dependent on surgeon preference.

Full tendon rectus muscle transposition

A full tendon rectus transposition procedure is indicated when there is complete or near complete paralysis of a rectus muscle, such as a lateral rectus muscle paralysis. The two adjacent rectus muscles are transposed to a position adjacent to the insertion of the paralyzed muscle. The intermuscular

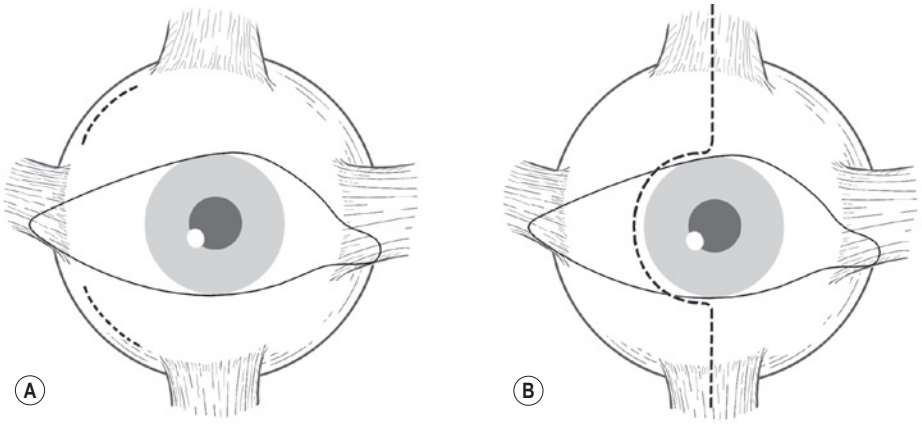

Fig. 86.46 Conjunctival incision for full tendon transposition. (A) Fornix incisions, and (B) limbal incision. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

septum of the adjacent rectus muscle is generously dissected for approximately 10–12 mm posterior to the insertion. The muscles are then detached from their insertions and sutured back to the sclera adjacent to the insertion of the paralyzed muscle (Fig. 86.47).

Transposition of both the superior and inferior rectus muscles was traditionally believed to be necessary for successful correction of esotropia due to complete sixth nerve palsy. Recently, superior rectus muscle transposition combined with medial rectus recession has been reported to be a successful alternative for the treatment of both isolated sixth nerve palsy and esotropia associated with Duane syndrome.[14]

Full tendon transposition with posterior fixation suture augmentation

A modification of the standard full tendon transposition involves placement of non-absorbable sutures to redirect the transposed muscle borders to the sclera adjacent to the borders of the paralyzed muscle 12–14 mm posterior to limbus[15] (Fig. 86.48). Concurrent recession of the antagonist muscle may result in overcorrection. Recession of the yoke muscle in the sound eye may be done if additional effect is needed. The procedure has been reported to improve ductions in the field of action of the paralyzed muscle. Augmentation of the standard full tendon transposition procedure, by suturing the border of the transposed muscles directly to the paralyzed muscle, has also been described.

Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

Vessel-sparing full tendon or near full tendon transposition

When concerned about the risk of anterior segment ischemia, transposition procedures may be modified to reduce compromise of the anterior segment circulation. Dissection with isolation and sparing of one or both anterior ciliary vessels associated with the vertical rectus muscle prior to transposition of the muscles is one such approach[16] (Fig. 86.49). Partial tendon transposition involving repositioning of ⅘ of the transposed rectus muscles leaving the remaining muscle and its intact anterior ciliary vessels intact has also been reported to be of value and avoids the need for tedious dissection of the anterior ciliary vessels in the former approach.[17]

Partial tendon transposition

Hummelsheim described a procedure involving transposition of the temporal half of the superior and inferior rectus muscles and suturing them to the lateral rectus muscle insertion. Today, half tendon transposition of adjacent rectus muscles generally involves suturing the transposed muscle segments directly to the sclera adjacent to the paralyzed muscle's insertion. This procedure can be used to treat any isolated rectus muscle paralysis in an eye. The effect can be augmented by simultaneously resecting a 5–7 mm section of the transposed muscle segments[18] (Fig. 86.50).

Nasal transposition of the lateral rectus muscle for third nerve palsy

Longitudinal splitting and redirection of the lateral rectus muscle posteriorly to the nasal side of the globe was reported to be a useful procedure in the management of third nerve palsy in a small series of patients. The procedure may be

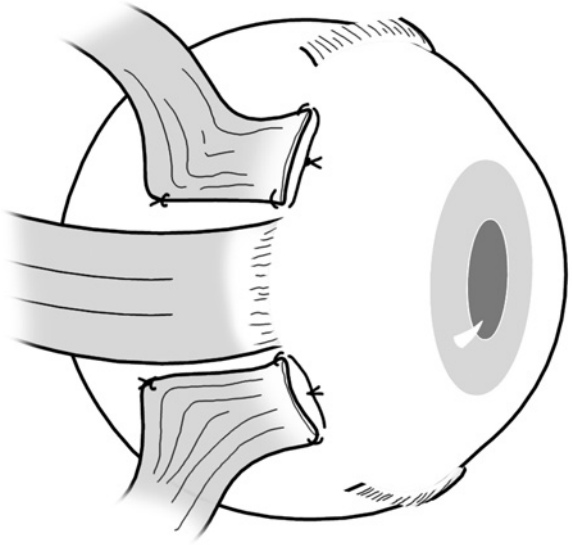

Fig. 86.48 Augmented full tendon transposition procedure described by Foster. difficult to perform on patients who have previously undergone lateral rectus muscle surgery due to tightness of the previously operated muscle, making it impossible to effectively transpose the muscle.[19]

Superior oblique tendon transposition

Superior oblique tendon transposition can be used to improve ocular alignment in patients with complete or near complete third cranial nerve palsy, and is most useful as an adjunct to other, more effective procedures. The superior oblique tendon is transected near the nasal border of the superior rectus muscle. It is then sutured to the sclera above the medial rectus muscle insertion under tension with non-absorbable suture, discarding the distal aspect of the tendon (Fig. 86.51). The procedure can be done with or without fracturing the trochlea.

Adjustable suture techniques

Some surgeons strongly believe that adjustable sutures offer a distinct advantage, improving outcomes, while other surgeons do not see a significant enough benefit to justify their use.[20] While this section highlights commonly used adjustable suture techniques, the reader should recognize that many variations have been reported. Adjustable suture techniques can be performed through a limbal or a fornix incision. The adjustment process can be done at the time of the primary surgery in the operating room, or even days after surgery in the office.

Technique for bow-type adjustable sutures

The bow-type technique can be applied to a recessed or resected rectus muscle. The suture ends are then tied into a half bow (Fig. 86.52A). To adjust the muscle position, the bow is untied, the muscle position adjusted, and the bow retied (Fig. 86.52B). The bow is then converted into a permanent knot after ocular alignment is satisfactory (Fig. 86.52C).

Technique for cinch knot adjustable sutures

After placement of the muscle sutures into the sclera, a second absorbable suture is tied around the two muscle sutures after they exit the sclera. Adjustment is later accomplished by sliding the cinch suture in an anterior or posterior direction, as needed (Fig. 86.53A). When the desired position of the muscle has been achieved, the muscle sutures are then tied securely over the cinch knot (Fig. 86.53B).

Special procedures

Mechanical fixation of the globe

When standard strabismus surgery techniques are not, or will not, effectively result in re-alignment of eyes with paralytic or restrictive strabismus, mechanical fixation of the globe near the primary position can be useful.

Autogenous periosteal flaps can be utilized to tether the globe in a fixed position.[21] The technique is effective and the

(D) View of the eye as it is rotated toward the muscle showing the new effective insertion site. *(Copyright 2006 Springer-Verlag; Coats DK, Olitsky SE. Strabismus Surgery and Its Complications. Berlin/Heidelberg: Springer-Verlag, 2006. Susan Gilbert, Illustrator.)*

involvement of an oculo-plastic surgeon skilled in surgery on the orbit is helpful. An apically based periosteal flap can be created from any one of the four orbital walls. A periosteal elevator is used to separate the flap from the underlying bone and a 5-0 Mersilene® suture secured to the anterior edge of the flap. The flap is then sutured to the sclera anterior to the paralyzed rectus muscle insertion. The globe is then rotated toward the periosteal flap and tied into place. The surgeon may not be able to actually visualize the surgical site as the flap is secured into place on the sclera. Initial overcorrection is desirable.

Plate and suture fixation procedure

A titanium plate is affixed to the orbital wall adjacent to the paralyzed rectus muscle. A suture, affixed to the posterior aspect of the plate is brought anteriorly and sutured to the sclera anterior to the paralyzed rectus muscle insertion. This suture is then tied to fixate the eye near the primary position. An initial overcorrection is desirable.

Posterior fixation suture

Cuppers first described the posterior fixation suture technique for the treatment of incomitant strabismus.[22] The mechanism of action of the posterior fixation suture that has historically been taught is that the procedure shifts the effective insertion site of the rectus muscle posteriorly. Recently this has been challenged and studies have demonstrated that posterior fixation sutures posteriorly displace the pulley sleeve during contraction of the muscle and that mechanical restriction after surgery might actually be the mechanism by which this technique works. Non-absorbable sutures are used to secure the muscle belly to the sclera 12–16 mm posterior to the limbus. The suture can be placed with or without prior recession of the muscle (Fig. 86.54). A similar effect can be achieved using pulley fixation rather than fixation in the sclera.[23]

Introduction

There is a trend in most surgical specialties to move towards minimally invasive surgery with reduced incision sizes. They help achieve the same effects as conventional surgery, with the added advantages of reduced tissue trauma, improved wound healing, shortened recovery times, and improved cosmesis.[1]

The most striking example of reduction in wound size in ophthalmology has been in cataract surgery,[2] but minimally invasive surgery has been also been used to correct ptosis,[3] in penetrating and non-penetrating surgery for glaucoma,[4,5] smaller gauge instruments for vitreoretinal procedures,[6,7] and endonasal dacryocystorhinosotomy for lacrimal surgery.[8]

Minimally invasive strabismus surgery (MISS) is a term introduced to encompass strabismus surgery techniques that minimize tissue disruption and improve postoperative comfort and cosmesis. This is achieved by creating several small keyhole openings through the conjunctiva through which the procedure is performed instead of the usual large opening. Due to the nature of the incisions, the view of the extraocular muscles is limited; if necessary, tunnels can be created between these incisions to facilitate ease of maneuver and carry out further surgical steps. Most types of strabismus surgeries can be carried out in this manner including rectus muscle recession, resection, plication, advancement, transposition and retroequatorial myopexy, and oblique muscle recession, myectomy, or plication. It is also possible to carry out strabismus procedures on adjustable sutures and vessel-sparing rectus muscle displacements.

As this form of surgery minimizes conjunctival trauma and restricts dissection of the muscle and perimuscular tissue, it results in reduced postoperative inflammation, congestion, chemosis, and improved cosmesis. It also reduces hospital stay and allows patients to resume normal activities sooner.

Conjunctival incisions in strabismus surgery

Strabismus surgery was first described in 1739. Various conjunctival incisions have been used through the ages.

Swan[9] described a transconjunctival incision over the rectus muscle insertion, followed by a radial incision of Tenon's capsule over the bulk of the muscle. This incision is seldom used now because it can be associated with intraoperative hemorrhage from the muscular vessels and postoperative scarring over the muscle.

The most widely used incision in strabismus surgery is limbal, which was initially described by Harms in 1949 and later popularized by Von Noorden.[10] This involves a peritomy along the limbus, as well as radial conjunctival relaxing incisions. It offers excellent exposure of the muscle, prevents the need to carry out the procedure over the muscle belly, and facilitates the use of adjustable sutures. However, as the conjunctival incision involves the limbus, it can lead to significant postoperative discomfort, dellen formation in the perioperative period, and long-term perilimbal scarring. Perilimbal conjunctival scarring often results in conjunctival tearing and buttonholing during re-operations.

Parks[11] described a fornix cul-de-sac incision that is usually placed in the lower fornix and is thus completely covered by the lids. The incision can also be placed in the superior fornix for the superior rectus muscle or if muscles are to be superiorly transposed. While this incision affords excellent cosmesis, it is hampered by reduced access to the extraocular muscles, the need to stretch the conjunctiva over the muscle insertion, which is not always possible in older patients or during re-operations, and difficulty in placing the scleral sutures.

There has been an effort to achieve the same goals through smaller incisions, and alternative techniques have been described by Velez,[12] who suggested a radial incision covered by the upper lid, and Santiago,[13] who advocated a paralimbal approach between the limbus and muscle insertion.

Gobin[14] described accessing the rectus muscles through two small radial openings along the superior and inferior muscle margin to perform loop recession or resection. Mojon[15] has adapted this technique and has described using it to carry out most forms of strabismus surgery including primary or repeat plication, recessions, transpositions, and retroequatorial myopexies. It can also be utilized for oblique muscle recession, plication, and transposition.

Principal and methods of minimally invasive strabismus surgery

MISS is carried out by accessing the muscle through two small keyhole openings and dissecting the muscle from its surrounding tissue followed by resection, plication, or transposition. The majority of the surgical procedures include perimuscular dissection and suturing of the muscle to the sclera. To facilitate some surgical maneuvers, it may be necessary to create tunnels between these incisions. These openings are kept as far away from the limbus as possible, in such a way that if needed they can be joined together to form a larger opening, which may be helpful in the early stages of surgical transition to these technique. The incisions are covered completely by the lids except in upgaze or extreme lateral gazes.

Use of the microscope is advocated for this technique as it aids better visualization of the tissues, smoother dissection and recognition of the sclera while passing sutures, making the procedure safer by avoiding scleral perforation.

Surgical procedure

The surgical procedure is carried out using the operating microscope and can often be completed without the need for an assistant. The globe is stabilized through a limbal traction suture (Ethicon Prolene 6-0 C-1). This is secured using an artery forceps to direct the eye away from the field of action of the muscle to be operated upon. It is essential to ensure this suture does not abrade the cornea during the procedure and this can be accomplished by tying them over the speculum.

The edges of the muscle are then visualized and two small radial incisions placed along either border of the insertion, starting at the insertion and traveling backwards along the length of the muscle. On rotation of the eye, the linear muscle vessels do not move in relation to the insertion, while conjunctival vessels do, and this can be used to aid localization of the muscle before making these incisions (Fig. 87.1A).

The size of the incisions depends upon the amount of muscle displacement to be achieved and in most cases an incision of 1 mm less than the displacements of up to 5 mm, and 2 mm less than those more than 5 mm, is adequate. The conjunctiva needs to be stretched backwards in order to pass the scleral sutures. In older people or those undergoing re-operations, the conjunctiva is relatively inelastic, making this difficult, and larger openings maybe required. The same is true for children below 2 years of age, due to the abundance of Tenon's tissue, which impairs visualization.

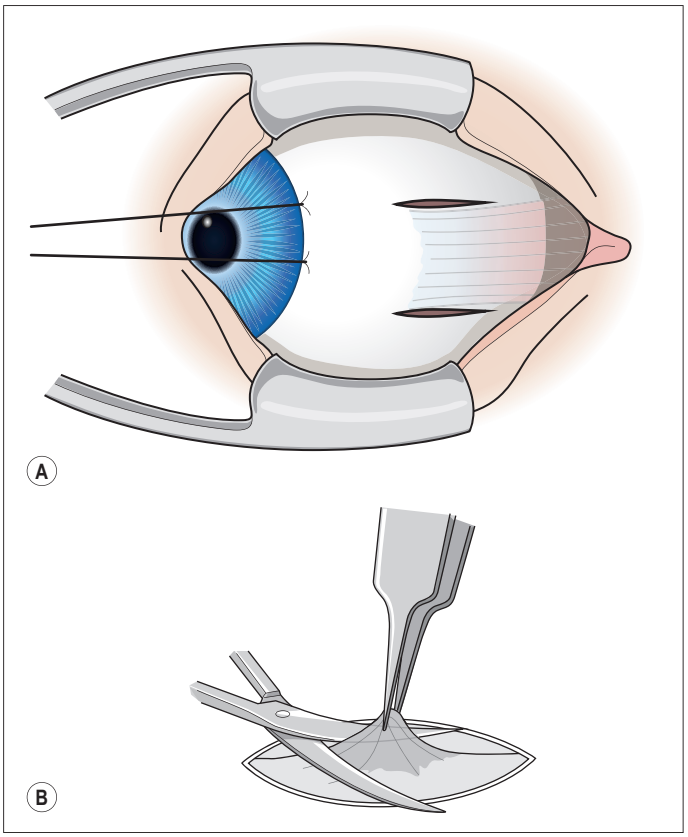

Fig. 87.1 (A) The eye is held in adduction by a stay suture placed at the limbus. The edges of the muscle (the medial rectus in this case) are then identified and two small radial incisions placed along either border of the insertion, starting at the insertion and traveling backwards along the length of the muscle. (B) Using Westcott scissors, the episcleral tissue is separated from the upper and lower edges to better delineate the borders of the muscle. The dissection can then be continued over the insertion of the muscle to join the two incisions, thereby creating a tunnel, and backwards to include the check ligaments and intramuscular septum.

Once the incisions are made, a small squint hook can be inserted to ensure the edges of the muscle have been clearly identified. Using Westcott scissors, the episcleral tissue is separated from the edges to better delineate the borders of the muscle. The dissection can then be continued over the insertion of the muscle to join the two incisions, thereby creating a tunnel (Fig. 87.1B).

Once this is complete, the muscle can be hooked and a dissection of check ligaments and intramuscular septum carried out to about 6–7 mm behind the insertion (Fig. 87.2A).

Recessions

To perform a recession, hemostasis is first achieved at the muscle insertion using a 20 g bipolar monoaxial cautery. Then, the cut ends of two sutures (Vicryl 6-0 ¼ circle-shape S-14 needle, Ethicon) are applied to the superior and inferior borders of the muscle tendon for the horizontal recti (nasal and temporal for the vertical), as close as possible to the insertion (Fig. 87.2B). The amount of recession is measured, marked on the sclera (Fig. 87.3A), and both sutures attached (or preplaced) at these points (Figs 87.3B and 87.4A). The tendon is then disinserted from the globe using Westcott

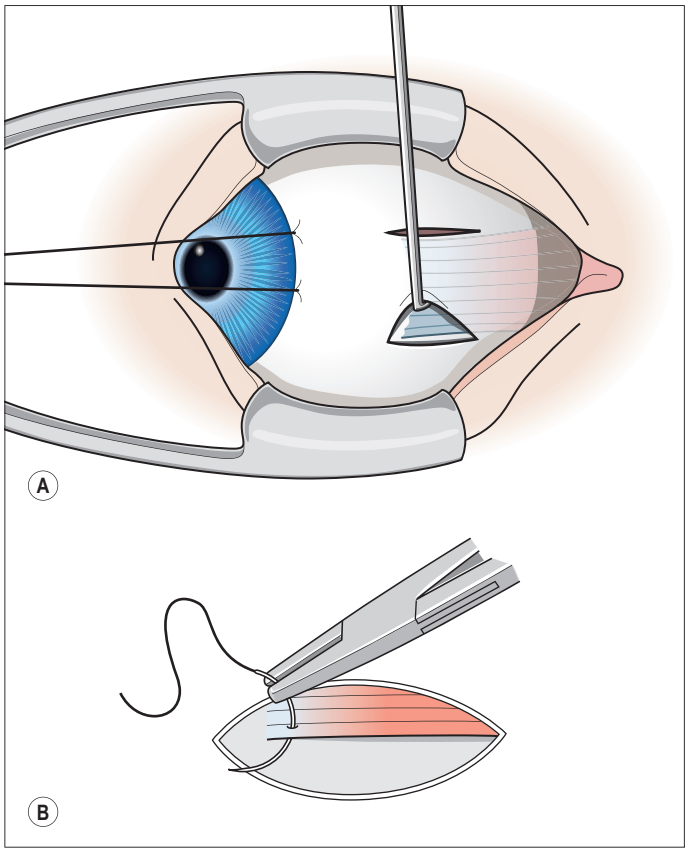

Fig. 87.2 (A) The conjunctiva is then retracted over the muscle to expose the tendon, and (B) a full-thickness pass made through the muscle tendon using 6-0 Vicryl suture that has been cut in half. This is then knotted to ensure the tendon edge is secured to the suture. An alternative method to perform this step is using the TRASU technique that is illustrated in Fig. 87.9.

scissors, taking care to not damage the sutures (Fig. 87.4B). The sutures can then be tied off safely (Fig. 87.5A,B) and the conjunctiva re-sutured (Fig. 87.6A,B) (Vicryl Rapid 8-0, with a spear-shaped GS-9 spatulated needle, Ethicon). The advantage of preplacing the sutures is that once the muscle is disinserted they can be tied off, obviating the need to pass scleral sutures under suboptimal viewing conditions if the muscle bleeds. This technique also results in precise displacement of the muscle along its original path. The disadvantage is the risk of inadvertently cutting the sutures. The alternative is placing the sutures once the muscle has been successfully taken off the globe, which requires meticulous hemostasis.

In fibrotic muscles, as in Duane retraction syndrome or thyroid eye disease, it may not be possible to place scleral sutures before the eye is adequately turned away from the field of surgery. Therefore, in such cases, scleral anchoring at the new site can only be performed after muscle disinsertion. Some surgeons prefer adjustable sutures for these cases.

Plications

The cut ends of two sutures (¼ circle Vicryl 6-0 S-14 needle, Ethicon) are applied to the edges of the muscle tendon at a distance corresponding to the plication amount (Figs 87.7 and 87.8). The sutures are then passed through the sclera at the tendon insertion site. Using an iris spatula, the muscle is drawn forward and plicated by tying the ends of the sutures. The conjunctiva is sutured as above (Figs 87.9–87.11)

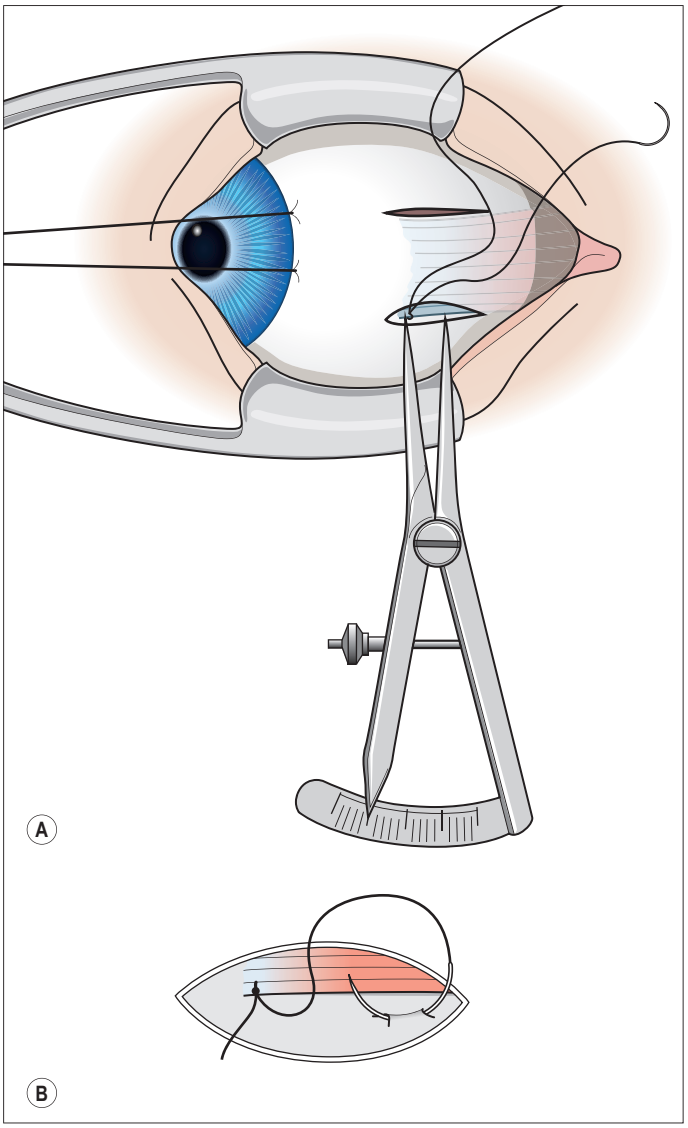

Fig. 87.3 (A) The amount of recession is measured, marked on the sclera, and (B) the suture preplaced at this point through a partial-thickness pass.

Resections

The muscle is grasped at a distance equal to the amount to be resected. If there are any prominent vessels present at this site, they are cauterized. The cut ends of two sutures (Vicryl 6-0 with ¼ circle-shape S-14 needle, Ethicon) are applied to the superior and inferior borders of the muscle tendon at a distance corresponding to the resection amount and then to the sclera at the insertion. The muscle is divided under the conjunctiva and drawn up to the insertion site as the sutures are tied off. The conjunctiva is sutured with 8-0 Vicryl suture as previously described.

Retroequatorial myopexy

This is carried out by placing two L-shaped cuts slightly anterior to the location where the musculo-scleral sutures

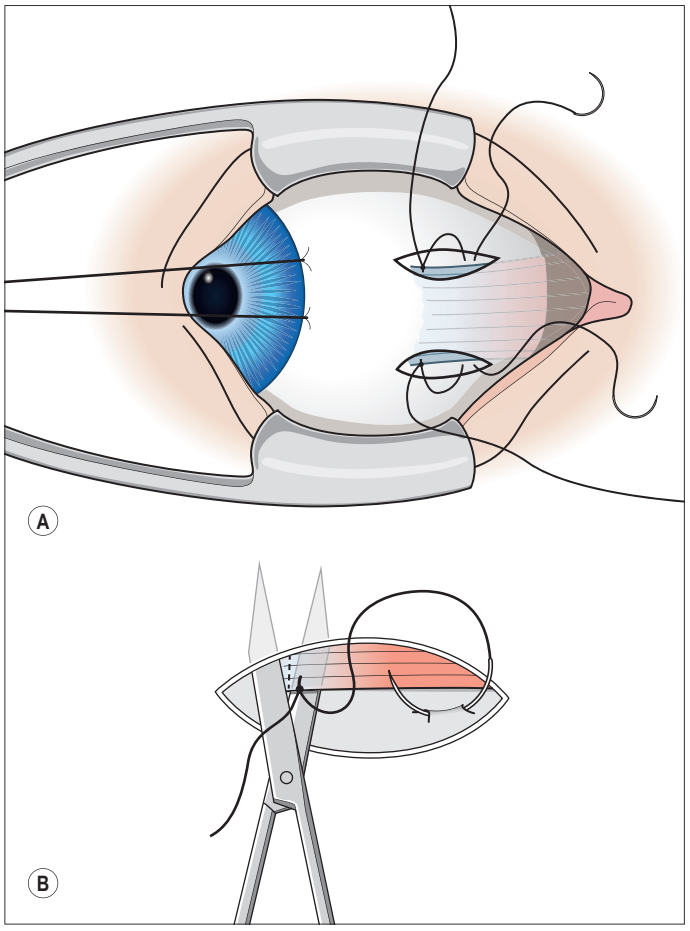

Fig. 87.4 (A) A similar procedure is repeated at the superior edge. Once both sutures have been preplaced, (B) the muscle is disinserted off the globe using a Westcott scissors, under the conjunctiva, taking care not to damage the sutures.

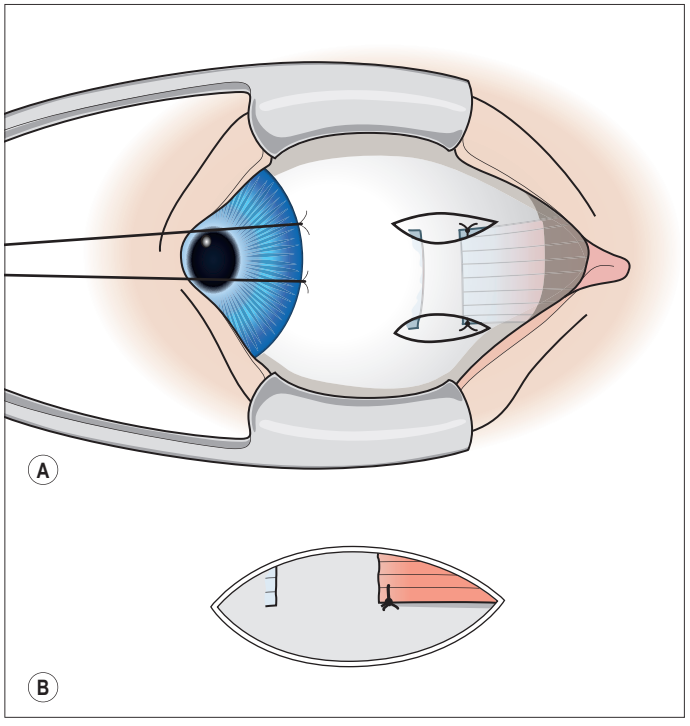

Fig. 87.5 (A) The muscle is secured to the sclera at the intended distance from the limbus by tightening the sutures, (B) which are then tied off.

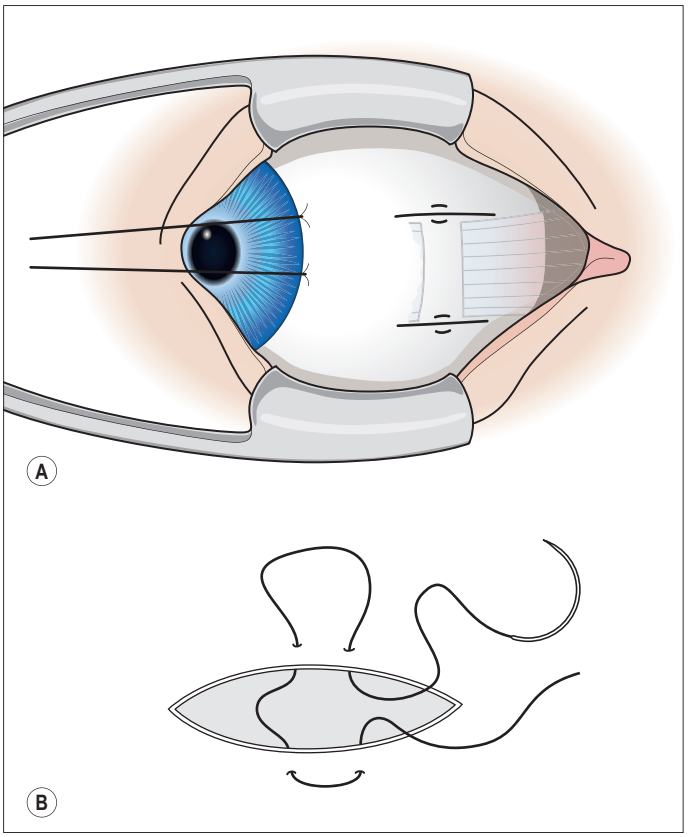

Fig. 87.6 (A) The conjunctival openings are closed with 8-0 Vicryl sutures. (B) The sutures are applied in a manner that ensures the knot is buried within the wound to aid cosmesis and comfort postoperatively.

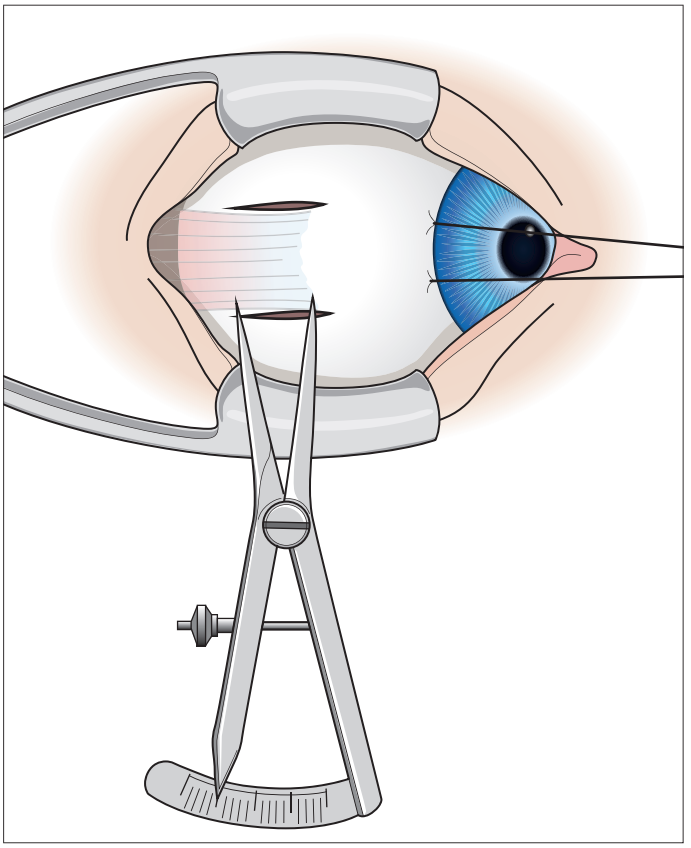

Fig. 87.7 To carry out a plication, the conjunctival openings are fashioned as above along the superior and inferior aspects of the lateral rectus. The amount of plication to be carried out is measured via calipers.

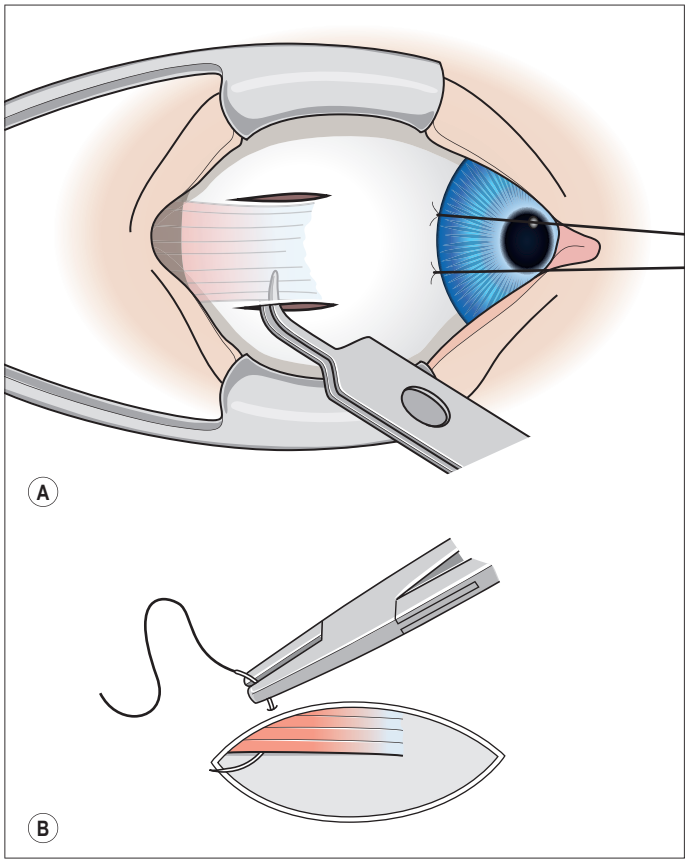

Fig. 87.8 (A) The muscle tendon is grasped at the desired amount of plication with a jeweler's forceps or similar, and (B) a 6/0 Vicryl suture passed through the conjunctiva, Tenon's capsule, and full-thickness of the muscle belly, emerging through the conjunctival opening.

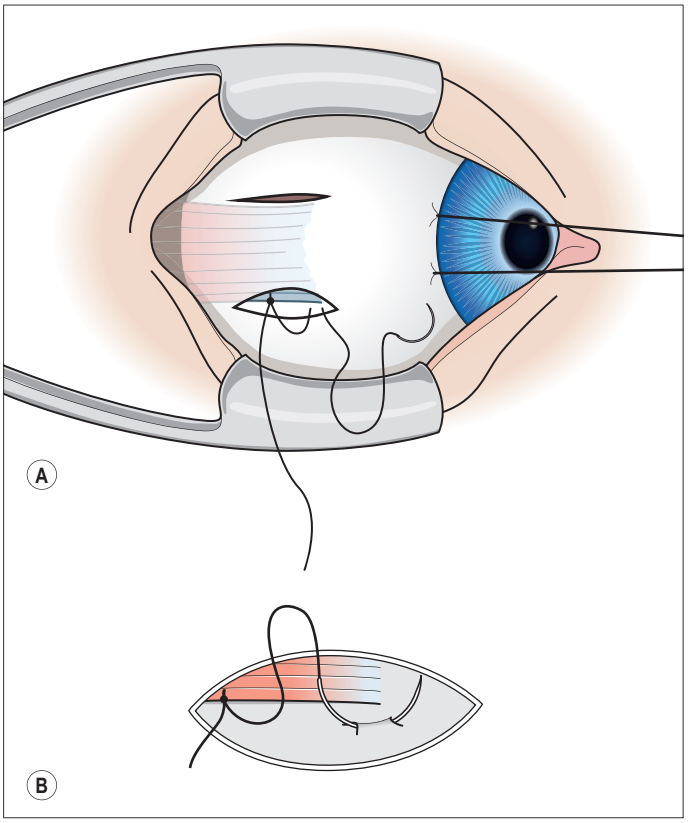

Fig. 87.10 (A) The needle is then passed partial thickness through the sclera, (B) adjacent to the insertion of the muscle tendon. This procedure is then repeated at the superior edge of the muscle.

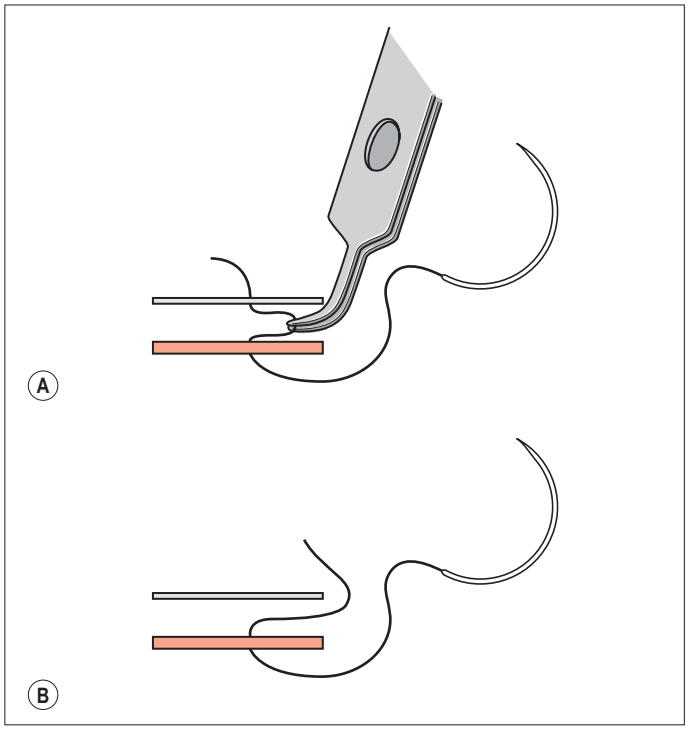

Fig. 87.9 (A) The suture is grasped between the muscle and conjunctiva and drawn out the incision site, (B) freeing up the conjunctiva and Tenon's tissue, and leaving the suture running just through the muscle. This is then tied off to secure the tendon.

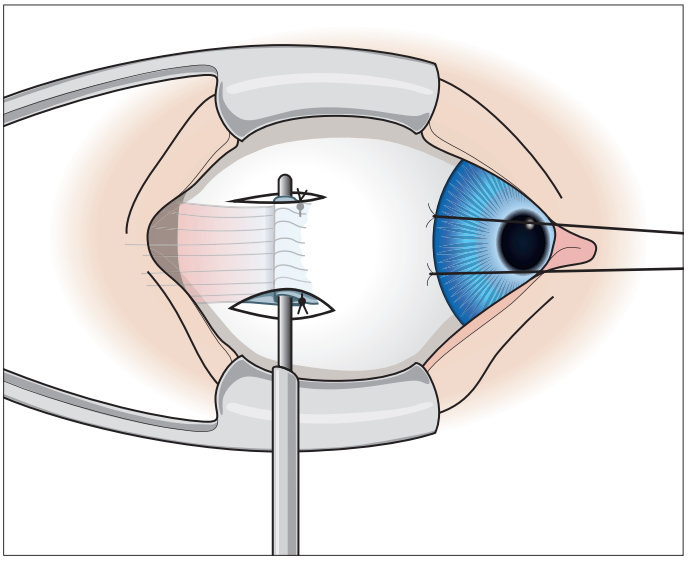

Fig. 87.11 The muscle tendon is drawn forward using an iris spatula or similar instrument and the sutures tied off to achieve plication of the muscle. The conjunctiva is then closed off using 8/0 Vicryl as above.

will be passed. This is usually 14 mm, or so, posterior to the limbus to ensure the suture is posterior to the equator. With Westcott scissors, the episcleral tissue is dissected from the muscle sheath and sclera. The posterior fixation is then carried out by passing a non-resorbable suture through the sclera, followed by the muscle, to include approximately one-third of the tendon on both sides. Anterior elongation of the cuts will allow retroequatorial suturing to be combined with a MISS recession or plication of the same rectus muscle.[16]

Transpositions

Either partial- or full-tendon transpositions can be carried out using this technique. Partial transposition of two adjacent rectus muscles can be performed using four incisions, while six openings are necessary for complete transposition. Partial transposition is more effective at sparing vessels, which might become important should there be a need to recess the ipsilateral antagonist of the paralyzed rectus muscle in the future. However, this technique is more at risk of inducing postoperative cyclodeviations and vertical deviations.

The half-muscle to be transposed is exposed by a small, radial cut. Perimuscular dissection is carried out as above to 7 mm posterior to the insertion. A curved ruler is used to measure the muscle insertion width and to determine its midpoint. Starting at the midpoint, the muscle is gently split using a small muscle hook from a point 15 mm away, all the way to the scleral insertion. Two single sutures (¼ circle, Vicryl 6-0 S-14 needle, Ethicon) are applied to the muscle tendon, which will be transposed, and the split half-muscle is disinserted. The same technique is used to split the other rectus muscle. Precise splitting usually avoids unwanted postoperative deviations. The minimally invasive transposition is now performed by exposing the weak rectus muscle through two small parainsertional keyhole cuts. In order to safely displace the needles, a blunt 20G sub-Tenon's anesthesia cannula is inserted through one of these openings and advanced in order to emerge through the incision next to the half-muscle to be displaced. After scleral anchoring, the half-muscles are transposed by gently pulling the sutures. If additional force has to be generated, the weak muscle can be crossed under by the two half-muscles. In the authors' experience, the effect of this undercrossing is similar to a full transposition to the adjacent rectus muscle insertion border.

For full-tendon transpositions, two additional keyhole openings must be performed at the rectus muscle insertions lying opposite to the paralyzed muscle.[17]

MISS transposition surgery is no more demanding than open transposition surgery. However, there is an increased risk, at least in the beginning, of inducing involuntary cyclodeviations and deviations perpendicular to the new force vector if asymmetric portions of the muscles are transposed, as precise splitting is more difficult to perform through smaller openings.

Re-operations

Prior to operating on an eye that has undergone previous muscle surgery, it is helpful to delineate the position of the extraocular muscles. This can be done preoperatively, using the slit lamp, or intraoperatively, by observation of the movement of the vessels. The advantage of using MISS in these eyes is that the surgeon will not have to open scarred and fragile perilimbal conjunctiva. Once the position of the muscles has been established, incisions can be placed adjacent to them. Most of the scar tissue involving the muscle can be released by blunt dissection under direct visualization. However, the surgeon should be prepared to extend the incision if visualization is inadequate. Since the incisions can often be placed far from the limbus, postoperatively, the incisions are often barely visible and there is minimal discomfort.[18]

Oblique muscle surgery

Minimally invasive surgery for superior and inferior oblique recessions of up to 6 mm can be performed using one incision; but for larger recessions, two keyhole openings are required. The first is used to disinsert the muscle insertion and the second for scleral anchoring. In order to safely pass the needle between the two cuts, a blunt 20G sub-Tenon's anesthesia cannula is used to transpose rectus muscles. MISS inferior and superior oblique muscle plications are carried out through one L-shaped opening over the insertion.[19]

MISS transconjunctival suturing technique

MISS transconjunctival suturing technique (TRASU) allows large recessions to be performed without the need to open the conjunctiva where the muscle is re-attached to the sclera. The suture is performed as usual and the needle exits completely through the sclera but also through the overlying Tenon's capsule and conjunctiva. The needle is then retrieved by pulling backwards on the suture allowing the surgeon to place a standard knot.[20] This allows larger recessions than previously possible without increasing the length of the conjunctival incision.

Marginal dissection of rectus muscles

To further refine the surgical technique for plications, the marginal dissection of rectus muscles (MADI) technique[21] can be utilized. The amount of dissection of perimuscular tissue is reduced using this technique. Instead of creating a tunnel between the two conjunctival openings (total dissection [TODI]), dissection is performed only along the margins of the muscle to be plicated. This eliminates the need of an iris spatula. The authors have found that this technique is associated with the same dose–response relationship, but with better postoperative recovery and less tissue trauma.

Specific complications of minimally invasive strabismus surgery

The keyhole conjunctival incisions may tear while moving instruments. If the tear does not involve Tenon's capsule, it is usually of no consequence. If Tenon's capsule tears, a visible scar may result. If the tear occurs over the muscle, increased scarring may make re-operations more difficult. If the muscle is removed too close to the sclera, a visible bluish line may be visible; if too far away, the remaining tendon may visibly elevate the conjunctiva. If excessive bleeding occurs, it maybe necessary to enlarge the incisions or even convert to a limbal opening. Sometimes, a relatively large subconjunctival hemorrhage may develop. In one case, the authors observed the extrusion of non-resorbable sutures through the keyhole openings 2 years

after Faden surgery. They cannot yet determine if such events occur more frequently when compared with Faden procedures performed through Harms' opening.

Advantages and disadvantages of minimally invasive strabismus surgery

Postoperatively, the MISS openings will all be covered by the eyelids, thus minimizing their visibility and patient discomfort. Since they are far from the limbus, the risk of corneal complications (e.g. dellen formation) is reduced. The long-term benefits include decreased scarring of the perimuscular tissue, which facilitates re-operations and preserves the limbal conjunctival and stem cells. This technique is especially valuable for re-operations, since it avoids re-opening the scarred perilimbal conjunctiva. MISS preserves the perilimbal episcleral vessels and, therefore, reduces the risk of anterior segment ischemia. Since MISS also reduces the anatomical disruption between the muscle and the surrounding tissue, re-operations will be easier.

Disadvantages of minimally invasive strabismus surgery (MISS) include a higher risk of sclera perforation and a long learning curve.

Strategies to aid beginners

Surgeons switching from magnifying loupes to the operating microscope should first perform several procedures under the microscope with their customary technique before using keyhole openings. They should start with primary horizontal rectus muscle displacements of 4 mm or less. In the authors' experience, plications and resections yield the same dose–response relationship. Therefore, they suggest switching to plications, since the less traumatic MADI rectus muscle reinforcement technique can be used. The resultant muscle knuckle is visible under the conjunctiva for the first few days but soon ceases to be visible. Patients between ages 14 and 40 years are ideal for MISS. Abundant Tenon's tissue in very young patients makes the surgery more difficult. Reduced conjunctival elasticity in older patients increases the risk for a conjunctival tear when introducing or manipulating instruments through the keyhole openings. Ideally, a surgeon interested in using this technique should observe a surgeon experienced using MISS. The authors of this chapter would be happy to have surgeons wanting to learn this technique to observe them performing MISS

When switching to MISS, surgeons usually find their surgical times are increased. However, once surgeons become experienced, they can perform rectus muscle resections or plications faster using MISS. The MADI plication technique, in particular, is very quick. Oblique muscle procedures will not be significantly faster. Conversely, rectus muscle transposition can be performed much faster using MISS.

One of the initial stumbling steps is incorrect placement of incisions by situating them too far from the muscle or on top of the muscle. In the former case, this causes difficulties in the isolation and dissection of muscles and hemorrhage and scarring in the latter. This can be avoided by identifying the muscle insertion using the differential movement of the muscular and conjunctival vessels on movement of the globe. A small incision by the insertion can then be made and enlarged as necessary.

Hemorrhage from scleral or anterior ciliary vessels can also be a challenge and is best avoided by using bipolar coaxial diathermy that allows gentle cauterization of vessels while preventing damage to overlying conjunctiva.

Adequate exposure to perform posterior scleral bites during recessions can be difficult to achieve and inadequate visualization increases the risk of scleral perforation. This can be prevented by using longer incisions, at least initially, rotating the eye in the opposite direction of the muscle being operated upon, and stretching the conjunctiva to obtain adequate exposure

Instrumentation for minimally invasive strabismus surgery

When performing routine strabismus surgery via a limbal opening, the size of the instruments is not critical. However, if large instruments are used with small MISS openings, conjunctival tearing will occur. The following instruments are helpful for MISS:

- Clamping a small artery forcep to the traction sutures, using a forceps over the eyelid speculum, will prevent the sutures from rubbing on the cornea.
- Colibri forceps with interdigitating teeth are used to fix the conjunctiva when creating keyhole openings and to stabilize the eye for traction and scleral anchoring sutures.
- Small, curved needle holders are ideal to suture through small openings, especially if the TRASU method is used.
- Small conjunctival scissors with a curved, blunt tip are used to cut the conjunctiva, the sutures, and muscle or tendon insertions.
- Curved forceps with serrated tips should be used to hold the conjunctiva after performing the keyhole openings, since this will prevent unnecessary conjunctival trauma.
- Spatulas of different sizes are helpful to visualize tissue through the cuts. Diathermy is best performed using a system with a bipolar, coaxial tip. This allows gentle cauterization of vessels at the muscle insertion through the tunnel, without damaging the overlying conjunctiva.
- A small strabismus hook can easily be introduced through the small openings and will allow, if necessary, another instrument to be introduced through the same cut.
- Angled forceps are necessary to stabilize the muscle insertion during disinsertion. If they are not used, the traction suture should be slightly released before disinserting the muscle; otherwise there is a considerable risk that the insertion will tear. By pressing the blunt tips of a Castroviejo caliper for approximately 10 seconds against the sclera, a bluish indentation mark is formed, which will be visible for up to 1 minute. This indentation technique also works transconjunctivally to perform TRASU since no dye is necessary.

- A blunt cannula is helpful to safely displace needles through the tunnel between two key openings when rectus muscles are transposed, or for larger, graded oblique muscle recessions.

Adjustable sutures

Adjustable suture can be used with MISS surgery. The adjustable sutures have to be placed in a manner that they become visible after removal of the conjunctival sutures, in the event an adjustment becomes necessary. An adjustment will not increase the postoperative discomfort and visibility of the incision sites. After an adjustment, the conjunctiva only needs to be closed if the adjustable sutures protrude through the openings. Frequently, an adjustment can be performed at the slit lamp.

Conclusion

MISS is a safe and effective alternative to traditional strabismus surgery that that is associated with reduced postoperative discomfort, improved cosmesis, and a reduced incidence of postoperative corneal dellen and perimuscular scarring.

Severe complications of strabismus surgery are rare but they can be devastating. This chapter will explore the frequency and management of problems related to this surgery; it will also discuss the consent process to ensure patients are well informed.

Incidence

The incidence and outcomes data quoted here were obtained from a 2-year prospective survey of severe complications of strabismus surgery coordinated through the British Ophthalmic Surveillance Unit (BOSU)[1] and data from the available literature. The incidence of severe complications of strabismus surgery was 1 per 400 operations, with equal frequency in adults and children. Globe perforation is the most common complication with an incidence of almost 1:1000. Retinal detachment and endophthalmitis were the least commonly reported (Fig. 88.1 and Table 88.1). Anterior segment ischemia (ASI) was not part of the BOSU study, but may occur in 1:13,000 operations.[2]

The group devised a five-point scale depending on the severity of outcome of the complication. This is outlined in Box 88.1. The number of complications in the five categories split into adults and children is shown in Table 88.1 with the *p*-values. Although there were more infections and globe perforations in children and more surgically induced necrotizing scleritis (SINS) and lost muscle in adults, only SINS reached statistical significance.

Looking at the outcome, 16% of patients with a complication had a poor or very poor outcome. This means that about 0.04% or 1:2400 of patients operated on had a poor or very poor outcome.

Mild complications (Box 88.2)

Dellen

Dellen tend to occur in the peripheral cornea, specifically nasal and temporal quadrants in the first 1–2 weeks following strabismus surgery. Dellen are thinning of the cornea due to the drying out of the collagen in the stroma related to poor corneal wetting. They are related to tear film disruption and altered anterior segment contour due to swollen conjunctiva, which prevents the smooth travel of the eyelids. They are more common in adults, but may occur in children (who are rarely examined on the slit-lamp). The reported incidence is between 0.3% and 22%.[3] It is usually self-limiting or responds to topical lubricants; rarely, a bandage contact lens is required.

Chronic red eye

Redness is common, especially after repeated strabismus surgery, but some patients have a persistent red eye for many weeks or months. These patients are unhappy, feeling their appearance is harmed. Some of this may be related to a corneal wetting issue and responds to topical lubricants. Prolonged postoperative inflammation or violation of the orbital fat may contribute to a chronic red eye, most often of the medial rectus and surrounding tissue. This complication is reduced by meticulous surgical procedure with avoidance of orbital fat, careful hemostasis, and thinning and reduction of thickened and redundant medial conjunctiva, especially in adults with longstanding or consecutive exotropias. The authors give such patients intensive topical steroid drops for a month following strabismus surgery. Occasionally, long-term lubricants and topical steroids are required. If the eye is still red after 3 months, one can give subconjunctival depot steroids to settle the inflammation and reduce the conjunctival bulk.

Pyogenic granuloma

This fleshy mass appears a few weeks after surgery and is composed of inflammatory cells and capillary proliferation. It may be confused with a suture granuloma. It responds to topical steroids but occasionally requires surgery.

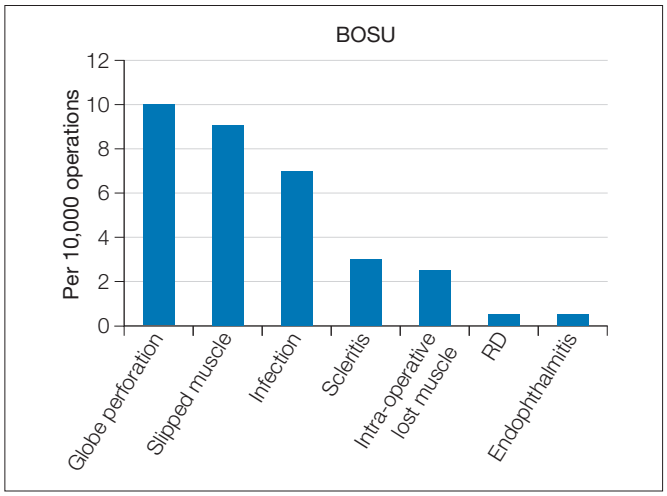

Fig. 88.1 Incidence of severe complications of surgery, per 10,000 operations. BOSU, British Ophthalmic Surveillance Unit; RD, Retinal detachment.

Prolapsed Tenon's capsule

This occurs in children and young adults with a prominent Tenon's layer. It is caused by poor conjunctival closure. If the prolapse is large, it may need to be trimmed, but it usually resolves spontaneously.

Epithelial inclusion cyst (Fig. 88.2)

This rare complication is caused by deposition of conjunctival epithelial cells into deeper tissues. Most are small, but some can be large, especially those at muscle insertions. They enlarge and need surgical removal.

Chemosis

Chemosis occurs after most strabismus surgery. It is rarely severe, but it can be so severe that the conjunctiva is exposed and the chemosis is exacerbated by drying: intensive topical lubricants and steroids usually resolve it. Rarely, it may be necessary to tape the lid shut or perform a temporary

Box 88.1

Classification of outcome

Grade 1: Good outcome
Grade 2: Surgical or medical intervention but good outcome
Grade 3: Surgical or medical intervention asymptomatic but compromised outcome
Grade 4: Surgical or medical intervention but poor outcome, e.g. double vision or up to two lines of vision loss on a Snellen chart
Grade 5: Very poor outcome, greater than two lines of visual loss on a Snellen chart

"superglue" tarsorrhaphy (with caution in children because of distress and amblyopia risk). An option is to suture the conjunctiva into the fornices.

Suture granuloma

A granuloma is a reaction to a foreign body characterized by the organized presence of macrophages, which can be infective or, in this case, a reaction to a foreign material. All absorbable sutures cause some form of inflammatory reaction; this is how they dissolve. In most cases this is mild, but less commonly a more severe reaction occurs causing pain, discharge, and redness around the suture. Often this can be managed by topical steroids and analgesia until the suture dissolves. This takes 56–70 days in the case of coated Vicryl® (Ethicon), probably the most common suture used. Even more rarely is the reaction so severe that the suture needs to be removed. It is best not to re-suture the tissue in order to prevent another reaction; this is not usually a problem with conjunctiva over a week postoperatively, but if the reaction is around a muscle suture, this may mean replacement with a non-absorbable suture. It is difficult, clinically, to tell if a reaction around a muscle suture is a sterile one and it is prudent, therefore, to assume it is infective until proved otherwise.

Severe complications (Box 88.3)

Anterior segment ischemia (Fig. 88.3)

Two anterior ciliary arteries (branches of the ophthalmic artery) run on each rectus muscle to supply the anterior segment, except for the lateral rectus, which has only one. The obliques have no anterior ciliary arteries.

The incidence of significant ASI is approximately 1 : 13,000 cases.[2] It was not surveyed in the BOSU study because the incidence of ASI is difficult to determine; it is probably under-reported, especially in children where postoperative slit-lamp examination is not normally performed. Severe outcomes are rare, although phthisis bulbi has been reported.[2] Risk factors for ASI include increasing age, previous rectus surgery, operations on multiple muscles (especially recti) in the same eye, circulatory problems (hypertension or diabetes), similar surgery on adjacent rectus muscles, surgery on vertical rectus muscles, and limbal incision.

In children, it may be safe to operate on more than two rectus muscles per eye at once; most surgeons avoid operating on all four rectus muscles simultaneously. If it is necessary

to operate on more than two rectus muscles on one eye in an adult, or if the patient has a very high risk of developing ASI, anterior ciliary artery-sparing surgery can be performed by dissecting out the anterior ciliary arteries from the muscle or performing a partial tendon transposition, sparing at least one of the anterior ciliary arteries.

Symptoms and signs of ASI can vary from mild uveitis and reduced iris perfusion to keratopathy[2,4] (Table 88.2).

- Grade 1 ASI can only be detected by iris angiography.
- Grade 2 ASI is caused by areas of iris hypoperfusion, sometimes an abnormally shaped pupil. It rarely requires treatment.
- Grades 3 and 4 ASI usually require treatment with topical or systemic corticosteroids. Unusual treatments include hyperbaric oxygen. The vast majority recover with only minor sequelae including iris atrophy, corectopia, or a poorly reacting pupil.

Globe perforation (Fig. 88.4)

Globe perforation is the commonest severe complication of strabismus surgery, reported in 0.13% to 1% of cases.[5,6] In the BOSU study, the incidence was 1 : 1000. Although, as noted previously, this complication was more common in children, possibly due to surgical access issues, it did not reach statistical significance. One patient developed endophthalmitis and had to have an evisceration. Although globe perforation is relatively common, a poor or very poor outcome is extremely rare. Complex surgery, such as faden procedures may have a higher incidence of globe perforation.

In the BOSU study, globe perforation sometimes occurred when placing a traction suture. This resulted in some cases of penetration into the anterior chamber and a soft eye, making strabismus surgery difficult. Most cases of posterior segment perforation had immediate treatment, usually cryotherapy or laser. There was one case of retinal detachment in a high myope who had bilateral globe perforation from bilateral Harada–Ito procedures.

The management of globe perforation is not evidence-based. Ninety percent of cases are treated with cryotherapy and/or laser.[7] In children, where globe perforation is more likely, retinal detachment is unlikely as they have formed vitreous. The authors perform a fundus examination to confirm the diagnosis with the pupil dilated peroperatively by injection of 1 or 2 mL of local anesthetic sub-Tenon's. The authors do not perform peroperative treatment themselves, but seek a vitreoretinal opinion, if available. In adults, they do a fundus examination and, in patients with a high risk of retinal detachment (i.e. high myopes), they perform peroperative treatment of the hole and then seek vitreoretinal opinion. They do not treat those at low risk, but seek a later vitreoretinal opinion. All patients have systemic antibiotics to reduce the risk of endophthalmitis. The BOSU study reported one case of endophthalmitis leading to evisceration in a 3-year-old.

Rathod[7] reported two cases of endophthalmitis, two retinal detachments, one suprachoroidal hemorrhage, and one choroidal scar.

Strategies to prevent globe perforation include:

1. avoiding suturing in areas with scleral thinning;
2. techniques (i.e. hang-back procedures) that do not involve direct scleral suturing in thinner areas or where access is difficult.

Orbital infection (Fig. 88.5)

Orbital infection following strabismus surgery tends to be equally either diffuse orbital cellulitis or an abscess at the muscle insertion. In the BOSU study there were 13 cases, only

Table 88.2 Grading of anterior segment ischemia

Grade	Clinical feature
Grade 1	Reduced iris perfusion
Grade 2	Pupillary abnormalities
Grade 3	Postoperative uveitis
Grade 4	Keratopathy

two in adults. Three muscle insertion abscesses developed a slipped muscle requiring surgical exploration. Kothari[8] reported a similar bilateral case. Management depends on whether it is a diffuse orbital infection; systemic antibiotics are usually curative. A muscle insertion abscess, if associated with a slipped muscle, requires surgical exploration and drainage, and systemic antibiotics.

Histolopathological examination of a number of eyes with endophthalmitis after strabismus surgery (Professor Simonsz, personal communication) showed that infection gained access to the eye from a postoperative muscle insertion infection, suggesting that a more aggressive approach to postoperative muscle insertion infections is indicated. No such cases occurred in the BOSU study.

Surgically induced necrotizing scleritis

SINS is a rare but serious complication of strabismus surgery. There is only one pediatric case in the literature,[9] but the BOSU study identified six adult cases (i.e. an incidence of 1 in 4000), which presented 1–6 weeks postoperatively, usually with ocular pain. They were treated usually with topical and systemic non-steroidal anti-inflammatory drugs (NSAIDs) or steroids. One severe case required treatment with cyclophosphamide and developed posterior synechiae and a cataract reducing the vision to logMAR 0.60 (6/24, 20/80, 0.25). Another patient, who presented 14 days following surgery, had a corneal melt and required a conjunctival autograft nearly 2 years later with a good visual acuity. Fifty percent of cases had a poor or very poor outcome. Most patients were elderly but two were in their 20s. Figure 88.6 shows a case of SINS. This responded to oral and topical non-steroidal agents with no significant sequelae. Presentation of postoperative scleritis can be delayed (up to 40 years).[10] The BOSU study follow-up was for 6 months only, and so the reported incidence may represent an underestimation. In this study, information was not collected on pre-existing conditions that might predispose to scleritis such as systemic autoimmune conditions and ischemia. O'Donoghue et al.[11] reported a high prevalence of collagen vascular disease in postoperative scleritis. Bearing this in mind, together with the poor prognosis that the BOSU study highlighted for this condition, patients with SINS may best be seen by an inflammatory diseases specialist.

Mild scleritis may be common following strabismus surgery, presenting with pain – more severe and deep-seated than normal – with diffuse scleral inflammation requiring oral NSAIDs. Risk factors include advancing age, poor circulation, scleral diathermy, and ischemia.

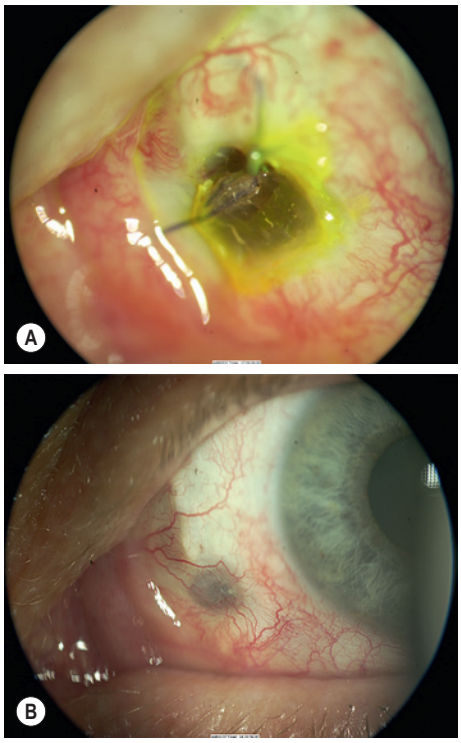

Fig. 88.6 (A) This 56-year-old male developed surgically induced necrotizing scleritis having had medial rectus recession on adjustable sutures after a blow-out fracture. There is a suture holding the conjunctiva covering the area of scleritis. (B) The appearance after treatment with topical steroids and oral non-steroidal agents.

Lost muscle

In the BOSU study, lost muscle was defined as a muscle lost peroperatively. There were six lost muscles, five in adults (i.e. an incidence of 1 in 4000). Most were in elderly patients, four of whom had undergone previous strabismus surgery. The lost muscles were medial recti (four) and lateral recti (two). Medial recti are the most common muscles lost at surgery.[10,11] This may relate to how frequently the muscle is operated on, or to its anatomy. The other recti have attachments to the oblique muscles, which prevents the muscle retracting into the orbit. All patients with lost muscles in the BOSU study had the muscle found preoperatively; only one had a poor or very poor outcome (only one had diplopia in the primary position). They must have been managed well and all had the lost muscle found.

If a muscle is lost, it is best to find it immediately. A common mistake is to look for the muscle around the globe when in fact the rectus muscles lie slightly away from the globe. Get help from an experienced surgeon, use suitable retractors for exposure, and control hemostasis. Careful exploration usually finds the muscle sheath and the muscle within. Some authors have suggested using the oculo-cardiac reflex to help identify the muscle, since traction on muscle fibers result in cardiac slowing. This technique is not always helpful. If the muscle cannot be found, suture the check ligaments and Tenon's surrounding the muscle to the original muscle insertion[9]; some muscle action may be transferred though these tissues to the eye. A muscle transposition could be performed; however, beware of ASI in adults. A more experienced strabismus surgeon may be able to find the muscle at a subsequent exploration. Postoperative investigations may include magnetic resonance imaging and computed tomography scans, especially with lost muscles due to trauma or where the orbits are congenitally abnormal or traumatized. An orbital approach may be necessary to retrieve a posteriorly situated lost muscle.[10]

Slipped muscle (Fig. 88.7)

In the BOSU study, slipped muscle was defined as a patient with a postoperative overcorrection and 50% or more reduction in movement in the action of a previously operated muscle. There were 18 cases (i.e. incidence of 7.5 per 10,000 operations), slightly more common in children. In three of these, the slipped muscle resulted from a muscle insertion infection. Three other patients had a poor or very poor outcome; all were children.

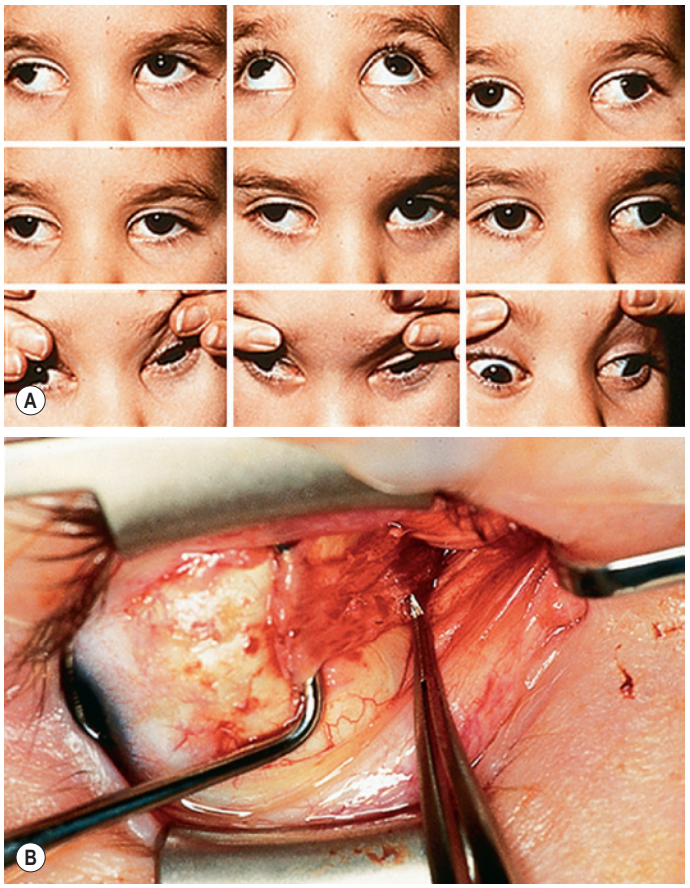

Fig. 88.7 Patient with slipped right medial rectus muscle. (A) Note large exodeviation and underaction of right medial rectus. (B) Findings at surgery: strabismus hook under pseudotendon of medial rectus 11 mm from limbus. Forceps indicating proximal end of medial rectus muscle. Note the change in color between muscle tissue and pseudotendon. *(Courtesy of Mr Robert Morris.)*

Slipped muscles take two main forms. A true slipped muscle is similar to a lost muscle: a problem with the sutures or insertion soon after the operation. The suture fails and the muscle slips. One deals with this as with a lost muscle. The more common presentation occurs many weeks to even years later, with a gross limitation of action of the muscle that has slipped. Exploration often finds the muscle on a large pseudotendon, not attached directly to the sclera but indirectly via stretchy scar tissue. This may occur due to stretching of a poorly inserted muscle over time. The pseudotendon is removed and the muscle re-attached to the globe. Because a contracture of the ipsilateral antagonist may have occurred, this muscle may need to be recessed along with its overlying conjunctiva.

Adherence syndrome

This is a restrictive condition, often progressive, caused by orbital fat prolapsing through a surgically disrupted posterior Tenon's. Surgery to the inferior oblique is often implicated. Occasionally it is caused by trauma or by lid surgery. To prevent this, care must be made to visualize the posterior edge of the inferior oblique so only the muscle is hooked at the time of surgery, avoiding damage to Tenon's and fat. Excessive bleeding may interfere with visualization and contributes to the scarring process. If orbital fat prolapses during surgery it can be repositioned or excised and the posterior Tenon's repaired. Often the problem is found postoperatively as the patient develops progressive hypotropia and limitation of elevation (Fig. 88.8). Surgical options are to explore the inferior fornix, excise any orbital fat, repair the posterior Tenon's capsule defect, and then recess the inferior rectus, Tenon's, and conjunctiva, followed by an amniotic membrane graft.

Endophthalmitis

There was one case of endophthalmitis in the 2 years of the BOSU study, giving an incidence of 1:24,000 cases. For diagnosis and treatment of endophthalmitis, see Chapter 15.

Consent in strabismus surgery

Placing a signature on a consent form should be the last event in a patient's journey from first appointment to the operating theater.[11] The principle of taking consent prior to treatment is directed towards protecting a patient's autonomy. To be valid, it must be given voluntarily by an informed patient with capacity to consent.[12,13] According to the Mental Capacity Act 2005[13] (UK Law), capacity is defined by a person's ability to fulfill the following four conditions below. The patient is able to:

1. retain information;
2. understand the information;
3. use the information to weigh up risk and benefit;
4. communicate the decision.

Consent is a process, not an event

During consent, the patient should develop a clear understanding of options, rationale, and outcomes, then weigh risks and benefits to make an informed decision and develop reasonable expectations for surgical results.

It is considered best practice to document the discussions you have with your patient at each stage of the consent journey and record what written information is given. Adequate time for discussion in clinic and gaining consent before the day of surgery allows the patient to reflect upon their decision. Any additional queries can be answered during confirmation of consent on the day of surgery.[14] Some authorities recommend that consent should be performed by the physician providing treatment,[15] whilst others allow delegation of consent to another team member so long as they have sufficient knowledge to describe risks and benefits, and to answer questions.[16]

Surprisingly, there is no specific "risk threshold" that mandates which complications need to be mentioned preoperatively. The legal standard describing what risks should be disclosed to the patient varies within and between countries. The standard of ethical care expected of health care professionals by their regulatory bodies may exceed the legal requirements. It is advisable to inform your patient (Box 88.4)[16,17] of all significant possible adverse outcomes or unavoidable risks of surgery, and make a record of the information given.[12]

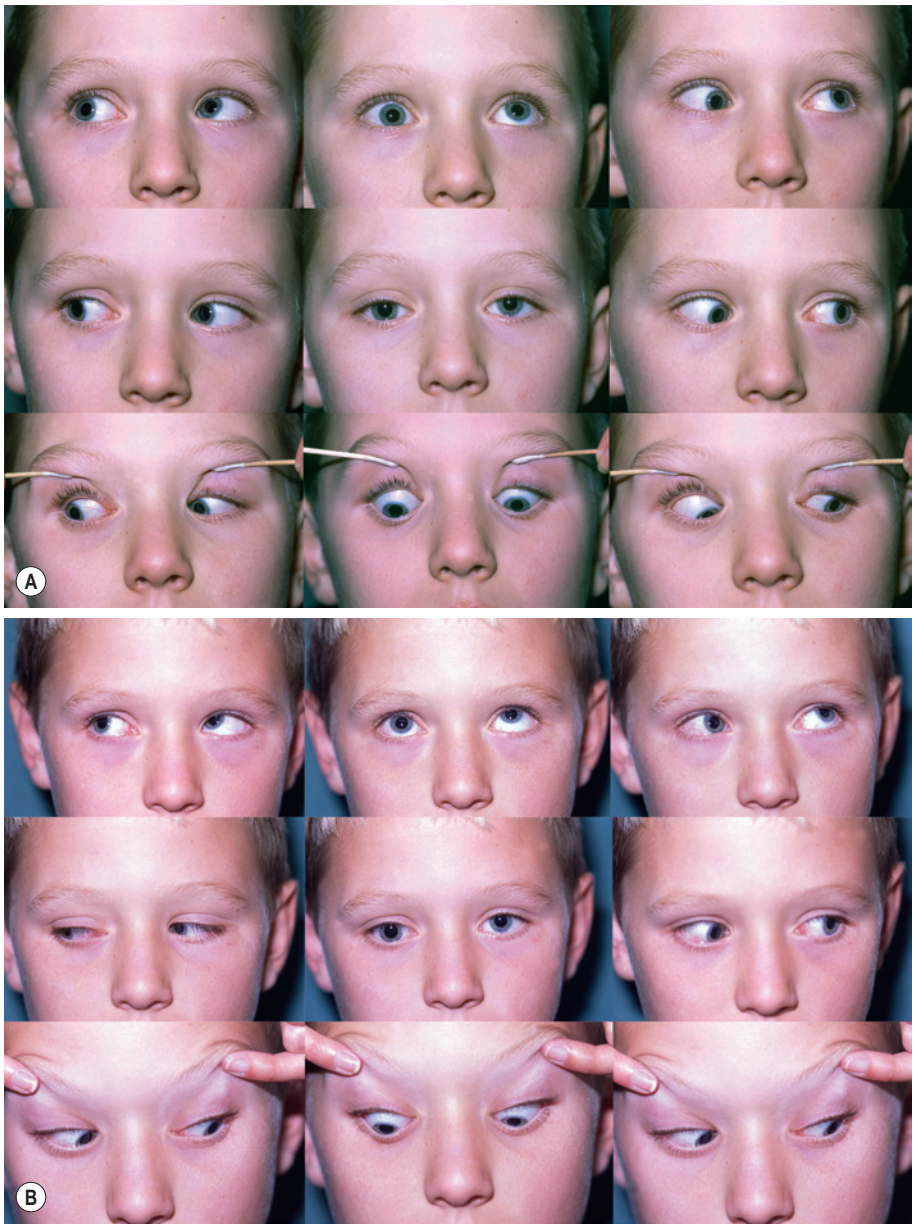

Fig. 88.8 A 14-year-old boy underwent routine right inferior oblique myectomy for a right fourth nerve palsy. (A) Two weeks postoperatively he developed restriction in elevation in the right eye as a result of right inferior fornix adherence syndrome. (B) His postoperative ocular motility showed improvement in elevation of his right eye.

Box 88.4

Informed consent should cover these areas[16,17]

Diagnosis
Treatment options, including no treatment
Other possible procedures that may be necessary during surgery
Common side effects/complications
Rare, significant complications
Anesthetic options and risks

Encourage a dialogue between you and your patient

A careful balance needs to be struck between listening to what your patient wants and ensuring they have sufficient information (Box 88.5) to make an informed decision.[18,19]

It is the duty of the surgeon to ascertain the patient's needs and wishes and discuss everything relevant to them,[16] to present information in a balanced way, and check that the patient has understood the information. In many countries, the surgeon also explains the risks of anesthesia, including morbidity and death; in others this is done by the anesthetic team.

Decision making in children should be centered around shared responsibility between surgeon and parents

For minors, informed consent is required from a parent or legal guardian prior to medical treatment. In most cases, a decision will be made that represents the best interests of the child. Although only one parent signature is required, it may be appropriate to involve both parents in decision making.

Box 88.5

Ophthalmic Mutual Insurance Company informed consent for strabismus surgery

Major risks of strabismus surgery:

1. Need for additional surgeries
2. Persistent misalignment, altered eyelid position, limitation of eye movements, persistent visual problems
3. Double vision
4. Scar tissue formation
5. Infection
6. Hemorrhage or bleeding
7. Severe infection or bleeding leading to damage to the eye or rarely visual loss
8. Allergic reaction
9. Temporary side effects, such as corneal abrasion, conjunctivitis, eye ache

Consider an adolescent's developing capability for involvement in decision making[20,21]

A young person's ability to consent depends more on their understanding of the nature of the proposed treatment and its possible consequences than on their age.[18,22] There is no simple criterion or measure of competence; your skill lies in assessing the young patient's competence in a particular context for a specific decision.[23] The legal age at which a minor may give consent varies widely from country to country and should be considered on a case-by-case basis.[24,25] The law on consent is constantly evolving and varies internationally. Legal advice should always be sought if there is doubt regarding the legal validity of a proposed intervention.

Introduction

Nystagmus consists of rhythmic ocular oscillations. Pathological nystagmus is involuntary, although it may be modulated when performing certain tasks such as reading. Infantile nystagmus is defined as nystagmus developing in the first 3–6 months of life. Nystagmus can be acquired later in life, usually due to neurological diseases. Patients with acquired nystagmus have oscillopsia, the illusion that the environment is moving. Patients with infantile nystagmus, however, usually have a stable view of the environment, probably due to neuronal plasticity and adaptation during visual development.

Nystagmus in childhood can be idiopathic or associated with retinal diseases, low vision in infancy, and a variety of syndromes and neurological diseases. Nystagmus associated with neurological disorders in childhood may be similar in appearance and pathophysiology to acquired nystagmus. Onset may also be after 6 months of age. The estimated prevalence of nystagmus (including both infantile and acquired nystagmus) is 24 in 10,000. The prevalence of infantile nystagmus is 14 per 10,000.[1] Among the infantile forms of nystagmus, idiopathic nystagmus is the most common, followed by nystagmus associated with ocular disease. The clinical diagnoses associated with infantile nystagmus are shown in Figure 89.1.

Causes of infantile nystagmus

The causes of most forms of infantile nystagmus are as yet unknown, although this is currently an active field of research.[2] In general, infantile nystagmus is considered to be a disorder of gaze-holding and slow eye movement systems,[3] leading to sinusoidal oscillations and/or drifts of the eye away from the intended point of fixation. These involuntary slow eye movements constitute nystagmus slow phases. The slow phases are interrupted and shaped by the interposition of nystagmus quick phases, which serve to re-align the eyes.

Many types of infantile nystagmus are associated with the presence of sensory abnormalities during early visual development.[4–9] With afferent diseases such as achromatopsia and congenital cataract, the nystagmus is clearly the result of changes in the otherwise healthy ocular motor systems in response to afferent deficits present during visual development. For other conditions such as albinism and various syndromes, it is uncertain whether the nystagmus is also due to afferent deficits or directly caused by abnormalities in ocular motor neural circuitry.

Quality of life and infantile nystagmus

Investigations into the quality of life of adults and children with infantile nystagmus show that the effects on visual function are considerable and are comparable to the effects of diseases such as age-related macular degeneration.[10] Infantile nystagmus has a much wider impact than simply reducing vision. It affects social interaction, due to lack of confidence caused by the cosmetic appearance of nystagmus, and restriction in mobility of many patients, as they are not able to drive. Consequently, treatment of nystagmus should not only aim at improving visual acuity but also at improving cosmesis. This might include, for example, the correction of abnormal head postures and the reduction of nystagmus intensity in patients with poor visual potential. Patients may also benefit from counseling services and support groups such as Nystagmus Network, UK (http://www.nystagmusnet.org) or the American Nystagmus Network (http://www.nystagmus.org).

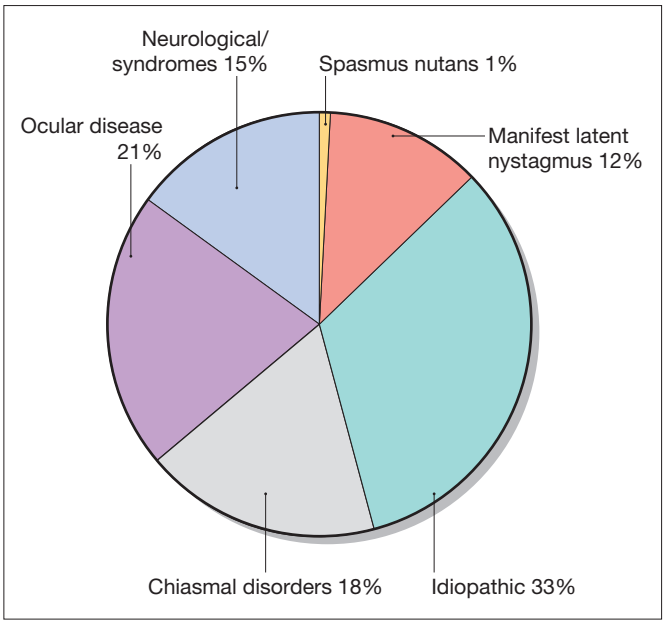

Fig. 89.1 Prevalence of the main types of nystagmus in childhood. A breakdown of the various disorders in individuals 18 years and under with infantile nystagmus from the Leicestershire Nystagmus Survey.[1] The majority of patients with chiasmal disorders had albinism.

Classification of infantile nystagmus

There has been significant controversy over the classification and terminology used in nystagmus. This is because some researchers have been mainly interested in the morphology of nystagmus waveforms and others in clinical etiology.

The advantages of using a clinical classification of infantile nystagmus based on the associated diseases are that the clinical implications such as prognosis, possible genetic counseling, or treatment options are immediately highlighted.[11] Figure 89.2 lists examples of disorders using this type of classification. Idiopathic nystagmus has historically been a diagnosis of exclusion where all other eye examinations are negative. The visual acuity is 0.3 LogMAR or better in most patients, suggesting relatively good retinal function.[12,13] However, retinal abnormalities have been recently identified in idiopathic nystagmus using optical coherence tomography (OCT).[6] Mutations in the *FRMD7* gene have been identified as a major cause of X-linked idiopathic nystagmus.[14,15] Several genetic mutations are known for other disorders such as albinism[16,17] and achromatopsia.[18] It is likely that the nystagmus genotype will be the principal method of classification in the future.

The Committee for the Classification of Eye Movement Abnormalities and Strabismus Workshop (CEMAS; http://nei

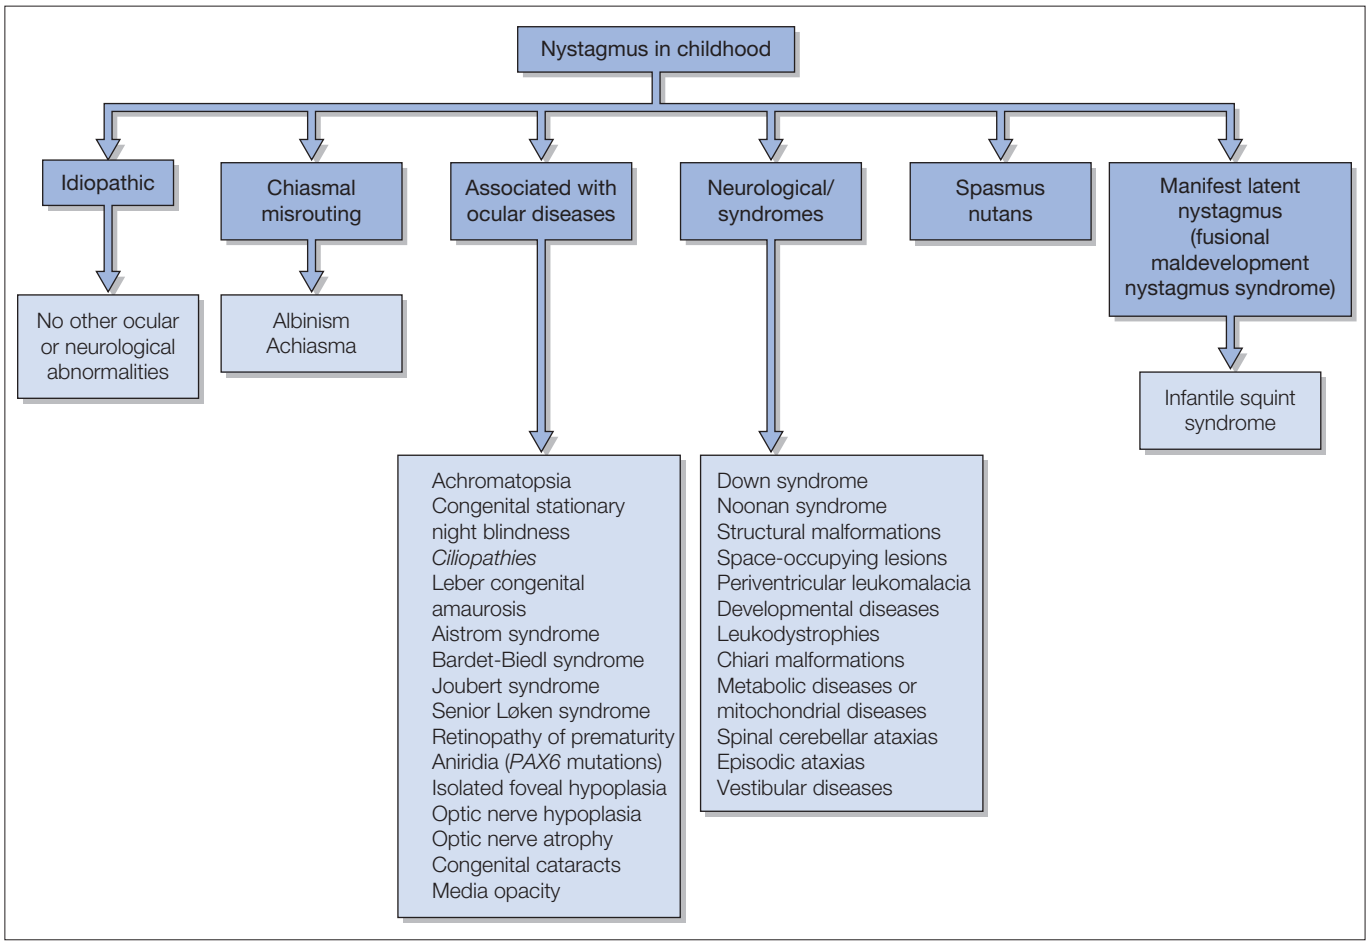

Fig. 89.2 Classification of nystagmus based on associated diseases.

.nih.gov/sites/default/files/nei-pdfs/cemas.pdf) have grouped together idiopathic nystagmus, nystagmus associated with ocular diseases, and nystagmus associated with chiasmal misrouting into one category called "infantile nystagmus syndrome." In a clinical setting, this classification is less helpful and makes unconfirmed assumptions about a common mechanism leading to nystagmus in all of the underlying pathologies.

Clinical assessment

History

It is important to establish the time of onset for the nystagmus since infantile nystagmus occurs usually in the first 3, or sometimes 6, months of life.

As several forms of infantile nystagmus are hereditary, establishing whether other family members have nystagmus or associated ocular diseases can help with the diagnosis. If there is a positive family history, determining the mode of inheritance is very important. Idiopathic nystagmus often occurs in an X-linked pattern in which heterozygous females are fully affected in approximately 50% of cases (i.e. 50% penetrance).[14,15] In contrast, only males are fully affected in X-linked congenital stationary night blindness (CSNB),[19] blue cone monochromatism,[18] or ocular albinism.[17] Oculocutaneous albinism[16] and achromatopsia[18] are usually autosomal recessive. The most common form of autosomal dominant nystagmus is caused by mutation in *PAX6* genes.[20]

Where neurological deficits such as cerebral palsy, metabolic diseases, or other causes of developmental delay are present, they are likely to play a key role in the etiology of the nystagmus.

It is important to establish whether parents think their child has poor vision. Although nystagmus can be of very large amplitude at onset and parents can have the impression that the child is visually unresponsive, usually the nystagmus amplitude is considerably smaller by 6–9 months of age.[21] Explaining to parents that nystagmus generally changes and becomes less evident as their child becomes older is important, and therefore caution should be taken about predicting poor vision later in life.

Often children with nystagmus have head nodding or bobbing. This seems to be an independent abnormal head movement, which can decrease or disappear with age. Only in spasmus nutans has head nodding been shown to reduce or abolish nystagmus (Fig. 89.3D).

A history of photophobia should be specifically asked for. This would be indicative of a retinal disease, particularly achromatopsia or blue cone monochromatism. Similarly, a history of night blindness should be specifically asked for. This suggests a rod–cone dystrophy and is common in congenital stationary night blindness.

Symptoms of oscillopsia are a feature of acquired nystagmus and seldom occur in children. Some patients with infantile nystagmus, however, perceive oscillopsia if they look away from the null region[22] or if the nystagmus changes, for example in manifest latent nystagmus (MLN), which can change with the degree of strabismus. The oscillopsia in acquired nystagmus is usually sudden in onset and severe. In contrast, the time of onset of oscillopsia in infantile nystagmus is generally not as well defined and the symptoms are milder.

Clinical examination

Visual acuity

Visual acuity (VA) needs to be examined with the best optical correction and tested with both eyes open and either eye covered with a free head position. This is important, as manifest latent nystagmus, alone or superimposed on other infantile nystagmus waveforms, can increase the nystagmus and decrease VA when one eye is covered. VA should also be measured at distance and near. In infants, VA tests can be performed using preferential looking cards. In patients with horizontal nystagmus, measurement of VA can be assisted by vertically aligning the cards,[23] making it easier to identify changes in fixation when the child looks up or down at the visual targets on the card. This can be masked by the horizontal nystagmus if the card is aligned horizontally. The presence of vertical optokinetic nystagmus can also be used to predict the likelihood of better VA in horizontal nystagmus.

Abnormal head posture

Abnormal head posture (AHP) (or torticollis) occurs commonly in nystagmus because many patients can reduce their nystagmus by looking in a certain direction of gaze, for example by directing gaze towards the null region. In most patients, the full extent of torticollis is only observed during visual effort. So to identify the full amount of AHP, ask the patient to read or look at pictures (Fig. 89.5A). Glasses can prevent the patient adopting the full head turn due to the spectacle frame and optical decentration. VA measurements should be repeated, therefore, without spectacles. Figure 89.5B shows a child with idiopathic infantile nystagmus (IIN) and a right head turn increasing as he reads smaller letters. With a greater visual demand, a large head turn is adopted and he looks over his glasses or prefers to read without glasses since the full head turn is prevented by the glasses.

Manifest latent nystagmus dampens on adduction. As a result, the patient adopts a head turn to keep the fixing eye adducted (Fig. 89.5C). In manifest latent nystagmus, the head position also needs to be examined with each eye covered, as the head position can change depending on the fixing eye (Fig. 89.5D). Patients with "A" or "V" pattern strabismus may adopt a chin-up or -down head position in order to maintain binocular function and thus reduce the amplitude of the nystagmus (Fig. 89.5E). Eye movement recordings are helpful in understanding abnormal head postures, for example in establishing whether the head posture is due to idiopathic nystagmus (see Fig. 89.4A) or manifest latent waveforms (see Fig. 89.4C). They can also be used to determine whether the adopted head posture leads to a reduction or change in the nystagmus.

Orthoptic examination

Orthoptic examination should include an assessment of strabismus at distance and near, the range of motility of each eye, binocularity, stereopsis, and fusion ranges if binocular vision is present.

Color vision testing

This is important to detect achromatopsia and other retinal or optic nerve diseases.

Terminology used in nystagmus

Nystagmus can be characterized by clinical examination of the patient. Eye movement recordings can help by providing greater precision in detecting and describing nystagmus waveforms, which can assist in the diagnosis (Figs 89.3 and 89.4). The following parameters can be used to describe nystagmus:

Plane: The plane of oscillation can be horizontal, vertical, torsional, or a combination of more than one plane (e.g. Fig. 89.3C2).

Intensity: The intensity of the nystagmus is a measure of the speed of the eye movements and is obtained by multiplying the nystagmus amplitude (in degrees) and frequency (oscillations per second in Hertz).

Waveform: Nystagmus can be broadly classified into jerk and pendular waveforms. Jerk nystagmus consists of alternating slow and quick phase eye movements. The nystagmus direction is defined using the quick phase. Slow phases can have an increasing velocity profiles where the eyes start slowly and accumulate speed (e.g. Fig. 89.4A in right gaze). Alternatively, slow phases may have decreasing velocity (e.g. Fig. 89.4C) or linear velocity profiles. In contrast, pendular nystagmus consists of approximately sinusoidal oscillations without quick phases (e.g. Fig. 89.4A at null region). Dual jerk nystagmus is a combination of large jerk nystagmus waveforms with small pendular nystagmus waveforms superimposed along the same plane.

Conjugacy: If both eyes move together, i.e. with the same amplitude, frequency and plane, the nystagmus is conjugate. Dysconjugacy or dissociated nystagmus occurs if the eyes move with different amplitude (e.g. torsional eye movements in Fig. 89.3A3), frequency, phase (e.g. vertical eye movements in Fig. 89.3C2) or along different planes.

Foveation: Most types of infantile nystagmus show periods in the nystagmus cycle when the eyes move at a slower velocity. These slow periods are often used to align the fovea with visual targets to improve visual acuity, and hence are called foveation periods.

Null region: Many patients with infantile nystagmus prefer a particular gaze direction where the nystagmus is reduced in intensity and visual acuity is optimal. This is called the null region. If the null region is not in the primary position, patients may adopt an abnormal head posture (AHP) using the null region to improve vision when looking straight ahead. An example is shown in Figure 89.4A2 where the null region is in right gaze.

Infantile nystagmus is not always uniform but can change depending on several factors:

Change with gaze: Patients with nystagmus associated with albinism and idiopathic nystagmus usually have a null region. The nystagmus becomes more jerk-like (see Fig. 89.4A1) and intense (see Fig. 89.4A2) away from the null region.

Change with time: Most patients have a consistent oscillation when attempting to maintain a fixed gaze position. However, certain types of nystagmus vary with time. In periodic alternating nystagmus (PAN) the fast phase beats periodically to the right and to the left with quiet periods at the changeover periods (see Fig. 89.4B).

Change upon covering one eye: In manifest latent nystagmus (MLN), the fast phase of nystagmus changes direction beating towards the open or fixing eye (see Fig. 89.4C).

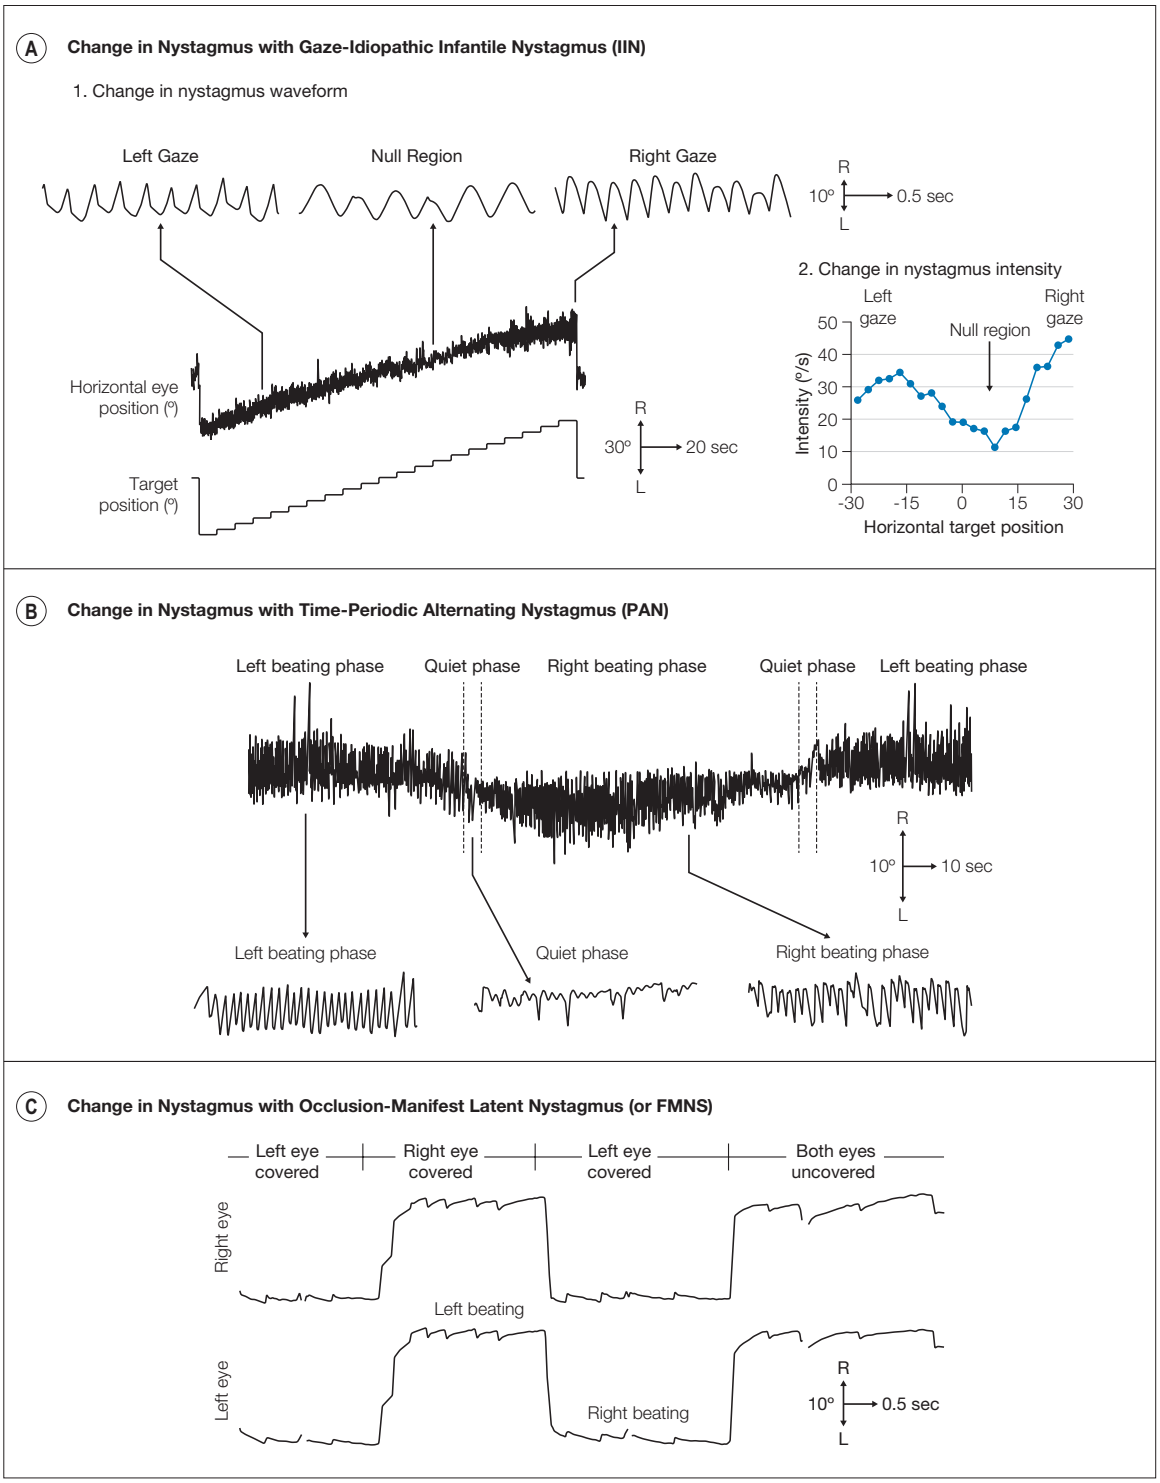

Fig. 89.4 Change in nystagmus with (A) gaze, (B) time and (C) occlusion. (A) Shows an example of the null region in a patient with idiopathic infantile nystagmus using original eye movements from a patient. The patient follows a target moving from the left to right in steps of 3° every 8 seconds (lower traces). The horizontal nystagmus changes both in waveform (A1) and intensity (A2) as the direction of gaze changes. The changing waveforms can be seen from the expanded views in the upper traces. At the null region, which is 9° to the right of central fixation, the nystagmus waveform is predominantly pendular, with occasional foveating saccades. Jerk waveforms are present to the left and right of the null region, with the nystagmus beating to the left in left gaze and right in right gaze. A plot of the nystagmus intensity in relation to the horizontal gaze angle is shown in A2. (B) Shows a patient with idiopathic infantile nystagmus and periodic alternating nystagmus as an example of a nystagmus waveform changing with time. The nystagmus completes a full cycle of left beating and right beating nystagmus every 200 seconds, with short quiet phases of several seconds between each change in beating direction. Expanded views are shown in the lower traces. (C) Shows a patient with manifest latent nystagmus illustrating the change in beating direction on covering either eye. The eyes always beat towards the open or fixing eye. The waveforms all show decreasing velocity slow phases. Note the step change in eye position on covering either eye, which is due to a large esotropia. The left eye is the dominant eye. The nystagmus is less intense when both eyes are open.

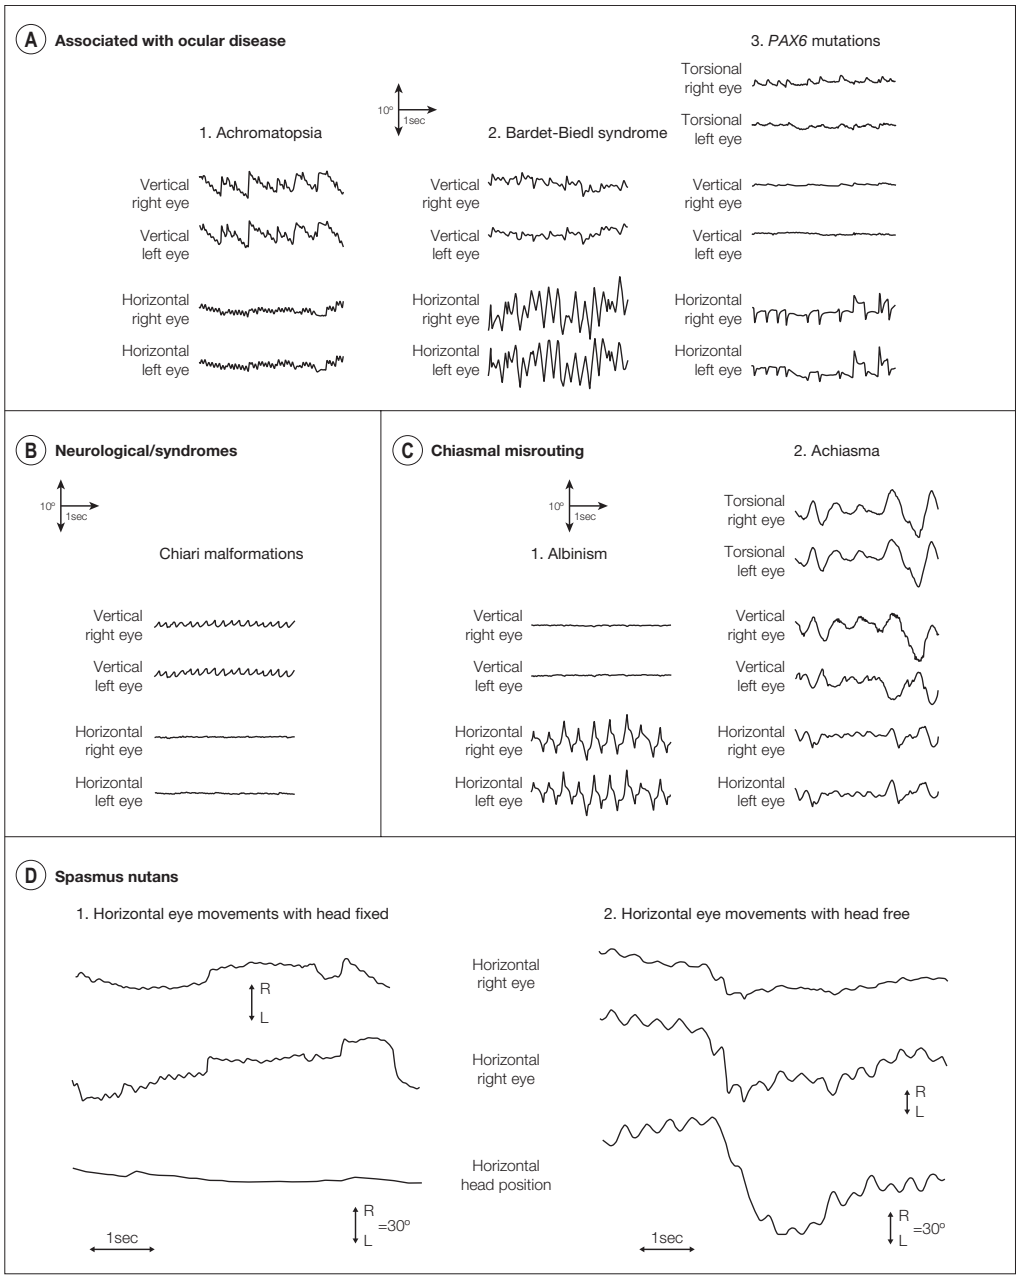

Fig. 89.3 The use of eye movement recordings in the diagnosis of nystagmus. Examples of eye movement recordings from patients with infantile nystagmus associated with (A) ocular diseases, (B) neurological disorders and syndromes, (C) chiasmal misrouting disorders, and (D) spasmus nutans. (A) Ocular diseases: In achromatopsia, a fine pendular nystagmus with a vertical component is often present. In the achromat shown (A1), a fine mainly horizontal pendular nystagmus of 1–2° amplitude and 8 Hz frequency co-exists with a vertical upbeat jerk nystagmus of approximately 5° and 1.5 Hz. A patient with Bardet–Biedl syndrome (A2) has horizontal pendular oscillations that are much larger than in the achromat (8–10° amplitude and 3 Hz frequency in the example shown), but the vertical component to the nystagmus is smaller. *PAX6* mutations (A3) lead to a variety of waveforms, with the two eyes sometimes showing dysconjugate eye movements. The example here shows unusual horizontal waveforms with both increasing and decreasing velocity components. A significant torsional component is apparent, which is larger in the right eye. (B) Neurological disorders and syndromes: These can be associated with vertical eye movements. The example shown is from a patient with a Chiari malformation leading to a downbeat jerk nystagmus of 2–3° amplitude and 3–4 Hz frequency, with little horizontal nystagmus. (C) Chiasmal routing disorders: Similar to idiopathic infantile nystagmus (see Fig. 89.4A), nystagmus associated with albinism (C1) can have pendular or jerk waveforms but always along the horizontal plane and usually with a null region. Jerk waveforms can be left beating, right beating, or bidirectional as shown in example here. Achiasmatic disorders (C2) lead to seesaw nystagmus, so called because the eyes give the appearance of rotating around an invisible pivot positioned somewhere between the two eyes. Consequently, as one eye moves up, the other eye moves down, leading to a dysconjugate vertical waveform. The eye moving up intorts and the eye moving down extorts, leading to a large-amplitude torsional nystagmus. There is also a horizontal component to seesaw nystagmus. (D) Spasmus nutans: Nystagmus in spasmus nutans is altered by head movements. When the head is fixed, a rapid pendular oscillation develops, which is dysconjugate between the two eyes. When the head is free, head bobbing occurs with the eyes moving in the opposite direction due to the vestibulo-ocular reflex. This leads to suppression of the rapid oscillation. *([D] Reproduced from Gottlob I, Zubcov AA, Wizov SS, et al. Head nodding is compensatory in spasmus nutans. Ophthalmology 1992; 99: 1024–1031.)*

Fig. 89.5 Abnormal head postures. (A) Patient with IIN and a mild head tilt to the left when reading large letters on VA chart (A1), which significantly increases (A2) when reading smaller letters. (B) Moderate head turn to the right due to IIN when reading large letters (B1). As the patient reads smaller letters, the head increasingly turns to the right and the patient looks over his glasses as the frames do not allow a larger head turn to the right (B2). He prefers to read without glasses in order to adopt a large head turn (B3). (C) Child with a blind right eye due to optic nerve hypoplasia adopting an extreme head turn and tilt to the left to dampen manifest latent nystagmus (C1). When the left eye is covered and there is no vision, the head turn is absent (C2), which shows that there is no muscular torticollis. (D) Manifest latent nystagmus and alternating exotropia. The patient turns the head alternately to the right to fix in adduction with the right eye (D1), or the left to fix in adduction with the left eye (D2) to dampen the manifest latent nystagmus. When one eye is patched, he turns the head continuously to the right when the right eye is open (D3), and to the left when the left eye is open (D4). (E) Girl with manifest latent nystagmus adopting chin elevation while reading (E1). She has "V" pattern exotropia with bilateral inferior oblique overaction (E2–E5). On downgaze she has some amount of binocularity (Bagolini positive), which causes the nystagmus to dampen. Hence she adopts a chin-up position when reading the visual chart. (F) Head turn to the left due to IIN (nystagmus null region to the right), which does not allow the patient to wear glasses as the frame is obstructing her vision (F1). After Kestenbaum surgery (F2), her head is straight and she is able to wear her 4 diopters of astigmatic correction, significantly improving her vision. (G) A patient with albinism and pronounced head tilt to the left before surgery when reading the visual acuity chart (G1). After surgery, he reads the same line on the acuity chart without a head tilt (G2).

Examination of light sensitivity and nyctalopia

Photophobia is easily noted on slit-lamp or fundus examination and points to achromatopsia or other retinal dystrophies. Nyctalopia can be objectively measured using dark adaptometry and indicates congenital stationary night blindness or other retinal dystrophies.

Structural examination

The most common abnormal sign of the anterior segment is iris transillumination, which is strongly associated with albinism. The amount of iris transillumination varies and can be easily missed on examination if it is mild, especially in patients with dark irides or in small children. Slit-lamp examination should be performed in a completely dark room with retroillumination. It is helpful to examine the parents also, as carriers commonly have mild iris transillumination. It is important to examine for corneal changes, aniridia, or abnormal iris structure and the presence of cataracts. The retina can appear normal in the early stages of retinal dystrophy. Foveal hypoplasia often manifests as a missing foveal reflex and abnormal vessels in the foveal area. This can be difficult to establish in a child with nystagmus. In retinal diseases such as achromatopsia and congenital stationary night blindness, the retina can appear normal. Optic nerve hypoplasia or atrophy can cause nystagmus, particularly if it is bilateral. Large refractive errors are also commonly a sign of retinal dystrophies, albinism, *PAX6* mutations, or other diseases associated with low vision. Paradoxical pupillary response (initial pupillary constriction when the room light is turned off) can be a sign of retinal diseases.

Electrophysiology

Every patient with infantile nystagmus should have an electrophysiological examination. Hemispheric visual evoked potentials (VEPs) represent the gold standard examination for determining increased crossing of the optic nerves in albinism and reduced crossing in achiasma (see Chapters 41 and 57).

Electroretinography (ERG) is essential to investigate possible retinal dystrophies (Fig. 89.6).

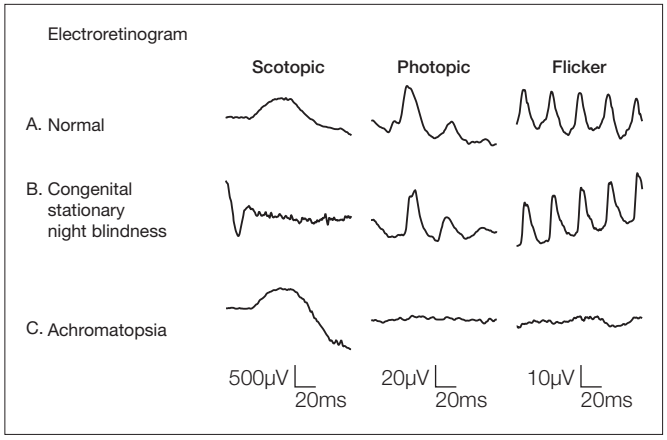

Fig. 89.6 Electroretinography in infantile nystagmus. Examples of scotopic, photopic, and flicker electroretinograms (ERGs) of (A) a normal subject, (B) a patient with congenital stationary night blindness (CSNB) with a negative scotopic ERG, and (C) a patient with achromatopsia with extinguished photopic ERG and flicker ERG.

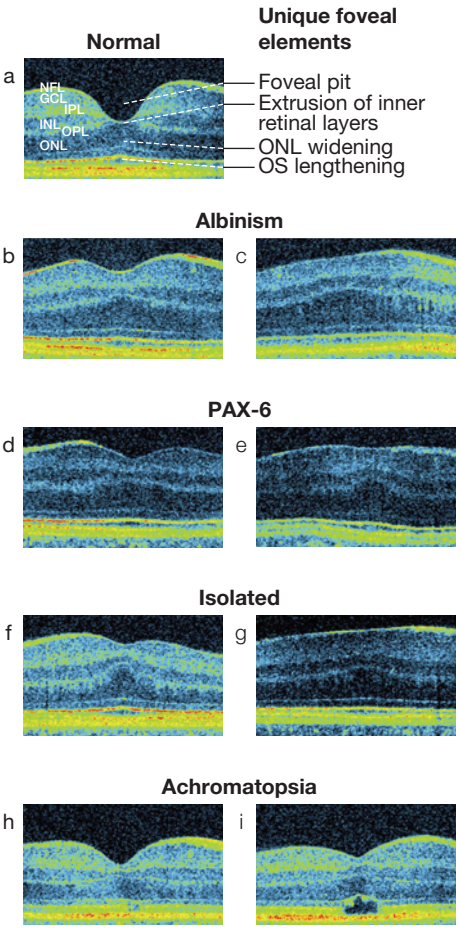
Eye movement recordings

Eye movement recordings are very useful in clarifying the pathophysiology of the nystagmus, in differential diagnosis, and in planning surgery. Figures 89.3 and 89.4 show examples of eye movement recordings in each of the main classes of infantile nystagmus.

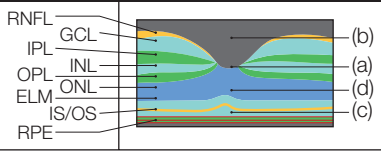
Nystagmus associated with albinism (see Fig. 89.3C1) or idiopathic nystagmus (see Fig. 89.4A) is conjugate, almost always horizontal, with a combination of pendular and jerk waveforms that vary with gaze.[12] Away from the null region, the slow phases typically increase in velocity and drift towards the null region (see Fig. 89.4A). In contrast, nystagmus associated with manifest latent nystagmus usually has decreasing velocity slow phases (see Fig. 89.4C). Nystagmus waveforms associated with retinal diseases are variable and can be dissociated, vertical, and can have increasing or decreasing slow phase velocities (see Fig. 89.3A). Vertical nystagmus is also often associated with neurological disorders (see Fig. 89.3B).

Optical coherence tomography



OCT has recently been added as a useful investigative tool for the differential diagnosis of nystagmus and can be performed easily and quickly.[5–9] It is particularly helpful in identifying foveal hypoplasia and results can be obtained at the time of appointment. Figure 89.7 shows OCT images of a control subject and patients with albinism, idiopathic foveal hypoplasia, *PAX6* mutation, and achromatopsia. If foveal hypoplasia is detected on OCT, the most likely diagnosis is albinism[5]; however, mutations in the *PAX6* gene or idiopathic foveal hypoplasia cannot be ruled out.[8] These diseases have similar morphological changes in the fovea. In contrast, foveal hypoplasia in achromatopsia is atypical.[4,7,24] In many patients with achromatopsia, there is a pathological continuation of inner and outer plexiform layers. Typically, there is disruption of the inner segment/outer segment junction and cone outer segment tip, and thinning of the outer nuclear layer. The most striking sign is a "punched out" hyporeflexive zone, which often only appears in older patients. Morphological changes in achromatopsia appear to increase with age on OCT.[4,7,24] Structural grading of foveal hypoplasia based on retinal imaging using OCT can be used to estimate VA (Fig. 89.7[2]).[5,8]

Hand-held OCT is also now available for use in infants and children, and can assist in diagnosing patients that are too young to comply with other diagnostic tests.[25] Figure 89.8 shows a diagnostic algorithm for infantile nystagmus that has been developed for use in infants and children using hand-held OCT.



Magnetic resonance imaging of the brain

Magnetic resonance imaging (MRI) is necessary if the nystagmus is not typical of idiopathic nystagmus (i.e. dysconjugate, vertical, or oblique) and cannot be explained by ocular or systemic disease. MRI is generally not indicated when the associated disease (e.g. albinism, achromatopsia, or manifest latent nystagmus/infantile squint syndrome) has been determined and when no other neurological/developmental problem is present. Any suspicion of neurological disease, optic atrophy, optic nerve hypoplasia, or developmental delay should prompt neuroimaging. In the presence of optic nerve hypoplasia,

Fig. 89.7 Optical coherence tomography (OCT) in infantile nystagmus. (A) Optical coherence tomograms are shown for (a) a normal fovea, (b,c) albinism, (d,e) associated with *PAX6* mutations, (f,g) isolated cases, and (h,i) an atypical form of foveal hypoplasia seen in achromatopsia. In (i), hyporeflective zone (cavitation) is also seen, indicating cone photoreceptor degeneration. Foveal hypoplasia of varying degrees is seen in all disorders. In achromatopsia, there is an atypical form of foveal hypoplasia with a shallower pit, incursion of the plexiform layers, and disruption of the inner segment/outer segment junction. INL, Inner nuclear layer; IS, inner segment; NFL, nerve fiber layer; ONL, outer nuclear layer; OS, outer segment. (B) Illustrates the principles used for structural grading of foveal hypoplasia. A schematic of the unique features of a normal fovea detectable on optical coherence tomography is shown with the typical and atypical grades of foveal hypoplasia through a series of schematics. All grades of foveal hypoplasia had incursion of inner retinal layers. Atypical foveal hypoplasia also had incursion of the inner retinal layers. Grade 1 foveal hypoplasia is associated with a shallow foveal pit, outer nuclear layer (ONL) widening, and outer segment (OS) lengthening relative to the parafoveal ONL and OS length, respectively. In grade 2 foveal hypoplasia, all features of grade 1 are present except the presence of a foveal pit. Grade 3 foveal hypoplasia consists of all features of grade 2 foveal hypoplasia except the widening of the cone outer segment. Grade 4 foveal hypoplasia represents all the features seen in grade 3, except there is no widening of the ONL at the fovea. The final image shows an atypical form of foveal hypoplasia in which there is a shallower pit with disruption of the inner segment/outer segment (IS/OS) junction, possibly a sign of photoreceptor degeneration. The atypical form of foveal hypoplasia is seen with achromatopsia, whereas grades 1–4 are seen with albinism, *PAX6* mutations, and isolated cases. ELM, External limiting membrane; GCL, ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; OPL, outer plexiform layer; RNFL, retinal nerve fiber layer; RPE, retinal pigment epithelium. *(Reproduced from Thomas MG, Kumar A, Mohammad S, et al. Structural grading of foveal hypoplasia using spectral-domain optical coherence tomography a predictor of visual acuity? Ophthalmology 2011; 118: 1653–60.)*

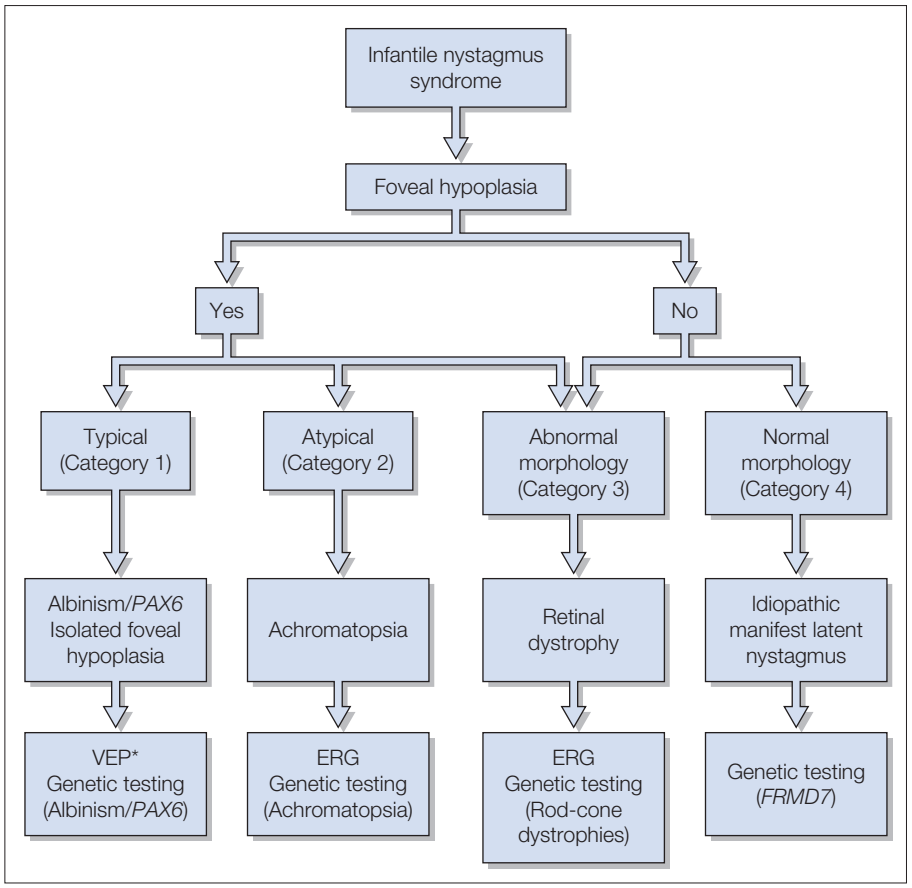

Fig. 89.8 A diagnostic algorithm for using hand-held optical coherence tomography (OCT) to diagnose the type of infantile nystagmus in infants and children. Four diagnostic categories can be ascertained on the basis of OCT findings. Depending on the presence or absence of foveal hypoplasia or the presence or absence of other abnormal macular morphology, the cause of nystagmus can be predicted and diagnostic tests can be selected to confirm the diagnosis. *In the presence of grade 1 foveal hypoplasia (see Fig. 89.7) with no evidence of crossed asymmetry, visual evoked potential (VEP) testing for mutations on the *FRMD7* gene should be considered. ERG, Electroretinogram; *FRMD7*, FERM domain containing 7 gene; *PAX6*, paired box 6 gene. *(Reproduced from Lee H, Sheth V, Bibi M, et al. Potential of handheld optical coherence tomography to determine cause of infantile nystagmus in children by using foveal morphology. Ophthalmology 2013; 120: 2714–24.)*

investigation for septo-optic dysplasia (de Morsier syndrome) and hormone deficiency is important.

Clinical characteristics of infantile nystagmus types

Idiopathic infantile nystagmus

IIN has historically been diagnosed by exclusion of other ocular or neurological pathology. Anterior segment, fundus examination, VEPs and ERGs are normal. However, retinal abnormalities may be apparent on OCT imaging such as shallow foveal pits and smaller optic discs, cups, and retinal nerve fiber layer thickness.[6] If the IIN is familiar, the most frequent inheritance mode is X-linked, where approximately 50% of female carriers are clinically affected.[14,15] Autosomal dominant inheritance has also been described. Recently the first gene (*FRMD7*) in which mutations cause X-linked IIN has been found.[14,15] Knockdown of *FRMD7* during neuronal differentiation results in altered neurite function.[26]

Patients with IIN have a median VA of 6/9.5, strabismus is uncommon (less than 10%), and good stereoacuity is often present.[13] Interestingly, patients with mutations in the *FRMD7* gene often have less abnormal head postures compared to patients with IIN without mutations in this gene.[13] Nystagmus is conjugate and usually horizontal, especially when associated with *FRMD7* mutations (see Fig. 89.4A).[13] Nystagmus waveforms in IIN have been described as having increasing velocity slow phases. However, the nystagmus is usually more complex, consisting of underlying pendular oscillations regularly interrupted by quick phases (see Fig. 89.4A). Increasing velocity slow phases are more apparent away from the null region.

Nystagmus waveforms are often of very large amplitude in the first few months of life but become smaller as children become older. Changes in waveform characteristics also occur, with more jerk waveforms becoming apparent with age.[21] Possibly these are adaptive mechanisms to allow better vision through the development of foveation periods – periods where the eyes move at a relatively slower velocity. Typically, the nystagmus has a null region where nystagmus intensity is reduced, causing an abnormal head posture if the null region is not in the primary position of gaze (see Fig. 89.4A). Over 20% of patients with idiopathic nystagmus due to mutations in *FRMD7* have PAN, but this is usually not detected clinically, only on eye movement recordings (see Fig. 89.4B).[27] Albeit rare, IIN can be vertical.

Chiasmal misrouting

Albinism has very similar nystagmus characteristics to IIN (see Fig. 89.3A,C). The diagnosis of albinism can be easily missed

and signs such as iris transillumination, hypopigmentation of the retina, optic nerve hypoplasia, and abnormal crossing on VEP need to be assessed carefully. OCT is very helpful in detecting foveal hypoplasia (see Fig. 89.7B,C). Albinism is discussed in detail in Chapter 41.

Patients with achiasmia have congenital seesaw nystagmus. The diagnosis is confirmed on MRI and VEP. Achiasma is discussed in detail in Chapter 57.

Nystagmus associated with ocular disease

Nystagmus can occur in most types of retinal dystrophy. The diagnosis of achromatopsia (Fig. 89.6) or blue cone monochromatism is likely in a patient with marked light sensitivity, poor vision, poor color discrimination in combination with a small-amplitude and high-frequency nystagmus. Inheritance is autosomal recessive in achromatopsia, and mutations in four genes have been described for which molecular genetic testing is available.[18] Patients with mutations in the same gene can have widely varying phenotypes.[18] This can range from profound visual impairment with no color vision, to incomplete achromatopsia with some color perception, and, less commonly, to oligocone trichromacy with almost normal color vision and visual acuity as good as 0.1 LogMAR.[28] Patients with achromatopsia often have fast pendular nystagmus superimposed on jerk nystagmus, and also vertical nystagmus (see Fig. 89.3A1).[29] Recently, atypical findings on OCT examination have been described in achromatopsia (see Fig. 89.7H,I).[4,7,26] The diagnosis can be confirmed by extinguished or severely reduced photopic electroretinography (see Fig. 89.6C). In blue cone monochromatism, the VA is usually better and the inheritance is X-linked.[18]

Congenital stationary night blindness (CSNB) is often associated with nystagmus that can have waveforms corresponding to infantile or manifest latent nystagmus. Patients have variable VA, reduced night vision, often high myopia, and the ERG is negative (see Fig. 89.6B). Pendular, oblique, and mostly dysconjugate nystagmus of high frequency and low amplitude and dual jerk nystagmus has been described. Inheritance is most commonly X-linked and mutations of two genes have been found to be causative.[19] Nystagmus in retinal dystrophies can occur in ciliopathies, which consists of dysfunction of the primary cilium, an organelle involved in intracellular and intercellular sensing and signaling (e.g. Alström syndrome, Bardet–Biedl syndrome, Joubert syndrome, Senior–Løken syndrome, and Leber congenital amaurosis). In retinal dystrophies, nystagmus can occasionally appear later in life as the VA deteriorates.

Nystagmus can be associated with low vision in early infancy due to numerous causes such as retinopathy of prematurity, congenital cataracts, corneal opacity, and optic nerve hypoplasia. In these patients, nystagmus can have the same characteristics as in achromatopsia or CSNB, or have characteristics of manifest latent nystagmus. Early treatment of cataract or other media opacities can prevent the development of nystagmus. Mutations in the *PAX6* gene, inherited in an autosomal dominant pattern, are associated with nystagmus that can be horizontal, vertical, or torsional (see Fig. 89.3A3).[9,20] OCT typically shows foveal hypoplasia (see Fig. 89.7D,E) but the VEP does not show misrouting of the optic nerve that is characteristic of albinism. Aniridia is common but not always present.

Nystagmus in neurological diseases or syndromes

Childhood nystagmus is a common feature of a range of syndromes, developmental and neurological disorders, for example Down syndrome, Noonan syndrome, structural malformations, space-occupying lesions, periventricular leukomalacia, cerebral palsy, leukodystrophy, Chiari malformation, metabolic disease, or mitochondrial disease.[30] Vertical, torsional, seesaw, or dysconjugate nystagmus waveforms are common in neurological disorders (see Fig. 89.3B, showing vertical nystagmus in Chiari malformation). MRI is essential if there are other neurological symptoms, developmental delay, optic atrophy, or any suspicion of atypical nystagmus.

Spasmus nutans

Spasmus nutans consists of a triad of nystagmus, head nodding, and abnormal head posture. The onset is later than in infantile nystagmus, usually developing after 6 months of age. The nystagmus is of high frequency and pendular. The nystagmus may be intermittent and dysconjugate between both eyes or sometimes clinically apparent in only one eye (see Fig. 89.3D).[31] Clinically the nystagmus usually disappears spontaneously 1–2 years after onset, although subclinical nystagmus persists on eye movement recordings. In spasmus nutans, head nodding suppresses the nystagmus since the vestibulo-ocular reflex stabilizes the eyes, which can permit development of binocular vision (see Fig. 89.3D).[31] The etiology of spasmus nutans remains unclear; however, it has been associated with a lower socioeconomic status.[32] The same nystagmus characteristics combined with head nodding and torticollis can also occur in suprasellar tumors such as chiasmal glioma.[33] If there is afferent pupillary defect or optic nerve pallor, a tumor should be suspected. Some retinal diseases such as achromatopsia and CSNB can mimic spasmus nutans.[34] The authors recommend, therefore, that ERG and/or MRI be performed in children presenting with spasmus nutans.

Manifest latent nystagmus

MLN or fusional maldevelopment nystagmus syndrome (FMNS) is part of the congenital squint syndrome. The nystagmus is typically larger upon covering one eye, the fast phase beats to the fixing or open eye, and the slow phase has decreasing velocity (see Fig. 89.4C). FMNS is discussed in Chapter 76.

Treatment

Spectacles and contact lenses

The incidence of refractive error in nystagmus is high.[35] Children with nystagmus under 6 years of age, therefore, need repeated refraction every 3–12 months to prevent amblyopia. Contact lenses can be helpful because they may give better optical correction. Contact lenses allow patients to adopt large AHPs with better optical correction, as contact lenses do not have

the problems of decentration and obstruction of the visual axis by spectacle frames (see Fig. 89.5B). Some studies have also suggested that contact lenses reduce nystagmus by providing sensory feedback through the eyelids, although recent studies suggest that improvements are not clinically significant.[36]

Surgical treatment and treatment with prisms

Patients often use compensatory strategies to reduce nystagmus. These strategies are different in individual patients. Fully understanding the compensatory mechanisms used by a patient allows formulation of a therapeutic plan. Compensatory mechanisms can often be assisted using surgery or prisms. Surgery for abnormal head postures usually yields excellent and sustained improvement.

Kestenbaum-type procedures

Patients with infantile nystagmus, especially idiopathic nystagmus and nystagmus associated with albinism, commonly have a null region, i.e. a direction of gaze in which nystagmus intensity is reduced and foveation is increased. If the null region is not in the primary position, patients often adopt an abnormal head posture using the eccentrically positioned null region for better vision (see Figs. 89.4A [null region on eye movement recordings] and 89.5A,B,F,G; Case study 1). Usually the null region is either in the primary position of gaze or along the horizontal plane. Some patients, however, despite having horizontal nystagmus, have vertical head postures or head tilts, or a combination of abnormal head postures in different planes. Patients with infantile vertical nystagmus can also show horizontal head postures. These mechanisms are not well understood.

If patients have vertical head postures, recess or resect procedures can be performed on vertical and/or oblique rectus muscles. For head tilt, rotatory Kestenbaum procedures can be performed, either by recession and resection of oblique muscles or by inducing torsion by moving the insertion of the rectus muscles.[37] If the two horizontal or vertical rectus muscles are operated on in either eye, they can be shifted up and down or left and right from the insertion to induce a rotator effect on the eye. If the patient has manifest strabismus, surgery for the abnormal head posture needs to be performed on the fixing eye. The amount of strabismus resulting from preoperative strabismus and possibly surgery for the abnormal head posture can be corrected in the non-fixing eye (Case study 2). Significant amounts of horizontal muscle recession and resection are necessary for large head turns.[38]

Surgery for abnormal head postures is usually very successful. Surgery can be performed at any age; however, it is important to wait until the cause of the head turn can be well established. If amblyogenic factors are caused by the child not being able to wear glasses due to a large abnormal head posture, surgery should be performed as early as possible. Otherwise a convenient age for surgery is around 6–8 years of age, when the child is cooperative and can be easily examined. However, the time of surgery needs to be assessed with the parents and child according to the child's symptoms. It should also be borne in mind that head turns do not often fully develop until school age, when the head posture may become more frequent and pronounced with increasing school work. Kestenbaum-type procedures are effective even in adults. It is preferable to record eye movements before and after surgery to better understand mechanisms.

Artificial divergence

Convergence reduces the intensity of infantile nystagmus in many individuals. In these patients, artificial divergence can be induced to increase convergence and to trigger a convergence impulse, even at distance. Good binocular vision is essential for the effectiveness of artificial divergence. Without binocular vision, surgery or prisms would simply change the angle of squint without inducing convergence. Fusion range and the optimal strength of base-out prisms to reduce the nystagmus should be tested. It is often best to wear Fresnel prisms for at least 1 or 2 weeks during normal activities and to adjust the amount of prisms, if needed, before making a surgical decision. If prisms are small, then they can also be incorporated into glasses.

Nystagmus blockage syndrome

Some patients with manifest latent or infantile nystagmus can dampen nystagmus by over-convergence (Fig. 89.9). Bilateral medial rectus recession can help to permanently dampen the nystagmus (Case study 3).[39] This forces the patient to maintain convergence in order to keep the eyes straight and in doing so improves the visual acuity.

Adduction

Adduction dampens manifest latent nystagmus. If, for example, the left eye is dominant, the patient will fix in adduction with the left eye and turn the head to the left (see Fig. 89.5C). If strabismus surgery is performed, the dominant fixing eye should be operated on to correct the abnormal head turn simultaneously. If a patient with manifest latent nystagmus has an alternating strabismus, the head turn can change in the

Case study 1

A 4-year-old girl with idiopathic infantile nystagmus needed spectacle correction of 4 diopters astigmatism in each eye. Since she had a large head turn to the left she could not wear her glasses because the frame obstructed the view. She had 12-mm recession of the right lateral rectus muscles and left medial rectus muscle and 12-mm resection of the right medial rectus muscle and left lateral rectus muscle. After surgery, her head was straight. Because she could now wear her glasses, her binocular visual acuity increased from 0.6 to 0.2 LogMAR (see Fig. 89.5F). The head position remained straight at follow-up 8 years later.

Case study 2

A 9-year-old boy came to clinic because of nystagmus and a pronounced head tilt increasing on visual effort. He also had "V" pattern esotropia and bilateral inferior oblique overaction. Surgery consisted of moving the right lateral rectus and left medial rectus muscle one tendon-width down and the right medial rectus and left lateral rectus muscle one tendon-width up. In addition, recession of the left medial rectus for esotropia and bilateral inferior oblique recession to correct overaction and "V" pattern was performed. After surgery the head tilt was significantly reduced (see Fig. 89.5G).

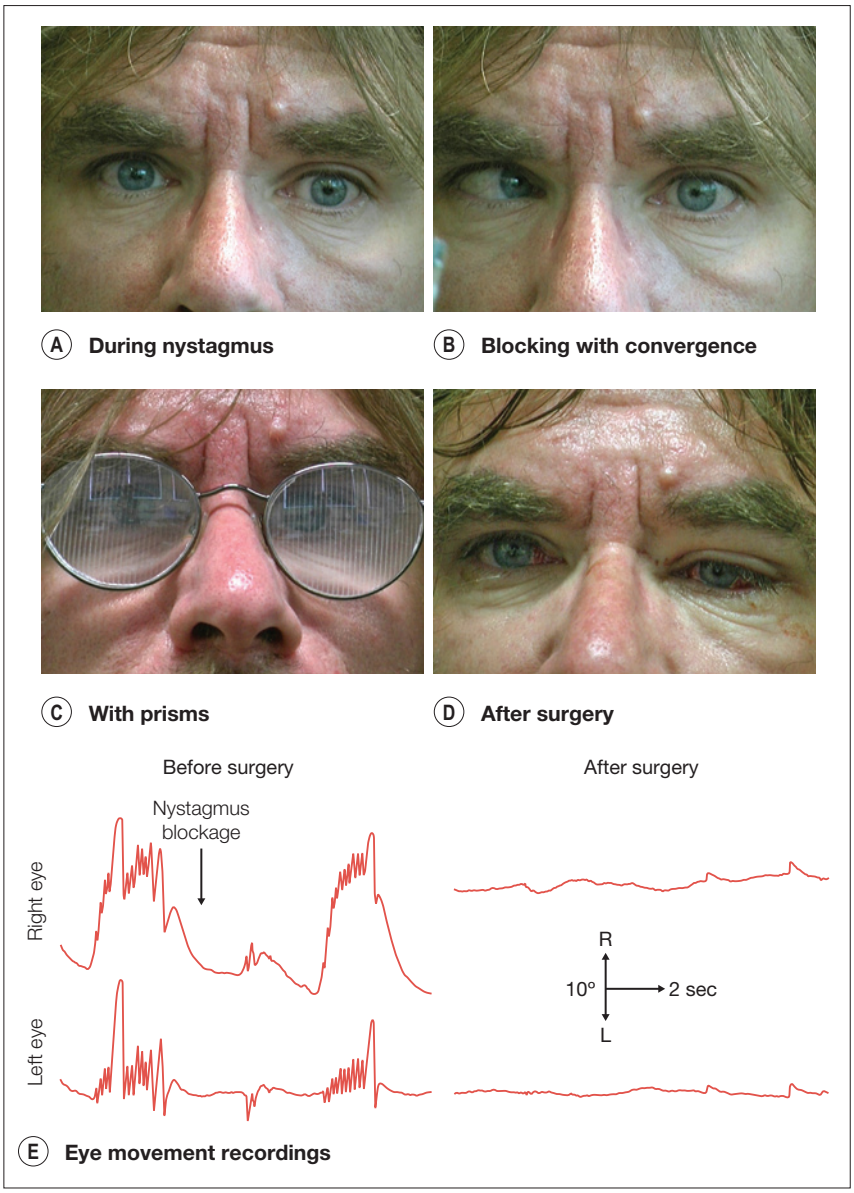

Fig. 89.9 Nystagmus blockage syndrome (see Case study 3).

direction of the fixing eye and this can give the false appearance of PAN (Case study 4) where more than one head posture can be adopted (see Fig. 89.5D). If a patient with manifest latent nystagmus fixes with one eye at near and the other at distance, the head turn may change accordingly.

Reduction of strabismus

Reduction of strabismus and improvement of binocular vision in manifest latent nystagmus can reduce nystagmus intensity.[40] Thus, patients with "A" and "V" pattern strabismus may adopt a chin-up or chin-down head position in order to reduce the angle of strabismus and improve the nystagmus (see Fig. 89.5E). In patients with manifest latent nystagmus, strabismus surgery, ideally with the objective of achieving a degree of binocular vision with microstrabismus, can substantially improve nystagmus (Case study 5).

Periodic alternating nystagmus

If the quiet phase of PAN is not static, then the head posture can slowly oscillate from left to right. It is very important to recognize if a patient has PAN before surgery is performed, as Kestenbaum procedures may increase the head turn to one side in PAN. About 23% of patients with IIN associated with mutations in *FRMD7* and 29% of patients with albinism have PAN.[12,27] Ideally patients should have eye movement recordings over a period of at least 8 minutes as the cycle of PAN in infantile nystagmus has been found to be between 90 and 280 seconds (see Fig. 89.4B).[27] However, many patients with PAN do not have alternating head position, probably because their null region is not moving. In PAN, one can recess all four horizontal muscles to improve head position.

Tenotomy of four rectus muscles

This procedure consists of detaching and re-attaching the rectus muscles at their insertion. It has been reported that tenotomy reduces nystagmus and broadens the null region due to changes in proprioceptive feedback from the eye muscles.[41] The procedure can be performed on horizontal or vertical muscles and be combined with correction of strabismus. More results and corroboration between several research groups need to be obtained before drawing firm conclusions over the value of tenotomies.

Pharmacological treatment

Baclofen, gabapentin, cannabis, memantine, aminopyridines, and several other drugs were primarily used in acquired nystagmus.[42] Baclofen was also found to be effective in infantile PAN.[43] Recently, gabapentin and memantine have been found to be effective in a double-masked randomized controlled study including patients with infantile nystagmus.[44] Gabapentin (up to 2400 mg) and memantine (up to 40 mg) were used in slowly increasing dosages. Although the medications are effective in IIN, it is not clear which patients respond best to which type of treatment. Larger trials are now underway.

Other treatments

Botulinum toxin has been reported to reduce infantile nystagmus.[45] However, injections need to be repeated and can induce strabismus and ptosis. Other methods such as auditory feedback have been shown to be ineffective or impractical in infantile nystagmus.

Acknowledgement

The authors wish to thank Rebecca McLean for help with preparation of the video recordings and figures in the chapter. They would also like to thank Geoffrey Woodruff for his careful and critical feedback in reading the manuscript. Finally, they also thank the Ulverscroft Foundation for their continuous support.

Case study 3

A patient with nystagmus from birth complained about constant "unquiet eyes" and needing to make an effort to turn in one eye in order to have better vision. On examination, he had nystagmus and intermittent large-angle esotropia. Eye movement recordings showed jerk nystagmus with waveforms showing IIN and manifest latent nystagmus reducing on convergence. Bilateral medial rectus recessions of 5 mm reduced the nystagmus and esotropia. Visual acuity with both eyes open improved from 6/12 to 6/9 (Fig. 89.9).

Reproduced from Lorenz B, Brodsky MC, editors. Pediatric Ophthalmology, Neuro-Ophthalmology, Genetics: Strabismus – New Concepts in Pathophysiology, Diagnosis, and Treatment. Berlin; London: Springer, 2010.

Case study 4

A 5-year-old boy attended clinic complaining of an alternating head turn and exotropia. He had manifest latent nystagmus confirmed on eye movement recordings, bilateral inferior oblique overaction and a large exotropia. To correct the head turn large bilateral medial rectus recessions of 10 mm were performed to limit adduction. However, since medial rectus recession would increase the exotropia, simultaneously bilateral lateral rectus recessions of 16 mm were performed. Postoperatively the head turn disappeared but a remaining moderate exotropia was present. Seven years after surgery, however, the exotropia and the nystagmus were reduced (see Fig. 89.5D).

Case study 5

A patient reported having nystagmus since birth but his vision had deteriorated over the last year. On examination, he had manifest latent nystagmus and exotropia without any binocular function. Pictures from several years ago showed that the patient previously had a small esotropia. Base in prisms were fitted to restore the esotropic microstrabismus. The patient had subnormal binocular vision (Titmus fly positive) and reduced nystagmus. Binocular visual acuity increased by 2 LogMAR lines.

Fig. 89.4 Change in nystagmus with (A) gaze, (B) time, and (C) occlusion. (A) Shows an example of the null region in a patient with idiopathic infantile nystagmus using original eye movements from a patient. The patient follows a target moving from the left to right in steps of 3° every 8 seconds (lower traces). The horizontal nystagmus changes both in waveform (A1) and intensity (A2) as the direction of gaze changes. The changing waveforms can be seen from the expanded views in the upper traces. At the null region, which is 9° to the right of central fixation, the nystagmus waveform is predominantly pendular, with occasional foveating saccades. Jerk waveforms are present to the left and right of the null region, with the nystagmus beating to the left in left gaze and right in right gaze. A plot of the nystagmus intensity in relation to the horizontal

Bonus e-book content online—cont'd

gaze angle is shown in A2. (B) Shows a patient with idiopathic infantile nystagmus and periodic alternating nystagmus as an example of a nystagmus waveform changing with time. The nystagmus completes a full cycle of left beating and right beating nystagmus every 200 seconds, with short quiet phases of several seconds between each change in beating direction. Expanded views are shown in the lower traces. (C) Shows a patient with manifest latent nystagmus illustrating the change in beating direction on covering either eye. The eyes always beat towards the open or fixing eye. The waveforms all show decreasing velocity slow phases. Note the step change in eye position on covering either eye, which is due to a large esotropia. The left eye is the dominant eye. The nystagmus is less intense when both eyes are open.

Fig. 89.9 Nystagmus blockage syndrome (see Case study 3).

Introduction

Abnormal eye movements in the infant or young child can be congenital or acquired, associated with abnormal early visual development, or a sign of underlying neurologic or neuromuscular disease or orbital disease. Abnormal eye movements in an apparently well child should never be labeled as congenital or benign without careful investigation, including medical history, clinical examination, neuroimaging, laboratory testing, and electrophysiologic investigation of the visual sensory system. Ocular motility analysis can indicate the type of eye movement disturbance and whether this is associated with an underlying ocular or neurologic condition.

Anatomy and physiology (Table 90.1)

Neural integrator

The neural integrator is an engineering term applied to an ocular motor "function" carried out by groups of cells in the cerebellum (flocculus and paraflocculus) and the prepositus hypoglossus and medial vestibular nucleus (MVN).[1] The neural integrator is needed for all conjugate eye movements. To move the eyes at a constant speed or hold them in an eccentric gaze position, two neural signals must overcome the elastic tendency of the eyes to go back to their "resting" position. These signals are the desired speed (phasic component) and a tonic component that counterbalances the elastic restoring forces. A changing tonic component can be precisely generated by a premotor neural signal that mathematically computes the "integration" of the velocity signal, thus the term "neural integrator." The role of the neural integrator in generation of saccades and maintenance of eccentric gaze positions occurs after inhibitory burst neurons (IBNs) are inhibited and excitatory burst neurons (EBNs) fire rapidly, yielding an intense phasic signal that is transmitted to the appropriate yoked pair of extraocular muscles via the appropriate cranial nerves. The "burst" signal is also transmitted to the neural integrator, which "integrates" that burst signal (counts the number of discharge spikes) and generates a neural signal (again transmitted via the cranial nerves) appropriate to hold the eye steady at the new position (tonic discharge).

The neural integrator is not perfect and the "tonic" signal slowly decays or "leaks" over time. This decay is normally not seen in lighted conditions because visual feedback, with the use of the smooth-pursuit (SP)/fixation system, aids in holding the eye steady.[2] At birth, the neural integrator is leaky, but by about 1 month of age it functions well.[3]

Saccadic system

A saccade is a rapid eye movement, which may occur volitionally (voluntary saccade), reflexively, or as part of the fast phases of nystagmus, which serves to purposefully redirect the fovea to a specific target. Voluntary saccades may be predictive command generated (i.e. look right), memory guided, and antisaccades. Involuntary saccades include the fast phase of nystagmus, spontaneous saccades, and reflexive saccades. The pathway of saccades proceeds through the anterior limb of the internal capsule and then through the diencephalon. It then divides into dorsal and ventral pathways, the dorsal limb going to the superior colliculi and the ventral limb (which contains the ocular motor pathways for horizontal and vertical eye movements) to the pons and midbrain. The superior colliculus acts as an important relay for some of these projections.[4] In the brainstem, the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) and pontine paramedian reticular formation (PPRF) provide the saccadic velocity commands, by generating the "pulse of innervation" immediately before the eye movement, to cranial nerves III, IV, and VI. Horizontal saccades are generated by EBNs in the PPRF, which are found just ventral and lateral to the MLF in the pons, and by IBNs in the nucleus paragigantocellularis dorsalis, caudal to the abducens nucleus in the dorsomedial portion of the rostral medulla (Fig. 90.1). Vertical and torsional components of saccades are generated by EBNs and IBNs in the riMLF, located in the midbrain[4] (Fig. 90.2).

Table 90.1 Types of eye movements

Type of eye movement	Function	Stimulus	Clinical tests
Vestibular	Maintain steady fixation during head rotation	Head rotation	Fixate on object while moving head; calorics
Saccades	Rapid re-fixation to eccentric stimuli	Eccentric retinal image	Voluntary movement between two objects; fast phases of OKN or of vestibular nystagmus
Smooth pursuit	Keep moving object on fovea	Retinal image slip	Voluntarily follow a moving target; OKN slow phases
Vergence	Disconjugate, slow movement to maintain binocular vision	Binasal or bitemporal disparity; retinal blur motion	Fusional amplitudes; near point of convergence

OKN, Optokinetic nystagmus.

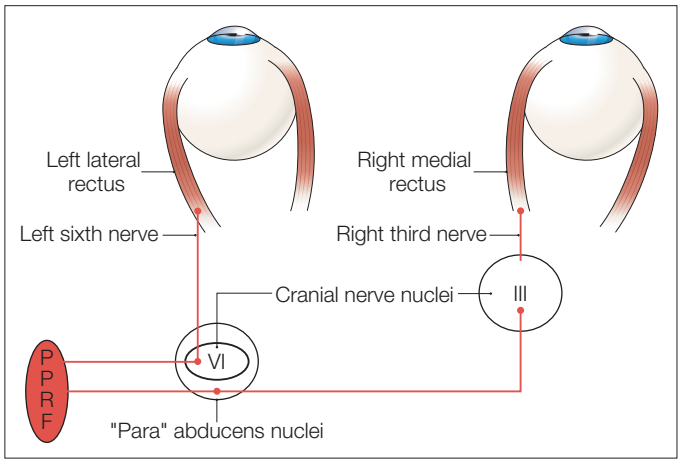

Fig. 90.1 Schematic of brainstem pathways coordinating horizontal saccades. The pontine paramedian reticular formation (PPRF), after receiving input from the ipsilateral cortical centers and superior colliculus, stimulates two sets of neurons in the abducens nucleus: (1) those that send axons to innervate the ipsilateral lateral rectus, and (2) those whose axons join the medial longitudinal fasciculus (MLF) and subsequently activate the medial rectus subnuclei of the contralateral third nerve. III, Third cranial nerve nuclei; VI, sixth cranial nerve nuclei.

Following a saccade, a "step of innervation" occurs, during which a higher level of tonic innervation to ocular motor neurons keeps the eye in its new position against orbital elastic forces that would restore the eye to an anatomically "neutral" position in the orbit. For horizontal saccades, the step of innervation comes from the neural integrator (NI), most importantly from the nucleus prepositus–MVN complex. The eye is held steady at the end of vertical and torsional saccades by the step of innervation provided from the interstitial nucleus of Cajal in the midbrain.[4,5] Other burst neurons termed long-lead

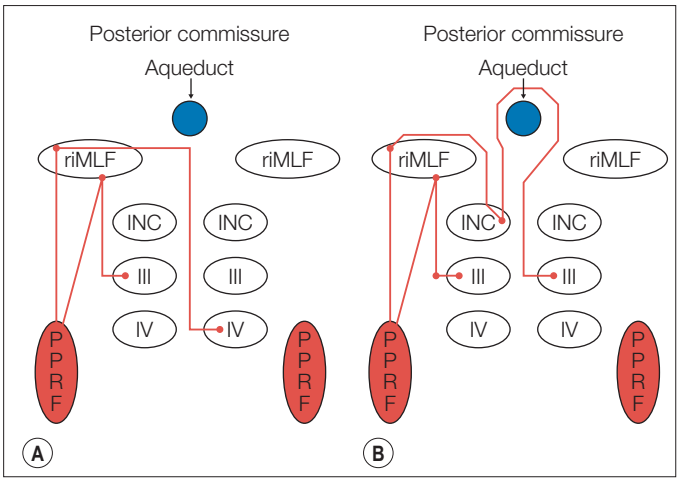

Fig. 90.2 Schematics of brainstem pathways coordinating downward (A) and upward (B) saccades. (A) The pontine paramedian reticular formation (PPRF) activates neurons in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) that send fibers caudally to synapse upon the inferior rectus subnucleus of the ipsilateral third nerve and the contralateral superior oblique nucleus. Not shown in this diagram, fibers from the contralateral PPRF carry corresponding signals simultaneously. (B) The PPRF activates neurons in the riMLF that send fibers through the posterior commissure to the superior rectus subnucleus of the contralateral third nerve and fibers to the inferior oblique subnucleus of the ipsilateral third nerve. Not shown in this diagram, fibers from the contralateral PPRF carry corresponding signals simultaneously. III, Third cranial nerve nucleus; IV, fourth cranial nerve nucleus; INC, interstitial nucleus of Cajal.

burst neurons (LLBNs) discharge 40 ms prior to saccades, whereas excitatory burst neurons (EBNs) discharge 12 ms prior to saccades. Some LLBNs lie in the midbrain, receiving projections from the superior colliculus and projecting to the pontine EBNs, medullary intermediate burst neurons (IBNs), and OPNs. Other LLBNs lie in the nucleus reticularis tegmenti pontis (NRTP), projecting mainly to the cerebellum but also to the paramedian pontine reticular formation (PPRF). It appears that LLBNs receiving input from the superior colliculus may play a crucial role in transforming spatially coded to temporally coded commands, whereas other LLBNs may synchronize the onset and end of saccades.[4,5]

The saccadic system is not fully developed until about 1 year of age; infants make multiple hypometric saccades to reach the target.[6] If the head is held still, this hypometria can be seen clinically in infants less than 3 months of age, especially for large saccades. There is a progression toward "normometria" during the first 7 months of life.[7] In healthy adults and children older than 1 year, saccades are typically hypometric, reaching about 90% to 100% of the target distance, followed by secondary saccades – normometria. In optokinetic nystagmus (OKN) and vertical nystagmus, quick phases occur less frequently in children than in adults.

Smooth pursuit system

The function of SP is to hold fixation on a moving target, and both eye and head movements are required. This requires a prediction to overcome the time delays of the visuomotor system and the ability to suppress the vestibulo-ocular reflex (VOR).[8] VOR suppression is required because, when the head moves, there is a reflexive VOR that moves the eyes equally in the opposite direction. SP and VOR suppression are probably

the same ocular motor functions. The frontal and extrastriate visual cortexes transmit information about the motion of both the target and the eyes to the dorsolateral pontine nuclei, thence to the paraflocculus, flocculus, and dorsal vermis, and then via the vestibular and fastigial nuclei to the ocular motor nerve nuclei III, IV, and VI. Unilateral lesions in the cortex and cerebellum affect ipsilateral SP. Brainstem lesions are less well defined clinically.[1]

SP is present in the first week of life but is immature in the young infant. Horizontal gaze probably develops before vertical gaze.[9] SP gain increases with age, and at 5 months the SP is more apparent. It is not known at what point in time pursuit matures to the adult form. It does not appear to happen before 6 months of age, and may not be until late adolescence.[10]

Vestibulo-ocular response system

The vestibular apparatus drives reflex eye movements to keep images steady on the retinas as we move our heads. The eyes move in the opposite direction to the head so that they remain in a steady position in space. The three-neuron arc – vestibular ganglion, vestibular nuclei, and ocular motor nuclei – are the principal connections. The direct neuronal pathways include both excitatory and inhibitory contributions. Each semicircular canal influences a pair of extraocular muscles that move the eyes in the plane of that canal (Table 90.2). The anatomy of the vestibular nuclei has been well characterized[11]; they receive projections from the 14,000 to 18,000 axons of the vestibular nerve.[11]

There are four major vestibular nuclei and accessory subgroups, including the interstitial nucleus, with its cells distributed among the vestibular rootlets as they enter the brainstem, and the y-group, near the superior cerebellar peduncle. The MVN has the greatest volume and is the longest vestibular nucleus. The lateral vestibular nucleus (LVN) also has projections to the spinal cord, mainly via the ipsilateral lateral vestibulospinal tract but also through the contralateral medial vestibulospinal tract. In its most rostral aspect, the dorsal vestibular nucleus (DVN) also projects to the ocular motor nuclei.

The primary vestibular afferents enter the medulla at the level of the LVN. Almost all bifurcate, giving a descending branch to terminate in the MVN and DVN and an ascending branch to the superior vestibular nucleus (SVN), with a final destination in the cerebellum, especially the anterior vermis and the nodulus and uvula. All canals and otoliths project to the borders of ventromedial LVN, medial MVN, and dorsomedial DVN. All canals also converge on a small patch in the ventromedial SVN. Utricular afferents project to the rostral MVN and saccular afferents project to the y-group. For both the horizontal and vertical VOR, many neurons in the vestibular nuclei that receive inputs from primary vestibular afferents encode head velocity, eye position, and varying amounts of SP and saccadic signals. Vestibular nuclei neurons do not project just to motor neurons; they also send collaterals to the nucleus prepositus hypoglossi, the nucleus of Roller, and the cell groups of the paramedian tracts.[11]

When testing the VOR in the infant, it is not unusual to find a slightly high VOR gain, which gradually decreases during preschool years, and a short VOR time constant.[12] In the premature infant and in some healthy full-term infants, rotation induces a tonic deviation or "locking up." The eyes deviate in the direction opposite to rotation when the doll's head maneuver or the Barany chair rotation test is used. They deviate in the same direction as the rotation when the infant is rotated at arm's length. A "corrective" fast phase develops at approximately 45 weeks postconceptual age.[6] This lock up may be prolonged in the infant with delayed visual maturation. Usually there are no more than a couple of beats of postrotational nystagmus when the child stops spinning; if there are more than a few beats of nystagmus, a severe visual deficit or abnormality of the SP pathway should be suspected.[13] This test can be influenced by behavioral state and wakefulness.

Vergence system

Vergences are eye movements that turn the eyes in opposite directions so that images of objects will fall on corresponding retinal points. In other words, it is the ability to change the angle between the two visual axes to permit near (convergence), far (divergence), and torsional (cyclovergence) foveation, for binocular vision. Three major stimuli are known to elicit vergences: (1) retinal disparity that leads to fusional vergences; (2) retinal blur that evokes accommodative

Table 90.2 Effect of stimulating a single semicircular canal

Canal	Head movement	Eye movement in		Agonist		Antagonist	
		R gaze	L gaze	R	L	R	L
R Post	R and up	L Tors	Down	SO	IR	IO	SR
R Ant	R and down	Up	L Tors	SR	IO	IR	SO
R Lat	R	L	L	MR	LR	LR	MR
L Post	L and up	Down	R Tors	IR	SO	SR	IO
L Ant	L and down	L Tors	Up	IO	SR	SO	IR
L Lat	L	R	R	LR	MR	MR	LR

Ant, Anterior; IO, inferior oblique; IR, inferior rectus; L, left; Lat, lateral (horizontal canal); LR, lateral rectus; MR, medial rectus; Post, posterior; R, right; SO, superior oblique; SR, superior rectus; Tors, torsional (cyclotorsion with upper poles of eyes moving to subject's right/left).
Data from Leigh RJ, Zee DS. The Neurology of Eye Movements, 4th ed. New York, NY: Oxford University Press, 2006.

vergences; and (3) motion induces both disparity and accommodative vergence. The neural substrate for vergence lies in the mesencephalic reticular formation, dorsolateral to the oculomotor nucleus where neurons discharge in relation to vergence angle (vergence tonic cells), velocity (vergence burst cells), or both angle and velocity (vergence burst–tonic cells). Although most of these neurons also discharge with accommodation, some remain predominantly related to vergence.[2,14] Like versional movements, a velocity-to-position integration of vergence signals is necessary: the NRTP is important in this integration. The cells in the NRTP that mediate the near response are separate from cells that mediate the far response. Lesions of the NRTP cause inability to hold a steady vergence angle. The NRTP has reciprocal connection with the cerebellum (nucleus interpositus) and receives descending projections from several cortical and subcortical structures.[2,14]

The eyes of neonates, particularly if premature, often appear divergent, and there is little voluntary convergence until 2–3 months. By 3 to 6 months of age, 75% of premature and 97% of full-term infants have no deviation.[9] Fusion is not completely established until 6 months. Accommodation-driven vergence can be detected at 2 months of age and disparity-driven vergence at about 4 months, which is when stereopsis and fusion develop.

Optokinetic system

The optokinetic system is responsible for conjugate slow following of the eyes to movement of large areas of the visual field. Optokinetic nystagmus (OKN) is a reflex conjugate physiologic nystagmus in which a slow-phase pursuit response to movement of the visual surround (optokinesis) is followed by a corrective saccade or quick phase. OKN is elicited naturally during head and eye movements, or unnaturally by looking out of the window of a moving vehicle. Together with the vestibular system, the optokinetic system holds images steadily on the retina during sustained motion of the head or world or both. The neural substrate for optokinesis includes the nucleus of the optic tract and accessory optic pathways. Optokinesis can be elicited by either full-field (natural head or eye movements) or small-field (foveal) motion (a moving drum or tape). Both SP and optokinetic systems contribute to the stabilization of images of stationary objects during head rotations. In primates, OKN has two components, each of which has a separate but parallel neural pathway.[11] Delayed (indirect, slow) OKN (OKNd) has a slow buildup (tens of seconds) and gives rise to optokinetic after-nystagmus (OKAN), which is a gradual decay of the nystagmus after the lights have been extinguished. OKNd is closely related to VOR and is driven by visual motion signals in the visual cortex via the nucleus of the optic tract in the pretectum and the vestibular nuclei.[15] Early (direct, fast) OKN (OKNe) has a rapid buildup (<1 s) and does not give rise to OKAN; it ceases promptly in the dark. The OKNe pathway is similar to the SP pathway, which is mediated by a corticopontocerebellar route, and it is doubtful that the pretectum has a direct role in OKNe/SP, although it may be involved in its adaptive control.[15]

Finally, the cerebellum plays an important role in eye movements. Together with several brainstem structures, including the nucleus prepositus and the medial vestibular MVN, it appears to convert velocity signals to position signals for all conjugate eye movements through mathematical integration. Figure 90.3 shows the anatomical areas of the brain responsible for the " localizing " forms of acquired nystagmus.

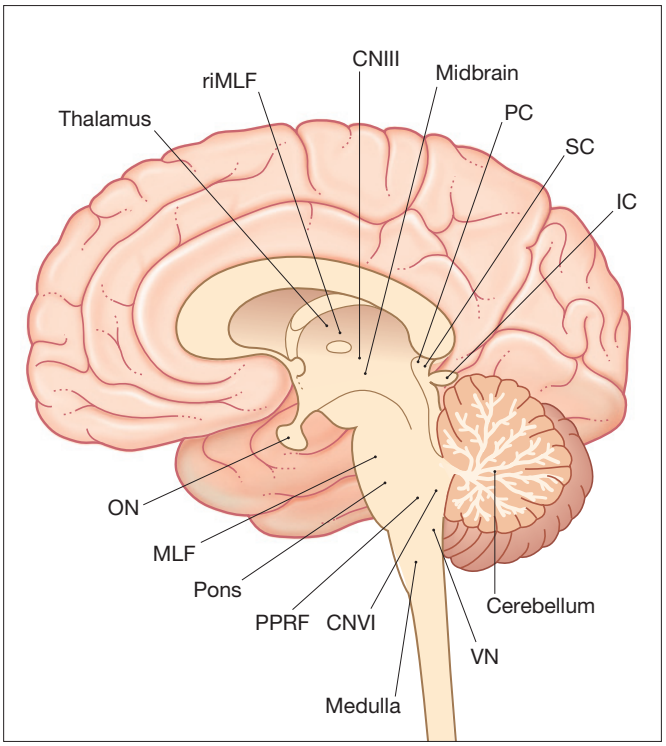

Fig. 90.3 Midline sagittal section of a human brain. Sites within the brain responsible for the "localizing" forms of acquired nystagmus. CNIII, Third cranial nerve nuclei; CNVI, sixth cranial nerve nuclei; IC, inferior colliculus; MLF, medial longitudinal fasciculus; ON, optic nerve; PC, posterior commissure; PPRF, pontine paramedian reticular formation; riMLF, rostral interstitial nucleus of the medial longitudinal fasciculus; SC, superior colliculus; VN, vestibular nucleus.

Clinical assessment

General patient investigations

The workup of supranuclear eye movement disorders and nystagmus is directed toward identifying associated ophthalmic and neurologic features with which, if found, the etiology is usually apparent by history, examination, or neuroimaging.

General examination

The history and physical examination determines whether the nystagmus has been present from early or acquired later. A family history of neonatal eye disease, the pregnancy, labor, delivery, and growth and development since birth should be sought. Neonatal forms are generally benign, while acquired forms require further investigation. Since anxiety can affect nystagmus, the eye movements should be observed at a comfortable distance, in a non-threatening manner, while talking to the child or the parent. The most important features of nystagmus can usually be ascertained while "playing" with the child. Head turns or tilts while the child is viewing distant or near objects should be noted. An adequate fundus examination is a necessary part of the evaluation of eye movement

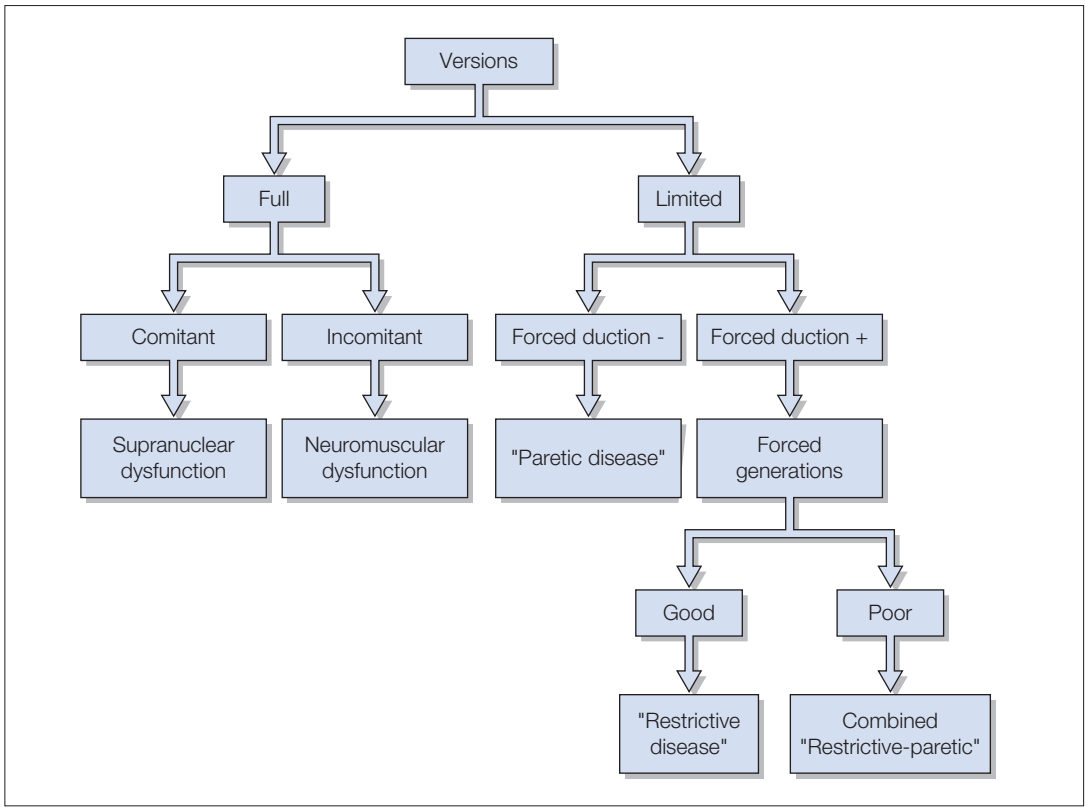

Fig. 90.4 Clinical evaluation of range of eye movements. Versions and cover test measurements allow the examiner to decide whether the eye movements are normal (no limitation) or limited. Forced duction testing is used to differentiate a restriction (positive resistance to movement of the globe) from a "paresis" (no resistance to movement of the globe).

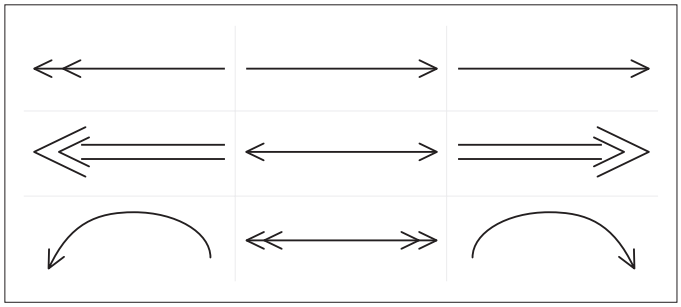

Fig. 90.5 Diagram of nystagmus in nine positions of gaze. Arrowheads indicate direction of jerk fast phase if on one end, pendular nystagmus if on both ends, and increasing frequency with more arrowheads. Additional lines indicate increased nystagmus amplitude. The curved lines indicate torsional nystagmus.

disorders and involuntary ocular oscillations in infants and children (Figs 90.4 and 90.5).

Vision testing

Subjective accuracy of vision testing depends on the patient's age and their neurologic status. The "binocular acuity" should be tested first. The patient must be allowed to assume any anomalous head posture (AHP). During the examination of visual acuity in nystagmus patients with an AHP, the direction of the posture must be observed over a 5- to 7-minute period. Up to 17% of patients with infantile nystagmus and some forms of acquired nystagmus have a periodicity to the direction of their fast phase with a changing head posture.

Binocular acuity is the "person's" acuity and monocular acuity is the "eye's" acuity; they are often very different in patients with nystagmus. In a non-verbal child or adult, various tests can be used to help determine both binocular and monocular acuity. These include fixation behavior, the 10-prism diopter base-down test, Teller acuity cards, and matching of single, surrounded, HOTV optotypes or Lea symbols. Simple testing of binocular function is always attempted as the results are important if convergence is to be stimulated or fusion is to be aided by refractive therapy, e.g. Worth four-dot and near stereopsis.

Refraction

In older children, a subjective refraction is the foundation for any type of refractive therapy. All refractionists develop their own idiosyncrasies that assist them with rapid and accurate refraction. Try to ignore the oscillation and start with distance retinoscopy in a phoropter for patients without an AHP or trial frame (for those with a significant AHP). The next step is to do binocular refraction: this is the most important step in these patients because some patients have significant changes in their nystagmus under monocular conditions. The best way to do this is to fog the eye not being refracted with enough plus to decrease the vision by 1–3 lines.

It is important in infants and young children to perform an objective refraction procedure; a cycloplegic refraction provides additional and important data for treatment decisions. In those patients in whom there is a different refraction under cycloplegia, record both subjective and objective refraction for decision-making regarding spectacle prescription.

Ocular motility evaluation

Clinical evaluation of the ocular oscillation includes fast phase direction, movement intensity, conjugacy, gaze effects, convergence effects, and effect of monocular cover. The amplitude, frequency, and direction of the nystagmus in all directions of gaze can be documented with a simple diagram (see Fig. 90.5). The clinician can also observe the nystagmus while moving the patient's head. Associated motility systems (e.g. strabismus, pursuit, saccades, and VOR) can be clinically evaluated and recorded. Changes in the nystagmus with convergence or monocular viewing should be noted. If the nystagmus increases beneath closed eyelids, vestibular or brainstem pathology should be suspected since visual fixation may suppress nystagmus from lesions in these regions. Conjugacy of eye movements should be observed.

Ocular motility recordings

Eye movement recordings provide a basis for eye movement abnormality classification, etiology, and treatment, and have impacted on eye movement systems research (Figs 90.6 and 90.7). There are four commonly used methods:

- electro-oculography;
- infrared reflectance oculography;
- scleral contact lens/magnetic search coils: this is the most sensitive technique and is minimally invasive, but its use in children between 6 months and about 10 years is difficult (see Figs 90.6 and 90.7);
- video oculography.

Practical applications of eye movement recording technology in clinical medicine include diagnosis/differentiation of eye movement disorders and utility as an "outcome measure" in clinical research.[16,17] Eye movement recordings display the data during continuous periods of time. Position and velocity traces are clearly marked, with up being rightward or upward eye movements and down being leftward or downward eye movements. The basic types of nystagmus patterns observed after eye movement recordings are shown in Figure 90.8.

Specific system evaluation

Neural integrator

To test the neural integrator clinically, observe primary position fixation, fixation in eccentric gaze, saccades, pursuit, and OKN, and also test for rebound nystagmus and VOR cancellation. To examine for rebound nystagmus, first ask the patient to fixate on a target from the primary position, then to re-fixate on an eccentric target for 30 seconds, and then return to the primary position target. A patient with rebound nystagmus shows transient nystagmus with the slow phases toward the previous gaze position. To evaluate a child's VOR cancellation, it is easiest to place your hand on top of the patient's head to control both the head and a fixation target that will extend in front of the child's visual axis. If the child is unable to cancel the VOR, you will observe nystagmus instead of the steady fixation expected in normal subjects.

"Gaze-evoked" nystagmus is a sign of a leaky neural integrator and occurs with attempts to maintain eccentric gaze.

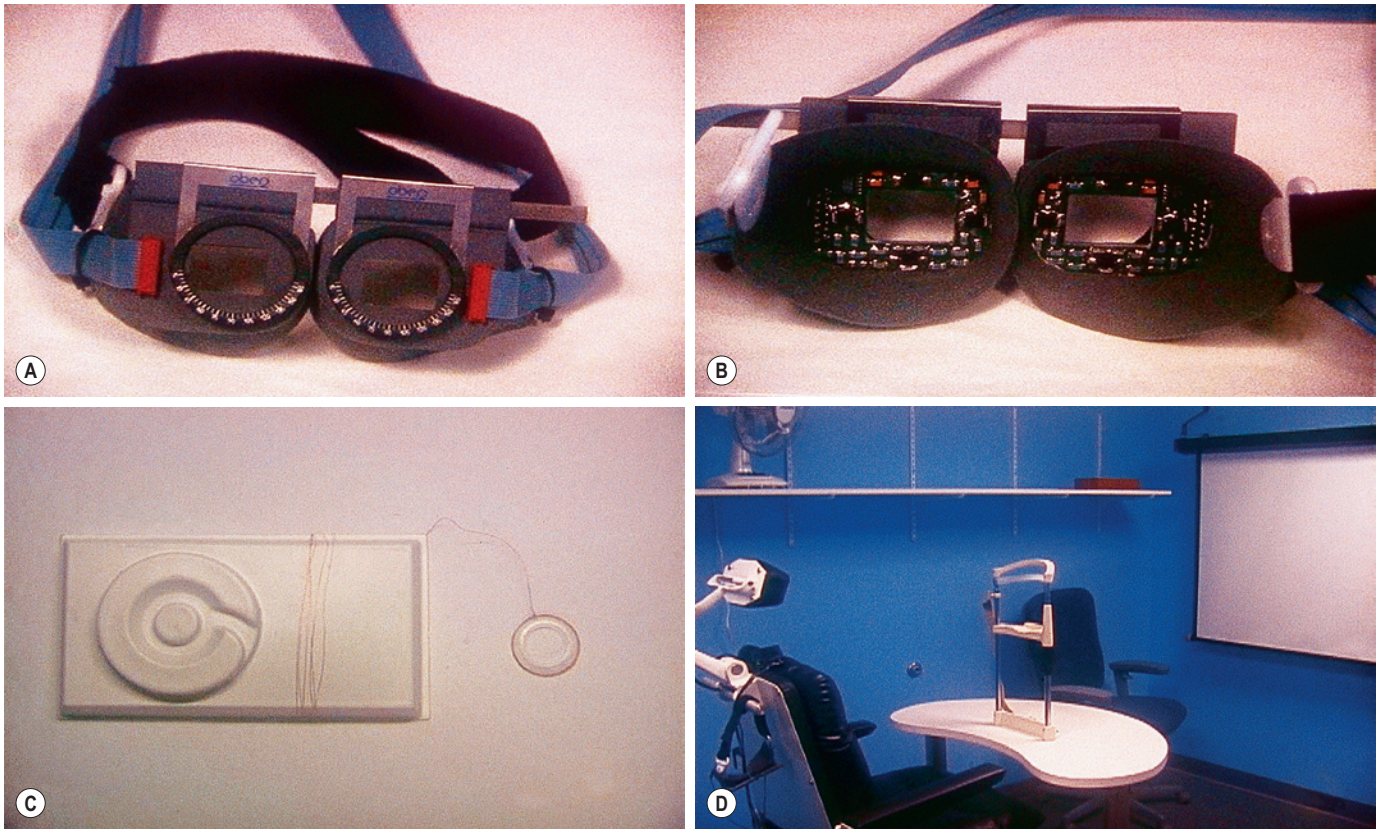

Fig. 90.6 Ocular motility recording equipment. Ocular motor laboratory showing infrared reflectance goggles – front (A), back (B); silicone contact lens (C); flexible exam chair, chin rest, and stimulus screen (D).

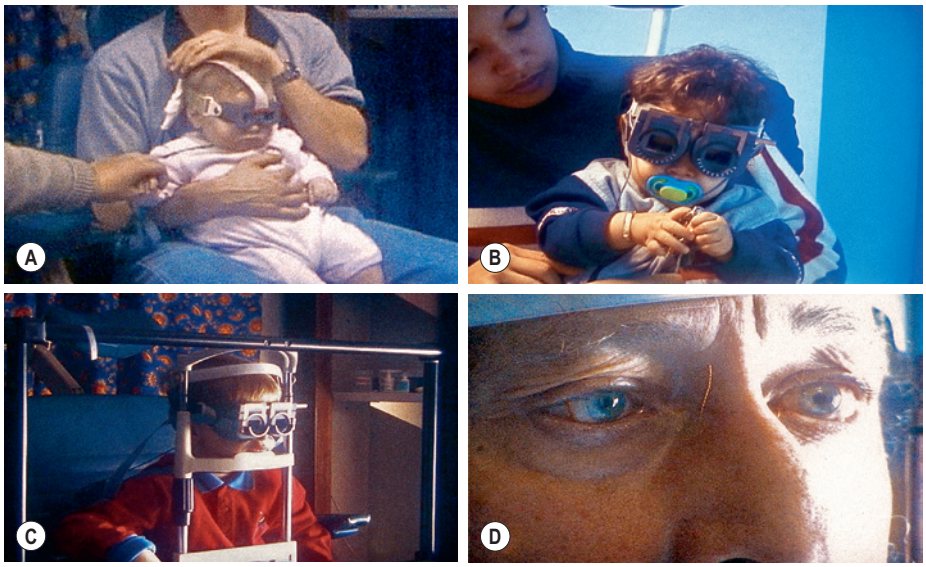

Fig. 90.7 Ocular motility recording techniques. Infrared reflectance performed on an infant (A), toddler (B), and a young child (C), and scleral search coil recordings performed on an adult (D).

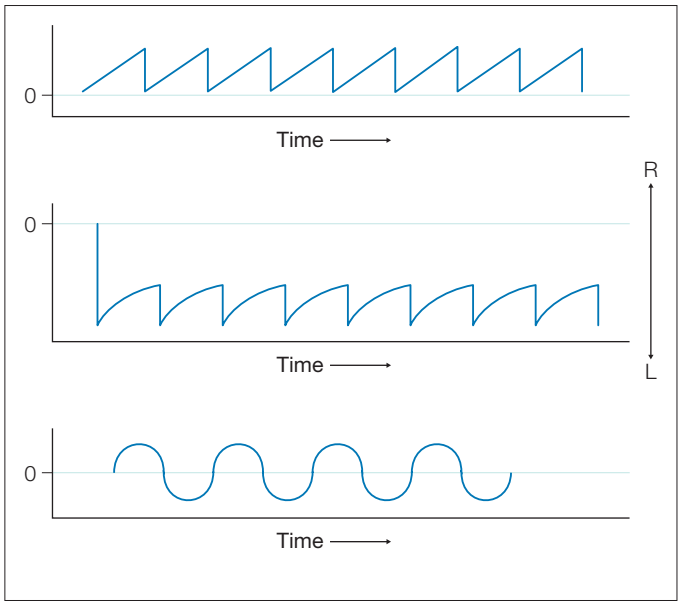

Fig. 90.8 Ocular oscillations. Artist's representation of major types of nystagmus waveforms. Continuous periods of time are depicted in each tracing. Rightward eye movements are up and leftward eye movements are down. The top trace shows pure jerk left nystagmus with linear slow phases to the left interrupting fixation in primary position. The middle trace shows jerk left nystagmus in left gaze with decreasing velocity slow phases. The bottom trace shows pure pendular nystagmus interrupting primary position fixation.

These "beats" of nystagmus toward the eccentric position persist as long as the child attempts to view a peripherally placed target. This is different to physiologic endpoint nystagmus, where only a few beats of nystagmus, gradually decreasing in amplitude, are present while viewing eccentrically placed targets.

Saccades

If an abnormality of saccadic eye movements is suspected, the quick phases of vestibular and OKN can be easily evaluated in infants and young children. To produce and observe vestibular nystagmus, hold the infant at arm's length, maintain eye contact, and spin first in one direction and then in the other (Fig. 90.9A,B). An OKN response can be elicited in the usual manner by passing a repetitive stimulus, such as stripes or an OKN drum, in front of the baby, first in one direction and then in another (Fig. 90.9C). In addition, reflex saccades will be induced in many young patients when toys or other interesting stimuli are introduced into the visual field. Older children are asked to fixate alternately upon two targets so that the examiner can closely observe the saccades for promptness of initiation, speed, and accuracy (Fig. 90.10). However, do not confuse a saccade toward sound as a visually guided saccade in a child with poor vision; it should first be established that the child can see. In children with strabismus, it is necessary to test saccades monocularly. The OKN drum/tape or the VOR response can also be used to assess saccadic function. It is sometimes easier to observe the eyelashes moving vertically while testing vertical saccades using a vertically rotating OKN drum (see Fig. 90.9C).

Smooth pursuit and vestibulo-ocular response systems

SP is tested by having the child follow a slow-moving, easily seen target (e.g. a brightly colored toy or mirror), both horizontally and vertically. The child's head should initially be kept still. If the child is uncooperative or is thought to have hysterical blindness, a mirror should be slowly rotated before his/her eyes, or an OKN drum or tape can be used. When examining the pursuit system, one should always include an assessment of VOR suppression, which is an essential component of the SP task during motion. In the older child, VOR suppression can be examined by asking the child to hold his/her finger about 6–8 cm in front of their face. The child is then asked to slowly rotate his/her head with their finger from left to right while maintaining fixation on their finger. If the VOR response is suppressed, there is no movement of the eyes relative to the head. Failure of VOR suppression results in a jerk nystagmus beating in the direction of the rotation. In an infant or young child, you can test VOR suppression by holding the child in outstretched arms and spinning in both clockwise and counterclockwise directions, while encouraging the child to fix on your face.

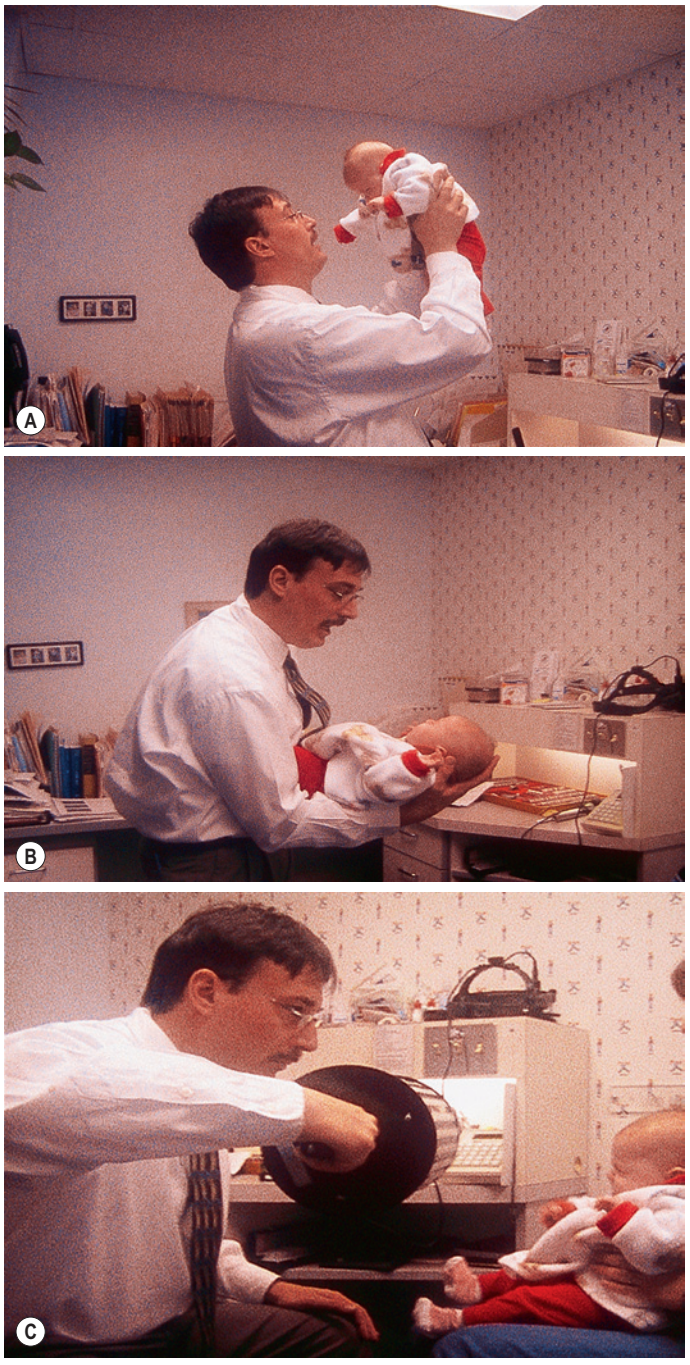

Fig. 90.9 Clinical evaluation of infant eye movements. The child is rotated in the examiner's arms in the vertical (A) and horizontal (B) planes to test the vestibulo-ocular, optokinetic, and saccadic systems. (C) An optokinetic drum is rotated close to the child in the vertical direction to assess visual fixation and saccadic and optokinetic functions.

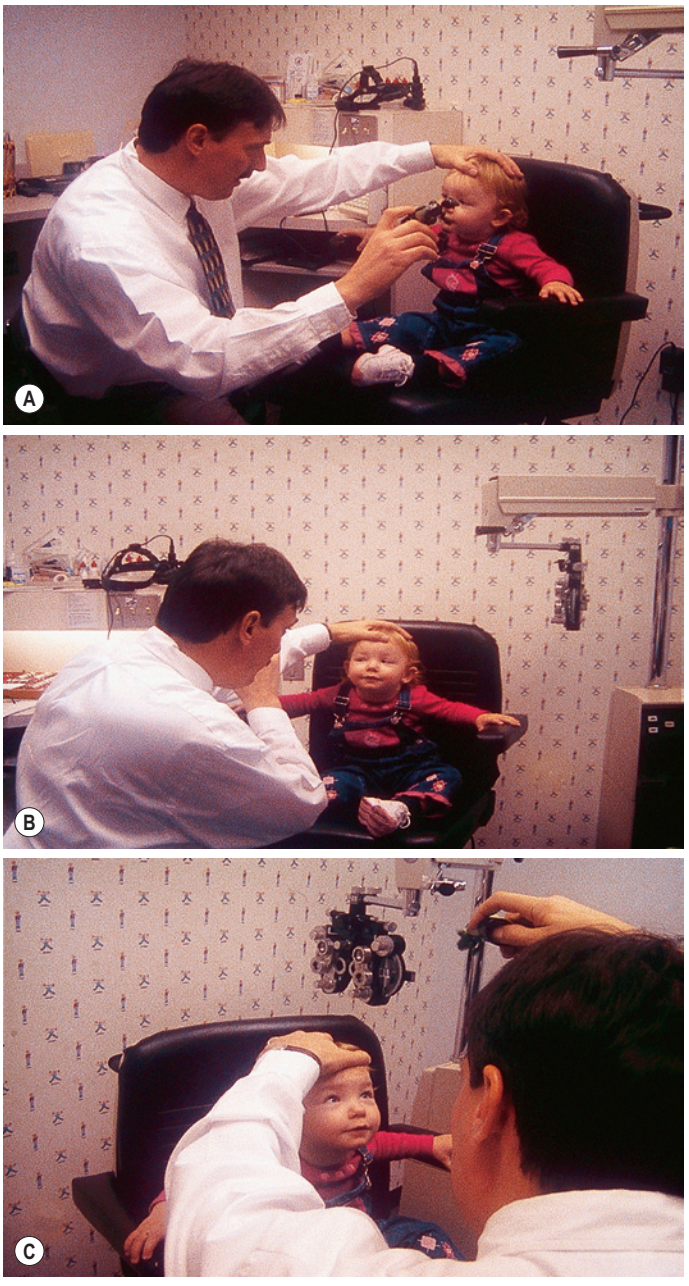

Fig. 90.10 Clinical evaluation of child voluntary saccadic eye movements. The child is seated while the head is held steady and targets are placed in the peripheral visual field horizontally (A,B) and vertically (C).

Vergence system

Vergence is usually tested by objective tests such as cover/uncover testing, alternate cover testing, prisms in front of the eye, and manual tests of near point of accommodation and vergence. Subjective aspects of vergence are tested by measuring the child's ability to perceive stereopsis. Many of these tests are dependent on the child's ability to cooperate, but alternate cover testing can be performed as soon as the child is able to fix on a near object.

Optokinetic system

Both slow and fast phases of OKN can be elicited by using OKN drum, tape, or full-field OKN stimuli (see Fig. 90.9C). OKN responses are observed with both eyes open in the full-term infant on the first day of life.[18] In healthy neonates, a monocular OKN response can be obtained when the stimulus is moved in the temporal-to-nasal direction, but not in the nasal-to-temporal direction (physiologic/developmental, monocular OKN asymmetry). After 3 months, this monocular OKN asymmetry declines for moderate stimulus speeds, but persists beyond 6 months of age at high stimulus speeds.

Disorders of supranuclear eye movements

Neural integrator

Neural integrator dysfunction

Neural integrator dysfunction manifests clinically as gaze-evoked nystagmus and is often associated with low pursuit gain (gaze-holding deficiency nystagmus, eccentric gaze nystagmus) and rebound nystagmus. Quick phases are away from the central position (see Fig. 90.8). Neurologic signs and symptoms include vertigo, nausea, dizziness, and oscillopsia. Gaze-evoked nystagmus is induced by moving the eye into lateral or vertical gaze, with sustained attempts to look eccentrically (Fig. 90.11). After the eyes are then returned to the central position, a short-lived nystagmus with quick phases opposite to the direction of the prior eccentric gaze occurs (rebound nystagmus). Abnormal suppression of the VOR and low-gain OKN responses are also associated with clinical findings and, again, probably reflect cerebellar disease[19,20] (see Fig. 90.11).

Most types of pathologic nystagmus increase their intensity as the eyes move in the direction of the fast phase (Alexander's law); this is believed to be due to a physiologically adapted "leaky" neural integrator responding to the pathologic vestibular imbalance that is part of the nystagmus.[19,20]

Most frequently, gaze-holding deficiency nystagmus is seen in conjunction with use of anticonvulsants and sedatives, cerebellar and brainstem disease, or other drug intoxication. Magnetic resonance imaging (MRI)/computed tomography (CT) scan of the brain reflects underlying disease and ocular motility recordings show slow phases that have decelerating velocity characteristics.[19,20] Acquired eye movement abnormalities suggesting defective neural integration, whether isolated or associated with other neurologic deficits, alert the examiner to investigate for a serious central nervous system (CNS) abnormality. Structural anomalies affecting the brainstem and cerebellum, e.g. Arnold–Chiari malformation, as well as metabolic, vascular, and neurodegenerative disorders, may also produce abnormalities of the neural integrator.

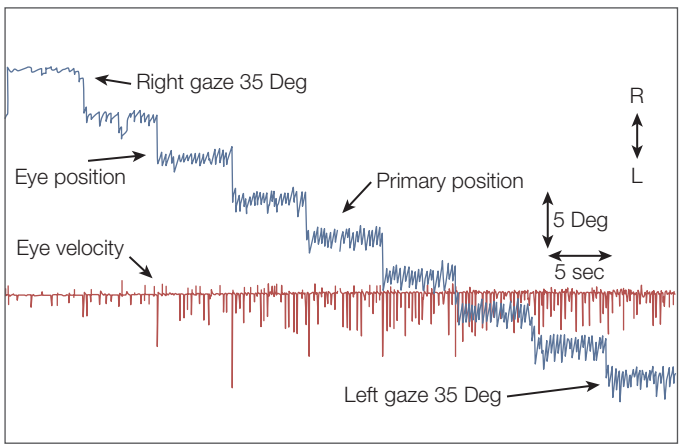

Fig. 90.11 Ocular motility recording of gaze-evoked nystagmus. This is a typical 45 s position and velocity trace of ocular motor recordings from the right eye of a patient with left gaze-evoked nystagmus. Right gaze 35° shows minimal intensity jerk left nystagmus with linear/decreasing velocity slow phases, while increasing left gaze, shows increasing intensity jerk left with linear and decreasing velocity slow phases. The horizontal arrows point to 35° right gaze and primary position. Deg, Degrees; L, leftward eye movements and left gaze; R, rightward eye movements and right gaze; sec, seconds.

Disorders of saccades

Saccadic accuracy

Normal and abnormal saccades are often dysmetric (inaccurate). Saccadic inaccuracy can be a result of gain dysmetria or pulse-step dysmetria. In saccadic dysmetria, the saccade misses the target and corrective saccades are needed for foveation (Fig. 90.12). If the saccades fall short of the target, they are known as hypometric; if they overshoot the target, they are hypermetric. In both cases, one or more secondary saccades are needed to eventually fixate the target. Hypometria is often seen in cerebellar disease, including autosomal dominant spinocerebellar ataxia type 3, and ocular motor apraxia (OMA). It is far more common than hypermetria. Consistent marked hypometria below 90% that persists beyond 7 months of age suggests neurologic disease. Hypometric saccades can be secondary to changes in visual magnification; for example, the removal of aphakic spectacles may lead to a temporary hypometria until adaptation takes place.[21]

Hypermetria is much less common and appears flutter-like (but should not be mistaken for ocular flutter). With the exclusion of centripetal saccades, hypermetria is abnormal at any age, and, when conjugate, it is almost always associated with cerebellar disease, including spinocerebellar ataxia type 1. If hypermetria is severe, the corrective saccade may be as large as the primary saccade, thus causing the eyes to oscillate back and forth with saccades. This phenomenon has been termed "macrosaccadic oscillations." After recovery of opsoclonus, there may be persistent hypermetric saccades (see Fig. 90.12).[22,23]

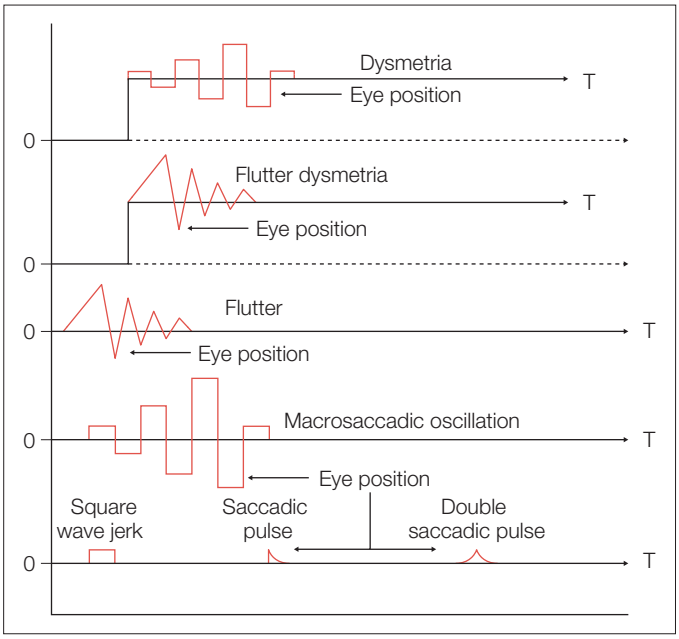

Fig. 90.12 Saccadic intrusions. Artist's representation of major types of saccadic instabilities and their ocular motor characteristics. Continuous periods of time are depicted in each tracing. Rightward eye movements are up and leftward eye movements are down. 0, Primary position fixation; T, target.

Saccadic velocity

Slow saccades may not be obvious clinically, especially in children. They may result from an abnormality involving the paramedian pontine reticular formation and have been thought to be pathognomonic of burst cell dysfunction. Slow saccades may be seen in mitochondrial disorders, progressive external ophthalmoplegia, myasthenia gravis, basal ganglia disease, Duane syndrome, and families with spinocerebellar ataxia type 2. Slow horizontal, and sometimes vertical, saccades may occur in patients with Gaucher type 3 disease.[24]

Saccadic latency

The time between the onset of a stimulus and the beginning of a saccade in healthy infants is up to about 1 s (about 200 ms in adults). In childhood, prolonged saccade latencies usually occur in association with saccade initiation failure.

Saccade initiation failure/ocular motor apraxia

The term saccade initiation failure (SIF) or OMA is used to specify impaired voluntary saccades and variable deficit of fast-phase saccades during vestibular or OKN.[24] Congenital OMA is characterized by defective horizontal saccades, but it does not represent a true apraxia since reflex saccades may also be impaired.[25]

Patients with congenital SIF show abnormal initiation and decreased amplitude of voluntary saccades; saccadic velocities in these patients are normal and fast phases of nystagmus of large amplitude can occasionally be generated. This suggests that the brainstem burst neurons that generate saccades are intact.[24,26] Acquired SIF may be due to conditions as listed in Table 90.3. Some of these patients with the acquired type, such as those with Gaucher disease (type 1 and some type 3 patients), have abnormal saccadic velocities.[27] Although the exact cause or localization of the defect in congenital SIF has not been determined, there is strong evidence that most can be localized subtentorially, particularly to the cerebellar vermis.[24,26]

Affected infants and children with poor head control are commonly thought to be blind since the expected re-fixations are not observed. In such an infant, demonstration of vertical saccades, vertical pursuit, OKN response in any direction, and normal acuity on visual-evoked response testing suggests the diagnosis of SIF. Another clinical sign in young infants is an intermittent tonic deviation of the eyes in the direction of slow-phase vestibular or OKN; in these infants, fast-phase saccades may be impaired.

By 4–8 months of age, the child develops a striking "head thrusting" behavior in order to re-fixate. First, the eyelids blink ("synkinetic blink") and the head begins to rotate toward the object of interest (Figs 90.13 and 90.14). Next, the head continues to rotate past the intended target allowing the tonically deviated eyes, which are now in an extreme

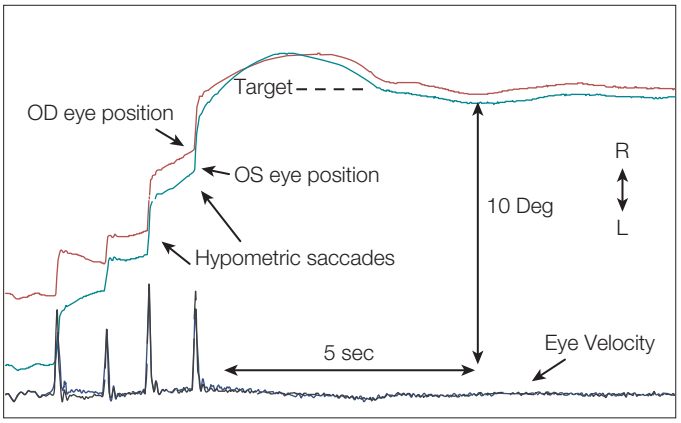

Fig. 90.13 Ocular motility recording of saccadic initiation failure. This is a 12 s position and velocity trace of ocular motor recordings from a patient with saccadic initiation failure. Attempts at fixation of rightward 10° target are followed by hypometric saccades, followed by a dysmetric fixation on the target. Deg, Degrees; L, leftward eye movements; OD, right eye; OS, left eye; R, rightward eye movements.

Table 90.3 Congenital and acquired saccade initiation failure (SIF)

Classification by cause	Specific etiologies
Idiopathic	
Perinatal problems	Cerebral palsy; hypoxia; hydrocephalus; seizures
Congenital malformations	Agenesis of corpus callosum; fourth ventricle dilation, and vermis hypoplasia; Joubert syndrome; macrocerebellum; dysgenesis of cerebellar vermis and midbrain; Dandy–Walker malformation; immature development of putamen; heterotropia of gray matter; porencephalic cyst; hamartoma near foramen of Munro; macrocephaly; microcephaly; posterior fossa cysts; chondrodystrophic dwarfism and hydrocephalus; encephalocele; occipital meningocele; COACH syndrome (cerebellar vermis hypoplasia, oligophrenia, congenital ataxia, coloboma, hepatic fibrocirrhosis)
Neurodegenerative conditions with infantile onset of SIF	Infantile Gaucher disease (types 2 and 3); Gaucher disease type 2; Pelizaeus–Merbacher disease; Krabbe leukodystrophy; propionic acidemia; GM1 gangliosidosis; infantile Refsum disease; 4-hydroxybutyric aciduria
Neurodegenerative conditions with later onset of SIF	Ataxia telangiectasia; spinocerebellar degenerations; juvenile Gaucher disease (type 3); Huntington disease; Hallervorden–Spatz disease; Wilson disease
Acquired disease	Post-immunization encephalopathy; herpes encephalitis; posterior fossa tumors
Other associations	Alagille syndrome; Bardet–Biedl syndrome; carotid fibromuscular hypoplasia; Cockayne syndrome; Cornelia de Lange syndrome; juvenile nephronophthisis; Lowe syndrome; neurofibromatosis type I; orofacial-digital syndrome; X-linked muscle atrophy with congenital contractures

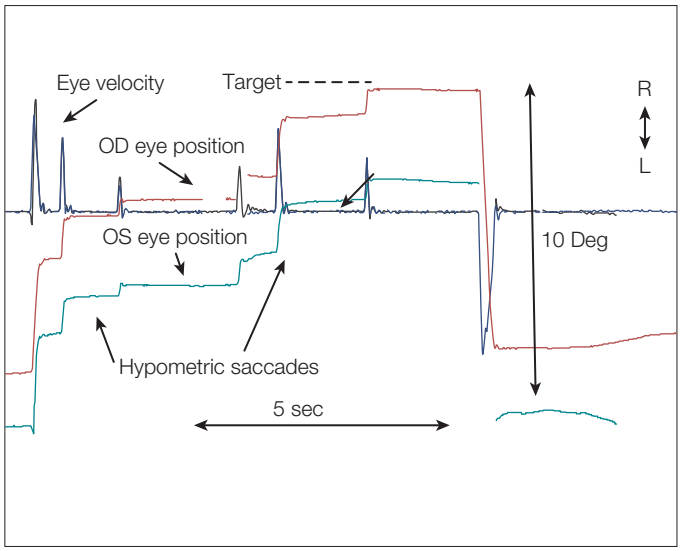

Fig. 90.14 Ocular motility recording of saccadic initiation failure. This is a 15 s position and velocity trace of ocular motor recordings from a patient with saccadic initiation failure during the resolution phase. Multiple hypometric ("staircase") saccades to the right with eventual excellent fixation are illustrated. Deg, Degrees; L, leftward eye movements and left gaze; OD, right eye; OS, left eye; R, rightward eye movements and right gaze; sec, seconds.

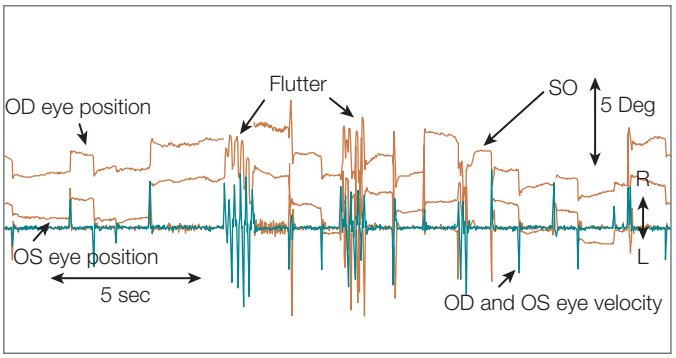

Fig. 90.15 Ocular motility recording of flutter and saccadic oscillations. This is a typical 20 s position trace of ocular motor recordings from a patient with ocular flutter. Back-to-back saccades with macro-sacccadic oscillations (SO) and without (flutter) an intersaccadic interval, both interrupting fixation and occurring on re-fixation are demonstrated. Deg, Degrees; L, leftward eye movements and left gaze; OD, right eye; OS, Left eye; R, rightward eye movements and right gaze; sec, seconds.

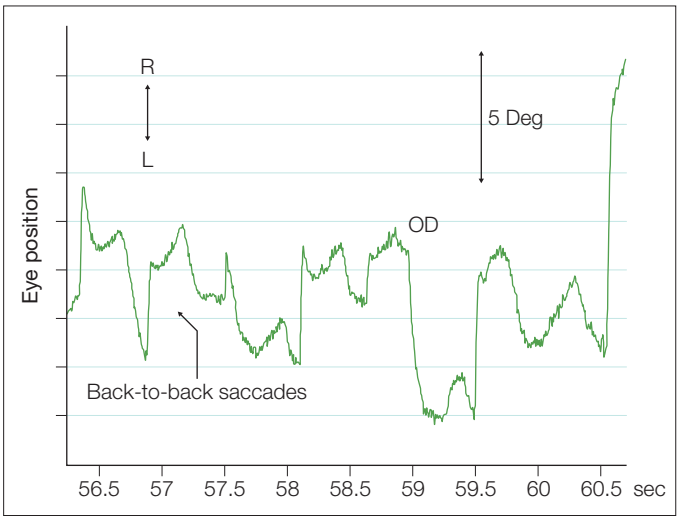

Fig. 90.16 Ocular motility recording of opsoclonus. This is a typical 4 s position trace of ocular motor recordings from a patient with opsoclonus. High-frequency back-to-back saccades without (flutter) an intersaccadic interval are demonstrated (arrows). Deg, Degrees; L, leftward eye movements and left gaze; OD, right eye; R, rightward eye movements and right gaze; sec, seconds.

contraversive position, to come into alignment with the target. Finally, as the eyes maintain fixation, the head rotates slowly back so that the eyes are in primary position. This apparent use of the VOR to re-fixate continues for several years, but with increasing age, patients demonstrate less prominent head thrusting and may even be able to generate some saccades, although they are abnormal. The blink–saccade synkinesis adaptation may persist. In some infants, generalized hypotonia may be associated.[28]

A brain MRI is necessary for suspected neurologic disorders to look for midline malformations, particularly around the fourth ventricle and cerebellar vermis.

Gaucher disease, ataxia telangiectasia and its variants, and Niemann–Pick variants may also present with the inability to generate saccades, as well as blinking and head thrusting prior to re-fixation. Unlike SIF, these disorders generally involve vertical as well as horizontal saccades and eventually manifest systemic signs.

The prognosis of the congenital type is good. Many adapt to allow gaze shifts with less head thrusting and can generate some saccades, albeit abnormal. There is no treatment for SIF, but children who have this condition should be investigated appropriately and recognized as having learning and living difficulties, and they should receive extra help and other educational benefits at school. Whether the condition improves with age is not known; any apparent improvement may be a result of the improvement of the adaptive strategies these children use to enable rapid shifts of gaze.

Opsoclonus/ocular flutter

Opsoclonus, also referred to as "saccadomania" or dancing eyes, is a rare, but striking, saccade disorder characterized by intermittent involuntary bursts of wild conjugate multidirectional back-to-back saccades.[23] If the eye movement is purely horizontal, it is known as ocular flutter (Fig. 90.15). During resolution, opsoclonus may revert to ocular flutter, and finally saccadic dysmetria, before eventually reverting to normal eye movements. Opsoclonus is often triggered by attempted fixation, SP, convergence, upgaze, eyelid closure, or OKN or vestibular nystagmus. The frequency is high, usually ranging between 5 and 13 Hz, and the amplitude can be tens of degrees, although it may be so small that the oscillations cannot be seen without a slit-lamp, ophthalmoscope or eye movement recordings (Figs 90.16 and 90.17). Opsoclonus usually persists during sleep, although it may be diminished or even absent.[23] Acquired opsoclonus is often associated with limb myoclonus. In such cases, it is described as opsoclonus–myoclonus, dancing eye–dancing feet syndrome, myoclonic encephalopathy of infants, or infantile polymyoclonia.[23] Opsoclonus–myoclonus syndrome is more common in children.[23]

Onset may be acute or subacute and is often accompanied by ataxia, vomiting, and irritability. It may be a manifestation of occult malignancies, in particular, neural crest tumors

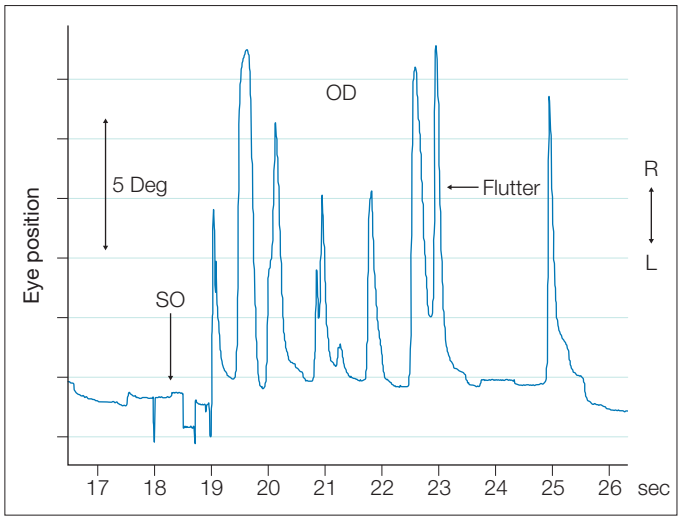

Fig. 90.17 Ocular motility recording of opsoclonus. This is a 20 s position trace of ocular motor recordings from a patient with opsoclonus. Asymmetric, conjugate, multiplanar, small amplitude, high-frequency back-to-back saccades without an intersaccadic interval (flutter) are present. Deg, Degrees; L, leftward eye movements and left gaze; OD, right eye; R, rightward eye movements and right gaze; sec, seconds; SO, saccadic oscillation.

(neuroblastoma, ganglioneuroblastoma, ganglioneuroma), hepatoblastoma, infection (Coxsackie B, human immunodeficiency virus [HIV], mumps, parainfluenza virus, psittacosis, *Salmonella*, syphilis, St. Louis encephalitis, rickettsia, enterovirus, Epstein–Barr virus), or toxic (amitriptyline, cocaine, diazepam, lithium, phenytoin) or metabolic disorders (biotin-responsive multiple carboxylase deficiency, hyperosmolar non-ketotic coma).[6]

In children with neural crest tumors or brainstem encephalitis, opsoclonus is commonly accompanied by diffuse or focal myoclonus. Although opsoclonus–myoclonus is rarely a presenting feature of neuroblastoma, it is seen in about 50% of children with an occult neuroblastoma, and the presence of opsoclonus confers a favorable survival rate.[29] Paraneoplastic opsoclonus is associated with a single copy of the N-*myc* oncogene, and those children with amplification of this oncogene who do not develop opsoclonus carry a worse prognosis.[30] It is hypothesized that in paraneoplastic opsoclonus, the tumor and some CNS structures share an epitope, and that this common epitope triggers an immune response against the tumor and the CNS, resulting in the neurologic symptoms.[30]

Opsoclonus may be mistaken for nystagmus and vice versa. Formal eye movement recordings will differentiate the two, demonstrating that opsoclonus is a burst of back-to-back saccades with no intersaccadic interval, without the slow phases of nystagmus (see Figs 90.15–90.17). However, on rare occasions, there may be a constant high-frequency acquired pendular nystagmus. Once opsoclonus has been confirmed, children should be screened for urinary vanillylmandelic acid (VMA) and homovanillic acid (HVA), and have an oncologic workup. This may include chest and abdominal CT and/or MRI. Elevated levels of urinary VMA and HVA are diagnostic; however, normal levels occur in 26% of children with paraneoplastic opsoclonus.[30] Blood and cerebrospinal fluid (CSF) samples should also be taken and sent for virology and bacteriology. CSF pleocytosis has been reported in children with paraneoplastic opsoclonus and there are occasional oligoclonal bands. There have been occasional reports of autoantibodies, including anti-Hu and antibodies against neurofilaments, in the sera of children with paraneoplastic opsoclonus.

Acquired opsoclonus is probably immune mediated. Its neural substrate remains a mystery, and there may be no single site involved in the causation of opsoclonus.

Opsoclonus–myoclonus, especially when it occurs with brainstem encephalitis, may be a benign self-limiting condition. Although children with paraneoplastic opsoclonus tend to have a better oncologic prognosis, the neurologic outcome is unpredictable. Children who have become cancer free may have significant neurologic sequelae. Adrenocorticotropic hormone or systemic steroid treatment has a dramatic short-term effect on symptoms in 50% to 90% of children with opsoclonus.[31] However, not all children have such a good response, and the opsoclonus and ataxia may become steroid dependent, re-emerging when treatment is tapered or during intercurrent illnesses. Other drugs used to treat opsoclonus–myoclonus include intravenous immunoglobulin G, azathioprine, propranolol, and divalproex sodium. A combination of systemic steroids and high-dose immunoglobulin can be used for the treatment of opsoclonus–myoclonus in patients who do not respond to first-line therapy with steroids.

Regardless of the short-term response, these children often have long-term developmental problems, including speech, motor, and cognitive disabilities.[32] Abnormal eye movements may persist. Parents, teachers, and caregivers should be informed of such problems. Occupational therapists, psychologists, and social services should be involved at an early stage.

Antisaccades

An antisaccade requires the subject to suppress a reflexive saccade to an abruptly appearing peripheral target, and generate a voluntary saccade in the equidistant but opposite direction. The ability to suppress reflexive responses in favor of voluntary motor actions is necessary in everyday life, and both of these abilities can be assessed with use of the antisaccade task. The correct execution of an antisaccade requires at least two functioning subprocesses: an intact fixation system and the ability to generate a voluntary saccade in the opposite direction. Infants as young as 4 months have a fixation system adequate to allow inhibition of reflex saccades, but the ability to generate a voluntary antisaccade develops much later, usually over 10 years of age, with a steep decrease in the mean error rate from 10 to 15 years, then a more gradual decrease toward 20 years.[33] Difficulty in making antisaccades has also been described in people with schizophrenia, children with attention-deficit hyperactivity disorder, autosomal dominant cerebellar ataxia type 2, male dyslexics, and Tourette syndrome.[34]

Saccadic intrusions and oscillations

There are saccadic eye movements that may intrude on steady primary position fixation or interrupt re-fixation and, hence, mimic nystagmus (see Figs 90.12, 90.17, and 90.18). Saccadic intrusions (SIs) must be differentiated from nystagmus, in which a drift of the eyes from the desired position of gaze is the primary abnormality, and from saccadic dysmetria, in which the eye over- or undershoots a target, sometimes several times, before achieving stable fixation. Only eye movement recordings can definitively distinguish SIs and saccadic oscillations (SOs) from nystagmus.

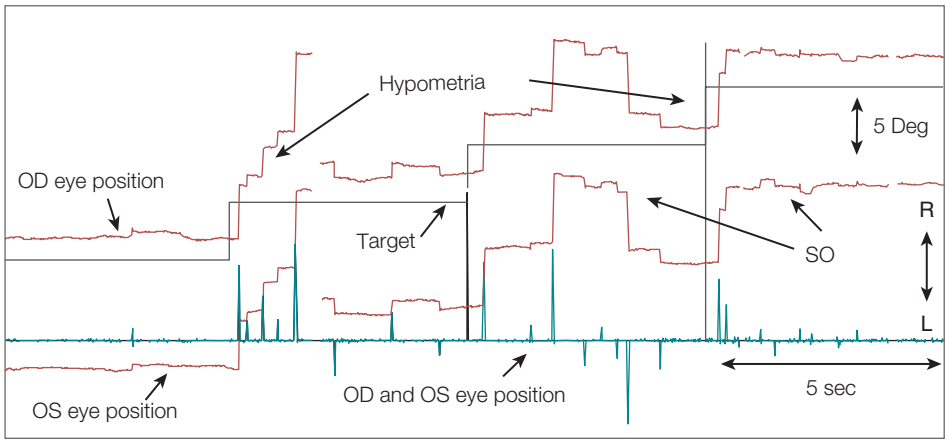

Fig. 90.18 Ocular motility recording of saccadic intrusions. This is a 20 s position trace of ocular motor recordings from a patient with saccadic intrusions. Small to moderated amplitude back-to-back saccades with an intersaccadic interval occur on re-fixation and interrupt fixation and are present throughout the recording. There are associated hypometric saccades to peripheral targets. Deg, Degrees; L, leftward eye movements and left gaze; OD, right eye; OS, left eye; R, rightward eye movements and right gaze; sec, seconds; SO, saccadic oscillation.

Square wave jerks consist of a conjugate displacement of the eyes up to 5° from fixation, followed by a re-fixational saccade after a normal intersaccadic interval of 200 ms. They occur in normal healthy subjects of any age. However, if they are more frequent (more than 9 square wave jerks per minute in a young person should be considered abnormal), they are referred to as square wave oscillations, and are seen in cerebellar disease, progressive supranuclear palsy, and multiple sclerosis.[35] Square wave jerks and oscillations are rarely seen in childhood (see Fig. 90.18).

Macro-square wave jerks are also rare in childhood. They consist of conjugate displacement of the eyes away from fixation by more than 5°, and, after a shorter than normal latency of 80 ms, there is a re-fixation saccade. They occur in bursts and may be mistaken for flutter. The amplitude is variable, and they are present in the dark. They occur in diseases that disrupt cerebellar outflow, i.e. multiple sclerosis or olivopontocerebellar degenerations, including Huntington disease.[35]

Macrosaccadic oscillations represent a severe form of saccadic hypermetria. They are characterized by conjugate oscillations of the eyes around fixation, with a normal intersaccadic interval of 200 ms. Oscillations increase and then decrease in amplitude during each episode. They are a result of lesions affecting the midline cerebellum and underlying nuclei. They are not present in darkness.

Disorders of smooth pursuit

Smooth-pursuit asymmetry–initiation failure

Monocular SP asymmetries may persist in patients with early-onset, but not with late-onset, strabismus. Impaired SP to the side of the lesion has been most frequently reported in patients with lesions restricted to the posterior cortical areas and underlying white matter, but it also occurs with frontal lobe lesions and in hemidecortication. Ipsilateral pursuit deficit may also be seen in unilateral lesions of the lower portions of the pursuit pathway, including the thalamus, midbrain tegmentum, dorsolateral pontine nucleus, and cerebellum. Nuclear vestibular lesions may affect either ipsilateral or contralateral SP.[36]

Abnormal smooth-pursuit gain

Low pursuit gain, which may be seen clinically as saccadic or jerky pursuits, occurs in the elderly and in patients with basal ganglia disease, cerebellar disease, large cerebral lesions, or posterior cortical lesions. Low pursuit gain has been described in spinocerebellar ataxia types 1 and 3. If gaze-holding deficiency nystagmus is associated with saccadic pursuit, the lesion is most likely to be cerebellar, whereas saccadic pursuit in the absence of gaze-holding deficiency nystagmus is more likely to indicate a cerebral lesion.

Abnormal visual fixation

Steady fixation may be disrupted by slow drifts, nystagmus, or involuntary saccades. The frequency of square wave jerks increases in certain neurologic conditions, i.e. progressive supranuclear palsy, Friedreich ataxia, and focal cerebral lesions. Detection of nystagmus during attempted steady fixation is abnormal. If the slow-phase velocity or intensity of nystagmus is similar both during fixation and when fixation is prevented (e.g. by Frenzel goggles or in darkness), then a disorder of the fixation system is inferred.

Disorders of the visual system lead to instability of gaze, the extreme example being blindness. Monocular loss of vision may lead to unstable gaze in the affected eye, which is predominantly due to slow, low-frequency vertical drifts. Binocular loss of vision causes loss of gaze stability and a continuous horizontal and vertical nystagmus.[37] This nystagmus characteristically changes direction over the course of seconds and minutes, a feature also encountered following experimental cerebellectomy. Thus, the nystagmus that follows bilateral visual loss reflects a gaze-holding mechanism that has never been calibrated by visual inputs. Acquired lesions of the cerebellum without specific involvement of the visual pathways may disrupt fixation with SIs and with slow drifts, especially in the vertical plane, that lead to nystagmus. The pathogenesis of pendular oscillations occurring in association with visual loss is unknown.[38]

Disorders of vergence

Strabismus

See Chapters on Strabismus.

Spasm of the near reflex (convergence spasm)

Spasm of the near reflex, also referred to as convergence spasm, is characterized by intermittent spasm of convergence, of miosis, and of accommodation. Symptoms include headache, photophobia, eye strain, blurred vision, and diplopia. Patients

may appear to have bilateral sixth nerve palsies, but careful observation will reveal miosis and high myopia (8–10 D) on dry retinoscopy, accompanying the failure of abduction. This key clinical clue will prevent misdiagnosis and misdirected testing. Most commonly, spasm of the near reflex is psychogenic, and treatment may include simple reassurance, psychiatric counseling, or cycloplegia with bifocals.

Spasm of the near reflex associated with organic disease has been reported with encephalitis, tabes, labyrinthine fistulas, pituitary adenoma, Arnold–Chiari malformation, posterior fossa lesions, trauma, myasthenia gravis, anticonvulsant toxicities, midbrain lesions, metabolic problems, and cyclic oculomotor palsy. Disturbances that are clearly functional do not exclude co-existing organic disease!

Divergence insufficiency/paralysis

Divergence insufficiency is characterized by an esotropia for distance and orthophoria for near and normal convergence; the esotropia may be constant or intermittent. The fusional divergence may be reduced or completely absent. Divergence paralysis is characterized by complete loss of divergence amplitude. It appears as a constant esotropia for distance, with normal convergence, and it usually indicates an underlying neurologic problem, such as a tumor or head trauma resulting in elevated intracranial pressure, or the onset of Miller Fisher syndrome. Bilateral sixth nerve paresis should be excluded in these cases.

Convergence insufficiency/paralysis

Convergence insufficiency is characterized by reduced fusional convergence at near and a variable exophoria (occasionally intermittent exotropia) at near. It usually appears in adolescence and gives rise to vague symptoms of eye strain, headache, diplopia, and blurring associated with close work. Eye movements and reading acuity are normal, and there should be no neurologic abnormalities.

Convergence insufficiency usually has no underlying cause, but it can be associated with stress, fatigue, and anxiety, and it may follow infection or trauma.[39] Underlying intracranial lesions are rare. The child and parents should be reassured that there is no disease, and orthoptic near-point exercises can be tried. If orthoptic exercises fail, prisms may be required.

Complete convergence paralysis is highly suggestive of an intracranial lesion, such as encephalitis, demyelination, neurosyphilis, or a condition resulting from trauma or toxins. The patient is usually completely unable to converge.

Disorders of the vestibulo-ocular response system

Abnormal VOR gain

VOR gain is the peak slow-phase velocity divided by rotation speed and is higher in infants than in adults. Abnormalities of VOR gain in the small child are not easily detected clinically but require eye movement recordings. If VOR gain is abnormal, a child's visual acuity will deteriorate by several lines while moving the head compared to the acuity taken with the head stationary. Abnormally high gain has been described in lesions of the cerebellar flocculus and the inferior olive. Mildly high gains have also been reported in familial vestibulocerebellar disorders.[40]

Abnormal VOR time constant

The time constant is measured as the time taken for the eye velocity of per-rotational or postrotational nystagmus measured in the dark to fall to 37% of its initial value. As a rule of thumb, the nystagmus will persist for a total time of about three times the time constant. Measurements in animals have shown that the time constant of the decay of per-rotatory or postrotatory nystagmus as measured at the vestibular ganglion is about 5 or 6 s. However, the nystagmus takes much longer to decay, with a time constant of approximately 12 s in humans. This augmentation of the cupula time constant is known as the velocity storage mechanism (VSM). It is also under adaptive control by the nodulus and uvula in the cerebellar vermis, and experimental lesions result in a prolonged VSM time constant. Abnormally short time VSM constants can be caused by disease of the end organ, the vestibular nerve, or central disease. Very short time constants have been reported in Chiari type I malformation, olivopontocerebellar degeneration, demyelinating disease, congenital and acquired blindness, and bilateral vestibulopathy secondary to ototoxic drugs. Abnormally long time VSM constant is rarely seen.

Absent VOR quick phases

Absent quick phases are seen in children with SIF. Most of these children will show a similar failure during OKN, but occasionally only vestibular nystagmus demonstrates the failure. This may indicate a very subtle form of saccade failure, and as an isolated phenomenon it is probably of little clinical significance. Absent quick phases may also be seen in neonates up to 2 to 3 weeks, or in older infants with delayed visual maturation.[13]

Absent VOR

The VOR appears clinically absent or very erratic in children with infantile nystagmus, whether elicited by calorics, constant rotation, or sinusoidal oscillation.[41] The VOR may be absent in children with the CHARGE association and in children with Usher syndrome type 1.

Disorders of the optokinetic system

Absence of OKN

No OKN can be elicited in a completely blind child, as it is a visually induced reflex. However, the absence of OKN alone must not be used as an indicator of visual acuity, as the sighted infant who may appear visually unresponsive may have absence of OKN for another reason. The response to a full-field OKN stimulus is difficult to suppress, so the very presence of OKN demonstrates some vision. Bilateral lesions of the optokinetic pathway in the cortex, cerebellum, or brainstem may completely obliterate all OKN and SP. Infants with cortical dysplasia may have absent OKN, they may be cortically blind, or they can have a normal visual evoked potential and no OKN. If the optokinetic response is assessed with a hand-held device in the clinic, quick-phase failure in children with SIF can be mistaken for absent OKN if the eyes are not driven to the limit of gaze. If there is any doubt, the child should have full-field OKN assessment, which will readily demonstrate the typical "locking up" of SIF.

Binocular asymmetry of OKN

Any unilateral lesion in the optokinetic pathway, as it passes through the brainstem, cerebellum, or parietal lobe, can result in asymmetric abnormalities of binocular OKN and SP. With brainstem and cerebellar lesions, there may be accompanying localizing neurologic signs, whereas isolated binocular OKN asymmetry is suggestive of a parietal lesion and has been reported in children as young as 4–5 months.

Monocular asymmetry of OKN

With early disturbances of binocular vision caused by strabismus, anisometropia, or unilateral congenital cataract, the normal early monocular OKN asymmetry persists in both eyes[42]; after 1–2 years, the monocular asymmetry persists.[42] The persistence of monocular OKN asymmetry and poor binocular vision, together with the fact that OKN becomes symmetric in normal infants around the time that binocular function is detectable, has led to the hypothesis linking binocularity and OKN asymmetry, but they may be separate processes.[19]

Miscellaneous disorders

Induced convergence retraction (dorsal midbrain syndrome)

Lesions of the posterior commissure in the dorsal rostral midbrain may result from many disease processes and can affect a variety of supranuclear mechanisms, including those that control vertical gaze, eyelids, vergence, fixation, and pupils. Other terms such as pretectal syndrome, Koerber–Salus–Elschnig syndrome, Sylvian aqueduct syndrome, posterior commissural syndrome, and collicular plate syndrome all refer to this condition.

Among the many underlying causes of this condition are hydrocephalus, stroke, and pinealomas. Table 90.4 lists other reported etiologies and systemic associations.

Limitation of upward saccades is the most reliable sign of the convergence retraction. Upward pursuit, Bell phenomenon, and the fast phases of vestibular and OKN may also be affected, either at presentation or with progression of the underlying process. It is rare for upgaze to be unaffected. Pathologic lid retraction and lid lag are also common (Collier's sign).

Unlike the pathways from upward saccades, the pathways for downward saccades do not appear to pass through the posterior commissure (see Fig. 90.2). Perhaps because of this, disturbances of downgaze are not as predictable or uniform. Usually down-going saccades and pursuit are present, but they may be slow. Sometimes, especially in infants and children, there is a tonic downward deviation of the eyes that has been designated the "setting sun" sign, and downbeating nystagmus may also be observed. The setting sun sign may also be seen in children with hydrocephalus.

Convergence spasm may occur during horizontal saccades and result in a "pseudoabducens palsy", since the abducting eye moves more slowly than the adducting eye. All children with convergence retraction deserve thorough, prompt neurologic and neuroradiologic evaluation, since timely intervention may be decisive. The natural history of this disorder is dependent on the underlying etiology.

Table 90.4 Causes of childhood dorsal midbrain syndrome

Classification by cause	Specific etiologies
Tumor	Pineal germinoma, teratoma and glioma; pineoblastoma; others
Hydrocephalus	Aqueductal stenosis with secondary dilation of third ventricle and aqueduct, or with secondary suprapineal recess compressing posterior commissure, commonly caused by cysticercosis in endemic areas
Metabolic disease	Gaucher; Tay–Sach; Niemann–Pick; kernicterus; Wilson disease; others
Midbrain/thalamic damage	Hemorrhage; infarction
Drugs	Barbiturates; carbamazepine; neuroleptics
Miscellaneous	Benign transient vertical eye disturbance in infancy; trauma; neurosurgery; hypoxia; encephalitis; tuberculoma; aneurysm; multiple sclerosis

Transient vertical gaze disturbances in infancy

Vertical gaze abnormalities may be benign and transient in infants. Infants with episodic conjugate upgaze that became less frequent over time have been described. During these episodes, normal horizontal and vertical vestibulo-ocular responses could be observed.[27]

Tonic downgaze has been observed in 5 of 242 consecutively examined healthy newborn infants as well as in other infants. Again, the eyes can easily be driven above the primary position with the VOR. Premature infants with intraventricular hemorrhage may also develop tonic downgaze, usually in association with a large-angle esotropia. These infants do not elevate the eyes with vestibular stimulation. Upgaze often returns during the first 2 years of life, but the esotropia does not resolve when upgaze returns.

Internuclear ophthalmoplegia

In the absence of peripheral lesions such as myasthenia gravis, failure of adduction combined with nystagmus of the contralateral abducting eye is termed internuclear ophthalmoplegia (INO) and localizes the lesion to the medial longitudinal fasciculus (MLF) unequivocally.

The abducens nucleus consists of two populations of neurons that coordinate horizontal eye movements (see Fig. 90.1). Fibers from one group form the sixth nerve itself and innervate the ipsilateral lateral rectus muscle; fibers from the second group join the contralateral MLF and project to the subnucleus of the third nerve, which supplies the contralateral medial rectus muscle. In this way, the neurons of the sixth nerve nucleus yoke the lateral rectus with the contralateral medial rectus.

Clearly, lesions of the abducens nucleus will cause ipsilateral conjugate gaze palsy. Lesions of the MLF between the midpons and oculomotor nucleus will, in turn, disconnect the ipsilateral medial rectus subnucleus from the contralateral sixth nerve nucleus and cause diminished adduction of the ipsilateral eye on attempted versions. The signs of INO may be accompanied by an ipsilateral hypertropia or skew deviation.

A host of structural, metabolic, immunologic, inflammatory, degenerative, and other processes can interfere with the

function of the MLF and nearby structures. In young adults, multiple sclerosis is by far the most common cause of INO.[43] Additional causes of INO include Arnold–Chiari malformation, hydrocephalus, meningoencephalitis, brainstem or fourth ventricular tumors, head trauma, metabolic disorders, drug intoxications, paraneoplastic effect, carcinomatous meningitis, and others. Peripheral processes, particularly myasthenia gravis and Miller Fisher syndrome, may closely mimic INO and should be considered in any patient with INO-like eye movements.[44]

Variable diplopia and/or ptosis most often prompt an ophthalmologic evaluation. Since there is no stereotypical myasthenic eye movement, this diagnosis should be considered in any child with an unexplained, acquired ocular motility disturbance and clinically normal pupils – particularly when the deviation is variable – whether or not ptosis is present. Any pattern of abnormal motility is suspect, including an apparent gaze palsy, INO, isolated cranial nerve palsy, one and one-half syndrome, incomitant strabismus, accommodative and vergence insufficiency, and gaze-evoked nystagmus. Prolonged OKN may demonstrate slowing of the quick phases; large saccades may be hypometric; small saccades may be hypermetric; and characteristic "quiver movements," which consist of an initial small saccadic movement followed by a rapid drift backward, may be seen.[44]

Acquired and neurologic nystagmus

Eye care practitioners may be among the first to evaluate infants and children with involuntary ocular movements, producing anxiety in the medical care provider as well as the family. The eye care professional choosing to specialize in infants and children may, in fact, see more patients with nystagmus than any other specialist. This is due to the frequent association of nystagmus with strabismus.[17] It may be that nystagmus gets "less press" (e.g. literature, teaching, research, education) because there is less we understand or can do about it than strabismus or other childhood eye diseases.

Historical perspective

Nystagmus comes from the Greek word "nystagmos," to nod, drowsiness and from "nystazein" to doze, probably akin to Lithuanian "snusti," also to doze. It is a rhythmic, involuntary oscillation of one or both eyes. Using the information obtained from complete histories, physical examinations, and radiographic and oculographic evaluations, over 40 types of nystagmus can be distinguished. Some forms of nystagmus are physiologic, whereas others are pathologic. Although nystagmus is typically described by its more easily observable fast (jerk) phase, the salient clinical and pathologic feature is the presence of a slow phase in one or both directions. Thus, clinical descriptions of nystagmus are usually based on the direction of the fast phase and are termed horizontal, vertical, or rotary, or any combination of these. The nystagmus may be conjugate or disconjugate. The nystagmus may be predominantly pendular or jerky, the former referring to equal velocity to-and-fro movement of the eyes, and the latter referring to the eyes moving faster in one direction and slower in the other. Involuntary ocular oscillations containing only fast phases are "saccadic oscillations and intrusions" and not nystagmus. It is well documented that these differences may be difficult, if not impossible, to differentiate clinically. Recent advances in eye movement recording technology have increased its application in infants and children who have clinical disturbances of the ocular motor system (see Figs 90.8 and 90.12).

Incidence

In 1991, Stang retrospectively reviewed the records of Group Health Inc. (White Bear Lake, MN) and in their pediatric population of 70,000 found a prevalence of clinical "nystagmus" of 1 in 2850.[32] Other estimates of its incidence range from 1 in 350 to 1 in 6550.[45,46] It is difficult, if not impossible, to give accurate prevalence/incidence on all types of nystagmus combined, but it is known that up to 50% of the infantile strabismic population will have some associated nystagmus. This could increase the prevalence of nystagmus to up to 0.5% of the population.

Etiology

All the theoretical neuronal mechanisms of nystagmus are constantly evolving and are beyond the scope of this chapter. Particularly controversial is the role of cortical motion processing in the development of some forms of infantile nystagmus. However, major supranuclear inputs to the oculomotor system are reasonably well accepted for their role in stabilization of eye movements. These include the pursuit system, vestibular system, and the neural integrator. The vestibular system maintains a constant resting firing rate that tends to drive the eyes contralaterally. This tendency is counterbalanced by the vestibular system on the opposite side unless the balance is changed by head rotation. The counterbalance is lost with unilateral vestibular damage, and the eyes tend to drift toward the affected side. A corrective saccade is then made toward the unaffected side. The slow phase of the nystagmus toward the affected side is of constant velocity as recorded by ocular motility recordings. This is a distinguishing feature of vestibular nystagmus. Most forms of acquired nystagmus are due to disease of the vestibular system (centrally or peripherally). Ocular motility recordings show various combinations of uniplanar or multiplanar, simple pendular, linear, or decelerating velocity slow phases[47] (Fig. 90.19).

Neurologic and acquired nystagmus types

Spasmus nutans

Spasmus nutans is an ocular oscillation beginning in infancy and consisting of the association of high-frequency, small-amplitude, disconjugate oscillations, a head nodding oscillation, and a head tilt (Fig. 90.20). The head nodding associated with spasmus nutans syndrome (SNS) is a combination of vertical head nodding together with a lateral shaking of the head in an unpredictable pattern. The head nodding is of lower frequency than the nystagmus and becomes prominent when the child attempts to inspect something of interest. It disappears during sleep but may persist when the child is lying down. The head tilt in SNS is a variable finding that is present in less than half of cases. Although the reason for the associated head tilt is unclear, Gottlob et al. have suggested that it may serve to directionalize the head nodding to its optimal trajectory.

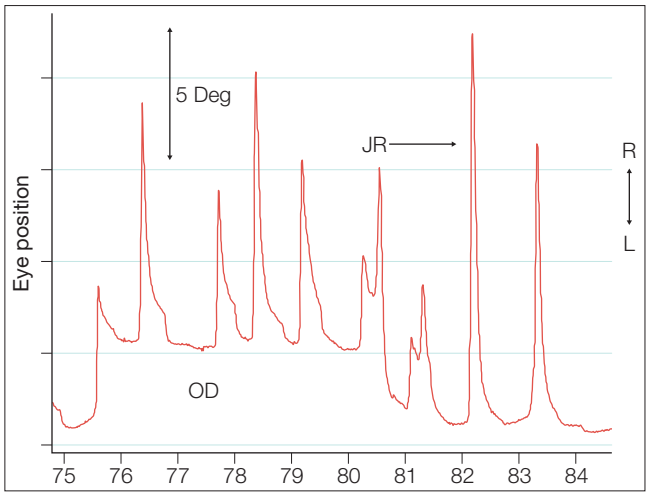

Fig. 90.19 Ocular motility recording of acquired jerk nystagmus. This is a typical 10 s position trace of ocular motor recordings from a patient with acquired jerk nystagmus. The jerk right nystagmus has decreasing velocity slow phases. Deg, Degrees; JR, jerk right; L, leftward eye movements and left gaze; OD, right eye; R, rightward eye movements and right gaze.

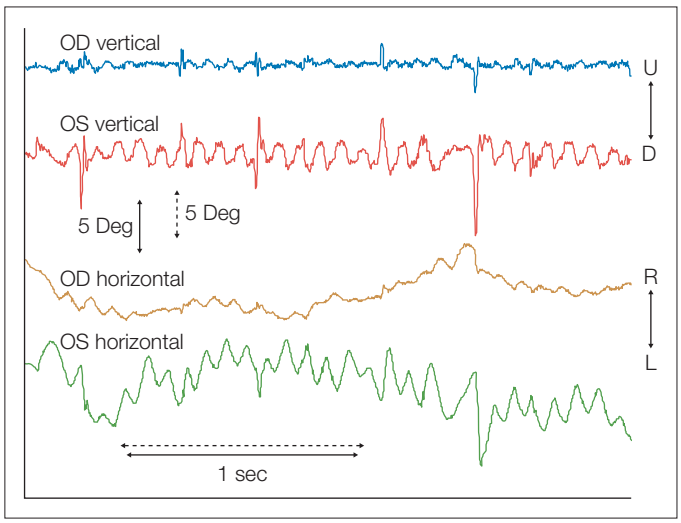

Fig. 90.20 Ocular motility recordings of spasmus nutans. OU open high-frequency (12–14 Hz), asymmetric, disconjugate, multiplanar (torsional), pendular nystagmus typical of spasmus nutans. Continuous periods of time are depicted in each tracing. Rightward eye movements (R) are up and leftward eye movements (L) are down. Deg, Degrees; OD, right eye; OS, left eye; OU, both eyes; sec, second; U, up; D, down.

The characteristic feature of spasmus nutans is the very fine, rapid, pendular nature of the nystagmus. The eyes appear to have a shimmering movement. It may be horizontal, vertical, or torsional. It is usually asymmetric to the point that it may appear unilateral. Pure unilateral forms are not uncommon. It may appear to switch eyes with changes in direction of gaze, and frequently appears worse in the abducting eye. Tremendous asymmetry is associated with amblyopia of the more involved eye.[17,48] A key clinical eye movement recording observation is the variable phase difference between the two eyes, which is reflected clinically as an asymmetry in the oscillations between the two eyes.

Spasmus nutans may be a completely benign condition with onset in infancy and resolution within 2 years. However, tumors of the diencephalon can cause a condition indistinguishable from spasmus nutans. Consequently, neuroimaging or careful monitoring for visual, neurologic, or endocrinologic decline is essential. An intracranial tumor should be strongly suspected in any child who develops spasmus nutans after 3 years of age. Neurodegenerative disorders such as Pelizaeus–Merzbacher disease and Leigh disease may produce nystagmus and head nodding that are indistinguishable from spasmus nutans. These disorders should be suspected in children with clinical signs of ataxia or developmental delay, or with MRI evidence of white matter signal abnormalities. Achromatopsia, congenital stationary night blindness, and Bardet–Biedl syndrome can also masquerade as spasmus nutans.

Drugs/toxins

Many drugs (some in therapeutic dosages) or toxins can cause nystagmus. The most common of these include anticonvulsants (i.e. phenobarbital, phenytoin, and carbamazepine), sedatives, hypnotics, and alcohol. Aspirin and quinine drugs causing nystagmus include chloroquine, quinidine, and quinine. Loop diuretics causing nystagmus include bumetanide, ethacrynic acid, furosemide, and torsemide. Aminoglycoside antibiotics causing nystagmus include amikacin, dihydrostreptomycin, gentamicin, neomycin, netilmicin, ribostamycin, streptomycin, and tobramycin. Antineoplastic drugs causing nystagmus include carboplatin and cisplatin. Environmental chemicals/toxins causing nystagmus include butyl nitrite, carbon disulfide, carbon monoxide, hexane, lead, manganese, mercury, styrene, tin, toluene, trichloroethylene, and xylene.[49,50]

Intracranial disease

Developmental, traumatic, and inflammatory brain diseases commonly cause acquired nystagmus. Consequently, nystagmus associated with other systemic, historical, and physical findings nearly always requires further neurologic and radiologic evaluation (see "localizing" forms of nystagmus below for further discussion.)

Voluntary flutter

Voluntary flutter ("nystagmus") (present in 7% to 15% of the population) is a misnomer, referring to a series of volitional, rapid alternating saccades with little to no intersaccadic interval[25] (see Figs 90.12 and 90.15). They are usually horizontal, but may be vertical or torsional, and can only be sustained for a few seconds. Voluntary nystagmus is a popular "party trick," and is often seen in patients with functional visual complaints. It is frequently associated with convergence of the eyes or facial grimacing. Voluntary nystagmus warrants no laboratory or radiographic investigation.

"Localizing" forms of nystagmus due to neurologic disease (Box 90.1)

(A)periodic alternating nystagmus

Periodic alternating nystagmus may resemble infantile nystagmus or be "acquired." Patients with acquired form usually have vertigo, nausea, dizziness, and oscillopsia. The key clinical component is that the null point shifts position in a cyclic pattern. This results in changes in the amplitude and direction of the nystagmus every few minutes. Adequate observation of the patient for several minutes should exclude this diagnosis. However, it should be considered any time a

Box 90.1

Neurological nystagmus types

See-saw nystagmus

Rostral midbrain lesions
Parasellar lesions (e.g. pituitary tumors)
Visual loss secondary to retinitis pigmentosa

Downbeat nystagmus

Lesions of the vestibulocerebellum and underlying medulla (e.g. Arnold–Chiari malformation, microvascular disease with vertebrobasilar insufficiency, multiple sclerosis, Wernicke encephalopathy, encephalitis, lithium intoxication)
Heat stroke
Approximately 50% have no identifiable cause

Upbeat nystagmus

Medullary lesions, including perihypoglossal nuclei, the adjacent medial vestibular nucleus, and the nucleus intercalatus (structures important in gaze holding)
Lesions of the anterior vermis of the cerebellum
Benign paroxysmal positional vertigo

Periodic alternating nystagmus

Arnold–Chiari malformation
Demyelinating disease
Spinocerebellar degeneration
Lesions of the vestibular nuclei
Head trauma
Encephalitis
Syphilis
Posterior fossa tumors
Binocular visual deprivation (e.g. ocular media opacities)

Pendular nystagmus

Demyelinating disease
Monocular or binocular visual deprivation
Oculopalatal myoclonus
Internuclear ophthalmoplegia
Brainstem or cerebellar dysfunction

Spasmus nutans

Usually occurs in otherwise healthy children
May be caused by chiasmal, suprachiasmal, or third ventricle gliomas

Torsional

Lateral medullary syndrome (Wallenberg syndrome)

Abducting nystagmus of internuclear ophthalmoplegia

Demyelinating disease
Brain stem stroke

Gaze-evoked

Drugs: anticonvulsants (e.g. phenobarbital, phenytoin, carbamazepine) at therapeutic dosages

patient's head turn is different from one examination to the next. This is more common in patients with oculocutaneous albinism.[51,52]

Periodic alternating nystagmus is usually congenital and benign. However, it may be associated with vestibulocerebellar lesions, neurodegenerative conditions such as Friedreich ataxia, or even visual loss. Neuroimaging is warranted in all cases unless the nystagmus has been stable for a prolonged period of time. Periodic alternating nystagmus may respond to treatment with low doses of baclofen in acquired forms of periodic alternating nystagmus.[53]

Gaze-evoked nystagmus

Gaze-evoked nystagmus is a jerk nystagmus that occurs in the direction of eccentric gaze. In contradistinction to infantile nystagmus, most forms of gaze-evoked nystagmus can be stabilized by visual fixation and are accentuated by darkness or image blur (see Fig. 90.11). Gaze-evoked nystagmus is called gaze-paretic nystagmus if it occurs in the direction of limited eye movement, as it may be associated with a cranial nerve palsy or myasthenia gravis. Gaze-paretic nystagmus may appear dissociated if the limitation of eye movement is asymmetric between the two eyes. One form of gaze-evoked nystagmus that is completely benign is endpoint nystagmus. This occurs in extreme positions of lateral or upward gaze. It can be distinguished from pathologic forms of gaze-evoked nystagmus by its low amplitude, symmetry on right and left gaze, poor sustainability, and absence of associated neurologic abnormalities. With endpoint nystagmus, the eyes attempt a saccade out to an extreme gaze position and have an initial difficulty finding this position. After a short amount of jerk nystagmus, the position is found, and the eyes maintain the eccentric gaze. Endpoint nystagmus is a normal finding and differs from gaze-evoked nystagmus by the fact that gaze-evoked nystagmus is a constant nystagmus with larger amplitude (defined as 4° or more) and is often asymmetric. Gaze-evoked nystagmus is caused by a deficiency, usually a structural lesion, in the neural integrator network. Gaze cannot be held at an extreme position, and the eyes drift back toward the null point of the integrator, which often is straight-ahead gaze. A corrective saccade is attempted to move the gaze back to the eccentric position, and the process repeats.

Disease in the posterior fossa or drugs, particularly anticonvulsants and sedatives, are the most common causes of pathologic gaze-evoked nystagmus. Disease of the cerebellum or vestibular system usually results in asymmetry of gaze-evoked nystagmus between directions of gaze. For example, tumors of the cerebellopontine angle may result in high-amplitude, low-frequency nystagmus (caused by cerebellar damage) when looking to the side of the lesion, and low-amplitude, high-frequency nystagmus (caused by vestibular imbalance) when looking to the contralateral side, a condition known as Brun nystagmus. Associated neurologic abnormalities such as ataxia, hearing loss, tremor, or hemiparesis should always be sought.

Vestibular nystagmus

Certain characteristics of vestibular nystagmus can localize the etiology to the peripheral or central neuronal pathways of the vestibular systems. Central vestibular nystagmus is frequently uniplanar in contrast to peripheral vestibular nystagmus, which is usually torsional or multiplanar. Visual fixation easily inhibits peripheral vestibular nystagmus, but not central vestibular nystagmus. Vertigo and tinnitus are common in peripheral vestibular nystagmus, and uncommon in central vestibular nystagmus.

Acquired pendular nystagmus

Acquired pendular nystagmus may be due to tumors, infarction, inflammation, or degeneration of the brainstem or cerebellum. The nystagmus may be horizontal, vertical, or

both. A single lesion in the brain will result in horizontal and vertical components that oscillate at the same frequency of 2–7 cycles per second. If the horizontal and vertical components are in phase, the nystagmus will appear oblique. If they are out of phase, it will appear circular or elliptical. Circular or elliptical nystagmus that is constantly changing character is due to horizontal and vertical components oscillating on different frequencies.

See-saw nystagmus

See-saw nystagmus is a pendular, upward incyclotorsion of one eye with a simultaneous downward excyclotoresion of the other eye. The pendular waveform see-saw nystagmus is commonly due to a midline mesodiencephalic, bilaterally compressing mass[54] (see Fig. 90.21). See-saw nystagmus can also be associated with traumatic or congenital chiasmal abnormalities,[54] and is mostly due to a unilateral lesion in the mesodiencephalic junction. Congenital see-saw nystagmus is a rare form of neonatal nystagmus with upward excyclotorsion of one eye and concomitant downward incyclotorsion of the other eye.

Downbeat nystagmus

Downbeat nystagmus is usually produced by lesions in the cerebellum that also damage pathways that control horizontal tracking and visual–vestibulo-ocular interactions.[53,55] The most frequent causes are infarction, cerebellar and spinocerebellar degeneration syndromes, and multiple sclerosis and developmental anomalies affecting the pons and cerebellum.[53,55] It is also commonly due to drugs (particularly lithium or sedatives) or lesions at the cervicomedullary junction.[53,55] In children, it is usually due to Arnold–Chiari malformation or syringomyelia. Without a drug history, downbeat nystagmus should be evaluated in all patients with a sagittal MRI scan of the brainstem and cervical spinal cord. All patients have jerk-down nystagmus in some positions of gaze and a few patients have jerk-down nystagmus only with convergence, in the dark, or with positioning of the head and body. Horizontal gaze increases the nystagmus. The nystagmus slow components usually have constant velocity or increasing-velocity waveforms. Associated patterns of abnormal horizontal eye movements are characteristic of damage to the midline structures of the cerebellum (impaired pursuit, impaired OKN, and inability to suppress VOR).

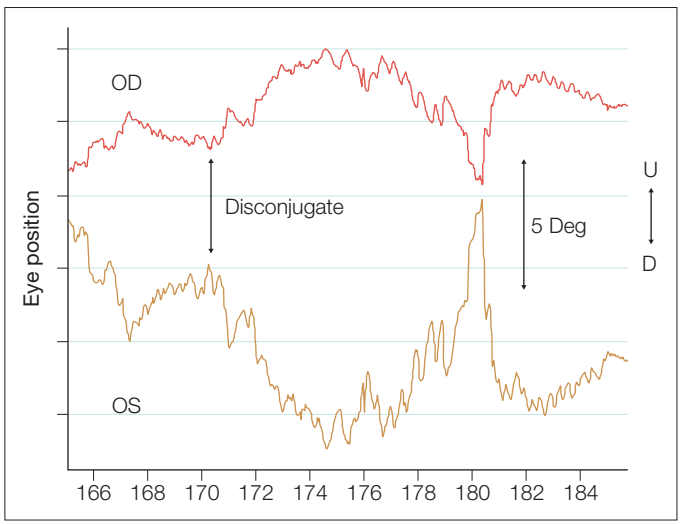

Fig. 90.21 Ocular motility recording of see-saw and pendular nystagmus. This is a 20 s vertical position trace of ocular motor recordings from a patient with see-saw and pendular nystagmus. On a background of a continuous, 2–4 Hz, pendular, small-amplitude, conjugate, ocular oscillation there is a slower, vertically out of phase, disconjugate oscillation representing the see-saw component. D, downward eye movements and downgaze; Deg, degrees; JL, jerk left nystagmus; OD, right eye; OS, left eye; U, upward eye movements and upgaze.

Upbeat nystagmus

Upbeat nystagmus with its fast upward movement usually increases on extreme upgaze and generally follows Alexander's Law. The oscillations may be enhanced by a head tilt, and with convergence the nystagmus can increase or change to downbeat nystagmus. Upbeat nystagmus is probably caused by midbrain dysfunction or cerebellar disease. It is very similar to downbeat nystagmus but is generally less common.

Treatment and prognosis

There are a number of signs and symptoms due to nystagmus that are amenable to treatment. The first and most obvious is decreased vision ("central visual acuity," "gaze-angle acuity", near acuity). Correction of significant refractive errors in children with nystagmus is the single most powerful therapeutic intervention for improving vision and visual function in these patients. Refractive etiologies of decreased "vision" include either one or a combination of conditions, e.g. myopia, hyperopia, astigmatism, and anisometropia. These refractive conditions can contribute significantly to already impaired vision in patients with other "organic" etiologies of decreased vision, e.g. amblyopia, optic nerve and/or retinal disease, oscillopsia, and the oscillation itself. The use of telescopes, magnification, and other low-vision aids are valuable refractive adjuncts that can be used situationally in nystagmus patients with and without associated sensory system deficits. The second is AHP. The etiology of the AHP includes a "gaze null" due to INS or acquired nystagmus (e.g. chin-down in downbeat nystagmus), an "adduction null" due to infantile nystagmus or latent/manifest latent nystagmus (manifest strabismus with the preferred eye fixing in adduction), convergence damping ("nystagmus blockage"), and a periodically changing head posture due to (a)periodic alternating nystagmus. The third is oscillopsia, which is usually due to either acquired nystagmus or a change in the sensory/motor status of the patient with infantile nystagmus (e.g. "decompensated" strabismus, a change in the gaze null angle, or decreasing acuity).[56] Other less common associated signs and symptoms include hypoaccommodation and photophobia (i.e. congenital cone dystrophy and albinism).

The prognosis of all these ocular oscillations depends on the type of underlying ocular and systemic disease. In general, infantile forms improve with time unless they are associated with a degenerative ocular or systemic disease. Acquired forms are more visually disturbing and follow the course of the underlying neurologic disease.

"I think my baby can't see!"

Ingele Casteels

Normally, a full-term baby shows visual fixation at birth or shortly afterward. Absent, poor, or delayed visual contact is a common reason parents bring their baby to their ophthalmologist. They are anxious to understand why the baby seems not to see, and want to know the cause and prognosis. Although this is not usually a medical emergency, parents need to have their baby diagnosed soon. In some babies, the underlying cause is evident on clinical examination; in others, additional investigation will be necessary. The diagnosis depends on a thorough birth, family, and clinical history and a systematic clinical examination (Fig. 91.1). The clinician should verify the cause and degree of visual impairment, give a prognosis, and make a plan of management and counseling for the family.

History

It is important to take a detailed history from the parents and caretakers. While talking to the parents, you can observe the infant's visual behavior. The history of the pregnancy, delivery, and postnatal development is important. Was the baby premature? Visual development depends on the postmenstrual age at birth. Premature infants with intraventricular hemorrhage are at risk of optic atrophy (see Chapter 56), hydrocephalus, and cerebral visual impairment (CVI) (see Chapters 59 and 60). Visual development in premature babies can also be delayed due to associated retinal or neurological problems. The presence of seizures, developmental delay, and dysmorphic features may suggest a brain problem. Maternal infections, trauma, hypoxia, and medication during pregnancy can have significant visual consequences. Babies exposed to opiates and benzodiazepines *in utero* may present with nystagmus and reduced visual acuity, due to insults to the central nervous system.[1]

It is important to find out whether there is a significant problem or whether the baby is just different from others. Some normal babies can just be less responsive. Has there been a change in visual behavior since birth? Vision can deteriorate after the onset of seizures or progressive neurological or ocular diseases.

A positive family history, or a history of consanguinity, makes certain diseases more likely. For instance, a baby whose parents are first cousins and who has searching eye movements and hypermetropia is liable to have a congenital retinal dystrophy (see Chapter 46). The pediatric ophthalmologist should inquire about other family members, examine them and the first-degree relatives. Specific questions to parents or caregivers regarding the visual behavior in dark or bright light can give an additional clue to the diagnosis: some congenital retinal disorders, especially achromatopsia, cone–rod dystrophy, and Leber congenital amaurosis, may present with photophobia or day blindness (see Chapter 46). Babies with CVI can show reluctance to look at a light, or, in contrast, will develop light-gazing (see Chapter 60).[2] Lens (see Chapter 37) and corneal opacities (see Chapters 34 and 35), i.e. congenital glaucoma (see Chapter 38), albinism (see Chapter 41), and aniridia (see Chapter 39), can cause photophobia.

Have the parents noticed wobbling eyes? Nystagmus and searching eye movements can be the presenting symptoms in many babies with poor vision from birth, but usually appear at 2–3 months of age. Roving or drifting eye movements are often seen in babies with very poor vision.

Are there any specific hand movements? Blind babies tend to press or poke their eyes (Fig. 91.2). Some visually impaired children rapidly flicker their fingers in front of their eyes while staring at lights[3] (Fig. 91.3).

Examination

It is often difficult to quantify visual acuity in babies, especially in those with poor visual contact. Parental estimations of vision and changes in vision can be helpful, but it is relevant to obtain a measure of overall visual function. Despite advances in research, behavioral observations remain of primary importance in assessing visual function in infancy. In a term baby, a visual following response should be present by 2 months, and the baby should smile responsively to a parent. At 4 months, a child should reach for an object. Complex stimuli with contrast should interest a happy and wakeful baby. The presence of optokinetic nystagmus (OKN) in a baby excludes a very severe visual problem. In congenital ocular motor apraxia (saccadic initiation failure), the eyes will deviate on being spun around without developing the fast "return" phase of nystagmus ("locking up" in sidegaze). In most cases, the vertical OKN is normal. A measure of vision can also be achieved with the dynamic vestibulo-ocular reflex (VOR) by evaluating the "after" nystagmus, which is much longer in a blind baby. In addition to the normal immaturity of pursuit and saccadic movements in the newborn, congenital ocular motor

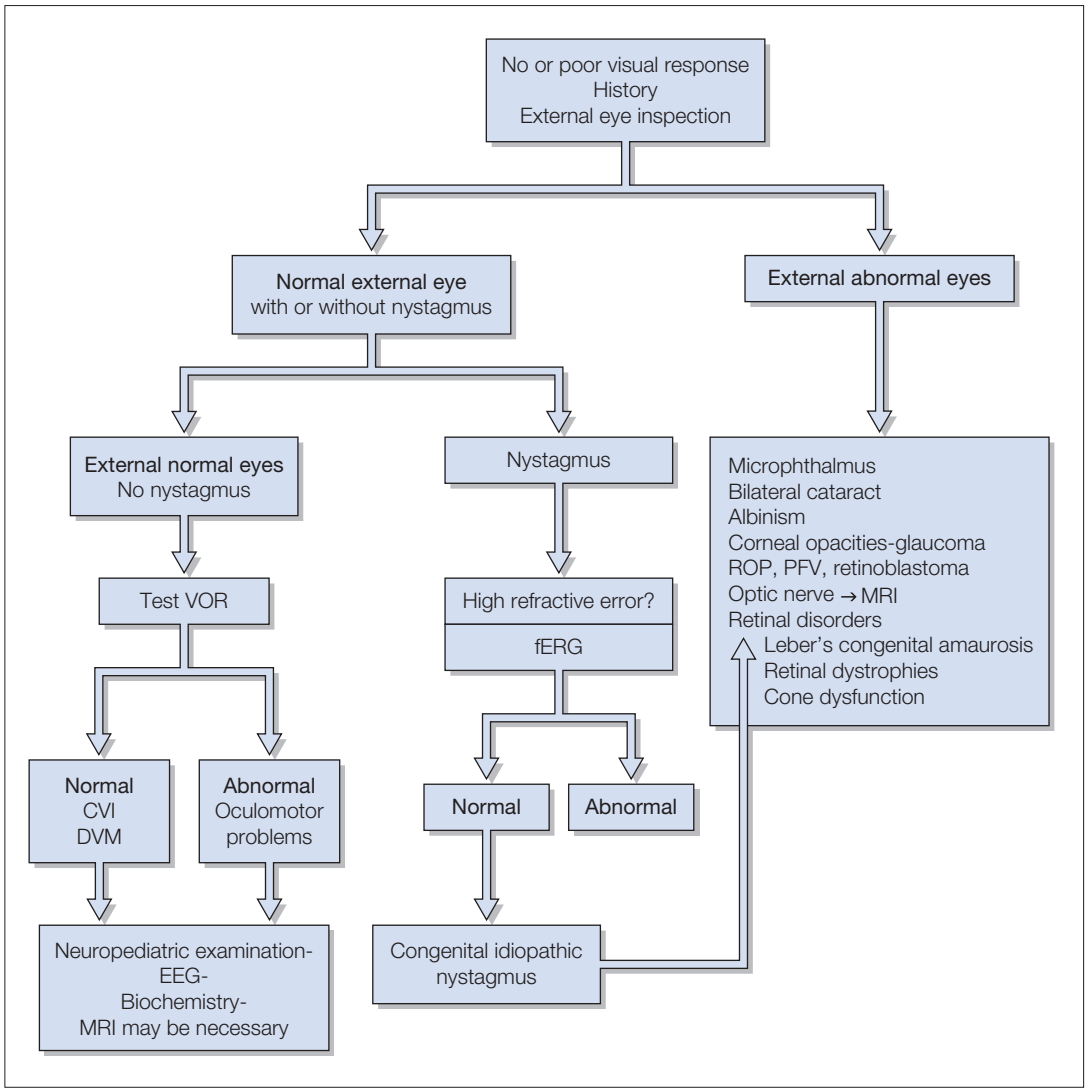

Fig. 91.1 Evaluation of an apparently blind infant. CVI, Cerebral visual impairment; DVM, delayed visual maturation; EEG, electroencephalogram; fERG, flash electroretinogram; MRI, magnetic resonance imaging; PFV, persistent fetal vasculature; ROP, retinopathy of prematurity; VOR, vestibulo-ocular reflex.

Fig. 91.2 Eye poking in a blind baby with Leber amaurosis.

Fig. 91.3 Babies with limited vision tend to wave their hands between their eyes and a light source.

Table 91.1 Common causes of poor vision in infants with apparently normal eyes on clinical examination

Diagnosis	Clinical signs apart from poor vision	Pupils	Slit-lamp	Ophthalmoscopy	Refraction	Flash ERG	Flash VEP	Pattern VEP	MRI	Neuropediatric examination/ EEG	Visual outcome
DVM	Poor visual contact	Normal	Normal	Normal	Normal	Normal	Normal	Normal	Normal	Normal	Normal
Cerebral visual impairment	Eccentric viewing/ light gazing	Normal	Normal	Usually normal	Normal	Normal	Usually abnormal	Usually abnormal	Usually abnormal	Usually abnormal	Usually poor perceptual defects
Idiopathic nystagmus syndrome	Nystagmus Head tilt	Normal	Normal	Normal	Normal/ abnormal	Normal	Normal	Abnormal	Normal	Normal	Good
Leber congenital amaurosis	Roving eyes Photophobia Eye poking	Paradoxical Sluggish or normal	Normal	Usually normal	High hypermetropia	Absent	Abnormal	Absent	Usually normal	Normal	Poor
Retinal dystrophy	Nystagmus Night blindness	Usually normal	Normal	Usually abnormal	Usually normal	Abnormal	Usually normal	Abnormal	Normal or abnormal	Normal or abnormal	Poor
Achromatopsia/ cone dystrophy	Photophobia Day blindness Color blindness Nystagmus	Paradoxical or normal	Normal	Normal	Normal or high hypermetropia Blue cone dystrophy, myopic	Absent cone response	Normal	Abnormal	Not indicated	Normal	Poor, photophobia Stationary
Bilateral optic nerve hypoplasia or atrophy	Poor vision Roving eye movements	Afferent defect	Normal	Abnormal, direct ophthalmoscopy necessary	Normal	Normal	Abnormal	Abnormal	Normal or abnormal	Normal or abnormal + endocrine exam	Variable
Albinism	Nystagmus Photophobia	Normal	Abnormal	Abnormal	Myopia or astigmatism	Normal or enhanced	Crossed asymmetry	Crossed asymmetry	Usually not indicated	Normal	Variable

DVM, Delayed visual maturation; EEG, electroencephalogram; ERG, electroretinogram; MRI, magnetic resonance imaging; VEP, visually evoked potential.

apraxia, Möbius syndrome, and bilateral Duane syndrome may be the cause of apparently poor visual contact because the baby cannot move the eyes. Rotation to induce VOR should exclude an eye movement defect.[4]

Examination of the eyes and eye movements may reveal nystagmus and strabismus. It is difficult to distinguish between nystagmus waveforms clinically. Eye movement recordings have shown some useful clinical information. A high-frequency, low-amplitude pendular nystagmus in otherwise normal eyes is often seen in cone dystrophies[5] (see Chapter 46). Searching eye movements with very poor vision are seen in Leber congenital amaurosis (see Chapter 46). Early-onset nystagmus can be divided into three groups: sensory defect nystagmus, in which there is a proven sensory defect; congenital idiopathic nystagmus (sometimes called motor nystagmus), in which no visual or neurological impairment can be found; and neurological nystagmus, which is associated with neurological disease.[6]

Pupil reactions can be useful and should be examined carefully (see Chapter 66). In most babies, the cause of poor vision from birth is obvious to a pediatric ophthalmologist after clinical examination. A structural abnormality (e.g. microphthalmos) may be obvious at first glance. The presence of the red reflex excludes media opacities. Slit-lamp examination may reveal anterior segment problems: cataracts (see Chapter 37), colobomas, aniridia (see Chapter 39), or albinism (see Chapter 41), and is particularly important in infants with nystagmus. In cases of albinism, iris transillumination is evident. Especially in ocular albinism, the diagnosis is less straightforward without a good look at the anterior segment. Slit-lamp examination should be repeated after dilatation of the pupils in order to better visualize lens opacities or lens subluxation.

Bilateral pupillary dilatation is necessary in order to perform indirect and direct funduscopy and retinoscopy. On funduscopy, attention is paid to both the vitreous and the retina. Vitreous haze and hemorrhages, seen in bleeding disorders, uveitis (see Chapter 40), retinal vasculitis, non-accidental injury (see Chapter 70), retinopathy of prematurity (see Chapter 44), retinal dysplasia (see Chapter 46), hyaloid abnormalities, and retinoblastoma (see Chapter 43), may be found. Indirect ophthalmoscopy will reveal retinal problems such as chorioretinal colobomas, macular toxoplasmosis (see Chapter 40), retinal detachment (see Chapter 52), retinal folds, chorioretinal dysplasia, and sometimes, retinal dystrophy. However, many cases of congenital retinal dystrophies will present with a normal-appearing retina on ophthalmoscopy.

Direct ophthalmoscopy and fundus photographs are best for subtle optic disc anomalies such as colobomas and optic disc hypoplasia or dysplasia (see Chapter 53). An examination under sedation or anesthesia may occasionally be necessary to see the optic nerve in detail.

Refraction is essential. High refractive errors – hypermetropia in particular – can give rise to poor visual contact from birth. Correction of moderate and high myopia in babies with apparent delayed visual maturation may improve poor visual behavior.[7] Refractive errors can provide a clue to the underlying diagnosis.

When the eyes of a baby with poor visual contact appear to be normal, with or without nystagmus, further investigation is necessary (Table 91.1). The flash electroretinogram (fERG) may diagnose retinal diseases. The fERG and flash visually evoked potential (VEP) have conspicuous immature features during the early months and may not aid in establishing the diagnosis. The fERG may be more useful at a later age.[8,9]

A pediatric neurological consultation and further investigations, such as biochemistry and brain magnetic resonance imaging (MRI), are carried out where indicated. Babies affected with CVI usually have a normal eye examination, no nystagmus or strabismus; some have associated optic nerve atrophy (see Chapter 60).

An electroencephalogram (EEG) should also be included in the initial investigation of every infant with apparent delayed visual maturation (DVM) in order to detect a treatable underlying seizure activity.[10] "Delayed visual maturation" is a term used to describe a normal baby with a transient visual deficit (see Chapter 4). There are no data to establish that any primary visual system is delayed in its development (see Chapter 3). DVM is a retrospective diagnosis, which can only be made after a long enough follow-up to exclude neurological problems. DVM is not a single diagnostic condition but rather a sign common to neurological abnormalities affecting several areas of the brain (see Chapter 3). The visual prognosis of infants with isolated delayed visual maturation is good, but there is an increased risk of neurodevelopmental and educational problems in the future.[4]

An incorrect or unclear diagnosis of visual impairment in an infant can be devastating to the family. In most infants presenting with poor visual contact, clinical signs are diagnostic, but additional studies may be necessary to establish the correct diagnosis. A long enough follow-up by the ophthalmologist in collaboration with the pediatrician should be planned and it is essential to be encouraging whenever you can, but not to be dogmatic about either the diagnosis or the prognosis, as both can change!

"My baby's got a red eye, Doctor!"

Giovanni Castano

Introduction

The classical clinical description of conjunctival injection differentiates clearly deep and superficial congestion. Dilation of the superficial posterior conjunctival vessels is more intense at the fornix; the vessels branch irregularly, appearing bright red. This type of congestion indicates a purely conjunctival problem. Pericorneal or deep injection is more intense at the limbus, where the ciliary vessels radiate in a regular pattern and are violet or rose colored. Deep congestion is present when a pathological process involves the eyeball itself, particularly when anterior segment structures are affected. Both may co-exist but the ophthalmologist must determine which is more prominent to make the correct diagnosis.[1]

Babies with a red eye must have a complete ocular examination. Although ideally slit-lamp biomicroscopy should be a part of this evaluation, assessment with simple magnification may be all that is possible and is often sufficient to make a diagnosis. Red-free illumination is very useful to differentiate the type of conjunctival congestion; fluorescein staining helps to reveal conjunctival and corneal epithelial defects or foreign bodies.[2]

In some instances, a red eye might be considered "normal" in an infant. Transient subconjunctival hemorrhages are not rare in newborns, especially after vaginal delivery.[3] During the first hours of life, the conjunctival vessels have also been described as prominent.[4] Crying (a frequent feature when visiting the ophthalmology clinic) is a Valsalva maneuver and thus may induce ocular congestion.[5] This phenomenon is extremely variable during the exam, an important difference from the constant abnormal injection.[6] As a rule, however, a red eye in an infant must be considered a pathological sign. Certain clinical "red eye" situations in infancy may prompt a search for distinct diagnoses.

Superficial conjunctival congestion with discharge

Conjunctivitis is the most common cause of red eye in infancy.[7] The presence of superficial congestion and purulent discharge suggests a diagnosis of bacterial conjunctivitis. Conjunctivitis of the newborn, once a typical gonococcal infection, is now more frequently caused by *Staphylococcus aureus* than by *Chlamydia trachomatis*. Nevertheless, in endemic areas, chlamydial and gonococcal etiologies are of concern.[8]

Fornix conjunctival injection with a watery discharge is a sign of viral conjunctivitis. Neonates with this clinical picture could have Herpes simplex-2 conjunctivitis acquired through the birth canal. In an older infant with bilateral conjunctival congestion and watery discharge, follicular adenoviral conjunctivitis is a probable diagnosis, especially if there is clear history of close contact with another infected person.[9]

Superficial conjunctival congestion with itching

Although allergic conjunctivitis is rare in infancy, babies living in highly polluted areas may develop this.[10,11] When there is no corneal involvement, bilateral superficial congestion and itching become diagnostic features.[12]

Pericorneal or deep injection

Pericorneal injection must be recognized because it is associated with serious ocular diseases. Limbal congestion may be present in a 360° distribution pattern. This finding means a diffuse or serious involvement of any structure of the anterior segment, and its cause must be identified in all patients.[13]

Limbal congestion with photophobia and tearing

Keratitis of any etiology can cause these symptoms. Children with infectious keratitis are at risk of developing visual loss from structural damage or amblyopia. Although keratitis may be present at birth as a result of intrauterine infection, it is usually acquired. Trauma, contact lens wear, previous corneal surgery, exposure, immunodeficiency, and prolonged steroid treatment are the most frequent predisposing factors.[14,15] Although frequent in childhood, herpetic keratitis is rare in infants.[16,17]

Corneal abrasions or ulcers may occur in aphakic contact lenses wearers, and may resolve with conservative treatment.[18] Diffuse punctate keratitis is the hallmark of congenital corneal anesthesia and hypoesthesia. A similar picture is seen in patients with congenital alacrimia. Intense lubrication and every other barrier or surgical method are necessary to avoid corneal perforation and blindness.[19–21]

Localized punctate epithelial defects or ulcers are common in exposure keratitis. The most important clinical clue is a localized pericorneal injection. Preterm babies in the neonatal intensive care unit or sedated infants in intensive care unit are at risk of developing lagophthalmos with inferior corneal exposure.[22] Exposure keratitis also occurs in patients with eyelid defects such as congenital ectropion and coloboma.[23,24] Congenital entropion, distichiasis and isolated trichiasis can also induce keratitis.[25,26] Facial nerve paralysis in patients with Möbius syndrome does not usually cause exposure keratitis because Bell's phenomenon usually protects the corneas, except in some cases with limited elevation or defective corneal sensation where corneal integrity is severely threatened.[27,28] Isolated facial nerve palsy in the newborn has been related to birth trauma. Although complete recovery is common, attention must be paid to the ocular surface to prevent exposure and complications.[29] Forceps-induced injuries may include Descemet's membrane rupture.[30] Retrobulbar masses and infections, or shallow orbits in patients with craniosynostosis, can induce exposure keratitis or even globe luxation.[31,32]

Corneal dystrophies and deposits affecting the epithelium can cause a red eye, photophobia, and tearing in infancy. This can be seen in tyrosinemia II and Reis–Bücklers dystrophy.[33,34]

Primary congenital glaucoma presents in infancy with corneal opacification, buphthalmos, tearing, photophobia, and perilimbal injection.[35] Babies with secondary glaucoma can have a similar clinical picture. Pathophysiological mechanisms include uveitic or lens-induced pupil block, and anterior displacement of the iris–lens diaphragm, as seen in stage 5 retinopathy of prematurity and growing intraocular tumors. Anterior chamber deposits with cellular accumulations (pseudo-hypopyon) may be seen in babies with retinoblastoma and leukemia.[36–38] Any orbital tumor can induce vascular engorgement or exposure of the globe, causing a red eye. Conjunctival congestion may persist after treatment and, in these cases, therapy-associated keratitis could be a common cause.[39–41]

Accidental and non-accidental injuries are not rare in infants. A common cause of corneal ulcer or abrasion is accidental self or "sibling-inflicted" trauma. Pericorneal congestion is usually localized and its location indicates the exact place where the cornea is affected. Subconjunctival hemorrhages are also frequent is these cases. A unilateral, watery red eye in an irritable baby is the classical clinical picture. Corneal foreign bodies may have a similar presentation.[42] As in every non-accidental trauma, inconsistent history of mechanism of injury and particular social and demographic risk factors require investigation for possible child abuse.[43] Chemical and toxic keratitis have been described as part of non-accidental injuries.[44,45] Iatrogenic instillation of formaldehyde instead of prophylactic antibiotic just after delivery has been described to cause cloudy cornea and deep congestion, which cleared up after a few months.[46]

The painless red eye

Conjunctival nevi and limbal dermoids can be vascularized, causing a red eye.[47] Conjunctival hemangiomas may occur, characteristically enlarging some weeks after birth.[48] Dilated episcleral vessels may be a feature of Sturge–Weber syndrome. These patients may also develop glaucoma with additional ciliary injection.[49] Conjunctival angiomas and telangiectases are found in many patients with other vascular phacomatoses.

Hyphema could be present in ocular trauma of any origin, but spontaneous bleeding is seen in patients with juvenile xanthogranuloma. Identifying the typical skin lesions that are sometimes present in this disorder could avoid an erroneous diagnosis of child abuse.[50]

Unexpected causes of a red eye in infants

Neonatal chemical conjunctivitis associated with prophylactic silver nitrate eye drops is now rare, but current prophylactic drugs, including povidone-iodine, could also induce a transient red eye.[51,52] Topical latanoprost causes conjunctival hyperemia in infants with glaucoma and, sometimes, atropine causes a red eye.[53,54]

Scleritis and episcleritis are rare in infants. When present, a localized area of vascular congestion is the key for the right diagnosis. B-scan ultrasound is a helpful confirmatory test.[55–57]

Bacterial endophthalmitis is also uncommon in infancy. Open-globe trauma and glaucoma surgery are the most frequent causes in children. Endogenous origin is the least common cause. The severity of the clinical picture, including the ocular congestion, correlates with the virulence of the infecting microorganism.[58]

Uveitis causes circumcorneal injection. Although intraocular inflammation is seldom seen in infants, its presence often indicates a serious underlying problem. It is a challenge to detect anterior chamber cells and flare in a baby, but biomicroscopic examination is essential in infants with unexplained perilimbal congestion. Deep injection could be minimal, and its intensity is usually proportional to the severity of uveitis.[59] Besides traumatic etiology (accidental, non-accidental, or surgical), uveitis in an infant could be part of Kawasaki disease (acute systemic vasculitis plus coronary findings), ocular intrauterine infection, atypical intraocular tumor, and other unusual etiologies.[60–69] Although Blau syndrome (dominantly inherited, granulomatous dermatitis, symmetric arthritis, and recurrent uveitis) can start in the neonatal period, uveitis is usually seen later in childhood.[70] Outbreaks of acute enterovirus uveitis have been reported in infants.[71] Although reported only in adults, uveitis after intravitreal injection of bevacizumab will become an important issue in preterm babies, as more patients with retinopathy of prematurity are treated with anti-vascular endothelial growth factor (anti-VEGF) molecules.[72,73]

In severe vitamin A deficiency, conjunctival congestion is present due to dry eye, corneal vascularization, and Bitot's spots. Early administration of high doses of vitamin A may restore the ocular surface, and retinal function, preserving the patient's vision.[74]

Acute Horner syndrome usually causes transient conjunctival congestion in the ipsilateral eye.[75] Similarly, carotid artery aneurysm also causes transient ipsilateral conjunctival injection by impeding cavernous sinus venous return.

"My child keeps blinking and closing his eye"

Kimberley Tan

Introduction

This common problem in pediatric ophthalmology practice has several possible causes. The diagnosis is usually apparent after a careful history and examination. Parents are often anxious that these overt, potentially stigmatizing movements could be a sign of more sinister neurological or complex behavioral disorders. The vast majority of children have ocular surface irritation, usually allergic eye disease, or a simple, isolated tic.

Etiology

The causes of a child presenting with blinking/closing an eye include:

1. tic;
   a. transient tic disorder (provisional tic disorder);
   b. chronic tic disorder;
   c. Tourette syndrome;
   d. functional blinking;
2. excessive blinking in response to ocular irritation;
3. closing one eye in intermittent exotropia;
4. "squinting" to see (pinhole effect);
5. rarer causes (Table 93.1).

The pediatric ophthalmologist will usually see either of the first two conditions, often a combination of the two. Eyelid tics may be isolated, or part of more generalized tic disorder. It should be emphasized that they are a common finding in normal children.

In a prospective, consecutive case series of 99 children presenting with excess blinking, Coats et al.[1] found an underlying etiology that would be discovered by a standard comprehensive ophthalmological examination in 62%. Anterior segment and/or lid abnormalities were the underlying cause in 37% of children, uncorrected refractive errors in 14%, and intermittent exotropia accounted for 11%. Tic disorder was divided into "habit tic" and "psychogenic blepharospasm" by the presence of an identified stressful event, and accounted for 23% and 10% respectively. Vrabec et al.[2] found a temporally related stressful event, which coincided with the onset of the blinking, in 41% of children they classified as "functional blinking." Other authors have shown a much higher proportion of tic disorder in children presenting with frequent eye blinking. Jung and coworkers[3] prospectively examined a series of 50 children with frequent eye blinking, excluding children with refractive error, intermittent exotropia, or lid disorders. Eighty-six percent were diagnosed with a tic disorder, with 78% being transient tic disorder. Seven out of the 50 children had ocular surface disease, mostly allergic conjunctivitis. In contrast to Coats et al.,[1] Jung[3] found that treatment of the surface disorder did not resolve the frequent eye blinking.

As a first step in making a diagnosis, exclude any serious ocular cause of irritation that could be the primary cause of the blinking behavior. Ocular irritation may also be the trigger to precipitate a bout of blinking from an alternative etiology, such as a tic. The comprehensive ophthalmological examination will exclude any significant ocular allergy, glaucoma, or keratitis, as well as eliminating intermittent exotropia as a reasonably common cause of monocular closure. Coats et al.[1] found vision-threatening ocular disorders in six of 99 children with excessive blinking. These included trichiasis, foreign bodies, and keratitis. These conditions should be obvious if a comprehensive ocular examination is performed. Here, blinking is simply a reaction to the ocular irritation. The overlap between ocular allergy and tic disorders, frequently seen in the same age group, is more subtle. The ocular allergy may be a primary cause of blinking, or a part contributor to episodic exacerbations of the blinking tic. A trial of a preservative-free mast cell stabilizer, such as topical ketotifen or olopatadine may be helpful.

Investigations for serious neurological disease

Coats and colleagues[1] found that four of their 99 children had life-threatening neurological disease. However, the existence of the life-threatening condition was known before the presentation of excess blinking, thus the blinking disorder did not prompt re-investigation.

The similarities between excess blinking and the predominantly adult disorders of blepharospasm, and other focal dystonias seen in basal ganglia disease,[4,5] suggest that neurological disease needs to be considered and excluded. A careful history is important to ensure there are no symptoms of more significant neurological disease, as these conditions will almost always have associated symptoms and signs (see Table 93.1). Ask about altered consciousness, other

Table 93.1 Less common differential diagnoses of simple eyelid blinking tic, with differentiating features and pathological concern

Differential diagnosis of simple tic	Historical clue	Differentiating examination sign(s) and concern
Seizures	Altered consciousness	Abnormal eye movement, lids, gaze and facial signs, field deficits, visual hallucinations[16]
PANDAS	Explosive onset	Concurrent streptococcal infection, choreiform movements[13]
Lid nystagmus		Rapid, jerky upper lid movements. Other ocular motility signs. Needs imaging: dorsal midbrain, cerebellar disease[17]
Myokymia		Fine, undulating, rippling superficial muscle contractions. If persistent, brainstem glioma needs exclusion[2]
Myoclonus		Prolonged orbicularis contraction. Cannot be suppressed. Occurs on eye closure. Investigate for epilepsy. Jeavon syndrome: eyelid myoclonia with absence spells[18]
Blepharospasm	Usually adult	Forceful, sustained contracture of orbicularis oculi. Neurometabolic work-up and imaging necessary. Exclude Wilson, Huntington[4]
Hemifacial spasm	Usually adult	Contracture entire half of facial nerve musculature. Neuroimaging of posterior fossa required for vascular anomaly or tumor[19]
Huntington disease, basal ganglia disease	Usually adult	Systemic basal ganglia signs: rigidity, myoclonus, bradykinesia[5,6]
Oculogyric crisis/ocular flutter/opsoclonus		Usually repetitive eye movements, not just lid disorder. Seizures, toxicity, cerebellitis, neuroblastoma[8]
Ocular motor apraxia		Blink is used to break fixation in saccadic initiation failure. Due to a wide variety of intracranial pathology and neurodegenerative etiologies[20]
Schwartz–Jampel syndrome		Short stature, blepharophimosis, spinal anomalies, general myotonia[21]
Phenothiazines, antiseizure drugs, stimulants, cocaine, heroin, carbon monoxide, mercury	History of drug use or toxin exposure[6]	

PANDAS, Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection.

abnormal movements, or more generalized tics. Inquire about development, milestones, and other events that may represent muscle weakness or seizures. If a careful history and comprehensive ophthalmological examination reveal no other concerns, then further investigation, including neuroimaging, is unnecessary.[1,6,7]

Table 93.1 lists the less common differential diagnoses of simple eyelid blinking tic, along with differentiating features in the history and clinical examination. The clinical findings guide the need to investigate for any possible sinister etiology.

Tic disorders

Given the prevalence of tic disorders, a basic understanding of their nature is helpful. Tics are involuntary, sudden, repetitive, purposeless, stereotyped intermittent movements or sounds.[6,8] They are fragments of normal movements or sounds that are inappropriate for the situation or context. The patient can voluntarily inhibit them, but the tic itself is not truly voluntary. The tics are suppressible but irresistible, and therefore still fundamentally involuntary. Tics have a key relationship to voluntary movements in the same body area: for example, eye-blinking tics will abate during visual tracking.[7] In contrast, dystonia, myoclonus, and simple partial seizures override voluntary movement, and psychogenic tics are often worse with voluntary movement in that same body area.[7]

Tics are common in children. A meta-analysis published in 2012 found a prevalence of 2.99% for transient tic disorder (TTD), 1.61% for chronic tic disorder (CTD), and 0.77% for Tourette syndrome (TS).[9] All are more common in boys. The primary differences between the three disorders are defined by the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR).[6] In TTD, the tics wax and wane but are not present for longer than 12 consecutive months. In CTD, the tics are present for longer than 1 year, with no tic-free period of more than 3 consecutive months. TS is similar to CTD but with multiple motor and one or more vocal tics.[6]

The onset of tics is usually between the ages of 3 and 8 years,[9] and for chronic disorders, the tics are usually at their greatest intensity between the ages of 10 and 12 years. For most children, the tic severity and related impairment improve through late adolescence and early adulthood.[10,11] The tics usually occur in bouts or clusters, aggravated by stress, tiredness, or boredom. They are often more prominent watching television[6] and thus bother the parent or carer seemingly more than the child.

Tic severity is rated by tic intensity (forceful or loud), tic complexity (longer bouts or orchestrated patterns), as well as tic interference (impeding intended actions). The combination of the three is used to grade the likely overall impact of the tic disorder on the patient.[10] However, the majority of children (between 50% and 90%) with chronic tic disorders have a co-occurring condition, and the comorbidity is often the primary source of functional impairment and disability.[6] The commonest co-occurring condition seen with CTD is attention-deficit hyperactivity disorder (ADHD), followed by social phobia, generalized anxiety disorder, and obsessive compulsive disorder.[10] These disorders contribute to poorer global psychosocial functioning. The pediatric

ophthalmologist needs to be aware of their likely existence to facilitate appropriate referral.

Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS)

A group of children present with tics and obsessive–compulsive symptoms after streptococcal infection. There is still some debate about the existence of this subgroup as a recognized separate classification.[12] However, in children where the tic onset is abrupt, even "explosive, overnight," PANDAS should be considered. Further, these children usually present within 7–14 days of the streptococcal infection, and the subsequent course is episodic, relapsing–remitting rather than the usual waxing and waning of common CTD.[13] Throat cultures and anti-streptococcal titers should be obtained where appropriate, and consideration given for treatment if acute streptococcal infection is demonstrated.

Management of eyelid blinking tics

The clinician should keep in mind that tics may be suggestible, so discussion of the problem may result in re-emergence of a specific tic.[6] Standard neurologic exam is important but is "inevitably normal." With no other symptoms or signs, neuroimaging is unnecessary.[6]

Transient tics or mild CTD need child and parental reassurance and information. An explanation of the involuntary, but suppressible, nature of tics is important. The clinician should try to establish if there are any comorbidities, and refer appropriately. If isolated, the diagnosis of "transient" tic disorder is nicely optimistic for the clinician and the parents. However, recognition of the possibility of chronicity should be mentioned. In a series of 43 children from a pediatric neuro-ophthalmic practice,[8] 44% of the children who presented with eye "rolling/blinking and widening" tics had become chronic, but the vast majority of these had noted an improvement in the severity of their tics. Only one patient (3%) had been formally diagnosed with Tourette syndrome.[8] Parents can be reassured that most children with CTD or TS still show improvement in their tic severity through adolescence and into early adulthood.[10,11]

If the tics do not settle, successful treatments exist. *Habit-reversal training* is a proven behavioral treatment used by pediatric psychologists to decrease tic severity, and should be considered as first-line therapy.[14] This behavioral treatment has been shown to reduce tic severity and improve global functioning.[15] If it is unsuccessful or adjunctive therapy is required, various medications have been used to treat the comorbid disorder, such as ADHD, as well the tics themselves. These include alpha-2-adrenergic agonists like clonidine.[6] Dopamine antagonists such as haloperidol are very effective for tics but may have significant side effects.[7]

"My child seems to hate the bright light"

Luis H Ospina

See online for supporting video for this chapter.

Introduction

Light intolerance in a child may be isolated or, more frequently, may present in combination with other symptoms prompting consultation. In most cases, the child is likely to have a benign condition, or simply have lower tolerance to light, as "thresholds" vary among normal individuals.[1] The causes of photophobia are, nonetheless, heterogenous and include ocular or neurologic conditions, some potentially serious (Table 94.1).

An organized approach should facilitate the diagnosis of the etiology of photophobia.

Clinical approach

Clinical history

Given that ocular causes of photophobia outnumber neurological causes in a pediatric ophthalmology practice, a good strategy is to start with a targeted history by focusing on the symptoms and signs that accompany the ocular pathologies. A neurological history can then be taken subsequently, if appropriate. The patient's age, the laterality, duration, and nature of the symptoms should be noted (Table 94.2).

Physical exam

Given the nature of the problem, the examination can be challenging. The targeted history should guide your targeted exam. While talking to the parents, observe the child carefully: eyelid and conjunctival redness or swelling, blinking, watering and rubbing may suggest ocular surface disease. Nystagmus may indicate retinal pathology, or a small pupil in a red eye may indicate uveitis. Assessing visual acuity and pupillary responses is essential: a paradoxical pupillary response can indicate retinal dystrophies, especially in the presence of poor vision and nystagmus. Slit-lamp examination will confirm anterior segment causes of photophobia. Topical anesthetic drops and fluorescein help to diagnose a surface problem. Significant ametropia on cycloplegic refraction can accompany retinal disease, such as hypermetropia seen in achromatopsia or myopia in blue cone monochromatism. A hand-held refractometer may facilitate the exam of a photophobic child. A dilated fundus evaluation is important.

Ancillary testing

Testing color vision and visual fields is appropriate when compressive optic pathway lesions are suspected. Decreased color vision can also indicate retinal dystrophy.

Electroretinography and neuroimaging can be necessary to evaluate retinal and neurological disease respectively, and should be ordered on a case-by-case basis. Optical coherence tomography may be useful, e.g. determining foveal hypoplasia in achromatopsia.

Ocular causes

Corneal and ocular surface disorders

Given that the surface of the eye is richly innervated, the sensation of light intolerance is closely linked to that of pain.[2] Consequently, the pathologies that irritate the eye surface constitute the commonest ocular cause of photophobia: traumatic abrasions, foreign bodies, herpetic and other infectious keratitis, blepharokeratoconjunctivitis, allergic keratoconjunctivitis, etc. Establishing the diagnosis is relatively easy, based on the clinical presentation and slit-lamp findings. Dry eye, a common cause of adult photophobia,[2] is less prevalent but certainly under-recognized in children. It occurs in multiple syndromic and systemic diseases, after bone marrow transplantation, and even in common disorders like allergic conjunctivitis.[3]

The crystalline infiltration of the cornea in cystinosis causes significant photophobia that starts early (3–4 years) and will be present in varying degrees in most patients by the age of 10 years, especially if surface breakdown occurs.[4,5] Similarly, the accumulation of glycosaminoglycans in mucopolysaccharidosis can also lead to light sensitivity.

The corneal dystrophies can cause light aversion. Congenital hereditary endothelial dystrophy (CHED), sometimes seen soon after birth, presents with epiphora, corneal clouding, and photophobia. Later in childhood, Meesmann and Reis–Buckler corneal dystrophies (MECD and RBCD) can present with pain, hyperemia, and photophobia, notably with corneal epithelial erosions on waking that are common to these pathologies.[6]

Table 94.1 Important causes of photophobia in each age group

Infants	Infantile glaucoma Inherited corneal dystrophies, especially congenital hereditary endothelial dystrophy (CHED) Keratitis Descemet's break due to forceps delivery Cerebral visual impairment (CVI) Stationary cone dysfunction syndromes, e.g. achromatopsia and blue cone monochromatism
Young children	Glaucoma Corneal abrasions and foreign bodies Blepharokeratoconjunctivitis Vernal keratoconjunctivitis Herpes simplex or bacterial keratitis Meesmann and Reis–Buckler corneal dystrophies (MECD and RBCD) Cataract Albinism Aniridia Stationary cone dysfunction syndromes, e.g. oligochrome trichromacy and bradyopsia CVI Acquired central nervous system (CNS) pathology
School-age children	Progressive cone dystrophies Partial aniridia Cataract or ectopia lentis Intermittent exotropia Migraine Acquired CNS pathology

Modified from Funnell CL. My child seems to hate the bright light. In: Hoyt C, Taylor D, editors. Pediatric Ophthalmology and Strabismus, 4th ed. Edinburgh: Elsevier/Saunders, 2012: 968–70.

Table 94.2 Considerations in photophobia

Severity?	If severe photophobia, consider infantile glaucoma, corneal surface disease, achromatopsia, oculocutaneous albinism, or aniridia Migraine, and less often other central nervous system (CNS) pathologies can cause significant photophobia
Recent onset or present since very young?	Acquired corneal pathology is common in children Longstanding problem more likely to be due to an inherited corneal or retinal disease New-onset photophobia with a normal ocular examination may be due to migraine, or less often, to other acquired CNS pathologies
Reduced vision?	Most corneal and retinal pathologies causing photophobia also reduce visual acuity Cerebral visual impairment (CVI)
Nystagmus?	Common in retinal dystrophies, albinism, aniridia Absent or rare in CVI
One or both eyes?	Acquired corneal and ocular surface disease is often asymmetric Unilateral photophobia can occur in unilateral anterior uveitis, unilateral iris or lens defects, and trigeminal autonomic cephalalgias
Constant or intermittent?	Consider migraine or fluctuating corneal pathology (e.g. recurrent erosion in MECD and RBCD)
Associated redness of eyes?	Suggests corneal and eye surface pathology Anterior uveitis Unilateral redness can occur in trigeminal autonomic cephalalgias
Squint?	Intermittent exotropia
Family history or history of consanguinity?	MECD and RBCD, aniridia, and many congenital cataracts are dominantly inherited Cystinosis, and achromatopsia are recessive Albinism has multiple modes of inheritance CHED can be autosomal dominant or recessive
Medical history in CVI?	History of hypoxic–ischemic brain injury with or without prematurity, CNS infections, hydrocephalus, trauma (e.g. shaken baby), infantile spasms, brain malformation, metabolic disease. Seek other neurobehavioral signs: light-gazing, variable visual performance, head shaking, etc.

CHED, Congenital hereditary endothelial dystrophy; MECD, Meesmann epithelial corneal dystrophy; Reis–Buckler corneal dystrophy.
Modified from Funnell CL. My child seems to hate the bright light. In: Hoyt C, Taylor D, editors. Pediatric Ophthalmology and Strabismus, 4th ed. Edinburgh: Elsevier/Saunders, 2012: 968–70.

Descemet's breaks due to use of forceps or glaucoma can induce photophobia.

Infantile glaucoma

The triad of excessive tearing, blepharospasm, and photophobia in an infant or young child must prompt consideration of glaucoma, especially in the context of an enlarged cornea.

Lens abnormalitites

Light scattering through a partially opacified lens, or ectopia lentis, can induce photophobia.

Uveal abnormalities

Iris defects (colobomas, aniridia, dilated pupil, iris transillumination in albinism) can cause overstimulation of photoreceptors. Concomitant cataracts or corneal epithelial defects contribute to photophobia in aniridic patients. In albinism, the lack of retinal pigmentation further contributes to the photophobia.

Photophobia is a well known symptom of anterior uveitis.

Retinal dystrophies

Photophobia is common in the stationary cone dysfunction syndromes and progressive cone and cone–rod dystrophies. It starts in early infancy in achromatopsia and blue cone monochromatism, and early childhood in oligochrome trichromacy and bradyopsia[7,8] (see Chapter 46). The progressive cone dystrophies tend to become symptomatic in later childhood or early adulthood, and light aversion is often a prominent early symptom that can precede visual deterioration.[8] Features that should raise suspicion of retinal disease include decreased vision, hemeralopia (the inability to see clearly in bright light), nystagmus, significant ametropia, and paradoxical pupillary responses. When any of these diseases are suspected, electroretinography is necessary.

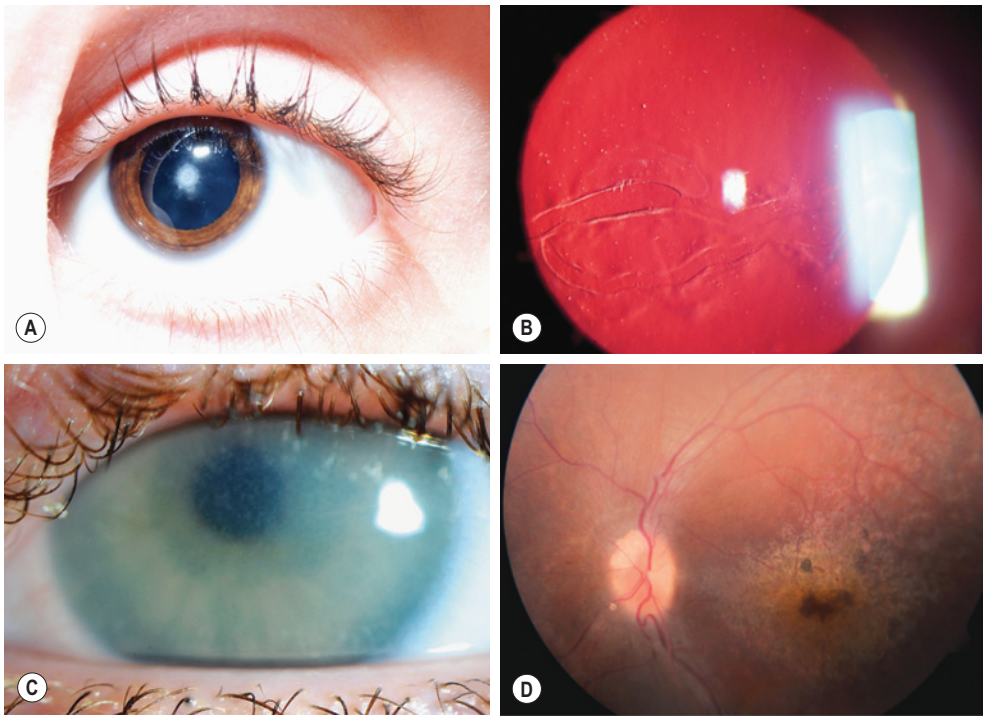

Fig. 94.1 Photophobia of ocular origin. (A) Anterior polar cataract causing glare to a 9-year-old boy who sees 20/50. (B) Five-year-old boy with Haab striae. His glaucoma is well controlled but he is photophobic from light scattering through Descemet tears. (C) Corneal clouding in a photophobic 12-year-old girl with muchopolysaccharidosis type 6. (D) Sixteen-year-old boy with progressive cone–rod dystrophy linked to Alström syndrome, known to cause photophobia starting early in life. *([A] and [B] courtesy of Dr Patrick Hamel.)*

Strabismus

Patients with intermittent exotropia often close one eye when outdoors in bright light (Fig. 94.1).

Neurologic causes

The most common neurological cause of light aversion is migraine, a frequent disorder in children and adolescents (prevalence estimated at 9.2%).[9] Photophobia is one of the major criteria used to diagnose migraine without aura,[10] the most frequent variant affecting children. Younger children may not verbalize photophobia, but it can be inferred from their preference to seek comfort in a dark room. Light exposure can trigger or exacerbate migraine attacks. The presence of symptoms such as irritability, nausea, or phonophobia can substantiate this diagnosis. Cluster headache, hemicrania continua, and other *trigeminal autonomic cephalagias* are especially rare in children. Unilateral photophobia associated with ipsilateral autonomic symptoms (i.e. eyelid edema, nasal congestion, conjunctival hyperemia, etc.) and ipsilateral retro-ocular pain are commonly associated with these diagnoses.[11]

One-third of children with *cerebral visual impairment* (CVI) are photophobic, irrespective of the cause. This is counterintuitive in view of their well-known habit of light-gazing.[12] Their photophobia decreases over time. A history of poor vision along with neurological insults such as hypoxic-ischemic brain injury, prematurity, encephalitis, brain malformation, or hydrocephalus is often present.[13]

Children with *meningitis* and *subarachnoid hemorrhage* will rarely present first to the ophthalmologist. Photophobia accompanies the traditional symptoms and signs in both pathologies. Headache and light sensitivity are common complaints following *traumatic brain injuries*.[2]

Compressive lesions seldom present with photophobia. The triad of ipsilateral photophobia, tearing, and torticollis has been described in children with *posterior fossa astrocytomas*.[14,15] *Chiasmal lesions* have been described in adults with isolated photophobia,[16] and should be considered in children.

Blepharospasm may be associated with photophobia, but this is exceptional in childhood.

Role and mechanisms of photophobia

Photophobia is thought to have a protective role by reducing the intensity of migraine headaches and pain from eye diseases.[17] It may also protect the central retina, since subjects exposed to central photic stimulation are more photophobic than those exposed to eccentric stimulation.[18] Furthermore, shorter wavelength light, which is potentially more damaging, induces more photophobia.[18]

The elucidation of neural pathways whereby light stimulation triggers trigeminal pain in both ocular surface diseases and migraine has provided a partial explanation of the mechanism of photophobia.

In ocular diseases, a pathway allowing photic stimulation to stimulate the abundant nociceptors of the cornea, uvea, etc., has been demonstrated. Retinal ganglion cells project signals to the olivary pretectal nucleus that in turn projects to the superior salivatory nucleus. The latter, via the sphenopalatine ganglion, causes release of parasympathetic neuropeptides,

inducing ocular vasodilatation and activation of nociceptors on blood vessels.[19,20]

Migraine worsening with light could be explained by photic signals arising from retinal ganglion cells that converge onto trigemino-vascular neurons of the posterior aspect of the thalamus. From there, axons project to cortical vision- and pain-processing areas. Interestingly, migraine patients with little residual vision can also experience photophobia, due to the involvement of image-forming and non image-forming retinal ganglion cells. The light sensitivity occurring during migraine attacks would result from nociceptive stimuli passing through the posterior thalamus and then arriving at the visual cortex.[21,22]

Proposed mechanisms to explain photophobia in CVI include damage of luminance-sensitive cells in the cerebral cortex and thalamic involvement. Unlike controls, children with CVI have improved grating acuity in low-luminance conditions.[23]

Postulated explanations for photophobia related to chiasmal lesions include chemical meningeal irritation, stretching of meningeal or vascular pain-sensitive structures of the cranial base,[16] as well as thalamic injury.[24]

Management

The treatment of photophobia depends on the underlying pathology. Wearing a sunhat, promoting home and school activities in areas with comfortable illumination conditions, and facilitating access to low vision services when deemed appropriate are examples of general supportive measures that help improve the child's quality of life.

Darkly tinted lenses can also be helpful, but their use should not be generalized because decreasing the dark-adapted state is important.[2] Tinted lenses can be considered in albinism. FL-41 tinted lenses (rose-colored) appear to decrease the frequency of migraine attacks in children.[25] Deep red- or brown-tinted contact lenses can provide comfort and improve vision in cone dystrophies.[26,27] Responsible handling must be assured. Filter lenses sometimes decrease dazzle in children with CVI, and their value is best assessed in low vision centers.

"My child's eyes keep watering!"

Anthony G Quinn

Up to 20% of infants have a watery eye in the first month of life.[1] The vast majority have congenital nasolacrimal duct obstruction; the rest may have potentially serious problems. Acquired watering eyes present another range of diagnoses.

Congenital nasolacrimal duct obstruction and its management are discussed in Chapter 21.

Signs and symptoms

History

A child with excessive tearing can be a source of concern. Mucus in the tear film causes "stickiness" and constant spillage of tears causes redness and irritation of the lower lid skin. The lids may be stuck together on waking and require frequent cleaning. Parents may complain that the appearance "ruins" childhood photographs and they may feel the child's appearance reflects poorly on them as a parent. The primary care physician may feel compelled to prescribe repeated courses of topical antibiotics, to no lasting effect.

Try to establish whether the watering had its onset soon after birth, or if it is recent. Photophobia must specifically be asked about, as it is common in congenital glaucoma. The typical presentation is a child who avoids opening their eyes in normal daylight, often burying the eyes behind an arm or hand. Photophobia is also a symptom of corneal disease (such as cystinosis; see Chapter 34), uveitis, and a foreign body in the conjunctival sac or cornea. The possibility of trauma needs to be kept in mind, as children cannot always give a detailed history. Herpes simplex conjunctivitis can sometimes be associated with canalicular stenosis and scarring, causing a watery eye. A child with excessive lacrimation may have a watery nostril on the same side as the watery eye. Ask if the child rubs the eyes, or has a history of eczema, suggesting allergic eye disease. A history of eye rubbing or poking and concerns about whether the child can see suggests a retinal dystrophy, such as Leber congenital amaurosis (see Chapter 46).

Examination

External inspection

Tearing, red macerated skin, and stickiness may be seen. Look for misdirected lashes or lid malposition such as entropion, particularly if trachoma is possible. Check there is no facial nerve weakness, which would compromise the tear "pump." In nasolacrimal duct obstruction, the tear lake is thickened, brimming the lower lid margin. Normally, the tear film is virtually invisible, and, with fluorescein staining, measures less than 1 mm. With obstruction, it typically measures 2 mm or more. Look for perilimbal injection suggesting keratitis or uveitis, and look for evidence of blepharoconjunctivitis. Generalized corneal haze with secondary corneal epithelial edema may be a sign of glaucoma. An estimate should be made of horizontal corneal diameters using a ruler held close to the lid. A congenital swelling over the nasolacrimal sac is probably a dacryocystocele.

Slit-lamp examination

This is often best done with a portable model in young children. Look for presence or absence of puncta, punctal ectopia or fistula, or epiblepharon with inturned eyelashes. Inspect the inferior conjunctival fornix looking for diffuse redness and swelling of the conjunctiva, suggesting chlamydia conjunctivitis. Everting the upper lid is unlikely to be possible in a young, awake child, but it is possible to retract the upper lid digitally and inspect the tarsal conjunctiva and fornix with the portable slit-lamp, looking from below. Corneal crystals, abrasions, scars, ulcers, and foreign bodies can be excluded, as can signs of uveitis, e.g. keratitic precipitates, hypopyon, posterior synechiae, or cataract (also check red reflex). Haab striae and corneal edema should be excluded.

Fluorescein testing

This is a very sensitive test for detecting any defect in the corneal epithelium, and fluorescein will diffusely stain the cornea with epithelial edema. The fluorescein dye disappearance test is excellent for confirming nasolacrimal duct obstruction (see Chapter 21). Place a drop of fluorescein 1–2% in the conjunctival sac; in a normal child, the fluorescein will disappear from the tear meniscus after 5 minutes; the presence of fluorescein after 5 minutes indicates obstruction of both canaliculi or nasolacrimal duct. Fluorescein may also appear in the nose, confirming drainage.

Intraocular pressure

It is possible to check this in the majority of awake infants or young children with an Icare tonometer (see Chapter 38). If congenital glaucoma is likely, an examination under anesthesia

may be necessary. Tactile measurement is inaccurate and may mislead.

Cycloplegic refraction, fundus examination

Refraction and fundus examination will highlight unilateral myopia in a child with unilateral glaucoma, posterior synechiae, disc cupping, and any posterior segment pathology such as retinoblastoma, which can present as a red, watery eye with a "pseudohypopyon." Unilateral congenital nasolacrimal duct obstruction can be associated with anisometropia and amblyopia.

Causes and treatment

Non-patent nasolacrimal drainage system (see Chapter 21)

Spontaneous resolution occurs, with about 70% of affected children free of symptoms by 3 months of age and over 90% resolving by their first birthday. Spontaneous resolution may also occur later than 12 months of age, and those children whose epiphora does not resolve spontaneously after age 2 years are likely to have more complex lacrimal drainage problems. Children with white eyes (no evidence of secondary conjunctivitis) should not be treated with antibiotic drops. Many physicians advocate massage of the lacrimal sac, but its efficacy is not known. Lid cleaning may help prevent secondary infection and skin excoriation. Sometimes epiphora due to nasolacrimal duct obstruction will spontaneously resolve, only to recur with an upper respiratory tract infection, due to mucosal edema in the nasolacrimal system.

Treatment

There are a number of treatments (see Chapter 21); the commonest, probing, is safe,[2] but even in the best circumstances can have complications; it is sometimes traumatic and may, rarely, cause canalicular stenosis.

Occasionally an older child may acquire watery eyes due to punctal stenosis. This can be treated with punctal enlargement, but first may require an examination under anesthetic to determine the cause.

Foreign body/corneal abrasion

A history of sudden onset of pain, epiphora, conjunctival redness, and a foreign body sensation suggest either a corneal/conjunctival abrasion or foreign body. A careful history from the child and/or caregivers is essential in understanding the likely injury and predicting its severity. Fluorescein stains a corneal or conjunctival abrasion, and staining vertical scratches suggest a superior subtarsal foreign body caused by the foreign body being dragged over the corneal surface with each blink. If there is a full-thickness corneal laceration, the Seidel (fluorescein leak) test will sometimes be positive. A corneal foreign body is often visible with a check of the red reflex using the direct ophthalmoscope, but the portable or table-mounted slit-lamp is the ideal way to examine the cornea.

Corneal abrasions usually resolve quickly with antibiotic ointment and no patching is required. Removal of an embedded corneal foreign body in a child may require general anesthesia.

Fig. 95.1 Thygeson superficial punctate keratitis (TSPK). This 8-year-old child had a variably watering eye for 9 months that did not respond to a variety of treatments. TSPK follows a relapsing and remitting course over several months.

Loosely adherent foreign bodies in the conjunctival sac or on the cornea may be removable with a sterile cotton bud.

Keratitis and conjunctivitis (see Chapter 16)

A watery eye is a common symptom in keratitis (Fig. 95.1). There is frequently associated photophobia, conjunctival injection, increased mucus production, and a foreign body sensation. Visual acuity is often reduced in keratitis. Conjunctivitis is not associated with photophobia, unless there is an accompanying keratitis. Conjunctivitis is commonly infective (viral, bacterial), or allergic or traumatic. Allergic conjunctivitis typically presents as itchy, watery eyes, and is often a bilateral, although sometimes asymmetrical, problem. There may be a family history of allergic disease, and a clinical history of exacerbations in spring/summer, or of other allergic diseases such as eczema, hay fever, or asthma. "Shield" ulcers associated with giant subtarsal conjunctival papillae produce a characteristic loss of corneal epithelium and are easily seen with fluorescein and slit-lamp microscope.

Contact lens-related epiphora

In the older child, or the aphakic infant with contact lenses, epiphora may result from numerous causes. Poorly fitting lenses, change in corneal curvature, build-up of deposits on the contact lens, and chips or tears at the edge of the contact lens can all cause watery eyes from epithelial trauma or drying. The superior tarsal conjunctiva must be assessed for giant papillary conjunctivitis (GPC) in the long-term contact lens wearer. Treatment may include revising contact lens hygiene, replacing lenses, refitting lenses, replacing lenses with a different material or edge design, and treatment of GPC with appropriate pharmacologic agents (see Chapter 16). Infectious keratitis or corneal abrasion should be actively excluded and parents warned to be sure to remove the lens and seek ophthalmological advice within a few hours if the child's eye becomes red, sticky, watery, or photophobic.

Congenital glaucoma

Epiphora with photophobia may indicate a diagnosis of congenital glaucoma. Buphthalmos, corneal clouding, Haab

striae, increased intraocular pressure, and enlarged optic disc cup are also usually present. Anisometropia and strabismus may occur (see Chapter 38). Prompt treatment, usually surgical, is needed to prevent optic nerve damage.

Crocodile tears

One peculiar form of tearing occurs only when the patient salivates, typically when eating, but is also possible when the patient is thinking of a good meal. This is usually a congenital problem, and is an example of a range of disorders known as "congenital cranial dysinnervation disorders." Crocodile tears can also occur after trauma or surgery on the ear, or as a sequel to Bell palsy, representing aberrant nerve regeneration.

CHAPTER 96

Proptosis at different ages

Alan A McNab

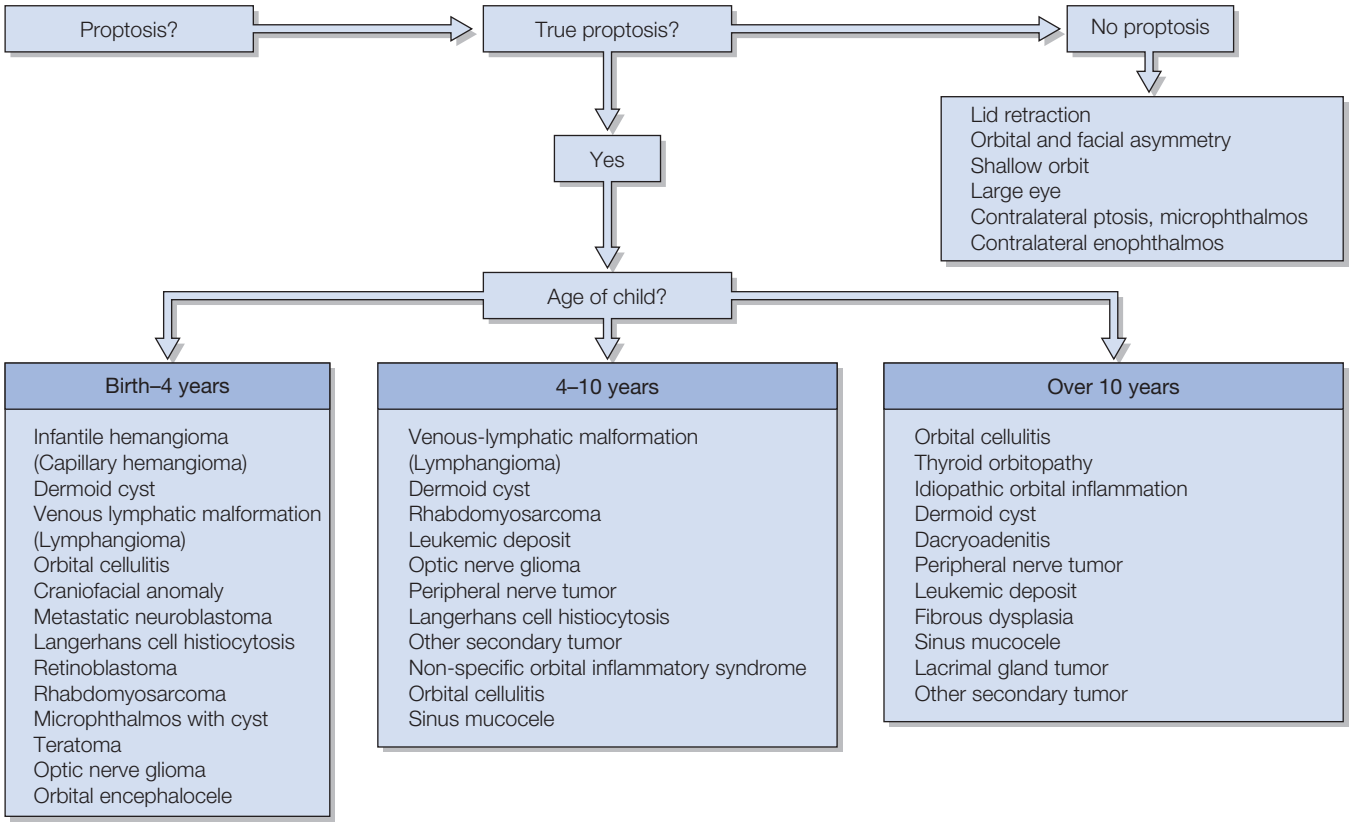

Fig. 96.1 The causes of proptosis vary with the age of the child and there is considerable overlap between age groups. This figure lists causes in approximate order of frequency. Details of each condition should be sought in the text. In making a clinical diagnosis, the history and progression of the condition, as well as the clinical findings, are of vital importance. See Chapter 22 for a more detailed approach.

"My child's teacher says she can't see properly!"

Hanne Jensen

Mode of presentation

When a child is brought to the ophthalmologist because his/her teacher suspects reduced vision it suggests that the parents have not been aware of any such problems. This may be because the parents do not expect the child to see any better or that the child's visual disability has been constant and non-progressive. The child who never had normal vision will not complain, but problems may become apparent as education makes increasing visual demands.

The teacher may notice problems with reading (near work), looking at the blackboard (distance vision), problems with color pictures in textbooks, reports of strange color combinations, or peculiar behavior in class. The child may miss what is going on, appear uninvolved, or may need extra time to keep up with the class. There may be problems in the playground: the child doesn't want to play, gets tired, often falls, is light-shy, or has an abnormal head posture. Other symptoms might be squeezing the eyes or complaining of headache.

Table 97.1 describes the signs and symptoms that might arise from various ocular abnormalities.

Diagnosis

History

Specific questions are necessary because parents may not associate the visual problems with a change in behavior. Is there a history of trauma? Has the child's situation been longstanding or has a change occurred with higher demands? Does the child like to play where it is dark? Is he/she comfortable walking alone or do they always want to hold someone's hand? Has his/her behavior suddenly changed? Aggression or passivity can be symptoms of progressive visual loss. Any other systemic symptom must be noted. It is sometimes necessary to talk with the child without the parents present. Children may only distinguish blurred vision (de-focus) from reduced vision when they are older.

Blurred vision implies an optical problem. A complaint of decreased vision after strenuous exercise or after warm baths suggests Uhthoff's sign of demyelinating disease. You must ask for the family history: an affected uncle in the mother's family may indicate a X-linked disease; likewise, consanguinity may suggest a recessive disease. Finally, it is important to ask for any drug history and make certain that no medicines have been given that might influence the vision or the visual field, e.g. vigabatrin.

Examination

Observe the child entering the clinic: are there difficulties; is the child afraid or curious; and can the child hear? Children who have been attending several clinics throughout childhood are often afraid and shy with professionals: it is important to make the child feel safe and cooperative.

Ocular examination

Measure the visual acuity; an accurate refraction is a vital part of the examination of a child with reduced vision. The media should be examined before and after the pupils are dilated, either with a slit-lamp, ophthalmoscope, or retinoscope. Direct ophthalmoscopy should be used for fundus details, including subtle changes in the retinal nerve fiber layer and fovea. Indirect ophthalmoscopy is useful to obtain an overall view of the retina and its periphery; problems such as bull's eye maculopathy, less obvious at high magnification, may become apparent with the indirect ophthalmoscope.

The optic nerve is assessed by its appearance but also by testing pupillary responses, contrast sensitivity, color vision, and visual fields. Color vision and pupillary responses are often normal in retinal diseases with markedly reduced visual acuity, whereas they can be abnormal even in mild optic nerve disease.

Neurological examination

Neurological examination is necessary in children with reduced vision since many systemic diseases cause eye symptoms. It is important to inquire about other symptoms, including hearing problems, in every child with visual loss. Children with concentration deficits must be examined by a neurologist to exclude a seizure disorder, autism, or attention disorders.

Special investigations

Electrophysiology such as electroretinography, visual evoked potential, and electro-oculography, as well as ultrasound and optical coherence tomography, can be very useful supplements. A magnetic resonance imaging (MRI) scan may be necessary if there are any indications of intracranial pathology.

Table 97.1 Symptoms and signs giving clues to the diagnosis

The teacher describes problems with:	Refractive error	Accom. spasms	Convergence insufficiency	Media opacities	Corneal dystrophies	Keratoconus	Macular disorders	Retinal dystrophies	Optic nerve disorder	Neurological disease	Metabolic disease
Reading	X	X	X	X	X	X	X	X	X	X	X

Head tilt	X									X	X
Color vision							X		X	X	X
Eye movements								X		X	X
Concentration	X	X	X							X	X

X, Present; (X), rarely present.

Causes and treatment

Refractive errors

Uncorrected refractive error is the most common reason for a child to not see properly at school. Cycloplegic refraction is helpful in children to detect hypermetropia and in order not to overestimate the degree of myopia.

Accommodative anomalies

Older school children often have problems when looking at the blackboard, but not when reading a book. This is most commonly due to progressive myopia. However, this complaint may also be caused by a high accommodative tone, which induces a myopic refractive error. It is important to do a cycloplegic refraction to avoid missing this diagnosis and prescribing myopic glasses in error. Occasionally, treatment with cycloplegic drops and reading glasses is the only way to help the child relax accommodation. Children may accommodate to compensate for a low hypermetropic refractive error, but some children do not (e.g. Down syndrome, cerebral palsy) and they become asthenopic; reading glasses may help in this situation. Children with convergence insufficiency may have blurred vision while reading; they seldom complain of double vision. Orthoptic treatment may help, but surgery is sometimes necessary.

Orbital disease (see Chapter 22)

Orbital inflammation or tumor may present with proptosis, but the presenting symptom may be reduced vision accompanied by restriction of eye movement and eventually pain and redness. Distortion of the globe results in astigmatism and hyperopia, which, left untreated, may reduce visual acuity.

Media opacities

Corneal diseases (see Chapter 34)

Corneal clouding due to keratitis from any cause may reduce acuity with irritation and watery discharge. Symptoms due to keratoconus usually present during the second decade as slowly progressive visual loss, often leading to multiple attempts at correction with glasses or contact lenses. Dystrophies presenting at a young age (Fig. 97.1) can result in recurrent epithelial defects and reduced vision (see Chapter 35).

Anterior chamber anomalies

Blurred vision due to anterior segment inflammation is usually associated with pain, redness, and photophobia. In chronic uveitis, particularly related to juvenile idiopathic arthritis, vision may be reduced without symptoms (see Chapter 40).

Lens anomalies (see Chapter 36)

Dislocation of the lens is a rare but important cause of reduced vision, causing astigmatism and/or myopia. Glaucoma and retinal detachment can occur. In older children cataract can be detected by the parents or by professionals, due to blurred vision or photophobia, particularly if the child has a predisposing condition such as diabetes mellitus, long-term steroid treatment or there is a family history of juvenile-onset cataract (see Chapter 36).

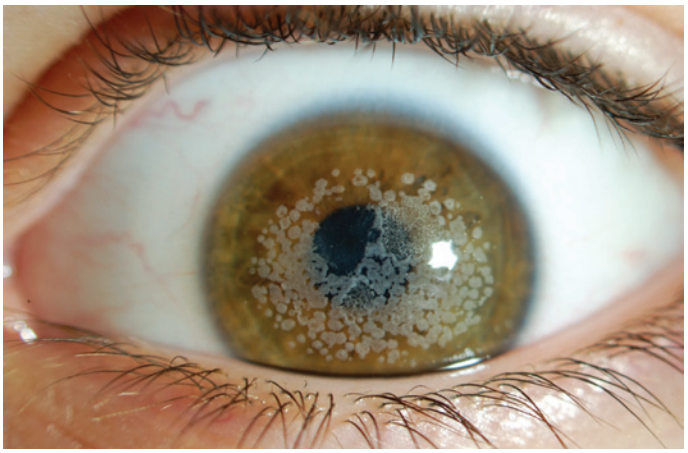

Fig. 97.1 This 8-year-old girl was referred when her dentist noticed a greyish corneal discoloration in both eyes. On examination, her visual acuity was 6/18. A diagnosis of Groenouw type 1 corneal dystrophy was made; the consanguineous parents were asymptomatic; both had subtle corneal abnormalities suggestive of this diagnosis.

Vitreous disorders

Vitreoretinal degenerations such as Stickler syndrome or juvenile X-linked retinoschisis may be diagnosed at or before school age because of reduced visual acuity from myopia or retinal detachment (see Chapter 52).

Vitreous opacities including hemorrhage, vitritis, and retinoblastoma seedlings are uncommon causes of blurred vision. When the vitreous is too opaque to allow retinal visualization, other diagnostic tests may be indicated, e.g. ultrasound, computed tomography (CT), or MRI.

Retinal disorders

Retinal dystrophies (see Chapter 46)

Visual disturbances with retinal dystrophies are variable. A family history of bilateral visual loss may be present, and there may be systemic findings. Blurred vision is rarely an early complaint in retinitis pigmentosa; night blindness and loss of peripheral visual field are more usual. These children often have high refractive errors (hypermetropia or myopia). Macular dystrophies make reading difficult, but there may be few fundoscopic signs at the first visit, so some children are suspected of visual conversion disorder (hysterical blindness) (Fig. 97.2).

Systemic disease

It is important to remember that systemic disease may cause characteristic retinal and other ocular findings; thus, ocular findings may lead directly to a systemic diagnosis. Diabetes mellitus may present early, but retinopathy is uncommon in the first decade of the disease. Blurred vision may result from myopia caused by rapid shifts in blood glucose levels, cataract, or from optic atrophy associated with DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness – Wolfram syndrome).

Many neurometabolic disorders, including Batten disease, mucopolysaccharidoses, and mucolipidoses, can present with reduced visual acuity from retinal dysfunction. However, they will often present before the vision is reduced, with

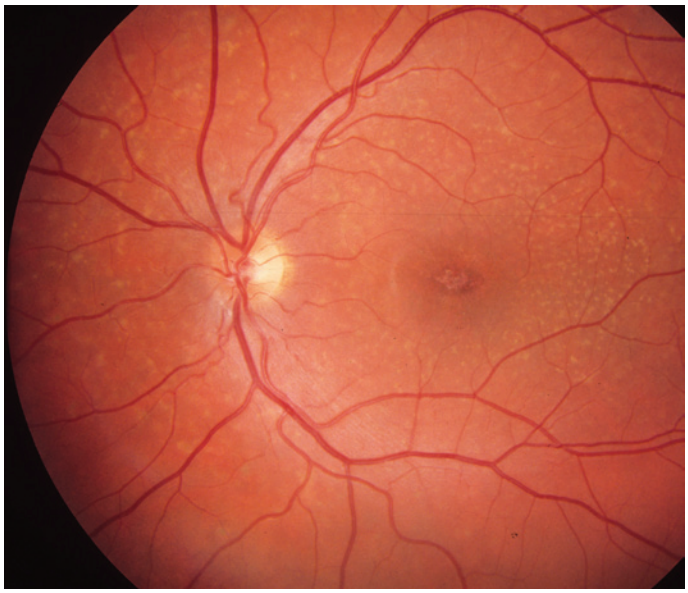

Fig. 97.2 This 14-year-old child with visual acuity of 6/12 had reading difficulty. Visual conversion disorder (hysterical blindness) was suspected, as the eye examination was normal. Four years later typical retinal changes of Stargardt disease were apparent. The visual acuity had decreased to 6/60 in each eye.

seizures, abnormal behavior, or even reduced visual fields. Electroretinography is often necessary to secure the diagnosis.

In leukemia (Chapter 67), vision may be affected by retinal, choroidal, or iris infiltration or hemorrhage.

Optic nerve diseases

Reduced visual acuity and color vision, central scotoma or constricted field, poor pupillary responses (an afferent defect), and variably swollen or atrophic optic discs in a child all point to optic neuropathy (see Chapters 54 and 56). Optic atrophy without ocular, post-inflammatory, or hereditary causes suggests a central nervous system abnormality. It is usually bilateral, but may present unilaterally. Congenital optic nerve anomalies (coloboma, hypoplasia) can be associated with poor vision and can be discovered late at school testing (see Chapter 53).

Central nervous system diseases

Visual pathway disease may result in decreased vision; a lesion proximal to the chiasm results in optic atrophy. Increased intracranial pressure may cause papilledema, usually without visual symptoms, but, if severe, there may be episodic or permanent loss of vision. A severely atrophic optic nerve cannot appear swollen despite increased intracranial pressure because there is no retinal fiber layer to swell. A child with a central nervous system tumor (especially in the posterior fossa) is often ill, vomiting, and complaining of headache, and will not be overlooked. These children may also have varying double vision from a cranial nerve palsy.

The parachiasmal syndrome of visual defect, growth, and other hypothalamic disturbances in children is often caused by optic gliomas or craniopharyngiomas. Various combinations of optic atrophy and papilledema occur, depending on the duration of the process and how rapidly the intracranial disease has developed (see Chapter 59).

Cerebral visual impairment is associated with very few ophthalmologic findings. The reduced visual acuity may vary according to the state of the child. Vision is often better when the child is relaxed, has no seizures or pain, and the surroundings are well known. It is sometimes very difficult to establish the visual function in the clinic (see Chapter 60).

Non-organic visual disorders

These are often seen in teenage girls who may have problems either in the family, with their friends, or related to schoolwork. They can be very difficult to diagnose, and some children may undergo several tests in order to be sure that no organic disability is present (see Chapter 63).

Varying degrees of acuity and visual field loss are found, often becoming worse with time, but rarely to an extent that the child becomes blind. The child's success in managing day-to-day visual tasks is out of keeping with the alleged severity of visual loss.

"My child could see perfectly but now the vision is weak!"

Luis Carlos Ferreira de Sá

Introduction

Visual loss in an otherwise healthy child is an alarming finding for both the family and clinician. Children often do not complain of decreased vision, and it is common for them to only present once the visual loss is severe. Visual loss may result from congenital problems, only noticed later in life when visual requirements increase at school, or when the child had normal vision followed by chronic or acute visual loss (Fig. 98.1).

When investigating acquired visual loss, a comprehensive medical history is essential. Ask about the pregnancy, delivery, gestational age, birth weight, perinatal problems, developmental milestones, ocular and medical anomalies, medications, and family history of systemic and/or visual problems (Fig. 98.2). Seek details regarding trauma, timing, duration, and severity of visual loss.

Irrespective of whether the onset of visual loss is acute or chronic, ophthalmic examination will, in most cases, reveal abnormalities in the anterior and/or posterior segment, although the site of visual loss may be intracranial (see Chapters 57 and 60). Details about photophobia and eye movement disorders, including strabismus and nystagmus, may be especially helpful in reaching a diagnosis.

Examination

First, observe the child's visual behavior. There may be different degrees of visual loss, including visual inattention. The child may not respond to visual stimuli such as lights, faces, or toys. The examiner should not use animated and noisy objects; the child may be attracted to the sound rather than the visual stimulus. Whenever possible, visual acuity should be measured with age-appropriate methods.

Pupillary responses (grade of reactions, presence of an afferent pupillary defect, or paradoxical reaction) and assessment of alignment and eye movement disorders provide the clinician with important diagnostic clues.

Anterior segment

Cornea

Developmental glaucoma may present with increased corneal diameter because of the elasticity of the collagen fibers in young children. Corneal transparency may be reduced by several conditions, including developmental glaucoma (see Chapter 38), infectious keratitis (see Chapter 34), and metabolic diseases (mucolipidoses, mucopolysaccharidoses, and cystinosis; see Chapters 34 and 65). Corneal shape is altered in keratoconus (see Chapter 34), which may be present in childhood and progress at puberty.

Iris

Iris abnormalities are usually not associated with acquired visual loss, although colobomas (see Chapter 39) and iris transillumination (albinism; see Chapter 41) may be related to fundus problems causing congenital visual loss.

Lens

The lens should be carefully evaluated. Developmental cataracts can be secondary to trauma, radiation, metabolic/storage diseases, medications, or associated with genetic syndromes that may develop later in childhood (see Chapter 37). Ectopia/subluxated lens may also be observed and can be related to trauma, genetic syndromes, and metabolic diseases (see Chapter 36).

Posterior segment

Vitreous

Signs of inflammation or hemorrhage related to uveitis, trauma, or tumors may be seen in the vitreous. Vitreous changes are part of a vitreoretinopathy (see Chapter 42). Past medical history of prematurity, high refractive errors, familial history of retinal detachment, joint pains, or cataracts may suggest retinopathy of prematurity, Stickler syndrome, familial exudative vitreoretinopathy, or congenital stationary night blindness. Electroretinography (ERG) may be useful. Ultrasound, magnetic resonance imaging (MRI), or computed tomography (CT) scans may be indicated when vitreous opacities impede observation of the retina, or when calcification is suspected (retinoblastoma).

Retina/choroid

The retina/choroid should be evaluated. Subtle, but important, anomalies are not always readily observed. Retinal dystrophy and metabolic/storage diseases (see Chapters 46 and 65) commonly start without pigmentary changes. They develop later as the disease progresses. When the condition is bilateral and present from birth, nystagmus develops as in cases of Leber congenital amaurosis, toxoplasmosis, and albinism.

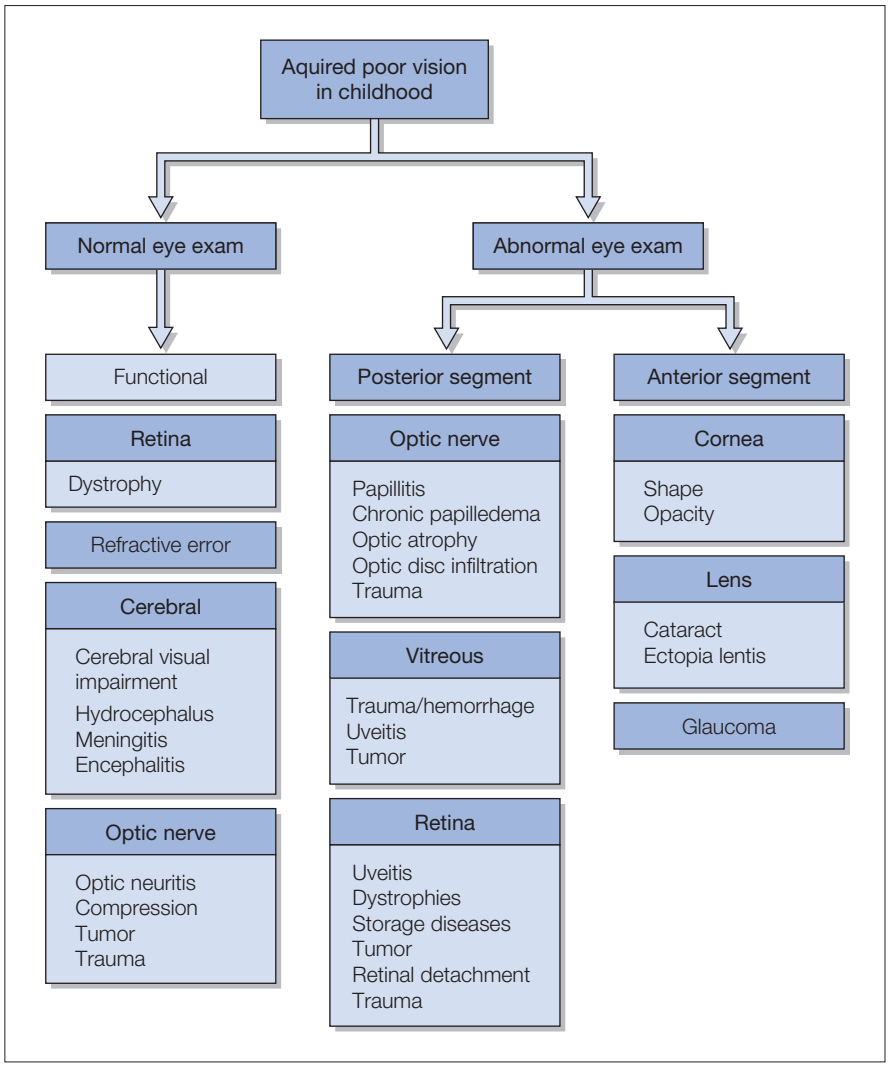

Fig. 98.1 Guidelines for diagnosis of acquired poor vision in childhood.

Color vision abnormalities and presence of paradoxical pupil reaction may suggest cone dysfunction. Retinal dystrophies will require ERG for specific diagnosis. Severely reduced electro-oculogram (EOG) is an important diagnostic feature of vitelliform dystrophy (Best disease; see Chapter 48). Recently, optical coherence tomography (OCT) has revolutionized the investigation, diagnosis, and management of many eye conditions. The development of handheld OCT has helped in the evaluation of visual loss in children associated with inherited retinal dystrophies and even chorioretinal vascular diseases when the appearance of the fundus is still normal using ophthalmoscopy (see Chapter 10). Fluorescein angiography, although difficult in children, is particularly useful in Stargardt disease ("dark choroid" sign), when visual loss and macular changes may be minimal (see Chapter 50). A work-up for uveitis (see Chapter 40) and retinal detachment (see Chapter 52) may be necessary. Both conditions develop at any age and are important causes of acquired visual loss.

Optic nerve, chiasm, and optic tract

The size, color, and contour of the optic disc merit attention since optic disc abnormalities may be related to congenital and acquired visual loss. In evaluating optic atrophy, the color of the optic disc is an important assessment. However, the optic discs may appear pale in infants compared to older children and adults. Moreover, inherited optic atrophy including Leber hereditary and autosomal dominant forms rarely manifests in the first year of life. Optic atrophy may be due to panretinal degeneration and ERG may occasionally be necessary. Optic atrophy may occur secondary to longstanding papilledema or compressive lesions of the anterior visual pathway; neuroimaging studies may be indicated. The chiasm and optic tract may be involved in a variety of conditions, including tumors (glioma, craniopharyngioma, neuroblastoma, and retinoblastoma "trilateral"), trauma, infection, inflammation (post-viral, post-immunization, and demyelinating diseases such as multiple sclerosis), vascular anomalies, and radiation. OCT can be useful to evaluate optic nerve head and retinal nerve fiber layer (RNFL). The RNFL is thicker in children with pseudotumor cerebri and may be thinner in patients with optic pathway gliomas, multiple sclerosis, optic neuritis, and disseminated encephalomyelitis.

Central nervous system and cortical visual impairment

Visual loss is frequently associated with disturbances of the visual cortex as the result of trauma, infection, hydrocephaly,

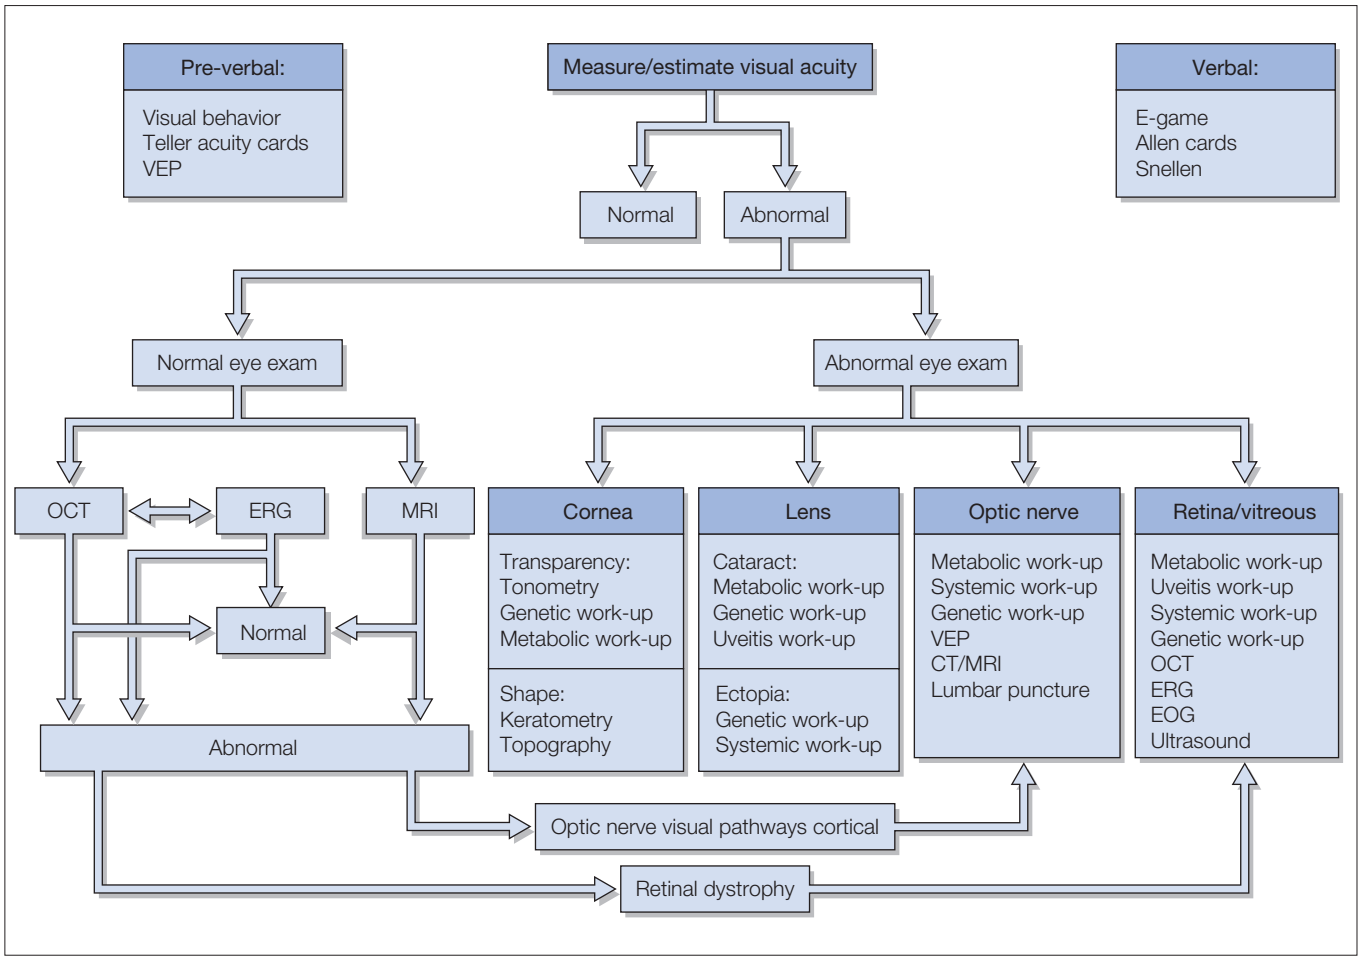

Fig. 98.2 Guidelines for investigation of acquired vision loss in childhood. CT, Computed tomography; EOG, electro-oculogram; ERG, electroretinogram; MRI, magnetic resonance imaging; OCT, optical coherence tomography; VEP, visual evoked potential.

hypoxemia, and vascular or metabolic insults (see Chapters 59 and 60).

What if the eye exam is normal?

In a child with acquired visual loss and no ocular explanation for it, it is important to rule out functional visual loss (see Chapter 63) and refractive errors. Electrophysiological tests, neuroimaging studies, and OCT may be necessary to rule out organic disease. In some patients, acquired visual loss is part of a multisystem disorder.

Electrophysiological tests (see Chapter 9)

ERG is invaluable in diagnosing the etiology of poor vision in children. It may be performed in a child with poor vision and normal ocular examination because many retinal disorders are not associated with any visible pigmentary changes early in the course of disease. EOG is rarely indicated for small children; conditions in which EOG is indicated (Best and Stargardt disease) rarely manifest in the first decade. Visual evoked potential (VEP) can be helpful for estimating visual acuity and in providing information about the neural visual pathway, as in optic neuritis where there may be a prolonged latency.

Neuroimaging studies

MRI and/or CT scan are indicated when the clinical examination and electrophysiological tests fail to explain the poor vision. Resolution of MRI is superior to that of a CT scan, providing better images of the central nervous system (CNS), and it does not expose the child to radiation. However, MRI acquisition time is longer, it does not visualize the bone as well as a CT scan, and may require anesthesia in small children. Neuroimaging studies are important in cases of compressive lesions of the visual pathways, cortical abnormalities, and demyelinating process.

The decision to perform electrophysiological tests before neuroimaging studies should be based on the individual child, availability of an electrophysiological test laboratory, and the possibility of associated CNS pathology.

Optical coherence tomography (OCT)

Advances in OCT technology, with enhanced image-acquisition speeds, wider fields, and handheld/portable units will allow OCT to be used as a routine investigative exam in children. OCT is a noninvasive investigative technique that can help to evaluate vision loss in a variety of conditions including amblyopia, glaucoma, chorioretinal vascular diseases, inherited retinal diseases, and optic nerve anomalies.

The child with a dual sensory loss (deafblind)

Nicoline Schalij-Delfos

Introduction

Deafblindness or dual sensory loss (DSL) is a combined vision and hearing disability; affected children have complete and incomplete loss of hearing and/or vision. It can be congenital or acquired. Congenital deafblindness is defined as blind and deaf from birth or very early in life, before the development of speech (pre-lingual deafblindness). Acquired deafblindness arises after the development of language (post-lingual deafblindness).[1–3] A Danish study found an overall prevalence of 1:15,000 among children <18 years and 1:29,000 for congenital deafblindness.[3,4] In the United States, a National Deaf-Blind Child Count is performed annually and remains relatively stable in the total population, with a slight shift towards the younger children. The 2014 count identified 7260 youngsters (3–18 years) and 561 infants (0–2 years); +/− 5.5% were totally blind and +/− 19% had a profound hearing loss.[5]

Etiology

Changes in health care have influenced the etiology for congenital deafblindness. Rubella has diminished significantly due to immunization programs, and perinatal causes such as prematurity and perinatal asphyxia have increased as a result of improved survival of extremely premature and sick babies.[1,3] Currently, the most common causes for congenital deafblindness are CHARGE syndrome, prenatal infection with cytomegalovirus (CMV), prematurity, and meningitis. The most important cause for acquired deafblindness is Usher syndrome. Infections can cause early as well as late vision and/or hearing loss dependent on type and time of occurrence. Apart from that, many other syndromes and genetic disorders are involved in vision and hearing loss[6,7] (Table 99.1).

Concomitant disorders

Vision and hearing are important tools for interaction. Loss of these functions has implications for communicative, cognitive, emotional, and social development and function. In addition, not being able to identify the origin of a source of sound or identify movement of objects may impact one's sense of safety. The earlier and more profound the defect, the more serious the consequences.[1]

Mental and behavioral disorders are much more frequent and autism spectrum disorder (ASD) has been found in 6% of children with DSL.[8,9] Intellectual disabilities (ID) and ASD are more difficult to detect in patients with DSL. Conversely, a high prevalence of undetected deafblindness has been reported in patients with ID, as common as 70% in patients with profound ID. Detection of ASD is significantly delayed due to an overlap in behaviors between children with DSL and ASD and the absence of adequate tests.[10–12] Lack of awareness delays detection and interferes with adequate interventions.

Ophthalmological assessment

Many countries have programs to detect hearing defects at a very early age. Despite the high prevalence (approximately 40–60%) of ophthalmic disorders in children with hearing loss, standard ophthalmological screening has not been widely implemented. Refractive errors (18–39%), strabismus (5.3–18%) with subsequent loss of stereopsis and amblyopia (4.4–14.4%) are the main disorders. Hyperopia is the most commonly reported refractive error, followed by myopia, astigmatism, and anisometropia.[13] Depending on the cause, cataract (Down syndrome), glaucoma (Stickler syndrome, Sturge–Weber syndrome), retinal changes, or a deficit in contrast sensitivity (Usher syndrome) may be found. Cerebral visual impairment (CVI) has seldom been studied in this specific population, but a study performed in 1995 identified CVI in 26% of deafblind subjects.[14] An increase can be anticipated as more extremely premature infants, an important risk factor for CVI, survive.[15]

Orthoptic and ophthalmologic examinations should include visual acuity measurements not only for distance but also for near, as children with vision and hearing loss often perform their tasks close up. Furthermore, assessment of binocularity, cycloplegic refraction, slit-lamp examination, and fundoscopy should be performed. Visual symptoms of acquired deafblindness are not always easy to detect at an early age. Subtle retinal changes in the eyes of children with Usher syndrome can be seen in the first decade, but often the characteristic retinal pigmentation develops later. Electroretinography (ERG) or visual fields can be performed for

Table 99.1 Causes for deafblindness categorized as: early (congenital or infantile) vision and hearing loss, early vision loss with subsequent hearing loss, early hearing loss with subsequent vision loss, and late vision and hearing loss

Early vision and hearing loss	Early vision – subsequent hearing loss
Congenital infections Cytomegalovirus (CMV) Toxoplasmosis Syphilis Herpes simplex Rubella Meningitis CHARGE association Down syndrome Premature birth Asphyxia Trisomy 13, 4p Chromosome 5p- (Cri du Chat) Ring chromosome 18 Other syndromes: Aicardi, Dandy–Walker, fetal alcohol, Smith–Lemni–Opitz, Waardenburg	Leber congenital amaurosis Norrie disease Alstrom syndrome Infections
Early hearing – subsequent vision loss	**Late vision and hearing loss**
CHARGE Trisomy 21 Usher type I, II syndromes Prematurity Infections Möbius syndrome Stickler syndrome Treacher Collins	Intracranial pathology Usher type II and III Trisomy 4p Chemical induced Infections Other syndromes: Alport, Apert, Bardet Biedl, Batten, Cockayne, Cogan, Cornelia de Lange, Crigler–Najjar, Crouzon, Hunter, Hurler, Kearns, Sayre, Klippel–Feill, Kneist, Leigh, Marfan, Maroteaux–Lamy, Marshall, neurofibromatosis type 1 and 2, Pierre Robin, Pfeiffer, Prader–Willi, Refsum, Sturge–Weber, Turner, Zellweger

early diagnosis. Institutes specialized in counseling of children with vision and hearing impairment should be involved in assessments for CVI and contrast sensitivity or illumination measurements.

Early identification is extremely important as disorders might be correctable, treatable, or require environmental adaptations and appropriate support from specialized services.[6] Optical correction or clear visual axes facilitates development of spoken or sign language, communication, and social interaction. Treatment of amblyopia or glaucoma can prevent children from additional deficits. Repeated ophthalmological assessment is necessary as disorders might deteriorate or appear later; however, no uniform screening guidelines are available.

Cochlear implantation

Cochlear implants (CI) are used in children with severe DSL with sensorineural hearing loss. In congenital cases this should preferably occur before the age of 2 years. Neonatal screening programs allow earlier detection of infants with sensorineural hearing loss. CIs are important for development of speech, language, and cognitive skills. The majority of infants with CI can use spoken language as the primary mode of communication. Again, the earlier the implantation, the greater the impact on rehabilitation, which is especially important in infants with a concomitant visual disability.[16,17]

Approach to the deafblind child

It is important to realize that children with dual sensory loss need a specialized approach. Children with hearing loss have difficulties perceiving speech, especially in a noisy environment, often have language and speech delay, concentrate on faces for speechreading, have difficulties in registration of the origin of sounds, and can be frightened by sudden noise. Infants often need longer pauses to process information or may exhibit unusual or stereotypic behavior.[18] A combined disability aggravates these symptoms, impedes eye contact, and can result in a sense of insecurity. Verify if the child is completely deafblind or if there is any residual function. Approaching a child with hearing loss and restricted visual fields from the side can cause adverse reactions. Always address the child with DSL by name. Appreciate the cognitive age. Look directly at the child in an appropriately lit room so he can see your face and articulate carefully. Do not speak too fast. Playing music for comfort or singing and making noises to attract attention is not helpful if the child is deaf, and makes understanding more difficult for the impaired. Facial expression can be hard to interpret. In consultation with the caregiver, tactile communication can be used in completely deafblind children.

"My little girl tells me she sees strange things"

Göran Darius Hildebrand

Introduction

Unusual visual experiences are not rare in children, but are often difficult to interpret due to the difficulty for the child to express the peculiar sensation. Most complaints will be of a benign and usually transient nature requiring only reassurance. However, a visual complaint may have a more significant meaning, indicating a serious underlying disorder. It is important to take the child's and parents' complaint seriously and to approach its evaluation systematically.

A short mnemonic may help when dealing with such cases. "OSCE" stands for:

O-ptical (refractive, optic media);

S-ensory (visual pathway);

C-erebral (neurologic, psychologic/functional, psychiatric);

E-fferent (motor, e.g. nystagmus, superior oblique neuromyokymia, or accommodative spasm) causes.

This should ensure that the evaluation of the problem is complete (Table 100.1). An appropriate history should be taken, followed by a clinical examination. Ancillary investigations and referral to other specialists may be required (Box 100.1). A definitive diagnosis is not always reached (Fig. 100.1). Remember that even apparently bizarre symptoms can arise from organic disease (Fig. 100.2).

Below the complaints are divided into individual visual symptoms and ranked from common to rare. There are excellent reviews of this subject.[1–8]

Entoptic phenomena

Entoptic phenomena are visual perceptions arising from sources within the eye rather than the outside world. Most are harmless phenomena that are usually either not perceived or ignored but that may be noticed by a bright young child. They are noticed under special viewing or light conditions. Most people will have experienced some of them at some point in their life. Clinicians use them to assess the presence of gross retinal and optic nerve visual function when no direct fundal view is possible due to dense media opacities. Children with very poor sight due to retinal causes will often rub and poke their eyes to stimulate entoptic phenomena (oculodigital sign; see Chapter 62).

Scheerer (*or blue field entoptic*) *phenomenon* consists of seeing tiny bright spots that rapidly move in squiggly lines, especially when looking into the bright clear blue sky or an open field of snow. They are thought to be due to the movements of white cells in the capillaries near the macula. Blue field entoptoscopy has been used to measure retinal capillary flow.

Most children with normal vision will notice *Purkinje trees*, which are images of their own retinal circulation. They are best seen when a bright light is shone through the closed eyelids, when the retinal vessels cast a shadow on the unadapted, underlying photoreceptors.

Other harmless entoptic phenomena include Purkinje blue arcs, Haidinger brushes, light diffraction through eye lashes, as well as floaters, photopsia, and phosphenes.

Photopsia and phosphenes

Phosphenes and photopsia are brief entoptic phenomena. Phosphenes can be induced by mechanical (eye rubbing, sneezing), electrical, and magnetic stimulation of the retina and visual cortex as well as by the spontaneous firing of retinal cells. *Pressure phosphenes* consist of seeing colors and lights with eye rubbing. *Flick phosphenes* are flashes of light that are seen during eye movements, especially when the retina is dark-adapted and the lids are closed. *Accommodative phosphenes of Czermak* occur with sustained accommodative effort and may be due to ciliary muscle traction on the peripheral retina.

Photopsia and phosphenes may also be pathologic and associated with several important pathologies of the retina (retinal traction, tear, detachments, retinal inflammation, outer retinal disease), the optic nerve (optic neuritis, papilledema), or the brain (typically migraine). In the anterior segment, irritating reflections, glare, and dysphopsia may be caused by corneal pathology, cataracts, the edge effect of a dislocated or scratched intraocular lens, or posterior capsular opacification. Thorough examination, especially of the peripheral retina, is indicated to exclude potentially sight-threatening pathology.

Floaters (myodesopsia, mouches volantes)

At birth, the tertiary vitreous is perfectly transparent. *Myodesopsia* is the perception of a floater caused by imperfections or deposits within the vitreous body that cast a moving shadow on the retina. Floaters have been likened to "flying flies" (synonyms: *mouches volantes* in French or *muscae volitantes* in

Table 100.1 Systematic approach to children who complain of seeing peculiar things

Mnemonic "OSCE"	
O-ptical	Refractive Optic media (red reflex)
S-ensory (visual pathway)	Anterior segment Posterior segment Optic nerve, chiasma, optic tract, visual cortex

Box 100.1

Overview of diagnostic management

History
Sensory assessment
- Visual acuity
- Color vision
- RAPD
- Amsler grid
- Visual field test (confrontation if young)

Optical media and refraction
- Red reflex/Brückner test
- Refraction

Ocular exam
- Examination of anterior segment
- Examination of posterior segment

Motor
- Hirschberg corneal reflex
- Cover and alternating cover test
- Extraocular movements (pursuit, saccades, convergence)
- Accommodation

Investigations
- Corneal topography (in keratoconus)
- Ocular imaging (OCT, AF, FFA, ultrasound)
- Neuroimaging (MRI, CT)
- Electrodiagnostic testing (ERG, VEP, EEG)
- Referral (pediatrician, neurologist, psychologist)

AF, Autofluorescence; CT, computed tomography; EEG, electroencephalography; ERG, electroretinography; FFA, fluorescein angiography; MRI, magnetic resonance imaging; OCT, optical coherence tomography; RAPD, relative afferent pupillary defect; VEP, visual evoked potential.
See also Chapters 7, 9 and 10.

Latin). The floater is most noticeable against a uniform, bright background and when it comes closest to the retina. Unlike a scotoma, which is fixed in space, a floater comes and goes and moves from second to second.

Most floaters are entirely harmless, albeit annoying, and require reassurance only. These are due to normal degenerative changes in the vitreous (vitreous syneresis, uncomplicated posterior vitreous detachment, Weiss ring) and become ubiquitous with increasing age, affecting myopes earlier than emmetropes. Occasionally, they are caused by asteroid hyalosis, synchysis scintillans, or a persistent primary vitreous remnant in Cloquet's canal, which are of no further consequence.

However, new floaters may be of concern, especially if associated with photopsia, a shadow, or reduced vision. This always warrants an ophthalmologic examination to exclude a retinal tear, retinal detachment, vitreous hemorrhage, or uveitis.

A visual sensation similar to a vitreous floater may be seen with precorneal tear film abnormalities (dry eye, meibomian gland dysfunction, foreign body), but can easily be differentiated from these by the clearing effect of blinking, the associated external symptoms of ocular irritation, and by ocular examination.

Fig. 100.1 This 9-year-old boy complained of constantly seeing a color grid in front of both eyes. Five months later, the color grid in one eye persisted, but changed to constant black and white vision in the other eye. He has no history of seizures or systemic illness or trauma. He is a well-adjusted boy who likes school. His ocular and neurologic examination and all his investigations, including brain magnetic resonance imaging and electrodiagnostic testing (electroretinography, visual evoked potential, and electroencephalography), have remained normal.

Benign blurred ("fuzzy") vision

Children will frequently complain of their vision being "fuzzy" or "blurry." The most common cause will be an unrecognized refractive error. Other frequent causes include intermittent or constant strabismus, amblyopia, afterimages after looking at bright light, entoptic phenomena, tear film, and conjunctival or corneal abnormalities (e.g. dry eye, unstable tear film with meibomian gland dysfunction).

Transient loss of vision

Important *non-ischemic* causes of transient visual loss include *migraine* (associated with nausea and headaches and photopsia/teichopsia), *ictal/postictal visual loss* in epilepsy (may be associated with motor, sensory, autonomic signs, or automatisms), *visual obscurations* in papilledema (associated with symptoms of raised intracranial pressure that are worse with postural change and Valsalva maneuvers), *optic neuritis*

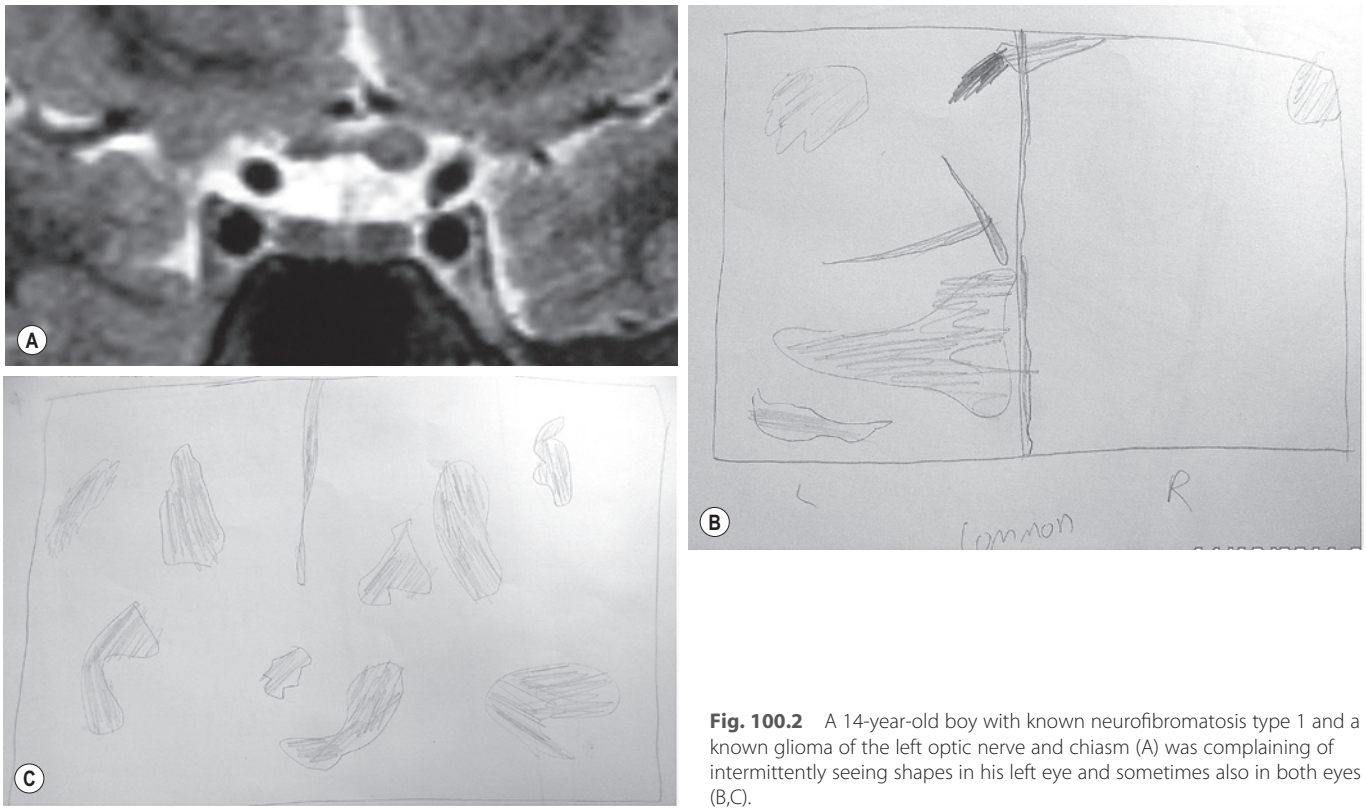

Fig. 100.2 A 14-year-old boy with known neurofibromatosis type 1 and a known glioma of the left optic nerve and chiasm (A) was complaining of intermittently seeing shapes in his left eye and sometimes also in both eyes (B,C).

(associated with discomfort with eye movements and recent infections/immunizations in children), *Uhthoff phenomenon* in optic neuropathy (loss of vision associated with rising body temperature, e.g. in a hot shower), *post-traumatic transient cerebral blindness* (associated with occipital lobe injury), *gaze-evoked amaurosis* due to transient compression of the intraorbital optic nerve or ophthalmic artery (associated with eye movements), transient *intraocular pressure* rise, poor diabetic control, *intraocular inflammation*, and *hemorrhages*.

Ischemic causes include hypertension/hypotension, cardiac (arrhythmia, septal defects), arterial (dissection, aneurysmal, vasculitis, moyamoya disease, vasospasm), and prothrombotic and rheologic/hematologic (polycythemia, leukemia) disorders, all of which require urgent pediatric referral.

Movement illusions (oscillopsia and Pulfrich phenomenon)

Visual perception of movements may be motor, sensory, or cerebral in origin. Motor causes are *oscillopsia* due to either *nystagmus*, in which case it tends to be acquired, or *superior oblique myokymia*. In superior oblique myokymia, the oscillopsia is monocular and vertical and/or torsional. The diagnosis is made by making the patient look into the field of action of the superior oblique and looking for brief saccadic movements on ophthalmoscopy. *Eyelid myokymia* are involuntary and usually harmless lid contractions that are differentiated from true oscillopsia by history and examination.

A sensory cause is the *Pulfrich phenomenon*, caused by delayed conduction in optic neuropathy. The stereoscopic effect is a result of the retinal disparity cue caused by the latency disparity between the two optic nerves. This can be tested by swinging a ball in a line perpendicular to the subject from side to side. Instead of seeing the object swing from side to side, the patient perceives an elliptical movement in a horizontal plane.

Epileptic kinetopsia is an ictal illusory perception of motion seen in temporal lobe epilepsy.

Color (dyschromatopsia)

Loss of color vision is physiologic under scotopic light conditions due to the relative insensitivity of cones compared to rods ("all cats are gray in the dark").[9] Children may describe colorful afterimages after looking at a bright object, which persist for a while, even when closing both eyes. A clear history and a simple explanation will reassure the child and parents.

True *dyschromatopsia* is a disturbance in color vision. Congenital color blindness is the most common cause for dyschromatopsia. Deuteranomaly affects approximately 5–8% of boys, but only 0.4% of girls. Commonly, this is noticed by others rather than the child, for example when observing the child naming or drawing objects' colors incorrectly or during vision screening at school. Acquired dyschromatopsia is common with media changes (e.g. cataract, vitreous hemorrhage), optic nerve disease (e.g. optic neuritis), and, less often, with retinal and macular disease (e.g. retinal and macular dystrophies). *Köllner's rule* pertains to the causes of acquired color vision loss and states that diseases of the outer retina (e.g. in macular disease) typically result in blue–yellow color defects, while disorders of the inner retina, the optic nerve, and beyond tend to cause red–green color loss; however,

important exceptions to this general rule include blue–yellow deficits in glaucoma and dominant hereditary optic atrophy, red–green deficits in Stargardt disease, and mixed red–green and blue–yellow deficits in optic neuritis. Relative bitemporal red desaturation on confrontation is an early clinical indicator of compression of the optic chiasm. Cerebral causes of color loss are rare (cerebral achromatopsia).

Seeing multiples (monocular diplopia, triplopia, and polyopia)

A child may use "seeing double" to simply express visual blur or shadowing around an object rather than true diplopia. A bright child noticing physiologic diplopia in front of or behind a fixation point is not an uncommon cause of referral. Most pathologic diplopia is binocular due to ocular misalignment. In patients with chiasmal disease and strabismus, complete bitemporal field loss can result in the slide phenomenon, diplopia, or central visual field loss. The hallmark of binocular diplopia is that the double vision disappears under monocular cover. True monocular diplopia and polyopia, however, persist under monocular conditions. Most monocular diplopia is due to an abnormality of refraction, the precorneal tear film, corneal pathology, cataract formation, lens dislocation, polycoria, or rarely a retinal cause. Cerebral causes of diplopia and polyopia are very rare and often associated with other defects (e.g. visual field) and are discussed in the section on visual perseveration, below.

Size (micropsia, macropsia, teleopsia, lilliputianism)

Objects may appear abnormally large (*macropsia*), far away (*teleopsia*), or small (*micropsia*) (Fig. 100.3). In *lilliputianism*, people appear to be very small. Simple benign global micropsia is an isolated complaint, affecting children mostly at school age. It may be associated with prior reading at night and resolve spontaneously after some months. Micropsia of macular origin is associated with reduced or distorted vision. Cerebral causes include migraine and, less frequently, epilepsy and infections.

If the micropsia is isolated and present in an otherwise healthy child with no distortion of reality or hallucinations, full visual fields, and normal orthoptic and ocular findings, clinical observation is reasonable. In all other cases or where symptoms do not resolve, investigations (pediatric assessment, infective screen, neuroimaging) are indicated.

Distortion (dysmetropsia, metamorphopsia, and "Alice in Wonderland" syndrome)

Dysmetropsia and metamorphopsia are related visual illusions where object shapes appear distorted and straight lines bent. Metamorphopsia is best assessed with an Amsler grid. Even relatively young children will be able to say whether the lines are straight or not and report "funny lines." Visual distortions are either optical (common), macular (occasional), or cerebral (rare) in origin. Optical causes include high corneal, lenticular, or retinal (staphylomatous) astigmatism, high ametropia, anisometropia, and new glasses. Macular causes include macular edema and choroidal neovascularization (e.g. associated with myopic Fuchs maculopathy, inflammatory ocular disease, and macular dystrophies). Rarely visual distortion is of cerebral origin, as in the "Alice in Wonderland" syndrome. A cerebral cause is likely to be accompanied by other neurologic symptoms and signs.

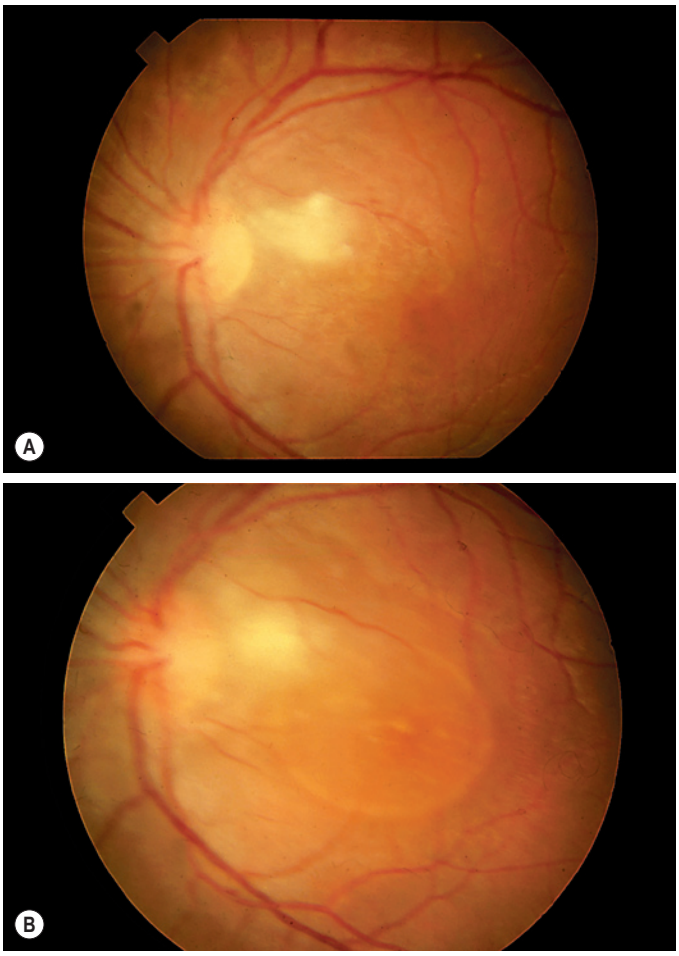

Fig. 100.3 Neuroretinitis with micropsia. This 9-year-old girl complained of dullness of vision in both eyes and smallness of objects with distortion on the left. (A) The white area temporal to the optic disc represents retinal nerve fiber swelling and vascular leakage, extending to the fovea. (B) As the retinal edema increased and extended across the macula, the acuity dropped to 6/36 and the micropsia disappeared.

If the Amsler grid confirms the presence of distortions, the management includes refraction and detailed slit-lamp examination of the anterior and posterior segments. Investigations may include optical coherence tomography or fundus fluorescein angiography with macular disease, corneal topography (if keratoconus is suspected) and neuroimaging (magnetic resonance imaging [MRI]) if a cerebral cause is suspected.

Metamorphopsia, micropsia, macropsia, and the Alice in Wonderland syndrome more commonly accompany childhood than adult migraine. Alice in Wonderland syndrome is frequently associated with migraine, but may also be due to epilepsy, drugs/medication (topiramate), varicella infection, or infectious mononucleosis.

Fig. 100.4 Picture drawn by a right-handed young person with an ultimately fatal metastatic carcinoma in the right parietal lobe. The presenting symptom was the recurrence of an image of the kitchen window that impinged itself involuntarily on the visual environment in different circumstances for several hours after the original stimulus.

Bradyopsia

Rarely, children may take excessive time to adapt to changing levels of brightness and darkness and find it difficult to track moving objects due to a defect in the photoreceptor deactivation mechanism in the phototransduction cascade. In addition to markedly delayed dark and light adaptation, the visual acuity is moderately reduced. There is mild photophobia with normal color vision and normal fundi (see Chapter 46).

Visual perseveration and other rare cerebral visual disturbances

Palinopsia is the visual perseveration of an image in time (Fig. 100.4). In the immediate type, the image persists for minutes after the true object has disappeared. In the delayed type, the image of a previously seen object reappears, sometimes for days or weeks. The picture is formed and different from afterimages created by retinal overstimulation from prolonged looking at a light, for example. In *cerebral diplopia* or *polyopia*, the visual image persists in space and two or more copies of the same image are seen simultaneously. Unlike binocular diplopia, cerebral diplopia and polyopia is monocular and is differentiated from ocular causes of monocular diplopia and polyopia by refraction followed by examination of the eye to exclude corneal pathology, lens displacement, iris defects (polycoria), or cataract. In cerebral diplopia/polyopia, each perceived image is equally clear, pinhole viewing has no beneficial effect, and no difference is seen with binocular versus monocular viewing. In *illusory visual spread*, the image expands beyond the real object size. Palinopsia, polyopia, and illusory visual spread will often be seen in the context of other cerebral disturbances, such as homonymous visual field defects. In *cerebral akinetopsia*, any perception of motion is completely lost due to bilateral cerebral lesions. *Visual disorientation* and *simultanagnosia* is the ability to interpret individual parts of a picture, but not the totality of the image seen and is part of *Balint syndrome*.

Visual disturbances associated with migraine

Children with migraine can have a large spectrum of visual disturbances, classically visual hallucinations with enlarging scintillating scotomas and fortification patterns (*teichopsia*) or simple unformed light flashes (*cerebral photopsia*). Visual field loss (e.g. hemianopia) is a wellrecognized complication. Visual illusions of micropsia, macropsia, metamorphopsia, and Alice in Wonderland syndrome are associated with migraine. Other reported visual disturbances in migraine include palinopsia and polyopsia. Rarely, complex visual hallucinations containing people or animals (*zoopsia*) and out-of-body experiences may be experienced in which the migraineur views his own body (*autoscopy*). Other rare disturbances are complete achromatopsia (cerebral color loss), prosopagnosia (no recognition of faces), and visual agnosia (no recognition of objects).

Hallucinations

Hallucinations are sensory perceptions generated by the mind *sui generis* in the absence of true external stimulation (Fig. 100.5). Illusions are misinterpretations or distortions of existing external stimuli.

Hallucinations in darkness and with social deprivation

Non-formed random noise of tiny lights and dark points are seen with eye closure or in complete darkness (*closed-eye hallucinations and visualizations*). *Eigengrau* (German for "intrinsic gray") or *Eigenlicht* (German for "intrinsic light") is the gray or light seen in perfect darkness as a result of baseline intrinsic retinal electrical activity. The *Ganzfeld effect* describes visual hallucinations caused by prolonged staring into a featureless field of vision or field of color. Prolonged *sensory deprivation* in darkness (e.g. at night or in a dark room) may give rise to hallucinations of formed light of different colors or even human figures.

Charles Bonnet syndrome (visual release phenomenon)

Visual hallucinations may be release phenomena.[10] Visual hallucinations associated with visual loss in a lucid person who realizes that the hallucinations are not real are called Charles Bonnet syndrome. They can occur after simultaneous or sequential, not necessarily complete, bilateral visual loss (Fig. 100.6) due to any cause in the visual pathway (e.g. dense cataracts, macular, optic nerve, or cortical disease, after enucleation). The hallucinations are typically vivid, formed, and complex (often people or scenes), filling in the blind scotoma. The hallucinations are strictly visual (e.g. people do not speak in the hallucinations). They represent release visual phenomena caused by the loss of cortical stimulation after

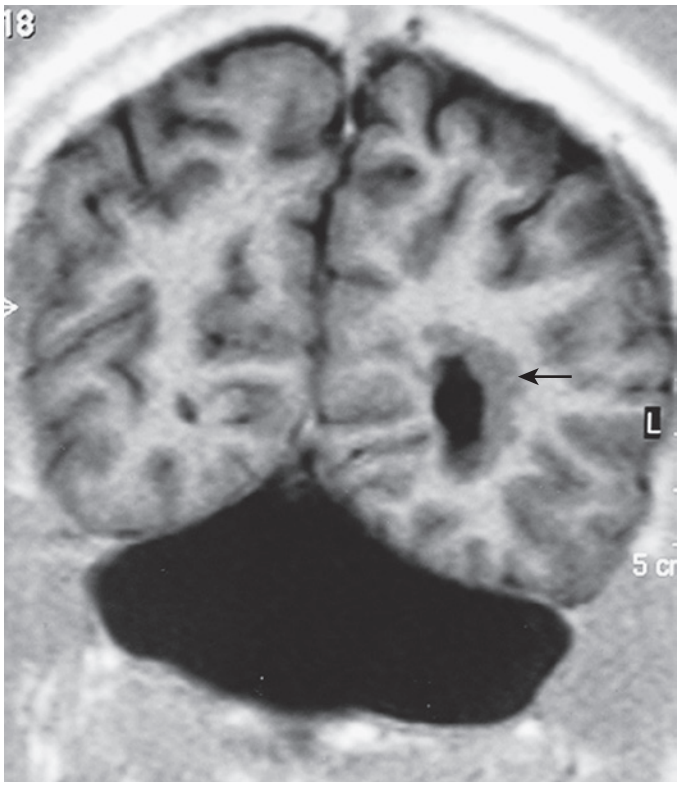

Fig. 100.5 This boy with a Möbius-like syndrome started, at the age of 18, to get unformed hallucinations in the right half of his visual field accompanied by nausea followed by sleepiness, without seizures. The magnetic resonance imaging shows an area of dysplastic ectopic gray matter in the left posterior parieto-occipital region (arrow).

visual loss and are potentially reversible (e.g. after successful cataract surgery). Many patients may be understandably very reluctant to admit to these hallucinations. The individual is typically relieved, once reassured of their true nature.

Hypnagogic and hypnopompic hallucinations

Visual hallucinations at sleep onset (hypnagogic) and on awakening (hypnopompic) are normal, but a child with daytime somnolence should be investigated for narcolepsy if hypnagogic hallucinations are associated with sleep attacks, cataplexy, or sleep paralysis.

Occipital and temporal lobe epilepsy

Another important cause of hallucinations is occipital and temporal lobe epilepsy (rarely parietal lobe). Visual hallucinations tend to be simple (photopsia, white phosphenes, steady colored lights) with occipital lobe epilepsy, and more often complex (e.g. faces, people) with temporal lobe epilepsy. Visual seizures will often be accompanied by other ictal signs, such as focal motor seizures, automatisms (e.g. lip pursing, chewing), and sensory (e.g. olfactory hallucinations) and autonomic changes (e.g. pupillary changes, salivation, urinary incontinence). Occipital lobe epilepsy with visual hallucinations only may be difficult to differentiate from acephalic migraine with visual aura.

Benign childhood epilepsy with occipital epilepsy is an idiopathic epilepsy syndrome in children of school age that ceases spontaneously when they become teenagers. The seizures are associated with simple or complex visual hallucinations (or transient visual loss), may progress to motor or partial complex seizures, and be followed by postictal headaches similar to migraine. Electroencephalography (EEG) is diagnostic and pharmacologic treatment is available.

Peduncular hallucinosis

In this rare syndrome, vivid, colorful, kaleidoscopic images, geometric patterns or elaborate pictures of landscapes, flowers, animals or even human beings are seen. The pathology typically involves the midbrain and may be associated with other signs of midbrain disease as well as sleep and cognitive disturbances.

Drug-induced hallucinations

Visual hallucinations and illusions may be caused by medication (e.g. steroids, lamotrigine, cyclosporin, digoxin, sildenafil [for pulmonary arterial hypertension], gancyclovir, vincristine, lidocaine, itraconazole, lithium, levodopa), its withdrawal (e.g. barbiturates in epileptic children, baclofen), anesthetics (ketamine), eye drops (idiosyncratic response to atropine and cyclopentolate), alcohol, as well as hallucinogens (e.g. LSD, phencyclidine [PCP], cocaine, marijuana).

Psychogenic ("functional") visual loss

Psychogenic, or "functional," visual loss is not uncommon in children. The estimated incidence is 1.4/1000 per year. It is more common in girls, clustered in immediate prepuberty and puberty teenage years. It should be suspected when an unexplained discrepancy exists between purported subjective visual loss and objective findings, or when reported visual findings are optically or physiologically contradictory (see Chapter 63). It is a diagnosis of exclusion. Some children with an element of psychogenic visual loss will also be found to have an underlying organic disease with time. The manifestations can be diverse and range from purported total loss of vision to relatively unusual visual experiences. Some children clearly are pretending, but most affected teenagers appear genuinely affected. Brodsky has classified these into four groups:

group 1: the visually preoccupied child;
group 2: conversion disorder;
group 3: possible factitious disorder;
group 4: psychogenic visual loss superimposed on true organic disease.

Medical conditions

Visual hallucinations and illusions may be seen in a number of medical conditions, including febrile delirium, encephalitis, and encephalopathy from metabolic disease. Urgent medical referral is required in the management of these cases.

Psychiatric disease

Hallucinations, in which all insight into the false nature of the perception is lost, are part of psychosis, a profound thought disorder in which the individual loses the control over his

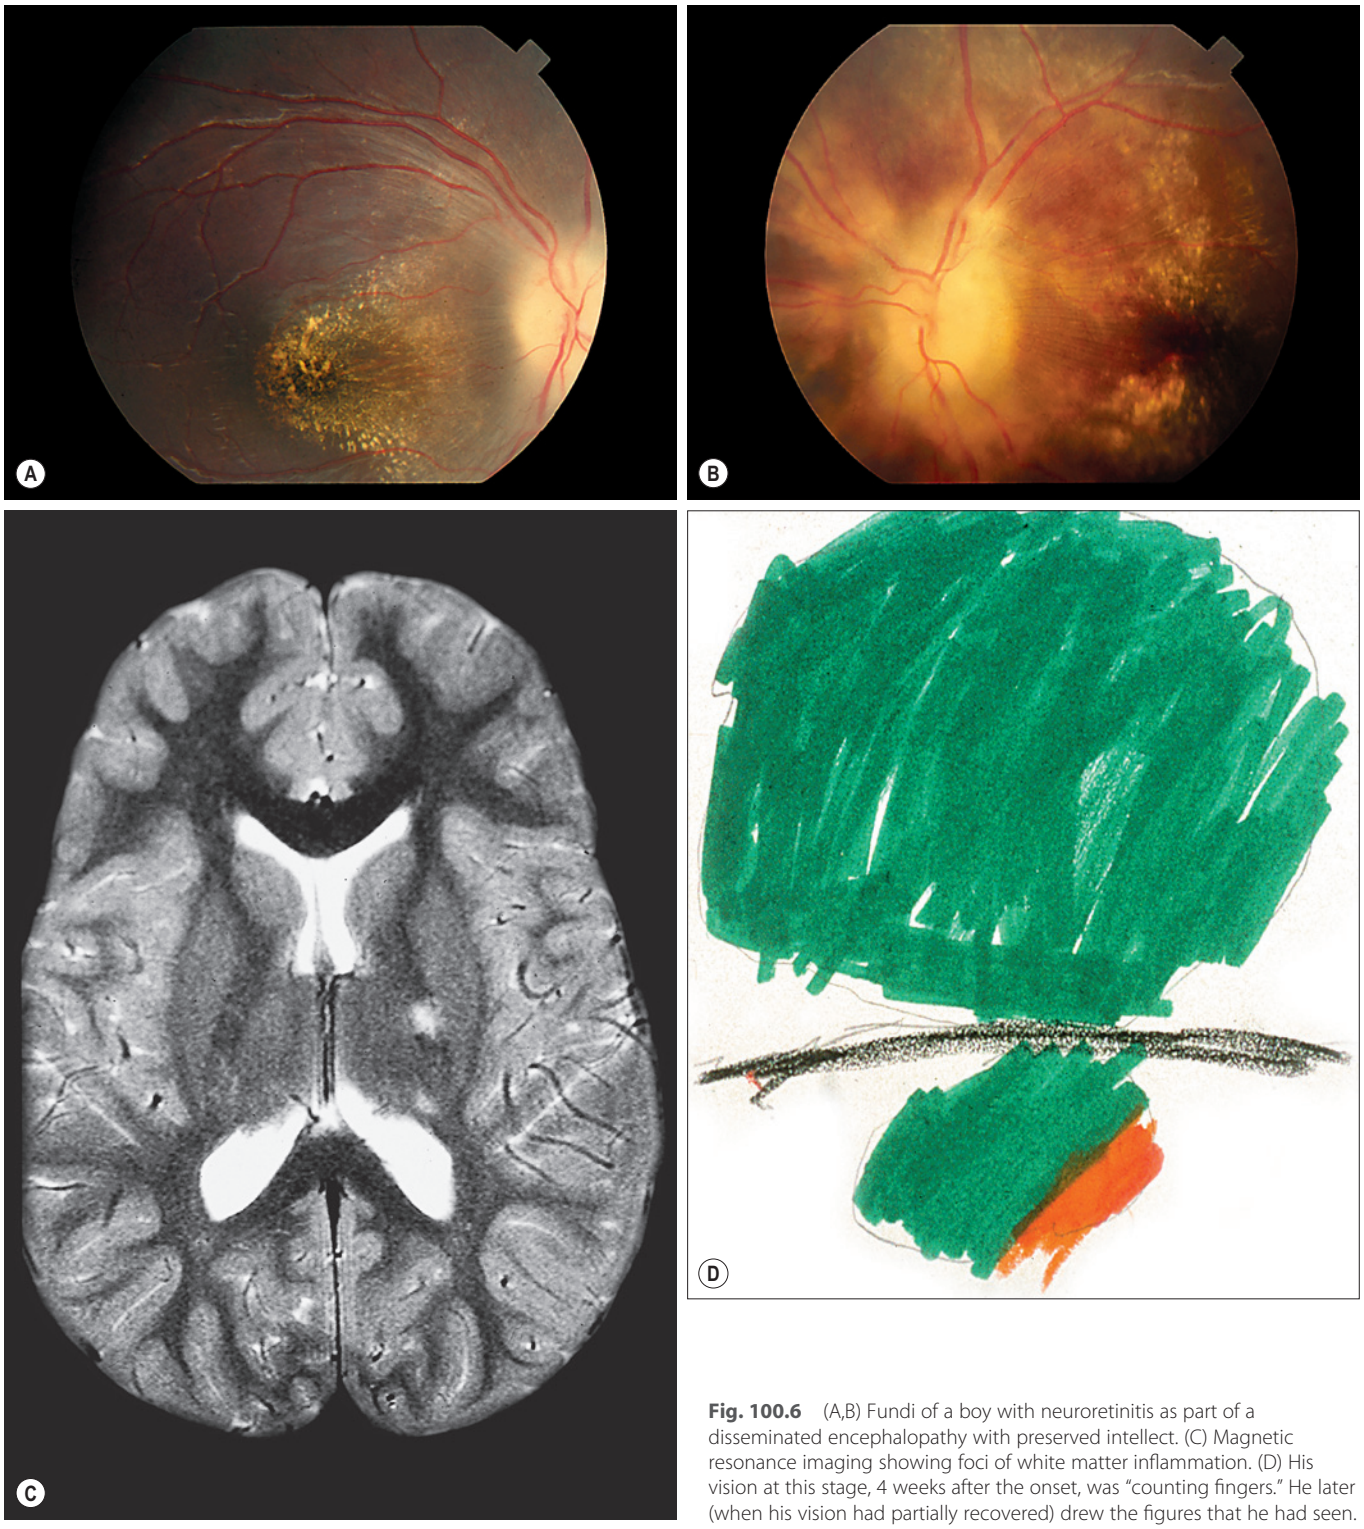

Fig. 100.6 (A,B) Fundi of a boy with neuroretinitis as part of a disseminated encephalopathy with preserved intellect. (C) Magnetic resonance imaging showing foci of white matter inflammation. (D) His vision at this stage, 4 weeks after the onset, was "counting fingers." He later (when his vision had partially recovered) drew the figures that he had seen.

sense of reality. Unreal voices and visions become real. Often frightening visual and acoustic (hearing voices) hallucinations are associated with delusional beliefs, bizarre behavior, and a general decline in self-care as part of this grave thought disorder. Recognizing a teenager with frank psychosis (not infrequently following the consumption of illicit drugs) is usually not challenging. Urgent referral to a psychiatric team is indicated due to the substantial risks of harm to the affected individual and others.

Psychiatric patients can have genuine visual problems as well. One should therefore take the psychiatric patient with visual complaints seriously if his/her complaint is persistent and consistent after the mental state has stabilized. The author recalls being asked to see a young psychiatric inpatient that

said that he could neither read well at near nor see people in the distance. His psychiatrist was doubtful of any organic basis to this, but referred him: he had marked keratoconus!

Wobbly eyes in infancy

Narman Puvanachandra

Below is a guide on how to differentiate the main types of nystagmus seen in children. But first, a brief summary of each group

Infantile nystagmus syndrome (INS)

This group includes:

- sensory nystagmus: with identifiable cause;
- idiopathic nystagmus (previously motor nystagmus), where vision is often good and no sensory cause can be found. Nystagmus in this group tends to be early onset before 3 months of age, uniplanar horizontal (but may have rotational and rarely vertical components), dampens on convergence, but worsens on attempted fixation and stress. Null points are often present.

Fusional maldevelopment nystagmus syndrome (FMNS)

Disorders in this group, which includes manifest latent nystagmus with strabismus, typically have infantile esotropia or exotropia. They are associated with dissociated vertical deviation (DVD) and a large latent component to the nystagmus. Some may have nystagmus blockage syndrome.

Spasmus nutans (SN)

A much rarer form of nystagmus, with high frequency, small amplitude dysconjugate nystagmus along with head nodding and head tilt. Most cases are early onset, but after 6 months of age, and have a benign recovery over years. A similar triad may be rarely seen with intracranial tumors, especially of the visual pathway. Imaging is warranted in children with onset after infancy and with other neurological signs.

Neurological nystagmus (NN)

This group includes all the other acquired nystagmus and is associated with later onset after 3 months and nystagmus atypical of INS. Neurological signs may be present, and further urgent investigation, in collaboration with pediatric neurologists, is required. It may be associated with a previous central nervous system insult, drugs, neurological or metabolic disease.

Nystagmus-like saccadic disorders, e.g. opsoclonus, ocular flutter

This comprises a range of erratic non-sustained non-repetitive movements that warrant further investigation as a general rule. Opsoclonus – "dancing eyes," for example, may be associated with neuroblastoma.

Here are some clues on how to assess and differentiate these types of nystagmus:

The history

Many important elements in the history can point to the etiology of the nystagmus, helping the clinician to advise the parents and guide investigations:

Prenatal insults Was there maternal diabetes, drug or alcohol ingestion in pregnancy?

Perinatal insults Was there any hypoxic insult, traumatic birth, or prematurity?

Development Does the child have global developmental delay, cerebral palsy, or other medical disorders, e.g. epilepsy, neurological or metabolic conditions?

Drug history Is the child taking drugs such as anti-convulsants?

Onset of nystagmus Was onset before 3 months of life? (If so, this is typical of INS rather than acquired NN, where onset is typically after 3 months of age.)

Visual response Do the parents feel the child looks at them? Poor visual response points to sensory INS, although can also be seen in acquired NN if visual pathways are significantly affected.

Pattern of nystagmus waveform over time Many parents state that the nystagmus was wide and roving to start with, becoming pendular and of smaller amplitude before ending up as rapid jerk nystagmus. This pattern is typical of INS.

Oscillopsia Does the older child complain of the world shaking? This is more typical of acquired NN, although can be intermittent in INS.

Family history Is there a family history of ocular disease such as retinal dystrophy, albinism, aniridia, congenital cataracts, idiopathic INS, neurological or metabolic diseases?

Observation by parents and clinician

The observations that parents make about their children over time and the clinician's observations prior to examining the child can prove useful.

Strabismus Is there a large-angle esotropia or exotropia present that appeared by 3 months of age? This suggests FMNS.

Head nodding Did the parents notice a tendency for head nodding, especially early after onset of the nystagmus? Does the child appear to see better when they nod (part of the triad of spasmus nutans).

Corrected head posture Does the child adopt a specific head posture? This is seen mainly in idiopathic INS, although it can be seen in SN.

Photophobia Exaggerated dislike of bright light may point to several pathologies such as achromatopsia, aniridia, cataract, Leber congenital amaurosis, and albinism, all causing sensory INS.

Observation of the nystagmus

The type of nystagmus may be distinguished from observation of the nature of the nystagmus and its variation:

Bilateral/unilateral True monocular nystagmus onset after 3 months of age is associated with unilateral reduced visual acuity in the context of optic nerve or chiasmal glioma. However, more commonly it is seen in strabismic amblyopia.

Direction INS tends to be horizontal but can have additional vertical and horizontal components. It is rarely purely vertical or rotational. This directional pattern rarely changes significantly over time in INS.

Amplitude Large amplitude nystagmus is associated with poorer vision, although this can vary from visit to visit and even during a single consultation.

Foveation period The longer this period is of relative stillness before the slow phase restarts, the better the vision generally is.

Latent component Increase in amplitude on covering one eye is seen in FMNS and INS. In FMNS, the nystagmus reverses in each eye with the fast phase away from the occluded side.

Assessment of vision

- Binocular vision is key; it is the most reliable due to the latent component of nystagmus that accompanies both FMNS and INS.
- If uniocular vision is attempted, then fogging one eye with a high plus lens is more accurate.
- Value the parents' opinion about vision, as they often see the child in a less stressful environment where they may perform better.
- Visual acuity measurements can vary significantly from visit to visit due to variation in the child's emotional stress, age, test, and tiredness.
- Near vision is often better than distance vision due to the dampening effect of convergence.
- Typically, vision of 6/6 to 6/24 is seen in idiopathic INS, while vision of 6/24 or worse is more usual in sensory INS.
- Color vision problems in the older child can point towards abnormal cone function.
- Lack of stereopsis in the older child can indicate FMNS, even in the absence of large-angle strabismus.
- Use of an optokinetic (OKN) drum can help establish if vision is present despite nystagmus. Reversal of the OKN response with the fast phase in the direction of the drum movement is seen in INS.

Examination of the eye

Careful assessment of the eye can identify causes for sensory INS.

Microphthalmia or, indeed, buphthalmos Developmental abnormalities of the eye or congenital glaucoma can lead to sensory nystagmus.

Media Bilateral opacity occluding the visual axis, such as corneal clouding, congenital cataracts or persistent fetal vasculature can cause sensory nystagmus.

Pupils Sluggish pupillary light reflexes indicate either aniridia (partial or complete) or profoundly decreased vision, e.g. Leber congenital amaurosis or optic nerve hypoplasia.

Iris Transillumination of the iris can be florid or subtle in albinism. Placing the baby at the slit-lamp in the "superman" position can often reveal even subtle transillumination defects.

Retina Severe bilateral macular pathology, e.g. toxoplasmosis scars, chorioretinal colobomas, foveal hypoplasia (typical of albinism), may be evident. Optical coherence tomography in the older child can help confirm the presence of foveal hypoplasia.

Optic nerve Optic nerve hypoplasia or pallor are sensory causes that are easily missed. Optic nerve swelling, e.g. accompanying optic nerve tumors, can also be the cause.

Table 101.1 When and when not to consider early investigation of nystagmus in children: a rough guide

	When early investigations are not indicated	When electrophysiology may be indicated	When early neurological imaging is indicated
Type	Idiopathic INS or sensory INS with identifiable cause, FMNS	Sensory INS without identifiable cause	NN/SN/opsoclonus (include abdomen and chest)
Onset	<3 months	<3 months	>3 months
Family history	Positive family history	–	–
Visual function	Good visual function	Poor visual function	Oscillopsia noted (if verbal child)
Eye exam	Identifiable cause found	Normal exam	RAPD, optic nerve swelling or pallor
Strabismus	Large infantile esotropia/exotropia	+/–	Incomitant strabismus, e.g. sixth nerve paresis
Nystagmus Waveform	Typical INS waveform	Roving, irregular	Opsoclonus; localizing nystagmus, e.g. convergence retraction, periodic alternating, Bruns, see-saw, up- or downbeat; pure vertical/rotational nystagmus
Dampening features	Null point with corrected head posture	–	Worse on eye closure, e.g. vestibular or brainstem related
Dissociated	If monocular with clear amblyogenic cause identified	–	Monocular or very asymmetric nystagmus without amblyopia
Conjugacy	Conjugate	–	Dysconjugate, e.g. internuclear ophthalmoplegia or convergence retraction
Neurological features	None	–	Seizures, ataxia, developmental delay, myoclonus, localizing neurological signs
Eye movement recording	Increasing velocity slow phase	–	–

FMNS, Fusional maldevelopment nystagmus syndrome; INS, infantile nystagmus syndrome; NN, neurological nystagmus; RAPD, relative afferent pupillary defect; SN, spasmus nutans.

Examine the parents

Although examination of the child can sometimes be limited due to cooperation, examining both parents can be very helpful to secure the diagnosis. This is particularly the case with transillumination defects of the iris (often seen in the mother of boys with ocular albinism), partial aniridia, anterior segment abnormalities, retinal dystrophies, and dominant optic nerve atrophy.

When to investigate

Some argue that electrophysiology, neurological consultation, neuroimaging, and eye movement recordings should be performed in all cases of nystagmus. However, most clinicians lack access to some of these and sedation is often needed to achieve neuroimaging. The table above gives rough guidelines on what features should point you toward early investigations, but it is clearly important to take the whole clinical picture into consideration. Electrophysiology can be delayed in some cases and avoided altogether in identifiable sensory INS and FMNS (see Table 101.1).

Abnormal head postures in children

Stephen P Kraft

Introduction

The medical term for an abnormal head posture (AHP) is "torticollis," from the Latin "tortus" (twisted) and "collum" (neck).[1,2] Torticollis from eye-related problems is termed "ocular torticollis".[1–4] Ocular torticollis that persists long term can lead secondarily to a musculoskeletal torticollis and even scoliosis.[1,4] The assessment of AHP in a child is often multidisciplinary, involving input from pediatricians, orthopedic surgeons, neurologists, psychologists, and occupational and physical therapists.[5] It is common for an ophthalmologist to be consulted to rule out ocular causes for an AHP.

Torticollis can involve rotation of the head around any of the three main axes (Fig. 102.1).[1,2] These include:

- vertical axis: head rotated to one side away from the primary (straight-ahead) gaze direction ("yaw");
- horizontal axis: chin elevated or depressed relative to the primary position ("pitch");
- anteroposterior axis: head tilted to one shoulder ("roll");
- combination of two or three orientations.

Congenital torticollis is most often due to muscular or skeletal anomalies.[1,6] Ocular torticollis almost never presents within the first few weeks of life.[1,4] Trauma must be ruled out as a cause of any acquired abnormal head posture, whether as a result of damage to the neck or due to disruption of eye muscle balance.[1,6]

Non-ocular causes of head postures (see Fig. 102.1; Box 102.1)[1]

Congenital disorders

Congenital muscular torticollis (CMT) is the most common type of birth-onset torticollis, caused by a painless, discrete "fibroma" on one side of the neck adjacent to the sternocleidomastoid muscle.[2,3,5,6] Other congenital causes include postural torticollis from an abnormal fetal position, and skeletal or osseous abnormalities in the cranial junction or cervical spine, such as Klippel–Feil syndrome.[6]

Acquired disorders

Acquired disorders include traumatic and non-traumatic causes. A traumatic cause, involving damage to bones, ligaments, muscle, or soft tissue, must be considered in any case of pediatric torticollis.[1,6]

Non-traumatic causes include skeletal or osseous pathology, postural torticollis produced by prolonged maintenance of the head in an awkward position, neurologic problems localized to the posterior fossa and spine, or associated with dystonia or medications, otolaryngologic diseases of the nasopharynx or inner ear, deafness, gastroenterologic illnesses, and psychologic disturbances.[1,6]

Specific note should be paid to a triad of photophobia, epiphora, and torticollis, which can be associated with posterior fossa lesions.[7] In addition, the "ocular tilt reaction," a triad of vertical divergence of the eyes, bilateral ocular torsion, and head tilt, is a postural reflex originating in the otolithic apparatus. It can be caused by lesions of the vestibular nucleus or its central connections.[8]

Ocular causes of head postures

The ophthalmologist's goal is to determine whether there is an ocular cause for the posture. If so, treatment can be planned to eliminate or reduce the problem, and restore a normal head posture.[9]

Ocular torticollis arises from disturbances in the input from the afferent visual pathway, ocular motor nerves, or the vestibular apparatus, leading to alterations in the normal balance of inputs to the neck muscles.[1,8] The posture may achieve one of several goals[1]:

1. optimize visual acuity (e.g. infantile nystagmus with an eccentric null zone);
2. maintain single binocular vision (e.g. incomitant strabismus);
3. center a narrowed visual field with respect to the body (with hemianopic field loss);
4. enable fixation with one or the other eye, when the patient is unable to center the eye due to extreme mechanical problems in the orbit or as a result of innervational problems to the eye muscles;
5. gain miscellaneous benefits (e.g. paradoxical tilt to maximize separation of diplopic images).

Diagnostic considerations

The child must be observed for an extended period of time to determine whether the torticollis is constant in orientation

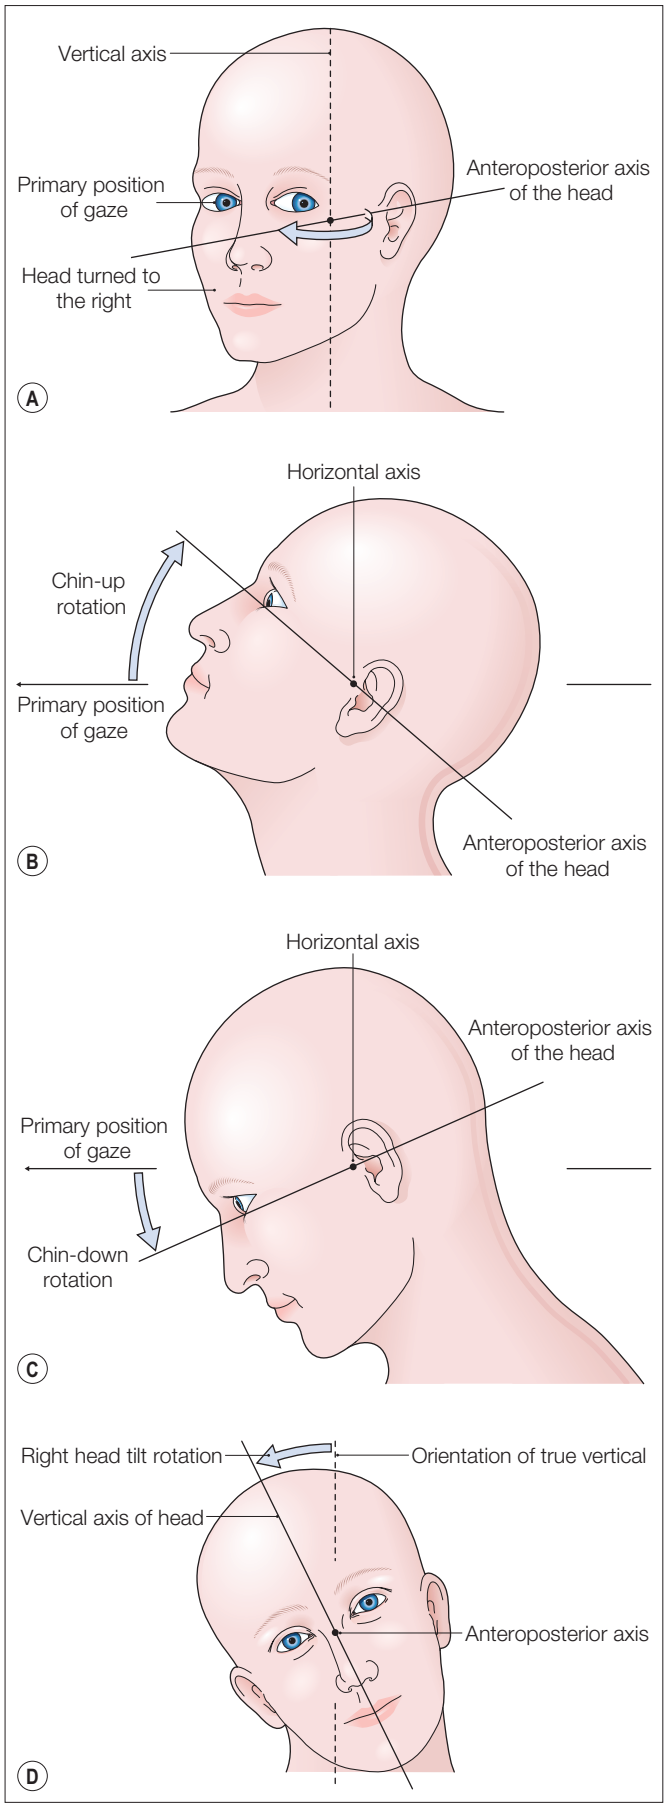

Fig. 102.1 Orientations of abnormal head postures. (A) Head turn to the right. The anteroposterior axis of the head is rotated from primary gaze direction to the right about the vertical axis. (B) Chin-up posture. The anteroposterior axis of the head is rotated upward from the primary gaze direction about the horizontal axis. (C) Chin-down posture. The anteroposterior axis of the head is rotated downward from the primary gaze direction about the horizontal axis. (D) Head tilt to the right shoulder. The vertical axis of the head is rotated away from the vertical axis about the anteroposterior axis.

         c. Pharmacologic
         d. Psychogenic/functional

or if it changes, and whether it is unchanging or is dependent on the visual task.[1,2] Abnormal physical features such as dysmorphism or manifest nystagmus may yield clues to the etiology. Photographic records or videos from the early years of life should be sought whenever possible.[1,2] To quantitate the different components, one can use an orthopedic goniometer or torticollometer.[2]

If the AHP helps maintain binocularity, then occluding one eye abolishes or reduces the magnitude of the posture.[2] Conjugate eye movements (versions) elicited early in the examination

can detect an incomitant strabismus or a nystagmus null zone. Another maneuver is to move the head into a position opposite to that adopted to expose a zone of increased nystagmus intensity or a larger heterotropia.[2] Eye movement recordings may confirm the presence of a nystagmus and the pattern of the nystagmus waveform.[10]

A common cause for vision-driven head postures is an uncorrected or partially corrected refractive error, or an incorrect prescription of glasses or contact lenses. A careful refraction is an essential: correcting a significant error may eliminate the head posture.[1,2]

Fundus evaluation can confirm cyclotropia with oblique muscle disorders or detect a sub-clinical low-amplitude nystagmus. In cases where strabismus or nystagmus do not seem to be causative factors, it is helpful to perform visual field testing to identify a field defect.[2] Finally, palpation of the neck muscles and passive straightening of the head can help detect congenital muscular torticollis.[1,2,5]

Causes of ocular torticollis (Fig. 102.2)

Uncorrected refractive errors, or incorrectly prescribed lenses, as well as nystagmus with an eccentric null zone can be causes of any orientation of head posture.[1,2] The additional etiologies specific for the various head positions are[1]:

Head turn

1. Incomitant strabismus: Innervational and/or orbital mechanical disorders in one both eyes leading to a worsening horizontal or vertical heterotropia in the field of gaze ipsilateral to the turn.
2. Comitant strabismus: An extreme exotropia or esotropia whereby neither eye can fixate in primary position.
3. Conjugate eye movement deficit (bilateral gaze palsy).
4. Contralateral complete homonymous hemianopia.
5. Miscellaneous causes – including spasmus nutans, periodic alternating nystagmus, eccentric fixation, oculomotor apraxia, and "heavy eye" syndrome with high myopia.

Chin-up

1. Incomitant strabismus: Innervational and/or orbital mechanical disorders in one or both eyes leading to a worsening vertical heterotropia in the upgaze field.
2. "A" pattern esotropia or "V" pattern exotropia.
3. Ptosis of one or both upper eyelids.
4. Bilateral superior homonymous visual field deficits.
5. Miscellaneous causes – including supranuclear gaze disorders and "heavy eye" syndrome.

Chin-down

1. Incomitant strabismus: Innervational and/or orbital mechanical disorders in one or both eyes leading to a worsening vertical heterotropia in the downgaze field.
2. "A" pattern exotropia or "V" pattern esotropia.
3. Bilateral inferior homonymous visual field deficits.
4. Miscellaneous causes – including supranuclear downgaze disorders.

Head tilt

1. Incomitant strabismus: Innervational and/or orbital mechanical disorders in one or both eyes leading to a worsening vertical or horizontal heterotropia in primary position and on tilt to contralateral side.
2. Dissociated vertical deviation (DVD).
3. Cyclotropia.
4. Ocular tilt reaction.
5. Miscellaneous causes – including spasmus nutans and paradoxical head tilt.

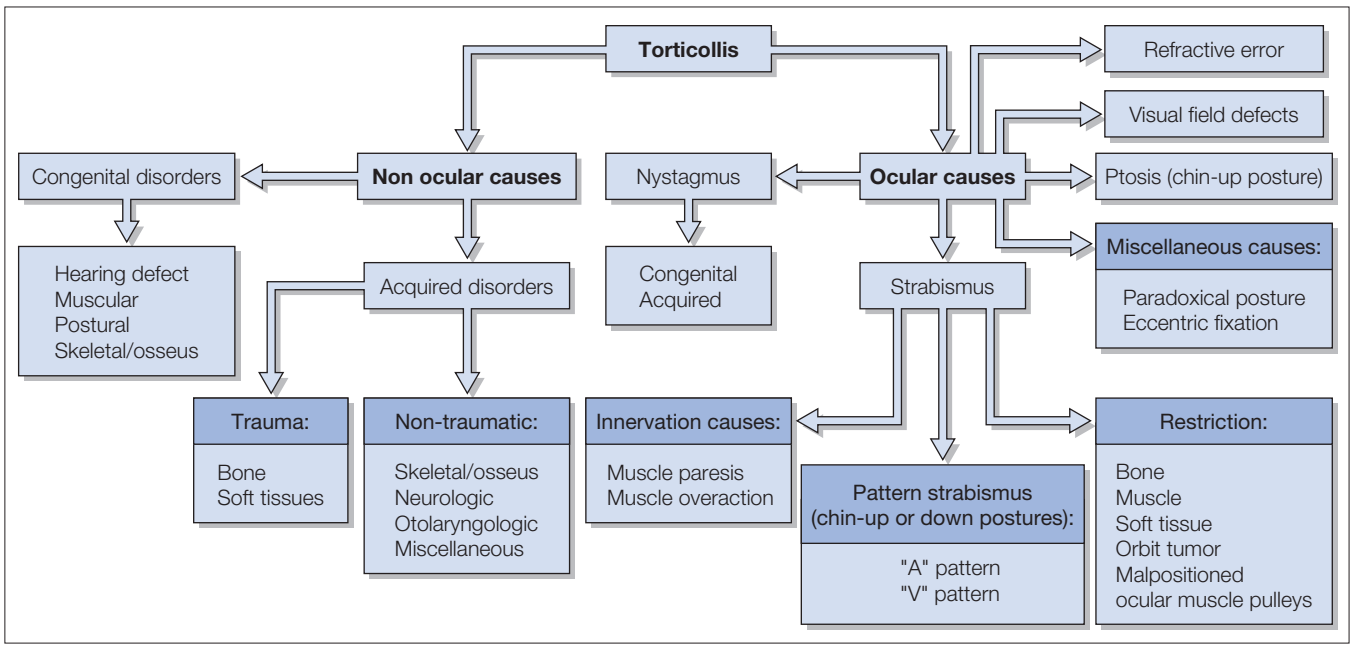

Fig. 102.2 Differential diagnosis of torticollis in children. The causes are divided into non-ocular and ocular causes (ocular torticollis). The non-ocular disorders include congenital and acquired conditions. Nystagmus, strabismus, and refractive errors must be ruled out as possible etiologies for any head posture orientation, whereas other etiologies apply to selected orientations.

Hand defects and the eye

Luis Carlos Ferreira de Sá and Chong Ae Kim

The combination of hand and eye defects is frequent and may be observed in several genetic disorders that includes chromosomal abnormalities (trisomies 21, 18, and 13) and monogenic disorders (Marfan and Cornelia de Lange syndromes, mucopolysaccharidosis, Desbuquois dysplasia, and hemifacial microsomia).[1,2]

Moreover, there are some cases in which an association of a genetic defect with environmental factors determines phenotypic abnormalities (Möbius sequence, fetal alcohol syndrome, and fetal warfarin syndrome) as well as developmental abnormalities (e.g. amniotic bands, oligohydramnios, and local vascular disruption are also associated with limb abnormalities).[1–3]

With recent advances in molecular and cytogenomic techniques, it is now possible to determine more genetic defects that lead to these anomalies, although it is not always possible to identify the underlying mechanism.

Embryology

It is important to consider the embryology of eye and hand development to understand why such defects may occur simultaneously. During the third week of gestation, at about 22 days, the optic primordium becomes identifiable in the human embryo. It is the first morphological evidence of the eyes. At 25 days, as the optic cup and embryonic fissure emerge, upper limb buds appear. By 36 days, closure of retinal fissure is almost complete and the retina is incompletely pigmented. At the same time, the hand plate has formed with condensation of mesenchyme. In the hand plate, a central carpal region is surrounded by a crescentic flange, the digital plate, from which originates the five-finger rays. At 45 days, the fingers are partially separated.

Etiology

The etiology of most limb defects (Table 103.1) is variable and, as mentioned, may include a genetic defect or an environmental factor.[1,2,4,5] It is essential to take a family history including pre- and postnatal history and to inquire about other *major* malformations (e.g. congenital cardiac defects, nervous system malformations) that may help establish the diagnosis. Furthermore, it is important to emphasize two basic concepts in monogenic disorders: phenotypic and genotypic heterogeneity. The first one refers to the clinical variability and the second happens when mutations in different genes lead to a same disorder.

Eye defects and hand/finger anomalies originate usually between the third and fifth week of gestation. The various hand and eye defects may be grouped according to their similarity in overall features, or according to one major feature among the patterns of malformation, in the same manner as Smith's Recognizable Patterns of Human Malformation.[2] Many conditions present with occasional hand and eye defects, but only the most important and consistent associations are described in Table 103.2.

Table 103.1 Common terms used for malformations of limbs and fingers

Anomaly	Definition
Arachnodactyly	Long and thin bones of the fingers
Brachydactyly	Abnormal shortness of the fingers
Camptodactyly	Permanent and irreducible flexion of fingers
Clinodactyly	Deviation or deflection of one or more fingers
Ectrodactyly	Absence of any number of fingers (split-hand or split-foot)
Macrodactyly	Abnormal largeness of the fingers
Meromelia	Absence of part of a limb
Micromelia	Shortening of all segments of a limb
Phocomelia	Absence of segment of a limb or limbs
Polydactyly	Extra digits or parts of digits
Syndactyly	Fusion of digits

Table 103.2 Disease and related eye/ocular region and hand/finger anomalies

Group/disease	Eye/ocular region anomalies	Hand/finger anomalies
CHROMOSOMAL SYNDROMES		
Down syndrome (trisomy 21)	Upslanting palpebral fissures, epicanthal folds, iris Brushfield's spots, keratoconus, strabismus, nystagmus, myopia, cataracts	Short metacarpals and phalanges, fifth finger mid-phalanx hypoplasia with clinodactyly, simian crease
Edwards syndrome (trisomy 18)	Short/slanted palpebral fissure, ptosis, hypertelorism, iris coloboma, cataract, microphthalmos	Clenched hand, overlapping of fingers, absence of distal crease, hypoplasia of nails, hypoplastic or absent thumb, syndactyly, polydactyly, ectrodactyly, short fifth metacarpals
Patau syndrome (trisomy 13)	Microphthalmia, iris coloboma, retinal dysplasia, hypotelorism, hypertelorism, anophthalmos, cyclopia, slanting palpebral fissures, shallow orbital ridges, absent eyebrow	Flexion of fingers, overlapping, camptodactyly, polydactyly, syndactyly, retroflexible thumb
Triploidy syndrome and diploid/triploid mixoploidy syndrome	Hypertelorism, coloboma, microphthalmia, iris heterochromia	Syndactyly, simian crease, clinodactyly, proximally placed thumb
Aniridia–Wilms tumor association (Deletion 11p13)	Aniridia, cataracts, nystagmus, ptosis, glaucoma	Clinodactyly of fifth finger
VERY SMALL STATURE, NOT SKELETAL DYSPLASIA		
Cornelia de Lange syndrome	Bushy eyebrow, synophrys, long, curly eyelashes	Micromelia, phocomelia, oligodactyly, simian crease, proximal implantation of thumbs
Rubinstein–Taybi syndrome	Heavy/highly arched eyebrows, long eye lashes, epicanthal folds, strabismus, nasolacrimal duct stenosis, ptosis	Broad thumbs with radial angulation, fingers broad, clinodactyly, persistent fetal fingertip pads
MODERATE STATURE, FACIAL, GENITAL		
Smith–Lemli–Opitz syndrome	Ptosis, epicanthal folds, strabismus	Simian crease, occasional flexed fingers, short fingers, polydactyly
Williams syndrome	Epicanthal folds, stellate iris pattern, occasional strabismus, hypotelorism	Hypoplastic nails, occasional clinodactyly
Noonan syndrome	Hypertelorism, downslanting palpebral fissures, prominent corneal nerves, myopia, keratoconus, strabismus, nystagmus	Clinodactyly, brachydactyly, blunt fingertips
UNUSUAL BRAIN AND/OR NEUROMUSCULAR FINDINGS WITH ASSOCIATED DEFECTS		
Cohen syndrome	Decreased visual acuity, strabismus, constricted visual fields, chorioretinal dystrophy, optic atrophy	Narrow hands, mild shortening of metacarpals, simian crease
Zellweger syndrome	Cataracts, optic nerve hypoplasia, retinal pigmentary changes, glaucoma, nystagmus	Variable contractures, camptodactyly
FACIAL DEFECTS AS MAJOR FEATURE		
Möbius sequence	Sixth and seventh nerve palsy, strabismus	Syndactyly, limb reduction defects
Fraser syndrome	Cryptophthalmos, associated with eye defects	Partial cutaneous syndactyly, occasional absent phalanges/thumb
FACIAL–LIMB DEFECTS AS MAJOR FEATURE		
Miller syndrome	Eyelid coloboma, ectropion	Absence of fifth digits, syndactyly
Oculodentodigital syndrome	Microphthalmos, microcornea, short palpebral fissures, epicanthal folds, fine porous iris	Syndactyly, camptodactyly, phalangeal hypoplasia
Stickler syndrome (hereditary arthro-ophthalmopathy)	Myopia, chorioretinal degeneration, retinal detachment, cataract	Severe arthropathy, occcasional arachnodactyly
Ectrodactyly–ectodermal dysplasia–clefting (EEC) syndrome	Blue iris, photophobia, blepharophimosis, lacrimal system anomalies, blepharitis	Syndactyly, ectrodactyly, nail dysplasia

Continued

Table 103.2 Disease and related eye/ocular region and hand/finger anomalies—cont'd

Group/disease	Eye/ocular region anomalies	Hand/finger anomalies
CRANIOSYNOSTOSIS SYNDROMES		
Apert syndrome (acrocephalosyndactyly)	Hypertelorism, strabismus, shallow orbits, downslanting of palpebral fissures	Osseous and/or cutaneous syndactyly, broad distal phalanges of thumb, fingers may be short
Pfeiffer syndrome	Ocular hypertelorism, shallow orbit, proptosis	Broad distal phalanges, syndactyly
Carpenter syndrome	Cornea opacity, microcornea, optic atrophy	Brachydactyly, syndactyly, polydactyly, clinodactyly, camptodactyly
OTHER SKELETAL DYSPLASIA		
Weill–Marchesani syndrome	Spherophakia, ectopia lentis, myopia, glaucoma	Brachydactyly, broad metacarpals and phalanges, stiff joints (hands)
CONNECTIVE DISORDERS		
Marfan syndrome	Lens luxation/subluxation, myopia, retinal detachment, glaucoma	Arachnodactyly
Homocystinuria	Lens subluxation (inferiorly), myopia, cataract, glaucoma, optic atrophy	Arachnodactyly
Ehlers–Danlos syndrome	Blue sclera, myopia, microcornea, glaucoma, ectopia lentis, keratoconus	Hyperextensibility of joints
Osteogenesis imperfecta	Blue sclera (thin and translucent), keratoconus, embryotoxon posterior	Hyperextensibility of joints, fractures, occasional syndactyly
HAMARTOSES/PHAKOMATOSIS		
Linear sebaceous nevus sequence	Esotropia, lipodermoid, cloudy cornea, coloboma, optic atrophy, microphthalmia	Polydactyly, syndactyly
Klippel–Trénaunay–Weber syndrome	Glaucoma, cataracts, heterochromia	Asymmetric limb hypertrophy, occasional macrodactyly, syndactyly, polydactyly or oligodactyly
ENVIRONMENTAL AGENTS		
Fetal alcohol syndrome	Optic nerve hypoplasia, coloboma, nystagmus, cataract, ptosis, microphthalmos	Small distal phalanges, small fifth finger nail
Thalidomide	Duane/ocular motility disorders, lacrimation	Phocomelias or longitudinal deficiencies of the extremities, sometimes in combination with absent hand function
Anticonvulsants	Myopia, prominent long eye lashes	Hypoplasia of the distal phalanges of the fingers; shortening of the distal phalanges and hypoplasia or aplasia of the nails. Possible simian creases
MISCELLANEOUS SYNDROMES/ASSOCIATIONS		
Bardet–Biedl syndrome (Laurence–Moon–Biedl)	Retinal dystrophy (retinitis pigmentosa), astigmatism, nystagmus, cataracts	Polydactyly, syndactyly, brachydactyly
Goltz syndrome	Coloboma, microphthalmia, strabismus	Syndactyly

Optimizing compliance in patching therapy

Christy Giligson and Vaishali Mehta

Occlusion therapy remains the first line of treatment for amblyopia for many ophthalmologists and orthoptists. One of the main predictors of success with this treatment is the ability of parents and children to do this.[1] Many factors influence a family's compliance with the treatment as prescribed. Identifying these factors allows the clinician to offer advice and tailor management to optimize compliance and results. These strategies could be applied to all types of amblyopia therapy including optical and pharmacologic treatments.

The family does not understand the treatment

- Insufficient patient and family education: If the family does not understand the problem and the rationale and goals of treatment, they are far more likely to deviate from the treatment plan between visits.[2]
- Cultural beliefs: When caring for a socially, ethnically, or religiously diverse patient population it is important to recognize that a treatment may not be equally acceptable or even possible across all groups. These considerations may include family structure and roles of the caregiver, and social concerns about appearance associated with wearing a patch or glasses.
- Language barriers: Patient and family understanding will be affected if the patient/parent and the clinician do not speak the same language.
- Multiple caregivers: When advising a family that their child should wear a patch and/or glasses, try to identify the individuals who will be supervising the child. This may include multiple family members, daycare workers or teachers, among others.[3]

To address these issues:

- Take adequate time for patient and parent education; discussion as well as written information are helpful when the treatment is first prescribed.[2] This will often prevent false starts and will save time at future appointments. Written information may also be provided for caregivers who may supervise treatment but are unable to attend clinic appointments.
- During the patient education process, concerns related to cultural beliefs may be discussed and a management plan developed that will best fit with the family's values.

When language barriers exist have a translator

This is particularly important at the first visit. When available, translated copies of written information should be given. Remember that even professional translators may have difficulty with medical terms, so explanations are best given in simple language. Family members, particularly older siblings, may act as translators.

Inconsistencies in occlusion regimens between team members

The treatment is sometimes started by one clinician but follow-up may be performed by a different team member. Changes in management plans or differences in information provided can lead to confusion and questions about the validity of treatment.[3]

To address these issues:

- Ideally the clinician who will be following the patient during their treatment should educate the patient and family and set the treatment plan from the beginning.
- In clinics where it is difficult to schedule all follow-up appointments with the same team member, record and communicate clearly to the team the information that has been provided to each patient along with treatment plan.
- A documented clinic protocol for amblyopia management including occlusion times, intervals between visits, and indications for adjusting treatment based on outcomes can be a valuable tool to ensure consistency.[4]

Motivation

- Understanding the reasons for treatment and treatment goals: As discussed above, patients and families will find it difficult to follow treatment regimens if they do not understand why it is being done and the expected outcomes.

- Lengthy intervals between visits: While it may seem that prescribing shorter daily intervals of occlusion with long intervals between visits is an advantage to both the family and the clinic, it can be difficult for patients to keep up with a treatment regime without reinforcement over several months.[1] This is particularly the case when the child does not cooperate with treatment well.
- Lack of improvement at subsequent visits: When the amount of occlusion time prescribed is at the minimum shown to give results there is a great risk that it will be reduced, falling below an effective therapeutic dose.[5] A child who is not cooperative will often stubbornly fight occlusion during these short daily intervals, leading to an exhausted parent and lapses in treatment. Families are likely to become disillusioned when they return after months of struggle to see no improvement in visual acuity.
- Positive reinforcement for the child: Maintaining a positive attitude and explaining to a child that the treatment is not a punishment can be a challenge.

To address these issues:

- The authors recommend starting with a longer daily patching schedule and a short interval between visits. This is based on the belief that enforcing longer patching time (up to full-time) for the first few days or weeks will often overcome any initial resistance from the child. It has been the authors' experience that a longer daily patching schedule establishes a routine for the child, ensures that an effective therapeutic amount is done, even if the full amount prescribed is not done. This is likely to result in a tangible improvement at each visit.
- The child may become motivated to wear the patch in several ways: The authors recommend positive rewards for good patching behavior, with daily or weekly small prizes such as stickers or small toys. A child's favorite activities may be reserved for patch time. Child-friendly computer games are an engaging distraction from the patch; those with large and brightly colored images may be possible even with a reduced visual acuity. Younger children may need more interaction with other children or a caregiver during treatment periods. Clinicians can also offer rewards if the child's vision has improved at follow-up.
- iTunes (itunes.apple.com) and Android (play.google.com) applications are available at little to no cost to manage and track goals: such as iRewardChart, EasyKidToken and Behavior World Reward Chart. Patch Pirate is an app specifically to track and encourage amblyopia treatment.

Level of vision

- Poor visual acuity levels, particularly at the beginning of treatment, can make patching more challenging.[5]
- In school-aged children, families and teachers are often concerned that patching may affect their educational experience.[6]

To address these issues:

- Families should be told about the child's visual level and educated regarding safe and unsafe activities while patching. Often, the child's function is not as limited as expected.
- Offer suggestions on how activities may be adapted for school. In the preschool and early elementary grades, print materials are often in a very large font that the child may still see when patched. If the amblyopia is severe, many preschool and early years activities are still possible while patched.
- In very severe amblyopia, such as that associated with ocular anatomic abnormalities, the child's function may be severely limited while patching; each case must be considered individually to plan the best course of action.

Adverse reactions to the treatment method

- Children may have skin reactions related to wearing or removing an adhesive patch.
- Adverse reaction to pharmacologic penalization.

To address these issues:

- For skin irritation, a different brand of patch may be better tolerated. Patches may be removed after bath time when they become wet and loose; the adhesive may be softened by applying oil or lotion to the patch several minutes before removal. A compliant child who wears glasses could wear a sticky or cloth patch over one spectacle lens.
- Alternative treatment methods such as atropine penalization may be offered.

Cost

- Expense of patches, eye drops, or glasses.
- Time off work or school to attend appointments.

To address these issues:

- Adhesive patches or cloth patches can be homemade to reduce costs.

Glasses may be a major expense. In some areas, social programs or charitable organizations may offer assistance.

- Appointments can be scheduled to minimize impact on work or school.

Psychosocial concerns

Parents may worry about the potential for teasing, stigma, or the perception of disability when their child is wearing a patch.[6] The authors recommend a positive attitude in all discussions of the treatment. Less conspicuous treatment methods such as pharmacologic penalization are an option if these issues do arise.

Concurrent health concerns

Additional systemic health concerns and treatments in children with multisystem disorders can make it challenging to maintain consistency with amblyopia treatment. Families may need help identifying a routine that will have the best potential for success.[7]

Vision screening

Sean P Donahue

What is screening?

"Screening is the systematic application of a test or inquiry identifying individuals at sufficient risk of a specific disorder to benefit from further investigation or direct preventative action, amongst other individuals who have not sought medical attention and accounts of symptoms of that disorder."[1] In ophthalmology, healthy children are impacted primarily by amblyopia, strabismus, cataract, and uncorrected refractive error. Screening can detect each of these disorders. The need for screening has been recognized by the fact that over 50% of pediatric eye conditions that affect children's' sight are detected by pediatricians or family doctors.[2]

Screening of the visual system is performed by primary care providers and subspecialists at various times during childhood. The disease being screened for depends on the age of the patient. For example, screening for retinopathy of prematurity is performed primarily by pediatric ophthalmologists and retina specialists and is limited to children who meet certain criteria – in the United States, typically those children having birth weights less than 1250 g or gestational age less than 32 weeks.[3] Red reflex testing is performed by the primary care provider beginning in the neonatal nursery, and should be performed throughout childhood.[4] However, the primary purpose of this chapter is to discuss the role of screening for amblyopia and its risk factors (strabismus and high refractive error) in preschool children, and for other causes of decreased vision (primarily refractive error) in school-aged children.

When is screening appropriate in pediatric ophthalmology?

Some conditions are appropriate to screen for, whereas others are not. Conditions that should be detected by screening generally are of moderate prevalence, have a latent period, have a known treatment, and have a treatment that has a significant benefit. The World Health Organization (WHO) has defined criteria that are important for screening (Box 105.1).[5] Screening for retinopathy of prematurity in at-risk neonates, screening for amblyopia and its risk factors in preschool children, and screening for decreased acuity from refractive error at school entry all meet the criteria established by the WHO. On the other hand, screening for retinoblastoma in patients without a family history would not meet the WHO criteria because of the low prevalence of the disease in the population, and the relatively long period of time over which the disease could present. Similarly, screening for optic nerve hypoplasia, another rare condition, is also not recommended, because there is a low prevalence of the condition, no latent period, and no treatment.

Amblyopia

Amblyopia is a significant public health problem, with a prevalence of approximately 2%.[6,7] It is the most common cause of monocular visual impairment in children and young adults,[8] and is associated with increased risk of vision loss in the fellow eye.[9] A series of multicenter randomized clinical trials has demonstrated that amblyopia can be treated with a high likelihood of success provided it is detected early and treated appropriately.[10] The natural history of amblyopia has also been determined to not improve without treatment.[11] Screening for amblyopia meets the criteria established by the WHO.

Screening for amblyopia

Screening for amblyopia should occur during regular well child check-ups with the primary care physician. Initially, children should be screened for strabismus or asymmetries in the red reflex.[4] Once a child reaches approximately 1 year of age, he or she can cooperate for photoscreening. Photoscreening detects risk factors for amblyopia rather than amblyopia itself. Once a child can read the eye chart, direct detection of amblyopia by visual acuity testing is preferred.

Several studies have shown that screening for amblyopia is highly effective in decreasing the risk of reduced visual acuity in childhood.[12–15] Eibschitz et al. found the prevalence of amblyopia to be 1.0% in a population screened for amblyopia compared to 2.6% in the unscreened population.[12] Moreover, the prevalence of moderate amblyopia was only 0.1% in the screened population.[12] Kvarnstrom et al. found the prevalence of amblyopia in three Swedish municipalities dropped from 2% to 0.2% following the implementation of a screening program.[13] Finally, the ALSPAC study (Avon Longitudinal Study of Parents and Children) in the UK found that an intensive screening program brought the prevalence of amblyopia at the age of 7.5 years to 0.6% from a baseline of 1.8%.[14]

Box 105.1

World Health Organization criteria for an effective screening program

1. The condition should be an important heath problem
2. There should be a treatment for the condition
3. Facilities for diagnosis and treatment should be available
4. There should be a latent stage of the disease
5. There should be a test or examination for the condition
6. The test should be acceptable to the population
7. The natural history of the disease should be adequately understood
8. There should be an agreed policy on whom to treat
9. The total cost of finding a case should be economically balanced in relation to medical expenditure as a whole
10. Case finding should be a continuous process, not just a "once and for all" project

From Wilson JMG, Jungner G. Principles and practice of screening for disease. Public Health Paper No. 34. Geneva: WHO, 1968.

Previously, screening for amblyopia began when a child could read an eye chart. Various pictures and symbols were used for the pre-literate child. Currently, Lea or HOTV symbols are the preferred testing optotypes[16]; Allen figures, Lighthouse characters, Sailboat chart, tumbling Es, and Landolt "C" letters are no longer recommended, as these have been poorly validated. Optotype-based screening is technically feasible by age 3 years, but is very challenging in this age group, as it takes significant time, it is technically difficult, and there is minimal reimbursement. As a result, only a minority of 3-year-old children are screened using optotype techniques.

Mandatory eye examination bills have been proposed or passed in several state legislatures in the United States. In addition to having insufficient numbers of adequately trained specialists to screen the vast number of children, there are several problems with this approach. These bills have also been marred by the lack of mandate for cycloplegia, something which is mandatory for a pediatric refraction and ocular examination.[17] The unintended consequences of such legislation has been the prescription of unnecessary spectacles for children with healthy eyes,[18] anecdotal reports including "accommodative" esotropia in children produced by inappropriate spectacles dispensed without cycloplegia, and multiple referrals for "glaucoma" in children with healthy eyes.

Automated vision screening has become more widespread during the last decade. In contrast to traditional screening, which detects amblyopia and decreased visual acuity directly, automated vision screening detects risk factors for the development of amblyopia. Two advantages of the detection of risk factors rather than amblyopia *per se* are detection during a latent period before amblyopia begins and the ability to detect in younger children. However, these are offset by the fact that many children with risk factors for amblyopia never develop amblyopia; therefore, many children may be treated unnecessarily. Since the risk of amblyopia increases with increasing magnitude of refractive error, levels of refractive error that are felt to put a child at significant risk of developing amblyopia needed to be defined.

In 2003, a working group from the Vision Screening Committee of the American Association of Pediatric Ophthalmology and Strabismus (AAPOS) published guidelines delineating what levels of refractive error constituted risk factors for amblyopia.[19] These were very similar to the "targeted conditions" that had been similarly defined by the optometry-led Vision in Preschoolers Study.[20] An evidence-based update of the 2003 Amblyopia Risk Factors was recently published.[21] This refinement in amblyopia risk factors was based upon published prevalence studies, and the recognition that screening needs a high specificity in younger children, but a high sensitivity in older children.

Types of automated vision screening

There are generally two types of commercially available automated vision-screening instruments. Photoscreening makes use of an analysis of the red reflex to detect amblyopia risk factors. The original instruments used analog film, but now a digital capture of the image has allowed automated interpretation of the red reflex. In addition, the images obtained from some photoscreening devices can now be analyzed to detect strabismus and media opacities. However, it is difficult to create an algorithm to detect strabismus and media opacities with automated photoscreening.

Photoscreening

The MTI photoscreener was the original analog photoscreening instrument. Two linear flashes oriented orthogonally detected refractive error in each of two principal meridians. Manual interpretation of the images was necessary. The MTI instrument is no longer commercially available. However, multiple studies have demonstrated the usefulness of the MTI photoscreener.[22–24] Following successful validation studies using the MTI instrument, other instruments became commercially available. Business models include selling the photoscreening instruments to volunteer screening organizations and primary care providers, or contracting directly with school systems or physician groups for screenings.[25] Generally the other automated instruments have less published validation than the original MTI Photoscreener. However, the technology underlying automated photoscreening is evolving rapidly, and detailed discussion of each of these instruments is beyond the scope of this paper. Nevertheless, the American Academy of Pediatrics policy statement supports photoscreening as an appropriate technique for vision screening beginning as early as 1 year of age and continuing at yearly intervals until a child can reliably perform optotype-based screening.[4,16] In addition, the United States Preventative Services Task Force has also endorsed photoscreening as a technique to screen children in the 3–5 years age range.[26] (Table 105.1). This same organization provides an "insufficient evidence" rating for photoscreening in children aged 1–2 years; however, this should be obviated by a recent large study from Iowa demonstrating the effectiveness of community photoscreening in children in this age group.[27]

Autorefractors

The technology that underlies use of autorefractors for adult ophthalmology clinics has been retooled to make them appropriate for vision screening in children. Autorefractors provide an estimate of the refractive error for each eye (sphere, cylinder, and axis), and then an estimate of the difference

in refractive error between the eyes (anisometropia). These estimates can be compared to predetermined referral criteria to determine if it is appropriate to refer a child for care. Some autorefractors make their measurements binocularly and sequentially, whereas others provide binocular data acquisition and analysis. Some of the newer autorefractors also now make a preliminary assessment of ocular alignment to allow the detection of strabismus.

It is important to recognize that the referral criteria for an autorefractor are not the same as the actual amount of refractive error that should be detected (the AAPOS criteria; Table 105.2). Instead, the referral criteria are those estimates of refractive error that, when placed into the instrument hardware, provide the best likelihood of detecting children having a targeted condition. This is often misunderstood with automated preschool vision screening.

The first autorefractor that was designed and marketed for preschool vision screening was the Welch Allyn SureSight. It was extensively validated through the Vision in Preschoolers Study,[20] and has since had additional validation in the field.[28] The referral criteria initially specified by the manufacturer produced a low positive predictive value, and resulted in low specificity; new referral criteria were proposed by the Vision in Preschoolers Study[7] and validated in the field.[28] However, a limited ability to achieve high sensitivity without jeopardizing specificity has hampered the widespread implementation of this instrument in clinical practice,[29] and this device is being phased out by the manufacturer.

Table 105.1 Vision screening in children ages 1 to 5 years: clinical summary of United States Preventative Services Task Force recommendation

Population	Children younger than 3 years of age	Children ages 3–5 years
Recommendation	No recommendations	Provide vision screening
	Grade: I (insufficient evidence)	Grade: B
Screening Tests	Vision screening test are used in primary care to identify visual impairment in children, including: • Visual acuity test • Stereoacuity test • Cover–uncover test • Hirschberg light reflex test • Autorefraction • Photoscreening	

Two autorefractors have captured most of the market for automated vision screening in the United States. The plusoptiX instrument has undergone several modifications, with high levels of published validation.[30,31] Advantages of the most recent model include the ability to modify the referral criteria based upon age, and to choose several different possibilities for referral criteria based on desired sensitivity and specificity along a published ROC (receiver operator characteristic) curve.[30,31]

The SPOT vision screener was recently acquired by Welch Allyn, as another option to replace the Welch Allyn SureSight screening instrument. Validation of the SPOT instrument continues to evolve, but good outcomes have been reported from several field validation studies.[32,33] The SPOT instrument also allows the imputation of various referral criteria in an age-adjusted manner to maximize sensitivity and specificity for a particular screening environment. As these technologies are evolving rapidly, further discussion of the various instruments is beyond the scope of this chapter. Nevertheless, photoscreeners and autorefractors can both be used in the field with high degrees of effectiveness, and have been demonstrated to decrease the risk of amblyopia when used in these settings.[34–35]

Recently, a new technology that has the potential to detect amblyopia directly even in the pre-literate child has been described. This technology makes use of retinal birefringence to detect foveation.[36] The advantage of this technology is that it allows direct detection of amblyopia and that it appears to be highly sensitive to detect strabismic and anisotropic amblyopia. However, a disadvantage, in addition to it not being commercially available or well validated, is that it does not allow detection of amblyopia risk factors during a latent period prior to the development of amblyopia.[36] Further research is warranted and currently underway.

Traditional acuity screening

Traditional acuity visual screening using lines of optotypes is the gold standard for visual acuity testing in the screening environment. Because it detects decreased visual acuity directly, rather than risk factors for amblyopia, there is no intrinsic over-referral as is seen with automated screening instruments. In addition, by the age at which acuity can be tested directly, children are unlikely to develop amblyopia if they have a risk factor, so the detection of risk factors during a latent period is not relevant for this age group.

Table 105.2 American Association for Pediatric Ophthalmology and Strabismus Vision Screening Committee amblyopia risk factors

Age (months)	Refractive risk factors			
	Astigmatism	Hyperopia	Anisometropia	Myopia
12–30	>2.0 diopters	>4.5 diopters	>2.5 diopters	>–3.5 diopters
31–48	>2.0 diopters	>4.5 diopters	>2.0 diopters	>–3.0 diopters
>48	>1.5 diopters	>3.0 diopters	>1.5 diopters	>–1.5 diopters
	Non-refractive risk factors			
All ages	Media opacity >1 mm			
	Manifest strabismus >8 prism diopters in primary position			

For many healthy children, optotype-based acuity testing can occur at age 3 years, but for the normal child, high degrees of success are not typical until age 4 years or older. Screening using optotypes must be done monocularly, ensuring the child does not peek with the fellow eye. The choice of test method is crucial for obtaining the most accurate screening results.[16] Eye charts should use lines of optotypes (rather than isolated optotypes), or matching cards with crowding bars around each optotype. Use of single optotypes without crowding bars can overestimate visual acuity. The currently preferred optotypes are the Lea symbols or HOTV letters. Allen figures, Lighthouse characters, Sailboat charts, tumbling Es, and Landolt "C" charts are no longer recommended because they have relatively poor validation. Once children can read individual letters, the traditional Snellen chart or Sloan letter charts are preferred to picture-based acuity testing.

Testing can be performed either by *threshold line evaluation* or a *critical line evaluation*. For threshold line evaluation, the child starts to read at the top of the eye chart and continues down each line until he or she can no longer identify the optotypes. Threshold acuity testing is time honored and helps to identify the best levels of acuity in each eye. However, threshold line evaluation is quite time-consuming and can result in the loss of a child's attention, especially in young children.

Critical line evaluation is an effective alternative to threshold testing to identify children with decreased acuity, and is quicker than theshold testing. The "critical line" is the age-dependent line which a child is expected to see normally and pass.[16] For children age 36–47 months, the critical line is 20/50; for 48–59 months, it is 20/40; and for children 5 years and older it is 20/30 (or 20/32 on Sloan eye charts).

Traditional visual acuity testing requires a quiet examination room, free from distraction, as well as an appropriate test distance of 10 or 20 feet. However, computer-based applications are now becoming more common for screening purposes. The Jaeb visual acuity screener incorporates all current screening guidelines and is available free of charge for download and unlimited use at the following website (http://pedig.jaeb.org/JVAS.aspx).

Although traditional acuity testing remains time honored, it is unclear whether it is superior to photoscreening technology. For young children who are barely able to read optotypes, photoscreening may be better. In fact, a randomized controlled crossover trial of photoscreening and traditional acuity screening demonstrated that photoscreening (with the MTI photoscreener) substantially outperformed traditional acuity screening in children aged 3–4 years.[37] Nevertheless, there remains some age at which acuity screening of a healthy literate child will outperform photoscreening because of the lack of over-referrals and the ability to detect mild myopia. This age range remains a subject of further research.

Support for vision screening

The United States Preventative Services Task Force recently issued a policy statement that gives vision screening a "B" level evidence rating for children aged 3–5 years. Traditional visual acuity screening techniques as well as photoscreening are both recommended as appropriate methodologies for screening this age group (see Table 105.1). The United States Preventative Services Task Force gives an "insufficient evidence" rating for vision screening for children under the 3 years. It should be noted that this report was released prior to the publication of photoscreening data for this age group by the Iowa Group,[27] which demonstrated similar effectiveness of children who were photoscreened between 1–2 years of age as those who were aged 3–4 years. This should provide adequate evidence of effectiveness and raise the rating in the next statement cycle.

The American Academy of Pediatrics recently released a policy statement and accompanying clinical report entitled "Visual System Assessment in Infants, Children, and Young Adults by Pediatricians." This policy statement supplants the previous statements "Instrument Based Pediatric Vision Screening", "Eye Examinations in Infants, Children, and Young Adults by Pediatricians", and " Red Reflex Examination in Neonates, Infants, and Children." This policy statement outlines various types of visual system assessment for children from newborn through young adulthood. Highlights include the use of instrument-based screening when available, beginning as young as 1 year, and being offered at regular well-child visits.[16] Traditional screening can supplant photoscreening for the older individual.

Self-inflicted ocular injuries

David S Taylor

Dermatitis and keratoconjunctivitis artefacta

Self-inflicted injury to the skin around the eye (dermatitis artefacta, DA) and to the surface of the eye (keratoconjunctivitis artefacta, KA) are rare in childhood. Although not usually sight threatening, it may be a warning of physical or sexual abuse and there are often associated complex psychological and emotional problems, sometimes with underlying psychopathology. When DA or KA occur with a long history of psychiatric illness, recovery mostly occurs with a change in the patient's underlying disease. Affected children usually deny the cause of their injury and are deceptive. Their motivation, often not clear, may be a "cry for help." They are often difficult to treat, requiring skilled psychiatric intervention[1]; but when both patient and parents admit to the self-destructive nature of their problem, the outcome may be better. Malingerers, classically trying to escape military service,[2] were described by Dr Stanley Thompson as "villains who, with malicious intent, deliberately feign visual loss." Malingering is very rare in young children.

The diagnosis of KA is suggested by the combination of delineated lesions in the inferior and nasal quadrants of the cornea, bulbar and lid conjunctiva. DA is commonly associated with keratoconjunctivitis (Fig. 106.1). It is variable in character and it may contain some of the irritant such as chalk grains.[3] There is often an unconcerned attitude ("belle indifférence") and other psychological features.

Management

1. Consider the differential diagnosis and ensure that there is no possible, even rare, natural disease that could cause the symptoms and signs. It is not unusual for an initial diagnosis to be artefacta but the final one a significant disease. A positive diagnosis is not made because of an inability to identify a pathological disease but on the finding of *positive* evidence of a *clearly* artefactual cause.
2. A pediatric ophthalmologist might collaborate with a colleague who has appropriate expertise, such as an external eye diseases consultant, a dermatologist, or eye trauma expert.
3. Collaborate with a suitably qualified psychiatrist when the diagnosis is suspected.
4. In young children, rule out congenital anesthesia as a cause of keratoconjunctivitis (Fig. 106.2).
5. Stop the application of the noxious substance or substances. This is easy if the child and the parents can be helped to understand the cause and seriousness of the condition, but may need admission to an observation unit.
6. Treat the injury in a manner appropriate for the cause. If it is a non-specific irritant or inflammatory agent, then topical steroids may be appropriate.
7. The treating ophthalmologist needs to be open and honest with the parents and child, kind to both, and aware that the disease is very serious to the patient and family.

Trichotillomania

Trichotillomania, in which the affected person pulls out hair, sometimes the eyelashes and eyebrows, has a prevalence of between 1% and 5%.

Boys, although affected about half as frequently as girls, have an earlier age at onset (8 years)[4] and are less likely to pull their eyebrows and eyelashes. Trichotillomanics frequently conceal their habit; the hair pulling can become ritualized, with close inspection of the pulled hair, and the hair may be swallowed.

Affected lids and brows have healthy skin with multiple broken hair shafts (Fig. 106.3). Some patients are depressed. Stress at school or at home is implicated as a precipitating factor in many cases.

It is not usually a serious condition and the hair loss is reversible when the pulling stops, but it may become chronic and older ex-trichotillomanics may develop other, related disorders.

Management

1. Consider the differential diagnosis. Loss of eyelashes occurs with skin diseases such as alopecia, ichthyosis, and ectodermal dysplasia, following radiation or chemotherapy, after lid infections, or endocrine disease (see Chapter 19).
2. Most cases respond to reassurance and explanations after a detailed history by the ophthalmologist, which must include details that many ophthalmologists are not comfortable with probing. A psychosocial and

Fig. 106.1 This teenage girl had recurrent attacks of keratoconjunctivitis artefacta, which was associated with desquamation of the skin around the affected eye. The agent may have been alum.

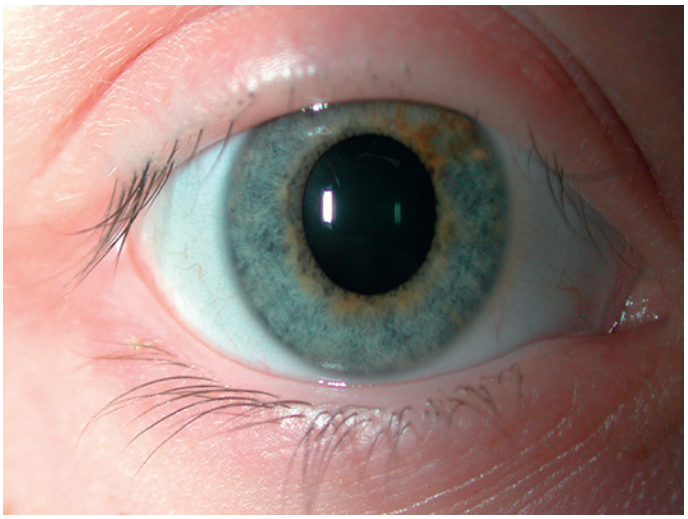

Fig. 106.3 Trichotillomania. The eyelids of both eyes of this 12-year-old girl have broken and missing lashes.

Fig. 106.2 Left corneal anesthesia. This child developed a recurrently red and irritable left eye from about 8 months of age from repeated corneal scratching (see Chapter 34). The diagnosis of Goldenhar syndrome, in which corneal anesthesia is not uncommon, was suggested by the right corneal dermoid and the preauricular tag seen in front of the left earlobe.

psychosexual history is often the key to the underlying cause and it is often best if a pediatrician collaborates.

3. Behavior therapy, drugs, and other treatment may sometimes help, as the condition has similarities to an obsessive–compulsive disorder.[5]

Ocular self-mutilation: direct eye trauma

Ocular self-mutilation typically occurs in young men with a history of severe psychiatric illness, especially schizophrenia, serious criminality, or drug abuse.[1]

From early childhood, self-inflicted injuries may occur in severely developmentally delayed children. The injury may be by laceration,[6] but is more frequently a result of severe direct blows[7] or headbanging.[8] Self-inflicted injuries occur more frequently in certain syndromes, mostly associated with severe mental retardation. At least 15 syndromes are associated with self-mutilation, of which the Lesch–Nyhan, Gilles de la Tourette, and Smith–Magenis syndromes are the most important to ophthalmologists. Self-inflicted injuries also occur commonly in children with autism spectrum disorder.[9]

A case where an apparently normal child injured herself in both eyes with needles[10] serves to remind us to be wary of cases that outlie the normal patterns of diseases and causes. Such cases also need inquiry into the possibility of an inflicted injury.

Autoenucleation

This occurs mostly in hallucinating young adult schizophrenics of either gender and is rare in children.[2,11]

Apps and all that … (How my smartphone changed my life)

Patrick Hamel

According to the website techcrunch.com,[1] as of June 2016, there were 2.6 billion smartphone subscriptions globally and the predicted total mobile subscriptions by 2020 is 9.2 billion. Indeed, in the United States, smartphone adoption rates, also called maturity, have been higher than for most, if not all, major technologies since the telephone was patented by Alexander Graham Bell in 1876.[2] The number of available applications for smartphones has also risen dramatically. A few years ago, typing the word "ophthalmology," into the search box of the Apple App Store revealed only a handful of relevant apps. Now they are so numerous that it is hard to decide which are useful.

As a pediatric ophthalmologist, I am always exploring new and useful resources in information technology that relate to my work. I will share the applications that have helped me the most in my practice. The list is far from being exhaustive and the applications have not been peer reviewed so the reader is warned to use them with caution, especially when referring to medical knowledge and expertise. Also, as some of them allow for data storage and/or transfer, one has to take care with regard to the handling of confidential patient-related information and the related legal implications.

All cited applications in this chapter can be used either on an iOS or an Android device, or both. Many of them can also be downloaded on a Windows-based or Mac OS computer. Some are free, while others are not.

Around the office

First, let's look at general applications. Without being purely medical, some apps can be extremely useful in our day-to-day life as healthcare workers. Dropbox (www.dropbox.com) and Google Drive (www.google.com/drive/) are cloud storage applications that allow easy sharing of documents between one's smartphone, tablet, and computer. Then, on iOS and Mac OS, iBooks (www.apple.com/ibooks) is an excellent way to store books and PDF documents, easily accessing and reading them as needed.

As many, if not most, documents are now circulated in a PDF format, the following apps allow for storage, viewing, editing, annotations, signature, questionnaire filling, and sharing: I find PDF Expert (www.readdle.com/products/pdfexpert5), iAnnotate (www.iannotate.com), PDFPen (smilesoftware.com/PDFpen) and Adobe Acrobat DC (acrobat.adobe.com) to be useful.

Microsoft Office (products.office.com) is now available for almost all recent OS platforms and also has its own cloud storage system. Therefore, Excel, Word, and PowerPoint documents can easily be created, shared, and edited on a smartphone, a tablet, a desktop or laptop computer. Apple (www.apple.com/iwork-for-icloud), through Pages, Numbers, and Keynotes offer the same functionalities, but only for its devices, unless used as web applications on Windows-based PCs.

If you want to write quick notes and have them available wherever you are, Evernote (evernote.com) is a world-renowned note taking and sharing software that is available for most operating systems and devices. Notes can be shared through ones own devices or between users.

Dragon (www.nuance.com) is a world leader in voice recognition and transcription. It comes in different styles and at different prices. The simplest version is very handy when dictating instead of typing an email on your smartphone's small keyboard. Alternatively, the very powerful desktop version comes with a whole medical lexicon.

With the rapidly growing number of usernames and passwords we need to remember, why not use software that will store them, and even type them for you? 1Password (agilebits.com) is one of the many available applications on the market for this purpose.

Applying one's handwritten signature directly in an electronic document, and then sending it though email, saves the trouble of printing and scanning. iOS 9 from Apple recently made it quite easy, but with Autograph (tenonedesign.com/autograph.php) it is possible to sign a Word or PDF document on a Mac computer, directly from the touch pad or on an iPhone hooked up through its USB port or through Wi-Fi.

With DocScanner (docscannerapp.com) or Scanner Pro (readdle.com/products/scannerpro), the smartphone or tablet's camera becomes a document scanner, saving the file in a digital form. It can then be saved or shared through devices or emailed to another user as a PDF document.

Medical references

Not so long ago, having medical references at hand meant carrying several heavy books. Most of them now have an

electronic version and many sources of information only exist on the Internet. ClinicalKey (www.clinicalkey.com) is a medical search engine and database that offers access to medical books, including this title, journals, clinical trials, drug monographs, guidelines, patient education material, and other sources of information owned by Elsevier.

Medscape (www.medscape.com) is both an application and a website with up-to-date medical news, information on diseases, drugs, and treatment procedures, and continuing medical education activities, just to name a few features. Lexicomp (www.wolterskluwercdi.com/lexicomp-online) and Pepid (www.pepid.com) are huge paid medical databases, differing somewhat in their content, but with drugs, toxicology, allergy, and infectious disease information, and can help in medical decision making. Epocrates (www.epocrates.com), now familiar to most physicians, has both free and paid versions, and carries a very up-to-date drug database. It is a must-have app on any smartphone or tablet, or as a website on a laptop or desktop computer. Eponyms (www.eponyms.net) provides short descriptions of common and rare diseases, symptoms and signs on your portable device. The Sanford Guide to Antimicrobial Therapy (www.sanfordguide.com) is a leading reference of its kind and provides information on antibiotic coverage, as well as bacterial sensitivity and resistance.

References in ophthalmology

There are many electronic references available that are specific to ophthalmology. Through Omnio (omnio.com), *The Wills Eye Manual: Office and Emergency Room Diagnosis and Treatment of Eye Diseases* can be bought and downloaded.

Expert Consult (expertconsult.inkling.com) is Elsevier's eBook platform. Among numerous titles, it hosts the online and enhanced digital version of this edition of *Pediatric Ophthalmology and Strabismus*, along with the video and extra images/content elements.

The American Academy of Ophthalmology has its own eBook reader (http://store.aao.org/shop-by.html?media_type=eBook) that makes it possible to carry the whole *Basic and Clinical Science Course* series, as well as other electronic references, in a tablet. *Eye Handbook* (www.eyehandbook.com) is an amazing source of information for ophthalmologists, with the following topics included: a disease database, symptom illustrations for showing patients, an eye atlas, a coding database, various calculators and patient tests. Optics Clinical Calculator (http://www.regularrateandrhythm.com/apps/optics.html) is one of the few apps that come handy for solving ocular optical problems. Eyetube (eyetube.net) is, according to their website, the largest online surgical video archive dedicated to ophthalmology.

Eye tests and vision screening

There are several applications available either for smartphones or tablets that reproduce different eye tests, which can be used either by the ophthalmologist or the patient. Many reading charts, for far or near vision testing, can be found, including Eye Chart Pro (www.eyechartproapp.com) and Optos' Chart Remote (blog.optos.com/index.php/optos-chart-remote-ipad-app). Some applications offer a certain number of tests, e.g. Ishihara color vision plates, Amsler grid, red desaturation, and more, such as eyeTests Easy (georgekongsoftwares.weebly.com) and Pocket Eye Exam (pocket-eye-exam.appstor.io).

With SightBook (www.digisight.net/patients/vision_testing), and Vision Test (https://itunes.apple.com/ca/app/vision-test/id380288414?mt=8 or https://play.google.com/store/apps/details?id=com.threesidedcube.visiondroid). Patients and anyone in the community can test themselves, friends, or family members. The AAPOS Vision Screening App (www.aapos.org/ahp/aapos_vision_screening_app) has optotypes for both adults and children, and can be used by anyone including healthcare workers. Optodrum (www.linsay.com/Linsay_Associates_Medical/OptoDrum.html) replaces the expensive and bulky optokinetic drum for adults and children. It even has a version for the iPad that uses its camera to record a video of the patient's eye movement while looking at moving patterns.

Videos and animations

My most frequent use of my smartphone in clinic is to play a video to capture a child's attention. I have found buying one of the Pixar Short Films Collections (itunes.com or play.google.com) to be very worthwhile.

Patient and family education

To help the ophthalmologist explain diseases and surgeries to patients and parents, Sight Selector (www.patienteducationconcepts.com/sight-selector-products), DrawMD (visiblehealth.com/drawmd), EyeDraw (www.optimed.co.uk/eyedraw), and Eye Sketch (www.edmondoborasio.com/Doctor_Edmondo_Borasio/The_Apps.html) use anatomy pictures, videos, and live annotation to help in patient education.

"Video game" for the ophthalmologist

Instead of a video game, why not combine business with pleasure by practicing your surgical dexterity "playing" the cataract surgery simulators CataractSurgery and CataractMobile (georgekongsoftwares.weebly.com)?

As a final word, there are so many different types of software and applications available to us that it is impossible to list them all. Changes are happening so fast in the world of technology that, as for CME (continuing medical education), we ought to have some kind of CTE (continuing technology education) to keep us up-to-date with all the new tools that are convenient, if not crucial, to our everyday life as ophthalmologists!

Strümpell-Lorrain disease, 590
Sturge-Weber syndrome (SWS), 197–198, 284–285, 710–713, 711*f*
dermatologic features of, 713, 713*t*
glaucoma and, 367, 376*f*
neurological features of, 712, 712*f*
ophthalmic features of, 712–713, 712*f*–713*f*
pathogenesis of, 712
Subacute necrotizing encephalomyelopathy, 590
Subarachnoid hemorrhage, photophobia and, 965
Subconjunctival abscess, 916*f*
Subconjunctival hemorrhage, 285–286, 286*f*, 716, 716*f*, 728–729, 729*f*
botulinum toxin A injection and, 874*f*
Subperiosteal abscess, 118–121, 120*f*
Sulfite oxidase deficiency, ectopia lentis, 344
Sumatriptan, 619
Sunscreens, albinism and, 409
Superficial conjunctival congestion
with discharge, 957
with itching, 957
Superficial dermoids, 267–268, 267*f*–268*f*
Superficial keratopathy, 318–319, 319*f*
Superior corneal thickness, 42
Superior maxilla, osteomyelitis of, 121
Superior oblique (SO) muscle, 763
anatomy of, 880*f*, 881
incarceration of, 834–835, 835*f*
myokymia, 983
overaction of, 830
palsy, 830, 831*f*
pulley, 764, 768
weakening of, 843
Superior oblique tendon
laxity of, 862
strabismus and, 881, 881*f*, 890
transposition, 902, 902*f*
Superior oblique tendon surgery, 894
isolation, 897, 897*f*
strengthening procedures in, 894–897
tendon expander, 898–899, 899*f*
tendon identification in, 896–897, 897*f*
tenotomy and tenectomy, 897–899, 899*f*–900*f*
tucking procedure in, 896–897, 898*f*
weakening procedures, 897–899
Superior rectus (SR) muscle
displacement of, 814*f*
pulley, 766
recession of, 833, 833*t*, 890, 891*f*
resection of, 835*f*
strabismus and, 881, 881*f*
Superior segmental hypoplasia, 567, 568*f*
Superior vestibular nucleus (SVN), 935
Supranuclear eye movements, 933–952
anatomy and physiology in, 933–936
disorders of, 941–948
general examination for, 936–937, 937*f*
Suprasellar tumors, 614
Surface ectoderm (SE), 17
Surfactant, 444
Surgically induced necrotizing scleritis (SINS), 917, 917*f*
Suture
double-armed, 887
placement of, 887, 887*f*
Suture fixation procedure, 904
Suture granuloma, 915
Suture techniques, adjustable, 902
Sweep visual evoked potential, 73*f*
Sylvian aqueduct syndrome, 683, 689
Symblepharon, 288, 288*f*
Sympathetic ophthalmia, uveitis and, 390
Sympathetic tone, changes of, in pupil, 688
Sympatholytic agents, for pupil anomalies, 689
Sympathomimetics
for glaucoma, 371
for pupil anomalies, 689
Syndactyly, 996*t*, 999*f*
Syndromic albinism, 403–404
Synkinesis, near, 681
Synophthalmos, 168–172
Synthesis, 809
Syphilis, 106
System of Ophthalmology, 5
Systemic agents, for pupil anomalies, 689
Systemic autoinflammatory disease/disorders, 395–396
uveitis and, 386*t*
Systemic disease, visual impairment and, 973–974
Systemic lupus erythematosus (SLE), 397
Systemic malformations, microphthalmos, 166–168
Systemic therapy, in amblyopia, 758

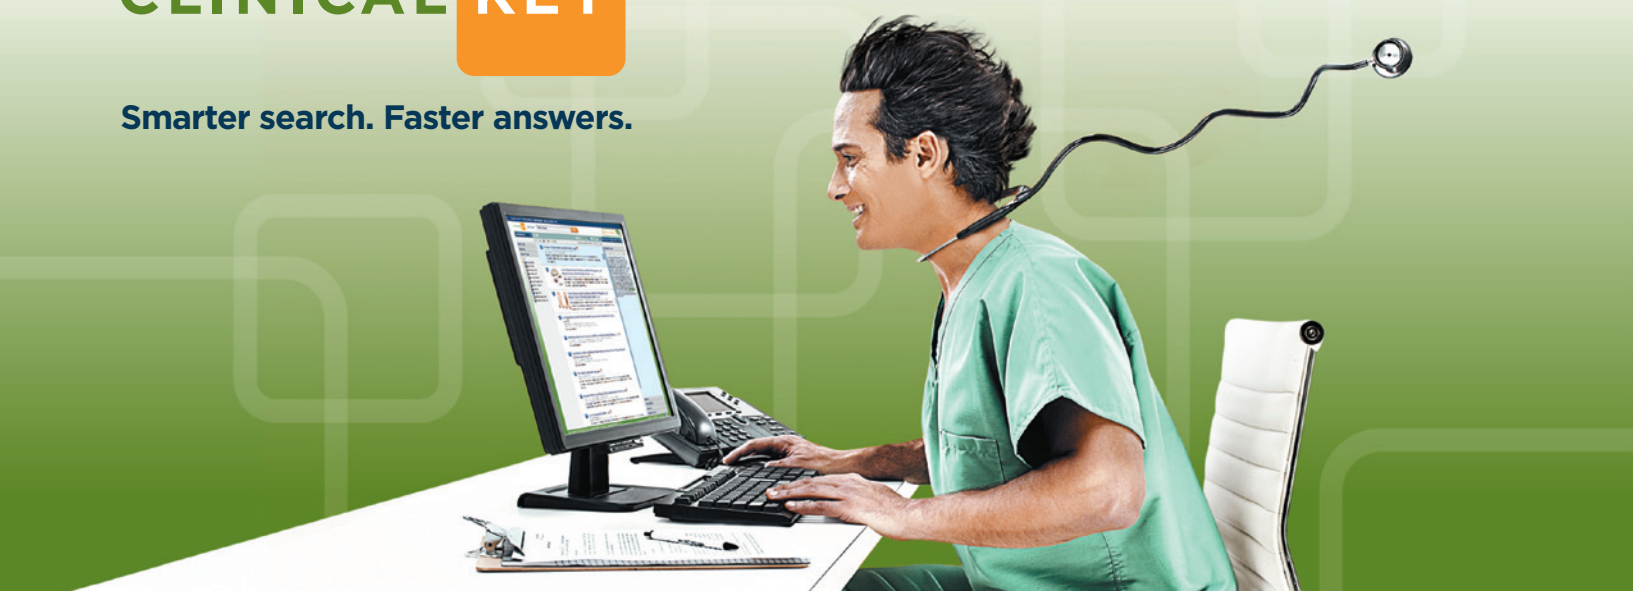
  retinoschisis, 419–420, 419*f*. *see also* Juvenile X-linked retinoschisis
    corneal changes and, 556, 556*f*
X-rays, orbital disease, 214

Y



"Y" pattern exotropia, 838, 839*f*
Yaw, 992
Yeast, leukemia and, 697

Z

Zellweger syndrome, 673–674, 673*f*, 673.*e*1*f*
  hand/eye anomalies, 997*t*–998*t*
  spectrum, 673–674, 673*f*
Zonular fibers, of lens, 337
Zoopsia, 985

CLINICAL KEY™

Smarter search. Faster answers.

Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ***ClinicalKey.com*** for more information and subscription options.
